(b) With High Dilution. The procedure analogous to that performed in the photolysis of Ia in methanol was used. The total amount of the quinone methide Ia which was irradiated in a period of 28 hr was 330 mg. After removal of the solvent under reduced pressure, the residue was chromatographed on 15 g of silica gel. Elution with 100 m*l* of petroleum ether-benzene (1 : 1) gave 207 mg of yellow crystals which were identified as IIa (by infrared spectrum). Further elution with 50 m*l* of petroleum ether - benzene (1 : 1) afforded 13 mg of a yellow oil which was not investigated. Elution with 250 m*l* of 32 mg of yellow crystals, which were identified as IIf (by infrared spectrum).

Photoinduced Reactions. XXXIV. Photosensitized Oxygenation of 2,4,5-Triphenylthiazole[1]

Teruo MATSUURA and Isao SAITO

Department of Synthetic Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

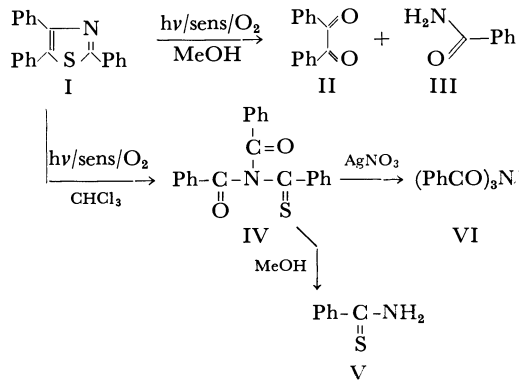
(Received March 28, 1969)

In connection with the photodynamic action of the biological systems, photosensitized oxygenation of a thiazole was investigated. Photooxidation of 2,4,5-triphenylthiazole in methanol in the presence of rose bengal resulted in the formation of benzil and benzamide. On the other hand, photooxidation of 2,4,5-triphenylthiazole in chloroform containing methylene blue as a sensitizer gave *N,N*-dibenzoylthiobenzamide in good yield. Possible mechanisms for these reactions, involving an *endo*-peroxide or a zwitterionic peroxide, are discussed.

Recently much attention has been drawn to the photosensitized oxygenation of five-membered heterocyclic bases in relation to the photodynamic action of the biological systems.[2] Although the photosensitized oxygenation of imidazoles,[3] pyrroles,[4] oxazoles,[5] indoles[6] and purines[7] has been studied extensively, the photooxidation of thiazole, which is an important part of thiamine, has never been investigated. In this paper, the photosensitized oxygenation of 2,4,5-triphenylthiazole is described. The results provide further information regarding the structure of the peroxide intermediate and the manner of its decomposition in the photosensitized oxygenation of five-membered heterocyclic compounds.

When a methanol solution of 2,4,5-triphenylthiazole (I) was subjected to photosensitized oxygenation in the presence of rose bengal, 0.45 mol equivalent of oxygen was consumed and benzil (II) and benzamide (III) were obtained in 11 and 18% yield, respectively.

On the other hand, when photosensitized oxygenation was carried out in chloroform using methylene blue as sensitizer, I afforded a different product. Thus, I gave, after consumption of 0.9 mol equivalent of oxygen, a red-colored compound $C_{21}H_{15}NO_2S$, an oxygen adduct of I, in 30% yield. The IR spectrum showed a broad carbonyl absorption band at 1700 cm^{-1}. In its UV spectrum a weak absorption maximum was observed at 500 mμ. Treatment of the adduct with boiling methanol gave thiobenzamide (V) in 50% yield. The adduct gave tribenzamide (VI) in aqueous silver nitrate solution in 10% yield. These reactions and spectral data are known to be generally found in the case of *N*-acylthiobenzamides.[8] The above results led us to assign structure IV to the adduct.



In the absence of the sensitizer, I did not consume oxygen and the starting material remained unchanged. This indicates that the presence of a sensitizer is a necessary condition for the present photooxygenation.

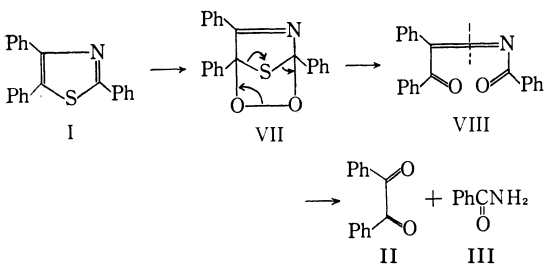
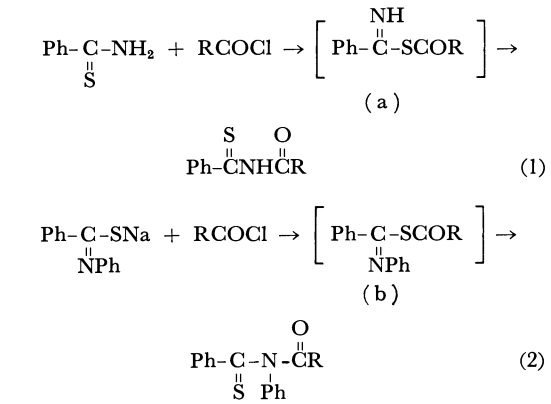
The formation of benzil (II) and benzamide (III) in the photosensitized oxygenation of I in methanol is well rationalized by a pathway involving a cyclic peroxide VII (Scheme 1). Such a cyclic peroxide is commonly recognized as an intermediate in the photosensitized oxygenation of five-membered heterocycles, *i. e.*, imidazoles,[3] pyrroles,[4] oxazoles,[5] isoindoles[9] and isobenzothiophenes.[10] The initially formed peroxide VII could undergo rearrangement to form a Schiff base VIII, which is hydrolysed to give II and III. The loss of a sulfur atom from VII has analogy in the photosensitized oxygenation of 1,3-diphenylisobenzothiophene leading to the *o*-dibenzoylbenzene.[10]



Scheme 1

In inert solvents such as chloroform, the photosensitized oxygenation of I takes a different course. Such a solvent effect on photooxidation has also been observed in the cases of purines[7] and oxazoles.[11] Two mechanisms seem to account for the formation of IV from I. In this case a zwitterionic peroxide IXa or IXb[3,7,12] is proposed for the first step intermediate. As shown in Scheme 2, IX could be rearranged to a four-membered cyclic peroxide X (path a), which undergoes ring cleavage to give *N*-benzoyl-*S*-benzoylisothiobenzamide (XI). Such a photooxidative cleavage of C=C double bond is analogous to the photooxidation of 1,2,3,4-tetraphenylpyrrole leading to α-*N*-benzoylamino-α'-benzoylstilbene.[13] The isothiobenzamide (XI) would then undergo further intramolecular rearrangement to give IV. Such a type of rearrangement has been proposed in the reaction of acyl chloride with thiobenzamide (Eq. (1))[8] and *N*-phenylthiobenzamide (Eq. (2)).[14] *S*-Benzoylisothiobenzamide (a) in the former and *N*-phenyl-*S*-benzoylisothiobenzamide (b) in the latter case are considered to be an intermediate.



An alternative pathway (path b) involving a cyclic peroxide VII, which is analogous to the photosensitized oxygenation of oxazole,[5] may also account for the formation of IV. The peroxide VII could be rearranged to give XII, which undergoes an intramolecular rearrangement, analogous to *N*-benzoylisoimide, to give IV.[5] The formation of the *endo*-peroxide VII may occur either directly from I or stepwise *via* the zwitterionic peroxide IXa.

Although the above two modes of the formation of IV cannot be distinguished from the available results, path a seems to be more favorable considering the reaction of Eq. (2).

triphenylthiazole[15] (I) (2.8 g. 9 mmol) in methanol (300 ml) containing rose bengal (50 mg) was irradiated at room temperature by a 100 W high-pressure mercury lamp through a Pyrex cooling jacket. During irradiation oxygen was bubbled by means of a circulating pump through a sintered-glass joint which was attached to the bottom of the reaction vessel. Oxygen consumption was manometrically followed. Oxygen absorption ceased after oxygen (105 ml, 4.2 mmol) had been taken up for 24 hr. After removal of the solvent *in vacuo*, the residue was chromatographed on a neutral alumina column (50 g). Elution with chloroform (400 ml) gave unchanged starting material (I) (0.95 g, 34% recovery). Further elution with chloroform (*ca.* 600 ml) gave benzil (II) (135 mg, 11% based on the reacted starting material). Recrystallization from ethanol gave yellow prisms, mp 93—94°C, which were identical with an authentic sample by comparison of their IR spectra. Chloroform (1000 ml) eluted benzamide (III) (95 mg, 18% based on reacted I). Recrystallization from ethanol gave crystals, mp 128°C.

B. In Chloroform. A solution of 2,4,5-triphenylthiazole (I) (2.4 g, 7.7 mmol) in dry chloroform (200 ml) containing methylene blue (50 mg) was irradiated by a 100 W high-pressure mercury lamp for 10 hr as described above, until oxygen (170 ml, 6.8 mmol) was consumed. The solvent was removed *in vacuo*, and the residue was dissolved in ether (100 ml). The ethereal solution was treated with Norit. After removal of the solvent, the residue was crystallized from ether to give *N,N*-dibenzoylthiobenzamide (IV) (0.78 g, 30%). Recrystallization from ether (5 ml) gave red-colored crystals, mp 102—103°C. $\lambda_{max}^{cyclohexane}$ 224 mμ (ε 29000), 233 (25000), and 500 (150); ν_{max}^{Nujol} 1700, 1600, and 1300—1200 cm^{-1}.

Found: C, 73.43; H, 4.47; N, 4.08; S, 9.24%. Calcd for $C_{21}H_{15}NO_2S$: C, 73.04; H, 4.63; N, 4.06; S, 9.28%.

Reactions of *N,N*-Dibenzoylthiobenzamide (IV). A. With Methanol. A solution of IV (100 mg) in methanol (40 ml) was boiled for 10 min. A thin layer chromatographic analysis (silica gel, chloroform-ethanol (20 : 1)) of the mixture showed that it consisted of at least five compounds among which thiobenzamide (V), (20 mg, 50%) was isolated by preparative thin layer chromatography.

B. With Silver Nitrate. To a suspension of IV (100 mg) in the mixture of methanol (10 ml) and water (10 ml) silver nitrate (400 mg) was added, according to the procedure of Goerdeler and Horstmen.[8] The solution was acidified, diluted with water (50 ml), and then extracted with ether (100 ml). After removal of ether, ethanol was added to the residue. The ethanol-insoluble solid was collected by filtration and was crystallized from boiling ethanol (*ca.* 80 ml) to give tribenzamide (VI) (10 mg, 10%), mp 198—200°C (lit,[16] mp 201—202°C), which was identical with the authentic sample prepared according to the method of Curtius[16] (by IR).

The authors wish to thank the Ministry of Education for a research grant.

Reactions of Diarylphosphines, Their Oxides and Sulfides with Isothiocyanates and Thiocyanic Acid

Iwao OJIMA, Kin-ya AKIBA and Naoki INAMOTO

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received April 10, 1969)

N-Substituted thiocarbamoyldiarylphosphine oxides and sulfides were prepared by the addition reaction of diarylphosphine oxides and diphenylphosphine sulfide with isothiocyanates. Diarylphosphine oxides and diphenylphosphine reacted with ammonium thiocyanate under hydrogen chloride stream to produce diarylphosphinyl- and diarylthiophosphinyl-substituted bis(iminomethyl) sulfides, which are a new type of sulfide. Diphenylphosphine also reacted with thiocyanic acid in ether to give thiocarbamoyldiphenylphosphine and bis(diphenylphosphinyliminomethyl) sulfide. Mechanisms for formation of these bis(iminomethyl) sulfides have been discussed.

In recent years, some attempts have been made to introduce the carbamoyl or thiocarbamoyl group to phosphines and phosphites.[1-3] Issleib and Harzfeld[3] prepared *N*-substituted thiocarbamoylphosphines by reactions of phosphines or their metal salts with isothiocyanates. *N*-Substituted thiocarbamoylphosphine oxides and sulfides were prepared by the reaction of the corresponding *N*-

substituted thiocarbamoylphosphines with oxygen and sulfur, respectively.

We found that diarylphosphine oxides (I) and diphenylphosphine sulfide (I′, R=C_6H_5) as well as phosphines reacted with isothiocyanates in the presence of a few drops of triethylamine[4] at 70—80°C to give *N*-substituted thiocarbamoyldiarylphosphine oxides (II) and sulfides (II′) in good yields, respectively. These results are summarized in Table 1. The elemental analyses and spectral data of these compounds support the structures (see Tables 2 and 3).

$$\begin{matrix} R_2P(=X)H & & R_2P(=X)CSNHR' \end{matrix}$$

I : X=O II : X=O
I′: X=S II′: X=S

As shown in Table 3, the UV spectra of II and II′ in ethyl alcohol displayed an intense band in the 290—350 mμ region, which presumably arises from the π–π^* transition in the C=S group. The n–π^* transition band appeared in the 390—450 mμ region.

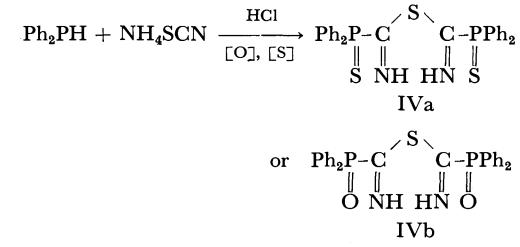
Lately, Vaughan and Lindsey, Jr., reported[5] that carbamoyldiphenylphosphine was prepared by the addition reaction of diphenylphosphine with isocyanic acid in benzene. Papp and Buckler also prepared it by the addition of aqueous potassium cyanate to the mixture of diphenylphosphine and acetic acid.[6]

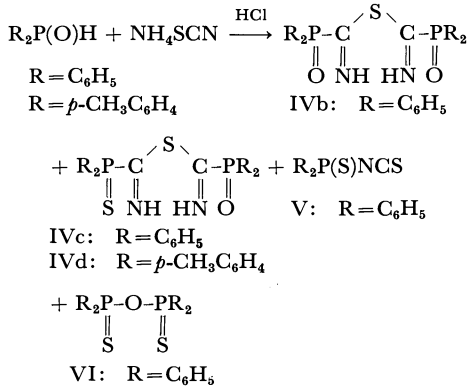
We extended the addition reaction of I and I' with isothiocyanates to the syntheses of thiocarbamoyldiphenylphosphine (IIIa) and its oxide (IIIb) by the reaction of diphenylphosphine and its oxide with thiocyanic acid. First, thiocyanic acid was generated *in situ* from the reaction of ammonium thiocyanate with dry hydrogen chloride analogously to the synthesis of diphenylthiourea from diphenylamine.[7]

Diphenylphosphine was allowed to react with ammonium thiocyanate and dry hydrogen chloride in chlorobenzene under nitrogen atmosphere at 80—85°C. However, bis(diphenylthiophosphinyliminomethyl) sulfide (IVa), which is a new type of sulfide, was obtained in 20% yield, instead of the expected IIIa. In benzene at 50°C, the corresponding phosphinyl compound(IVb) was obtained in 20% yield. The oxygen atoms in IVb might



be taken in during column chromatography on alumina, and the sulfur atoms in IVa might be taken in from some sulfur compound during the reaction. These reactions have not been known in the case of secondary amines.

A similar reaction of diphenylphosphine oxide in refluxing benzene gave the bis(iminomethyl) sulfides, IVb and IVc, in 28% and 13% yields, respectively. However, in chlorobenzene at 100°C, only IVc was obtained in 25% yield. In some cases, diphenylthiophosphinyl isothiocyanate (V) and diphenylthiophosphinic anhydride (VI) were obtained in 3—10% yield. A similar reaction of di-*p*-tolylphosphine oxide gave IVd (analogous to IVc) in 7—10% yield.



The structures of IVa, IVb, IVc, IVd, V and VI were supported by elemental analyses, IR, NMR and mass spectra. These data, however, can not exclude the possibility of structures VII or VIII, which are isomers of IV. II and II' are yellow

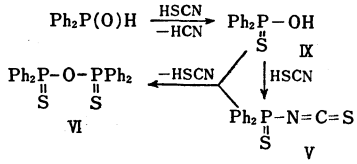
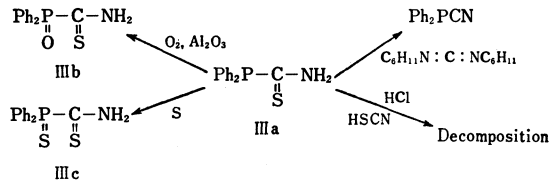
crystals and display the intense π–π* and n–π* transition bands which arise from C=S group in their UV spectra(Table 3). However, compounds IVa—d are colorless and their UV spectra did not show any peaks due to π–π* and n–π* transitions of C=S group (see Experimental). Therefore, the structures of these compounds were determined to be IVa—d, which do not contain C=S group. Possible pathways for the formation of V and VI might be as follows, from separate experimental results (see Experimental).



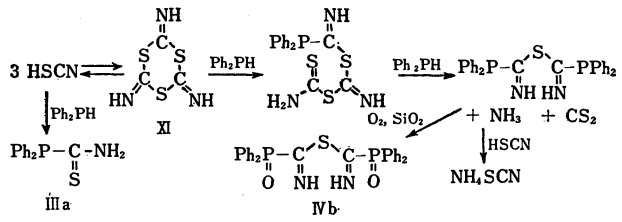
The formation of IVc or IVd from diarylphosphine oxide, ammonium thiocyanate and hydrogen chloride may be attributed to an oxygen-sulfur exchange reaction in P=O bond by thiocyanic acid during the course.

The compounds IVa, IVb and IVc were presumed to be formed by the condensation of IIIa or its oxide (IIIb) in the presence of hydrogen chloride. With this in mind, we let diphenylphosphine react with thiocyanic acid in ether[8] without hydrogen chloride under nitrogen atmosphere at room temperature for a week, and obtained IIIa (57%) and IVb (10%). The oxygen atoms in IVb might be taken in during column chromatography on silica gel. Thiocarbamoyldiphenylphosphine oxide (IIIb) and sulfide (IIIc) were prepared by the reaction of IIIa with oxygen and sulfur in 62% and 70% yields, respectively. These spectral data are listed in Table 4.



The condensation reaction of IIIa to IVa—c was attempted with hydrogen chloride or/and thiocyanic acid under various conditions. The expected condensation products (IVa—c) were not obtained, but only diphenylphosphine oxide and inorganic compounds (ammonium chloride or/and thiocyanate, from IR, respectively) were isolated. Namely, III decomposed in the presence of strong acid. This fact explains that no III could be obtained in the reactions of diphenylphosphine or diarylphosphine oxide with ammonium thiocyanate under hydrogen chloride at 50—100°C. This fact also made it certain that IV was not formed by the condensation of III.

Though the path of the formation of IV is not clear, one of possible paths is the addition of diphenylphosphine to a trimer (XI)*1 of thiocyanic acid which is assumed to be present analogously to cyamelide form,[9] as shown below.



8) R. Klason, *J. prakt. Chem.*, **35**, 407 (1887).

The reaction of IIIa with *N,N'*-dicyclohexylcarbodiimide as condensation reagent gave only diphenylcyanophosphine (X) in 71% yield, without any intermolecular condensation product, IV.

Experimental*2

Materials. Diphenylphosphine was prepared by the reduction of diphenylchlorophosphine with lithium aluminum hydride.[11] Bp 100—110°C/0.8—1.0 mmHg (lit 100—102°C/1.5 mmHg). Diphenylphosphine oxide was prepared by the hydrolysis of diphenylchlorophosphine.[12] Diarylphosphine oxides were prepared according to the directions of Grayson, Farley and Streuli.[13,14] $R_2P(O)H$: R=C_6H_5, mp 51—54°C (lit[12] 51—54°C); R=*p*-$CH_3C_6H_4$, mp 98—100°C (lit[14] 102—103°C); R=*p*-$CH_3OC_6H_4$, mp 121—124°C (lit[14] 125—126°C); R=*p*-ClC_6H_4, mp 130—133°C (lit[14] 131—133°C). Diphenylphosphine sulfide was prepared by the reaction of diphenylphosphine with sulfur.[15] Mp 96—97°C (lit[15] 95—97°C).

Reaction of Diarylphosphine Oxides and Diphenylphosphine Sulfide with Isothiocyanates. A typical procedure is described for the reaction of diphenylphosphine oxide with phenyl isothiocyanate. A mixture of diphenylphosphine oxide (2.0 g, 10 mmol) and phenyl isothiocyanate (1.35 g, 10 mmol) was heated without solvent in the presence of a few drops of triethylamine for 5 hr at 70—80°C. The crystalline product obtained was recrystallized from ethanol to afford 2.52 g (7.5 mmol, 75%) of *N*-phenylthiocarbamoyldiphenylphosphine oxide (IId), mp 163.5—164.5°C.

Physical properties and analytical data are shown in Tables 1—3.

Reaction of Diphenylphosphine with Ammonium Thiocyanate and Hydrogen Chloride. *a) In Chlorobenzene.* A solution of 18 g (89 mmol) of diphenylphosphine in 50 m*l* of chlorobenzene was vigorously stirred with 9 g (118 mmol) of dried ammonium thiocyanate powder under nitrogen atmosphere, and dry hydrogen chloride was passed through the mixture. After the initial exothermic reaction subsided, the reaction mixture was heated at 80—85°C for 1.5 hr. After removal of solvent under reduced pressure, the residue was chromatographed on alumina. Bis(diphenylthiophosphinyliminomethyl) sulfide (IVa) (4.2 g, 8.04 mmol, 20%) was eluted with dichloromethane and recrystallized from *n*-butyl alcohol; colorless needles, mp 221—222°C (dec.). IR(Nujol): 3370, 3230, 3150 (sh) (ν_{NH}), and 1525 cm^{-1} ($\nu_{C=N}$). $\lambda_{max}^{CH_3CN}$: 257(sh)mμ (ε=16000). NMR(DMSO): δ 8.16 (NH, doublet, J_{PCNH}=10.5 Hz). Mass spectrum (significant peaks): *m/e*=520 (M^+, 0.08), 488 (M^+-32, 14), 218 (Ph_2PSH^+, 86.5), 217 (Ph_2PS^+, 100), 185 (Ph_2P^+, 73), 140 ($PhPS^+$, 54.5), 108 (PhP^+, 50), 77 (Ph^+, 45.5), and 63 (PS^+, 50).

Found: C, 60.01; H, 4.34; N, 5.35; S, 18.47%. Calcd for $C_{26}H_{22}N_2P_2S_3$: C, 60.00; H, 4.23; N, 5.38; S, 18.46%.

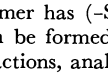
b) In Benzene. When this reaction was carried out in benzene at 50°C for 2hr, the corresponding phosphinyl compound (IVb) was obtained in 20% yield by a similar treatment. Mp 228—229°C (dec.). The IR spectrum was identical with that of the product obtained from the reaction of diphenylphosphine oxide (described below).

Reaction of Diphenylphosphine Oxide with Ammonium Thiocyanate and Hydrogen Chloride. *a) In Benzene.* A solution of 10 g (49.5 mmol) of diphenylphosphine oxide in 100 m*l* of benzene was vigorously stirred with 3.5 g (46 mmol) of ammonium thiocyanate under dry hydrogen chloride stream. After the initial exothermic reaction subsided, the reaction mixture was heated under reflux for 5 hr and then chromatographed on alumina. Diphenylphosphine oxide (3.5 g, 35%) was recovered from a benzene eluate. Elution with ether afforded diphenylphosphinyliminomethyl diphenylthiophosphinyliminomethyl sulfide (IVc) (500 mg, 0.99 mmol. 13.4%), colorless prisms from isobutyl alcohol, mp 230—231°C (dec.). IR(Nujol): 3450, 3280, 3150(sh) (ν_{NH}), 1545 ($\nu_{C=N}$) and 1180 cm^{-1} ($\nu_{P=O}$). λ_{max}^{EtOH}: 253 (sh) mμ (ε=19700) and two weak shoulders in 260—275 mμ region. NMR(DMSO): δ 8.30 (NH, doublet, J_{PCNH}=10.5 Hz). Mass spectrum (significant peaks): *m/e*=504 (M^+, 3), 488 (M^+-16, 27), 472 (M^+-32, 3.3), 218 (Ph_2PSH^+, 61), 217 (Ph_2PS^+, 100), 202 (Ph_2POH^+, 23), 201 (Ph_2PO^+, 77), 185 (Ph_2P^+, 57) 140 ($PhPS^+$, 16), 124 ($PhPO^+$, 14), 108 (PhP^+, 25), 77 (Ph^+, 66), 63 (PS^+, 31), and 47 (PO^+, 20).

Found: C, 61.82; H, 4.72; N, 5.58; S, 12.65%. Calcd for $C_{26}H_{22}N_2OP_2S_2$: C, 61.90; H, 4.36; N, 5.58; S, 12.75%.

Elution with ethyl acetate - ethyl alcohol (1 : 1) gave bis(diphenylphosphinyliminomethyl) sulfide (IVb) (2.0 g, 4.1 mmol, 27.6%), colorless prisms from isobutyl alcohol, mp 229—229.5°C (dec.). IR (Nujol): 3475(sh), 3250, 3150 (ν_{NH}), 1550 ($\nu_{C=N}$), and 1170 cm^{-1} ($\nu_{P=O}$) λ_{max}^{EtOH}: 253(sh) (ε=18300), 265(sh) (14800), and 272 (sh) mμ (11800). NMR($CDCl_3$): δ 9.93 (NH, doublet, J_{PCNH}=10.5 Hz). Mass spectrum (significant peaks):

*1 Thiocyanic acid reversibly polymerizes to trimer or hexamer,[10] whose structures are not clear. Although we assumed the existence of "thiocyamelide"(XI), in



so far as the polymer has (-S-C-)$_n$ structure, III, IV, NH_3 and CS_2 can be formed through ring opening or chain cleavage reactions, analogously to the case of XI.

m/e=488 (M^+, 2), 472 (M^+-16, 16), 202 (Ph_2POH^+, 60), 201 (Ph_2PO^+, 100), 185 (Ph_2P^+, 18), 124($PhPO^+$, 10), 108 (PhP^+, 7), 77 (Ph^+, 56), and 47 (PO^+, 28).

Found: C, 63.72; H, 4.78; N, 5.70; S, 6.77%. Calcd for $C_{26}H_{22}O_2P_2S$: C, 63.93; H, 4.51; N, 5.74; S, 6.56%.

b) In Chlorobenzene. When diphenylphosphine oxide (25 g, 124 mmol) was allowed to react with ammonium thiocyanate (11 g, 145 mmol) in 100 m*l* of chlorobenzene at 100°C for 1.5 hr under hydrogen chloride stream, only IVc was obtained in 25% yield. Mp 230—231°C (dec.). The IR and mass spectra were identical with those obtained by the reaction mentioned above.

Diphenylthiophosphinyl isothiocyanate (V), mp 48—49°C (lit[16] 48°C), and diphenylthiophosphinic anhydride (VI), mp 198—199°C (lit[17] 197—198°C), were often obtained in 3—10% yield in these reactions.

Reactions of Diphenylthiophosphinic Acid (IX) with Thiocyanic Acid and Diphenylthiophosphinyl Isothiocyanate (V). Diphenylthiophosphinic acid (IX) was prepared conveniently from diphenylphosphine oxide and sulfur in the presence of hydrogen chloride in refluxing benzene for 1.5 hr. The precipitated needles were washed once with carbon disulfide. Yield: 70%. Mp 142—144°C (lit[18] 143—144°C). IR(Nujol): 895 cm^{-1} (ν_{P-OH}). Two grams (8.6 mmol) of IX was allowed to react with 1.0 g (13.2 mmol) of ammonium thiocyanate and hydrogen chloride in chlorobenzene at 100—110°C for 1.5 hr. After the solvent was removed, the IR spectrum of the residue showed a strong band at 1960 cm^{-1} ($\nu_{N=C=S}$), which is identical with that of V. Diphenylthiophosphinyl isothiocyanate (V) (1.0 g, 4.0 mmol) and IX (0.5 g, 2.14 mmol) were mixed without solvent and heated at 90—96°C for 3 hr and the IR spectrum of the reaction mixture was measured. There appeared[16] strong new peaks at 940(sh), 925, and 915 cm^{-1} (ν_{P-O-P}) which is identical with that of VI.

Reaction of Di-*p*-tolylphosphine Oxide with Ammonium Thiocyanate under Hydrogen Chloride. Di-*p*-tolylphosphine oxide (10 g, 43.5 mmol) was reacted with ammonium thiocyanate (3.3 g, 43.5 mmol) in 100 m*l* of chlorobenzene under hydrogen chloride stream at 100—105°C for 1.5 hr. Treatment similar to that for the reaction of diphenylphosphine oxide gave di-*p*-tolylphosphinyliminomethyl di-*p*-tolylthiophosphinyliminomethyl sulfide (IVd) (7—10%), colorless prisms, mp 226—227°C (dec.). IR (Nujol): 3460, 3260, 3150 (sh) (ν_{NH}), 1540($\nu_{C=N}$), and 1175 cm^{-1} ($\nu_{P=O}$). NMR(DMSO): δ 8.15 (NH, doublet, J_{PCNH}=10.5 Hz). Mass spectrum (significant peaks): m/e=560 (M^+, 2.5), 544 (M^+-16, 90), 528 (M^+-32, 10), 246 (T_2PSH^+, 90), 245 (T_2PS^+, 100), 230 (T_2POH^+, 85), 229 (T_2PO^+, 95), 213 (T_2P^+, 85), 154 (TPS^+, 65), 138 (TPO^+, 50), 122 (TP^+, 80), 91 (T^+, 90), 63 (PS^+, 45), and 47 (PO^+, 25), where T represents *p*-$CH_3C_6H_4$.

Found: C, 63.83; H, 5.64; N, 4.96; S, 11.16%. Calcd for $C_{30}H_{30}N_2OP_2S_2$: C, 64.29; H, 5.36; N, 5.00; S, 11.43%.

IR spectrum, 1965 cm^{-1} ($\nu_{N=C=S}$), of a benzene eluate by column chromatography on alumina showed formation of isothiocyanate, which might be the *p*-tolyl derivative of V, but was not isolated in pure state. When this reaction was carried out in benzene under reflux for 2 hr, IVd, mp 226—227°C (dec.), was also obtained in 7% yield.

Reaction of Diphenylphosphine with Thiocyanic Acid. To ammonium thiocyanate (6.9 g, 91 mmol) in 7.0 g of water was added concd. sulfuric acid (4.5 g) in 9.0 g of water, and the aqueous solution was shaken twice with 50 m*l* of ether. According to Klason,[8] 95% of thiocyanic acid generated is extracted by ether. The ethereal solution of thiocyanic acid was added dropwise to 15.0 g (81 mmol) of diphenylphosphine in ether (20 m*l*) under nitrogen atmosphere and then the mixture was allowed to stand at room temperature for a week with stirring. The residue after concentration was chromatographed on silica gel (Davison No. 922). Unreacted diphenylphosphine was oxidized during chromatography and 5.0 g of diphenylphosphine oxide was eluted with benzene. Thiocarbamoyldiphenylphosphine (IIIa) was eluted with benzene-chloroform and recrystallized from isobutyl alcohol as colorless needles, mp 114—116°C. Yield: 7.8 g (31.8 mmol, 57%). Mass spectrum (significant peaks): m/e=245 (M^+, 90), 211 (M^+-34, 60), 186 (Ph_2PH^+, 95), 185 (Ph_2P^+, 35), 108 (PhP^+, 100), 77 (Ph^+, 30), and 60 ($CSNH_2^+$, 40).

Found: C, 63.85; H, 5.08; N, 5.57; S, 13.18%. Calcd for $C_{13}H_{12}NPS$: C, 63.67; H, 4.90; N, 5.72; S, 13.06%.

Bis(iminomethyl) sulfide (IVb) was also eluted with ethyl acetate and recrystallized from isobutyl alcohol. Yield: 1.35 g (5.6 mmol, 10.0%). Mp 228—229°C.

Preparation of Thiocarbamoyldiphenylphosphine Oxide (IIIb). Thiocarbamoyldiphenylphosphine (IIIa) (489 mg, 2.00 mmol) was dissolved in 50 m*l* of ethyl alcohol, and 3.0 g of alumina was suspended and oxygen was passed through the mixture under reflux for 2 hr. After removal of alumina and the solvent, the residue was recrystallized from isobutyl alcohol to give 325 mg (1.25 mmol, 62.3%) of pure IIIb, mp 205°C (dec.). Mass spectrum (significant peaks): m/e=261 (M^+, 11), 227 (M^+-34, 28), 202 (Ph_2POH^+, 100), 201 (Ph_2PO^+, 56), 185 (Ph_2P^+, 22), 124 ($PhPO^+$, 17), 108 (PhP^+, 17), 77 (Ph^+, 95), 60 ($CSNH_2^+$, 39), and 47 (PO^+, 95).

Found: C, 60.00; H, 4.68; N, 5.59; S, 12.74%. Calcd for $C_{13}H_{12}NOPS$: C, 59.77; H, 4.60; N, 5.37; S, 12.26%.

Preparation of Thiocarbamoyldiphenylphosphine Sulfide (IIIc). Sulfur (73 mg, 2.28 g atom) and IIIa (503 mg, 2.05 mmol) were dissolved in 50 m*l* of benzene, and the mixture was heated under reflux for 2 hr. After the solvent was removed, the residue was recrystallized from isobutyl alcohol. Yellow prisms thus obtained were washed once with 5 m*l* of carbon disulfide to afford 397 mg (1.43 mmol, 70%) of pure IIIc, mp 132—135°C. Mass spectrum (significant peaks): m/e=277 (M^+, 23), 243 (M^+-34, 10), 218 (Ph_2PSH^+, 100), 217 (Ph_2PS^+, 30), 185 (Ph_2P^+, 53), 140 ($PhPS^+$, 53), 108 (PhP^+, 47), 77 (Ph^+, 63), and 63 (PS^+, 77).

Found: C, 56.48; H, 4.09; N, 5.05; S, 22.98%. Calcd for $C_{13}H_{12}NPS_2$: C, 56.32; H, 4.33; N, 5.05; S, 23.10%.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 2981—2983 (1969)

Photolysis of Aromatic Oxime Benzoates

Taiichi OKADA, Mituyosi KAWANISI and Hitoshi NOZAKI

Department of Industrial Chemistry, Kyoto University, Sakyo-ku, Kyoto

(Received May 1, 1969)

Irradiation of aromatic oxime benzoates, $R^1R^2C{=}N{-}OCOPh$, in benzene solution gives the corresponding azines, $(R^1R^2C{=}N{-})_2$, and ketones, $R^1R^2C{=}O$, along with $PhCO_2NH_4$. $PhCO_2H$ and Ph_2 are also obtained in all cases. The reaction course can be explained by assuming a radical fission of excited $R^1R^2C{=}N{-}OCOPh$ which gives radicals $R^1R^2C{=}N\cdot$ and $\cdot OCOPh$ in the initial step. Sensitization experiment establishes the fact that a triplet state of the oxime benzoate is involved as a chemically reactive species.

Considerable interest has been focused on the photochemical rearrangement of enol esters, in which the acyl group migrates from oxygen to the vinylic carbon atom.[1] In continuation of our recent investigation on the photochemistry of *N*-acylketimine as an aza-analog of α,β-enone system,[2] we have studied the photochemical reaction of certain oxime benzoates,[*1,*2] which may be regarded as an aza-analog of enol benzoate and expected to rearrange photochemically in analogous manner. Actually, however, the reaction took place quite differently as described below.

Irradiation of a benzene solution of acetophenone oxime benzoate (Ia) was effected by means of 300 W high pressure mercury arc (Pyrex jacket) under N_2 atmosphere at room temperature. Chromatographic separation on silica gel column afforded acetophenone azine (IIa) (49%), acetophenone (IIIa) (30%), benzoic acid (9%) and diphenyl (11%). Ammonium benzoate (IV) (9%) deposited on the wall during the irradiation.

Irradiation of other oxime benzoates (Ib—d) was effected in the same way. The possible reaction sequences are given in Scheme 1 and the products isolated are summarized in Table 1. Ammonium benzoate (IV) was obtained in the photolysis of *p*-methylacetophenone oxime benzoate (Id) as well, which indicated that this had arisen from the benzoyloxy group of the original oxime benzoates.

Inspection of Table 1 leads to the conclusion that the photochemical primary step is the cleavage of N–O bond and all the products isolated may be ascribed to the imino radical (V) and benzoyloxy radical (VI). Recombination of radicals V yields azine II and abstraction of hydrogen even from benzene[5] gives the ketimine of the type $R^1R^2C{=}NH$ (VII), which possibly produces the corre-

*1 Photochemistry of oximes presents several interesting points. For details, see Ref. 3.

*2 As the *syn-anti* isomerization of the parent oximes has been reported to occur by the effect of ultraviolet illumination,[4] the same behavior could be expected in the present system. No attempt has been made to observe this kind of isomerization, as irradiation was conducted up to the complete disappearance of the strating I.

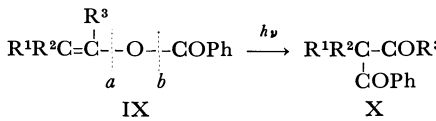
supported by the fact that the intended addition of a small amount of water into an equimolar mixture of benzoic acid and VII ($R^1=R^2=Ph$) in a benzene solution afforded IV and IIIb in a quantitative yield after standing overnight. Photolysis of Ib gave benzanilide in an 18% yield besides the normal products, but the origin is not certain yet.

A priori photocleavage of enol benzoates (IX) can proceed on both C–O bonds at *a* and *b*, but fission occurs exclusively at *b* to afford X through recombination in a solvent cage.[1] The present system



IX X

as an aza-analog of IX is characterized by the absence of participation of benzoyl radical, the fission exclusively occuring at the N–O bond. This is not surprising in view of the bond energies of N–O and C–O bonds calculated as 53 and 85.5 kcal/mol, respectively.[11] The preference of rupture at N–O bond can be considered as prevailing in the photochemical reaction of compounds containing >C=N–O– system, such as isoxazoles,[12] benzisoxazoles,[13] oxadiazoles[14] and anthranils.[15]

The benzophenone-sensitized reaction of Ia was induced by the light of wavelength longer than 350 nm*4 to afford the same products in almost same product distributions as in the case of direct photolysis (Table 1). This strongly suggests that a triplet state acts as a chemically reactive species in the photochemical reaction of the oxime benzoates I.

Experimental

All melting points were taken in capillaries and were uncorrected. The TLC was performed on silica gel G using benzene-ethyl acetate (10 : 1) as an eluent and the spots were visualized with iodine vapor. The UV spectra were obtained in ethanol on a Hitachi EPS-2 recording spectrophotometer.

Materials. Oxime benzoates (Ia—d) were prepared by benzoylation of the corresponding oximes by means of benzoyl chloride in the presence of excess pyridine. All the oxime benzoates were recrystallized several times from ethanol and had the same melting points as reported in the literature cited in the footnotes of Table 1.

General Procedure for Irradiation. Unless otherwise stated, experiments were conducted with the solutions of I (10 mmol) in benzene (300 m*l*) by means of immersion-type 300 W high pressure mercury arc (Pyrex jacket for water-cooling) under N_2 atmosphere at room temperature. The progress of the reaction was monitored by TLC analysis of the aliquots. After the starting materials had been completely consumed (*ca.* 50 hr) and the depositing solid was removed by filtration, the filtrate was concentrated *in vacuo* and the residue was chromatographed on silica gel. The products isolated are listed in Table 1.

Irradiation of Ia in the Presence of Benzophenone. A solution of Ia (2.40 g, 10 mmol) in benzene (200 m*l*) containing benzophenone (0.90 g, 5 mmol) was irradiated by light of wavelength longer than 350 nm (10% $CuSO_4$ aq. as a filter solution) under N_2 atmosphere at room temperature for 20 hr. Only benzophenone absorbs the incident light, as Ia has no absorption in this region. The reaction mixture was concentrated *in vacuo* and chromatographed on silica gel column. The products isolated are shown in Table 1. Unchanged benzophenone was recovered quantitatively.

A solution of Ia in benzene was also irradiated in the same manner as a reference. TLC examination of the reaction mixture indicated the complete recovery of Ia.

The Reaction of Benzoic Acid and Diphenylketimine in the Presence of Water. A solution of benzoic acid (1.22 g, 10 mmol) and diphenylketimine[16] (1.81 g, 10 mmol) in benzene (100 m*l*) was added with water (2 m*l*) under vigorous stirring and allowed to stand overnight. Ammonium benzoate IV (1.30 g, 95%) separated as a crystalline mass, which was collected by filtration and the filtrate was dried (Na_2SO_4) and evaporated. The residue was distilled at 120°C/2 mmHg to afford benzophenone.

The authors are grateful to Professor Keiiti Sisido for help and encouragement.

Studies on Hydrogenolysis. LIV.[1] Catalytic Hydrogenolysis of Optically Active 2-Methyl-2-phenylaziridine*[1]

Yoshihiro SUGI and Sekio MITSUI

Department of Applied Science, Faculty of Engineering, Tohoku University, Sendai

(Received May 9, 1969)

In order to obtain further information about the catalytic hydrogenolysis of benzyl-type compounds, the hydrogenolysis of optically active 2-methyl-2-phenylaziridine (I) over several group VIII transition metal catalysts was investigated in ethanol under ordinary pressure and at room temperature. 2-Phenylpropylamine (II) was obtained as the main product over all the catalysts. The configuration of II was inverted over the palladium catalyst. However, the hydrogenolysis over the platinum catalyst occurred with a significant retention of the configuration. Further, in the case of Raney nickel and Raney cobalt catalysts, the configurations of II were retained with the low stereoselectivities, and a small amount of 2-phenyl-2-propylamine (III) was also produced in addition to II. These results are attributable to the free-energy difference at the transition states to form π-benzyl intermediates, which depends on the affinity of these metals for the nitrogen lone-pair, the catalyst hindrance, and other factors. The S_N2-type reaction is favored over the palladium catalyst. On the other hand, the S_Ni-type reaction is favored over platinum, Raney nickel, and Raney cobalt catalysts, where the radical-cleavage reaction will participate in addition to the S_Ni-type reaction over the latter two catalysts. The differences in behavior between styrene imines and styrene oxides on the catalyst surface were also discussed.

The catalytic hydrogenolysis of benzyl-type compounds is an important method for investigating the mechanism of heterogenous catalysis. For several decades, much attention has been paid to the stereochemical courses of this reaction.[1–18] Some of the factors which affect the courses of the reaction are the structure of the compound,[1–9] the catalyst,[1–3,5,8–15] the additive,[13,16,17] and the medium.[16–18] Mitsui and his co-workers[1–3] suggested that the stereoselectivity of this reaction could be ascribed to the free-energy difference at the transition states to form π-benzyl intermediates. However, the corresponding stereoselectivity of benzylamine derivatives has been studied in detail by only Mitsui and Sato.[5] In this paper, we will describe the stereoselectivity of the catalytic hydrogenolysis of optically active 2-methyl-2-phenylaziridine, which has reactive carbon-nitrogen bonds. Moreover, the differences in behavior between styrene imines and styrene oxides on the catalyst surface are studied.

The hydrogenolysis of 2-methyl-2-phenylaziridine (I) in ethanol was carried out under ordinary pressure and at room temperature. The reaction mixtures were analyzed quantitatively by gas

chromatography. The results are summarized in Table 1. 2-Phenylpropylamine (II) was the main product over all the catalysts, but the following compounds were also obtained: 2-Phenyl-2-propylamine (III) over Raney nickel and Raney cobalt catalysts, 2-phenylpropane and 2-cyclohexylpropylamine over the platinum catalysts, and 2-phenylpropene over the Raney cobalt catalyst.

(+)-I has the S configuration, as will be described in the Experimental section. (−)-II also has the S configuration.[19,20] Therefore, when (+)-II is obtained from (+)-I, the reaction occurs with a retention of the configuration. On the basis of these relationships, the stereochemical consequences of the hydrogenolysis of I are found to be listed as in Table 1. The maintained optical activities and the configurations of II varied with the catalysts. The hydrogenolysis proceeded with a predominant inversion of the configuration over the palladium catalysts; the maintained optical activities were 50—70%. The configurations of II were retained significantly over platinum catalysts, but the maintained optical activity with platinum oxide was higher than that with platinum black. Further, the hydrogenolysis occurred with a predominant retention of the configuration over Raney nickel and Raney cobalt catalysts, but the maintained optical activities were only 10—20%. Since II was racemized only slowly under these conditions, the above results may be considered to exhibit the stereoselectivities of the hydrogenolysis of I.

It has previously been proposed that the catalytic hydrogenolysis of benzyl-type compounds proceeds *via* paths (1) and (2) unless the substituent X has a very strong affinity for the catalyst.[1-3] The configuration of the product is determined by the free-energy difference at the transition states **4** and **5** to form the π-benzyl intermediates **6** and **7**, respectively. When X is an electron-withdrawing group and has a relatively weak affinity for the catalyst, the stereoelectronic effect is operative, so path (1) becomes more probable than path (2). Consequently, the hydrogenolysis proceeds with a predominant inversion of the configuration. However, when X is not so bulky and has a relatively strong affinity for the catalyst, the strong chemisorption of X makes it so prone to the hydrogenolysis as to overcome the unfavorable stereoelectronic situation. Therefore, the free-energy level of the transition state **5** becomes lower than that of **4**, and the configuration of the product is retained predominantly. Further, when X has a very strong affinity for the catalyst, path (3) as well as path (2) participates in this reaction. The benzyl carbon-X bond cleaves into two radicals **8** and ·X, on the catalyst because of the strong chemisorption of X and the phenyl group. Consequently, the racemic product is obtained. In summary, the catalytic hydrogenolysis of benzyl-type compounds occurs competitively *via* paths (1), (2), and (3), and the configuration of the product is determined at the moment of forming π-benzyl intermediates.

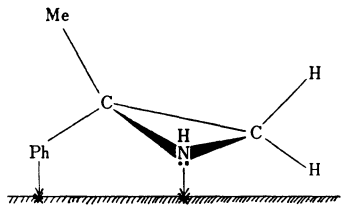
20) E. L. Eliel and J. P. Freeman, *J. Am. Chem. Soc.*, **74**, 923 (1952).

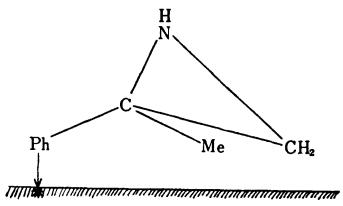
The mechanism of the hydrogenolysis of I will now be discussed on the basis of the above considerations.

In spite of the low reactivity of benzylamine derivatives, not only 2-phenylaziridines, as reported in this paper, but also 2-alkylaziridines undergo catalytic hydrogenolysis even under ordinary pressure and at room temperature.[21] These high reactivities is attributable to the high strain of the aziridine ring.

Because of the tetrahedral character of the nitrogen of aziridine, I will favorably be adsorbed edgewise on the catalyst as **11**, which corresponds to **3**. Since palladium has not such a strong affinity



11



12

for the nitrogen lone-pair, the benzyl carbon in **11** does not bear a sufficiently large positive charge and can not approach so closely to the catalyst as that in **12**, which corresponds to **2**. Moreover, the stereoelectronic requirement at the transition state to form the π-benzyl intermediate is fulfilled *via* the latter state. Therefore, the hydrogenolysis *via* **12** is more probable than that *via* **11**, and the configuration of II will predominantly be inverted over the palladium catalyst. Mitsui and Sato,[5] however, estimated that the hydrogenolysis of ethyl 2-amino-2-phenylpropionate (IV) over a palladium catalyst occurred with a predominant retention of the configuration on the basis of the assumption of the configuration of IV by Cram and his co-workers.[22] This estimation has been confirmed to be correct, for Mizuno and his co-workers[23] reported that (+)-IV has the S configuration. These differences in I and IV suggest the following considerations. The benzyl carbon of I in **11** can not approach so closely to the catalyst as that in **12**, as has been mentioned above, whereas the benzyl carbon of IV can approach to the catalyst at two states, those corresponding to **2** and **3**. Therefore, path (2) is more probable than path (1) in the hydrogenolysis of IV over the palladium catalyst in contrast with that of I.

In order to investigate the possibility of the addition of hydrogen from the top of π-benzyl intermediates, the hydrogenolysis of I was carried out with occluded hydrogen in palladium under a helium atmosphere. Similar results were obtained under both hydrogen and helium atmospheres. Kowaka[24] reported that the occluded hydrogen in palladium is more reactive than molecular or physically-adsorbed hydrogen in the catalytic hydrogenation of ethylene. From these evidences, the hydrogenolysis of I may be said to occur by means of chemisorbed hydrogen from the bottom of the adsorbed molecule on the catalyst surface. These considerations are supported also by the hydrogenolysis of 1-phenylcyclohexane-1,2-diol derivatives[3] and the hydrogenation of 1-phenylcyclohexene derivatives.[25]

The hydrogenolysis of styrene oxide derivatives over the palladium catalysts occurred predominantly with an inversion of the configuration similar to that of I, because of the small affinity of palladium for the oxygen.[13]

Several workers have reported the anchor effect of the nitrogen lone-pair for the platinum catalyst.[26-28] Platinum is less sensitive to the catalyst hindrance than palladium and nickel.[25] Therefore, path (2) is more probable than path (1) in the hydrogenolysis of I over the platinum catalysts, and the configuration of II will be retained predominantly. The maintained optical activity with platinum oxide was higher than that with platinum black, which was prepared by the hydrogen reduction of platinum oxide and by washing with water. This is the effect of alkaline substances contained in platinum oxide.[17] The hydrogenolysis of styrene oxide derivatives over platinum catalysts, however, occurs with an inversion of the configuration.[13] This difference may be ascribed to the differences in the electronegativity and in the affinity for platinum between nitrogen and oxygen.

Nickel and cobalt have stronger affinities for the nitrogen lone-pair than platinum and palladium.

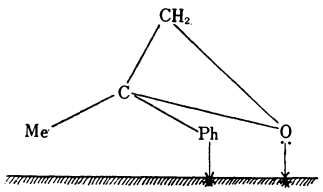
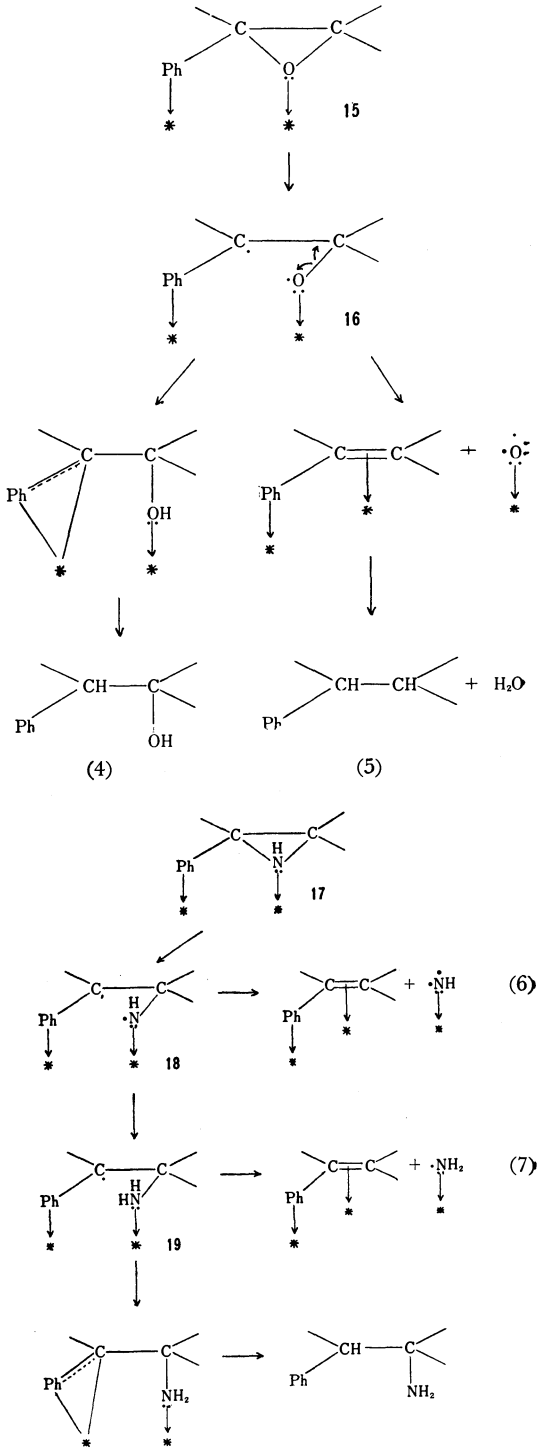
Therefore, the hydrogenolysis occurs *via* **11**. Both benzyl and homobenzyl carbons approach closely to the catalyst and bear positive charges because of the strong chemisorption of the phenyl group and the nitrogen. Therefore, hydrogen will attack nucleophilically not only the benzyl but also the homobenzyl carbons; consequently, II and a small amount of III will be obtained.*2 However, some of I will cleave to the radical because of the high strain of aziridine and the strong chemisorption of the phenyl group and the nitrogen. In this case, the attack of the electron on the radical will be retarded, so the radical will come to have a life long enough to be racemized almost completely. Therefore, the hydrogenolysis of I over Raney nickel and Raney cobalt catalysts will occur competitively *via* paths(2) andand(3), the low maintained optical activities may be attributed to the radical-cleavage reaction.

The hydrogenolysis of styrene oxide derivatives occurred predominantly with a retention of the configuration over Raney nickel and Raney cobalt catalysts, similar to the case of I.[13,29] However, α-phenetylalcohols were not obtained; this is in contrast with the case of I. This suggests the following considerations. The oxygen atom in oxirane has two lone-pairs. Therefore, styrene oxides will more probably be hydrogenolysed *via* **13**. The homobenzyl carbon in **13** is not so approachable to the catalyst surface and scarcely any attack on this carbon will occur. Further,



13

styrene oxide derivatives gave the corresponding hydrocarbons in addition to β-phenetylalcohols in the hydrogenolysis over Raney nickel and Raney cobalt catalysts.[29] Mitsui and his co-workers[29] confirmed these hydrocarbons to be formed *via* olefins and proposed a possible mechanism. Because oxygen has a strong affinity for nickel, the styrene oxide derivative **15** cleaves to the radical **16** in addition to nucleophilic reactions *via* paths (1) and (2). This radical follows competitively paths (4) and (5), and the alcohol and the hydrocarbon



are formed respectively. However, I, gave little hydrocarbon with the Raney nickel catalyst. This suggests that nickel can not stabilize ·NH and/or ·NH_2, which are formed according to paths (6) and (7), respectively. On the other hand, 2-phenyl pro-

*2 It suggests also an importance of the distances between the carbon and the catalyst surface that the less-substituted carbon-nitrogen bond cleaved selectively in the hydrogenolysis of 2-alkyl- and 2,2-dialkylaziridines over the Raney nickel catalyst.[21]

I, 1.33 g; Solvent: Ethanol, 20 m*l*; Under ordinary pressure and at room temperature.
*1 optically pure $[\alpha]_D^{22}$ +33.3° (*c* 9.22, ethanol). *2 optically pure $[\alpha]_D$ +29.5° (ethanol). *3 Under a hydrogen atmosphere. *4 Under a helium atmosphere. *5 2-Cyclohexylpropylamine. *6 2-Phenylpropane. *7 2-Phenylpropene.

pene was obtained from I with the Raney cobalt catalyst. The stabilizing ability of cobalt for $\cdot\dot{N}H$ and/or $\cdot\ddot{N}H_2$ is greater than that of nickel, because cobalt has a stronger affinity for the nitrogen.

In conclusion, the variations in the configuration and in the maintained optical activity of II in the hydrogenolysis of I are attributable to the free-energy difference at the transition states to form π-benzyl intermediates, which depends on the affinity of catalysts for the nitrogen, the catalyst hindrance, and other factors.

Experimental

S(+)- and R(−)-Ethyl 2-Amino-2-phenylpropionates (IV). 2-Amino-2-phenylpropionic acid was prepared according to the procedure of Steiger[30] and was converted into IV.[31] IV was resolved by the fractional recrystallization of its tartrate from ethanol. The resulting salt (mp 175.5—176.0°C, $[\alpha]_D^{20}$ +45.57° (*c* 8.91, water)) afforded S(+)-IV; bp 137—139°C/15 mmHg, α_D^{18} +10.80° (neat), $[\alpha]_D^{18}$ +25.02° (*c* 9.43, ethanol). R(−)-IV: $\alpha_D^{23.5}$ −5.00° (neat) was also obtained from mother liquor. For the rotation of optically pure IV, we adopted the greatest value (α_D^{24} +12.14° (neat))[22] hitherto reported for the ester.

S(+)-2-Amino-2-phenylpropanol (V). The amino-alcohol V was obtained according to the procedure of Tsuboyama[32] for the preparation of isoleucinol. S(+)-IV (38.6 g α_D^{20} +11.01° (neat), 90.2% optically pure) in ether (100 m*l*) was added dropwise with stirring to lithium aluminum hydride (8.0 g) in ether (100 m*l*), and the resulting mixture was heated under reflux for 2 hr. After cooling, water (30 m*l*) was added with vigorously stirring, and the ethereal layer was decanted from the precipitates. The resulting precipitates were dissolved with aqueous sodium hydroxide, and then the aqueous solution was continuously extracted with ether for 24 hr, the combined ethereal solution was dried over anhydrous sodium sulfate. After the evaporation of the ether, the oily residue was distilled under a nitrogen stream to give 23.0 g of S(+)-V; bp 116—118°C/0.4 mmHg, $[\alpha]_D^{22}$ +17.16° (*c* 9.39, benzene).

Found: C, 71.40; H, 8.72; N, 9.11%. Calcd for $C_9H_{13}NO$: C, 71.49; H, 8.66; N, 9.26%.

S(+)-2-Methyl-2-phenylaziridine (I). The imine I was prepared by the procedure of Brois[33] with slight modifications. A cold mixture of sulfuric acid (16.8 g) and water (50 m*l*) was added, with shaking, to a solution of (+)-V (23.0 g, $[\alpha]_D^{22}$ +17.16° (*c* 9.39, benzene) and water (50 m*l*). The water was removed by heating at 15—20 mmHg and finally at 0.5—1 mmHg below 140°C for 20 hr. A cold solution of 40% sodium hydroxide was added to the solidified product, and then the mixture was slowly heated in an oil bath. The basic material was steam-distilled into a cooled receiver and saturated with sodium hydroxide. The imine product was extracted with ether and dried over sodium hydroxide pellets. The evaporation of the ether and subsequent distillation under a nitrogen stream afforded 16.2 g of S(+)-I; bp 94—95°C/14 mmHg, α_D^{22} +45.60° (neat), $[\alpha]_D^{22}$ +30.04° (*c* 9.22, ethanol).

Found: C, 80.89; H, 8.47; N, 10.19%. Calcd for $C_9H_{11}N$: C, 81.15; H, 8.33; N, 10.52%.

Catalysts. The Raney nickel and Raney cobalt were prepared by the method used for W-4[34] and were stored in ethanol. The palladium hydroxide ($Pd(OH)_2$) was obtained by the method of Takagi *et al.*[35] The palladium hydride (Pd(H)) was prepared as has previously been described.[1] The platinum oxide was purchased from the Wako Junyaku Co., Ltd., Osaka. The platinum black was prepared by the hydrogen reduction of platinum oxide and was washed well with water.

Catalytic Hydrogenolysis. The following general

30) R. E. Steiger, "Organic Syntheses," Coll. Vol. III, p. 88 (1955).

procedure was used. After a definite amount of catalyst in ethanol had been agitated under a hydrogen atmosphere for 1 hr, 1.33 g (0.01 mol) of I in ethanol was added; the resulting suspension was agitated with hydrogen under ordinary pressure and at room temperature. After the theoretical amount of hydrogen had been absorbed, the catalyst was filtered off, and the mixture was analyzed by gas chromatography (polyethylene glycol 4000 and potassium hydroxide dispersed on firebrick at 150—180°C using helium-carrier gas). After the evaporation of the ethanol, the oily residue was distilled under reduced pressure to give II; 78—82°C/17 mmHg. When the unreacted imine was involved, the oily residue was treated with dilute hydrochloric acid. After standing for several hours, the hydrochloride solution was made basic with aqueous ammonia. The resulting suspension was extracted with ether, and the etheral solution was dried over anhydrous sodium sulfate. The evaporation of ether and subsequent distillation afforded II. Moreover, when the reaction mixture involved substances other than II, II was purified by preparative gas chromatography. The rotation of II was measured in ethanol at *c* 9.0—10.0. For the rotation of optically pure II, we adopted $[\alpha]_D$ 29.5° (ethanol), a value which was calculated from the values given by Levene *et al.*[24] and by Eliel and Freeman.[25]

The Claisen-Schmidt Condensation of Acetonitrile with Aromatic Carbonyl Compounds

Akira UCHIDA, Satoshi SAITO and Sumio MATSUDA

Faculty of Engineering, Osaka University, Suita, Osaka

(Received May 20, 1968)

The reaction of acetonitrile with aromatic carbonyl compounds in ether, using sodium amide as the catalyst, are known[1] to form the derivatives of 3-hydroxypropionitrile. This paper will deal with the same reactions in acetonitrile, using sodium as the catalyst.

It has been established that methane, sodium cyanide, and diacetonitrile are formed when sodium is dissolved in acetonitrile. Diacetonitrile is the addition product of cyanomethylsodium to acetonitrile[2] and is known to add to the aromatic carbonyl compounds.[3] Therefore, if some aromatic carbonyl compounds are added to a solution prepared by dissolving sodium in acetonitrile, the following reactions are expected to occur: the addition reactions of cyanomethylsodium to the carbonyl compounds (addition a), the addition reaction of cyanomethylsodium to acetonitrile (addition b), the addition reaction of diacetonitrile to the carbonyl compound, and the reaction of the carbonyl compound with the carbonyl compound (reaction c). These reactions might be competing reactions. If the addition a is faster than the addition b or the reaction c, the adducts of cyanomethylsodium to the carbonyl compounds must be formed. The reactions of benzaldehyde, acetophenone, or benzophenone with cyanomethylsodium in acetonitrile have been attempted in order to clarify this possibility.

When benzaldehyde or acetophenone was added to a solution which has been prepared by dissolving sodium in acetonitrile (solution I), 3-hydroxy-3-phenylpropionitrile or 3-hydroxy-3-phenylpropionitrile was isolated from the reaction products. This fact suggests that cyanomethylsodium in acetonitrile dose not react with acetonitrile as rapidly as anticipated.

When benzaldehyde is stirred into solution I

1) a) H. Lettré, G. Meiners and H. Wickmann, *Naturwissenschaften*, **33**, 158 (1946). b) While the present authors were preparing the manuscript of this paper, E. M. Kaiser *et al.* reported that 3-hydroxy-3,3-diphenylpropionitrile can be formed by the reaction of acetonitrile with benzophenone in the presence of *n*-butyl lithium. They obtained *β*-phenylcinnamonitrile, not as the reaction product, but only through the dehydration of 3-hydroxy-3,3-diphenylpropionitrile with mineral acid; *J. Org. Chem.*, **33**, 3402 (1968).

2) R. Holtzwart, *J. prakt. Chem.*, [2] **39**, 230.

3) E. Mohr, *ibid.*, [2] **56**, 125.

at room temperature, benzyl alcohol, 3-hydroxy-3-phenylpropionitrile, and a small amount of cinnamonitrile are formed. Although benzoic acid was not isolated, benzyl alcohol might be formed by the Cannizzaro reaction of benzaldehyde and cinnamonitrile might be formed by the Claisen-Schmidt condensation of acetonitrile with benzaldehyde.

In the case of acetophenone, 3-hydroxypropionitrile was isolated from the product when the reaction was carried out at room temperature, while β-methylcinnamonitrile, the product of the Claisen-Schmidt condensation of acetonitrile with acetophenone, was formed when the reaction mixture was refluxed for 3 hr.

When a solution of benzophenone in the solution I was stirred for 17 hr at room temperature, the product isolated was not the derivative of hydroxypropionitrile but β-phenylcinnamonitrile, the product of the Claisen-Schmidt condensation of acetonitrile with benzophenone. The yield of β-phenylcinnamonitrile increased markedly when the reaction mixture was heated under reflux for 9 hr.[4]

The formation of the derivatives of dicyanovinylidene by the reaction of malonitrile with ketones are well known,[5] but the formation of the derivatives of cinnamonitrile by the one-step reaction with aromatic carbonyl compounds has not been found. This reaction will serve as a convenient method for preparing β-phenylcinnamonitrile.

Experimental

All the mps are corrected, while the bps are not corrected. The NMR spectra were taken on a JNM-3H-60 (60 Mc) NMR Spectrometer, with tetramethylsilane as the internal standard. The chemical shifts (ppm) were followed by splitting patterns (s, singlet; d, doublet; t, triplet; q, quartet; m, multiplet) and relative strengths. The IR spectra were recorded on a Hitachi EPI-G2-type Grating Infrared Spectrophotometer. The molecular weight was determined on a vapor-pressure osmometer in a benzene solution.

The acetonitrile was dried over phosphorus pentoxide and was distilled before use. The benzaldehyde and acetophenone were distilled before use, while the benzophenone was used without purification.

The solution I was prepared by dissolving 4.6 g (0.2 g atom) of sodium in 150 m*l* of acetonitrile. The flask which contained the solution I was flushed with nitrogen, and the aromatic carbonyl compounds were added from a dropping funnel (benzaldehyde or acetophenone) or directly (benzophenone).

Reaction of Acetonitrile with Benzaldehyde. A mixture of 21.1 g (0.2 mol) of benzaldehyde in solution I was stirred for 5 hr at room temperature. The reaction mixture was then neutralized, and the precipitates were removed by filtration. The filtrate was dried over anhydrous magnesium sulfate, concentrated, and distilled *in vacuo* to give the following fractions: *fraction 1*, 1.5 g (7%) of benzyl alcohol (I); bp 61—67°C/1.5 mmHg; $n_D^{13.6}$ 1.5396 (lit[6] n_D^{20} 1.5403); IR (neat) 3300, 1370, 1010 cm^{-1} (OH); NMR ($CDCl_3$) τ 2.9 (s, 5), 5.6 (s, 2), 5.9 (s, 1); *fraction 2*, 2.0 g of a mixture of I, 3-hydroxy-3-phenylpropionitrile (II), and cinnamonitrile (III); bp 67—129°C/0.002 mmHg; NMR ($CDCl_3$) τ 2.9 (I+II), 4.2, 4.5 (III), 5.3 (II), 5.6 (I+II), 7.5 (II); *fraction 3*, 5.2 g (18%) of II; bp 127—131°C/0.002 mmHg; $n_D^{13.0}$ 1.5447; IR (neat) 3400, 1320, 1050 cm^{-1} (OH), 2230 cm^{-1} (CN); NMR ($CDCl_3$) τ 2.8 (s, 5), 5.3 (t, 1, J=6 cps, -C**H**(OH)-), 5.5 (s, 1, O**H**), 7.6 (d, 2, J=6 cps, -C**H**$_2$-); mol wt, Found: 146, Calcd for C_9H_9NO: 147; and *a residue*, 13.1 g of unknown compound.

When an ethanol solution of the fraction 3 was treated with hydrogen peroxide under alkaline conditions, white crystals were obtained; 3-hydroxy-3-phenylpropionamide, mp 124°C; Found: C, 65.71; H, 6.68; N, 8.90%; Calcd for $C_9H_{11}O_2N$: C, 65.44; H, 6.71; N, 8.48%.

The presence of I and II in the fraction 2 was confirmed by a study of NMR spectrum. Besides the resonance signals of I and II, there were other signals at τ 4.2 and 4.5. These signals were presumed to be signals of *cis*- and *trans*-III, because the following fraction was isolated from the reaction product which was obtained under similar reaction conditions: bp 81—84°C/4 mmHg; IR (neat) 2200 cm^{-1} (CN), 960 cm^{-1} (C=C); NMR ($CDCl_3$) τ 2.3—2.8 (m, 6), 4.3—4.9 (q, 1). When an ethanol solution of the fraction was treated with hydrogen peroxide under alkaline conditions, white crystals were formed; cinnamamide, mp 145—147°C; Found: C, 74.00; H, 6.16; N, 9.51%; Calcd for C_9H_9ON: C, 73.49; H, 6.16; N, 9.52%.

Reaction of Acetonitrile with Acetophenone. *1) Reaction at Room Temperature* A mixture of 24.0 g (0.2 mol) of acetophenone and solution I was allowed to stand at room temperature. The reaction product was then worked up to give the following fractions: *fraction 1*, 10.2 g (44%) of acetophenone; bp below 66°C/2 mmHg; $n_D^{13.3}$ 1.5342 (lit[6] n_D^{20} 1.5337); The IR was identical with that of acetophenone except for the weak absorption at 2180 cm^{-1} (perhaps from an impurity); *fraction 2*, 1.9 g of an unknown compound; bp 66—120°C/2 mmHg; *fraction 3*, 3.9 g of crude 3-hydroxy-3-methyl-3-phenylpropionitrile (VI); bp 120—129°C/2 mmHg; IR (neat) 3450, 1380, 1020 cm^{-1} (OH), 2185 cm^{-1} (CN), 1740 cm^{-1} (perhaps from an impurity); NMR ($CDCl_3$) τ 2.6 (m, 5), 6.5 (s, 1, -O**H**), 7.3 (s, 2, -C**H**$_2$-),

4) According to Holtzwart,[2] half of the sodium used was consumed in the formation of cyanomethylsodium by the following equation:

$$2CH_3CN + 2Na = CH_4 + NaCN + CH_2NaCN.$$

When a mixture of benzophenone (0.1 mol) and cyanomethylsodium in acetonitrile (0.2 g atom of Na in 150 m*l* of acetonitrile) was refluxed for 9 hr, the yield of β-phenylcinnamonitrile reached 88% (based on benzophenone). This suggested that 88% of the cyanomethylsodium formed was trapped by benzophenone and not by acetonitrile.

6) W. Foerst, "Ullmanns Enzyklopädie der technischen Chemie," 9. Band, Urban & Schwarzenberg, München-Berlin (1957), p. 559.

8.3 (s, 3, $-CH_3$) and small signals at τ 7.5 and 8.1 (perhaps from impurities), and *fraction 4*, 8.3 g (26%) of VI; bp 110—125°C/0.005 mmHg; mp 61—63°C (benzene); Found: C, 74.49; H, 7.65; N, 8.82%; mol wt, 157; Calcd for $C_{10}H_{11}ON$: C, 74.51; H, 6.88; N, 8.69%; mol wt, 161; (KBr Disk) 3430, 1378, 1028 cm^{-1} (OH), 2250 cm^{-1} (CN); NMR ($CDCl_3$) τ 2.7 (m, 5), 7.1 (s, 2, $-CH_2-$), 8.3 (s, 3, $-CH_3$).

2) Reaction under Reflux. A mixture of 24.0 g (0.2 mol) of acetophenone and solution I was refluxed for 3 hr. The reaction product was worked up to give the following fractions: *fraction 1*, 4.2 g (*ca.* 18%) of crude acetophenone; bp 61—91°C/3 mmHg; *fraction 2*, 7.0 g (25%) of β-methylcinnamonitrile (VII); bp 91—93 C/3 mmHg; $n_D^{25.0}$ 1.5836; IR (neat) 2210 cm^{-1} (CN), 830 cm^{-1} (C=C); NMR (neat) 2.7 (s, 5), 4.5, 4.6 (both q, total 1, J=*ca.* 1.5 cps, $-CH_3$); *fraction 3*, 0.8 g of a mixture of VI and VII; bp 140—170°C/0.001 mmHg; NMR (neat) τ 2.6 (m), 7.3 (s), 8.3 (s) which were the signals of VI and 2.7 (m), 4.5 (q), 7.7 (d) which were the signals of VII, and *a residue*, 15.5 g of an unknown compound.

Reaction of Acetonitrile with Benzophenone. A mixture of 18.2 g (0.1 mol) of benzophenone and solution I was refluxed for 9 hr. The reaction product was worked up to give the following fractions: *fraction 1*, 1.3 g of an unknown compound; bp below 160°C/1.5 mmHg; *fraction 2*, 18.1 g (88%) of β-phenylcinnamonitrile; bp 160—200°C/1.5 mmHg; mp 47—48°C (benzene-ethanol); Found: C, 88.28; H, 5.18; N, 6.79%; mol wt, 198; Calcd for $C_{15}H_{11}N$: C, 87.77; H, 5.40; N, 6.82%; mol wt, 205; NMR ($CDCl_3$) τ 2.7 (d, 10), 4.3 (s, 1, $-CH=C=$); IR (KBr Disk) 2200 cm^{-1} (CN), 840 cm^{-1} (C=C), and *a residue*, 3.0 g of an unknown compound.

When a mixture of 18.2 g of benzophenone and cyanomethylsodium (0.1 g atom of sodium in 100 m*l* of acetonitrile) was stirred for 17 hr at room temperature, 71% of benzophenone was recovered and 9% of the β-phenylcinnamonitrile was obtained. When the same reactants were refluxed for 6 hr, 35% of the benzophenone was recovered and 37% of the β-phenylcinnamonitrile was obtained.

Reactions of Organometallic Compounds with Conjugated Enol Ethers: Synthesis of β-Arylacrylates, Diarylmethylmalonates and Analogous Compounds

D. P. NABAR and S. V. SUNTHANKAR

Department of Chemical Technology, University of Bombay, Bombay, India

(Received July 17, 1968)

It has been reported earlier that the addition of enol ether such as ethoxymethylenemalonic ester (EMME) to aryl Grignard reagents at the ether reflux temperature leads to the formation of symmetrical diarylmethylmalonates in good yields. In order to get the mono-conjugate addition products, *i. e.*, the corresponding acrylates, the Grignard reaction was studied at lower temperatures, and the desired acrylates were obtained, as expected.

The temperature effect was studied by using 1-naphthylmagnesium bromide as the organometallic compound. At −50 to −60°C as well as at −10 to −14°C, diethyl 1-naphthylmethylenemalonate was obtained in 31.5% and 26.6% yield respectively. However, at 8 to 10°C both the acrylate as well as the second conjugate addition product were isolated indicating that higher temperatures promote the second conjugate addition. Phenyllithium when reacted with EMME at −50 to −60°C also gave the acrylate in 22.2% yield. The analogous compounds *i. e.* ethoxymethyleneacetoacetate and ethoxymethyleneacetylacetone, when reacted with Grignard reagents gave even at ether reflux temperature only the respective acrylates and not the double conjugate addition products.

In contrast to aryl Grignard reagents, benzylmagnesium chloride gave both the addition compounds at ether reflux temperature. The acrylate when further reacted with phenylmagnesium bromide at 0°C gave 1,2-diphenylethylmalonate, a product of second conjugate addition which was hydrolysed to a known acid.[1] The reaction of benzylmagnesium chloride with ethoxymethylenecyanoacetate and ethoxymethylenemalononitrile gave only the second conjugate addition products in over 50% yield and not the acrylates as in the above case.

Thus the conjugate addition reaction seems to depend on the structure of both organometallic compound as well as the conjugated enol ether.

Experimental

The reactions of Grignard reagents with these enol ethers were carried out by the normal procedure[2]

at suitable temperatures. The experiment given below will serve as an example.

Diethyl (1,2-Diphenylethyl)-malonate. To a filtered solution of phenylmagnesium bromide (from magnesium 0.7 g and bromobenzene 3.925 g) cooled in ice bath was added a solution of diethyl benzylmethylenemalonate (5.24 g) in ether (25 m*l*). The reaction mixture was stirred for 3 hr. After the usual work up the product was purified by fractional distillation at temperature 140—150°C/0.004 mmHg.

Found: C, 74.50; H, 7.50%. Calcd for $C_{21}H_{24}O_4$: C, 74.09; H, 7.11%.

We are grateful to Messrs Kay-Fries Chemicals, Inc., West Haverstraw; N. Y. (U. S. A.) for their generous gift of ethoxymethylenemalonate and analogous enol ethers used in this work.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 2993—2995 (1969)

The Reaction of Alcohols and Hydrocarbons in a Silent Electric Discharge. II. The Reaction of 2-Propanol with Ethylene— The Effects of the Reaction Conditions*1

Teruo HIRAKI

Institute of Commodities, Faculty of Economics, Kagawa University, Takamatsu-shi

(Received August 18, 1968)

It has been established that the α-C-alkylations of primary and secondary alcohols result from their peroxide-,[1] light-,[2] and gamma-rays-induced[3] reactions with olefins. However, no detailed study of the reaction of alcohol with olefin under a silent discharge has been reported.

A previous study[4] of the decomposition of 2-propanol under a silent discharge showed that an α-hydrogen atom in 2-propanol is replaced by alkyl groups. The present study was undertaken to ascertain whether or not a chain telomerization occurs in the reaction of 2-propanol and ethylene by a silent discharge, and to establish the difference in the chemical behavior of 2-propanol between that in the presence of ethylene and that in its absence. The author wishes to report some observations on the ethylene effects on the reaction of 2-propanol, and to report that no 2-methyl-2-hexanol (1 : 2 telomer) or higher telomers, derived from a 2-propanol-ethylene mixture excited by light, peroxide or γ-rays, were formed by the silent discharge.

Experimental

Materials. The 2-propanol was purified and the packing material was prepared by the methods described in a previous paper.[4] Commercial ethylene was used without purification. No impurity was found in either reagent by gas chromatography using columns of PEG-6000 and of activated charcoal respectively.

Apparatus and Procedure. The apparatus and the procedure were similar to those previously reported,[4] except that the reaction was carried out in the presence of ethylene. All the experiments were performed using a flow system. Ethylene coming from a reservoir was passed through a solid sodium hydroxide tube in order to remove any water, and was then introduced into a discharge tube with gaseous 2-propanol. The ethylene flow rate was measured by a calibrated flowmeter.

The reaction products coming through the tube were separated into a condensable part and non-condensable gases by three traps cooled at 0°C. The voltage was stepped up by a transformer (capacity: 15 kV) to give the required value.

Analyses. The non-condensable gases were identified by comparing their retention times on a gas chromatogram with those of authentic samples (Columns of activated charcoal, hexamethylphosphoramide, and molecular sieve-13X were used). The condensable products were identified by gas chromatography (column, tricresyl phosphate, PEG-6000 and silicone DC-550 at 120°C; carrier gas, He) as well as by derivatization.[5]

*1 The major part of these research results were presented at the 20th Annual Meeting of the Chemical Society of Japan, Tokyo, April, 1967.

* Siemens ozonizer was used.
** A 5 g of $Cu(OH)_2$ was filled in a glass filter.
*** The conversion efficiency was given by (grams of reaction product per grams of 2-propanol used) × 100.
**** The yields of each compound produced were given by (grams of each compound per grams of total reaction product) × 100.

Results and Discussion

Influence of Ethylene Addition on the Discharge Reaction of 2-Propanol. *a) With a Siemens Tube.* The main liquid products of the reaction in the Siemens ozonizer were acetone, acetaldehyde, 2-methyl-2-butanol, *dl*-2-butanol, *dl*-2-pentanol, and hydrocarbons (Run No. 1). The percentage compositions of these products shown in the tables are the averages of three experiments; the fluctuations in the yields of these compounds were less than 1%. The gaseous products were C_1-C_4-hydrocarbons, carbon monoxide, and hydrogen; they were not determined quantitatively. An unidentified brown solid was deposited on the glass wall.

All the compounds, except the deposit, had also been formed in the silent discharge-induced reaction of 2-propanol without ethylene.[4] However, the distribution of the products was different from that in the reaction without ethylene: (1) The acetone yield decreased greatly in the presence of ethylene, while the yields of 2-methyl-2-butanol, *dl*-2-pentanol, and hydrocarbons increased. These findings suggest that there is a close relationship between the formations of acetone and of these alcohols.

The radicals from 2-propanol in the silent discharge are mainly $(CH_3)_2\dot{C}OH$, $CH_3CHOH\dot{C}H_2$ and $\dot{C}H_3$, as has been described in the previous paper.[4] Acetone can be formed by the elimination of a hydrogen atom from the $(CH_3)_2\dot{C}OH$ and CH_3-$CHOH\dot{C}H_2$ radicals, while 2-methyl-2-butanol and *dl*-2-pentanol can be formed by adding these radicals to ethylene. Thus, the decrease in acetone in the presence of ethylene seems to be due to the latter addition reaction. A similar mechanism has also been observed in the light-[2] and γ-ray-induced[3] reactions.

The possible combination reaction of the $(CH_3)_2$-$\dot{C}OH$ radical with the $\dot{C}_2H_5$ radical which might explain 2-methyl-2-butanol has been discarded, since little or no *n*-butane, which would indicate the presence of $\dot{C}_2H_5$ radicals, was observed.

(2) The yield of *dl*-2-butanol was scarcely affected by the presence of ethylene. Possible ways of this production are thought to be as follows:

TABLE 2. TEMPERATURE DEPENDENCE OF THE YIELD

Run No.	10	11	12	14
Packing		$Cu(OH)_2$**		
Second. voltage, kV	0	15	15	15
Second. current, mA	0	1.4	1.2	1.0

Ethylene velocity, *l*/hr	2.80	2.44	2.62	2.74
Molar ratio (C_2H_4/*i*-PrOH)	0.96	0.87	0.89	0.93
Amount of liquid products, g	11.30	7.67	1.31	0.02
Conversion, %***	28.96	20.42	3.36	0.05
Composition of liquid products, %****				
Acetone	97.0	83.7	83.5	43.6
Acetaldehyde	0	1.7	4.3	5.1
2-Methyl-2-butanol	0	0.5	2.1	10.3
2-Methyl-2-propanol	0	0	1.1	Trace
dl-2-Butanol	0	0.1	0.8	Trace
dl-2-Pentanol	0	0	0.9	7.7
Methyl vinyl ketone	0	0	1.7	0
Hydrocarbons	1.3	13.5	4.8	7.7
The others	1.7	0.5	0.8	25.6

$$CH_3\dot{C}HOH + CH_2{=}CH_2 \rightarrow CH_3CHOH\dot{C}_2H_4$$
$$\xrightarrow[i\text{-PrOH}]{} CH_3CHOHC_2H_5 \quad (A)$$
$$CH_3CHOH\dot{C}H_2 + \dot{C}H_3 \rightarrow CH_3CHOHC_2H_5 \quad (B)$$

Thus, reaction B may be thought to be retarded in the presence of ethylene and reaction A, to be facilitated, because ethylene may act as a free radical scavenger; the reverse is the production of *dl*-2-butanol in the reaction without ethylene.

b) With a Special Tube. When the reaction of 2-propanol with ethylene was carried out in a special discharge tube filled with $Cu(OH)_2$ (Run No. 12), as compared with the reaction without ethylene (Run No. 13), the following differences were noticed in the liquid products: (1) the acetone yield increased remarkably, and (2) the yields of 2-methyl-2-propanol, methyl vinyl ketone, and hydrocarbons decreased. A similar tendency was observed when a reduced copper tube[4] was used.

Thomas *et al.*[6] showed that, in the decomposition of ethylene under a silent discharge, the products most frequently identified were hydrogen, acetylene, and a liquid.

In the present work the hydrogen thus produced may turn $Cu(OH)_2$ into some effective catalyst for the dehydrogenation of 2-propanol.[7] For this reason, the acetone yield might increase in the presence of ethylene.

Thomas *et al.*[6] have also shown that acetylene and hydrogen are formed through the vinyl radical, and that the radical could give 1-butene and 1,3-butadiene. These C_4-hydrocarbons were observed little in the reaction of 2-propanol with ethylene (Run No. 12), though some were obtained in the reaction without ethylene (Run No. 13). Thus, it is thought that most of the vinyl radicals produced decompose immediately to form C_2H_2 and H_2 when there is a high flow rate of ethylene in the presence of $Cu(OH)_2$. For this reason, the methyl vinyl ketone yield might decrease in the reaction with ethylene.

Temperature Dependence of the Yield. As may be seen from Run No. 10 in Table 2, the reaction of 2-propanol with ethylene at 150°C without an electrical field afforded a great quantity of acetone. Similar results were also observed in the silent-discharge-induced reaction at 150°C (Run No. 11). Thus, at such a high temperature, it may be said that the dehydrogenation to give acetone occurred preferably to an interaction of 2-propanol and ethylene induced by the discharge.

The author wishes to express his thanks to Professor Tamon Matsuura, Hiroshima University, and to Professor Kazuaki Kawamoto, Kagawa University, for their kind advice.

Antituberclous Compounds. XXVII. Synthesis of 7,8-Dihydropyrido-[2.3-*d*]pyridazin-(6*H*)-one[1]

Shichiro KAKIMOTO and Shuichi TONOOKA

Research Institute for Tuberculosis, Hokkaido University, Sapporo

(Received December 29, 1968)

In a previous paper,[2] it was reported that attempts to prepare some derivatives of dihydropyrido[2.3-*d*]pyridazine in order to study relationship between chemical constitution and tuberclostatic activity were not successful. In this paper, two different synthetic methods of 7,8-dihydropyrido[2.3-*d*]pyridazin-5(6*H*)-one will be reported; the synthesis of this substance was attempted previously.

Hurst and Wibberley[3] prepared ethyl 2-bromomethylnicotinate by the bromination of ethyl 2-methylnicotinate with *N*-bromosuccinimide (NBS). By the same method, its hydrobromide (I) was obtained directly in a pure state. When the compound was treated with hydrazine hydrate, two new compounds, (II), mp 213—215°C, and (III), mp 195—197°C, were obtained in good yields. The ratio of their yields was about 4 : 1. By treatment with alkali, III was converted to II, which was also obtained by the reduction of pyrido[2.3-*d*]pyridazin-5(6*H*)-on-thiol[4] (VI) with amalgamated aluminum. The IR spectrum of II has absorption bands at 3270 cm^{-1} (amino group) and at 1660 cm^{-1} (carbonyl group). The NMR spectrum indicates that it has three protons of the pyridine ring in an AMX-type arrangement and shows a 2-proton singlet of the methylene group at τ 6.45. The compound was oxidized to pyrido[2.3-*d*]pyridazin-5(6*H*)-one[2] (IV) by chromic acid anhydride in acetic acid or by aeration in the presence of peroxide. It was, therefore, concluded that II is 7,8-dihydropyrido[2.3-*d*]-pyridazin-5(6*H*)-one.

The behavior of the pyridine ring is different from that of the benzene ring. Methyl 2-bromomethyl benzoate was treated with hydrazine hydrate in the same way. Only phthalazin-1(2*H*)-one was produced, not 3,4-dihydrophthalazin-1(2*H*)-one. It is certain that the latter is easily oxidized during preparation. Hirsch *et al.*[5] found that some 4-substituted 3,4-dihydrophthalazine derivatives were oxidized to the corresponding phthalazinone by aeration without peroxide.

The IR spectrum of compound III has two bands, at 3330 cm^{-1} and 3270 cm^{-1} indicating an amino group, and one band, at 1690 cm^{-1}, indicating a carbonyl group. The NMR spectrum shows three 1-proton doublet-doublets due to the three protons of the pyridine ring, at τ 1.25, 1.90, and 2.60; a 2-proton singlet at τ 5.40 due to a methylene group, and a 2-proton broad peak at τ 5.65 due to an amino group. The amino group was acetylated with acetic anhydride. It is clear that III is 2-amino-dihydropyrrolo[3.4-*b*]pyridin-1-one.

Experimental[6]

Ethyl 2-Bromomethylnicotinate Hydrobromide (I). Ethyl 2-methylnicotinate (5g) was brominated with NBS in carbon tetrachrolide as usual. Dried hydrobromic acid was introduced into the reaction mixture, and then hydrobromide was separated from the mixture as a yellow crystalline substance. Recrystallization from ethanol - ligroin afforded 4.4 g of I, mp 157—159°C (decomp.). NMR (D_2O) τ: 4.93 ($-CH_2Br$, singlet). Found: C, 33.17; H, 3.62%. Calcd for $C_9H_{10}O_2NBr \cdot HBr$: C, 33.26; H, 3.41%.

7,8-Dihydropyrido[2.3-*d*]pyridazin-5(6*H*)-one (II). i) To a solution of 0.95 g of I in 20 m*l* of ethanol there was added 0.7 m*l* of hydrazine hydrate, and then the mixture was refluxed for 2.5 hr. After evaporation to a small volume, it was cooled to afford 320 mg of II, mp 213—215°C.

ii) A mixture of 0.5 g of VI, 0.5 g of amalgamated aluminum, and 100 m*l* of 50% ethanol was refluxed for 10 hr. The filtrate of the reaction mixture was then evaporated to dryness. The residue was extracted with water, and the aqueous solution was evaporated to give a crystalline product. Recrystallization from water afforded 0.1 g of II, mp 213—215°C, as needles with one mole of the water of crystallization.

IR: ν_{max} 3270, 3210 (NH), 1660 cm^{-1} (CO). NMR

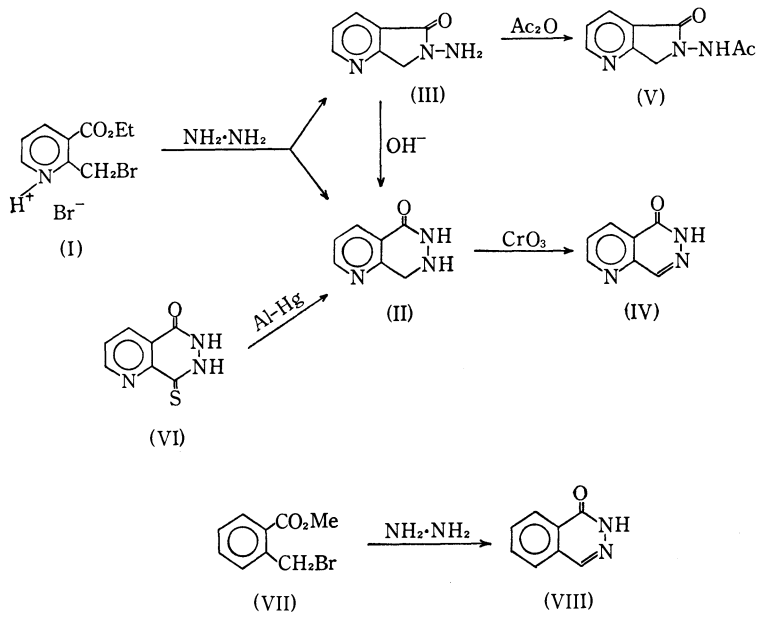
3) J. Hurst and D. G. Wibberley, *J. Chem. Soc.*, **1962**, 120.

4) S. Kakimoto, H. Shintani and K. Yamamoto, Annual Report of Research Institute for Tuberculosis, Hokkaido University, **27**, 1 (1966).

5) A. Hirsch and D. G. Orphanos, *J. Heterocyclic Chem.*, **3**, 38 (1966).

6) All the melting points are uncorrected; the IR spectra were measured in Nujol, while the NMR spectra were determined on a Japan Electron Optics 3H-60 high resolution NMR spectrometer, using TMS or DSS as the internal reference.



(D_2O) τ: 2.20 (H_α of pyridine-ring, doublet-doublet), 2.45 (H_γ of pyridine-ring, doublet-doublet), 3.40 (H_β of pyridine-ring, doublet-doublet), $J_{\alpha\beta}=5.0$, $J_{\beta\gamma}=8.0$, $J_{\alpha\gamma}=2.0$ cps. 6.45 ($-CH_2-$, singlet) Found: C, 50.29; H, 5.38; H_2O, 10.88%. Calcd for $C_7H_7ON_3\cdot H_2O$: C, 50.29; H, 5.43; H_2O, 10.77%.

Oxidation of II to IV. i) To a mixture of 0.1 g of II and 2 m*l* of acetic acid these were added 10 m*l* of a 1/5 N chromic oxide solution in acetic acid; the mixture was then allowed to stand for 1 hr. After the evaporation of the acetic acid under reduced pressure, the residue was recrystallized from water to give 0.1 g of white needles. Its identity as IV was established by a study of the IR spectra and melting points.

ii) A solution of 0.1 g of II in 5 m*l* of ethanol, along with several mg of benzoyl peroxide, was aerated at 50—60°C for 24 hr. During aeration the total volume was kept at about 5 m*l* by the addition of ethanol from time to time. After the ethanol had then been removed, the residue was recrystallized from ethanol-ligroin to give 35 mg of white needles. Its identity as IV was confirmed by a study of the IR spectra and melting points.

2-Aminodihydropyrrolo[3.4-*b*]pyridin-1-one (III). The mother liquor of II was evaporated to dryness and the residue was recrystallized from ethanol-ligroin to give 85 mg of III as white crystalline plates, mp 195—197°C. IR: ν_{max} 3330, 3270 (NH), 1690 cm^{-1} (CO). NMR ($CDCl_3$) τ: 1.25 (H_α of pyridine-ring, doublet-doublet), 1.90 (H_γ of pyridine-ring, doublet-doublet), 2.60 (H_β of pyridine-ring, doublet-doublet), $J_{\alpha\beta}=4.5$, $J_{\beta\gamma}=8.0$, $J_{\alpha\gamma}=1.5$ cps. 5.40 (methylene-group, singlet), 5.65 (amino-group, broad peak). Found: C, 56.37; H, 4.75%. Calcd for $C_7H_7ON_3$: C, 56.37; H, 4.73%.

2-Acetamidodihydropyrrolo[3.4-*b*]pyridin-1-one (V). III (60 mg) was dissolved in 5 m*l* of acetic anhydride, and the mixture was warmed on a steam bath for 4 hr. After the removal of the excess acetic anhydride under reduced pressure, the residue was recrystallized from ethanol-ligroin to give 25 mg of an acetyl compound, V, mp 173—175°C. IR: ν_{max} 3230 (NH), 1720 ($COCH_3$), 1690 cm^{-1} (CO). Found: C, 51.65; H, 5.35; H_2O, 8.99%. Calcd for $C_9H_9O_2N_3\cdot H_2O$: C, 51.67; H, 5.30; H_2O, 9.23%.

III to II. III (53 mg) was heated in a dilute potassium hydroxide solution on a steam bath for 1 hr. After neutralization with dilute hydrochloric acid, the solution was evaporated to dryness under reduced pressure, and the residue was extracted with ethanol. After the ethanol had then been removed under reduced pressure, the residue was recrystallized from ethanol-ligroin to give 20 mg of white needles. Its identity as II was established by a study of the IR spectra and melting points.

Phthalazin-1(2*H*)-one (VIII). Methyl 2-methyl benzoate was treated with NBS in carbon tetrachloride in the manner used to cause I to afford VII. Its NMR spectrum showed four protons of benzene at τ 2.0—2.6, a 2-proton singlet at τ 5.05, and a 3-proton singlet at τ 6.10. VII (2 g) was treated with hydrazine hydrate in the same manner as has been described for II to give 0.35 g of VIII, mp 181—183°C. Its identity with an authentic sample[7] was confirmed by a study of the IR spectra and a mixed-melting-point determination.

The Spectrophotometric Determination of Beryllium with Chromal Blue G

Katsuya UESUGI

Laboratory of Chemistry, Himeji Institute of Technology, Himeji

(Received January 16, 1969)

The present author and his co-workers[1-5] have studied the methods of the spectrophotometric determination of several metals using dyes of the triphenylmethane series, and have previously reported[5] a spectrophotometric determination of scandium with chromal blue G (sodium-2''-chloro-4''-nitro-4'-hydroxy-3,3'-dimethylfuchsone-5,5'-dicarboxylate, color index 43835), and found that a very small amount of beryllium also reacts with this reagent in a weakly acidic medium to form a complex. This paper will describe a spectrophotometric determination of beryllium using this reagent. The proposed method is not selective, like other reagents for beryllium, but it is more sensitive than the methods using chromazurol S,[6] eriochrome cyanine R,[7] or xylenol orange,[8] which have structures similar to that of this reagent.

Experimental

Reagents and Apparatus. *Standard Beryllium Solution.* A standard beryllium solution was prepared by dissolving 1.964 g of beryllium sulfate tetrahydrate (Mitsuwa Chemicals) in distilled water, then adding 10 m*l* of hydrochloric acid and diluting the solution to 1 *l*. The solution contained 100 μg of beryllium per milliliter. This standard stock solution was then further diluted to 10 ppm with distilled water.

Chromal Blue G Solution. The chromal blue G (Geigy Chemicals, New York, U. S. A.) was purified by recrystallization from ethanol before use, and then 0.1 g of it was dissolved in 100 m*l* of 95% ethanol. This solution was stable for at least a month.

All the other reagents and the apparatus used were the same as those reported previously.[5]

The Standard Procedure for Beryllium Determination. To a sample solution containing from 1 to 8 μg of beryllium, add 2 m*l* of the chromal blue G solution, then add 10 m*l* of an acetate buffer solution (pH 6.0), mix well, and make up to 25 m*l* with distilled water. Determine the absorbance at 610 mμ against a reagent blank solution treated in a similar manner. From the measured absorbance, determine the beryllium concentration of the sample solution by the use of a calibration curve.

Results and Discussion

Absorption Curves. The absorption curves of chromal blue G have been presented in a previous paper;[5] the maximum absorption is at 480 mμ below pH 4.0, at 430 mμ over the pH range from 5.5 to 10.0, and at 590 mμ above pH 10.5. The absorption curves of the beryllium-chromal blue G complex at various pH values are shown in Fig. 1. These curves were obtained by measuring the absorbance of the solution containing 0.12 ppm of beryllium and 80 ppm of chromal blue G at various pH values against a reagent blank solution. Above pH 5.0, the solutions give essentially identical absorption curves, with an absorption maximum

8) M. Otomo, This Bulletin, **38**, 730 (1965).

at 610 mμ. However, the reagent solution has a slight absorption at this wavelength in the pH range from 5.5 to 7.5. Below pH 4.5, the position of the maximum absorption shifts to 570 mμ. The curve obtained at pH 5.0 has a shoulder at about 580 mμ.

Effect of pH. The effect of pH on the color development of the complex was examined by measuring, at 610 mμ, the absorbance of a solution containing 0.12 ppm of beryllium and 80 ppm of the reagent at different pH values from 4.5 to 9.0. The results are shown in Fig. 2, from which it can be seen that the maximum absorbance of the beryllium complex occurs in the pH range from 5.8 to 6.4. The amount of the buffer solution (pH 6.0 and 0.2 M in acetate) was found to have no effect on the absorbance over the range from 5 to 10 ml per 25 ml of the solution.

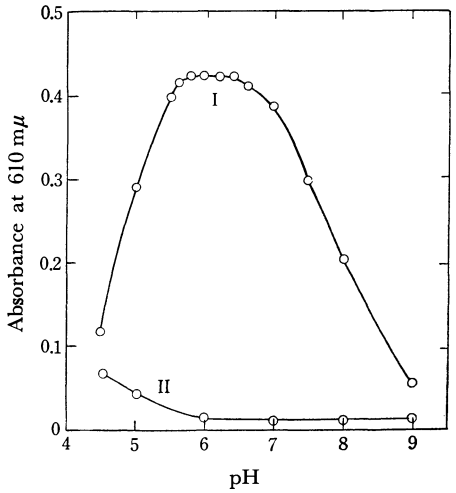

Fig. 2. Effect of pH on color development.
I: Be 0.12+Reagent 80 ppm (Reference: Reagent blank)
II: Reagent 80 ppm (Reference: Water)

Stability of Color. The color development between beryllium and the reagent occurs instantaneously at room temperature. The color intensity of the solution remains almost constant for at least 2 hr after preparation when measured against a reagent blank.

Effect of Reagent Concentration. The effect of the chromal blue G concentration on the color development was examined by varying the concentration of the reagent at a constant beryllium concentration. The absorbance of the beryllium complex at 610 mμ gradually increases at higher reagent concentrations. However, above 1.0 ml of a 0.1% reagent solution, the rate of the increase of the absorbance is relatively small. On the basis of these data, 2.0 ml of 0.1% reagent solution was chosen as the fixed quantity to be added. Two milliliters of a 0.1% chromal blue G solution for 25 ml of the solution was found to be a sufficient amount for less than 0.3 ppm of beryllium.

Effect of Temperature. The effect of the temperature on the color development was examined by measuring the absorbance of colored solutions kept at various temperatures for 20 min after preparation. There was no variation in the absorbance of the colored complex over the temperature range from 10 to 40°C. At temperatures over 40°C, however, the color intensity decreased.

Beer's Law and Sensitivity. The linearity between the absorbance of the beryllium-chromal blue G complex and the beryllium concentration was examined by varying the beryllium concentration and by measuring the absorbance at a wavelength of 610 mμ and at pH 6.0. The beryllium complex was found to follow Beer's law up to a beryllium concentration of at least 0.3 ppm. The molar absorptivity is 31000 at 610 mμ. The spectrophotometric sensitivity[9] is estimated to be 3×10^{-4} μg of beryllium per cm², corresponding to $\log I_0/I=0.001$.

Effect of Diverse Ions. A study was made of the effect of several cations and anions. The most commonly-encountered ions were added individually to a solution containing 10 μg of beryllium. From the results, it can be concluded that copper(II), aluminum, iron(III), nickel, scandium, yttrium, and rare earth elements interfere seriously with the determination of beryllium.

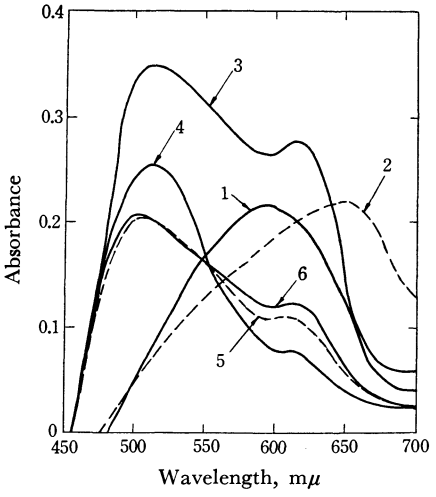

Fig. 3. Absorption spectra of aluminum, iron(III), yttrium, lanthanum, gadolinium, and erbium complexes at pH 6.0.
Reagent 80 ppm, Reference: Reagent blank
1 : Al 0.13 ppm, 2 : Fe(III) 0.26 ppm, 3 : Y 1.5 ppm, 4 : La 1.5 ppm, 5 : Gd 1.5 ppm, 6 : Er 1.5 ppm

9) E. B. Sandell, "Colorimetric Determination of Traces of Metals," 3rd Ed., Interscience Publishers, New York (1959), p. 83.

Sulfate, chloride, nitrate, and acetate ions, on the other hand, do not interfere. Oxalate, fluoride, citrate, phosphate, and EDTA bleach the complex.

The absorption curves of the complexes of aluminum, iron(III), yttrium, and some of the rare earth elements at pH 6.0 are shown in Fig. 3. The maximum absorption of the aluminum complex is at 590 mμ, much like that of the scandium complex,[5] while that of the iron(III) complex is shifted toward a longer wavelength. The complexes of yttrium, lanthanum, gadolinium, and erbium at pH 6.0 have two absorption maxima, as is shown in Fig. 3.

Complex Formation. The composition of the beryllium-chromal blue G complex was established by the continuous variation method.[10] The results are shown in Fig. 4, which indicates that a 1-to-2 complex is formed between beryllium and chromal blue G at pH 6.0. Similar relations were also observed for scandium and the chromal blue G complex.[5] In order to estimate the composition of the complex formed below pH 4.5, the method of continuous variation was employed. The results indicated that the combining ratio of beryllium and chromal blue G is 1 to 1. These results were confirmed by the mole ratio method.

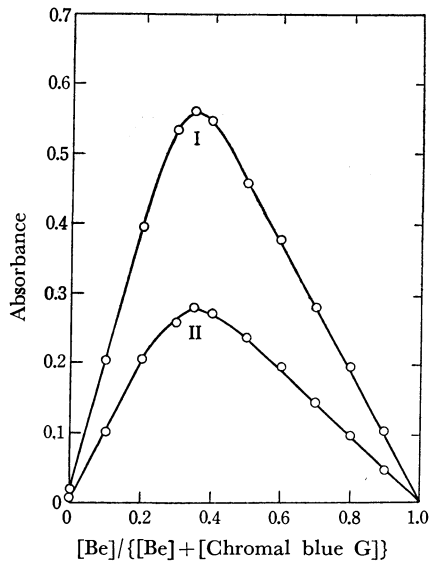

Fig. 4. Continuous variation method.
pH 6.0, Wavelength: 610 mμ
I: [Be]+[Chromal blue G]=8.52×10^{-5} M
II: [Be]+[Chromal blue G]=4.26×10^{-5} M

10) P. Job, *Ann. Chim.*, **9**, 113 (1928).

The formation constant of the beryllium complex was determined spectrophotometrically by the method used in a previous paper.[5] The conditional formation constant for the complex at pH 6.0 and 20°C was calculated, from the curves of the continuous variation, to be 4.3×10^{10}.

The proposed method was compared with the methods using some other reagents with structures similar to that of this reagent. The results are listed in Table 1. The proposed method using chromal blue G has some advantages: the sensitivity is very high, the solution is stable and the calibration curve is very reproducible, and the procedure is simple.

Table 1. Comparisone with other method

Method	Molar absorptivity [Sensitivity]	Precision

Reaction of α-Phenethyl Radical in Liquid Sulfur Dioxide

Masashi IINO,*1 Tsutomu ENOMOTO and Niichiro TOKURA

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Suita-shi, Osaka

(Received January 21, 1969)

Squire and Waters found that in the reaction of phenyl radical with sulfur dioxide diphenyl disulfone was formed by coupling reaction of benzene sulfonyl radicals, but diphenyl sulfone could not be obtained.[1] On the other hand, in the reaction of methyl radical with sulfur dioxide both dimethyl disulfone and dimethyl sulfone were formed.[2]

We have investigated the reaction of sulfur dioxide with α-phenethyl radical formed by the decomposition of 1,1′-azo-bis-1-phenylethane or by the abstraction of α-hydrogen atom from ethyl benzene.

We obtained neither disulfone ($CH_3CH(C_6H_5)$-$SO_2SO_2CH(C_6H_5)CH_3$) nor monosulfone (CH_3CH-$(C_6H_5)SO_2CH(C_6H_5)CH_3$) in thermal or photochemical decomposition reaction of 1,1′-azo-bis-1-phenylethane in liquid sulfur dioxide, although 2,3-diphenylbutane, the coupling product of α-phenethyl radicals, was obtained. The same results as described above have been obtained in the reaction of ethylbenzene and benzoyl peroxide in the presence of sulfur dioxide.

These results are interesting, contrasting with those of reactions of methyl and phenyl radical. It is reasonable to consider that α-phenylethane sulfonyl radical is formed in these reactions, and has little reactivity toward coupling reaction, because in the radical copolymerization of styrene and sulfur dioxide[3] styrene polysulfone ($-CH_2CH$-$(C_6H_5)SO_2-$) is formed and a substituted α-phenylethane sulfonyl radical ($-CH_2CH(C_6H_5)$-$SO_2\cdot$) seems to be one of the chain carriers. At present, however, the reason why we have obtained neither disulfone nor monosulfone is not clear.

Experimental

Materials. 1,1′-Azo-bis-1-phenylethane was prepared from acetophenone.[4,5] 1,1′-Azo-bis-1-phenylethane obtained was recrystallized three times from 99% ethanol. Found: C, 79.93; H, 7.24; N, 12.22%. Calcd for $C_{16}H_{18}N_2$: C, 80.67; H, 7.56; N, 12.22%. mp 70.2—73.0°C (lit[5] 72.3—72.9°C), λ_{max} 355—357 mμ.

Liquid sulfur dioxide was dehydrated with phosphorus pentoxide and distilled. Ethylbenzene was washed with concentrated sulfuric acid and water successively, dried with anhydrous magnesium sulfate, and then distilled. Commercial benzoyl peroxide was used without further purification.

Reaction of 1,1′-Azo-bis-1-phenylethane with Sulfur Dioxide (Thermal Decomposition of 1,1′-Azo-bis-1-phenylethane in Liquid Sulfur Dioxide). Into a glass pressure vessel (about 300 m*l* capacity)[6] charged with 1,1′-azo-bis-1-phenylethane (3 g), liquid sulfur dioxide (45 g) was introduced by using a pressure resistant buret[6] after the replacement of oxygen in the vessel by nitrogen stream. This reaction vessel was then immersed in boiling water (95—97°C) and kept for eight hours. Sulfur dioxide in the vessel was then evaporated under reduced pressure. Extraction with petroleum ether from the residue (3.2 g) and removal of the solvent from the extract (petroleum ether-soluble part) gave a viscous oil (2.1 g). This oil was then dissolved in about 10 m*l* of petroleum ether and chromatographed on an alumina column. Elution with petroleum ether gave colorless crystals of 2,3-diphenylbutane (0.1 g), which were recrystallized from methanol. Found: C, 91.44; H, 8.56%. Calcd for $C_{16}H_{18}$: C, 91.37; H, 8.63%. mp 123.5—124.5°C (lit[5] 125.3—125.9°C). Elution with benzene gave yellow crystals of acetophenone-azine (1.0 g), mp 122—123°C (recrystallized from ethanol) (lit[5] 122.2—123.0°C), which showed no depression of melting point by mixing with an authentic specimen. Further elution with benzene gave a yellow liquid of actophenone (small amount) which was identified by its transformation into 2,4-dinitrophenylhydrazone.

As the petroleum ether-insoluble part was found to be acidic, about 30 m*l* of water was added into the substance and the resulting solution was neutralized by aqueous sodium hydroxide solution. The solution was then extracted with diethyl ether. Acetophenone (0.3 g) was obtained from the ethereal solution by evaporating ether and then distilling the residue under reduced pressure. Addition of aqueous barium chloride solution to water layer gave 0.3 g of barium sulfate.

Neither disulfone nor monosulfone could not be identified, and IR spectra of petroleum ether-soluble and insoluble parts did not show their presence.

On the other hand, acetophenone and sulfate ion obtained from the petroleum ether-insoluble part are considered to be formed by the decomposition of petro-

Table 2. Photochemical reaction of 1,1'-azo-bis-1-phenylethane (APE) with sulfur dioxide

Reactant (g)		Solvent (g) ethyl-benzene	Reaction temp. (°C)	Reaction time (hr)	Product (mol%)*			
APE	SO_2				2,3-diphenyl-butane	acetophenone azine	aceto-** phenone	SO_4^{2-} **
2.9	45		room temp.	24	5.7	trace	19.8	16.3
3.0	15	82	room temp.	24	20.4	12.1	16.5	9.5

* This value was calculated from the molar ratio of product *vs.* APE.
** Sulfate ion and probably a part of acetophenone was formed from the decomposition of an unidentified product by water.

leum ether-insoluble product by water. This materials was at first a white solid and then turned into a yellow and sticky solid on exposure to air, and had the absorption near 2600 cm^{-1} (broad) and 1200 cm^{-1} which disappeared after the addition of water. Although the structure of the product is not yet established, it is considered to be neither disulfone nor monosulfone from its chemical behavior.

Similar experiments were carried out at different reaction temperatures, or by using solvents. The results are summarized in Table 1. Table 1 also shows that the decomposition of 1,1'-azo-bis-1-phenylethane in ethyl benzene gave 2,3-diphenylbutane. No reaction occurred at room temperature in the 1,1'-azo-bis-1-phenylethane - sulfur dioxide system, although mixing of the two reactants exhibited a yellow coloration due, probably, to the formation of a charge-transfer complex.

Reaction of 1,1'-Azo-bis-1-phenylethane with Sulfur Dioxide under Irradiation of Ultraviolet Light. 1,1'-Azo-bis-1-phenylethane has a strong absorption in the region of 320 mμ to 400 mμ (λ_{max} 355—357 mμ). The reaction vessel was a quartz cylindrical vessel equipped with a stainless steel joint connected by a stopcock[6] to a pressure-resistant buret.[6] The reaction was carried out under irradiation by using a 300 W mercury lamp. Other details of the experimental procedure were the same as described in the case of the thermal decomposition of 1,1'-azo-bis-1-phenylethane in liquid sulfur dioxide and the results obtained are summarized in Table 2.

Table 2 shows that the same products as listed in Table 1 were obtained and no sulfone could be detected.

Reaction of Ethylbenzene and Benzoyl Peroxide in the Presence of Sulfur Dioxide. A Solution of benzoyl peroxide (30 g) in ethylbenzene (300 m*l*) in a 1 *l* round-bottomed flask was heated at 70°C under a reflux condenser, and sulfur dioxide was passed into slowly through an inlet glass tube extending to the bottom of the flask. Passage of sulfur dioxide was continued for 42 hr. The treatment of the reaction mixture afforded 14.2 g of benzoic acid, 0.4 g of 2,3-diphenylbutane and 4.5 g of low molecular-weight styrene-polysulfone, but no sulfone having α-phenethyl group could be obtained.

The authors wish to thank the Seitetsu Kagaku K. K. for the donation of liquid sulfur dioxide.

Preparation and Ion-exchange Behavior of Potassium Zinc Ferrocyanide

Shoichi KAWAMURA, Katsumi KUROTAKI and Masami IZAWA

Chemistry Division, National Institute of Radiological Sciences, Anagawa, Chiba-shi

(Received January 22, 1969)

Since the early work of Miller[1] in 1896, a number of compounds containing potassium, zinc and ferrocyanide have been prepared and their compositions investigated mainly for the study of volumetric determination of zinc ion or of ferrocyanide ion.[2-7] During the past few years, considerable interest has been shown in the ion-exchange property of zinc ferrocyanide.[8-12]

In an attempt to elucidate this property of the ferrocyanides, the authors tried to prepare zinc ferrocyanide $Zn_2Fe(CN)_6$, according to the procedure described by Kohn.[13] The resulting product was found to be potassium zinc ferrocyanide $K_2Zn_3[Fe(CN)_6]_2$, but not zinc ferrocyanide. This paper describes some ion-exchange properties and X-ray diffraction data concerning potassium zinc ferrocyanide and zinc ferrocyanide.

Experimental

Preparation by the Kohn Method.[13] Into 300 m*l* of 0.1 M $K_3Fe(CN)_6$, 630 m*l* of 0.1 M $ZnSO_4$, 180 m*l* of 15% sodium acetate and 300 m*l* of 3% hydrogen peroxide were added little by little in this order. On continuous stirring, the slurry was heated on a boiling water bath until its color changed from yellow to white. It was then poured into cold water, tenfold in volume of the slurry, allowed to stand for 24 hr, filtered, washed thoroughly and dried at 60°C for 24 hr.

Zinc Ferrocyanide.[10,11] Zinc ferrocyanide was prepared by mixing 300 m*l* of 0.1 M $Na_4Fe(CN)_6$, and 900 m*l* of 0.1 M $Zn(NO_3)_2$. The white slurry was obtained by dropping the solutions little by little simultaneously into a beaker for 30 min under stirring. It was heated with stirring on a boiling water bath for 2 hr, allowed to stand for 24 hr, filtered, washed thoroughly and dried at 60°C for 24 hr. The ferrocyanides thus prepared were compressed into pills under a pressure of about 300 kg/cm^2, allowed to break down in water for several days, air dried, and sieved into 200—300 mesh.

Analyses. The ferrocyanides were dissolved with a minimum amount of 0.1 M EDTA-ammonium solution, followed by dilution with water to a given volume, to be subjected to the determination of potassium, zinc and ferrocyanide. Zinc and ferrocyanide were determined by volumetric analysis, and potassium by atomic absorption spectroscopy.

Distribution Coefficient. Distribution coefficients (ml/g) for cesium were determined by equilibrating 0.1 g of the ferrocyanides with 5 m*l* of NH_4NO_3 solutions (3×10^{-2}—3.5 M) containing 5×10^{-2} mmol of $CsNO_3$ tagged with ^{137}Cs, followed by centrifugation at 1000 g for 15 min. The radioactivity of the supernatant was measured by a well type scintillation counter.

Results and Discussion

The product prepared by the Kohn method[13] was analyzed, the result of which is shown in Table 1. The stoichiometrical composition is best represented by $K_2Zn_3[Fe(CN)_6]_2$. The same compound can be prepared by adding 0.1 M potassium ferrocyanide to 0.1 M zinc nitrate in the mole proportion of 1 : 1.5, followed by the same treatment as with zinc ferrocyanide. Adsorption rates of cesium ion on potassium zinc ferrocyanide and zinc ferrocyanide[10,11] were determined. Figure 1

X-ray powder patterns were taken on an apparatus from Rigaku Denki Co., Ltd., Tokyo, Japan, using filtered CuK_α radiation (1.5418Å).

shows that the adsorption rate of potassium zinc ferrocyanide is significantly higher than that of zinc ferrocyanide.

Comparison of these ferrocyanides was made by means of X-ray diffraction. Table 2 shows that the X-ray diffraction patterns of potassium zinc ferrocyanide are quite different from those of zinc ferrocyanide. The discrepancy of X-ray data, *viz.*, the difference in crystal structure, may be comparable to the difference of the adsorption rate.

Ion-exchange behaviors of both ferrocyanides were studied in ammonium nitrate solutions. The relations of the log K_d *versus* log[NH_4] showed a straight line of slope -1. Further experiments showed that, in the batch equilibration in the concentration <0.01 M Cs, potassium ions in the potassium zinc ferrocyanide are equivalently replaced by the adsorption of cesium ion in the external solution and zinc ions in the zinc ferrocyanide by the adsorption of cesium ion in the external solution. Therefore, the precipitation mechanism reported by Veseleý and Pekárek[14] was not observed in either ferrocyanide.

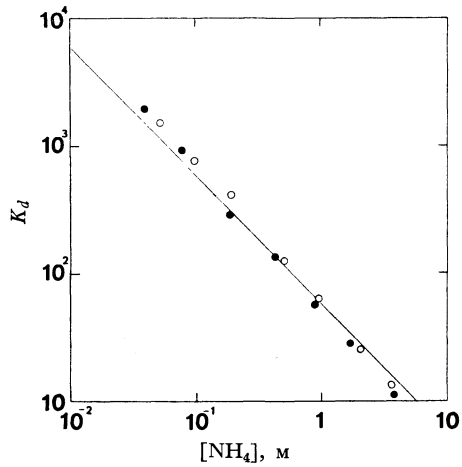

Fig. 2. Relationship between distribution coefficient for Cs and ammonium ion concentration.
-●- $Zn_2Fe(CN)_6$ -○- $Na_2Zn_3[Fe(CN)_6]_2$

These results indicate that the reaction is an ion-exchange ruled by the mass action law. The ferrocyanides were unfavorable for column work, since both were relatively fine powder and broken down slightly in aqueous suspension. However, the powdery characters were suitable as an adsorbent in thin layer chromatography. Potassium zinc ferrocyanide could advantageously be applied to a rapid separation of sodium, potassium, rubidium and cesium by thin layer chromatography.[12] This might be attributed to its rapid adsorption rate.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 3005—3007 (1969)

Photoreaction of 2,6-Diphenyl-4*H*-thiopyran-4-one

Noboru SUGIYAMA, Yoshiaki SATO, Hiroshi KATAOKA, Choji KASHIMA and Kazutoshi YAMADA

Department of Chemistry, Tokyo Kyoiku University, Otsuka, Bunkyo-ku, Tokyo

(Received March 17, 1969)

Although numerous reports on the photoreaction of nonbenzenoid aromatic compounds have been published,[1] there has been only one report on the photochemistry of a γ-pyrone-type compound, *i. e.*, 2,6-dimethyl-4*H*-pyran-4-one.[2] This paper will be concerned with the photoreaction of 2,6-diphenyl-4*H*-thiopyran-4-one(I).

The irradiation of I in a benzene solution (0.3 mol/*l*) by a high-pressure mercury lamp gave pale yellow crystals (II), mp 160—161°C, in a 25% yield. When the benzene solution of I was irradiated by a high-pressure mercury lamp with a Pyrex filter or a low-pressure mercury lamp with a quartz filter, the yield of II decreased to 8 or 2% respectively. When a solution of I in ether, methylene chloride, or ethanol was irradiated, hardly any formation of II detected. By the irradiation of I in the solid state, only an oily substance was produced. It was observed that a conversion of II to I of several per cent took two weeks to proceed at room temperature, but it occurred quantiatively at the melting point of II in only five minutes. In the boiling benzene, this conversion occurred with a half-life of five hours.

The structure of II was determined as follows. The NMR spectrum of II showed a singlet signal at τ 5.50 whose intensity was equivalent to that of a vinyl proton at τ 3.41. The IR spectrum of I showed a carbonyl band at 1600 cm^{-1}, but that of II showed it at 1640 cm^{-1}. The thermal formation of I from II and the NMR and IR spectra of II suggested that the structure of II was a dimer of I containing a cyclobutane ring.

For this type of dimer, four isomers are possible. However, their NMR spectra would show their cyclobutane methine protons as singlets in each case, for the environments of both methine protons would be equivalent. In order to distinguish the two protons, II was converted to a monobromo-derivative (III) by treating with a half mole of bromine. In its IR spectrum III showed carbonyl bands at 1657 and 1640 cm^{-1}. This fact indicates that the substitution with bromine occurred at the α-position of one enone system. This was also supported by the UV spectrum of III, which showed at 339 nm(ε 11200) the absorption maximum which was observed at 335 nm(ε 13200) in II. In the NMR spectrum of III, two singlet signals, at τ 5.31 and 5.28, show that both methine protons are situated at 1,3-positions in the cyclobutane ring. If both the protons are situated at 1,2-positions, they should have the coupling constant of 2.7—11 Hz.[3] Thus, the structure of II was

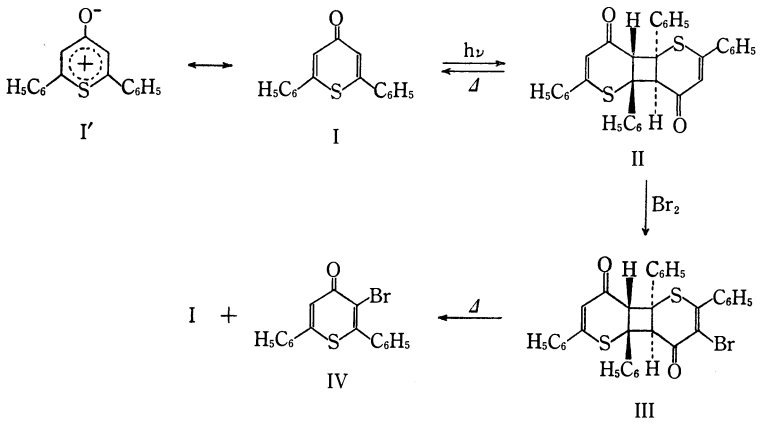

Fig. 1

1) *E. g.*, T. Tezuka, Y. Akasaki and T. Mukai, *Tetrahedron Letters*, **1967**, 5003.

2) P. Yates and M. J. Jorgenson, *J. Am. Chem. Soc.*, **85**, 2956 (1963); P. Yates and J. W. J. Still, *ibid.*, **85**, 1208 (1963).

3) I. Fleming and D. H. Williams, *Tetrahedron*,, **23**, 2747 (1967).

determined to be a head-to-tail dimer.

Moreover, the chemical shift of the vinyl proton of III is exactly the same as that of II. This fact indicates that the vinyl proton of III is not affected by the substitution with the bromine atom, though the chemical shifts of two methine protons of III are moved to a lower field. Therefore, the anti type is the preferable structure.

When III was heated at the melting point, both I and IV were quantitatively obtained. IV was identified with the authentic sample, which was synthesized from 2,6-diphenyl-tetrahydro-4*H*-thiopyran-4-one (V).

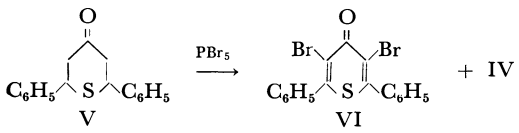

Fig. 2

In conclusion, it was proved that an anti, head-to-tail dimer was produced by the irradiation of I. This result indicates that the behavior of I in the excited state is similar to that of the enone system[4] in spite of its aromaticity. In the case of the irradiation of I in polar solvents, there was no product of II. This result seems to be attributable to the readier π-electron decrease (I') in its ring in the polar solvent, which gives rise to its aromaticity. This theory may be supported by the UV and NMR spectra of I in various solvents, shown in the Experimental section.

Experimental

Preparation of 2,6-Diphenyl-4*H*-thiopyran-4-one (I). I was synthesized by Arndt's method.[5] Mp 131—132°C (lit 132—133°C).

UV: $\lambda_{max}^{Benzene}$ nm(ε), 278(22500)
λ_{max}^{Ether} nm(ε), 276(22600)
$\lambda_{max}^{CH_2Cl_2}$ nm(ε), 266(26800), 300(15700)
λ_{max}^{EtOH} nm(ε), 265(19000), 304(21400)
IR: ν_{max}^{KBr} cm^{-1}, 1600
NMR: (τ in CCl_4), 2.2—2.7(m. 10H), 3.01(s.2H)
(τ in Ether), 2.2—2.7(m.10H), 2.97(s. 2H)
(τ in CH_2Cl_2), 2.2—2.7(m.10H), 2.85(s. 2H)
(τ in $CDCl_3$), 2.2—2.6(m.10H), 2.80(s. 2H)

Irradiation of I. On the irradiation of a benzene solution of I (0.3 mol/*l*) with a high-pressure mercury lamp under a nitrogen atmosphere for a week, pale yellow crystals (II) were produced on the wall of the reaction vessel in a 25% yield. These crystals were collected, chromatographed on silica gel with chloroform, and recrystallized from benzene or a chloroform-*n*-hexane mixture.

UV: $\lambda_{max}^{CHCl_3}$ nm(ε), 283(23700), 335(13200)
IR: ν_{max}^{KBr} cm^{-1}, 1640, 1560

a) Recrystallization from Benzene. Upon recrystallization from benzene, II gave pale yellow prisms. Mp 160—161°C. Found: C, 79.78; H, 5.29%. Calcd for $C_{34}H_{24}O_2S_2 \cdot C_6H_6$: C, 79.19; H, 4.98%.
NMR: (τ in $CDCl_3$) 2.4—2.8(m.26H), 3.41(s.2H), 5.50(s.2H).

b) Recrystallization from Chloroform-n-Hexane. This recrystallization of II gave pale yellow leaflets; mp 159—160°C. Found: C, 70.38; H, 4.17%. Calcd for $C_{34}H_{24}O_2S_2 \cdot 1/2CHCl_3$: C, 70.35; H, 4.32%.
NMR: (τ in $CDCl_3$) 2.4—2.8(m.20H), 3.41(s.2H), 5.50(s.2H). From these data of elemental analyses and NMR spectra, it can be said that II, which was recrystallized from benzene or chloroform-*n*-hexane, contains the solvents of crystallization. These solvents were not removed by heating under reduced pressure because of the instability of II described above.

When a high-pressure mercury lamp with a Pyrex filter or a low-pressure mercury lamp with a quartz filter was used under the same conditions, the yield of II was decreased to 8 or 3% respectively. By the irradiation of I in ether (0.1 mol/*l*) or in benzene (0.03 mol/*l*), only a trace of II was detected. However, on the irradiation of I in methylene chloride (0.3 mol/*l*) or in ethanol (0.1 mol/*l*), II was not detected at all. From the irradiated solutions, I was mainly recovered.

Irradiation in the solid state with a high-pressure mercury lamp produced an oily substance.

Preparation of the Monobromo-substituted Dimer (III). To an ice-cooled chloroform (5 m*l*) solution of II (80 mg) there was added a chloroform (2 m*l*) solution of bromine (24 mg). After the solution had been stirred for half an hour, the solvent was evaporated. The residue was chromatographed on silica gel with chloroform. As the main product, III (40 mg) was obtained; it was recrystallized from chloroform-*n*-hexane to afford colorless crystals; mp 170—171°C.

Found: C, 66.47; H, 3.95%. Calcd for $C_{34}H_{23}O_2S_2Br$ C, 67.21; H, 3.79%.
UV: $\lambda_{max}^{CHCl_3}$ nm(ε), 281 (21900), 339(11200).
IR: ν_{max}^{KBr} cm^{-1}, 1657, 1640, 1555.
NMR: (τ in $CDCl_3$) 2.3—2.8(m.20H), 3.41(s.1H), 5.28(s.1H), 5.31(s.1H).

Preparation of 3-Bromo-2,6-diphenyl-4*H*-thiopyran-4-one(IV) and 3,5-Dibromo-2,6-diphenyl-4*H*-thiopyran-4-one(VI). A benzene solution (10 m*l*) of 2,6-diphenyl-tetrahydro-4*H*-thiopyran-4-one (V) (530 mg) was refluxed with phosphorus pentabromide (3 g) for 5 hr. To the reaction mixture a saturated aqueous sodium thiosulfate solution (50 m*l*) was then added, and the mixture was extracted with benzene. The benzene solution was washed with water and dried over sodium sulfate. After the removal of the solvent, the residue was chromatographed on silica gel with benzene and benzene-ethyl acetate (19 : 1). VI (60 mg) and IV (30 mg) were obtained from the former and the latter respectively. The structure of VI was supported by its IR, UV and NMR spectra. The recrystallization of IV from carbon tetrachloride gave colorless needles; mp 121—123°C.

Found: C, 59.37; H, 3.27%. Calcd for $C_{17}H_{11}OSBr$: C, 59.42; H, 3.21%.

The Effects of Outer Sphere Cations and Halide Ions on Infrared Spectra of Pentahalogenonitrosylruthenium(III) Complexes

Eiichi MIKI, Tatsujiro ISHIMORI, Hideo YAMATERA* and Hisateru OKUNO

Department of Chemistry, College of Science, St. Paul's (Rikkyo) University, Nishi-Ikebukuro, Toshima-ku, Tokyo
**Department of Chemistry, Faculty of Science, The University of Nagoya, Chikusa-ku, Nagoya*

(Received March 20, 1969)

On the infrared spectra of alkali metal salts of nitrosylruthenium(III) complex anions, studies have been made on the effects of outer sphere cations and coordinated halide ions. The wave number of the N–O stretching vibration decreases in the order of K^+, NH_4^+, Rb^+ and Cs^+ for $M_2[RuCl_5(NO)]$ (M=K, NH_4, Rb and Cs)[1] and in the order of NH_3, Cl^-, Br^- and OH^- for $[RuX(NH_3)_4(NO)]^{n+}$ ion (X=NH_3, Cl, Br and OH *trans* to NO group).[2] Sinitsyn and Petrov have reported that, for $M_2[RuX_5(NO)]$ (M=Na, K, Rb and Cs; X=Cl, Br and I), the wave number of the Ru-N stretching as well as the N–O stretching vibration increases in the order of I, Br and Cl for a given alkali metal salt.[3] However, a distinction between the two skeletal vibrations of the RuNO group does not seem to have been fully made. Recently, we have made a clear assignment on the skeletal vibrations of the RuNO group of $K_2[RuX_5(NO)]$ (X=Cl and Br).[4,5]

We studied the infrared spectra of $M_2[RuX_5(NO)]$ (M=K, Rb and Cs; X=Cl, Br and I) and measured the wave numbers of the N–O stretching, Ru–N stretching, RuNO bending and Ru–X stretching vibrations. This report presents interesting observations on the shifts of the wave numbers of the vibrations by the replacement of the outer sphere cations and the halide ions.

In Table 1 are shown the wave numbers of the vibrations measured for $M_2[RuX_5(NO)]$.

For these compounds, the effects caused by the replacement of the outer sphere cations were observed on the Ru–N stretching and especially on the Ru–X (X *cis* to NO) stretching vibrations as well as on the N–O stretching vibration, but hardly any on the RuNO bending vibration. The wave

numbers of the N–O, the Ru–N and the Ru–X (X *cis* to NO) stretching vibrations decreased regularly in the order of M=K, Rb and Cs.

On the other hand, the shifts caused by the replacement of the halide ions were observed on the N–O stretching and especially on the RuNO bending vibrations, but hardly any on the Ru–N stretching vibration; replacing Cl^- with Br^- and I^-, the wave numbers of the N–O stretching and the RuNO bending vibrations decreased regularly in the order of X=Cl, Br and I. Although the N–O stretching and the RuNO bending vibrations shifted, the wave numbers of the Ru–N stretching vibration hardly changed at all by the replacement of the halide ions. This seems to be due to the fact that the RuNO bending vibration (E) is nearer the Ru–X (X *cis* to NO) stretching vibration (E) than the Ru–N stretching vibration (A_1) is to the Ru–X (X *trans* to NO) stretching vibration (A_1).

The effect on the vibrations caused by the replacement of the outer sphere cations and the halide ions can be qualitatively explained by the difference in electronegativities of the outer sphere cations and halide ions as suggested by Sinitsyn *et al.*[1-3] Although the positions of the cations in the crystals have not been determined yet, it should be noted that the outer sphere cations have an appreciable effect on the N–O, the Ru–N and the Ru–X (*cis* to NO) stretching vibrations.

Studies of Heteroaromaticity. XXXI.[1] New Reactions of Aromatic Amidoximes with Diketene

Tadashi SASAKI and Toshiyuki YOSHIOKA

Institute of Applied Organic Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya

(Received March 22, 1969)

While diketene is known to react with thiourea, amidines and guanidines affording uraciles,[2-4] no report has been given on the reactions with amidoximes. As a continuation of the previous papers[1,5] concerning the reactivity of aromatic amidoximes, this note deals with their new reactions with diketene.

Treatment of *p*-nitrobenzamidoxime (Ia) with a small excess amount of diketene in refluxing toluene afforded a quantitative yield of colorless product (IIIa); the infrared spectrum in a potassium bromide pellet showed a strong carbonyl absorption at 1720 cm^{-1} and the NMR spectrum in deuteriochloroform exhibited chemical shifts at 1.70 τ (singlet, 4 H, *p*-substituted phenyl protons), 5.81 (singlet, 2 H, methylene) and 7.60 (singlet, 3 H, methyl). From these data and microanalysis, compound IIIa was concluded as 3-(*p*-nitrophenyl)-5-acetonyl-1,2,4-oxadiazole. This result is of interest, when compared with our previous report[6] that 3-(5-nitro-2-furyl)-5-methylisoxazole was prepared by the reaction of diketene with 5-nitro-2-furhydroxamoyl chloride. Similarly, the products, IIIb and IIIc, were obtained from *m*-nitrobenzamidoxime (Ib) and 5-nitro-2-furamidoxime (Ic) respectively. These results are summarized in Table 1.

When treated with diketene in acetic acid or in pyridine at room temperature, Ic afforded a quantitative yield of 5-nitro-2-furamidoxime *O*-acetoacetate (IIc), a ring-opened product of IIIc, as thin yellow crystals of mp 136—138°C, which was readily cyclized to IIIc by refluxing in toluene. This provides good evidence that the formation of IIIc from Ic might proceeds *via* an intermediate IIc and that this reaction is initiated by the nucleophilic attack of diketene to the hydrogen of hydroxime, not to that of amine.[7] When diketene was replaced by ethylene carbonate, phenyl glycidyl ether or β-propiolactone in the above reactions, no reactions could be observed.

When the *N*-phenyl- (IVc) or the *N*-methylamidoxime (IVc') was treated with diketene instead of Ic under the reaction conditions similar

to those of *N*-non-substituted amidoximes, the product, VIIc or VIIc′, showed a different UV-spectral pattern, as seen by comparing Tables 1 and 2. The NMR spectrum of the product VIIa′ from *N*-methyl *p*-nitrobenzamidoxime (IVa′) and diketene showed a methine signal at 4.92τ, in addition to those at 7.88 (singlet, 3 H, methyl), 6.78 (singlet, 3 H, methyl), and 2.04 (quartet, 4H, J=9 cps, *p*-nitrophenyl protons). Similarly, the NMR spectrum of the product VIIa from the *N*-phenyl amidoxime (IVa) and diketene showed a methine signal at 5.45τ, in addition to those at 7.91 (singlet, 3 H, methyl), 2.40 (singlet, 5 H, *N*-phenyl protons) and 2.0 (quartet, 4 H, J=9 cps, *p*-nitrophenyl protons). Acidic hydrolysis of VIIc afforded a 50% yield of 5-nitro-2-furanilide, mp

171—173°C[8] together with a 30% yield of IVc, which was also produced directly from VIIc and hydroxylamine hydrochloride in boiling ethanol, though IIIb afforded the corresponding ketoxime (Xb) under similar reaction conditions. The mechanism for the formation of VII from IV might be explained similarly by the intermediate formation of a simple adduct (V) which is in tautomeric equilibrium with its enol form (VI), and VI is cyclized to VII after removal of water. In fact, an oily product obtained from IVc and diketene in acetic acid at room temperature was thermally converted to VIIc.

Similar treatment of 1-(5-nitro-2-furoyl)aziridine oxime (VIIIc) with diketene afforded a simple addition product (IXc); this structure was confirmed on the basis of analytical and spectral data.

As previously reported about VIIIc,[1] IXc remained also unchanged upon treatment with sodium iodide in boiling acetone.

Experimental

NMR spectra were measured by a Varian A-60 spectrometer at 60 Mc using tetramethylsilane as an internal standard and DMSO-d_6 as a solvent, unless otherwise stated. The chemical shifts were expressed in τ-values.

3-(*p*-Nitrophenyl) - 5 - acetonyl - 1,2,4 - oxadiazole (IIIa). A mixture of Ia (0.5 g) and diketene (1 m*l*) was refluxed in toluene (20 m*l*) for 10 hr. After removing toluene under reduced pressure from the reaction mixture, water was added to the residue and extraction was carried out with ether. The ether layer was washed with dilute hydrochloric acid. The residue obtained after removing ether was recrystallized from a mixture of ethanol and petroleum ether to afford IIIa. Similar treatment of Ib and Ic afforded the corresponding oxadiazoles, IIIb and IIIc, respectively. All the results are summarized in Table 1.

5-Nitro-2-furamidoxime *O*-Acetoacetate (IIc). A mixture of Ic (0.5 g) and diketene (0.5 m*l*) was dissolved in acetic acid (10 m*l*) and the solution was stirred for 2 hr at room temperature. The precipitated crystals were collected and recrystallized from a mixture of ethanol and benzene to afford 0.35 g of IIc. Further 0.3 g of IIc were obtained from the filtrate. The total yield was over 90%. Mp 136—138°C. ν_{max}^{KBr} 3570, 3400 (NH), 1770 (OCO), 1720 (CO) cm^{-1}.

Found: C, 42.47; H, 3.46; N, 16.25%. Calcd for $C_9H_9O_6N_3$: C, 42.36; H, 3.56; N, 16.47%.

When the same procedure was applied to Ic in pyridine instead of acetic acid, a quantitative yield of IIc was also obtained.

The Thermal Conversion of IIc to IIIc. IIc (0.4 g) was dissolved in toluene (25 m*l*) and the solution was refluxed for ten days. The precipitates were filtered after cooling and recrystallized from a mixture of ethanol and benzene to afford 0.1 g (30%) of Ic, which was identified by IR-spectral comparison with a specimen prepared by the above method. The filtrate was condensed under reduced pressure and the residue was recrystallized from a mixture of benzene and petroleum ether to afford 0.2 g (50%) of IIIc. When this thermal conversion was carried out in the presence of diketene, IIIc was obtained almost quantitatively.

3-(5-Nitro-2-furyl)- methyl- 5 -acetonylidene - 1,2, 4-oxadiazoline (VIIc). A mixture of IVc (0.5 g) and diketene (1 m*l*) was dissolved in toluene (20 m*l*) and the solution was refluxed for 11 hr. The reaction mixture was condensed and ethanol was added to the residue. The resulting crystals were filtered and recrystallized from ethanol several times to give 0.6 g (90%) of thin yellow needles, VIIc, having a mp 195—196°C (decomp.). ν_{max}^{KBr} 1660 (CO) cm^{-1}. The results are given in Table 2.

Acidic Hydrolysis of VIIc. VIIc (0.4 g) was added to a mixture of concd. hydrochloric acid (0.6 m*l*) and water (20 m*l*) and the mixture was stirred at 85—90°C for 7 hr. The crystals precipitated after cooling were collected and recrystallized from a mixture of benzene and petroleum ether to give 0.24 g (50%) of 5-nitro-2-furanilide.[8] The filtrate was made alkaline with sodium carbonate and the resulting crystals were collected and characterized as *N*-phenyl 5-nitro-2-furamidoxime IVc by IR-spectral comparison with a specimen prepared by another method.[5] The yield was 30% (0.2 g).

1-(5-Nitro-2-furyl)aziridine Oxime *O*-Acetoacetate (IXc). VIIIc (0.46 g) and diketene (1 m*l*) were dissolved in toluene (20 m*l*) and the solution was refluxed for 10 hr. After removing toluene under reduced pressure, the residual oil was recrystallized from ethanol to give 0.6 g (90%) of IXc, mp 195—196°C (decomp.). ν_{max}^{EtOH} ($\varepsilon \times 10^{-4}$) 320 (1.4), 245 (1.1) m$\mu$. ν_{max}^{KBr} 1775 (OCO), 1710 (CO) cm^{-1}.

Found: C, 46.71; H, 3.89; N, 14.96%. Calcd for $C_{11}H_{11}O_6N_3$: C, 46.98; H, 3.94; N, 14.94%.

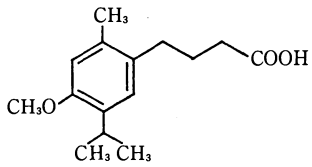
Synthesis of 2-Methoxycarbonyl-5-methyl-7-methoxy-8-isopropyl-tetrahydronaphthalen-1-one and Rearrangement of Isopropyl Group of γ-(5-Isopropyl-4-methoxy-2-methylphenyl)-butyric Acid in Polyphosphoric Acid Cyclization

Kiyoyuki YAMADA, Susumu TAKADA, Yoshihiro HAYAKAWA and Yoshimasa HIRATA

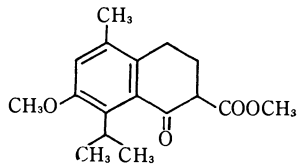
Department of Chemistry, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya

(Received March 24, 1969)

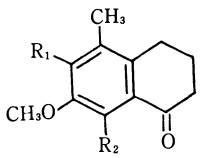
This paper describes the synthesis of the title compound, a tetralone derivative (II) which is regarded as an important intermediate in our synthetic project of sesquiterpenes. Rearrangement of the isopropyl group in γ-(5-isopropyl-4-methoxy-2-methylphenyl)-butyric acid (I) occurred during the cyclization by polyphosphoric acid (PPA). In the course of the preparation of II, a tetralone (III) was required. It was previously reported that tetralone (III) was prepared by a Friedel-Crafts reaction of the acid chloride of I, employing stannic chloride.[1] We attempted to prepare tetralone (III) in a single step by cyclizing butyric acid (I) with PPA.



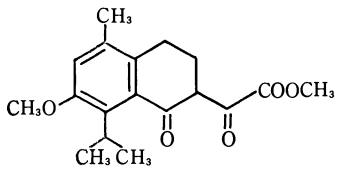
I



II



III: R_1=H, R_2=*i*-C_3H_7
IV: R_1=R_2=H
V: R_1=*i*-C_3H_7, R_2=H



VI

When acid (I) was treated with PPA (77% as P_2O_5), a mixture of three compounds, A, B, and C was obtained in the ratio of 3 : 68 : 29 (determined by gas chromatography). The minor product A, obtained in a crystalline form was found to be the expected tetralone (III) by comparison with authentic III prepared by the unambiguous route.[1] The major product B was a desisopropyl tetralone (IV), which was identified with the authentic specimen[2] prepared from *m*-cresol methylether. Though elimination of alkyl groups (usually *t*-butyl group) on a benzene ring is a recognized feature in certain Friedel-Crafts reactions, very few cases of dealkylations have been recorded for the intramolecular ring closure reactions.[3,4]

The third product C was isomeric with tetralone (III). The NMR spectral patterns of C were similar to those of tetralone (III) except for two signals. The signal (7.31 ppm) due to an aromatic proton in product C appeared at a significantly lower field than the corresponding signal (6.71 ppm) in tetralone (III), and the reverse relationship was observed with the signal due to a methine proton of the isopropyl group (3.40 ppm in C and 3.82 ppm in III) (Fig. 1 and Fig. 2). These differences were ascribed to the anisotropic effect of the carbonyl group and structure V was assigned to product C. Formation of tetralone (V) evidently indicated that a rearrangement of the isopropyl group occurred during cyclization of I. In order to determine whether or not the rearrangement took place after cyclization, tetralone (III) was

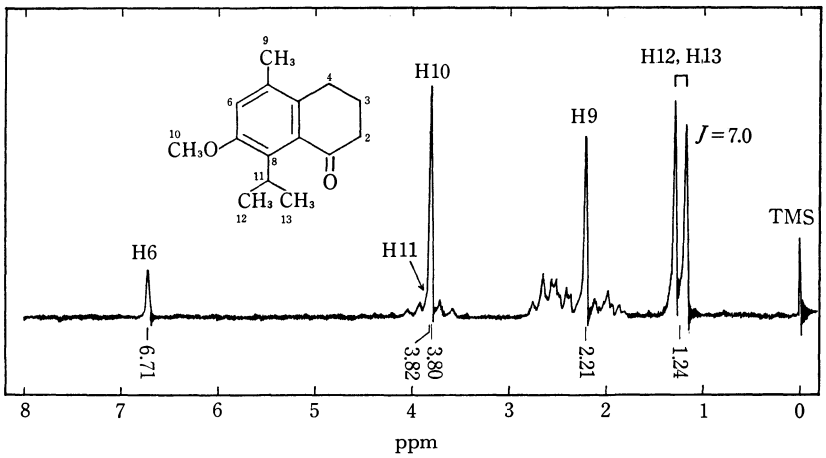

Fig. 1. NMR spectrum of III (CCl_4).

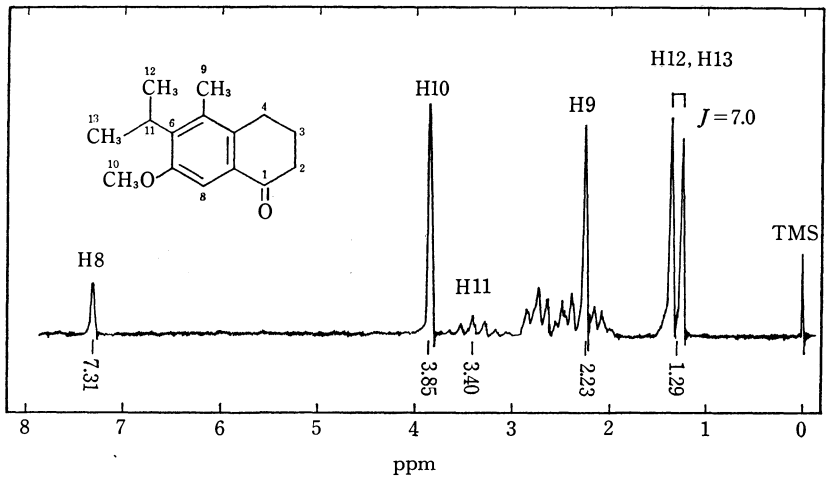

Fig. 2. NMR spectrum of V (CCl_4).

treated with PPA under the same conditions as employed for cyclization of I, affording IV and V. The result indicated that elimination and rearrangement of the isopropyl group occurred after cyclization.

It is of interest that on treatment of tetralone (IV) with PPA in the presence of isopropyl alcohol tetralones (III) and (V) were formed in an almost equal amount after a short period of time, while tetralone (V) was a sole product after a long reaction time. From the findings described above it was deduced that the rearrangement of isopropyl group observed in PPA cyclization of butyric acid (I) was an intermolecular one, the process of which would be as follows. Butyric acid (I) was initially transformed into a normal product, tetralone (III), which underwent elimination of the isopropyl group to give tetralone (IV); some IV further reacted with isopropyl carboium ion which resulted from the reaction, III→IV, at the C-6 position to afford tetralone (V).

Attempts were made to introduce a carboxyl function in the C-2 position of III for the preparation of tetralone (II) having a cadalene skeleton. Among the reactions examined the following sequence of reactions was found to be satisfactory.

Tetralone (III), when treated with dimethyl oxalate in the presence of sodium methoxide, afforded a product (VI), which was decarbonylated by heating with powdered glass to give a crystalline product (II). The spectral data obtained for this compound were in complete agreement with the assigned structure.

Experimental

Melting points and boiling points were uncorrected. The IR spectra were measured on a JASCO IR-S spectrophotometer and the UV spectra (ethanol as solvent) on a Beckman DK-2 spectrophotometer. The NMR spectra (carbon tetrachloride as solvent) were

recorded on a Varian A-60 spectrometer: only prominent peaks are cited; chemical shifts are given in ppm relative to internal tetramethylsilane (TMS); s, singlet; d, doublet; m, multiplet; coupling constants are given in cps. Mass spectra were obtained on a Hitachi RMU-6D mass spectrometer equipped with an all glass inlet system. The gas chromatographic analysis was performed on a Hitachi K-52 instrument. Thin layer chromatography (TLC) was carried out on silica gel G, (E. Merck, A. G., Germany) and column chromatography on silicic acid (100 mesh, Mallinckrodt, U. S. A.).

Polyphosphoric Acid Cyclization of Butyric Acid (I). A solution of acid (I) (3 g) in PPA (70 g: 77% as P_2O_5) was kept at 70°C for 7 hr and left at room temperature overnight. The resulting reddish solution was poured into ice-water. The mixture was extracted with three 30 m*l* portions of ether. The ethereal extract was washed with water, a 5% sodium hydroxide solution (20 m*l*), water (twice) and a saturated sodium chloride solution, and dried over sodium sulfate. On acidification of the sodium hydroxide solution (I) (240 mg) was obtained. The ethereal solution was concentrated to afford a neutral oil (2.2 g), GLC analysis (2 m column, SE-30 on Chromosorb W, 210°) of which showed three peaks, III, IV, and V in the ratio of 3 : 68 : 29. The oily mixture was distilled under reduced pressure (bp 141—144°C/ 2 mmHg) to give an almost colorless liquid, which solidified on standing. The solid mixture was dissolved in hot ethanol and after cooling a crystalline precipitate of IV appeared, which was filtered (0.5 g). The filtrate was concentrated and the residue was chromatographed on silicic acid with ethyl acetate - *n*-hexane (v/v 1 : 25): early fractions afforded crystalline III (40 mg), which was recrystalized from *n*-hexane, and from later fractions a colorless liquid (*ca.* 0.7 g) was obtained, which was distilled to give pure V (*ca.* 330 mg; analytical sample was obtained by preparative GLC); elution with ethyl acetate - *n*-hexane (v/v 1 : 10) gave IV (430 mg), which was recrystallized from *n*-hexane. Spectral and analytical data of III, IV, and V were as follows.

III: mp 88—89°C (lit[1] 88°C); IR (CCl_4), 1685, 1590 (weak) cm^{-1}; UV, 325 mμ (ε, 2400), 259 (6100), 220 (19000); NMR (see Fig. 1).

Found: C, 77.87; H, 8.62%. Calcd for $C_{15}H_{20}O_2$: C, 77.55; H, 8.68%.

IV: mp 57—58°C (lit[2] 57—57.5°C); IR (KBr), 1680, 1605 (medium), 1580 (shoulder) cm^{-1}; UV, 321 mμ (ε, 3200), 257 (8400), 218 (20000); NMR, 2.23 (3H, s, aromatic CH_3), 3.77 (3H, s, OCH_3), 6.79 (1H, d, J=3.0, meta coupling, aromatic H), 7.24 (1H, d, J=3.0, meta coupling, aromatic H).

Found: C, 75.73; H, 7.37%. Calcd for $C_{12}H_{14}O_2$: C, 75.76; H, 7.42%.

V: bp 156—157°C / 2 mmHg; IR (CCl_4), 1685, 1590 (weak) cm^{-1}; UV, 323 mμ (ε, 4000), 269 (12000), 224 (20000); NMR (see Fig. 2); Mass, M^+ 232.

Found: C, 77.20; H, 8.55%. Calcd for $C_{15}H_{20}O_2$: C, 77.55; H, 8.68%.

Action of Polyphosphoric Acid on III. A stirred solution of III (50 mg) in PPA (2 m*l*) was kept at 70°C for 8 hr and at room temperature for 2 days. The solution was carefully diluted with ice-water and extracted with ether. The ethereal extract was washed with water, a saturated sodium bicarbonate solution, water and a saturated sodium chloride solution, and dried over sodium sulfate. On removal of ether there remained an oil, GLC analysis of which showed formation of IV and V in the ratio of 88 : 12.

Action of Polyphosphoric Acid on V. A stirred solution of V (50 mg) in PPA (2 m*l*) was kept at 70°C for 7 hr and at room temperature overnight. After usual work-up the liquid product (47 mg) was obtained, which was shown to be V.

Action of Polyphosphoric Acid on IV in the Presence of Isopropyl Alcohol. a) A solution of IV (50 mg) in PPA (5 m*l* : 77% as P_2O_5) containing isopropyl alcohol (0.4 m*l*) was heated at 70 for 1 hr. The mixture was diluted with ice-water and extracted with three 10 m*l* portions of ether. The ethereal extract was washed with a 5% sodium hydroxide solution (5 m*l*), water and a saturated sodium chloride solution and dried over sodium sulfate. On removal of ether there remained a colorless oily mixture (*ca.* 50 mg), which consisted of V, III and IV in the ratio of 13 : 17 : 70 (GLC analysis).

b) The experiment in a) was repeated except that the reaction time was extended to 10 hr. GLC analysis of the resulting mixture showed the presence of V and IV in the ratio of 48 : 52.

Tetralone (VI). To a stirred solution of dimethyl oxalate (472 mg) and sodium methoxide (220 mg) in benzene (3 m*l*) was added dropwise a solution of III (455 mg) in benzene (3 m*l*) under ice-bath cooling. The operation was carried out under nitrogen. On standing at room temperature overnight the gray mixture partly solidified, to which 2 N hydrochloric acid was gradually added under cooling. The resulting mixture was extracted with ether repeatedly and the reddish ethereal extract was washed with water and a saturated sodium chloride solution, and dried over sodium sulfate. On removal of ether and excess dimethyl oxalate there remained a crystalline solid (*ca.* 500 mg), which was recrystallized from benzene to give pale yellow needles, VI; mp 133—134°C; IR (KBr), 1735, 1610, 1585 cm^{-1}; UV, 330 mμ (ε, 12000); NMR, 1.30 (6H, d, J=7.0, $\underline{CH_3}$-CH-$\underline{CH_3}$), 2.25 (3H, s, aromatic CH_3), *ca.* 2.7 (4H, m, $-CH_2-CH_2-$), 3.77 (1H, m, $CH_3-\underline{CH}-CH_3$), 3.82 (3H, s, OCH_3 or $COOCH_3$), 3.85 (3H, s, OCH_3 or $COOCH_3$), 6.77 (1H, s, aromatic H), 15.50 (1H, s, enolic OH due to β-diketone).

Found: C, 67.98; H, 7.11%. Calcd for $C_{18}H_{22}O_5$: C, 67.91; H, 6.97%.

Tetralone (II). Powdered glass was added to melted tetralone (VI) (100 mg) in a flask kept at 160°C. Gas was evolved for several minutes. After cooling the residue was extracted with benzene and the benzene extract was concentrated to give a solid. Recrystallization from methanol and from *n*-hexane afforded pure II (60 mg); mp 77—78°C; IR (KBr), 1745, 1685, 1595 (weak) cm^{-1}; UV, 328 mμ (ε, 2900), 262 (7000); NMR, 1.24 (3H, d, J=7.0, $\underline{CH_3}$-CH-CH_3), 1.27 (3H, d, J=7.0, $CH_3-\underline{CH}-\underline{CH_3}$), 2.21 (3H, s, aromatic CH_3), 3.65 (1H, m, $CH_3-\underline{CH}-CH_3$), 3.68 (3H, s, OCH_3 or $COOCH_3$), 3.80 (3H, s, OCH_3 or $COOCH_3$), 6.73 (1H, s, aromatic H); Mass, M^+ 290.

Found: C, 70.46; H, 7.95%. Calcd for $C_{17}H_{22}O_4$: C, 70.32; H, 7.64%.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 3014—3015 (1969)

The Chemiluminescence of Indole Accompanying Oxidation by Perbenzoic Acid

Yoshimori OMOTE, Hiroshi YAMAMOTO, Kazushige FUNASAKI, Masamoto AKUTAGAWA and Noboru SUGIYAMA

Department of Chemistry, Tokyo Kyoiku University, Otsuka, Bunkyo-ku, Tokyo

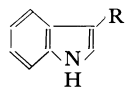
(Received March 26, 1969)

Previously we[1] investigated the chemiluminescence of indoles using two types of reaction: *A*, the indoles in alkaline ethanol, to which a mixture of 3% hydrogen peroxide and 3% potassium ferricyanide has been added, and *B*, the indoles in DMSO, to which a 5 N potassium hydroxide aqueous solution has been added. We[2] also proposed the mechanism of chemiluminescence in the system B, a mechanism which is in accord with the report by McCapra *et al.*[3]

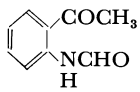
The previous papers[1-5] on the chemiluminescence of indoles have dealt almost exclusively with the reaction in a basic solution. Now we have found a chemiluminescent reaction of indoles which proceeds in a chloroform solution by means of perbenzoic acid. This is a new chemiluminescence of indoles in that it takes place in the absence of a base.

Results and Discussion

Indole (I), 3-methylindole (II), and 3-phenylindole (III) were chosen as typical indole compounds. The compound II is suitable for the investigation of the inductive effect of a 3-substituent on the indole nucleus, and compound III, for a study of the mesomeric effect.



I R=H
II R=CH_3
III R=C_6H_5



IV

Witkop and Fielder[6] reported that II gave *o*-formamidoacetophenone (IV) by perbenzoic acid oxidation. We observed the emission of light in this reaction. Thus we measured the chemiluminescence of indoles which accompanied the oxidation reaction caused by perbenzoic acid in chloroform. The relative intensities of the chemiluminescence of I, II, and III are summarized in Table 1. As a comparison, the relative intensities in the two systems, A and B, are also quoted from our previous report.[1]

Table 1. Relative intensities of chemiluminescence of indoles

Indoles (10^{-2} mol/*l*)	Perbenzoic acid (10^{-2})	Perbenzoic acid (10^{-1})	A	B
Indole (I)	0.6	9.6	1	1
3-Methylindole (II)	8.2	71	0.5	13
3-Phenylindole (III)	0.1	1.5	90	0

A: EtOH-KOH-H_2O_2-$K_3Fe(CN)_6$
B: DMSO-KOH-O_2

The intensity of chemiluminescence by perbenzoic acid decreases in the order: II> I> III, while that in the system A decreases in the order: III> I> II, and that in the system B: II> I> III. The order in each system is considered to depend on the substituents on the 3-position. The change in the order between the reaction systems suggests a difference in the reaction mechanism. It is probable that the mechanism of chemiluminescence in the system A involves the formation of a hydroperoxy radical, a process which can be expressed by the equation: $H_2O_2+Fe^{3+}\rightarrow HOO\cdot+Fe^{2+}+H^+$. The system B involves a cyclic peroxide intermediate.[2,3] As the order in the perbenzoic acid oxidation system is similar to that in the system B rather than to that in the system A, the mechanism of the chemiluminescence of oxidation by perbenzoic acid seems to be analogous to that of the chemiluminescence with a base and oxygen in DMSO.

After the chemiluminescent reaction of II by perbenzoic acid, the ultraviolet absorption maxima of II at 275 and 291 nm change to 260 and 320 nm and the fluorescence maximum, 465 nm,

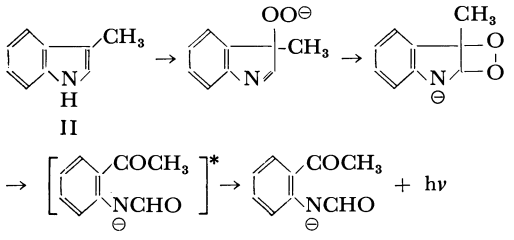
Perbenzoic acid	470	
Benzoic acid	no	

* in DMSO-alkali condition
( ) fluorescence after chemiluminescent reaction

The presence of benzoic acid or perbenzoic acid was not proved to have any influence upon the chemiluminescence. The chemiluminescent spectrum of II by perbenzoic acid in chloroform could not be measured because of the weakness of the emission and the short life-time of the emitter. However, it was proved that 40% of the IV was produced from the chemiluminescent reaction in chloroform by perbenzoic acid. The product was identified with an authentic sample by TLC and by a study of the spectral data.

The spectrum of the chemiluminescence of II in DMSO in the presence of oxygen and a base (type B) was also measured (Table 2); from its reaction mixture, 15% of the IV was obtained, along with some unreacted II. From the facts that the chemiluminescence maximum is in accord with the fluorescence maximum after the chemiluminescent reaction in the DMSO-oxygen-base system, we propose the following reaction mechanism for the chemiluminescence of II in a basic solution.



Scheme

It is clear that the emitter in a basic solution is the singlet excited state of the *o*-formamidoacetophenone anion (V). However, the excited state of V cannot be the emitter in the chemiluminescence by perbenzoic acid because the fluorescence maximum of IV in chloroform is different from that after the chemiluminescent reaction of II. Therefore, we tentatively suggest that the emitter of this chemiluminescence is different from the anion of IV, but it might be IV itself. The difference in the fluorescence maxima might result from the fluorescence of the unreacted indole or the peracid.

Experimental

Materials. The commercial indole (I) was recrystallized from ligroin and sublimed *in vacuo*. Mp 52°C. The commercial 3-methylindole (II) was also purified in the same way; mp 95°C. The 3-phenylindole (III) was synthesized by a modification of the procedure of Fischer;[7] mp 88.8°C. The *o*-formamidoacetophenone (IV)[8] was prepared from *o*-aminoacetophenone;[9] mp 78.2—78.5°C. The perbenzoic acid[10] was freshly prepared before the oxidation experiment.

Chemiluminescence Intensity. One milliliter of a indole chloroform solution (10^{-2} mol/*l*) was mixed with 1 m*l* of a perbenzoic acid chloroform solution (10^{-1} mol/*l*) in a glass tube (10 mm × 70 mm). Moreover, the light intensity was measured by a modified Model 139 Hitachi Photometer.

Spectra. The chemiluminescent spectrum was measured by means of a EPS-2 Hitachi Spectrophotometer into which 5 m*l* of a 3-methylindole DMSO solution (10^{-1} mol/*l*) and 2 g of solid potassium hydroxide were bubbled by an oxygen stream. The fluorescence spectrum was measured by the same photometer equipped with a high-pressure mercury lamp (365 nm line for excitation).

Separation and Identification of Products. Ten milliliters of a 3-methylindole solution (10^{-2} mol/*l*) were mixed with 10 m*l* of a perbenzoic acid chloroform solution (10^{-2} mol/*l*). The evaporation residue showed a main spot with R_f 0.60 (Wakogel B-5) upon TLC with a benzene-ether (1 : 1 v/v) mixture. The product was purified by means of a silica-gel column (Wakogel C-200) with benzene. The ultraviolet absorption spectrum of this product was identical with that of *o*-formamidoacetophenone.

Synthesis of 5-Chloro-6-Methoxy-*N*-Methylisatin

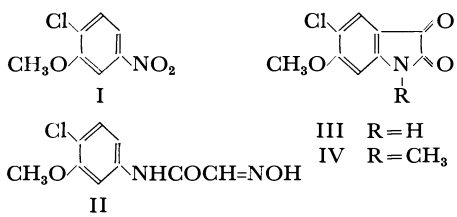
Yoshimori OMOTE, Hinako TAZAWA, Yoshimori FUJINUMA and Noboru SUGIYAMA

Department of Chemistry, Tokyo Kyoiku University, Otsuka, Bunkyo-ku, Tokyo

(Received March 27, 1969)

In connection with the investigation of melanin precursors, we have reported the synthesis of the DOPA dimer[1] and pipataline.[2] These substances are interesting as model compounds of melanin precursors. This paper will be concerned with the synthesis of 5-chloro-6-methoxy-*N*-methylisatin (IV), which would make a black pigment upon oxidative polymerization. The compound has been identified with a metabolite of *Micromonospora carbonacea* reported by Reimann and Jaret.[3]

Compound IV was prepared as follows. The chlorination of the diazonium salt obtained from 5-nitro-*o*-anisidine gave 2-chloro-5-nitroanisole (I) in the presence of cuprous chloride. The reduction of I with stannous chloride and hydrochloric acid afforded the corresponding amine; the amine was then converted to 4-chloro-3-methoxyisonitrosoacetanilide (II). After the cyclization of II into 5-chloro-6-methoxyisatin (III), it was methylated with methyl iodide to give IV. The spectral data (IR, UV, and NMR) of the synthetic substance are in good agreement with those of the natural substance, but the melting point of the synthetic substance is lower than that of the natural one.



Experimental

All the melting points are uncorrected.

2-Chloro-5-nitroanisole (I). 5-nitro-*o*-anisidine (20 g), suspended in concentrated hydrochloric acid (50 m*l*) and water (40 m*l*), was diazotized at 0—6°C with sodium nitrite (9 g) in water (50 m*l*). Then the cold diazonium solution was rapidly stirred into an ice-cooled cuprous chloride solution. As the commercial cuprous chloride considerably diminished the yield, it was freshly prepared.*1 The reaction proceeded very vigorously, with the release of nitrogen gas and the separation of the precipitates. The mixture was stirred for 1.5 hr at room temperature, warmed for 30 min at 50—60°C, and then heated to 80°C for 15 min to decompose the addition product completely. By the steam distillation of the reaction mixture, 2-chloro-5-nitroanisole (19 g, yield 85%) was obtained; mp 84—85°C (lit[4] mp 83°C).

4-Chloro-3-methoxyisonitrosoacetanilide (II). *a) Reduction of 2-Chloro-5-nitroanisole.* A solution of I (20 g) in glacial acetic acid (50 m*l*) was boiled. The heat was removed from the solution of I, to which stannous chloride (104 g) dissolved in concentrated hydrochloric acid was gradually added. A stannic chloride compound of the amine then began to crystallize. After the addition of the stannous chloride solution, the mixture was heated gently for 30 min and then cooled with ice water. The separated crystals were filtered and dried. The yield was 33 g.

b) 4-Chloro-3-methoxyisonitrosoacetanilide. To a solution of chloral hydrate (17 g) in water (200 m*l*), there were added, in order: crystallized sodium sulfate (240 g), a solution of the amine obtained above (32 g) in water (200 m*l*), and finally a solution of hydroxylamine hydrochloride (21 g) in water (90 m*l*). While the mixture was gently boiled for 1.5 hr, the precipitates of the isonitrosoacetanilide separated. After cooling with water, the precipitates were filtered, dried, and extracted with ethyl acetate. The removal of the solvent gave the crude isonitrosoacetanilide (17 .2g), which was reprecipitated from ethanol-water; mp 185°C.

Found: C, 47.40; H, 3.98; N, 12.32%. Calcd for $C_9H_9O_3N_2Cl$: C, 47.27; H, 3.97; N, 12.25%. UV λ_{max}^{EtOH} nm (ε) 215—220 (17800, sh), 290 (9600, sh), and 300 (10000). IR ν^{KBr} cm^{-1} 3305, 2860, 1620, 1603, 1549, 1289, 1257, and 1066.

5-Chloro-6-methoxyisatin (III). According to the method of the literature,[5] II (15 g) was treated with concentrated sulfuric acid (50 m*l*) to produce the corresponding isatin. The crude product was then purified by dissolving it in aqueous sodium hydroxide and by then slowly adding dilute hydrochloric acid. The

*1 A solution of cuprous chloride was prepared from crystallized copper sulfate (13 g), copper powder (7 g), sodium chloride (6 g) and concentrated hydrochloric acid (40 m*l*).

yellow precipitates that separated at first were filtered at once. The pale orange filtrate was acidified to congo red paper with hydrochloric acid. The solution was then cooled, and the isatin (III) which separated (2.3 g) was collected by filtration; mp 278°C.

Found: C, 50.16; H, 3.02; N, 6.96%. Calcd for $C_9H_6O_3NCl$: C, 51.09; H, 2.86; N, 6.62%.
UV λ_{max}^{EtOH} nm (ε) 220 (16500), 267 (25800), 273 (25100), 317 (7400), and 418 (110). IR ν^{KBr} cm^{-1} 3235, 1764, 1614, 1488, 1447, and 1038. This compound produced a black pigment when it was treated with hydrobromic acid.

5-Chloro-6-methoxy-*N*-methylisatin (IV). To a suspension of III (0.3 g) in methanol (3 m*l*) there was added a solution of sodium methoxide (0.12 g) in methanol (3 m*l*). After the mixture had been stirred for 10 min, the sodium salt precipitated was collected. The sodium salt suspended in methyl iodide (6 m*l*) was heated at 100°C for 2 hr in a sealed tube. After the removal of the excess methyl iodide under reduced pressure, the residue was purified in the manner described for the preparation of III. The yield was 0.08 g; mp 242—243°C.

Found: C, 52.92; H, 3.68; N, 6.13%. Calcd for $C_{10}H_8O_3NCl$: C, 53.24; H, 3.57; N, 6.21%.

The Cation-exchange Separation of Copper and Iron in Ammoniacal Pyrophosphate Media

Toshio NISHIIDO

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya-ku, Tokyo

(Received March 31, 1969)

Kharin and Soraka[1] and Marczenko[2] have reported the separation of copper and iron using cation exchange resin in the ammonium form, with sodium pyrophosphate as the eluting agent. In their method, however, much sodium pyrophosphate seems to prevent an ion exchange of copper because sodium ions also exchange with ammonium ions. However, their method merits further study.

The purposes of the present study are to establish a cation-exchange method for the separation of copper from iron using ammonium pyrophosphate instead of sodium pyrophosphate, and to apply it to the determination of copper in hot spring waters. This method is based on the difference in stability[3] between copper and iron pyrophosphate complexes. The separation of copper and iron with cation-exchange resin is affected by the pH and by the concentrations of pyrophosphate and ammonia.

Experimental

Reagent and Apparatus. *Pyrophosphate Solution.* 72 g of pyrophosphoric acid were dissolved in 100 m*l* of distilled water. The solution was adjusted to pH 5 with ammonia and then diluted to 200 m*l*. Copper and other impurities were removed from the solution by extraction with a dithizone carbon tetrachloride solution.

Ammonia Solution. 50 g of ammonium nitrate were dissolved in 50 m*l* of distilled water. Copper and other elements were removed as has been described above. The solution was diluted to 100 m*l* after 36 m*l* of 10 M distilled ammonia had been added. The final solution showed pH 10 and 10 M in ammonia, $NH_3+NH_4^+$.

Washing Solution. This solution was made by mixing 0.5 m*l* of the pyrophosphate and 10 m*l* of the ammonia solution and by then diluting to 100 m*l* with distilled water.

Resin and Column. Dowex 50×8 (50—100 mesh) was converted to the ammonium form with 1 M ammonium chloride. The ion-exchange column was 10 mm in diameter and 100 mm long.

Determination of Copper and Iron. The copper was determined colorimetrically using either cuprferazone[4] or dithizone.[5] The iron was determined by the *o*-phenanthroline method.[5] In order to promote color development, solutions were kept at 40°C after adding reagents, and the transmittance was measured at 500 mμ.

Procedure. To a solution containing 50 μg of copper and 500 μg of iron, 0.25 m*l* of the pyrophosphate and 5 m*l* of the ammonia solution were added. The solution was then diluted to 50 m*l* with distilled water and passed through the column at a flow rate of 1.0 to 1.2 m*l*/min. The column was washed with 50 m*l* of the washing solution. The effluent obtained was used to determine the iron. Then, the column was treated

with 50 m*l* of 2 N hydrochloric acid. This effluent was then used to determine the copper.

Results

The Effect of pH on Separation of Copper and Iron. The pH of the solutions was adjusted to between 8 to 11 with either nitric acid or sodium hydroxide. Iron passed through the column at any pH. The copper was entirely retained in the column at pH 9 to 10, but it was partly lost below pH 9. It was best to separate the copper and iron at pHs from 9 to 10; the recoveries were found to be 99% for copper and 100% for iron.

The Effect of the Concentration of Ammonia, $NH_3+NH_4^+$. The experiments were made on solutions containing up to 2 M of ammonia at pH 9.5. The results showed that the separation of copper and iron was favorable between 1 to 2 M in ammonia, but it was not suitable below 0.5 M because the copper partly passed through the column.

The Effect of the Concentration of Pyrophosphate. The effect of the concentration of pyrophosphate on the separation of copper and iron was examined using sodium, potassium, and ammonium pyrophosphate. The results showed that above 0.05 M sodium and potassium pyrophosphate disturbed the ion exchange of copper because sodium and potassium ions were exchangeable with ammonium ions in the column. On the other hand, ammonium pyrophosphate did not disturb the ion exchange of copper up to 0.5 M in pyrophosphate.

Application

The above method was used in the determination of copper in synthetic samples and hot spring waters.

Table 2. Determination of copper in synthetic solution*

* Synthetic solution was prepared by dissolving chemical reagent.

The components of these samples are shown in Table 1.

A 50-m*l* portion of the sample was placed in a beaker, and then 10 m*l* of the pyrophosphate and 20 m*l* of the ammonia solutions were stirred in.*1 The solution was diluted to 100 m*l* and passed through the column. The column was washed with 30 m*l* of the washing solution. Then, copper was eluted with 50 m*l* of 2 N hydrochloric acid and determined by the dithizone method.[5] The results are shown in Tables 1 and 2. Though traces of copper and a great quantity of iron were found, the error involved in this method was not significant. Moreover, the copper contents in hot spring waters determined by the present method were in good agreement with those reported by Ichikuni.[6]

The author wishes to thank Professor K. Noguchi and Dr. M. Ichikuni for their helpful discussions during this work.

*1 When much aluminum exists in the sample, aluminum hydroxide is gradually formed in the solution. In that case, the precipitate was separated from the solution with a centrifuge and was later dissolved in the elute containing copper.

Organische Metallkomplexe. VII.*1 Darstellung und Eigenschaften der Kupfer(II)chelate einiger *N*-Alkyliden-*N'*-alkanoyl-hydrazine*2

Hiroshi OHTA, Jun-ichi MATSUOKA, Toshihide ADACHI, Ken-ichiro YOSHIDA und Akio TAKUWA

Institut für Organische Chemie, Shimane Universität, Matsue

(Eingegangen am 3. April, 1969)

In der vorliegenden Arbeit werden die bisherigen Untersuchungen von einem von uns über die Metallchelate der *N*-Alkyliden-*N'*-benzoyl-hydrazine[1] weitergeführt und die Kupfer(II)chelate einiger *N*-Alkyliden-*N'*-alkanoyl-hydrazine dargestellt.

Als Ausgangsstoffe für die Komplexdarstellung haben wir **1 a1—f3** und die Metallacetate herangezogen. Im Gegensatz zu den beständigen Kupfer-(II)-(rötlich-violett) und Nickel(II)chelaten (orange-rot) der *N*-Alkyliden-*N'*-benzoyl-hydrazine, die leicht dargestellt und auf übliche Weise umkristallisiert werden können, sind diejenigen der *N*-Alkyliden-*N'*-alkanoyl-hydrazine ziemlich unbeständig, und trotz der verschiedenen Versuche wurden nur die Kupfer(II)chelate erhalten; die Darstellung der Nickel(II)chelate ist uns bisher nicht gelungen.

Wir fanden, daß die Kupfer(II)chelate bequem in Kristallen zugänglich sind, indem man nach dem Vermischen beider Komponente in Äthanol so viel Wasser bei Zimmertemperatur sorgfältig hinzufügt, bis die Lösung trüb wird, und die

1) H. Ohta, Dieses Bulletin, **33**, 1337 (1960).

trübe Lösung dann lange Zeit bei etwa 0°C stehen läßt. Die Chelate können folgenderweise umkristallisiert werden; sie werden in möglichst wenig Äthanol oder Methanol bei Zimmertemperatur schnell gelöst und längere Zeit bei etwa 0°C stehen gelassen. Ausnahmsweise ist das Bis-(*N*-äthyliden-*N'*-phenylacetyl-hydrazinato)kupfer(II) (**2 f1**) beständig und in kaltem Äthanol schwer löslich; es kann nur in üblicher Weise aus heißem Äthanol umkristallisiert werden.

Die Kupfer(II)chelate in Tabelle 3 sind in den meisten organischen Lösungsmitteln leicht löslich und zeigen bestimmte Schmelzpunkte auf Grund der längeren aliphatischen Ketten.[1,2] In reinem, trockenem Zustand sind sie ziemlich beständig, in Lösung aber, außer bei niedriger Temperature sind sie unbeständig. Die Instabilität dieser Chelate im Vergleich mit denjenigen der *N*-Alkyliden-*N'*-benzoyl-hydrazine würde auf die Alkyl-Reste in den Acylgruppen zurückzuführen sein. Aus einigen niedrigeren *N*-Alkyliden-*N'*-alkanoyl-hydrazinen konnten wir sogar die Kupfer(II)-chelate nicht erhalten.

Beschreibung der Versuche

Die Schmelzpunkte sind nicht korrigiert.

Allgemeine Vorschrift zur Darstellung der Bis(*N*-alkyliden-*N'*-alkanoyl-hydrazinato)kupfer-(II). (Tab. 2). Bei Zimmertemperatur gibt man zur Lösung von *a* mg **1 a1—f3** in *b* ccm Äthanol eine Lösung von *c* mg Kupfer(II)acetat in *d* ccm Äthanol, und darauf *e* ccm Wasser. Die trübe Lösung läßt man bei etwa 0°C stehen.

Die Ausgangshydrazine und die dargestellten Kupfer-(II)chelate sind in den Tabellen 1 und 3 zusammengefaßt.

Rotational Isomers in Two Crystalline Phases of *N*-Methylchloroacetamide

Tatsuo MIYAZAWA

Institute for Protein Research, Osaka University, Kita-ku, Osaka

(Received April 4, 1969)

In a previous investigation by Mizushima *et al.*[1] the internal rotation about the CH_2-CO bond was studied for *N*-methylchloroacetamide, $ClCH_2$-$CONHCH_3$, a model molecule of polypeptide chains. The infrared and Raman spectra and dipole moments were measured and the *trans* and *gauche* isomers (see Fig. 1 of Ref. 1) were found to coexist in the liquid phase.

1) S. Mizushima, T. Shimanouchi, I. Ichishima, T. Miyazawa, I. Nakagawa and T. Araki, *J. Am. Chem. Soc.*, **78**, 2038 (1956).

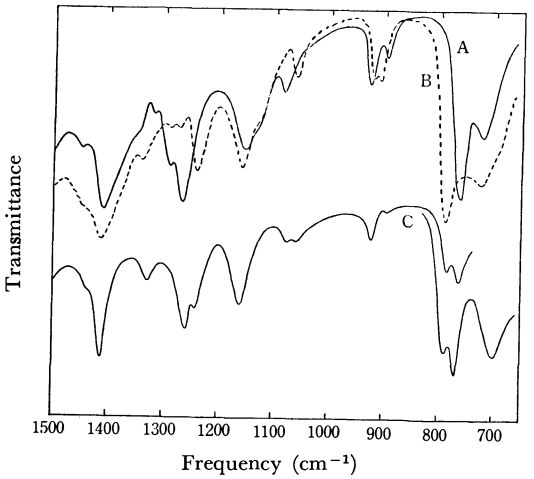

Fig. 1. Infrared spectra of solid films (at 20°C), (A) slowly cooled from the melt, (B) rapidly cooled from the melt, and liquid film (C) at 60°C. A Baird Infrared Spectrophotometer was used for absorption measurements.

In the present infrared study, however, two different spectra were obtained, one (A) for the solid film slowly cooled from the melt and the other one (B) for the solid film rapidly cooled from the melt (C). As seen in Fig. 1, these solid films A and B exhibit the infrared bands of the *gauche* (763 cm^{-1}) and *trans* isomer (786 cm^{-1}), respectively, of *N*-methylchloroacetamide. Apparently, the solid film A (with the *gauche* isomer) is stable at room temperature, while the solid film B (with the *trans* isomer) is metastable after being quenched.

The temperature effect on the infrared absorption of *N*-methylchloroacetamide was carefully observed; a narrow spectral region 950—870 cm^{-1} was repeatedly scanned while the sample temperature was lowered from 65°C down to 9°C in 75 min and subsequently was raised back to 63°C in 65 min. Reversible spectral changes (C)⇌(B)⇌(A) were observed and the transition point was found at about 38°C between the high-temperature phase (with the *trans* isomer) and the low-temperature phase (with the *gauche* isomer). Thus, *N*-methylchloroacetamide exhibits a new type of phase transition that is accompanied with the internal-rotation transition (*trans*↔*gauche*) of constituent molecules. The presence of the *gauche* molecules in the low-temperature phase was recently confirmed by an X-ray analysis of the crystal structure.[2)]

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 3022—3023 (1969)

Preparation of Ethyl 19-Bromononadecanoate by a Mixed Coupling Reaction

Yasuo SUHARA and Shoji MIYAZAKI

Government Chemical Industrial Research Institute, Tokyo, Shibuya-ku, Tokyo

(Received April 10, 1969)

Woolford *et al.*[1] prepared several long-chain ω-bromofatty esters from mixtures of ω-bromofatty acids and methyl hydrogen esters by a mixed coupling reaction. However, the yields of the desired cross-coupling products were generally low, and it was difficult to separate the coupling products by distillation. Therefore, two modifications of the procedure were attempted in this investigation: A) the ethyl hydrogen ester[2] was used instead of the methyl hydrogen ester and B) the coupling products were separated by column chromatography, not by distillation.

In the present investigation, 5: 1 to 1 : 5 mixtures of 11-bromoundecanoic acid (I) and ethyl hydrogen sebacate (II) were used for the electrolysis. By the electrolysis, ethyl 19-bromononadecanoate (III), 1,20-dibromoeicosane (IV), and diethyl octadecanedioate (V) were obtained as the coupling products. The coupling products were successfully separated by column chromatography on silica gel.

The lowest yield of III (29%) was given by an equimolar mixture of I and II, but the yield was increased when an excess of I or II was employed. The best yield in the present experiments was 54%; it was obtained from a 1 : 5 mixture of I and II. The largest amount of III, however, was given by an equimolar mixture of I and II.

For the identification of the coupling products, TLC on silca gel was preferable to GLC. Their R_f-values were as follows: IV, 0.80; III, 0.47; V, 0.25 (methyl ethyl sebacate, 0.37; methyl 11-bromoundecanoate, 0.15).

1) R. G. Woolford, W. Arbic and A. Rosser, *Can. J. Chem.*, **42**, 1788 (1964).

2) H. Agata and A. Tanaka, *Yakugaku Zasshi (J. Pharm. Soc. Japan)*, **76**, 960 (1956).

The IR spectrum of III showed bands at 1740 cm^{-1} (ester carbonyl group) and 645 cm^{-1} (C–Br linkage[3]). The NMR spectrum of III showed chemical shifts at 5.96 τ (F), 6.68 τ (A), 7.81 τ (E), 8.19 τ (B), 8.46 τ (D), 8.73 τ (C), and 8.77 τ (G).

$$\underset{A}{Br}\underset{B}{CH_2}\underset{C}{CH_2}(\underset{D}{CH_2})_{14}\underset{E}{CH_2}\underset{F}{CH_2}\underset{G}{COOCH_2CH_3}$$

Experimental

TLC was conducted on a silica-gel plate (0.25 mm, Merck, G, No. 7731), with ligroin (bp 85—115°C)-acetone (50 : 1, v/v) as the solvent. For the detection of the spots, the plate was sprayed with a 10% phosphomolybdic acid-ethanol solution and then heated at 140°C.

The IR spectra were recorded with a Perkin-Elmer 337 Grating Infrared Spectrophotometer in a KBr disk.

The NMR spectra were recorded with a Varian 100-HA Spectrometer for a 10% carbon tetrachloride solution, with tetramethylsilane as the internal reference.

Materials. The I was prepared from 10-undecenoic acid.[4] Mp, 52°C (50°C[4]). The II was obtained from sebacic acid and diethyl sebacate.[5] Bp, 150—154°C/1 mmHg (bp 183—187°C/6 mmHg[5]); mp 35.5—36.5°C (34—36°C[5]).

The IV was prepared from I by electrolysis,[6] and the crude product was recrystallized from ligroin with small amounts of silica gel for decolorization. Mp, 68.5—69°C (67.4—68°C[7]). The V was prepared from II by electrolysis. The crude product was distilled *in vacuo*, and a fraction boiling at 192—194°C at 1 mmHg was recrystallized from ethanol. Mp, 47—47.5°C (46.9—47.8°C[8]).

Procedures. The cell used was a 500 m*l* measuring cylinder fitted with a thermometer and two parallel platinum plates electrodes (4×3 cm) placed about 2 mm apart. The cell was surrounded with ice water to maintain the internal temperature within the range of 40—45°C.

Three and eithteen hundredth grams of I (0.012 mol), 13.82 g of II (0.06 mol), and 0.16 g of sodium (0.007 atom) were dissolved in 176 m*l* of methanol. A current of about 1.5 A was passed through for three times the theoretical time while the mixture was being stirred with a magnetic stirrer.

After the unreacted materials had been removed by washing with 5% potassium bicarbonate solution, the product mixture was distilled *in vacuo* to separate the non-coupling products as the distillate. The coupling products remaining as a residue (9.2 g) were separated by column chromatography on silica gel (110 g), with ligroin as the solvent.

The first fraction, melting at 65—68°C, was recrystallized from ligroin; white plate crystals were thus obtained. The crystals, which melted at 68.5—69°C, were shown to be IV by a study of their TLC, IR, and NMR spectra. The yield was 8% based on the moles of I employed. A mixed-melting-point determination with an authentic sample showed no depression.

The second fraction, melting at 47—49°C was recrystallized from ethanol; white flaky crystals were thus obtained. The crystals, which melted at 49.5—50°C, were shown to be III by elemental analysis, and by a study of their TLC, IR, and NMR spectra. The yield was 54% based on the moles of I employed.

Found: C, 62.40; H, 10.26; Br, 19.55%. Calcd for $C_{21}H_{41}O_2Br$: C, 62.21; H, 10.19; Br, 19.71%.

The third fraction, melting at 43—46°C, was distilled *in vacuo*; the distillate was recrystallized from ethanol to obtain white large flaky crystals. The crystals, which melted at 47—47.5°C, were shown to be V by a study of their TLC, IR, and NMR spectra. The yield was 57% based on the moles of II employed. A mixed-melting-point determination with an authentic sample showed no depression.

We are grateful to Mr. Masaru Yanagisawa for recording the NMR spectra, to Dr. Osamu Yamamoto for his helpful comments on the NMR spectra, and to Kajio Matsuoka and Sukehide Tsuchiya for their assistance in our experimental work.

Studies on Heterocyclic Chemistry. IV.[1] Preparation of Several Trifluoromethyl-substituted Heterocyclic Compounds and Observation of Metastable Ion in the Mass Spectra of Trifluoromethyl-pyrazoles

Tarozaemon NISHIWAKI

Department of Chemistry, Faculty of Arts and Sciences, Yamaguchi University, Yamaguchi

(Received April 11, 1969)

From a continued interest in mass spectrometry of heterocyclic compounds,[2,3] the preparation of trifluoromethyl-substituted heterocyclic compounds and determination of their mass spectra were considered. As it is known that trifluoromethyl-substituted benzene compounds eliminate CF_2 radical during a series of their electron-impact-induced decompositions,[4] it seemed interesting to see if this behaviour also holds for heterocyclic compounds.

Trifluoromethyl-pyrimidines (I, II, IV, V, VI) and trifluoromethyl-pyrazoles*1 (VII, IX, X) were prepared by standard procedures. New β-diketones (XI, XII) which are their precursors were obtained according to Reid and Calvin.[5] Fluorine analysis of XII was not sufficient to be recorded here, but its authenticity is established by its transformation into VI and IX.

Contrary to expectation, the spectra of the examined compounds (I, II, IV, VII, IX, X), where the molecular ion (M^+) is the base peak, have not the $(M-CF_2)^+$ ion at all, which is in line with the observation on trifluoromethylpyridines.[6]

It appears that loss of CF_2 radical from M^+ or its fragment ions takes place only in the benzene compounds. All of them have ions $(M-F)^+$, $(M-CF_3)^+$, and CF_3^+ as expected, and the fragmentation of the present pyrimidines can be nicely explained after the established patterns,[2,7] namely, loss of F and HF from M^+ competing with the elimination of HCN for I, or elimination of HF occurring after the loss of H from M^+ for II*2 and IV as supported by an appropriate metastable ion.

However, the pyrazole compounds (VII and X) have an interesting ion at (M-48) (Table). A low-intensity metastable ion observed in both spectra (*ca. m/e* 127 for VII and *ca. m/e* 132.5 for X) suggests that this might be generated in one step. An *m/e* 164 ion observed for VII shifts to *m/e* 169 for its pentadeuteriated analogue (VIII), where a metastable ion can be seen at *ca. m/e* 131.5, revealing no participation of benzene hydrogens in the lost 48 masses, and, further, retention of a phenyl group in the (M–48). Among several possible ion compositions to fulfill the *m/e* 48, N_2HF is the only rational one to agree with the observed labeling data. Further, exact mass measurements could establish the lost entity to be solely N_2HF for X. A metastable ion correspond-

*2 As previously shown,[2] labeling data can establish that the lost hydrogen from M^+ originates from the benzene hydrogens. But the structure of the resulting ion is not considered to be as simple as that suggested for the (M–1) of phenylphthalazine.[8] The fact that 2-amino-4-phenyl-6-methylpyrimidine shows a very intense(M–1),[2] while 4-phenyl-6-methylpyrimidine does not,[9] suggests this fragmentation to be closely associated with the presence of a functional group, at which the collapse of M^+ starts. It is likely that the pyrimidine ring has already lost its identity in the (M–1) ion.

X	7	8	19	28	3[g)]

a) Intensity is relative to the base peak. b) The spectrum (70 eV) was taken with a CEC-110-B spectrometer by a direct insertion procedure. c) Omitted from tabulation. d) Found: 178.059. Calcd for $C_{11}H_3F_2$: 178.060. e) Found: 197.058. Calcd for $C_{11}H_3F_3$: 197.058. f) Found: 169.996. Calcd for $C_8H_4F_2S$: 170.000. g) Found: 188.997. Calcd for $C_8H_4F_3S$: 188.999.

ing to the process $M^+ \rightarrow (M-48)^+$ was not well discerned in the spectrum of IX, which is probably due to its being recorded on a photographic plate, but the *m/e* 178 was exactly $(M-N_2HF)^+$.

One step loss of N_2HF from M^+, which does not exist as a structural entity in the original molecule, is rather surprising unless there operates a fluorine migration to a remote N_2H group. Fluorine shift can not necessarily be ruled out.[10] However, the $(M-F)^+$ and $(M-N_2H)^+$ ions are found in all spectra of VII, IX, and X, although metastable ions for the process $(M-F)^+ \rightarrow (M-N_2HF)^+$ and $(M-N_2H)^+ \rightarrow (M-N_2HF)^+$ are entirely absent. The most reasonable explanation is that loss of F and N_2H from M^+ is a slow step, both of the resulting ions $(M-F)^+$ and $(M-N_2H)^+$ rapidly lead to the $(M-N_2HF)^+$. The overall result thus appears to be one-step elimination of N_2HF with an accompanying metastable ion. Similar observations have been described recently.[11-13]

Experimental

Mass spectra were determined with a Hitachi RMU 6D mass spectrometer fitted with an all glass inlet system: ionization energy, 80 eV; total ion currents, 80 μA; ion source and inlet system temperature, 200°C. Exact mass measurements were carried out with a CEC-110-B spectrometer at 70 eV on a photographic plate. d_6-Benzene (99% isotopic purity) was purchased from Chiba Product.

Preparation of the Pyrimidines. The preparation of II is given as an example. Benzoyltrifluoroacetone (1.08 g) and guanidine carbonate (0.5 g) were melted in an oil bath (140—150°C) for 1 hr. After cooling a solid (0.80 g) was obtained and recrystallized from *n*-heptane as colorless needles, mp 133—133.5°C.

Found: C, 55.22; H, 3.42; N, 17.30%. Calcd for $C_{11}H_8F_3N_3$: C, 55.23; 3.37; N, 17.57%.

The following compounds were prepared by a similar procedure. I, mp 129°C (from cyclohexane), (Found: C, 40.83; H, 3.77; N, 23.59%. Calcd for $C_6H_6F_3N_3$: C, 40.68; H, 3.41; N, 23.73%); IV, mp 160—160.5°C (from cyclohexane), (Found: C, 44.37; H, 2.60; N, 16.90%. Calcd for $C_9H_6F_3N_3S$: C, 44.08; H, 2.45; N, 17.14%); V, mp 148°C (from *n*-heptane), (Found: N, 18.50%. Calcd for $C_9H_6F_3N_3O$: N, 18.34%); VI, mp 171—172°C (from petroleum ether), (Found: N, 16.37%. Calcd for $C_{12}H_{10}F_3N_3$: N, 16.60%).

Preparation of the Pyrazoles. The preparation of VII is given as an example. Benzoyltrifluoroacetone (0.30 g) and hydrazine hydrate (0.8 m*l*) were heated in water (1 m*l*) for 1 hr in a boiling water bath. Precipitates (0.23 g) were recrystallized from cyclohexane as colorless rectangular plates, mp 121—123°C.

Found: N, 13.13%. Calcd for $C_{10}H_7F_3N_2$: N, 13.21%.

The following compounds were prepared by a similar procedure. IX, mp 165—166°C (from cyclohexane), (Found: N, 12.39%. Calcd for $C_{11}H_9F_3N_2$: N, 12.44%); X, mp 118—120°C (from petroleum ether), (Found: N, 12.83%. Calcd for $C_8H_5F_3N_2S$: N, 12.84%).

Compound XI. To a stirred solution of d_6-benzene (4.0 g) in carbon disulfide (20 m*l*) anhydrous aluminum chloride (15.0 g) was added, and into the gently refluxing mixture acetic anhydride (4.1 g) was added and reflux was continued for 1 hr. After removing the solvent the residue was poured into a mixture of ice and hydrochloric acid and the organic matter was extracted with ether. The ethereal solution was washed with water, 10% aqueous sodium hydroxide, and water, dried ($CaCl_2$) and distilled (bp 50—54°C/1 mmHg) to give d_5-acetophenone, 1.8 g. To a stirred mixture of sodium methoxide (0.82 g) in anhydrous ether (15 m*l*) ethyl trifluoroacetate (2.1 g) was added. Homogeneous solution resulted, into which the above acetophenone (1.8 g) was added and stirred for 2 hr at room temperature. The following day any volatile material was removed *in vacuo* and the residue was acidified with 10% sulfuric acid. Precipitates were dried under reduced pressure to give almost pure β-diketone, mp 39—41°C, 2.0 g. Undeuteriated compound had mp 39—40.5°C.[5] Isotopic purity was d_5, 63%; d_4, 26%; d_3, 8%; d_2, 3% neglecting a small (M-1) (R.I. 2%) observed in the undeuteriated compound, where the base peak was CF_3^+. This β-diketone was condensed with hydrazine hydrate to VIII, mp 120—121°C (d_5, 68%; d_4, 27%; d_3, 4%; d_2, 1%) and

Monoterpene Constituents of the Essential Oil of Mitsuba (*Cryptotaenia japonica* Hassk.)

Shûichi HAYASHI, Toshiko OKUDA and Tamon MATSUURA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima

(Received April 17, 1969)

Mitsuba, *Cryptotaenia japonica* Hassk., which is an herb of the Umbelliferae family, is cultivated as a vegetable in Japan for its fresh flavor. The chemical constituents of the essential oil of mitsuba have been investigated by Hirao[1] in fairly long ago; he characterized the main component of the monoterpene fraction as a new terpene compound with a structure of 2-methylnonatriene, and he gave it the name "Cryptotaenene." However, its structure still has not been completely established.

The essential oil was obtained in a 0.013% yield by the steam distillation of the whole herb; it was then separated into a monoterpene fraction (26%) and a sesquiterpene fraction (40%).

A gas chromatogram of the monoterpene fraction is shown in Fig. 1.

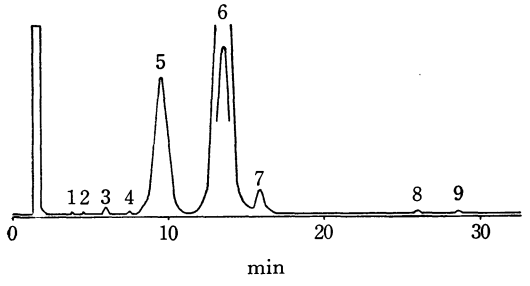

Fig. 1. Gas chromatogram of mitsuba oil at 65°C on Carbowax-6000 - Diasolid L.

The main component of the monoterpene fraction, Peak 6 in Fig. 1, was isolated by preparative gas chromatography as a colorless, oily compound with a characteristic odor. The compound had a molecular formula of $C_{10}H_{16}$ (M^+, m/e 136). Its IR spectrum indicated the presence of a terminal methylene group (890—910 cm^{-1}) and a conjugated diene system (1596 cm^{-1}), and its NMR spectrum showed the presence of two allylic methyl groups (1.59 and 1.67 ppm, each 3H), a vinyl group attributable to an ABX-type split (6.36, 1H, q, J=18, 11; 5.19, 1H, q, J=18, 1.2; 5.00 ppm, 1H, q, J=11 and 1.2 cps), and a terminal methylene group (4.96 ppm, 2H, s). These IR and NMR spectra and its mass spectrum were in good agreement with those[2,3] of β-myrcene.

An adduct of this compound with maleic anhydride and its free acid were found to be identical with those of β-myrcene by a mixed-melting-point determination; moreover, a bromide which was obtained by the reduction of this monoterpene with sodium and alcohol, followed by bromination, showed a melting point corresponding to that of tetrabromide of dihydromyrcene. Thus, it is certain that the main component is β-myrcene.

The components of the 3, 5, and 7 peaks were isolated and identified as α-pinene, (+)-β-pinene, and (−)-limonene respectively on the basis of the measurement of the IR and the mass spectra; the minor components of the 4 and 8 peaks were also identified as camphene and p-cymene by means of gas-chromatographic comparison with authentic specimens. In addition, α-thujene and sabinene were found to be included in Peak 3 or 5 in the gas chromatogram of Carbowax-6000 (Fig. 1).

The relative composition of this essential oil was calculated to be as shown in Table 1 from the peak areas in the gas chromatogram as measured by Carbowax-6000 at 65°C. The main components of the essential oil of *Cryptotaenia japonica* were β-myrcene and (+)-β-pinene.

Hirao's *cyrptotaenene*, which was separated by

* Operating condition. Apiezon L: 110°C, N_2 17 ml/min; β,β'-hydroxydipropionitrile: 60°C, N_2 15 ml/min.

fractional distillation only and which was characterized as a new terpene hydrocarbon on the basis of the difference of its physical properties from those of β-myrcene, seems to be β-myrcene contaminated with a small amount of (+)-β-pinene; this conclusion is based on the closeness of the boiling points of β-myrcene and β-pinene. This view is also supported by a comparison of the physical constants of cryptotaenene, bp 67—68°C/15 mmHg, $[\alpha]_D^{19.8}$ +2.66°, d_4^{25} 0.8128, n_D^{25} 1.47476, with those of β-myrcene and β-pinene.

Experimental

For the measurement of the gas chromatograms, a Shimadzu GC-2B apparatus equipped with a hydrogen-flame-ionization detector was used in combination with three kinds of separation columns (4 mm×3 m): Carbowax-6000 on Diasolid L (3%), Apiezon L on Gas-Chrom P (4.6%), and β,β'-hydroxydipropionitrile on Diasolid H (10%). Preparative gas chromatography was carried out by using Carbowax-6000 on Celite (20%) (8 mm×3 m). The NMR spectrum was measured in a $CDCl_3$ solution.

Steam Distillation of the Essential Oil. Mitsuba (1323 kg) cultivated in the suburbs of Hiroshima City was harvested, together with its roots, in May, 1966, by which time it had grown to a height of 40—50 cm. It was air-dried in the shade for several hours and then distilled with steam. In addition to an oil (I) (104 g, d_4^{25} 0.8637, $[\alpha]_D^{25}$ +52.44°, n_D^{25} 1.4888) floating upon the distilled water, an oil (II) (68 g, d_4^{25} 1.1101, n_D^{25} 1.4831) was obtained by extracting the distilled water with ether and chloroform. In the present experiment, the oil (I) (100 g) was fractionated into thirty-four fractions *in vacuo*; the monoterpene fractions (Fr. 1—11), bp 82—140°C/50 mmHg, totaled 26.46 g, and the sesquiterpene fractions (Fr. 12—34), bp 84.5—168.0°C/3 mmHg, 40.30 g.

α-Pinene and α-Thujene (Peak 3). The hydrocarbon, $C_{10}H_{16}$ (M^+, *m/e* 136), was isolated by the preparative gas chromatography of Fr. 2 (4.1 g, $[\alpha]_D^{18}$ +13.5°, 9% content of α-pinene). Its IR and mass spectra were in good agreement with those of α-pinene;[3,4] its identity was also confirmed by gas-chromatographic comparison with an authentic specimen, a comparison which was carried out by the use of three separation columns.

When the isolated hydrocarbon was re-gaschromatographed with Apiezon L or β,β'-hydroxydipropionitrile, it showed a small peak in addition to the main peak of α-pinene (*cf.* the third and fourth columns in Table 1). This small peak was assigned to α-thujene on the basis of a comparison with an authentic specimen.

(+)-β-Pinene and Sabinene (Peak 5). The hydrocarbon, $C_{10}H_{16}$ (M^+, *m/e* 136), was isolated from Fr. 2. Its IR and mass spectra and gas chromatogram were in good agreement with those of β-pinene.[3,4] In gas chromatography using Apiezon L or β,β'-hydroxydipropionitrile, this isolated hydrocarbon exhibited a small peak in addition to the main peak of β-pinene; this small peak was assigned to sabinene by using an authentic specimen.

The β-pinene in the essential oil was classified as *d*-form on the basis of the positive optical rotation of Fr. 3 containing 66% of β-pinene ($[\alpha]_D^{18}$ +14.7°).

β-Myrcene (Peak 6). The component was separated from Fr. 7 (3.7 g, $[\alpha]_D^{18}$ −1.4°). Its IR ν_{max}: 3080, 1792, 1633, 1596, 1378, 1104, 989, 902, 890 and 820 cm^{-1}. Its mass spectrum: *m/e* 136 (M^+, 3.9%), 93 (82.8), 69 (64.5) and 41 (100).

Maleic Anhydride Adduct and Its Dibasic Acid. To 2.5 g of Fr. 6 containing 85% of Peak 6, 1.7 g of maleic anhydride was added; the mixture, after having been allowed to stand for two days at room temperature in a tightly-corked tube, was distilled to obtain a maleic anhydride adduct (bp 158—164°C/2 mmHg, 2.86 g), mp 28—30°C.[5] Its IR ν_{max}: 1835 and 1772 cm^{-1}. This adduct, after being dissolved in ether, was treated with 3% aqueous solution of sodium hydroxide in order to convert it into free acid (1.24 g), which was obtained as white needles, mp 122—123°C, in recrystallization from acetone. No depression was observed in a mixed-

5) L. Ruzick, *Helv. Chim. Acta*, **19**, 423 (1936).

melting-point determination with an authentic specimen; mp 122—123°C.[5]

Tetrabromodihydromyrcene. 2.0 g of Fr. 7 containing 96% of Peak 6 was reduced with sodium (1.3 g) in absolute ethanol (15 m*l*) to obtain an oily product (bp 83—84°C/5 mmHg, 1.79 g). Its IR ν_{max}: 1660 and 823 cm^{-1}. The bromination of the product furnished a light yellow mass which showed a mp of 91.0—91.5°C[6] after being recrystallized from ethanol and ether. Its IR ν_{max}: 1370 and 1363 cm^{-1}.

(−)-Limonene (Peak 7). The hydrocarbon was isolated as an unreacted oil in the maleic anhydride-treatment of Fr. 10 (0.6 g, $[\alpha]_D^{18}$ −58.56°), which was contaminated with 10% of *β*-myrcene. It was gas-chromatographically identical with limonene; its IR and mass spectra also coincided with those of limonene.[3,4]

Camphene and *p*-Cymene. Although no attempt was made to isolate these compounds because of their minor components, the 4 and 8 peaks were identified as camphene and *p*-cymene respectively by comparison with authentic specimens in gas chromatography using the three separation columns.

The authors are deeply indebted to Professor Shô Itô of Tohoku University for his kind measurement of the NMR spectrum.

The NMR Study of Poly-L-Prolines I and II

Rume SAKAI,*1 Hirofumi OKABAYASHI and Toshizo ISEMURA

Division of Physical Chemistry, Institute for Protein Research, Osaka University, Kita-ku, Osaka

(Received April 22, 1969)

As is well known, poly-L-proline (PLP) takes two different helical structures, the so-called I and II forms, which were established by the X-ray diffraction method; one is a right-handed helix and the peptide bonds are in a *cis* configuration,[1] whereas the other is left-handed, with the peptide bonds *trans*.[2]

The rotation about the Cα–N bond of L-proline is severely restricted because the Cα–N bond participates in a pyrrolidine ring. The rotation about the Cα–CO bond of PLP is also definitely restricted by the steric hindrance, as can be verified by using atomic models.[3] According to Steinberg *et al.*[3] the hydrogen atom attached to the alpha carbon is restricted to the *cis* or the *trans* position in relation to the C–O bond, although the configurations have some rotational freedom around the Cα–CO bond.

Both helices of the poly-L-prolines take nearly the *trans* configuration about this bond. The *cis* configuration, in regard to the bond of PLP, is expected to exist only in a concentrated salt solution of lithium bromide[3] or calcium chloride.[4]

On the other hand, the conformation and the transconformation of PLP in solutions[5] have been studied by using its optical-active properties, such as ORD[6] or CD,[7] and its hydrodynamic property.[3] The results have shown that the poly-L-proline takes the PLP-I and II-helices in solutions, unlike the homo-polypeptides of the other α, L-amino acid. Moreover, it has been also reported that poly-L-α, amino acids show different nuclear magnetic resonance spectra because of their conformations.[8] Therefore, the study of PLP by the NMR method is interesting in that the confromational characteristics of PLP should be reflected in the NMR spectrum. The NMR method may also give us additional information on the property of PLP in solutions.

This communication will describe how poly-L-prolines have different NMR spectra according to their conformations. The poly-L-proline has the I-helical form immediately after the sample was dissolved in acetic acid. However, it changed into the II-helix within two weeks after dissolution when kept at 25°C. The value of $[\alpha]_{546}^{25}$ was

ca. +50°C for the I-helix and *ca.* −550° for the II-helix.[9] The conformation of PLP in the mixed solvent (CD_3COOD : $CDCl_3$=1 : 8) is considered to be a PLP-I-like helix, in which the value of $[\alpha]_{546}$ is +30°C and invariable. The NMR spectrum of the PLP-I-helical structure is shown in Fig. 1. A PLP solution which had a value of $[\alpha]_{546}$=−560° after the sample had been dissolved in an acetic acid and kept for two weeks was used for measuring the NMR spectrum of the PLP-II-helical structure, as is also shown in Fig. 1. The peak assignments were made from the ratios of the areas of the peaks; they are also shown in Fig. 1.

The magnetic shielding values of the hydrogen atoms a), b)-c), and d) for the poly-L-proline which has the PLP-I-helix were 5.5, 7.8—8.0, and 6.3_{ppm} respectively. The values for the PLP-II-helix were 5.2_3, 7.9_{ppm}, and 6.2_5 respectively.

The values for the peaks of the hydrogen atoms b)-c) and d) depend little on their conformations. However, the value of the hydrogen atom a) for the I-helix was in a field up by 0.3_{ppm} from that for the II-helix. The chemical shift of the αCH in the NMR spectra of the two poly-L-prolines seems to be influenced more by the configuration of the peptide group on the imino side than that on the carbonyl side; in both helices of the poly-L-prolines the hydrogen atom a) is nearly in the *trans* position relative to the C=O, where the chemical shift of αCH peaks is assumed to be decided by the relative position of the preceding or the following carbonyl group.

The difference between the magnetic shielding values of the αCH in the *cis* and *trans* configurations of the peptide groups is similar to that found for the N-CH_3 of *N*-methylformamide[10] in benzene,

a), b), c) and d) show the assignment of the hydrogen atoms of pyrrolidine ring.

where the solvent-solute interaction is involved. The difference in the shielding values of the αCH peaks of the two poly-L-prolines can be used in the study of the *trans*-conformation of PLP.

It should also be mentioned that, during the I ⇌ II transition of the poly-L-prolines, two αCH peaks were observed at 5.2 and 5.5_{ppm}; the ratios of the areas of the two peaks changed with time.

Quenching of Rubicene Fluorescence by Amines

Akira NAKAJIMA*1 and Hideo AKAMATU

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received May 6, 1969)

In a previous paper,[1] the charge transfer (CT) interaction between an excited fluorescer and a quencher was shown to play a significant part in the mechanism of fluorescence quenching on the basis of the correlation between the quenching constants and the electron affinities of quenchers. A study was made on quenching of fluorescence of anthracene and pyrene by electron-accepting substances. With the purpose of clarifying further the inner quenching mechanism, the present work was carried out for the systems of rubicene and various amines, where excited rubicene may be considered as an electron-acceptor and amines as electron-donors. Amines have been known to be effective quenchers, and if their large quenching abilities can be attributed to their strong electron-donating powers, it will be expected that in combinations of a given fluorescer and a series of amines their effective quenching radii are related to their ionization potentials.

The advantage in dealing with these systems is that rubicene fluoresces at a relatively long wavelength (553 mμ) and the amines employed scarecely absorb the exciting light (436 mμ), so that the possibility of the trivial "quenching" caused by the inner filter effect and the waste of exciting light can be excluded to permit one to make a more reliable discussion.

Experimental

Rubicene was synthesized from fluorenone[2] and recrystallized several times from toluene. The absorption spectrum of this sample agreed with that given in literature.[3] The liquid amines were fractionally distilled in a nitrogen atmosphere under reduced pressure after being dried with potassium hydroxide, and the crystalline amines were recrystallized and sublimed in a vacuum. Such amines as are very apt to be colored were purified by repeated distillations or sublimations in a vacuum until they became colorless. Toluene was distilled once from a G. R. grade reagent and used as a solvent for the measurement of fluorescence. For the observation of CT bands, spectro-grade carbon tetrachloride was used as a solvent and purified chloranil was employed as an electron-acceptor.

The apparatus and the procedure were almost the same as described in the previous paper.[1] The excitation wavelength was selected at 4358Å Hg line with a Bausch & Lomb grating monochromator. The concentration of rubicene was 4.96×10^{-5} mol/*l*.

Results and Discussion

The ionization potentials of the amines were estimated by making use of the CT absorption bands of chloranil complexes with these amines. It is well known that for a given electron-acceptor the CT absorption maximum, $h\nu_{CT}$, can be related to the ionization potential of a donor, I_p, as follows:[4]

$$h\nu_{CT} = aI_p + b$$

where a and b are the constants to be determined experimentally. Since the interaction between an aliphatic amine and chloranil (n–π interaction) may be different from that between an aromatic amine and chloranil (π–π interaction), the two cases should be treated separately.[4] Using those amines whose ionization potentials had been measured directly,[5] the following relations were obtained by the method of least squares:

$$h\nu_{CT} = 0.60\, I_p - 2.58 \text{ (eV)} \quad \text{(aliphatic)}$$

$$h\nu_{CT} = 0.45\, I_p - 1.32 \text{ (eV)} \quad \text{(aromatic)}$$

From these the ionization potentials of the other amines were estimated.[6] The I_p-values thus obtained as well as the positions of the CT bands observed are given in Table 1.

The quenching constants were evaluated from the Stern-Volmer equation:[7]

* Directly measured ionization potentials taken from Ref. 5, used for determining the values of a and b.

$$I_0/I = 1 + k[Q]$$

where I_0 and I are the fluorescence intensities respectively in the absence and presence of the quencher. The slopes of the plots of $(I_0-I)/I$ against [Q], the concentration of quencher, give the quenching constants, k, which are listed in Table 1.

Since the absorption spectrum of rubicene was not affected by the addition of an amine, it may be considered that a dynamical quenching process is predominant and the interaction of rubicene in the ground state with an amine is very small, but in the excited state, quite large.

For dynamical quenching, the quenching constant is approximated by the following formula:[7,8]

$$k = 4\pi N'\tau D(\gamma R)$$

where τ is the fluorescence life-time of rubicene in the absence of a quencher, N' is the number of the fluorescent molecules per millimol, *i. e.*, 6.02×10^{20}, D is the relative diffusion constant in toluene, *i. e.*, the sum of the diffusion constants for rubicene and a quencher, and (γR) represents the effective quenching radius. τ was estimated by the relation $\tau=\tau_0\phi$,[*2] where τ_0 is the natural life-time evaluated from the absorption spectrum of rubicene, and ϕ_0 is the fluorescence quantum yield of rubicene determined by comparing it with that of perylene in a degassed benzene solution.[9] The diffusion constants of the fluorescer and the quenchers were estimated by the method of Othmer and Thaker.[10] The (γR)-values obtained from the above formula are also listed in Table 1.

Since the effective quenching radius of a quencher can be reasonably taken as a measure for its quenching ability, it is of great interest to plot the effective quenching radii, (γR), against the ionization potentials, I_p, which is shown in Fig. 1.

As is seen from the figure, a good correlation can be recognized between (γR) and I_p; that is, the lower the ionization potential of an amine, the larger its effective quenching radius. This fact suggests that the charge transfer or electron trans-

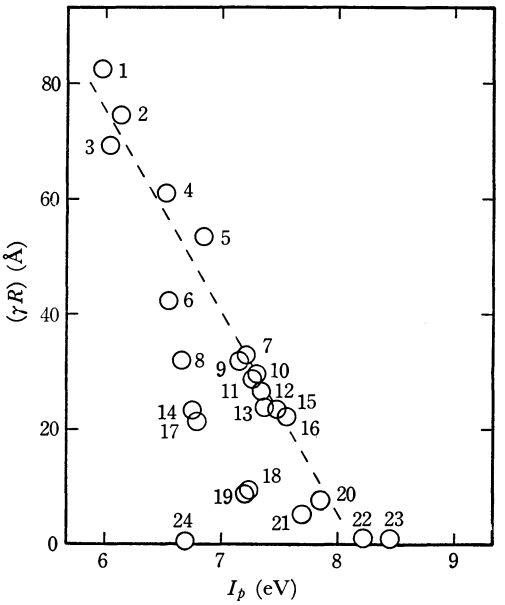

Fig. 1. Relation between the ionization potentials and the effective quenching radii of the amines. Numerals refer to the respective numbers of the compounds in Table 1. The broken curve is drawn tentatively.

fer mechanism[11] is especiallyi mportant for fluorescence quenching.

Because the absorption spectra of the amines and the fluorescence spectrum of rubicene do not overlap at all, the energy transfer mechanism,[12] in which excited rubicene is an energy-donor and amines are energy-acceptors, can be left out of account. The trend observed can not be explained by the mechanism of external heavy-atom effect, in which rubicene in the singlet excited state is converted into the triplet state.

As one can see from Fig. 1, the (γR)-values for some *N*-substituted amines*3 are considerably smaller than those expected from their I_p-values. This may be interpreted in terms of a kind of steric effect; *e. g.*, the steric effect of the massive groups attached to the nitrogen atom. A remarkable example is found in triphenylamine, whose molecular structure may be unfavorable for an interaction.

The relationship between (γR) and I_p will be useful for estimating the ionization potential of an amine from its (γR)-value.

The authors wish to thank Professor Hiroaki Baba for some valuable advice in preparing the manuscript.

Electronic Absorption Spectra of Cation Radicals of *p*-Dialkoxybenzenes in Concentrated Sulfuric Acid

Katsumi KIMURA*[1] and Hikoichiro YAMADA

Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka

(Received May 6, 1969)

The cation radicals of *p*-dialkoxybenzenes produced by different methods of oxidation have been studied mainly with ESR technique:[1-4] Oxidations have been performed with concentrated sulfuric acid,[1] lead tetra-acetate-boron trifluoride in dichloromethane,[2] aluminum chloride in nitromethane[3] and polarographically.[4]

This note is concerned with the electronic absorption spectra of cation radicals formed from several *p*-dialkoxybenzenes (hydroquinone, *p*-methoxyphenol, *p*-dimethoxybenzene, *p*-ethoxyphenol, *p*-

diethoxybenzene and 2,3,5-trimethylhydroquinone) in concentrated sulfuric acid. The electronic absorption bands of the cation redicals of these compounds in concentrated sulfuric acid were first measured (Fig. 1). These spectra may be ascribed to the cation radicals of the *p*-dialkyoxybenzenes, since the solution of hydroquinone gives an ESR spectrum identical to that already assigned to the cation.[1)]

In order to confirm the existence of the cation radicals, the absorption band obtained by the oxidation with concentrated sulfuric acid (Method 1) from *p*-dimethoxybenzene was compared with the absorption spectra which were obtained by other methods of oxidation: oxidation with $SbCl_5$ in acetonitrile at room temperature (Method 2), and photo-oxidation in a deaerated transparent rigid matrix of the mixture of concentrated sulfuric acid and glacial acetic acid at 77°K (Method 3). It was found that the electronic absorption bands around 450 mμ obtained by these three kinds of oxidation are very similar to one another. The absorption band obtained through photo-oxidation (Method 3) has been reported.[5)] However, in the present work, the photo-oxidation study has been carried out by means of optical absorption as well as ESR technique. The photolyzed solution was confirmed to have the ESR spectrum with the same hyperfine structure as that reported,[1)] when the photolyzed rigid solution is warmed up to room temperature.

It is interesting to note that when a concentrated sulfuric-acid solution of *p*-dimethoxybenzene was bubbled with nitrogen gas in order to remove oxygen, neither electronic absorption in the visible region nor the ESR spectrum of the cation was detected. This indicates that the oxygen molecule participates in the oxidation of the compound in concentrated sulfuric acid.

The cations of the compounds studied here are iso-electronic to one another, as well as to Würster's cations. Thus it seems that the absorption bands obtained herewith are similar to the long wavelength bands of Würster's cations. Electronic spectra of the cations of several aminophenols have been studied by Kimura *et al.*,[6)] and shifts in wavelength of the absorption spectrum from the absorption spectrum of the *p*-phenylenediamine cation were interpreted in terms of ionization-potential differences of the substituents by using a first-order perturbation theory. The same situation may occur in the case of the cations of *p*-dialkoxybenzenes. Let us consider how the ionization potential of a substituent affects the transition energy of the hydroquinone cation. Expressing its MO's with linear combinations of $2p\pi$ AO's ($\varphi_i=\sum_\mu c_{i\mu}\phi_i$), energies of the MO's may be given by $\varepsilon_i=\sum_{\mu\nu}c_{i\mu}c_{i\nu}F_{\mu\nu}$, where $F_{\mu\nu}$'s are Fock-Hamiltonian elements. Assuming the same molecular orbitals for all these cations to

the first approximation and taking only the differences ΔI_1 and ΔI_2 in the valence-state ionization potentials of two substituents at the *para* position into account, we find that the resulting differences in transition energy may be proportional to $\Delta I_1 + \Delta I_2$. This means that the effect of two substituents at the *para* position can be expressed as the sum of the ionization potentials of the substituents. In Fig. 2, the shifts ($\Delta\nu$ in cm^{-1} units) of the longest absorption bands of the several cations from that of the hydroquinone cation are plotted against the ionization-potential differences of the substituents (ΔI in eV units). In this calculation, values for ionization potentials of the hydroxy, methoxy and ethoxy groups were taken from those used in the previous calculations of phenol, anisole and phenetole.[7] It is seen from Fig. 2 that a good linearity is obtained between the band shift and the ionization potential difference.

Experimental

Commercial materials of the compounds studied; *e. g.*, hydroquinone, *p*-methoxyphenol, *p*-dimethoxybenzene, *p*-ethoxyphenol, *p*-diethoxybenzene and 2,3,5-trimethylhydroquinone were purified by vacuum sublimation. Commercial $SbCl_5$, sulfuric acid (95%), and glacial acetic acid of G. R. grade were used without further purification. Acetonitrile was distilled after reflux and dehydration on P_2O_5.

Measurement of electronic absorption spectra was carried out with a Cary spectrophotometer Model 15. ESR spectra were measured by a JES-3BX ESR spectrometer at 100 kc/s modulation.

We are grateful to Professor H. Tsubomura for his valuable discussion.

Nuclear Quadrupole Resonance in *syn*- and *anti*-7-Chloronorbornene

Hideaki CHIHARA and Nobuo NAKAMURA

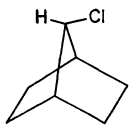
Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka

and Tadashi IRIE

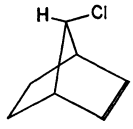
Shionogi Research Laboratory, Shionogi and Co., Ltd., Fukushima-ku, Osaka

(Received May 14, 1969)

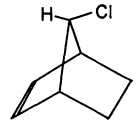
Norbornenyl halides and other derivatives show unusual rate effects in their solvolysis reactions:[1] *syn*-7-chloronorbornene (II) and its saturated analog (I) solvolyze in aqueous ethanol at comparable rates, whereas the *anti*-isomer (III) solvolyzes some 10^5 faster than I and II under the same conditions.[2] These and other large variations in the reaction rate in norbornenyl systems have been interpreted in terms either of the "*participation*" of the neighboring π-bond electrons in the initial carbonium ion formation or of some modification of the bridgehead molecular structure due to steric effects of the large substituents.[1]



I



II



III

To examine if such isomeric rate effect is associated with the nature of the C–Cl bonds or the valence state of carbon atom, we have measured the nuclear quadrupole resonance frequencies of ^{35}Cl in II and III. The details of the experimental procedures have been reported.[3]

The experimental results are given in Table 1, from which we recognize that two crystallographically nonequivalent molecules exist in each of the compounds II and III. The mean value of the resonance frequencies in II is some 860 kHz larger than that of III but their absolute values fall in the range generally found in compounds of the type $(CH_3)_nCH_{3-n}Cl$.[4] This means that the C–Cl bonds in II and III themselves are not unusual. On the other hand, the difference in the resonance frequencies in II and III seems to be significant,

4) E. I. Fedin and G. K. Semin, "Use of Nuclear Quadrupole Resonance in Chemical Crystallography II," in "The Mössbauer Effect and its Applications in Chemistry," Consultants Bureau Enterprises, Inc., New York (1964).

Table 1. The nuclear quadrupole resonance frequencies of ^{35}Cl at liquid nitrogen temperature

Substance	Resonance frequency (kHz)
syn-7-Chloronorbornene (II)	33016.3±0.2 33026.2±0.1
anti-7-Chloronorbornene (III)	32125.2±0.1 32191.4±0.1

because the intermolecular contributions to the NQR frequencies of chlorine bonded to carbon atoms are relatively small and vary regularly from compound to compound.[5]

The difference between the mean resonance frequencies of II and III may be attributed to a change in the hybridization of the C–Cl bond. Thus, in the case of simple molecules such as $CH_{4-n}X_n$ and $(CH_3)_nCH_{3-n}X$ (X=Cl, Br or I), it can easily be confirmed from $J(^{13}C\text{–}H)$ data[6] or from molecular geometry that the halogen nuclear quadrupole coupling constant in C–X bond increases with an increase in the *s*-character of the carbon atomic orbital bonded to the halogen atom.[7] On applying this relation to the case of the compounds II and III, we see that the *s*-character of the carbon atomic orbital in the C–Cl bond in II is larger than that in III and this trend agrees qualitatively with the direction of the shift of $J(^{13}C\text{–}H)$ observed in these two compounds[8] and in some similar compounds.[9] Such a difference in the carbon *s*-character is probably due to distortion of the C–Cl bond originating from the repulsion between the bulky chlorine atom and the carbon π-orbital in II although some delocalization of the π-electrons in III cannot be entirely excluded.[9]

Although both the NQR frequencies and $J(^{13}C\text{–}H)$ data can be explained consistently by the change in the carbon hybridization as mentioned above, the question of how the large reaction rate effect in 7-norbornenyl system can be interpreted by such a mechanism remains unclarified.

Another explanation for the difference of the NQR frequencies is to assume that a weak hydrogen bond is operating between the bridge carbon and the π-electrons. This makes the chlorine in III more electronegative than in II *via* the inductive effect between the hydrogen and the chlorine. In other words the chlorine in III is more ionic than in II and is more susceptible to solvolysis. Actually these two alternative explanations are compatible and are probably both correct. Though their relative significance is unknown, they complement each other in making the chlorine resonance displaced to a lower frequency in III.

The authors wish to thank Drs. K. Tori and H. Tanida of the Shionogi Research Laboratory for their helpful discussion.

5) See, for example, D. Biedenkapp and A. Weiss, *Ber. Bunsenges. Physik. Chem.*, **70**, 788 (1966); W. J. Considine, *J. Chem. Phys.*, **44**, 4036 (1966).

6) The *s*-character of the carbon hybrid orbital involved in the C–H bond is proportional to $J(^{13}C\text{–}H)$; see C. Juan and H. S. Gutowsky, *J. Chem. Phys.*, **37**, 2198 (1962).

7) A qualitative account for the relation between the carbon *s*-character and the NQR frequencies is as follows: From the point of view of Jaffe's electronegativity scheme (J. Hinze *et al.*, *J. Am. Chem. Soc.*, **84**, 540 (1962); *ibid.*, **85**, 148 (1963)), the increase in the *s*-character of the carbon orbital tends to increase the carbon orbital electronegativity. Therefore, the amount of the electron transfer, necessary for matching the orbital electronegativities, from the carbon hybrid orbital to the chlorine orbital may decrease and so the number of the unbalanced *p*-electrons at the chlorine increases, with the result of a higher NQR frequency.

8) M. Ueyama and K. Tori, private communication. The coupling constants, $J(^{13}C\text{–}H)$'s, between the bridge carbon and the hydrogen bonded to it were determined to be 156.5±1 Hz and 164.2±1 Hz for II and III, respectively.

Dissociation Pressure of Ferric Oxide

Kumasaburo KODERA, Isao KUSUNOKI and Minoru WATANABE*1

Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto

(Received May 20, 1969)

The dissociation pressure of various oxides was measured in a high vacuum, and the results were found to be in good agreement with the values calculated from standard free energy data.[1] However, it was also found that all metallic oxides evolved a large amount of carbon monoxide and carbon dioxide at lower temperatures.

Direct measurement of the oxygen dissociation pressure of ferric oxide at high temperatures is desirable. It is of interest to study the evolution of gases during the course of the reduction of ferric oxide by vacuum heat teratment.[2]

In the present experiment, the equilibrium pressures of ferric oxide and the desorbed gases have been measured with a McLeod gauge and the percentage compositions of the gases have been investigated by means of an omegatron mass spectrometer.

Experimental

The apparatus was similar to that described previously.[1] The sample of ferric oxide (α-type, diamagnetic) was a Merk reagent of extra pure grade (Germany) and was used without further purification.

Measurements were carried out under various initial conditions of the samples. In the first run, a freshly powdered sample of about 500 mg was placed in the decomposition cell and evacuated for a day in a high vacuum at room temperature. The sample was then heated to 300°C. The equilibrium pressure of the evolved gases was measured by a McLeod gauge and analyzed by an omegatron mass spectrometer. A similar procedure was repeated at temperatures from 300 to 1200°C. The sample which was heated to 1200°C in the first run was cooled in a vacuum and used again in the second run. The same procedure was repeated in the second run. Replacing the sample with a new one, the measurement was repeated several times.

Results and Discussion

Carbon dioxide, methane, and water were evolved from the new samples below 600°C and in some cases total pressure of these gases amounted to 10^{-3} Torr. However, the evolution of these gases decreased after the first vacuum heat treatment, and the reproducibility of the equilibrium pressures could not be obtained in different runs. On the other hand, the amount of carbon monoxide increased with the oxygen evolution at higher temperature and reproducible equilibrium pressure was attained ($P_{CO}=2\times10^{-2}$ Torr at 1150°C).

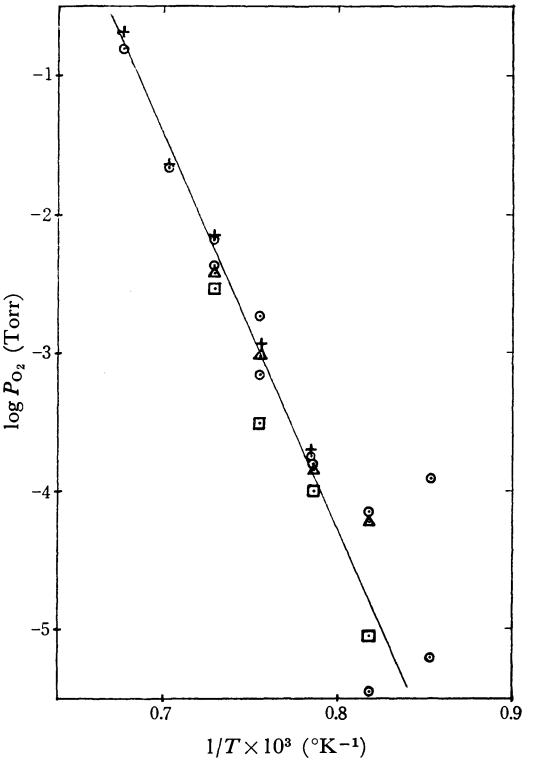

Fig. 1. Dissociation pressure of ferric oxide *vs.* $1/T$.
The values of different symbols show different runs.

Oxygen gas resulting from thermal decomposition can be observed above 900°C. In Fig. 1 the equilibrium pressures of oxygen are plotted against the reciprocal of the absolute temperatures. The straight line obtained in Fig. 1 can be represented by the following equation.

$$\log P_{O_2}\ (\text{Torr}) = -\frac{28.5}{T}\times10^3 + 18.5 \qquad (1)$$

*1 Present address: Tokyo Shibaura Electric Co.

1) K. Kodera, I. Kusunoki and S. Shimizu, This Bulletin, **41**, 1039 (1968); *Nippon Kagaku Zasshi (J. Chem. Soc. Japan, Pure Chem. Sect.)*, **86**, 814 (1965).

2) M. Onchi and I. Kusunoki, *Nippon Kagaku Zasshi (J. Chem. Soc. Japan, Pure Chem. Sect.)*, **85**, 612, 619 (1964).

The sample treated in the second run was analyzed by means of X-ray diffraction and confirmed to be a mixture of oxides Fe_2O_3 and Fe_3O_4. On the other hand, it was confirmed by X-ray analysis that the sample evacuated in vacuum at 1200°C for a day transformed into magnetite (Fe_3O_4, ferromagnetic). The sample did not evolve oxygen gas further at 1200°C. This result is consistent with the report[3] in which the preparation of Fe_3O_4 by heating Fe_2O_3 up to 1300°C in a vacuum was described.

Thus the reaction in the present experiment may be written as

$$6Fe_2O_3(s) \rightleftarrows 4Fe_3O_4(s) + O_2, \quad (2)$$

and the standard free energy change, $\Delta G°$, for the reaction may be given by

$$\Delta G°(\text{cal}) = 130600 - 71.51T. \quad (3)$$

On the other hand, the value obtained by Richardson and Jefes[4] is shown as

$$\Delta G°(\text{cal}) = 119240 - 67.24T. \quad (4)$$

These values are in good agreement in the temperature range of measurement.

SHORT COMMUNICATIONS

A New Alkaloid from *Aconitum sachalinense* Fr. Schmidt

Yoshiyuki ICHINOHE and Makiko YAMAGUCHI

Department of Chemistry, Faculty of Science and Engineering, Nihon University, Narashinodai, Funabashi, Chiba

(Received July 17, 1969)

It has been known that the roots of *Aconitum sachalinense* Fr. Schmidt, which is found throughout southern Sakhalin, contain two alkaloids, jesaconitine $C_{35}H_{49}O_{12}N$ (I) and kobusine $C_{20}H_{27}O_2N$ (II).[1]

This paper will report on the isolation of a further new toxic alkaloid, III, belonging to the group having a aconitine-type skeleton, from the same plant and from *Aconitum sachalinense* Fr. Schmidt var.*1

The III alkaloid was crystallized as its perchlorate (IV) mp 254—256°C (dec.), $[\alpha]_D$ −12° (Found: C, 52.49; H, 6.59%. Calcd for $C_{34}H_{47}O_{12}N\cdot HClO_4$: C, 52.26; H, 6.34%, from the mother liquor after the isolation of I and II. The hydrolysis of the amorphous base III with methanolic potassium hydroxide gave anisic acid, acetic acid (characterized as the silver salt), and an amorphous alkamine, V. V gave the crystalline hydrochloride (VI) (mp 174—179°C) and also the crystalline pentaacetyl derivative (VII), mp 240.5—241.5°C (Found: C, 58.62, 58.64; H, 7.01, 7.02%. Calcd for $C_{34}H_{49}O_{14}N$: C, 58.69; H, 7.09%), on acetylation with acetyl chloride.

From the above experiments, eight out of twelve oxygen atoms in the new alkaloid, III, have been shown to be present in the form of an acetyl group, an anisoyl group, and three free hydroxyl groups. In general, alkaloids with toxic aconitine-type skeletons have several methoxyl groups. The presence of four methoxyl groups in the V alkamine has been confirmed by the micro-Zeisel determination. The permanganate oxidation of anisoyltetraacetylalkamine (VIII) (mp 198—202°C), obtained by the acetylation of III with acetyl chloride, gave formaldehyde (characterized as the dimedone derivative), as in mesaconitine (IX)[2] or hypaconitine (X)[3]. This suggests the presence of an *N*-methyl group in III.

The above evidence shows that the formula of III may be extended as follows:

$$C_{19}H_{19}\begin{cases}(OCH_3)_4\\(OH)_3\\OCOCH_3\\OCOC_6H_4OCH_3(p)\\N\text{-}CH_3\end{cases}$$

As with other alkaloids in the aconitine group, the pyrolytic reaction of the new base, III, gave a pyro-base upon the elimination of the acetic acid. Although the molecular formula and the functional groups of the V alkamine corresponded to those of mesaconine, the alkamine from mesaconitine IX, VII and pentaacetylmesaconine were found to be different by comparisons of their IR spectra and melting points. It is very likely the new alkaloid, III, is an epimer with regard to a secondary hydroxyl or a methoxyl group of mesaconine.

The structural study of the new alkaloid, III, is now in progress.

*** *Department of Chemistry, Tulane University, New Orleans, La., U. S. A.*

(Received April 5, 1969)

As an extension of a previous study,[1] we have prepared a large number of copper(II) complexes with bidentate or tetradentate salicylideneimines and the appropriate anions. Tow types of complexes were prepared; the first (Group A), by the reaction of $Cu(Sal\cdot N\text{–}R)_2$ and cupric chloride or nitrate in hot ethanol, where $Sal\cdot N{=}{=}\cdot\overset{1}{O}\cdot C_6H_4\cdot\overset{2}{C}H{=}N\cdot$ and R = various alkyl or substituted phenyl groups; the second (Group B), from the reaction of $Cu(Sal\cdot N\text{–}CH_2CH_2\text{–}N\cdot Sal)$ with cupric chloride, nitrate, or perchlorate under similar conditions. Nearly all of these complexes have subnormal magnetic moments, suggesting the presence of a strong intramolecular spin-spin interaction. Most of them seem to be binuclear, $[Cu(Sal\cdot N\text{–}R)Cl]_2$; however, some complexes of the group B were found to be trinuclear when cupric perchlorate was used.

One of the most significant features of the chloro-complexes of the group A is the existence of a linear relation between the d–d band positions, $\bar{\nu}_{max}$ (cm^{-1}, kK), and the magnetic moments, $\mu_{eff}^{25°C}$ (B.M.), "lower moments——higher energies of d–d bands," where R = alkyl(10—14 kK, 1.5—0.9 B.M.) and substituted phenyl groups (11—12.5 kK, 1.5—1.1 B.M.), which is the same relation as that observed for the binuclear copper(II) halide complexes with substituted pyridine *N*-oxides (9—13.5 kK, 1.2—0.2 B.M.).[1] For *N*-phenyl-complexes *ortho*-substituents in the *N*-phenyl group increase the energies of the singlet-triplet separation and the d–d bands, irrespective of the polar nature of the substituents (CH_3, Cl, and NO_2). This same shielding effect of *ortho*-substituents was found previously for the pyridine *N*-oxide complexes. The chloro-complexes of Group A are mostly dark brown in color; a few, however, are orange with a broad band at longer wavelengths (9—11 kK). The orange complexes do not obey the above linear relation, suggesting a different structure even though they have the same composition as the binuclear complexes, $Cu(Sal\cdot N\text{–}R)Cl$. They also have the lowest moments of the two groups; for example, when $R=CH_3$ (0.90 B.M. orange; 1.5 B.M. brown) and $R=CH_2CH_2CH_2OH$ (1.06 B.M.), *o*- and *p*-NO_2-phenyl (1.06 and 0.97 B.M.), and $Cu(5\text{-}Cl\text{–}Sal\cdot N\text{–}CH_3)Cl$ (0.95 B.M.).

The nitrato-complexes of Group A are, in general, green with the d–d bands at much shorter wavelengths (13.5—15.5 kK) than those of the corresponding chloro-complexes (10—14 kK). They seem to have a phenolic oxygen-bridged binuclear structure; this is based on the observed chemical formula, $Cu(Sal\cdot N\text{–}R)NO_3$, the molecular-weight determination by osmotic pressure measurement, the observation of a bridging phenolic C–O band at 1550—1560 cm^{-1},[2,3] and the low magnetic moments, 1.1—1.4 B.M. Some nitrato-complexes with R = 3-CH_3– and 3-Cl-phenyl (green) or *t*-butyl group (greenish brown) have normal magnetic moments, 1.7—1.8 B.M. These complexes show a non-bridging phenolic C–O band at *ca.* 1530 cm^{-1}, suggesting a monomeric structure.[2,3] However, when R = isopropyl, a trinuclear complex, $2Cu(Sal\cdot N\text{–}R)_2\cdot Cu(NO_3)_2$, was produced, with a normal moment (1.84 B.M. at 19°C). The nitrato-complexes with subnormal magnetic moments did not show the linear relation between $\mu_{eff}^{25°C}$ and $\bar{\nu}_{max}$ which was observed for the corresponding chloro-complexes. This suggests that the dimeric structure of nitrato-complexes differs from that of chloro-complexes.

The binuclear chloro- and nitrato-complexes produced by reaction (2) (Group B) revealed two bands, at 18.5—19.5 kK and 10—11.5 kK, indicating that the environment of the two copper atoms in the molecule is greatly different. However, the bands of the chloro-complexes appeared at longer wavelengths than those of the corresponding nitrato-complexes, and the former exhibited a smaller magnetic interaction (1.5 B.M.) than the latter (1.2—1.3 B.M.). This is essentially the same trend as the linear relation observed for the chloro-complexes of Group A.

The Behaviour of Chemisorbed Species under the Reaction Conditions and the Mechanism of the Water-gas Shift Reaction on ZnO and MgO

Akifumi UENO, Toshiki YAMAMOTO, Takaharu ONISHI and Kenzi TAMARU

Department of Chemistry, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received June 3, 1969)

The importance of adsorption measurements during surface catalysis has previously been emphasized by one of the present authors.[1] The mechanism of the water-gas shift reaction on ZnO and MgO was studied by means of infrared techniques during the course of the reaction. It was found that a surface formate is formed on both of the catalysts as the reaction intermediate. The rate-determining step of this reaction was the decomposition of the surface formate.

When carbon dioxide and hydrogen were conducted onto ZnO at 150°C, the surface formate could be observed by infrared spectroscopy. The isotope shift of the C–H (and C–D) stretching vibration band was observed by employing deuterium gas. It was, however, difficult to find the surface formate in a mixture of carbon monoxide and water vapour on ZnO, though the surface OH group and CO(a) were found to be formed at a considerable rate. The dependence of the optical density of the infrared spectrum of the surface formate upon its coverage was obtained from a comparison of the spectroscopic and volmetric measurements on the adsorption of formic acid. The coverage of the surface formate during the overall reaction was obtained from the optical density.

The rate of the decomposition of the surface formate (v) was examined by means of infrared spectroscopy at the reaction temperature (230°C), forming the surface formate by introducing a known amount of formic acid vapour. Then the rate of the dehydration decomposition (v') was oatained by the following equation; $v'=v\times s$, where s is the selectivity, ([CO]/[CO]+[CO_2]), of the decomposition of the surface formate. It was then compared with the rate of the overall reaction ($H_2+CO_2 \rightarrow CO+H_2O$), v'', as measured by gas chromatographic analysis for the carbon monoxide produced. The two rates were in reasonable agreement within the limits of experimental error, provided the coverage was the same, which leads us to the conclusion that the surface formate is the reaction intermediate of the water-gas shift reaction and that its dehydration decomposition, step (2) in the following scheme, is the rate-determining step.

Run	Rate of overall reaction (v'') cc/g·hr	Rate of dehydration (v') cc/g·hr	Coverage
1	0.023	0.022	0.35
2	0.028	0.025	0.35
3	0.030	0.029	0.41

$$\left.\begin{array}{l} H_2(g) \rightleftarrows 2H(a) \\ CO_2(g) \rightleftarrows CO_2(a) \end{array}\right\} \overset{1)}{\rightleftarrows} HCOO(a) \overset{2)}{\rightleftarrows} H(a)$$

$$\left\{\begin{array}{l} OH(a) \rightleftarrows H_2O(g) \\ CO(a) \rightleftarrows CO(g) \end{array}\right.$$

When a mixture of carbon monoxide and water vapour was introduced over MgO, we confirmed the formation of a surface formate on the catalyst by means of infrared spectroscopy in a manner similar to that used in ZnO, as has been found by Scholten.[2] However, it was found that the surface formate could not be easily observed from a mixture of carbon dioxide and hydrogen on MgO.

We measured the rate of the dehydrogenation decomposition of the surface formate by infrared spectroscopy at 280°C in order to compare it with the overall reaction rate, as measured by gas-chromatographic analysis, for the carbon dioxide produced. As was the case over ZnO, the two rates were in reasonable agreement within the limits of experimental error if the adsorption of surface formate was the reaction intermediate of the reaction on MgO; the rate-determining step was the step of the dehydrogenation decomposition of the surface formate, step (1).

In the water-gas shift reaction over both ZnO and MgO, the change in the adsorptions of water, carbon dioxide, carbon monoxide, and hydrogen did not considerably influence the rate of the decomposition of surface formate under the reaction conditions employed.

Polymerization by the Active Species Produced from the Charge Transfer Complex. IV. Phototerpolymerization of *N*-Vinylpyrrolidone, Maleic Anhydride and Methyl Methacrylate

Hajime TAMURA, Makoto TANAKA and Niro MURATA

Department of Applied Chemistry, College of Engineering, University of Osaka Prefecture, Sakai, Osaka

(Peceived July 19, 1969)

It was found by us that the photo and thermal polymerizations of methyl methacrylate (MMA) were largely accelerated in the presence of both amide and maleic anhydride (MAH) and the acceleration was more effective in air than *in vacuo*. Besides, it was assumed that the radical species initiating the polymerization of MMA was produced *via* the complex between amide and MAH.[1)]

As *N*-vinylpyrrolidone (VPD) is an amide concontaining a vinyl group, it probably interacts with MAH, as a result the complex may participate in polymerization as a monomer unit. Therefore, it is expected that the terpolymerization of VPD, MAH, and MMA is induced by the VPD-MAH complex.

The mixture of VPD and MAH turned yellowish and then pink or scarlet upon UV irradiation. The spectra of the solutions of VPD and MAH in 1,2-dichloroethane are shown in Fig. 1. The results suggest a complex formation between VPD and MAH.

The composition of the VPD-MAH complex was determined by the continuous-variation method,

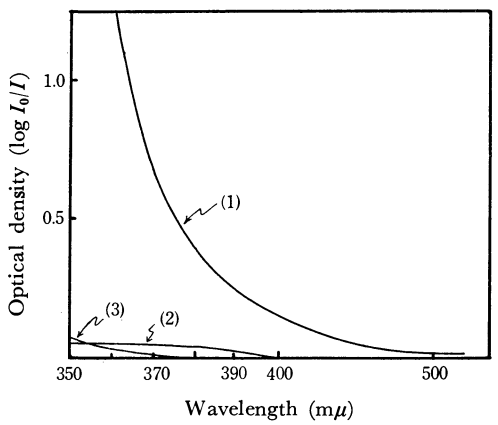

Fig. 1. Absorption spectra of the complex between VPD and MAH.

(polymerization time, 3 hr)

Experimental number	VPD (mol/*l*)	MAH (mol/*l*)	MMA (mol/*l*)	Polymer yield (g)
1	3.75	0.41	5.62	0.421***
*2	3.75	0.41	0	0.120
3	3.75	0	5.62	0.047
*4	0	0.41	5.62	0
**5	3.75	0.41	5.62	0.290

* The total volume was maintained at 5 m*l* by employing benzene instead of MMA or VPD.
** Polymerization was carried out for 2 hr using AIBN (2×10^{-2} mol/*l*) as the initiator.
*** The polymerization in the dark was almost negligible.

the results shown in Fig. 2 were obtained. The curves reached a maximum at the 0.5 mol fraction of MAH, and it was estimated that a 1 : 1 complex was formed between VPD and MAH.

The polymerization of the VPD-MAH-MMA system was induced, in fact, without any initiator, the results of the photopolymerization are shown in Table 1.

Polymerization by the Active Species Produced from the Charge Transfer Complex. V. The Thermal Copolymerization of *N*-Vinyl-pyrrolidone and Methyl Methacrylate

Hajime TAMURA, Makoto TANAKA and Niro MURATA

Department of Applied Chemistry, College of Engineering, University of Osaka Prefecture, Sakai, Osaka

(Received July 31, 1969)

It was previously reported by us[1] that the polymerization of the *N*-vinylpyrrolidone (VPD)-maleic anhydride(MAH)-methyl methacrylate(MMA) ternary system was induced photochemically in air at 30°C without any initiator and that the active species was presumably produced *via* the 1 : 1 complex between VPD and MAH. Furthermore, their polymerizations occurred thermally in air at 70°C.

In the photochemical polymerization, the lack of any one component remarkably lowered the polymer yield, but in the thermal polymerization it was found that the spontaneous copolymerization of VPD and MMA took place simultaneously in air after some induction period and that the copolymerization rate was quite fast, though it was somewhat smaller than that of the ternary system.

Therefore, the following experiments were carried out. The copolymerization of VPD and MMA did not occur at all *in vacuo*. This suggests that oxygen may participate in the reaction of the production of the active species. The copolymers were obtained from mixtures with various ratios of VPD and MMA, and the copolymerization rate was remarkably accelerated by adding a small amount of $ZnCl_2$. Neither VPD nor MMA alone was polymerized under the experimental conditions employed here. The results are shown in Table 1.

TABLE 1. THE SPONTANEOUS COPOLYMERIZATION OF VPD AND MMA AT 70°C

VPD (mol/*l*)	MMA (mol/*l*)	Polymer yield (g)	
		In air (%)*	*In vacuo*

* Weight %-conversion to the total monomer concentration.

** About 0.2 g of $ZnCl_2$ was added to the mixture of VPD and MMA.

*** The total volume was maintained at 5 m*l* employing benzene.

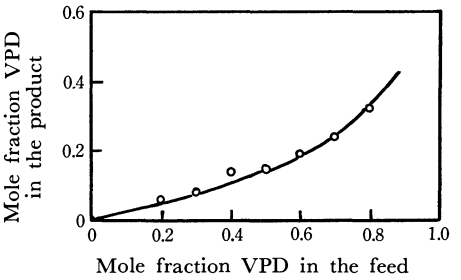

Fig. 1. Composition curve for the VPD-MMA copolymer (in air at 70°C).

It is known that the positive *e*-value of such monomers as MMA and acrylonitrile is elevated by the addition of a Lewis acid such as $ZnCl_2$.[2] Although there is no spectroscopic evidence for thr existence of the VPD-MMA complex, it is possible, judging from these results, that the active species is formed by the reaction of the VPD-MMA complex and oxygen.

The compositions of the copolymers were determined by elemental analysis, while the composition curve for the VPD-MMA copolymer was obtained as is sown in Fig. 1.

The monomer reactivity ratio (M_1=MMA, M_2=VPD) were decided from the Mayo-Lewis plots to be the following: $r_1=4.6\pm0.4$, $r_2=0.02\pm0.02$. The copolymerization of VPD and MMA by a radical initiator (AIBN) at 50°C has already been reported by Bork and Coleman,[3] who obtained the following values: $r_1=4.7\pm0.5$, $r_2=0.005\pm0.05$.

The results we have obtained here are quite consistent with theirs. This suggests that the spontaneous copolymerization of VPD and MMA proceeds by way of a radical mechanism. The details of the study will be reported later.

Hydrogen-Deuterium Exchange of Several Optically Active Complexes of Cobalt(III) in D_2O Solutions

Hideo YAMATERA and Miho FUJITA

Department of Chemistry, Nagoya University, Chikusa-ku, Nagoya

(Received July 28, 1969)

The rates of hydrogen isotope exchange were measured for several optically-active cationic cobalt complexes dissolved in D_2O containing an optically-active anionic species. The rate constant was obtained from the plot of $-\log(1-A_t/A_\infty)$ *vs.* t,[1] where A_t is the observed absorbance at 6000 cm^{-1} (due to HDO) at time t and where A_∞ is the equilibrium value. A Carl-Zeiss spectrophotometer PMQII was used for the measurements.

The rates of amino-hydrogen exchange for *d*- and *l*-$[Co(en)_3]^{3+}$ were measured in the presence of *d*-tartrate.*1 The results are given in Table 1. The conditions were practically the same within each pair of runs, except that different optical isomers of the complex were used. In the pair of runs, D-0 and L-0, where the solution contained no tartrate, but instead an acetate buffer, the rates of hydrogen exchange were very similar. In the presence of *d*-tartrate, however, the rate constants were appreciably smaller for *d*-$[Co(en)_3]^{3+}$ than for the *l*-isomer. This seems to imply that

*** Y=EDTA

there is some stereoselective interaction in the solution between the isomers of $[Co(en)_3]^{3+}$ and the *d*-tartrate ion. In this connection, it is interesting to note that Ogino and Saito obtained a higher association constant for the pair consisting of *d*-$[Co(en)_3]^{3+}$ and *d*-tartrate.[2]

Similar results were obtained for *d*- and *l*-$[Co(NO_2)_2(en)_2]^+$ in the presence of *l*-[Co(EDTA)]$^-$, as is shown in Fig. 1 and Table 2. In this case, the amino groups are not equivalent and *at least* two exchange rates may be expected.[3] Table 2 gives data for the smallest rate constant, which is probably due to amino groups *cis* to nitro groups.

Further results and a more detailed discussion will be given elsewhere.

Optical and ESR Studies on Triphenylimidazolyl Radicals Produced by Photolysis and Radiolysis at Low Temperature*[1]

Tadamasa SHIDA, Koko MAEDA* and Taro HAYASHI

The Institute of Physical and Chemical Research, Yamatomachi, Kitaadachi-gun, Saitama

** Department of Chemistry, Faculty of Science, Ochanomizu University, Bunkyo-ku, Tokyo*

(Received July 29, 1969)

In a previous paper[1] we reported that UV-illumination of the photochromic dimer of triphenylimidazolyl (photo-dimer, abbreviated as R_2) in EPA at −196°C induced a coloration which was attributed to the formation of a radical cation of the dimer.[1] We wish to report here that the coloration should be associated with the formation of triphenylimidazolyl radical R·, as in the case of photolysis of the dimer at room temperature.[2]

When a colorless solution of photo-dimer in methyltetrahydrofuran (MTHF) in a thin quartz cell was exposed at −196°C to UV-light (λ= 240—400 mμ), an absorption with λ_{max} 350, 556 mμ appeared which was almost the same as that of R· in MTHF at room temperature. The ESR spectrum of the solution at −196°C showed a broad doublet which is unambiguously attributable to the fine structure due to the close-lying two radicals. From these observations it is concluded that photo-dimer in MTHF at −196°C dissociates homolytically upon UV-illumination. When the same solution was radiolyzed at −196°C with γ-rays from a ^{60}Co source, an absorption spectrum very similar to that of the photolyzed solution appeared (λ_{max} 347, 552 mμ) indicating the formation of R·. The ESR spectrum of the radiolyzed solution, however, showed no sign of the doublet due to the radical pair but a sharp singlet of ΔH_{msl}=8.1 gauss. The line width is close to that of the monomeric R· in solutions photolyzed at room temperature. In the radiolysis of the rigid solution, R· is apparently formed not as a geminate radical pair but as a single isolated radical by the reaction $R_2+e^- \rightarrow R\cdot+R^-$. The reaction is consistent with the ESR result as well as several other observations.

When both photolyzed and radiolyzed solutions at −196°C were carefully warmed, a subtle color change was noticed just before the solution thawed. The warmed solution, when quickly dipped again in liquid nitrogen, exhibited another spectrum similar to the original, but with a significant red shift (λ_{max} 354, 566 mμ). In addition to the red shift the absorption bands became narrower and the band structure was more manifested. It is assumed that the newly appearing spectrum is associated with triphenylimidazolyl radical whose phenyl groups are more or less coplanar with the plane of the imidazole ring. The spectrum reported previously as the cation radical of R_2 might have been the spectrum of this conformational isomer of the radical.

We obtained quite analogous results in the studies on tetraphenylpyrryl radical produced by oxidation of tetraphenylpyrrole.

Acidity of Methine Hydrogen in Cyclopropyl Ketone—*Cis-Trans* Rearrangement of 1-Acetyl-2-phenylcyclopropane with Base

Katsuhiko ICHIKAWA, Osamu ITOH and Nobuyuki YAMAMOTO

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received August 5, 1969)

Acidity of methine hydrogen in cyclopropyl ketone is of current interest. Dessy *et al.* reported that the base catalyzed isotopic exchange of the methine hydrogen in cyclopropyl phenyl ketone proceeded 14 times faster than the methine hydrogen in isobutyrophenone in D_2O-DMF solution because of the *s*-character of the carbon orbital of cyclopropane.[1] Recent reinvestigation of the same reaction, however, has shown that the exchange in D_2O-DMF containing NaOD (0.17 M) underwent resistance in 14 hr at 60°C,[2] and accordingly the above conclusion should be modified.

Rappe and Sachs reported also that the exchange of cyclopropyl methine proton is much slower than that of isopropyl methine proton in the same system.[3] Van der Maeden *et al.*, however, gave results which suggest that the opposite may be the case.[4] It is clear that further investigations are required on the acidity of cyclopropyl methine hydrogen. We wish to report our results on this question.

cis-1-Acetyl-2-phenylcyclopropane rearranges to *trans* isomer readily in 75% ethanol solution containing potassium hydroxide. The rates of the reaction were followed by gas chromatographical method. The results showed that the reaction follows first-order rate law at various base concentrations at 40 and 60°C. Constant values of k_1/[KOH] were obtained at both temperatures (Table 1).

	0.194	0.204	32	16

Activation energy, 18 kcal/mol.

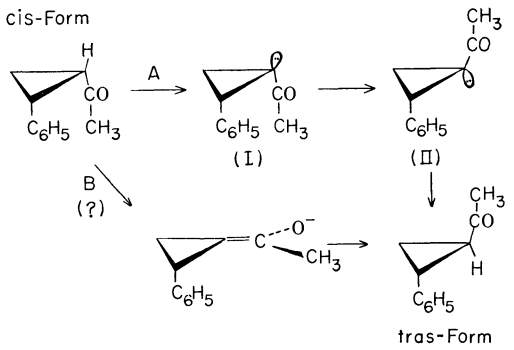

Fig. 1. Possible pathways for the rearrangement.

Two possible pathways of the reaction can be described (A and B in Fig. 1). Pathway B, however, appears to be unlikely, since enolization in this system is repressed because of steric inhibition.[2] The most probable mechanism A involves proton abstraction from cyclopropyl methine system to form carbanion. The rate determining step appears to be the proton abstraction, since no plausible reason for the stability of carbanion I can be found in this system. Large k_1 values obtained here make sharp contrast with those by isotopic exchange method. The reason for the disagreement might be found in the effect of the phenyl group attached to the cyclopropane ring. Assuming this to be the case, a pronounced effect through the ring is expected. Experiments along the line are under progress.

cis-1-Acetyl-2-phenylcyclopropane was prepared by alkaline deacetylation of 1,1-diacetyl-2-phenylcyclopropane[5] in 75% ethanol containing potassium hydroxide at 0°C. *Cis*- and *trans*-isomers were separated by column chromatography using WAKO GEL C-200 and hexane - ethyl acetate (90 : 10).

A New Pair of Isomers of a Schiff Base Nickel(II) Complex

Akira TAKEUCHI and Shoichiro YAMADA

Institute of Chemistry, College of General Education, Osaka University, Toyonaka, Osaka

(Received August 8, 1969)

It is well known that the bis(*N*-alkyl- or bis(*N*-aryl-salicylideneiminato)nickel(II) complex (abbreviated as Ni(X-SAL·R)$_2$, Fig. 1) in non-donor solvents exists as an equilibrium mixture consisting of the planar, tetrahedral and polymeric species. The equilibrium depends upon the nature of X and R, as well as upon concentration and temperature.[1,2] From the solutions, however, only one component is usually obtained as crystals. Two forms of crystals consisting of complexes with different configurations have so far been isolated for only a few sets of X and R.[3,4] For the complexes with R=*iso*-C_3H_7, where there is remarkable steric hindrance, either the planar or the tetrahedral form was isolated as crystals, depending upon the nature of X. No pair of isomers has ever been isolated for any substituent X. The present communication deals with successful isolation of two isomers of Ni(3-CH_3O-SAL·*iso*-C_3H_7)$_2$.

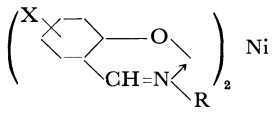

Fig. 1. Ni(X-SAL·R)$_2$

Isopropyl amine (0.04 mol) was added to a suspension of bis(3-methoxysalicylaldehydato)-nickel(II) dihydrate (0.02 mol) in methanol (100 m*l*), and the resulting solution was heated on a water-bath at about 40°C for one hour. A brown crystalline precipitate separated out from the brown solution. Recrystallization of the precipitate from methanol yielded brown crystals (Form I) of the desirable complex, Ni(3-CH_3O-SAL·*iso*-C_3H_7)$_2$. Spontaneous evaporation of a green solution of the precipitate in ethyl ether-methanol or ethyl ether - chloroform (20:1) yielded green crystals (Form II) of the same complex. Elemental analysis of both Form I and Form II agree with the formula Ni(3-CH_3O-SAL·*iso*-C_3H_7)$_2$. Both forms, when dissolved in the same solvents, show the same electronic spectra which are also dependent upon the concentration, solvents and temperature.

Since Form II is diamagnetic, it is considered to consist of uninuclear, planar complexes. The conclusion is supported by the electronic spectrum in the solid state, which is typical of the planar nickel(II) complex of this series. Form I is paramagnetic with a magnetic moment of 3.32 B. M. at room temperature, showing that this form does not consist of the planar species. The electronic spectrum of Form I in the solid state is typical of the tetrahedral nickel(II) complex, and is indeed quite similar to that of Ni(H-SAL·*iso*-C_3H_7)$_2$,[5] which was previously concluded to consist of the tetrahedral nickel(II) species.[6] So far as we know, this is the first isomeric pair of tetrahedral and planar nickel(II) complexes with the Schiff base to be isolated as crystals.

It is also interesting to note that on raising the temperature, Form II is transformed at 157—158°C into Form I, eventually showing the same behaviour as Form I, which melts at 187—188°C after sintering at 169—170°C.

The details of the work will be published elsewhere.

Rotational Raman Spectrum of Oxygen

Koichi ABE and Takehiko SHIMANOUCHI

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received August 14, 1969)

We have measured the Raman spectrum of oxygen at one atmospheric pressure, using a JEOL argon ion laser as the exciting source and a Nalumi Raman spectrometer. The monochromator is equipped with a 300 line/mm Bausch and Lomb 35—53—32—45 echelle grating. The focal length is 2m ($F=11$) and the twelfth order diffraction gives the linear dispersion of 2.4 cm^{-1}/mm at 5000A. Eastman Kodak 103-aF film was used and the exposure time was 5—24 hr. The Raman cell was placed in the laser cavity and the beam was focused at the Raman cell.

We have found that the lowest frequency Raman lines corresponding to the $N=1\rightarrow N=3$, $N=3\rightarrow N=5$ and $N=5\rightarrow N=7$ transitions have satellites on both sides of the main lines. The multiplicity is interpreted to be caused by the spin-spin coupling in the $^3\sum_g^-$ ground state of oxygen. The main line and the satellites are assigned to the $\Delta J=2$ and 0 and $\Delta J=1$, respectively, except for the $N=1\rightarrow N=3$ transition, where the case of $J=0\rightarrow J=2$ is included in the higher frequency satellite.

In the course of the study we were informed that Renschler, Hunt, McCubbin and Polo measured the same phenomena in the spectra excited in the cavity of the He-Ne laser (1). Since independent observation by the argon ion laser completely eliminates the possibility of ghosts, the result is reported here.

The microphotometer reproduction of the spectrum is shown in Fig. 1 with the assignments, confirming the interpretation given by Renschler *et al.*

We are grateful to Professor McCubbin for communicating the result before publication.

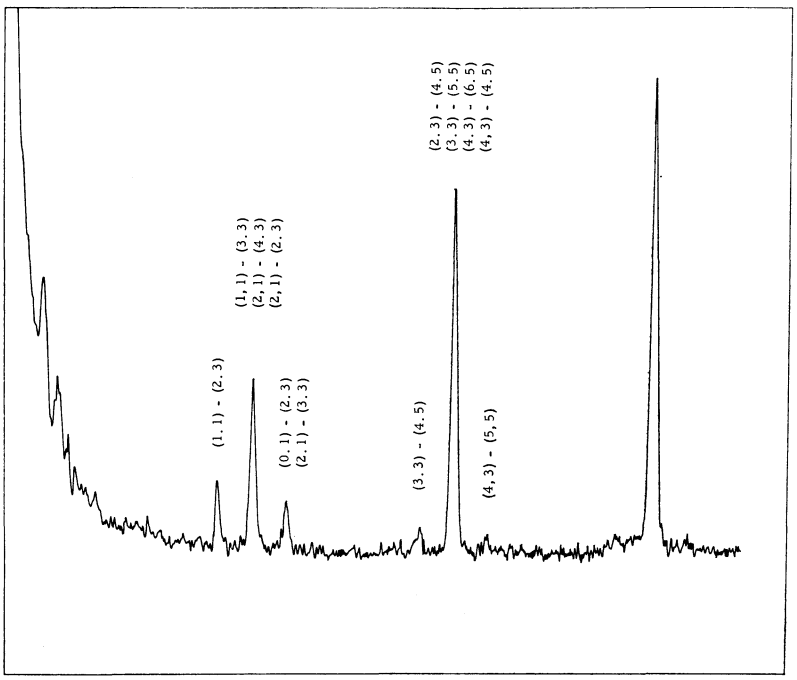

Fig. 1. Stokes lines with satellites. Assignments are shown as (J'', N'')-(J', N'). The Rayleigh line has the Stokes and Antistokes satellites corresponding to the $\Delta N=0$ and $\Delta J=1$ transition. However, it is accompanied also with ghost lines and the assignments are not definite.

An ESR Study of 1:1 Adducts of Bis-salicylaldehyde-imine-cobalt(II) Complexes with Oxygen in Solutions

Akira MISONO and Seiichiro KODA

Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received August 18, 1969)

The present authors have already reported[1] that oxygen coordinates reversibly in the ratio of 1 : 1 with bis-salicylaldehyde-imine-cobalt complexes supported on poly-4-vinylpyridine. In the present communication, they wish to report on the observation of the ESR spectra of 1 : 1 adducts of bis-salicylaldehyde-imine-cobalt(II) complexes with oxygen, which may exist equilibrially in solutions.

When a pyridine solution of *N,N'*-ethylene-bis(3-methoxysalicylideneiminato)cobalt(II) (Co 3-MeOsalen) was exposed to oxygen, there appeared an ESR signal in which hf structures caused by a cobalt nucleus were observed (eight lines, I (^{59}Co)= 7/2). This signal decreased when the solution was exposed to nitrogen and increased again when the solution was again exposed to oxygen. Similar spectra could be observed in substituted pyridines, *N,N*-dimethylformamide, and dimethyl sulfoxide used as solvents. Moreover, *N,N'*-ethylene-bis-(salicylideneiminato)cobalt(II) (Co salen) showed a similar spectrum in pyridine under oxygen.

These observations prove that there may be some amounts of a 1 : 1 adduct of bis-salicyl-aldehyde-imine-cobalt(II) complexes with oxygen in some solutions. The observed ESR spectra may be caused by the 1 : 1 adducts, for the existence of eight resolved lines in the spectra clearly shows that the adducts intrinsically contain only one cobalt atom. In fact, the observed ESR spectra closely resemble those of superoxocobalamin ($Co/O_2=1/1$).[2] Moreover, recently the preparation of the adduct, (Co 3-MeOsalen)·py·O_2 has been reported.[3]

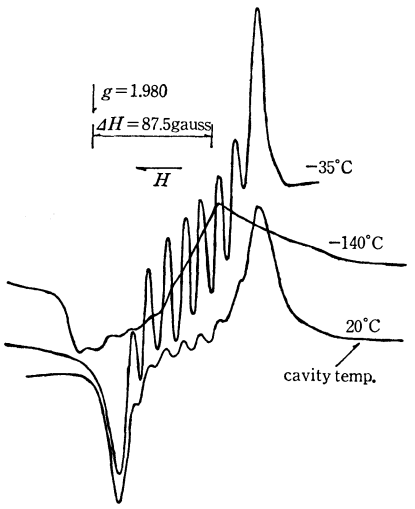

Fig. 1. ESR Spectra of Co 3-MeOsalen in pyridine under oxygen (1 atm).
complex concn. = 1.4×10^{-2} mol/*l*

The small A_{Co} values (A_{Co} is the mean interval of two adjacent lines among the eight lines) may mean that little of the unpaired spin is at the cobalt atom; if so, the adducts can be regarded as essentially superoxide cobalt(III) complexes. The explanation of the solvent effect is difficult, but it is reasonable that a solvent molecule coordinates to a cobalt complex in the *trans* position against oxygen and affects the electron distribution on the coordinated oxygen molecule.

TABLE 1. ESR CHARACTERS OF THE ADDUCTS

Complex	Solvent (complex concn., 10^{-2} mol/*l*)	*g*	A_{Co} (gauss)	Cavity temp. (°C)
Co 3-MeOsalen	Pyridine(1.4)	2.023	12.8	−35
Co 3-MeOsalen	Pyridine(1.8)	2.022*	—	20
Co 3-MeOsalen	4-Methylpyridine(1.7)	2.022*	13*	20
Co 3-MeOsalen	4-Ethylpyridine(1.7)	2.022	12.8	−10
Co 3-MeOsalen	DMF(1.4)	2.028	17.0	−15
Co 3-MeOsalen	DMSO(1.7)	2.028	17.3	20
Co 3-MeOsalen	DMF+Pyridine (1/1 vol)(0.9)	2.023	12.8	−10
Co salen	Pyridide(1.1)	2.022*	13*	20

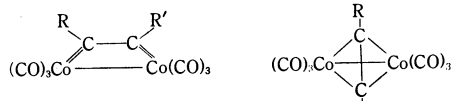
New Type Acetylene Compexes with Mixed Transition Metals

Katsutoshi YASUFUKU and Hiroshi YAMAZAKI

The Institute of Physical and Chemical Research, Yamato-machi, Saitama

(Received August 26, 1969)

At an early stage of acetylene complex chemistry, an assumed structure (I) was proposed for the complexes $RC_2R'Co_2(CO)_6$ by Sternberg *et al.*[1] Afterwards, X-ray diffraction study[2] verified that the structure is II which has been recognized as a general structure of the coordinated acetylenes in the acetylene complexes.

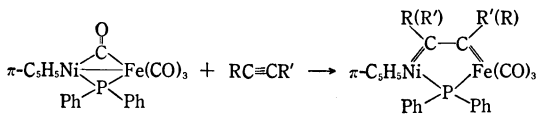


(I) (II)

In this communication, we wish to report the preparation of new type acetylene complexes in which the acetylene attaches to nickel and iron with the structure proposed by Sternberg.

Tolan and μ-diphenylphosphido-π-cyclopentadienyltetracarbonylironnickel(III)[3] were heated for six hours under reflux in benzene. After evaporation of the solvent, the residue was subjected to chromatography on alumina with hexane-methylene chloride mixture as an eluant. Concentration of the eluate gave air-stable brown crystals (IVa). (Yield 85%, mp 215—220°C (with decomp). Found: C, 65.02; H, 4.19%. Calcd for $C_{34}H_{25}O_3PFeNi$: C, 65.13; H, 4.00%.)

IR spectrum (KBr disk) showed bands of terminal carbonyls at 2010, 1960, and 1948 cm^{-1} (ν_{CO}). NMR spectrum (in $CDCl_3$) indicated phenyl protons at 2.0—3.2 τ and π-cyclopentadienyl protons at 4.93 τ. Mass spectrum showed a parent peak at *m/e* 626 corresponding to the formula $C_{34}H_{25}O_3P^{56}Fe^{58}Ni$. Peaks due to the successive loss of three carbonyl groups and tolan were also found at *m/e* 598, 570, 542, and 364.



(III) (IV)

a : R, R′=Ph
b : R, R′=CO_2CH_3
c : R=Ph, R′=CO_2CH_3
d : R=Ph, R′=CH_3

Following similar procedures, the complexes of dimethyl acetylenedicarboxylate (IVb), methyl phenylacetylenecarboxylate (IVc), and methylphenylacetylene (IVd) were obtained, in which IVc and IVd consist of two isomers respectively.

IVb: Yield 37%, mp 128—133°C. NMR: 1.9—2.9 τ (C_6H_5), 4.82 τ (C_5H_5), 6.11 τ (one CH_3), and 6.43 τ (another CH_3). M(*m/e*) 590.

IVc_1: (formerly eluted isomer): Yield 36%, mp 178—179°C. NMR: 1.9—2.9 τ (C_6H_5), 4.84 τ (C_5H_5), and 6.60 τ (CH_3). M(*m/e*) 608.

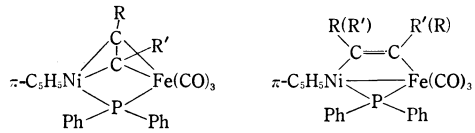
IVc_2: (lately eluted isomer): Yield 24%, mp 159—161°C. NMR: 2.0—3.0 τ (C_6H_5), 4.93 τ (C_5H_5), and 6.14 τ (CH_3). M(*m/e*) 608.

IVd_1: Yield 20%, brown oil. NMR: 2.1—3.0 τ (C_6H_5), 5.02 τ (C_5H_5), and 6.88 τ (CH_3, doublet, $J_{P-M=C-CH}$=4.8 cps). M(*m/e*) 565.

IVd_2: Yield 21%, mp 169—170°C. NMR: 2.1—2.9 τ (C_6H_5), 4.95 τ (C_5H_5), and 8.46 τ (CH_3, doublet, $J_{P-M=C-CH}$=13.2 cps). M(*m/e*) 565.

We suggest structure IV for these complexes. A relatively large coupling constant of CH_3 in IVd_1 and in IVd_2 with ^{31}P nucleus seems to give effective support.

Presence of dissimilar methyl groups in IVb and the presence of isomers in IVc and in IVd eliminate structure V. Another probable structure VI might be excluded from the absence of $\nu_{C=C}$ band in the IR spectra, and from steric consideration.



(V) (VI)

The complexes are new compounds for the following reasons: (1) They are the first complexes in which acetylene coordinates on two different transition metals, and (2) they are considered to coordinate on metals with the dicarbene structure. The configurations of the isomers have not been determined as yet. Detailed study of these complexes is now in progress.

2) W. G. Sly, *ibid.*, **81**, 18 (1959).

3) III was obtained in the reaction of $HPh_2PFe(CO)_4$ with $(C_5H_5)_2Ni$, which was an extention of the method by Benson *et al.* (*Chem. Commun.*, **1968**, 1506).

New Red-pentamminenitrosylcobalt(III) Complexes

Eiichi MIKI, Tatsujiro ISHIMORI and Hisateru OKUNO

Department of Chemistry, College of Science, St. Paul's (Rikkyo) University, Nishi-Ikebukuro, Toshima-ku, Tokyo

(Received September 16, 1969)

The black and red series of the compounds with the composition of $Co(NH_3)_5(NO)X_2$ have been extensively studied ever since they were originally prepared by Sand and Genssler.[1] The red series (Red salt I) are binuclear, and the two cobalt atoms are bridged through a hyponitrite ion.[2]

Recently, the present authors prepared the new "red-pentamminenitrosylcobalt(III) chloride and nitrate" (Red salt II) by the use of a procedure similar to that for the red series reported by Odell *et al.*[3] To a cobalt(II) chloride or nitrate solution (5 g of $CoCl_2 \cdot 6H_2O$ or $Co(NO_3)_2 \cdot 6H_2O$/20 m*l* H_2O), enough ammonia water was added to give about 5 mol/*l*; the solution was then exposed to air for more than 20 hr at room temperature. The solution was placed in a reaction apparatus which had been outgassed with nitrogen gas. When nitric oxide gas was passed into the solution cooled with an ice-water bath, the red precipitate was yielded. Red salt II (nitrate) obtained could be recrystallized only from dimethylsulfoxide, but not from an aqueous solution.

Found: Co, 21.5; N, 30.84; H, 5.42; NH_3, 32.0; Cl, 25.2%. Calcd for $[Co_2(NH_3)_{10}(NO)_2]Cl_4 \cdot 4H_2O$: Co, 20.97; N, 29.90; H, 6.81; NH_3, 30.30; Cl, 25.23%. Found: Co, 18.9; N, 33.63; H, 4.62; NH_3, 27.2%. Calcd for $[Co_2(NH_3)_{10}(NO_2)](NO_3)_4 \cdot 2H_2O$: Co, 18.64; N, 35.44; H, 5.42; NH_3, 26.94%.

The molar conductivities of Red salt II in aqueous and dimethylsulfoxide solutions were examined by the method of Feltham and Hayter[4]; the relations between the conductivities and the square root of the concentrations for these salts coincided with those for Red salt I. It was suggested that Red salt II was a 4 : 1-type electrolyte.

The infrared spectra of Red salt II were similar to those of Red salt I. For Red salt I, the shifts of three absorption bands on the ^{15}NO-substitution were observed (from 1137, 1048, and 930 cm^{-1} to 1112, 1027, and 916 cm^{-1}). These shifts coincide with those reported by Mercer *et al.*[5] On the other hand, for the chloride of Red salt II the absorptions at 1481, 1278, 1020 and 804 cm^{-1} shifted to 1450, 1259, 1019 and 783 cm^{-1} respectively.

The gaseous products obtained by the decomposition of Red salt I and II were detected by the use of an infrared spectrophotometer. The ^{15}NO-complex of Red salt II (chloride) was decomposed by the addition of 6 M H_2SO_4 to give $^{15}NOCl$ and a small amount of $^{15}N^{15}NO$, while only $^{15}N^{15}NO$ was derived from the ^{15}NO-complex of Red salt I (nitrate). In the thermal decomposition *in vacuo*, for Red salt II (chloride and nitrate) $^{14}N^{14}NO$ and $^{14}N^{15}NO$ were derived from both the ^{15}NO-complex and the mixture of the ^{14}NO- and ^{15}NO-complex (1 : 1), while for Red salt I (nitrate) $^{14}N^{14}NO$ and $^{15}N^{15}NO$ were derived from both the ^{15}NO-complex and the mixture of the ^{14}NO- and ^{15}NO-complex (1 : 1). A part of the N_2O was formed as a by-product in the thermal decomposition; it contained two nitrogen atoms which came from the nitrogen of ammines in the complex. The ^{15}NO-Red salt II yielded $^{15}N^{15}NO$ upon mild decomposition by an acid, and $^{14}N^{15}NO$ upon thermal decomposition *in vacuo*.

Thus, the chloride and nitrate of Red salt II may be represented as $[Co_2(NH_3)_{10}(NO)_2]Cl_4 \cdot 4H_2O$ and $[Co_2(NH_3)_{10}(NO)_2](NO_3)_4 \cdot 2H_2O$ respectively. Furthermore, it is considered that the two cobalt atoms are bridged through a hyponitrite ion in Red salt II and that the N–N bond strength in the hyponitrite bridge may be weaker than that for Red salt I. Crystal X-ray study has determined that, in Red salt I, one cobalt atom is bound to an oxygen atom and the other to a nitrogen atom.[2] Red salt II may be considered to be the linkage isomer of Red salt I with respect to the hyponitrite bridge.

The details of this study will be published later.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 3051—3055 (1969)

Magnetic and Optical Properties of Aromatic Hydrocarbon Cation Radical Salts

Yoichiro SATO, Minoru KINOSHITA, Mizuka SANO*1 and Hideo AKAMATU

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received September 29, 1968)

Stable cation radical salts were prepared by oxidation of perylene, 9,10-diphenylanthracene, 9,10-dimethylanthracene, and 9,10-dichloranthracene with antimony pentachloride. Perylene perchlorate was also obtained in a stable form. From the temperature variations of their paramagnetic susceptibilities, the exchange coupling constants for these salts were found to increase in the sequence of above listing ranging from ~ 0 to 8.5×10^{-2} eV. The absorption spectra of these solid compounds were compared with those observed with solutions. While the absorption bands of each salt in the visible region were found to correspond to those of the solution spectrum of the respective compound, an extra absorption band was observed in the near-infrared region for compounds with larger exchange coupling constants. The appearance of the new absorption band was reasonably ascribed to charge-transfer interaction between the radicals. These observations are considered to support further our previous suggestion that the magnitude of the exchange coupling constant obtained through magnetic measurements is basically determined by the stabilization energy due to the charger-transfer configurational interaction.

In the magnetic behaviors of organic radicals, when they are formed into solid, a deviation from the Curie or Curie-Weiss law has often been found in a commonly avaiable temperature range. The anomaly of paramagnestim is caused by the interaction between radicals, and has been interpreted in terms of an exchange-coupled linear chain model.[1-6] The model has been applied to various organic radical crystals and their magnetic behaviors have been characterized by an empirical parameter, that is by the exchange coupling constant (J). It should be noted that, if the parameter could be explained on the basis of molecular wavefunctions, the interaction in organic radical crystals would be better understood through such a parameter.

We have suggested the importance of charge-transfer interaction in the observed exchange coupling constant, based on the correlation found between the exchange coupling constants and the charge-transfer absorption bands for phenothiazine, *N*-methylphenothiazine and thianthrene cation radical salts.[7] The present work is intended to confirm the contribution of charge-transfer interaction to magnetic behaviors of organic radical crystals by the measurements of paramagnetic susceptiblities and charge-transfer absorption bands for aromatic hydrocarbon radical salts.

Lewis and Singer[8] have prepared a number of aromatic hydrocarbon cations in solution with a skillful technique, and observed their ESR hyperfine structures. We have tried extensively to obtain crystalline radical salts from a variety of aromatic hydrocarbons treated with antimony pentachloride. So far tested, perylene (P) and anthracene derivatives substituted at 9 and 10 positions, *i. e.*, 9,10-diphenylanthracene (DPA), 9,10-dimethylanthracene (DMA) and 9,10-dichloranthracene (DCA) have formed stable monopositive ion radical salts at room temperature. Another stable cation radical salt has been prepared from perylene as perchlorate.

Experimental

Preparation. Stable cation radical salts were prepared by the following procedures and the compositions of the solid salts were determined by elementary analysis of carbon, hydrogen and chlorine. No appreciable chlorination of the hydrocarbons was observed,

which was checked by elementary analysis of the hydrocarbons recovered from the salts by hydrolysis. X-Ray diffraction of the powdered samples of all the salts gave distinct, crystalline patterns.

DPA·$SbCl_6$: To a solution of 9,10-diphenylanthracene in dichloromethane was added a dichloromethane solution of $SbCl_5$ in an excess amount (2 to 3 equivs.). Dark blue crystalline powder precipitated, the composition of which was determined to be $C_{26}H_{18}\cdot SbCl_6$. This salt was found to be the most stable among the salts of aromatic hydrocarbons prepared here.

P·$SbCl_5$: Dark green powder with the composition of $C_{20}H_{12}\cdot SbCl_5$ was obtained by adding a dichloromethane solution of $SbCl_5$ to a solution of perylene.

DMA·$SbCl_5$: The greenish product of $C_{16}H_{14}\cdot SbCl_5$ was obtained from 9,10-dimethylanthracene by a similar procedure. The addition of a nearly equivalent amount of $SbCl_5$ seemed preferable for the preparation.

DCA·$SbCl_5$: The greenish product of $C_{14}H_8Cl_2\cdot SbCl_5$ was obtained when 9,10-dichloranthracene was used in place of 9,10-dimethylanthracene.

P·ClO_4: To a nearly saturated solution of 1 mmol perylene in dichloromethane, 1 mmol $AgClO_4$ dissolved in a very small amount of acetonitrile was added, and then mixed thoroughly. When a dichloromethane solution of 0.4 mmol iodine was poured into the solution with stirring, color characteristic of perylene monopositive ion appeared immediately, and then dark green powder precipitated. No noticeable oxidation of perylene occurred by the addition of either $AgClO_4$ or iodine only. An elementary analysis indicated the composition to be $C_{20}H_{12}ClO_4\cdot AgI$ with high reproducibility. An X-ray diffraction pattern of the product revealed the inclusion of silver and iodine in the form of AgI. From these observations, the product was found to be a homogeneous mixture of P·ClO_4 and AgI in an equivalent amount, which was formed as follows,

$$P + AgClO_4 + \frac{1}{2}I_2 \longrightarrow P^+ + ClO_4^- + AgI$$

Measurements. In the same manner as described in a previous paper,[1] the static susceptibilities of the salts were measured with a Faraday-type susceptibility microbalance in the temperature range from 77 to 296°K. The measurement was made at three different field strengths up to 15 k gauss in order to check ferromagnetic impurities. The susceptibility balance was calibrated by referring to distilled oxygen-free water, for which the susceptibility was taken to be -0.720×10^{-6} emu/g at room temperature.

The absorption spectra of solid radical salts dispersed in liquid paraffin were measured in the range from 340 to 2500 mμ at room temperature. The solution spectra were observed by using dichloromethane as a solvent.

Results

Magnetic Susceptibilities. The salts formed by the reaction with $SbCl_5$ were found to be strongly paramagnetic at room temperature. As the temperature was lowered, the paramagnetic susceptibilities of DPA·$SbCl_6$ and P·$SbCl_5$ continued to increase, while those of DMA·$SbCl_5$ and DCA·$SbCl_5$ reached a maximum at about 80°K. Perylene perchlorate was found to be diamagnetic and showed a little change in susceptibility with temperature.

Diamagnetic contribution was estimated from the value of diamagnetic susceptibility of each component. The experimentally determined value of diamagnetic susceptibility for a neutral organic molecule was used in place of the value for the molecular ion, *i.e.*, -167×10^{-6} for perylene, -234×10^{-6} for 9,10-diphenylanthracene, -146×10^{-6} for 9,10-dimethylanthracene, and -167×10^{-6} emu/mol for 9,10-dichloranthracene. The values for $SbCl_5^-$ and $SbCl_6^-$ were taken to be -124×10^{-6}, and -139×10^{-6} emu/mol, respectively, following Kainer and Hausser.[9] The diamagnetic susceptibilities calculated from these values are given in Table 1, together with the observed susceptibilities at 296°K and the paramagnetic susceptibilities χ_p estimated by subtracting the diamagnetic contribution.

The paramagnetic susceptibility of P·$SbCl_5$ was found to obey the Curie-Weiss law, while that of DPA·$SbCl_6$ obeyed the Curie law. The values of the Curie constant and the Weiss constant were determined by plotting the inverse paramagnetic susceptibility $1/\chi_p$ against temperature, as shown

TABLE 1. MAGNETIC SUSCEPTIBILITIES AND EXCHANGE COUPLING CONSTANTS

Substance	Observed susceptibility at 296°K $\times10^6$ (emu/mol)	Diamagnetic susceptibility $\times10^6$ (emu/mol)	Paramagnetic susceptibility at 296°K $\times10^6$ (emu/mol)	Weiss constant θ (°K)	Radical concentration (%)	Exchange coupling constant J (eV)
DPA·$SbCl_6$	752	−373	1125	0 ± 4	89	~0

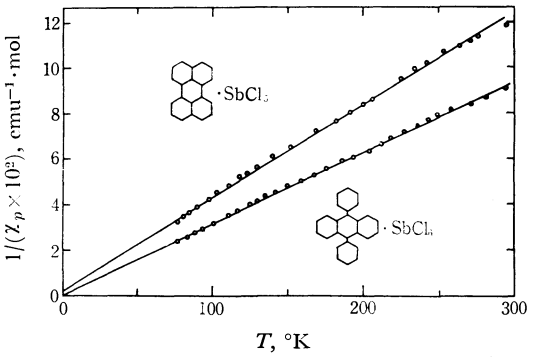

Fig. 1. The inverse paramagnetic susceptibilities of DPA·$SbCl_6$ and P·$SbCl_5$ as a function of temperature.

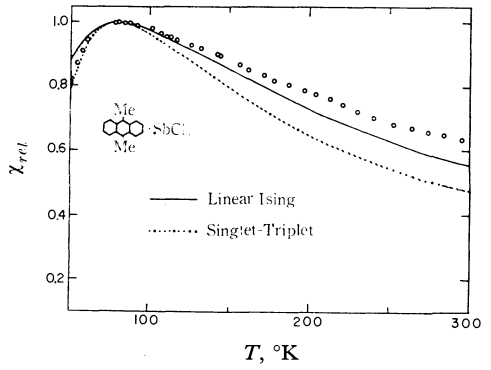

Fig. 2. The relative paramagnetic susceptibility of DMA·$SbCl_5$ as a function of temperature. The experimental plot and the theoretical curves are normalized at T_{max}=80°K.

in Fig. 1, and then the radical concentration was estimated from the Curie constant. DPA·$SbCl_6$ exhibited the highest radical concentration, which was consistent with its remarkable stability.

The paramagnetic susceptibility of DMA·$SbCl_5$ showed a broad maximum at approximately 80°K, when the measurement was made down to 50°K, as shown in Fig. 2. The reliable determination of both the Curie constant and the Weiss constant was not feasible, since the deviation from the Curie-Weiss law was appreciable even at high temperatures. DCA·$SbCl_5$ showed a quite similar behavior in susceptibility, though its radical concentration was lower. The relative paramagnetic susceptibilities for these two salts were found to coincide fairly closely with each other in a wide temperature range.

The apparent susceptibility of perylene perchlorate was found to be diamagnetic, after the correction was made for the susceptibility for AgI, which was taken to be -87×10^{-6} emu/mol. As shown in Fig. 3a, the apparent susceptibility showed a minimum around 200°K. The rise in susceptibility in the lower temperature region seems to

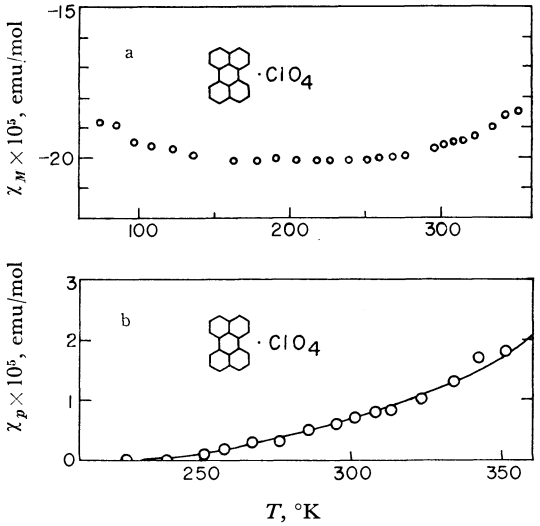

Fig. 3. The susceptibility of P·ClO_4 as a function of temperature. a, The observed susceptibility. b, The intrinsic paramagnetic susceptibility. The solid curve indicates the susceptibility calculated according to the singlet-triplet model for J= 0.085 eV.

indicate the presence of a small amount of paramagnetic impurities. Assuming that the susceptibility variation in the lower temperature region was dominated by the impurity paramagnetism which obeyed the Curie law, the diamagnetic susceptibility of the salt was estimated to be -209×10^{-6} emu/mol. After the correction was made for the diamagnetism and the impurity paramagnetism thus evaluated, the intrinsic paramagnetic susceptibility for the salt was obtained as a function of temperature. It increased with the increase in temperature, as shown in Fig. 3b.

Determination of Exchange Coupling Constant. The exchange coupling constant (J) was determined by the comparison between experimental and theoretical values. The paramagnetic susceptibility is expressed analytically as a function of temperature for two extreme cases of an exchange-coupled linear chain model. As it was discussed in a previous paper,[1] we will summarize the results only, for convenience of discussion. For the singlet-triplet case, the paramagnetic susceptibility is given by

$$\chi_p = (2N'g^2\beta^2/kT)[3+\exp(2J/kT)]^{-1} \quad (1)$$

where $2J$ corresponds to the singlet-triplet energy separation, and N' is the number of spin pairs. In a low temperature region, *i. e.*, $T \ll 2J/k$, Eq. (1) reduces to a simple form,

$$\chi_p = (2N'g^2\beta^2/kT)\exp(-2J/kT) \quad (2)$$

For the linear Ising case, the paramagnetic susceptibility is expressed by

$$\chi_p = (Ng^2\beta^2/4kT)\exp(-J/kT) \quad (3)$$

in the temperature range discussed.

We could find a relation between the exchange coupling constant J and the temperature T_{max} at which the susceptibility reaches its maximum value. The ratio, kT_{max}/J is 1.25 for the singlet-triplet model, 1.00 for the linear Ising model, and 1.28 for the regular chain Heisenberg model.[10]

In a high temperature region, *i. e.*, $T \gg J/k$, however, the paramagnetic susceptibility obeys the Curie-Weiss law,

$$\chi_p = C/(T-\theta) \quad (4)$$

where C is the Curie constant, and θ is the Weiss constant. The exchange coupling constant could also be evaluated from the Weiss constant. The relation, $J=-2k\theta$ holds for the singlet-triplet model, and $J=-k\theta$ for the linear Ising model.

The exchange coupling constant for P·$SbCl_5$ was estimated from the Weiss constant of -4°K to be 6.9×10^{-4} eV in the case of the singlet-triplet model, or 3.4×10^{-4} eV in the case of the linear Ising model. The coupling constant for DMA·$SbCl_5$ was evaluated from the temperature T_{max} of 80°K to be 6.9×10^{-3} eV according to the linear Ising model. The radical concentration for this salt was not known accurately, so that the relative paramagnetic susceptibility is shown in Fig. 2. It is compared with the theoretical curves for the singlet-triplet and the linear Ising models, which are normalized at the temperature T_{max}.

The exchange coupling constant for P·ClO_4 could be evaluated either from Eq. (1) or (2). As shown in Fig. 3b, the observed values fitted closely to the curve calculated from the singlet-triplet model with the exchange coupling constant of 0.085 eV. According to Eq. (2), a plot of $\log \chi_p \cdot T$ against $1/T$ gives a straight line, the slope of which corresponds to $-2J/k$. The slope is not affected by the change in radical concentration, so that this analytical method is useful in the case that radical concentration is unknown. The exchange coupling constant thus estimated was 0.09 eV for P·ClO_4.

Absorption Spectra. The absorption spectrum of solid DPA·$SbCl_6$ was found to greatly resemble the spectrum of the salt in solution, as shown in Fig. 4a. The spectrum was in agreement with that reported for 9,10-diphenylanthracene mono-positive ion by Shida and Hamill.[11] The spectrum of solid P·$SbCl_5$ was also found to correspond with that of the salt in dichloromethane, as shown in Fig. 5a. No extra absorption band could be detected in the near-infrared region. These solution and solid spectra of perylene ion are in good agree-

11) T. Shida and W. H. Hamill, *J. Chem. Phys.*, **44**, 4372 (1966).

ment with those observed by other investigators.[12,13]

In contrast with P·$SbCl_5$, solid P·ClO_4 showed broad absorption bands, and in addition, a new absorption band was observed at approximately 7700 cm^{-1} as shown in Fig. 5b. The spectra for solid DMA·$SbCl_5$ and DCA·$SbCl_5$ showed a shoulder at longer wavelengths, besides the absorption bands which corresponded to those in the solution spectrum, as shown in Figs. 4b and 4c.

Discussion

The high radical concentration in the salts studied here indicates that one unpaired electron is associated with each formula unit. An ESR measurement revealed that the aromatic hydrocarbon radical salts showed a single exchange-narrowed line with a *g*-value between 2.002 and 2.003, which was characteristic of aromatic hydrocarbon radicals.[14] It is, therefore, reasonable to ascribe the unpaired electron to the mono-positive ion radicals produced by oxidation of the aromatic hydrocarbons with $SbCl_5$.

The new absorption bands in the near-infrared region observed for solid P·ClO_4, DMA·$SbCl_5$ and DCA·$SbCl_5$ is reasonably explained by the charge-transfer interaction between aromatic ion radicals caused upon the formation of an aggregate state. An appearance of a similar absorption band for a number of organic radicals has been ascribed to the charge-transfer interaction between radicals. For example, a quite similar spectrum to that observed with solid P·ClO_4 has been reported in a previous paper for a solution of perylene mono-positive ions in a solvent of low dielectric constant.[15] We have attributed it to perylene ions in an associated state, and the absorption band in the near-infrared region has been suggested to originate from the charge-transfer interaction between perylene ions. Hausser and Murrell have also suggested charge-transfer between radical molecules for the appearance of a new absorption band in the solution spectra of Wurster's blue perchlorate and *N*-ethylphenazyl at low temperatures.[16]

The appearance of a charge-transfer band in a solid spectrum is noted to correlate to the deviation of paramagnetism from the Curie law or, equivalently, the magnitude of an exchange coupling constant. Solid P·ClO_4 shows the large values both in an exchange coupling constant and an intensity of a charge-transfer band, which indicates the presence of strong interaction between perylene ions. Solid DPA·$SbCl_6$ and P·$SbCl_5$, on the other hand, exhibit nearly free nature of their aromatic ions, which is reflected on the negligible value of exchange coupling constant and the absence of charge-transfer band. DMA·$SbCl_5$ and DCA·$SbCl_5$ are an intermediate case with respect to the intermolecular interaction.

It is likely that the correlation between the magnetic and optical properties holds generally for a variety of crystalline radicals. From the observations so far made, the following qualitative features have been derived: 1) The apparent susceptibility of a radical solid which shows an intense charge-transfer band is diamagnetic, or at most weakly paramagnetic at room temperature. The exchange coupling constant for such a solid is usually found to be larger than 0.05 eV. 2) The crystalline radicals with the exchange coupling constant $J \lesssim 0.02$ eV exhibit a fairly weak charge-transfer band, which is thus usually observed as a shoulder. 3) The charge-transfer band for the solid with $J < 10^{-3}$ eV is usually undetectable.

The parallelism found between the exchange coupling constant and the charge-transfer band is, therefore, considered to support strongly our previous suggestion that the value of exchange coupling constant obtained through magnetic measurements is basically determined by the stabilization energy due to the charge-transfer configurational interaction associated with the crystalline state of radical molecules.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 3056—3064 (1969)

The Effect of Organic Additives on the Autoxidation of Benzene and Toluene in the Aqueous Phase and the Kinetic Analysis*1

Hiroshi HOTTA, Nobutake SUZUKI and Kazuo ISODA

Japan Atomic Energy Research Institute, Takasaki-shi, Gunma

(Received November 6, 1968)

The effect of organic additives on the autoxidations of benzene and toluene was studied at 180°C in a ferrous sulfate aqueous solution. The additives were benzene, toluene, ethylbenzene, cumene, cyclohexene, cyclohexane, *n*-hexane, *t*-butyl alcohol, isopropyl alcohol, and ethyl alcohol. The yields of the phenol and benzaldehyde produced were measured as functions of the initial volume fraction of the additive. The yields decreased with the addition of a trace of the additive, and the yields increased still more with further addition. In order to interpret these results, the general expression for the yield of the main product was derived by the Gale-Wagner method and was analyzed numerically by using the IBM 7044. The mole fraction of the additive, corresponding to the maximum yield, can give information regarding the relative reactivity of the additive as compared with the results of the above numerical analysis. It is concluded from the present study that the experiment of the flow system for the autoxidation of toluene containing various additives is necessary to get exact kinetic information concerning these additives by using the present numerical analysis, because the equation is derived on the assumption that the concentration of the additive is constant.

It had been noted in a previous study that the yield of phenol from the autoxidation of benzene in an aqueous solution is considerably affected by impurities in benzene.[1] In the present paper, the effect of organic additives on the autoxidations of benzene and toluene is investigated in considerable detail and analyzed on the basis of the numerical analysis of the equation for the yield of the product as a function of the fraction of an additive, obtained as a result of the kinetic analysis of the binary autoxidation in the aqueous phase on the assumption of the reaction scheme previously established in our laboratory.[1-5]

Experimental

As in the previous study,[1] 1 cc of an organic mixture with benzene or toluene was put on 15 cc of a 0.01M ferrous sulfate aqueous solution in a hard-glass tube in a 50 cc stainless-steel reactor under an oxygen pressure of 30 atm. Then, this system was heated at 180°C for 30 min by means of a controlled heater. After cooling, the phenol from benzene was analyzed by the measurement of the optical absorbance in ether,[5] while the benzaldehyde from toluene was analyzed gas-chromatographically by using a column of PEG 6000.[3] These methods were described in detail in the previous papers.

The composition of the organic mexture is represented by the volume fractions of the additives, which were ethylbenzene, cumene, cyclohexene, cyclohexane, *n*-hexane, *t*-butyl alcohol, isopropyl alcohol, and ethyl alcohol. The autoxidation was carried out by using mixtures containing these additives in fractions of 0.0002, 0.001, 0.005, 0.01, and more than 0.01. The benzene was purified by the previous method,[1] and the toluene was of the spectro-grade, Merck. The additives were used without further purification.

Results

The Yields of Phenol and Benzaldehyde. The amounts of phenol and benzaldehyde produced from the mixture of benzene and toluene are plotted against the volume fraction of toluene in the original organic mixture in Fig. 1. The results for the systems containing benzene or toluene of less than a 0.05 fraction are shown in detail in Figs. 2(A) and 3(A).

The yields of phenol from the benzene mixtures and of benzaldehyde from the toluene mixtures are represented by the relative yield, namely, by the ratios of the amounts produced from these mixtures to those produced from the pure benzene or toluene, in Figs. 2 and 3. The additives are

In Fig. 1, the yield of benzaldehyde from the pure toluene is one-fifth as large as the yield of phenol from the pure benzene in spite of the fact that the dissociation energy of the $PhCH_2$–H bond is lower than that of the Ph–H bond, as has been pointed out in previous papers.[3,4] This may be partly attributed to the difference in the number of hydrogen atoms available for reaction. However,

recently, the solubility of benzene and toluene in water was measured between 100°C and 200°C.[6] According to these results, the main reason for the difference of their yield can be attributed to the difference in their solubility in water, which will be discussed in the following section.

The Relative Solubility in Water. Although the abscissas of the yield curves in Figs. 1, 2, and

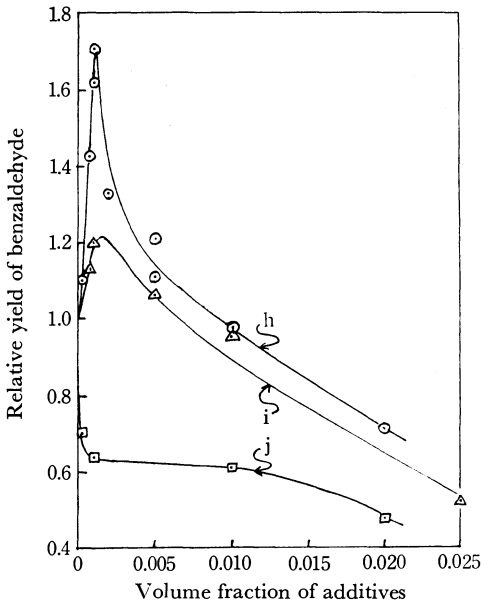

Fig. 3(C)
h) *t*-Butyl alcohol (⊙), i) isopropyl alcohol (△), and j) ethyl alcohol (▣).

3 represent the initial volume fractions of additives in the oil phase, v_B, it is necessary to know the mole fraction of additives to the total of the organic reactants in the aqueous phase, x_B, in order to make a kinetic analysis of these results. Although the measurement of the solubility at 180°C is not so easy, the x_B can be estimated by means of the following equation;

$$x_B = \frac{(BH)_{aq}}{(AH)_{aq} + (BH)_{aq}} \quad (1)$$

$$= \frac{y_B}{y_B + \frac{s_A}{s_B}(1 - y_B)} \quad (2)$$

where AH (or A) and BH (or B) represent a host reactant (benzene or toluene) and an additive respectively, and where s is the solubility of the pure AH or BH in water. If y_B, the mole fraction of an additive in the oil phase in equilibrium with x_B, is assumed to be equal to the initial one in the oil phase, it can easily be related to v_B. Furthermore, it is assumed in Eq. (2) that the ratio of the molar solubility, s_A/s_B, at 180°C is equal to that at room temperature; the figures for the latter are cited in Table 1 from the data of McAuliffe[7] except in the case of cyclohexene.[8] The solubility of benzene or toluene, measured in our laboratory, is 0.224M or 0.058M respectively at 180°C.[6] This ratio (3.86) is in good agreement with that at room temperature (3.90) shown in Table 1. For alcohols, since the values of v_B are very low, it is assumed

Discussion

The Reaction Scheme and the Kinetic Analysis. According to the previous studies,[1-5] the reaction scheme of the co-oxidation of AH and BH in an oxygenated aqueous solution containing metal ions (M^+ and M^{2+}) can be assumed to be as follows:

$$H_2O \xrightarrow{M^+ + O_2} \cdot OH \quad (3)$$

$$AH + \cdot OH \rightarrow A\cdot + H_2O \quad (4a)$$

$$BH + \cdot OH \rightarrow B\cdot + H_2O \quad (4b)$$

$$A\cdot + O_2 \rightarrow AOO\cdot \quad (5a)$$

$$B\cdot + O_2 \rightarrow BOO\cdot \quad (5b)$$

$$AOO\cdot + AH \rightarrow AOOH + A\cdot \quad (6aa)$$

$$AOO\cdot + BH \rightarrow AOOH + B\cdot \quad (6ab)$$

$$BOO\cdot + AH \rightarrow BOOH + A\cdot \quad (6ba)$$

$$BOO\cdot + BH \rightarrow BOOH + B\cdot \quad (6bb)$$

$$AOOH + M^+ \rightarrow AO\cdot + OH^- + M^{2+} \quad (7a)$$

$$AOOH + M^{2+} \rightarrow AOO\cdot + H^+ + M^+ \quad (8a)$$

$$BOOH + M^+ \rightarrow BO\cdot + OH^- + M^{2+} \quad (7b)$$

$$BOOH + M^{2+} \rightarrow BOO\cdot + H^+ + M^+ \quad (8b)$$

$$AO\cdot \rightarrow \text{Product A} \quad (9a)$$

$$BO\cdot \rightarrow \text{Product B} \quad (9b)$$

and partly:

$$AOO\cdot + AOO\cdot \rightarrow \text{Inactive products} \quad (10aa)$$

$$AOO\cdot + BOO\cdot \rightarrow \text{Inactive products} \quad (10ab)$$

$$BOO\cdot + BOO\cdot \rightarrow \text{Inactive products} \quad (10bb)$$

where M^+ and M^{2+} represent ferrous and ferric ions respectively for the present experiment. The rate constants of the respective reactions are represented by the subscript k; for example, k_{4a} indicates that for reaction (4a). The general expression for the yield of the product from such a chain process can be derived in the following manner by the Gale-Wagner method.[9,10]

When the yield of the hydroxyl radical from reaction (3) is represented by $Y(OH)$, the yield of A· or B· from reaction (4) is expressed in the form:

$$(A)_0 = a_0 Y(OH) \quad (11a)$$

$$(B)_0 = (1-a_0) Y(OH) \quad (11b)$$

where:

$$a_0 = \frac{k_{4a}(AH)}{k_{4a}(AH) + k_{4b}(BH)} \quad (12)$$

It is assumed in the derivation of Eq. (11) that the contribution of reaction (4 m)

$$M^+ + \cdot OH = M^2 + OH^- \quad (4m)$$

can be ignored because the hydroxyl radical usually reacts faster with organic reactants than with inorganic reactants.

After these radicals, A· and B·, are oxidized instantaneously to the peroxides by reaction (5), they give the hydroperoxides, AOOH or BOOH, and the equimolar radicals, A· or B·, by reaction (6). The relative reactivity of peroxy radicals (ROO·) toward hydrocarbons is fairly independent of the structure of R.[11] Recently, the dependence on the structure of R is illustrated rather finely.[12] When it is assumed in the present analysis that:

$$\frac{k_{4b}}{k_{4a}} = \frac{k_{6ab}}{k_{6aa}} = \frac{k_{6bb}}{k_{6ba}} = R_{b/a} \quad (13)$$

the yield of the products from reaction (6) is expressed in the forms:

$$(AOOH) = (A) = \frac{k_{6aa}(AH)}{k_{6aa}(AH)+k_{6ab}(BH)} \times a_0 Y(OH)$$
$$= a_0^2 Y(OH) \quad (14aa)$$

$$(AOOH) = (B) = \frac{k_{6ab}(BH)}{k_{6aa}(AH)+k_{6ab}(BH)} \times a_0 Y(OH)$$
$$= a_0(1-a_0) Y(OH) \quad (14ab)$$

$$(BOOH) = (A) = \frac{k_{6ba}(AH)}{k_{6ba}(AH)+k_{6bb}(BH)} \times (1-a_0) Y(OH)$$
$$= a_0(1-a_0) Y(OH) \quad (14ba)$$

$$(BOOH) = (B) = \frac{k_{6bb}(BH)}{k_{6ba}(AH)+k_{6bb}(BH)} \times (1-a_0) Y(OH)$$
$$= (1-a_0)^2 Y(OH) \quad (14bb)$$

because, on the assumption of Eq. (13),

$$a_0 = \frac{k_{4a}(AH)}{k_{4a}(AH) + k_{4b}(BH)} = \frac{k_{6aa}(AH)}{k_{6aa}(AH)+k_{6ab}(BH)} = \frac{k_{6ba}(AH)}{k_{6ba}(AH)+k_{6bb}(BH)} = \frac{1}{1+R_{b/a}\frac{(BH)}{(AH)}} \quad (15)$$

9) L. H. Gale and C. D. Wagner, *J. Am. Chem. Soc.*, **86**, 4531 (1964).

10) H. Kurihara and H. Hotta, This Bulletin, **40**, 719 (1967).

11) G. A. Russell and R. C. Williams, Jr., *J. Am. Chem. Soc.*, **86**, 2364 (1964).

12) B. S. Middleton and K. U. Ingold, *Can. J. Chem.*, **45**, 191 (1967).

The subscripts of Eq. (14) correspond to those or reaction (6). Therefore, the total yields of the hydroperoxides from reaction (6) are:

$$(\mathrm{AOOH})_1 = a_0 Y(\mathrm{OH}) \tag{16a}$$

$$(\mathrm{BOOH})_1 = (1-a_0) Y(\mathrm{OH}) \tag{16b}$$

Since these hydroperoxides are decomposed by reactions (7) and (8), the amounts of the products from them by these reactions are given by:

$$(\mathrm{AO})_1 = \frac{k_{7a}(\mathrm{M}^+)}{k_{7a}(\mathrm{M}^+)+k_{8a}(\mathrm{M}^{2+})} \times a_0 Y(\mathrm{OH})$$

$$= a_0 m_a Y(\mathrm{OH}) \tag{17a}$$

$$(\mathrm{AOO}) = \frac{k_{8a}(\mathrm{M}^{2+})}{k_{7a}(\mathrm{M}^+)+k_{8a}(\mathrm{M}^{2+})} \times a_0 Y(\mathrm{OH})$$

$$= a_0(1-m_a) Y(\mathrm{OH}) \tag{18a}$$

$$(\mathrm{BO})_1 = \frac{k_{7b}(\mathrm{M}^+)}{k_{7b}(\mathrm{M}^+)+k_{8b}(\mathrm{M}^{2+})} \times (1-a_0) Y(\mathrm{OH})$$

$$= (1-a_0) m_b Y(\mathrm{OH}) \tag{17b}$$

$$(\mathrm{BOO}) = \frac{k_{8b}(\mathrm{M}^{2+})}{k_{7b}(\mathrm{M}^+)+k_{8b}(\mathrm{M}^{2+})} \times (1-a_0) Y(\mathrm{OH})$$

$$= (1-a_0)(1-m_b) Y(\mathrm{OH}) \tag{18b}$$

where:

$$m_a = \frac{k_{7a}(\mathrm{M}^+)}{k_{7a}(\mathrm{M}^+)+k_{8a}(\mathrm{M}^{2+})}$$

$$m_b = \frac{k_{7b}(\mathrm{M}^+)}{k_{7b}(\mathrm{M}^+)+k_{8b}(\mathrm{M}^{2+})}$$

Equations (17) and (18) correspond to reactions (7) and (8) respectively.

The oxyradicals, given by Eq. (17), become the final products by means of reaction (9), while the peroxides regenerate the new peroxides and oxyradicals through the same cycle. When the above cycle, starting from the primary hydroxyl radical, is named the first cycle, the cycle started by these peroxides of Eq. (18) can be called the second cycles. Since the radicals, A· and B·, of Eq. (14) are oxidized instantaneously to the peroxides by reaction (5) the total yield of the peroxides formed during the first cycle or of the starting peroxides for the second cycle is given as the sum of Eqs. (14) and(18);

$$(\mathrm{AOO}) = a_0(2-m_a) Y(\mathrm{OH}) \tag{19a}$$

$$(\mathrm{BOO}) = (1-a_0)(2-m_b) Y(\mathrm{OH}) \tag{19b}$$

However, since some of them are terminated by reaction (10), the correction coefficient, c, must be multiplied to Eq. (19) as a measure of the fraction of the peroxides carrying the chain process to the next cycle without termination reactions like:

$$(\mathrm{AOO})_1 = a_0(2-m_a)c_a Y(\mathrm{OH})$$

$$= a_1 Y(\mathrm{OH}) \tag{20a}$$

$$(\mathrm{BOO})_1 = (1-a_0)(2-m_b)c_b Y(\mathrm{OH})$$

$$= b_1 Y(\mathrm{OH}) \tag{20b}$$

The yields of the products formed during the second cycle are expressed similarly with the first cycle as follows;

$$(\mathrm{AOOH})_2 = a_1 Y(\mathrm{OH})$$

$$(\mathrm{AOO})_2 = (\alpha a_1 + a_0 b_1) c_a Y(\mathrm{OH})$$

$$= a_2 Y(\mathrm{OH})$$

$$(\mathrm{AO})_2 = a_1 m_a Y(\mathrm{OH})$$

$$(\mathrm{BOOH})_2 = b_1 Y(\mathrm{OH})$$

$$(\mathrm{BOO})_2 = [\beta b_1 + (1-a_0) a_1] c_b Y(\mathrm{OH})$$

$$= b_2 Y(\mathrm{OH})$$

$$(\mathrm{BO})_2 = b_1 m_b Y(\mathrm{OH})$$

where;

$$\alpha = 1 - m_a + a_0 \tag{21a}$$

$$\beta = 2 - m_b - a_0 \tag{21b}$$

Generally, the yields of the products formed during the nth cycle are expressed in the forms;

$$(\mathrm{AOOH})_n = a_{n-1} Y(\mathrm{OH}) \tag{22a}$$

$$(\mathrm{AOO})_n = (\alpha a_{n-1} + a_0 b_{n-1}) c_a Y(\mathrm{OH})$$

$$= a_n Y(\mathrm{OH}) \tag{23a}$$

$$(\mathrm{AO})_n = a_{n-1} m_a Y(\mathrm{OH}) \tag{24a}$$

$$(\mathrm{BOOH})_n = b_{n-1} Y(\mathrm{OH}) \tag{22b}$$

$$(\mathrm{BOO})_n = [\beta b_{n-1} + (1-a_0) a_{n-1}] c_b Y(\mathrm{OH})$$

$$= b_n Y(\mathrm{OH}) \tag{23b}$$

$$(\mathrm{BO})_n = b_{n-1} m_b Y(\mathrm{OH}) \tag{24b}$$

Since Product A is formed from AO· by reaction (9), the total yield of product A over all the cycles can be estimated in the following manner:

$$Y(\text{Product A}) = \sum_n (\mathrm{AO})_n$$

$$= m_a Y(\mathrm{OH}) \left(\sum_n a_n\right) \tag{25}$$

$$= m_a Y(\mathrm{OH})(a_0 + F) \tag{26}$$

where:

$$F = \left[1 + \frac{c_a c_b a_0 (1-a_0)}{(1-c_a\alpha)(1-c_b\beta)}\right] \times \left[\frac{c_a a_0 (1-m_a)}{(1-c_a\alpha)} + \frac{c_a c_b a_0 (1-a_0)(1-m_b)}{(1-c_a\alpha)(1-c_b\beta)} + \frac{c_a a_0}{(1-c_a\alpha)}\left(1 + \frac{c_b(1-a_0)}{(1-c_b\beta)}\right)\right] \tag{27}$$

Reaction (10) might give AO··. When it is assumed that all the termination processes (reaction (10)) are the same type with the following reaction (28);

$$2\mathrm{ROO}\cdot \rightarrow 2\mathrm{RO}\cdot + \mathrm{O}_2 \tag{28}$$

the factor, $(1-c_a)/c_a m_a$, must be multiplied to Eq. (26).

Although α and β are not always less than unity, according to the definition of Eq. (21), the termination reaction (10), *i.e.*, the correction coefficient, c, controls the chain process like:

$$1 > c_a\alpha > 0 \text{ or } 1 > c_b\beta > 0 \tag{29}$$

It is assumed for the summation of Eq. (25) that c, $(M^+)/(M^{2+})$, and (BH)/(AH) are constant for all the cycles, but they may be at least somewhat different in a few cycles at the beginning from in the later cycles.

Numerical Analysis of Eq. (27). Equation (27) was analyzed numerically by means of the IBM 7044 against the mole fraction of BH, namely, x_B, as defined by Eq. (1), for all the combinations of $R_{b/a}$ (which was 0.1, 0.3, 1.0, 3.0, or 10.0), m_a and m_b (which were 0.8, 0.7, or 0.6), and c_a and c_b (which were 0.90, 0.85, 0.80, 0.75, 0.70, 0.65, or 0.60). Some examples are shown in Figs. 4—7 to illustrate the relationships between the yield of the product and these factors. In these figures, the value of F relative to F_0, which is for $x_B=0$, is plotted as F_{rel}. The F_{max} and x_{max} values in the following discussion mean, respectively, the maximum value of F_{rel} and the value of x_B, which gives F_{max} for certain conditions.

The F_{rel}-x_B curve against various $R_{b/a}$ values is shown in Fig. 4 for $m_a=m_b=c_a=c_b=0.7$. This figure indicates that F_{max} is almost independent of $R_{b/a}$ for a certain combination of other factors, while x_{max} decreases with an increase in $R_{b/a}$.

The F_{rel}-x_B curve against various m_a values is shown in Fig. 5 for $R_{b/a}=3.0$ and $m_b=c_a=c_b=0.7$. This figure indicates that F_{max} decreases with an increase in m_a, while x_{max} does not so vary with m_a. The curve becomes concave with a decrease in m_a in spite of an increase in F_{max}. The value of F_{rel} was not so affected by m_b, as numerical analysis showed.

The F_{rel}-x_B curve against various c_a values is shown in Fig. 6 for $R_{b/a}=3.0$ and $m_a=m_b=c_b=0.7$. This figure indicates that F_{max} decreases with a decrease in c_a, while x_{max} does not so vary with c_a. The curve becomes concave with an increase in c_a in spite of the increase in F_{max}.

The F_{rel}-x_B curve against various c_b values is

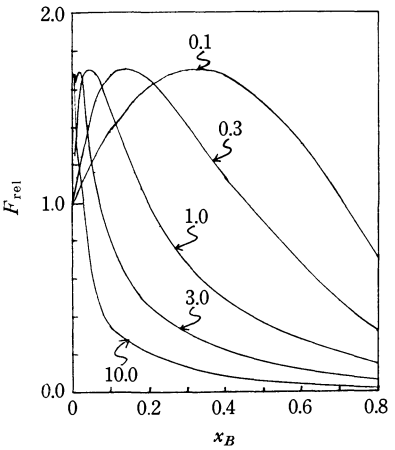

Fig. 4. The value of as F_{rel} the function of x_B for various $R_{b/a}$ ($m_a=m_b=c_a=c_b=0.7$).

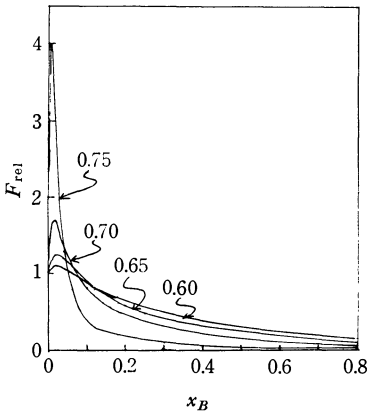

Fig. 6. The value of F_{rel} as the function of x_B for various c_a ($R_{b/a}=3.0$, $m_a=m_b=c_b=0.7$).

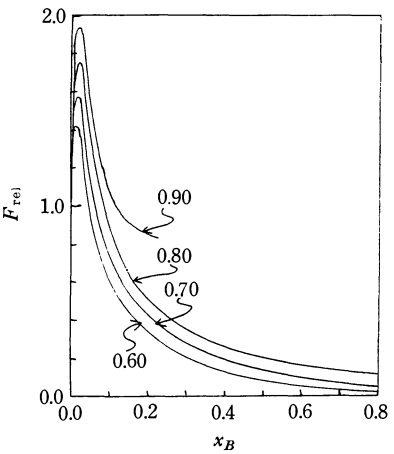

Fig. 7. The value of F_{rel} as the function of x_B for various c_b ($R_{b/a}=3.0$, $m_a=m_b=0.8$, $c_a=0.75$).

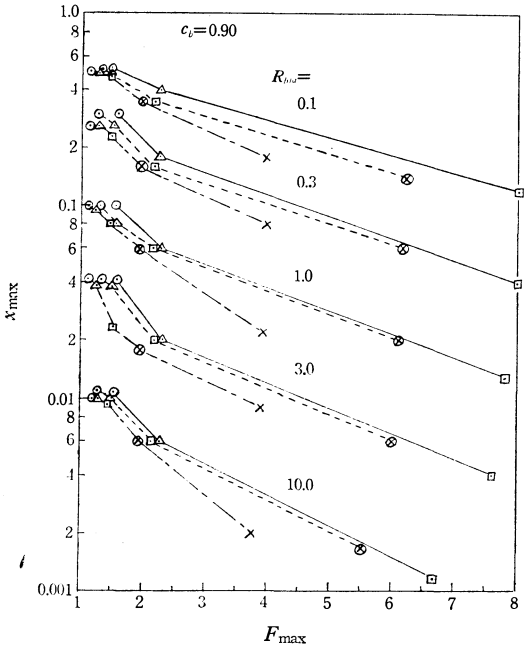

Fig. 8. Conditions for the relative peak height of the yield curve at c_b=0.90. Figures give the value of $R_{b/a}$. —— for m_a=0.6, ------ for m_a=0.7, —·— for m_a=0.8, × for c_a=0.80, ⊗ for c_a=0.75, ⊡ for c_a=0.70, △ for c_a=0.65 and ⊙ for c_a=0.60.

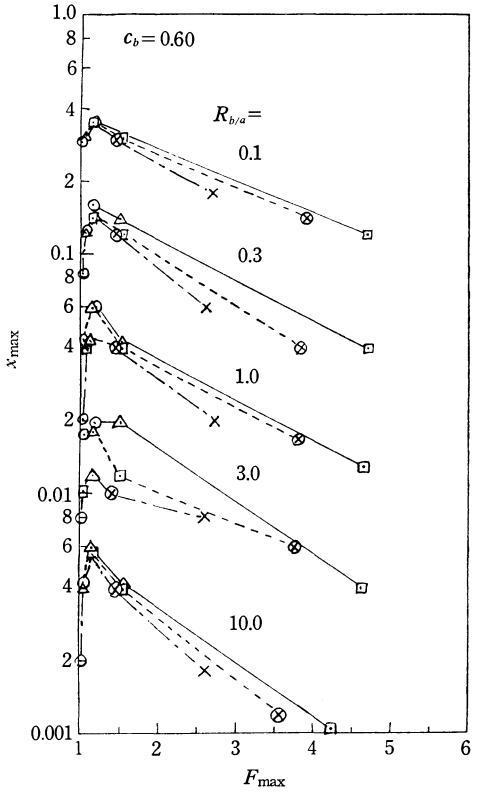

Fig. 9. Conditions for the relative peak height of the yield curve at c_b=0.60. Figures give the value of $R_{b/a}$. Marks are the same as in Fig. 8.

shown in Fig. 7 for $R_{b/a}$=3.0, $m_a=m_b$=0.8, and c_a=0.75. This figure indicates that F_{max} decreases with a decrease in c_b, while x_{max} and the shape of the curve do not so vary with c_b.

These relationships are summarized in Fig. 8 for c_b=0.90 and in Fig. 9 for c_b=0.60. Although the two figures are separated so as not to confuse the plottings, they should be overlapped in order to make the dependence on c_b clear. The F_{max} values are plotted against log x_{max} for various conditions. Since the points for the respective $R_{b/a}$ values are in a group, the value of $R_{b/a}$ is indicated above the group. They are classified by the m_a value in the group, that is, by solid lines for m_a=0.60, by dotted lines for m_a=0.70, and by broken lines for m_a=0.80. The values of c_a are indicated by the marks explained in Fig. 8.

The patterns of the points for the respective $R_{b/a}$ values differ a little. Since the values of F were computed from point to point for x_B, the patterns are similar between the $R_{b/a}$ groups in a close computation, as may be expected from Fig. 4. The larger $R_{b/a}$ gives the smaller x_{max} for the same F_{max}, and the smaller c_a gives the smaller F_{max}, as may be seen clearly in Figs. 8 and 9.

As may be seen in Figs. 5 and 6, the concavity or shape of the F_{rel}-x_B curve also gives kinetic information. Therefore, the values of x_B, giving F_{rel}=1 after passing F_{max}, may be classified as in Figs. 8 and 9. Although this figure is omitted in the present paper, is shown a regularity similar to that of Figs. 8 and 9.

Oxidation of Toluene Mixtures. As may be seen in Fig. 3, the yield of benzaldehyde decreases at first with the addition of a trace of the additive, but the further addition of it causes the yield to to increase to a maximum yield. The minimum or maximum relative yields ($Y(A)_{min}$ or $Y(A)_{max}$), the values of v_B, corresponding to them in Fig. 3, (v_{min} or v_{max}), and the values of x_{min} or x_{max}, as estimated from these v values by means of Eq. (2) on the assumption presented above, are listed in Table 2, in which the additives are listed in the order of x_{max}. Similar values for the yield of phenol from benzene, obtained from Fig. 2, are also listed in Table 2.

When the x_{max} and $Y(A)_{max}$ for hydrocarbons added in Table 2 B) are applied to the diagram in Figs. 8 and 9, which indicate the relationship between x_{max} and F_{max} ($Y(A)_{max}$) as the function of $R_{b/a}$, the reactivities of these hydrocarbons for the reaction of the type:

$$ROO\cdot + RH \rightarrow ROOH + R\cdot \qquad (30)$$

are in the order of:

benzene<cyclohexene<toluene[13,14]<cyclohexane[14]
<ethylbenzene[13]<cumene[13]<n-hexane (31)

Table 2. The minimum or maximum relative yields and the corresponding compositions of additives

Additives	Minimum condition			Maximum condition		
	v_{min}	x_{min}	$Y(A)_{min}$	v_{max}	x_{max}	$Y(A)_{max}$
A) Oxidation of Benzene

Cumene	0.001	6×10^{-5}	0.79	0.01	6×10^{-4}	1.34
n-Hexane	0.001	2×10^{-5}	0.97	0.015	3×10^{-4}	1.08
t-Butyl alcohol	n.d.	—	n.d.	0.001	0.01	1.7
Isopropyl alcohol	n.d.	—	n.d.	0.001	0.015	1.2
Ethyl alcohol	n.d.	—	n.d.	n.d.	—	n.d.

"n.d." means "not detected."

When $R_{b/a}$ is defined as in Eq. (13). The order between toluene, cyclohexane, ethylbenzene, and cumene has been cofirmed by other investigators.[13-15] However, cyclohexene has been expected to be more reactive than cumene.[15]

The present computation of Eq. (27) gave no curve with both the minimum and maximum seen in Figs. 2 and 3 for any combination of various parameters; rather it gave a curve which has only the maximum seen in Figs. 4—7 or a curve which decreases monotonously. Since Eq. (27) is derived on the assumption that (BH)/(AH) is constant throughout the cycles, another equation was derived by the same procedure on the assumption that all amount of an additive added is consumed by the fourth cycle. This equation gave a monotonously decreasing curve for the numerical analysis over the same range of parameters as with Eq. (27), except for the combination, $m_a=0.8$, $m_b=0.6$, and $c_a=c_b=0.8$, which gives both the minimum and the maximum. In the light of these results, the present curves in Figs. 2 and 3 suggest that, when x_B is very small, all of the additive is consumed within a few cycles at the beginning in a batch system like the present reactor.

Cyclohexene is fairly soluble in water, as may be seen in Table 1, and it would be very reactive for reaction (30).[15] In fact, the oil phase after the reaction was greatly colored only in the case of cyclohexene. Therefore, the irregularity of cyclohexene in the series 31 may be concluded to be due to the shift in the maximum in Fig. 3(B), because if cyclohexene is present in the later cycles without such consumption, the value of x_{max} would be even smaller.

Since *n*-hexane is very insoluble in water, as may be seen in Table 1, there is no trouble with the consumption, as has been mentioned above. Supporting this conclusion, the $Y(A)_{min}$ of *n*-hexane is nearly equal to unity. Therefore, although there has been no report about the relative reactivity of *n*-haxane for reaction (30), the x_{max} value of *n*-hexane in Fig. 3(A) is the most reliable.

The v_{max} values of the other additives are more or less shifted to larger values due to the consumption of the smaller x_B. Therefore, an experiment on the flow system, for which (BH)/(AH) can be kept constant, is necessary for the useful application of the diagram in Figs. 8 and 9. Furthermore, the direct measurement of the solubility without the use of Eq. (2) is necessary in order to get exact information from it. Toluene is the most suitable as the host reactant (AH), for the reaction scheme (reactions (3)—(10)) is correct for it.[3,4]

Another problem is that the x_{max} value as esti-

13) G. A. Russell, *J. Am. Chem. Soc.*, **78**, 1047 (1956).
14) D. J. Carlson and K. U. Ingold, *ibid.*, **89**, 4891 (1967).
15) J. A. Howard and K. U. Ingold, *Can. J. Chem.*, **45**, 793 (1967).

mated by Eq. (2), is too small, for the value of $R_{b\,a}$ obtained from it by using Figs. 8 and 9 is too large compared with the data provided by the other methods at lower temperatures.[13-15] It is not clear whether this discrepancy is due to reaction temperature, a characteristic of the aqueous phase, or some approximation for the derivation of Eq. (26).

The values of $Y(\mathrm{A})_{max}$ for alcohols are in the order of:

$$t\text{-butyl} > \text{isopropyl} > \text{ethyl} \qquad (32)$$

In the diagram of Figs. 8 and 9, the larger $Y(\mathrm{A})_{max}$ or F_{max} value corresponds to the larger c_a value. This means that reaction (10) for toluene is suppressed by alcohol, which has a more complex structure or is more oxidable.

Oxidation of Benzene Mixtures. According to the previous studies, the autoxidation of benzene is initiated by reaction (4) with impurities in benzene, which are more reactive than benzene.[1] Even though the hydroxyl radical reacts with benzene, reaction (4) may involve addition. Furthermore, more than one half of the phenol produced is formed not through $C_6H_5O\cdot$ but through $C_6H_5^+$.[4] Therefore, Eq. (25) must be modified for benzene to the form:

$$Y(\text{Phenol}) = \sum[(1-i)m_a + if]a_{n-1} + \sum ifb_{n-1} \qquad (33)$$

where i is the fraction of phenol produced through $C_6H_5^+$, which can be determined by using oxygen-18, as has been seen in a previous study,[4] and where f, which is not necessarily equal to a_0 as defined by Eq. (12) for the case of benzene, is defined in the form:

$$f = \frac{k_{6aa}(\mathrm{AH})}{k_{6aa}(\mathrm{AH}) + k_{6ab}(\mathrm{BH})} = \frac{k_{6ba}(\mathrm{AH})}{k_{6ba}(\mathrm{AH}) + k_{6bb}(\mathrm{BH})} \qquad (34)$$

instead of Eq. (15).

The order of the x_{max} values in Table 2A is not always the same as in series 31. This is due to the difference between benzene and toluene in the reaction mechanism, as has been mentioned above. Since the mechanism for benzene is rather complex, benzene is not a suitable standard reactant (AH) for a study of the relative reactivity using the present method. The value of x_{max} for toluene (0.002) suggests that toluene is more reactive than benzene in the series 31 in spite of the fact that the yield of phenol is larger than that of benzaldehyde in Fig. 1. This subject has already been discussed in the section on the yields of benzaldehyde in "Results."

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 3064—3072 (1969)

An X-Ray Emission Spectroscopic Investigation of the Chemical Bond of Sulfur. III. The Profile of S$K\beta$ Band in Sulfur Compounds

Yoshihito TAKAHASHI and Katsumasa YABE

Government Industrial Development Laboratory, Hokkaido, Higashi-tsukisamu, Sapporo

(Received February 15, 1969)

The profile of the S$K\beta$ band in various sulfur compounds, including many organic compounds, was separated into peaks, and the wavelength values and the intensities of the separated peaks were discussed in relation to the chemical bonding. The band of sulfone and sulfoxide consists of three or four peaks. We named the peaks A, B, C (the strongest), and D, beginning from the longer-wavelength side. The relative intensity of the peak A (generally named $K\beta'$) increases as the number of valence electrons of the sulfur atom decreases. The peak B may be attributed to the non-polar single bond of sulfur in sulfone and sulfoxide. The clear peak, D, appears only in the band of sulfite and sulfoxide. The band of the compounds of thiourea type consists of two peaks. Using the results of the above study, the chemical structures of aldehyde-bisulfite adducts and 2-mercaptobenzimidazole, *etc.*, were discussed.

In a previous paper,[1] we reported a study of the number of valence electrons of the sulfur atom in compounds in relation to the shifts of the S$K\alpha$ wavelength. However, the S$K\alpha$ line has no direct relation to the valence electrons which are con-

1) T. Sato, Y. Takahashi and K. Yabe, This Bulletin, **40**, 298 (1967).

nected with the chemical bond, for the S$K\alpha$ line arises from the inner-shell electron transition (2p→1s). On the contrary, the S$K\beta$ band arises from the transition of the valence electron (valence level→1s), so the structure of the S$K\beta$ spectrum is greatly influenced by the chemical state of the attributed compounds.

Faessler and Schmid has reported that the S$K\beta$ band spectra of sulfates have peculiar structures, unlike the bands of sulfides and rhombic sulfur.[2] Schnell studied the structures of the $K\beta$ band spectra, together with the relative intensity of $K\beta$ to $K\alpha$, in the elements of sulfur, phosphor, silicon, and aluminum in various compounds.[3] Also, Wilbur and Gofman studied the S$K\beta$ spectra of comparatively many materials, stressing the intensity.[4] Besides, the SL bands (valence level→2p) of various compounds were investigated by Fischer and Baun.[5] However, no sufficiently systematic investigation of the S$K\beta$ spectra of various organic compounds and liquid samples has yet been made. Moreover, no separation of the S$K\beta$ band spectrum into its component peaks has ever been attempted.

Our purpose was to make clearer the relationship between the character of the chemical bond and the S$K\beta$ band structure.

Experimental

The spectra were obtained on the improved Rigaku-Denki K-3 Fluorescent X-ray Spectrograph. Its details have been presented in the previous paper.[1] However, the glancing angle, α (the take-off angle of the X-ray), was changed to 35°. A flat sodium chloride crystal ($2d$: 5.6396 Å) was used as the analyzing crystal. Two Soller slits were inserted into the light path; the one situated between the sample and the crystal was 10 cm long, with 0.15 mm spacing, while the other, between the crystal and the detector, was 5 cm long and had 0.10 mm spacing. The helium path was maintained using a flow of 2 l/min. The Machlett OEG-50S chromium target X-ray tube was usually operated at 40 kV, 30 mA.

In the measurements of most of the liquid samples, a liquid sample holder with a Mylar-film window (10 μ thick) was employed, but in the cases of concentrated sulfuric acid, sulfuryl chloride, and thionyl chloride, the Mylar-film window was replaced by a polyethylene film window (30 μ thick).

The band profile was obtained as follows: the X-ray intensities were measured for a minute at each 3′(2θ) stage, and then these intensities, each measured maximum intensity having been made the same values, were plotted against the wavelength. The background was measured at 129°00′(2θ) (5.0902 Å), on the longer-wavelength side of the S$K\beta$ band, because, on the the shorter-wavelength side of the S$K\beta$ band, the absorption edge is near the band and, moreover, its position varies with the kind of compound.

The wavelength of the band was determined within an accuracy of ±0.0008 Å by referring to the third-order reflection lines of Ni$K\alpha_1$ (4.97352 Å) and Ni$K\alpha_2$ (4.98507 Å). On the measurement of the half-peakwidth, the half-linewidth of third-order reflection line of Ni$K\alpha_1$, 16.0′(2θ) (2.8 eV), was chosen as the standard.

Most of the sample materials were guaranteed or extra pure reagents. The materials which we prepared in our laboratory were confirmed by X-ray diffraction or infrared analysis. The surface temperatures of the samples were 30—40°C while the measurements were being carried out.

Results

The profiles of the S$K\beta$ band are related to the various bonding forms of the sulfur atom. We may divide them roughly into five classes according to the bonding form. The profiles of the S$K\beta$ band on several materials of each class are shown in Figs. 1—5, while the wavelength values, half-peakwidths, relative integrated intensities, and other data on the peaks of the S$K\beta$ band spectrum are listed in Tables 1—5.

are almost identical in shape, but they slightly differ in position and in the width of the band. From their simple profiles, it can be assumed that the S$K\beta$ spectrum of inorganic sulfide consists of only one peak. The peaks of sulfides in which the coordination number of sulfur atom is six show a little longer-wavelength values and smaller asymmetry indexes than those of the other sulfides.

2) Sulfate and Sulfone. In Figs. 2—4, the dotted lines show the results obtained by the separation into peaks, using the profile of the S$K\beta$ band of sodium sulfide (shown in Fig. 1) as the standard shape of a single peak. A peak profile of an arbitrary size was made by lengthening or shortening the standard single peak in the direction of the ordinate or abscissa, while keeping the degree of asymmetry unchanged. Each of their spectra consists of two, three, or four peaks, which are named as A, B, C, and D beginning from the longer-wavelength side.

3) Sulfite and Sulfoxide. A feature of this class is the appearance of a remarkable peak D. The relative intensities of the peak A in this class generally take smaller values than those in the

sulfate and sulfone class.

4) Thiourea Derivatives, Thiocyanates, Isothiocyanates, and Monothiophosphate (Abbr.: Thiourea Class). Each of their spectra consists of two main peaks, but in certain cases, as when a large tail exists on the longer-wavelength side, there seems to be another very weak peak.

5) Organic Sulfide, Thiol and Rhombic Sulfur. All of their spectra have broader bands. As with thiophene and phenothiazine, the spectrum of the compounds with a sulfur atom in unsaturated ring shows a prominent inflection on the shorter-wavelength side of the band.

Discussion

Inorganic Sulfide. The relationship between the $SK\beta$ bandwidth and the ionic character of the

Wavelength values of $SK\alpha$ line were refered from Ref. 7.

bond is shown in Fig. 6. As the ionic character of the bond increases, the bandwidth becomes narrower. On rhombic sulfur and organic sulfide, taken for reference, their S$K\beta$ bandwidths show the values to be expected from Fig. 6.

The S$K\beta$ band of cuprous sulfide takes a unique shape (see Fig. 1). It may be that its prominent shoulder on the shorter-wavelength side of the main peak is caused by the conduction electrons. Cuprous sulfide exhibits a highly electronic conductivity.

Sulfate, Sulfone, Sulfite and Sulfoxide. Concerning the energy differences between the peaks A and C in the S$K\beta$ band spectrum, no noticeable distinction can be found among the sulfates, sulfones, sulfites, and sulfoxides measured at about 14 eV. Since no peak corresponding to A can be found in the S$K\beta$ spectrum of sulfur compounds except for oxocompounds of sulfur, and since the energy difference varies almost not at all with the compound, the peak A may be attributed to the SO bond.

Figure 7 shows that the relative intensity of the peak A increases as the electronegativity value of the atom that is combined with the sulfonyl or sulfinyl group increases. In other words, as the plus charge on the sulfur atom increases, the intensity of the peak A increases. Figure 8 shows the relationship between the relative intensity of the peak A and the effective charges of the sulfur atom in sulfone and sulfoxide.[1] In Fig. 7, with regard to the relative intensity of the peak A of the sulfones and sulfoxides which have the same functional group (for example, $(EtO)_2SO_2$ and $(EtO)_2SO$, Cl_2SO_2 and Cl_2SO, $(CH_3)_2SO_2$ and $(CH_3)_2SO$, *etc.*), the former have values about twice as large as the latter. This fact shows that the increase in the relative intensity of the peak A is mainly influenced by the oxygen atom in the double bond. Therefore, with regard to the relative intensity of the peak A, comparing alkyl sulfate with alkyl sulfone and alkyl sulfite with alkyl sulfoxide, diethyl sulfate has twice as many oxygen atoms in a molecule as dimethyl sulfone, but the relative intensity of diethyl sulfate is considerably smaller than twice the value of dimethyl sulfone; moreover, though diethyl sulfite has three times as many oxygen atoms in a molecule as dimethyl sulfoxide, the relative intensity of the former is considerably smaller than three times the value of the latter. These facts show that, in the contribution to the increase in the relative intensity of the peak A, the oxygen atom in the single bond is smaller than that in the double bond. Assuming that the alkyl group scarcely contributes at all to the electron transfer, the above facts can be explained in terms of the concept that the inductive effect of the oxygen atom in the double bond is much larger than that of the oxygen atom in the single bond.

Most sulfones and sulfoxides have the peak B between the peaks A and C in the S$K\beta$ spectra. The sulfone combined with the same two functional groups has a symmetrical peak B in the spectrum. On the other hand, the sulfone combined with two different groups has a partly asymmetrical peak B, which might consist of two peaks. Figure 9 shows

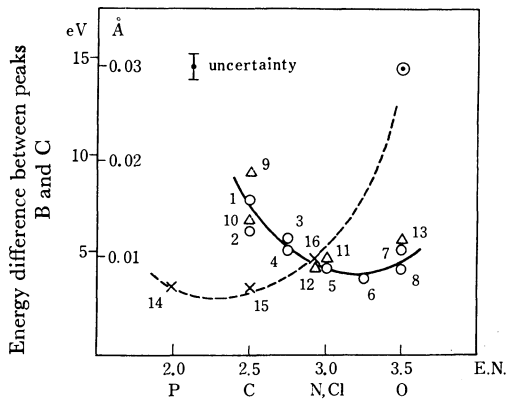

Fig. 9. Behavior of peak B.

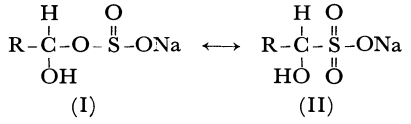
the relationship of the energy difference between the peaks B and C to the kind of atom combined with the sulfonyl and sulfinyl groups. There is no clear distinction in the energy difference among the elements of chlorine, nitrogen, and oxygen, but on carbon the peak B appears further apart from the peak C than in the cases of the other elements. In the compounds combined with amino or hydroxyl groups, the reltive intensity of the peak B is generally small (see Tables 2 and 3). The hydrogen atom in an amino or hydroxyl group is rather dissociable. A more dissociable group, such as –ONa, contributes very little to the intensity of the peak B. In sulfonamides, the relative intensity of the peak B is larger in the order: tertiary, secondary, and primary amino groups. This order is the reverse of the order of the number of dissociable hydrogen atoms in the amino group. These facts suggest that the evolution of the peak B is more affected by the non-polar single bond of sulfur in sulfone and sulfoxide.

In the spectrum of sodium bisulfite (see Fig. 3), a weak peak B is observed, so its hydroxyl group seems not to be very dissociable.

In the spectrum of concentrated sulfuric acid, the peak B is also observed; the peakwidth and the relative intensity of the peak are similar to those of diethyl sulfate rather than to those of diluted sulfuric acid or sodium sulfate (see Table 2). Consequently, the hydroxyl groups of concentrated sulfuric acid seem to be rather undissociable.

The appearance of the peak D is clear only in the spectra of sulfites and sulfoxides. But then, the peak corresponding to the peak D of sulfur compounds has been observed in the B$K\alpha$ band spectra of boric oxide $(B_2O_3)_n$ and boric nitride $(BN)_n$.[5] The boron atom in their compounds has a sp^2 hybrid orbital, analogous with the sulfur atom in a sulfite ion. Therefore, the peak D may result from the presence of the sp^2 hybrid orbital. In the spectra of some sulfones, a very weak peak like D was separated by the separation into peaks.

The S$K\beta$ spectra of aldehyde-bisulfite adducts are shown in Fig. 10. Their peak C shifts about 0.001 Å to the shorter-wavelength side from the position of bisulfite salt or sodium formaldehyde sulfoxylate ($HOCH_2SO_2Na$), and the relative intensities of the peak A are larger, and those of the peak D are smaller, than those of sulfites and sulfoxides (see Table 6). These take values rather closer to those of such sulfones as hydroxymethansulfonate ($HOCH_2SO_3Na$). Moreover, the wavelength of the S$K\alpha$ line of the adducts take values closer to those of sulfones. Two structural formulas in the equilibrium state may be given for the aldehyde-bisulfite adduct;



(I) (II)

According to this fact, a considerable portion of the materials have sulfone-type structures (II). This conclusion is supported by the results of the X-ray structural analysis.[8]

Thiourea Class. The values of the energy differences between the peaks B and C range from 3 to 5 eV, much as with those of sulfones. However, it cannot be asserted that this peak B has virtually the same quality as those of sulfones because the two bonding forms which seem to be attributable to the peak B are different; that is, in sulfnones,

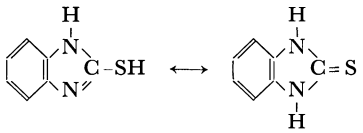
* Ref. 7. ** Ref. 1.

there is a single bond, and in the thiourea class, a double bond.

On 2-mercaptobenzimidazole, 2-mercaptobenzoxazole, 2-thiouracil, and 2-thiobarbituric acid, we can assume two structural formulas, *i. e.*, thiol and thiocarbonyl forms. For example, 2-mercaptobenzimidazole may have the following two forms:



(III) (IV)

However, in the solid state and in a pyridine solution, its S*Kβ* spectrum differs from those of thiols and is similar to those of thiocarbonyl-type compounds, as is shown in Fig. 11. Furthermore, the wavelengths of the S*Kα* lines also have values closer to that of thiourea. Consequently, they may be said to have thiocarbonyl forms (IV) in the solid state and in a pyridine solution at room temperature.

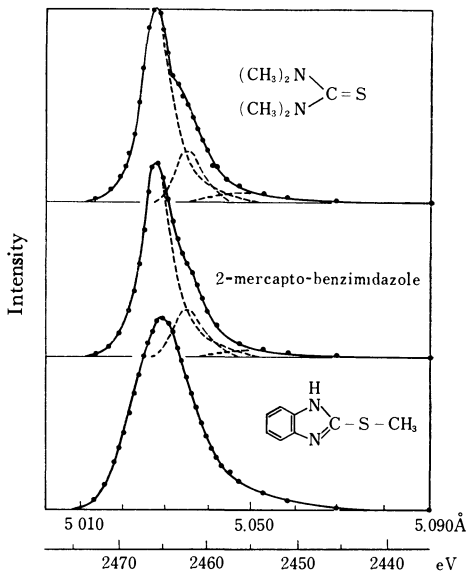


Fig. 11. Comparison of S*Kβ* spectra of 2-mercaptobenzimidazole with thiourea and 2-methylthiobenzimidazole.

Conclusion

In this study, we found that S*Kβ* spectra give appreciable information relating not only to the kind of bonding but also to the kind of atom combined with the sulfur atom in compounds. Especially, we have obtained much information on sulfones and sulfoxides. If the separation into peaks were more accurate, a more detailed discussion could be made with respect to the peaks B and D, thus making the analysis of the bonding state feasible, even in a mixture.

The authors wish to thank Dr. T. Sato, Dr. E. Asada, Professor T. Sagawa, and Dr. Y. Gohshi for their helpfull advice.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 3073—3075 (1969)

Energy Transfer between Benzene and Toluene in the Singlet States at 90°K

Akihiko NAKAHARA, Motohiko KOYANAGI, Yoshio MURAKAMI, Takao EDAMURA and Yoshiya KANDA

Department of Chemistry, Faculty of Science, Kyushu University, Fukuoka

(Received March 11, 1969)

The fluorescence spectrum of toluene in benzene has been photographed at 90°K and analyzed accurately. Systematic studies of concentrations made it possible to estimate the efficiency of energy transfer from the singlet state of the host molecule to that of the guest molecule. The fluorescence spectrum of pure benzene has also been studied at 4.2°K and 90°K for comparison, and the effect of toluene as an impurity in the benzene spectra has been discussed.

Leach, Lopez-Campillo and Lopez-Delgado[1] studied the effect of occluded gas and the thermal treatment of a sample on the probability of electronic-energy transfer between benzene and toluene at 80°K. We have also studied electronic-energy transfer in the lowest excited singlet states of benzene and toluene and estimated the rate of energy transfer in the system.

Experimental

The benzene was purified by the way described in a previous paper.[2] Commercial benzene often contains toluene as an impurity at a concentration of about 10^{-2}—10^{-3} mol/*l*. The purification was repeated until no toluene bands in the fluorescence spectrum could be detected within the experimental limits employed in this work.

The toluene was purified according to the method of Schwalbe.[3] A gaseous mixture of nitric and nitrous oxide was introduced into toluene, and then 2% of sulfuric acid was added 2 or 3 hr later. The toluene was stirred for 5 min and then left standing for 15 min. The lower layer was removed. This operation was repeated three times. When the acid part became faint yellow, the toluene was washed with a dilute caustic soda solution until no color change was detected in the solution. It was then dried over calcium oxide and distilled.

The optical setup was exactly the same as that described previously.[2] A super-high-pressure Hg lamp (ORA CHM-12) was used as a light source, and the Hg 2537 Å was projected on a sample through a filter system. The sample solutions employed were 10^{-5}, 10^{-4}, 5×10^{-4}, 10^{-3}, 5×10^{-4}, 10^{-2}, 10^{-1}, and 1 mol/*l* of toluene in benzene. For comparison a solution of 10^{-3} mol/*l* of toluene in cyclohexane was also studied. A sample solution was cooled rapidly by liquid air. While it was being frozen in a cell, the cell was pumped so that all occluded gas in the solution was removed.

The fluorescence spectrum of toluene in benzene was photographed with a Shimadzu quartz spectrograph, QM-60. The exposure time was fixed as 1 hr with a slit width of 50 μ, and Eastman-Kodak 103 a-O plates were used.

Results and Discussion

The fluorescence spectrum of the benzene crystal and the spectrum of toluene in benzene at various concentrations were studied. The microphotometer tracing curves are shown in Fig. 1. The spectral data of toluene in benzene and in cyclohexane are given in Tables 1 and 2 respectively. The spectrum of toluene increases in intensity with an increase in the concentration. It is, therefore, possible to make a quantitative analysis of toluene in benzene. Commercial benzene often contains toluene as an impurity the concentration of which can be estimated by, for example, comparing the height of a band 0—623 of toluene with that of a band, 0—992, of benzene of the tracing curves assumed as intensity (since the spectrum of toluene overlaps that of benzene so extensively that it is impossible to integrate a band intensity). By the way, the 0–0 band of the benzene crystal was not photographed under these experimental conditions, its spectral position was determined with plates subjected to prolonged exopsure.

At a concentration of 10^{-5} mol/*l*, no toluene fluorescence, but rather benzene fluorescence, was observed under the present experimental conditions and only toluene fluorescence was photographed at concentrations of more than 10^{-1} mol/*l* of toluene in benzene. The fluorescence of benzene disappeared at concentrations between 3×10^{-2} and 4×10^{-2} mol/*l* of toluene.

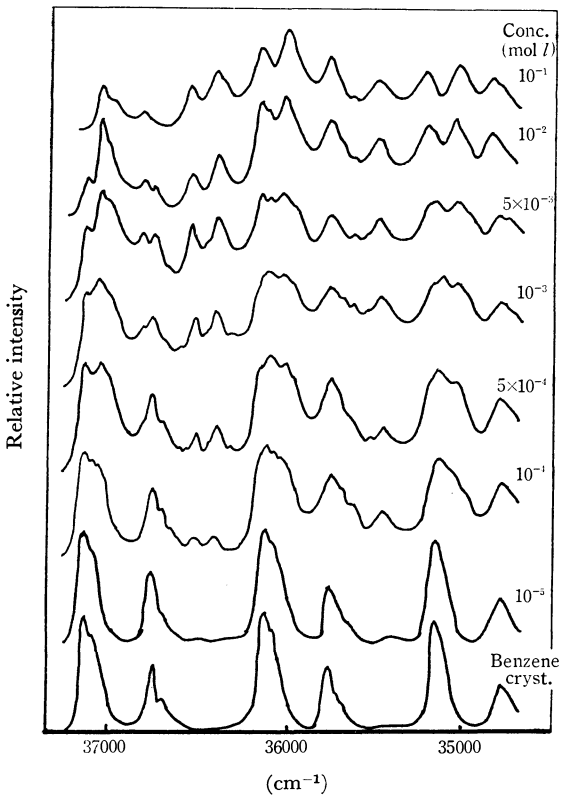

Fig. 1. Fluorescence spectra of toluene in benzene at various concentrations.

If there is no energy transfer from benzene to toluene, the ratio of the fluorescence intensity of toluene to that of benzene should be equal to the ratio of the molar fractions of toluene and benzene molecules, provided that the absorption coefficients of toluene and benzene at the wavelength of the excitation are the same and that the quantum

yields of toluene and benzene are also the same. However, the numbers of benzene molecules are much greater than those of toluene molecules at the various concentrations employed here. This suggests that a considerable amount of energy transfer takes place from benzene to toluene.

The rate of energy transfer between toluene and benzene can now be calculated. Let us assume the following processes:

$$B + h\nu \longrightarrow B^* \qquad \alpha I \qquad (1)$$
$$B^* \longrightarrow B + h\nu'_F \qquad k_1[B^*] \qquad (2)$$
$$B^* \longrightarrow B \qquad k_2[B^*] \qquad (3)$$
$$B^* + T \longrightarrow B + T^* \qquad k_3[B^*][T] \qquad (4)$$
$$T + h\nu \longrightarrow T^* \qquad \beta I \qquad (5)$$
$$T^* \longrightarrow T + h\nu''_F \qquad k_4[T^*] \qquad (6)$$
$$T^* \longrightarrow T \qquad k_5[T^*] \qquad (7)$$

where I means the intensity of excitation absorbed by molecules per unit time and where α and β are the fractions of the absorption of benzene and toluene respectively. Namely, $\alpha=\varepsilon_B[B]/(\varepsilon_T[T]+\varepsilon_B[B])$ and $\beta=\varepsilon_T[T]/(\varepsilon_T[T]+\varepsilon_B[B])$, where ε stands for the absorption coefficient.

If the excitation is of a constant intensity and if the whole system is in equilibrium, we obtain:

$$[B^*] = \alpha I/(k_1+k_2+k_3[T]).$$

From Eq. (2) the fluorescence intensity per unit time of benzene is expressed as follows:

$$F_B = k_1[B^*] = k_1\alpha I/(k_1+k_2+k_3[T]) = Q_B\alpha I/(1+K[T]).$$

Q_B and K are defined by the following relations;

$$Q_B = k_1/(k_1+k_2) \text{ and } K = k_3/(k_1+k_2).$$

Similarly, we obtain for toluene:

$$F_T = k_4[T^*] = Q_T I\{\beta+K[T](\alpha+\beta)\}/(1+K[T]).$$

If $\varepsilon_T \approx \varepsilon_B$ and $Q_T \approx Q_B$, we obtain:

$$F_T/F_B = Q_T(\beta+K[T])/\alpha Q_B = \{[T]+K[T]([T]+[B])\}/[B].$$

Therefore, we obtain:

$$K = (F_T/F_B)[B]/[T]([T]+[B]) - 1/([T]+[B]).$$

According to Robinson and Frosch,[4]

$$k_1 = 1.5 \times 10^6 \text{ sec}^{-1},$$

we obtain from this definition:

$$k_2/k_1 = (1-Q_B)/Q_B.$$

According to Lim,[5]

$$Q_B = 0.2 \text{ in EPA at } 77^\circ\text{K}.$$

If we use his data in our case, we obtain:

$$k_1 + k_2 = 5k_1 = 7.5 \times 10^6 \text{ sec}^{-1}.$$

The F_T/F_B ratio was estimated from the total fluorescence intensities of toluene and benzene, which were themselves derived from the fractional intensities of the key bands, of 0—623 of toluene and 0—992 of benzene, relative to the total intensities of toluene and benzene respectively. The results are shown in Table 3.

Table 3. Rate of energy transfer from benzene to toluene at various concentrations

Toluene in benzene (mol/l)	F_T/F_B	k_3 (mol^{-1} sec^{-1})
10^{-4}	5.4×10^{-1}	4.1×10^{10}
5×10^{-4}	1.3	2.0×10^{10}
10^{-3}	2.1	1.6×10^{10}
5×10^{-3}	2.7	4.1×10^{9}
10^{-2}	9.5	7.1×10^{9}

Colson, Kopelman, and Robinson[6] studied the selection rules of the Frenkel exciton for the $k=0$ transition in molecular crystal. They assumed the $g\leftrightarrow u$ selection rule. We photographed the fluorescence spectrum of the benzene crystal at 90°K and found the very weak 0-404 band at 37400 cm^{-1}. It is believed that this experimental evidence provides important information for discussing the intermolecular interactions of the molecular crystal.

Pesteil and Zmerli[7] reported two phosphorescence spectra from benzene crystal at 20°K and ascribed them to the 1st and 2nd triplet–ground state transitions. We checked their spectra in detail and assumed that their spectra might be due to some impurity in benzene since the analysis looked too artificial to be understood. They placed the 0–0 bands at unobserved positions at 30574 cm^{-1} and 38724 cm^{-1} and analyzed the spectra of the 1st and 2nd transitions respectively. We studied the phosphorescence and fluorescence spectra of toluene of 10^{-3} mol/l in benzene at 4.2°K and 77°K and found that they coincided with the spectra of the 1st and 2nd transitions respectively, as established by Pesteil and Zmerli. The phosphorescence spectrum of toluene in benzene was observed at 4.2°K, but it could not be observed at 77°K.

The band at 28985 cm^{-1} was taken as the 0–0 band, and vibrational frequencies of 225, 226, 450, 622, 699, 795, 988, 1174, 1586, and 1609 cm^{-1} were found. They corresponded to the Raman frequencies[8] of 216(b_2), 216×2, 623(b_1), 695(b_2), 786(a_1), 1004(a_1), 1177(a_1), 1585(b_1), and 1604(a_1) cm^{-1} respectively. The fluorescence spectrum was observed even at 77°K and 90°K, as has been described previously. Pesteil[9] has also published a paper concerning Wannier exciton bands. The absorption band at 37112 cm^{-1} of the benzene crystal in his Fig. 4 must be ascribed to the 0–0 band of toluene. By the way, a similar explanation may be given for the band at 31061 cm^{-1} of the naphthalene crystal in his Fig. 6, which is to be ascribed to the 0–0 band of β-methylnaphthalene.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 3076—3083 (1969)

The Intensity of the n–π^* Absorption Bands of Several Aliphatic Carbonyl Compounds

Kayoko Ozeki,[*1] Masaji Inagaki[2*] and Jiro Tanaka

Department of Chemistry, Nagoya University, Chikusa-ku, Nagoya

(Received April 15, 1969)

The mechanism of the intensity gain of the n–π^* transition has been investigated in several carbonyl compounds; (1) cyclohexane-1,4-dione, (2) *d*-α-bromocamphor, (3) bromonoranisatinone, (4) *d*-α-cyanocamphor, and (5) spiradine A methiodide. The results on the polarized absorption spectra of single crystals at room temperature have revealed that several mechanisms are involved in the appearance of the carbonyl n–π^* band. These mechanisms, (1) the vibronic coupling, (2) the lowering of the symmetry properties of the n and π orbitals by the substituent perturbations, and (3) the charge transfer from the substituents, are discussed theoretically and compared with the experimental results. It is shown that the in-plane components, either parallel or perpendicular to the carbonyl axis, are predominant as the source of the band intensity. The ratio of intensities parallel and perpendicular to the carbonyl axis is estimated by the use of the polarization results.

Since McMurry[1] first discussed the nature of the n–π^* transitions of the carbonyl compounds, there have appeared many experimental and theoretical studies of the mechanism of the intensity gain of the n–π^* electronic transitions.[2] The intensities of the symmetry-forbidden transitions can be observed by vibrational or other kinds of perturbations; the detailed mechanism of these transitions are important in elucidating the origin of the optical activity of the carbonyl compounds.[3] Pople and Sidman[4] studied the vibronic coupling in formaldehyde, considering especially the mixing of the A_2-type n–π^* excited state with the B_1 and B_2-type excited states. Their conclusions were in agreement with those of the classical experimental work of Dieke and Kistiakowsky,[5] who had decided that the transition is allowed along the direction in plane and perpendicular to the carbonyl axis. Cookson and his group[6] noticed the intensification of the n–π^* transition in the β,γ-unsaturated carbonyl compounds; Labhart and Wagniere[7] explained it by the charge-transfer mechanism. Vala and Tanaka[8] have demonstrated that the direction of the n–π^* transition moment of 4,4′-dichlorobenzophenone is parallel to the carbonyl axis and have discussed the mechanism of the intensity gain. In the present paper we will present results on the polarized absorption spectra of several compounds containing carbonyl groups.

The results of the low-temperature spectral studies of cyclohexane-1,4-dione, which are consistent with the present results, will be presented in a separate paper.

The optical activity of the carbonyl compounds have attracted much attention from the organic chemical point of view,[9] and the "octant-rule" has been establisehd[10] and discussed in many papers.[11] The direction of the n–π^* transition moment is definitely important in clarifying the mechanism of the octant rule.[12] The present results will provide fundamental information con-

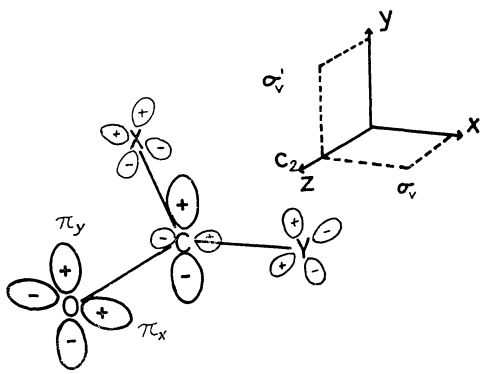

Fig. 1. The perturbing orbitals of all substituents are schematically shown at X and Y. The coordinates for the carbonyl group are shown together, the z is the direction of the carbonyl axis, x is in the plane and perpendicular to the axis, and y is in the direction out of the plane.

cerning the origin of the optical rotatory power of the carbonyl compounds.

Theoretical Considerations

The origin of the electronic transition of formaldehyde is shown to be intensity borrowing by the vibronic interactions. The theory of Pople and and Sidman,[4] confirmed by several experiments,[13] is that the transition moment is along the x axis, as is shown in Fig. 1. However, a little component is found along the carbonyl axis, though it is not big enough to explain the optical activity of the asymmetric ketones.[14] The vibronically-perturbed n-π^* excited states for the C_{2v} symmetry system may be given by:

$$\Phi(n\text{-}\pi^*) = \varphi_{A_2}(n\text{-}\pi^*) + \sum_a \frac{\langle \varphi_{A_2}(n\text{-}\pi^*) | \left(\frac{\partial H}{\partial q_a}\right) q_a | \varphi_{B_1}(n\text{-}\sigma^*) \rangle}{\varepsilon_{A_2}(n\pi^*) - \varepsilon_{B_1}(n\sigma^*)} \varphi_{B_1}(n\text{-}\sigma^*) + \sum_b \frac{\langle \varphi_{A_2}(n\text{-}\pi^*) | \left(\frac{\partial H}{\partial q_b}\right) q_b | \varphi_{B_2}(\sigma\text{-}\pi^*) \rangle}{\varepsilon_{A_2}(n\pi^*) - \varepsilon_{B_2}(\sigma\pi^*)} \varphi_{B_2}(\sigma\text{-}\pi^*) + \sum_c \frac{\langle \varphi_{A_2}(n\text{-}\pi^*) | \left(\frac{\partial H}{\partial q_c}\right) q_c | \varphi_{A_1}(\pi\text{-}\pi^*) \rangle}{\varepsilon_{A_2}(n\pi^*) - \varepsilon_{A_1}(\pi\pi^*)} \varphi_{A_1}(\pi\text{-}\pi^*) \quad (1)$$

where q_a, q_b, and q_c refer to the normal coordinates of the b_1, b_2 and a_1-type vibrational motions. The mixing with higher excited states will allow the n-π^* transition to appear along the x, y, and z axes respectively. A quantitative calculation of these terms is difficult for complex molecules; however, the selection rules can be confirmed by the polarized absorption measurements.

In β,γ-unsaturated ketones the intensity of the n-π^* transition is greatly enhanced, as is shown in Table 1. Labhart and Wagniere[7] suggested that the configurational interaction with the charge-transfer state is the major source of the intensity enhancement. The mixing of the charge transfer in the n-π^* state may be described by:

$$\Phi(n\text{-}\pi^*) = \varphi_{A_2}(n\text{-}\pi^*) + \frac{\langle \varphi_{A_2}(n\text{-}\pi^*) | \mathbf{H} | \varphi_{CT} \rangle}{\varepsilon_{A_2}(n\pi^*) - \varepsilon_{CT}} \varphi_{CT} \quad (2)$$

Where φ_{CT} indicates the charge-transfer state from the β,γ-unsaturated bond to the carbonyl group. The other charge-transfer configuration, one which involves the transfer of the nonbonding electron of the carbonyl group to the unsaturated bond, will have a higher energy because of the large ionization potential of the nonbonding electron

Table 1. The energies and intensities of the n-π^* transitions

	Crystal		Solution			
	ν_{max}	ratio $I_x : I_z$	ν_{max}	ε_{max}	$f \times 10^3$	$\Delta(\varepsilon_l - \varepsilon_r)$
Cyclohexane-1,4-dione	35.5	74 : 26	35.0	58	1.50	
d-Camphor			35.1	36	0.80	1.30
d-α-Cyanocamphor	35.0	80 : 20	34.7	42	1.00	0.64
d-α-Bromocamphor	32.0	57 : 43	32.8	107	2.11	1.81
Bromonoranisatinone	32.5	56 : 44				
Dihydrospiradine A			33.3	35	0.65	3.50
Spiradine A			32.8	194	3.18	2.30
Spiradine A methiodide	33.0	0 : 100?				

Here ν_{max} is the frequency of the absorption maximum in the crystalline state and in solutions.
The ratio is that of two components x and z by assuming that the polarization of the transition moment is in the plane of the carbonyl group (see Fig. 1).
ε_{max} is the maximum molar extinction coefficient.

13) J. C. D. Brand, *J. Chem. Soc.*, **1956**, 858.

14) J. Tanaka and K. Ozeki, to be published.

and small matrix elements; therefore, it will be neglected in further discussions. The transition moment induced by the charge-transfer configuration will have the direction inherent in the charge-transfer transition. Although Labhart and Wagniere[7] have not discussed the direction of the induced n–π^* transition, it is along the line connecting the centers of the electron donor and the acceptor groups. Another source of the intensities of the n–π^* transition is the deformation of the nonbonding and π orbitals by the perturbation of the adjacent conjugated systems.

The symmetry properties of the n and π molecular orbitals of the carbonyl group are destroyed when the substituents are located asymmetrically to the plane of the carbonyl group. For instance, the vacant π^* orbital involves not only the $2p\pi_y$ a.o., but also the $2p\pi_x$ a.o. of the carbon and oxygen atoms, because the maximum stabilization of the energy is obtained after the mixing of the orbitals of asymmetric substituents with all the orbitals of the carbonyl group. If we denote the asymmetric substituents by X and Y, as is shown in Fig. 1, the wavefunction of the carbonyl group will be given by:

$$\varphi_n = a_O\pi_x(O) + a_C\pi_x(C) + a_O'\pi_y(O) + a_C'\pi_y(C) + a_X\pi_x(X) + a_Y\pi_x(Y) + a_X'\pi_y(X) + a_Y'\pi_y(Y)$$

$$\varphi_\pi = b_O\pi_y(O) + b_C\pi_y(C) + b_O'\pi_x(O) + b_C'\pi_x(C) + b_X\pi_y(X) + b_Y\pi_y(Y) + b_X'\pi_x(X) + b_Y'\pi_x(Y)$$

$$\varphi_{\pi^*} = c_O\pi_y(O) + c_C\pi_y(C) + c_O'\pi_x(O) + c_C'\pi_x(C) + c_X\pi_y(X) + c_Y\pi_y(Y) + c_X'\pi_x(X) + c_Y'\pi_x(Y)$$

The electronically-allowed component of the n–π^* transition will be given by the transition matrix elements of the type;

$$\langle \sum_I a_I\pi_x(I) | \mathbf{r} | \sum_I c_I'\pi_x(I) \rangle$$

and

$$\langle \sum_I a_I'\pi_y(I) | \mathbf{r} | \sum_I c_I\pi_y(I) \rangle$$

both of which are polarized along the z-axis. The coefficients a_X, b_X,$\cdots$ will be large when the X and Y groups have pronounced substituent effects. However, they will be zero for the strict C_{2v} symmetry system.

A semiquantitative discussion of the mixing of n, π, and π^* orbitals has been presented by Allinger and Tai.[15]

Since the polarization properties of the n–π^* transition produced by these mechanisms are different, it is important to determine the direction of the electronic transition moment with several kinds of carbonyl compounds in order to clarify which mechanism is predominant as the source of the n–π^* intensity.

Experimental

The electronic absorption spectra of the following compounds; (1) cyclohexane-1,4-dione, (2) *d*-α-bromocamphor, (3) bromonoranisatinone, (4) *d*-α-cyanocamphor, and (5) spiradine A methiodide were measured in ethanol or EPA solutions and in the crystalline states. The polarized crystalline absorption spectra were measured by means of an ultraviolet microspectrophotometer described previously.[16] The materials used were recrystallized from ethanol or ligroin. The bromonoranisatinone and spiradine A were gifts from Professor Hirata of our department. The crystalline axes of these crystals were confirmed by the X-ray method before the measurement of the crystalline absorptions.

Results

1) Cyclohexane-1,4-dione. The crystal structure of cyclohexane-1,4-dione has been determined by Mossel and Romers,[17] and by Groth and Hassel.[18] The crystal is monoclinic, with a space group of $P2_1$ with two molecules in a unit cell. The projection of the molecules in the unit cell on the $(10\bar{1})$ plane, which is the most frequently developed face, is shown in Fig. 2. The crystalline spectra of cyclohexane-1,4-dione at room temperature are shown in Fig. 3. The spectrum in an EPA solution at room temperature is also shown there; its maximum is observed at 35500 cm^{-1}, with a molar extinction coefficient of 60. The crystalline absorption bands were observed

in the same region; they show intervals of 1100 cm^{-1}. The dichroic intensity ratio parallel to and perpendicular to the b axis ($I_b : I_{ac}$) is 1.0 : 1.3. Since the absorption intensities are weak and since the strong transitions are located in the higher-energy region, it is safe to use the oriented gas intensity ratio in discussing the direction of the transition moment. If the transition were allowed along the y axis in Fig. 1, the absorption intensity would be far stronger along the b axis than along the [10$\bar{1}$] direction. The experimental results are contrary to this presumption; therefore, we may disregard the possibility of the y axis polarization for the n–π^* transition in this compound. Although Brand[19] discovered an out-of-plane component in some α,β-conjugated carbonyls, none of the present results showed any evidence for an out-of-plane component, at least in the saturated ketones. If we restrict the polarization in the plane of the carbonyl group, neither x nor the z axis polarization alone can explain the observed intensity ratio. Therefore, the whole band may be considered to consist of two components, x and z; the ratio of the components has been determined to be $I_x : I_z =$ 0.74 : 0.26. This result indicates that more than two different mechanisms are operative in the present molecule. The low-temperature spectra, which will be presented in the succeeding paper, support this idea by showing the details of the vibrational progressions of this band.

2) d-α-Bromocamphor. The crystal structure analysis of d-α-bromocamphor and d-α-cyanocamphor has been made by Wiebenga and Krom.[20]

19) J. C. D. Brand, J. G. Callomon and J. K. G. Watson, *Discussions Faracay Soc.*, **35**, 175 (1963); J. C. D. Brand and G. D. Williamson, *ibid.*, **35**, 184 (1963).

These two compounds are isomorphous. They belong to a monoclinic system, the space group being $P2_1$; two molecules are contained in the unit cell. The crystals develop (001) faces. The projection of the molecules is shown for *d*-α-bromocamphor in Fig. 4, while the spectrum in the ethanol solution is shown in Fig. 5. The maximum of the absorption is shifted about 2300 cm^{-1} to the red and intensity is increased to about three times that of *d*-camphor. This shift was explained by Allinger, Tai and Miller[21] as being due to the effect of the σ^*(C-Br) orbital at the axial position, but the enhancement of the intensity was qualitatively shown and it was not enough to account for the large value observed. The direction of the transition moment was not discussed by these investigators.

The crystalline absorption spectra for the (001) plane are shown in Fig. 5; the dichroic intensity ratio is $I_a : I_b = 1.5 : 1.0$. The out-of-plane component is again neglected with this molecule, since otherwise the *b*-axis spectrum would be much stronger. If the increase in the intensity is produced by the $n\sigma^*$ mixing, the charge-transfer component from the n to σ^* orbital may be expected. Another possible mechanism is the symmetry breakdown of n and π^* orbitals by the axial bromine atom; it would produce the transition along the z axis. The analysis all of the band intensities into the x and z components yielded the value of $I_x : I_z = 0.57 : 0.43$. The direction of the n-σ^* transition nearly coincides with the z axis on this crystalline plane; therefore the increase in the z component may be attributed to either the inherent moment increased along the z axis or to the charge-transfer moment of the n-σ^* type transition. This point will be discussed below.

3) Bromonoranisatinone. Anisatine is a toxic terpenoid separated from seeds of *Illicium Religiosum Siebold et Zuccarini* (Japanese star anise). The crystal structure of bromonoranisatinone was analyzed by Furusaki, Tomiie, Nitta, Sakabe, and Hirata.[22] It has one carbonyl group and two ester groups. The ester groups absorb in the 50000 cm^{-1} region; therefore, we will consider only the carbonyl group in the 33000 cm^{-1} region. The carbonyl is adjacent to the bromine atom at the α position; this conformation can be explained as an intermediate of the axial and equatorial positions. The substituent effect is found to shift the band by just the same order or magnitude as in the case of *d*-α-bromocamphor. The projection of the molecules onto the developed (100) plane is shown in Fig. 6, while the crystalline absorption spectra are shown in Fig. 7. The dichroic ratio was $I_b : I_c = 1.0 : 2.0$. The separation of the band intensities along the x and z components of the carbonyl group showed that the ratio is $I_x : I_z = 0.56 : 0.44$. This finding is very close to that with *d*-α-bromocamphor. The enhancement along the z axis may be originated by a mechanism similar to that of *d*-α-bromocamphor; it will be discussed in the last section.

—— in ethanol ------ I_a —— I_b

d-α-bromocamphor except that the bromine atom is replaced by the cyano group. The spectrum in the ethanol solution is shown in Fig. 8, together with the crystalline spectra. The maximum of the absorption was observed at 33000 cm^{-1}, while the molar extinction coefficient was 42. The integrated intensity ratio for the light polarized parallel to the *b* and *a* axes was $I_b : I_a = 1.0 : 0.74$.

As has been found in the cases of cyclohexane-1,4-dione and *d*-α-bromocamphor, the out-of-plane (y aixs) component is negligible; otherwise, the *b*-axis polarized band would be much stronger.

The total band intensity was divided into the x and z components; the ratio was then obtained as $I_x : I_z = 0.80 : 0.20$. The effect of the cyano group at the axial β,γ-position is not very prominent, except that the intensity is slightly increased. The donor property of the cyano group is very poor, and the overlapping of cyano π orbitals with the n and π orbitals of the carbonyl group is not very large; therefore, few charge transfer effects may be anticipated. Another reason for this may be that the cyano group does not have a strong π-π^* transition in the ultraviolet region; therefore the perturbation is correspondingly small.

5) Spiradine A Methiodide. Spiradine A methiodide, an alkaloid botained from *spiraea japonica*,[23] has an ethylenic bond at the β,γ-position. The absorption intensity for spiradine A in the ethanol solution is $\varepsilon = 194$ at 32800 cm^{-1}, about six times that of the dihydro spiradine A, which has $\varepsilon = 35$ at 33300 cm^{-1}. This increase in the intensity is typical of β,γ-unsaturated ketones. The crystalline structure analysis was made by Sakabe, Sasaki and Hirata,[24] the molecule is projected onto the developed crystalline plane in Fig. 9. The crystalline absorption spectra are presented in Fig. 10. The measurement of the absorption intensities showed that $I_b : I_c = 1.0 : 1.75$. This result may be explained by the direction of the transition moment, which is parallel to either the carbonyl axis or the ethylenic bond. The charge-transfer mechanism produces the moment along the line connecting the donor and acceptor groups the ethylenic and the carbonyl groups. Therefore, the present results show that the charge-transfer contribution is not a major source of the intensity and

that the x component also contributes little. Accordingly the origin of the intensity enhancement may be ascribed to either of two reasons; either the symmetry of the carbonyl group is broken by the adjacent double-bond or the ethylenic π-π^* transition moment is mixed in the n-π^* transition of the carbonyl group by the perturbation of the dipole-dipole interaction. The question which of these two alternative mechanisms is predominant can not be answered from the present results only. In addition, the mixing of these two states is not conceivable, since in that case the direction of the transition moment would deviate from the confirmed direction. Further experiments on other β,γ-unsaturated carbonyl compounds are desirable in order to clarify these ambiguities.

Discussion

The findings on spectral data are summarized in Table 1. Cyclohexane-1,4-dione and d-α-cyanocamphor show large x components, 74 and 80%, with the absorption maximam at 35500 and 34700 cm^{-1}, respectively. Pople and Sidman[4] stated that the n-π^* transition induced by the vibrational interaction gives the main component in the x direction in formaldehyde. Although these molecules have heavier atoms attached to the carbonyl group, most of the intensity gain seems to be the same in origin as that of formaldehyde. However, a certain amount of the intensity is found along the z axis; this has significance for the quantitative estimate of the optical activity of asymmetric ketones. This point will be discussed in the succeeding paper.

The maximum frequencies of the absorption spectra for d-camphor, d-α-cyanocamphor, and d-α-bromocamphor in the solution of ethanol are at 35100, 34700 and 32800 cm^{-1} respectively. The effects of the substituents are slightly different; there is a little blue shift for the cyano group and a large red shift for the bromine atom. The maximum molar extinction coefficients are 36, 42, and 107, indicating a typical bathochromic effect, particularly in the bromine atom. According to Allinger, Tai and Miller,[21] the interaction between the σ^* orbital of the C–Br bond and the π^* orbital depresses the transition energy of d-α-bromcaomphor. Mixing of this type induces the transition moment along the line connecting the centers of the σ^* and π^* orbitals. Another possibility is the deformation of the n and π^* orbitals, which would give a transition moment parallel to the carbonyl axis. If the direction of the transition moment could be determined exactly, the contribution of these alternative mechanisms would be elucidated.

Both bromonoranisatinone and d-α-bromocamphor have a bromine atom in the α-position relative to the carbonyl group; the former has its in the position intermediate between the equatorial and axial axes, while the latter has its in the axial axis. Bromonoranisatione shows its absorption maximum at 32500 cm^{-1}; the similar red shift indicates the bathochromic effect of the substituent bromine atom, even for the intermediate geometry. In d-α-bromocamphor the direction of the transition moment could not be conclusively determined, for the carbonyl axis and n-to-σ^* orbital directions are nearly parallel on the measured crystalline plane. Bromonoranisatinone shows a crystalline plane in which the directions of the π-π^* and n-σ^* (C–Br) transitions are different; therefore, these different mechanisms could be distinguished by the polarization measurements. The observed results show that the z component is 43%; this value is exactly the same as that of d-α-bromocamphor. This means that the n-σ^* transition moment contributes little to the enhancement of the overall transition moment; the assumed deformation of π, π^*, and n orbitals seems to be more attractive.

In the n-π^* transitions of the carbonyl group, the magnetic transition moment has a component in the z-axis direction, so if there is to be optical activity there must be an electronic transition moment parallel to the z-axis direction. The optical rotational strength of d-α-bromocamphor is three times those of d-camphor and d-α-cyanocamphor. This may mean that the z component of the transition moment is about three or more times larger in d-bromocamphor than in d-camphor and d-α-cyanocamphor. This would agree with the present findings regarding the crystal spectra; the increase in the z component is established in d-α-bromocamphor and bromonoranisatinone.

The absorption spectra of spiradine A (β,γ-unsaturated ketone), dihydro spiradine A and spiradine A methiodide were investigated in an ethanol solution. The maximum wave numbers differ only slightly, but the maximum molar extinction coefficient increases drastically for β,γ-unsaturated ketone. The β, γ double bond has a great effect on the intensification of the n-π^* transition. Although the mixing of the charge-transfer state was suggested by Labhart and Wagniere, the crystal spectrum gives rather negative evidence for the contribution of the CT transition moment.

The wavefunction for the perturbed n-π^* state of β,γ-unsaturated ketone may be given by:

$$\Phi(n\pi^*) = a\varphi_z(n\pi^*) + b\varphi(\pi\pi^*;\ \text{C=O}) + c\varphi(\text{CT}) + d\varphi(\pi\pi^*;\ \text{C=C}) \qquad (3)$$

$$c = \frac{\langle\varphi_{n\pi}{}^*|\mathbf{H}|\varphi_{\text{CT}}\rangle}{E_{n\pi}{}^* - E_{\text{CT}}}$$

$$d = \frac{\langle\varphi_{n\pi}{}^*|\mathbf{H}|\varphi_{\pi\pi}{}^*;\ \text{C=C}\rangle}{E_{n\pi}{}^* - E_{\pi\pi}{}^*;\ \text{C=C}}$$

The appearance of the b term is mainly due to the deformation of the π and n orbitals, as has been

discussed previously, or to the second-order perturbations. The first term, which includes the vibronic mechansisms, is not significant for the whole transition moment, the second will give a component along the carbonyl axis, and the last one, one along the unsaturated carbon-carbon bond. The experiment indicates that either the second or the last one is most important for the present system. Conclusive proof on this point must, however, await some more experiments on other crystalline systems. However, recent results by Kearns, Marsh and Schaffner[25] seemingly show that in α,β-unsaturated ketone the 0-0 transition of the $n-\pi^*$ band is allowed electronically. Further effort along these lines is desirable for the elucidation of the source of the $n-\pi^*$ intensity of the unsaturated ketone.

Our thanks are due to Professor Yoshimasa Hirata of our department for his gift of samples.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 3083—3087 (1969)

The Radiolysis of Liquid Nitrogen Containing Hydrocarbons. I. Ethylene and Propylene

Takefumi OKA, Yoshikazu SUDA and Shin SATO

Department of Applied Physics, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received April 22, 1969)

The γ-radiolysis of liquid nitrogen containing ethylene and propylene has been investigated. As the nitrogenous products, hydrogen cyanide (0.18) and acetonitrile (0.04) were observed in the case of ethylene, and acetonitrile (0.12), in the case of propylene. The values in the parentheses are the *G*-values estimated on the basis of the energy absorbed by liquid nitrogen. In order to elucidate the mechanism of the reaction between nitrogen atoms and propylene, the mixture of C_3H_6 and C_3D_6 and the $CD_3CH=CHD$ compound have also been used as solutes. The acetonitrile obtained was mainly CH_3CN and CD_3CN in the former case, and CD_3CN in the latter. These results suggest that a nitrogen atom produced in the system attacks the carbon atom in the middle of propylene and produces acetonitrile, leaving a methyl radical, the carbon atom in which was originally attached to the double bond.

As an important branch of reaction kinetics, numerous investigations have been made of reactions between simple atoms and hydrocarbons.[1] Among them, the reaction between nitrogen atoms and hydrocarbons has been the most annoying one to investigators, because the reaction mechanism has to be formulated on the basis only of the measurement of a fragmentation product, hydrogen cyanide.[2] This compound is always observed as the principal product of the reaction between active nitrogen and hydrocarbons in the gas phase. Several researchers have reported that some other nitrogenous compounds, such as ammonia, acetonitrile,[3] and pyrrole,[4] are formed in the reaction between active nitrogen and hydrocarbons. However, the yields of these products are always too small compared with hydrogen cyanide to help to elucidate the reaction mechanism. Recently, though, Safrany and Jaster proposed a new approach to the reaction between active nitrogen and hydrocarbons;[5] they think that hydrogen cyanide obtained is not formed in the direct reaction between nitrogen atoms and hydrocarbons, but in the reaction between nitrogen atoms and the hydrocarbon radicals eventually formed in the reaction system.

With these things in mind, we have examined the γ-radiolysis of liquid nitrogen containing several hydrocarbons, and have found that hydrogen cyanide is not necessarily the principal nitrogenous product. For example, when propylene is used as the solute, the formation of hydrogen cyanide is not observed, but acetonitrile is formed. The

preliminary results with several hydrocarbons have been previously reported in a short communication.[6] These results suggest that the γ-radiolysis of a liquid nitrogen solution of hydrocarbons is a promising method for the study of the reactions between nitrogen atoms and hydrocarbons. In the present paper, we will report the details of the experimental method and procedure along with the results obtained with ethylene and propylene.

Experimental

Nitrogen gas of a high purity purchased from the Takachiho Trading Co. was bubbled through sulfuric acid before use. The gas-chromatographic analysis showed that the contamination of oxygen did not exceed 0.01%. All the hydrocarbons except the deuterated ones were of a pure grade purchased from the Takachiho Trading Co. The deuterated propylenes (C_3D_6 and $CD_3CH{=}CHD$) were synthesized from methylacetylene-d_4 by a method already reported.[7]

The vessel for γ-irradiation consisted of a simple Pyrex tube connected with a high-pressure stopcock through a joint held by a small spring. When the pressure in the tube rose over 2 atm, the spring was disengaged so as to avoid an explosion. The tube was graduated from the bottom in m*l*. To prepare the irradiation sample, a certain amount of a hydrocarbon volumetrically measured in advance was first condensed in the tube by means of liquid nitrogen. Then, nitrogen gas of a high purity was introduced under a pressure of about 1.5 atm. The gas was easily liquefied at the bottom of the tube. After a certain amount (usually 3 m*l*) of liquid nitrogen had been liquefied, the stopcock was closed and the tube was taken off the apparatus and shaken to dissolve the hydrocarbon in the liquid nitrogen. This sample tube was then irradiated with ^{60}Co-γ rays in a liquid-nitrogen Dewar flask. The exposure-dose rate used was 1.0×10^6 R/hr, and the irradiation time was usually 3 hr.

After the irradiation, the sample tube was evacuated at 77°K and the condensable product was analyzed by gas chromatography. For the analysis of acetonitrile, a 2.5-m column packed with polyethylene glycol-on-celite was used, while for hydrogen cyanide, a 2-m column of dioctyl phthalate was used. To detect the presence of ammonia, the irradiation product was treated with a Nessler reagent and the solution was analyzed spectrophotometrically at 430 mμ. The hydrocarbons were usually analyzed with a 4-m column of active alumina at a temperature of 40—60°C. To identify the nitriles, use was made of infrared and mass spectrometers.

Since the solubilities of hydrocarbons in liquid nitrogen could not be found in the literature, a rough estimate was made as follows. An excess amount of a hydrocarbon and a certain amount of liquid nitrogen were introduced into a sample tube which had a second thimble. After the ingredients had been mixed well, the solution was decantated into the second thimble, which was then evacuated at 77°K and fused. Then, the amount of the hydrocarbon remaining in the other thimble was measured volumetrically. Table 1 shows the results thus obtained. The numerical values should not be taken strictly, however.

Table 1. Solubilities of ethylene and propylene in liquid nitrogen

Hydrocarbons	Solubility (mole fraction)
Ethylene	1×10^{-3}
Propylene	3×10^{-4}

Results

γ-Radiolysis of Liquid Nitrogen Containing Ethylene. The observed products were acetylene, hydrogen cyanide, acetonitrile, ethane, propane, *n*-butane, 1-butene, C_6-hydrocarbons, a trace of ammonia, and the polymer. Figure 1 shows the amount of hydrogen cyanide produced as a function of the irradiation time using two concentrations of ethylene. Figures 2 and 3 show the *G*-values

of the observed products as a function of the amount of ethylene introduced into the 3-m*l* portion of liquid nitrogen. The irradiation time was 3 hr at the dose rate of 1.0×10^6 R/hr. Obviously, nitrogenous products and hydrocarbons are different in their dependency upon the amount of ethylene introduced. The *G*-values of acetonitrile and hydrogen cyanide are practically constant over the range of mole fractions investigated, while the *G*-values of hydrocarbons increased initially and then leveled off over the mole fraction of 4×10^{-4}. When the liquid nitrogen was contaminated by oxygen, no products other than acetylene were observed and sometimes light emission and explosion occurred when the condensable product was warmed up for analysis.

γ-Radiolysis of Liquid Nitrogen Containing Propylene. The observed products were acetonitrile, propane, ethylene, ethane, isobutane and/or allene, 1,5-hexadiene, 4-methylpentene-1 and/or, 2,3-dimethylbutane, a trace of ammonia, and the polymer. The dose dependence of the formation of acetonitrile is shown in Fig. 4. The *G*-values of the observed products are shown in Figs. 5 and 6 as a function of the amount of propylene introduced. The dependences of the *G*-values of

$CD_3CH=CHD$	100	18	18	4

the products upon the amount of propylene are similar to those obtained with ethylene. Here, it should be noted that the formation of hydrogen cyanide is not observed.

To elucidate the mechanism of the formation of acetonitrile, deuterated propylenes were used as solutes. Table 2 shows the distributions of the isotopic acetonitriles obtained with a partially-deuterated propylene ($CD_3CH=CHD$) and a 1 : 1 mixture of C_3H_6 and C_3D_6. Obviously, the main process of the formation of acetonitrile does not involve radical reactions. If it did, the d_1- and d_2-acetonitriles would be comparable in the amount with the d_0- and d_3-acetonitriles. The *G*-value of acetonitrile from a deuterated propylene solution was smaller than that from a usual propylene solution, although it was not measured quantitatively.

The Polymer Formation. Although the amount of the polymer formed was not measured in either radiolysis, its formation was detected as

follows. After the analysis of the volatile products, the tube was heated in the air; thereby small black particles, probably carbon, were obtained on the inside wall.

Discussion

As has been stated above, ethylene and propylene are soluble in liquid nitrogen, although their amounts are very small. Moreover, as has been reported in a short communication,[6] hydrocarbons with high melting points gave no nitrogenous products.*1 This is probably due to the small solubilities of these hydrocarbons in liquid nitrogen. From these facts, it may be concluded that the nitrogenous compounds observed are formed in homogeneous reactions in liquid nitrogen.

The initial reactions occurring in a γ-irradiated liquid nitrogen solution may be described as follows:

$$N_2 \text{ -}\!\!\sim\!\!\rightarrow [N_2^+ + e] \quad (1)$$

$$\text{-}\!\!\sim\!\!\rightarrow N_2^* \quad (2)$$

$$\text{-}\!\!\sim\!\!\rightarrow [N^+ + N + e] \quad (3)$$

Here, brackets denote spurs. For the estimation of the G values of free ions, the $\exp(-r_c/r)$ factor is known to be important; it corresponds to the probability that a thermalized electron at the distance, r, from its parent positive ion can escape from the Coulombic field. Here, r_c stands for the Onsager length ($e^2/\varepsilon kT$).[8] Since the dielectric constant of liquid nitrogen, ε, is close to 1.45, the Onsager length in liquid nitrogen is very much larger than that in a hydrocarbon liquid, for example, cyclohexane, at room temperature.[9] The G-values of free ions in cyclohexane are known to be about 0.1.[10] Therefore, the G values of free ions in liquid nitrogen will be much smaller than 0.1.

Since the concentration of the solute in the present experiment does not exceed 10^{-3} in the mole fraction, the reaction between the solute molecules and the ions in spurs may be ignored.*2 In other words, almost all the electrons produced in the reactions (1) and (3) return to their respective ions and are neutralized, leaving an excited nitrogen molecule in the reaction (1) and two nitrogen atoms in the reaction (3).

In the gas-phase experiments, a long-lived excited state of the nitrogen molecule is known to be $N_2(A\ ^3\Sigma_u^+)$.[12] This excited state is not easily quenched by nitrogen molecules, and the life-time is estimated to be more than 10^{-2} sec. The active species responsible for the successive reactions in the liquid nitrogen solution, therefore, are probably nitrogen atoms and the excited molecules, $N_2(A\ ^3\Sigma_u^+)$. In many reports on the reactions of active nitrogen, it seems to have been established that the nitrogenous compounds observed are produced in the reaction of nitrogen atoms, but not in that of excited nitrogen molecules. Accordingly, the hydrogen cyanide and acetonitrile obtained in the present experiment may have been produced in the reactions of nitrogen atoms.

In the system of ethylene and liquid nitrogen, the formation of both hydrogen cyanide and acetonitrile has been observed. The reactions may be written as follows:

$$C_2H_4 + N \longrightarrow HCN + CH_3 \quad (4)$$

$$\searrow\ CH_3CN + H \quad (5)$$

This mechanism contradicts that recently proposed by Safrany and Jaster.[5] According to them, hydrogen cyanide is mainly produced in the reaction between nitrogen atoms and such alkyl radicals as C_2H_5. However, the γ-radiolysis of the liquid nitrogen solution containing ethane gives more acetonitrile than hydrogen cyanide as the nitrogenous product.[13] This suggests that, even if it occurs, the reaction between ethyl radicals (this radical most probably exists in the present system) and nitrogen atoms gives mainly acetonitrile.

$$C_2H_5 + N \longrightarrow CH_3CN + H_2 \text{ (or 2H)} \quad (6)$$

Reaction (5) has not been proposed in the gas-phase experiment. If ethyl radicals are produced in the system of ethylene and liquid nitrogen, as

*1 In the short communication, we have classified hydrocarbons into two groups, I and II. The group I involves ethylene, propylene, propane, allene, and 1-butene, which give nitrogenous products in the γ-radiolysis of the liquid nitrogen solution and which have melting points lower than -130°C, while those of the group II (acetylene, *trans*-2-butene, and 1,3-butadiene) do not give nitrogenous products and have melting points higher than the group I.

*2 The time taken for the geminate recombination after the ionization is estimated to be $10^{-10\pm1}$ sec.[9] On the other hand, the average time between two successive collisions of an ion A, with the solute, B, is estimated by means of this equation:[11]

$$t=\{4\pi(D_A+D_B)(R_A+R_B)n\}^{-1} \quad (I)$$

Here, D is the diffusion constant, R is the collision radius, and n is the concentration of the solute, B. By assuming $D_{N_2^+}=10^{-5}$ cm^2/sec, $D_{C_2H_4}=5.3\times10^{-5}$ cm^2/sec, $R_{N_2^+}=2.4$ Å, $R_{C_2H_4}=1.9$ Å, and $t=10^{-10}$ sec, n is calculated to be 2.9×10^{20} molecules/cc, which corresponds to 1.7×10^{-2} in the mole fraction. This value is about 10^2 times the solute concentration in the present experiment.

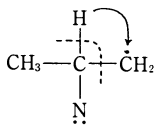
will be discussed later, the reaction (6) might be the only source of acetonitrile.

In the system of propylene and liquid nitrogen, the nitrogenous product was acetonitrile. The reaction may be written as follows:

$$C_3H_6 + N \longrightarrow CH_3CN + CH_3 \quad (7)$$
$$\searrow X \text{ (unknown)} \quad (8)$$

The reaction (8) has to be involved because, in the case of ethylene, the total G-value of the nitrogenous products was 0.22, while that obtained with propylene was 0.12. The difference may be attributed to the formation of unknown products. A more thorough investigation of the products is obviously needed.

The results shown in Table 2 are very suggestive as to the details of the reaction (7). If the formation of acetonitrile is mainly due to the reaction between nitrogen atoms and some radicals, the acetonitrile obtained with the 1 : 1 mixture of C_3H_6 and C_3D_6 should contain many more d_1- and d_2-compounds than those shown in Table 2. Moreover, the results obtained with a partially-deuterated propylene ($CD_3CH{=}CHD$) clearly show that most of the methyl radical in propylene remains, as it is, in the acetonitrile produced. The bond cleavage in the intermediate, if it is produced, may be visualized as follows:



The reaction between nitrogen atoms and alkyl radicals, however, cannot be entirely ignored, because the formation of the d_1- and d_2- compounds has been observed with the 1 : 1 mixture.

In a previous note[14] on the γ-radiolysis of nitrogen gas, we have estimated the G-values of nitrogen atoms to be 0.8. This value is more than three times the G-value (0.22) of the nitrogenous products formed in the system of ethylene and liquid nitrogen. Since the cage effect has to be considered in the liquid, the value of 0.22 may not be far from the G-value of nitrogen atoms in liquid nitrogen.

The reaction of $N_2(A\,^3\Sigma_u^+)$ with ethylene may be written as follows:[15]

$$N_2(A^3\Sigma_u^+) + C_2H_4 \longrightarrow N_2 + C_2H_4^*$$
$$C_2H_4^* \longrightarrow C_2H_2 + H_2 \text{ (or } 2H)$$
$$\searrow C_2H_3 + H$$

These reactions will be followed by such radical reactions as:

$$H + C_2H_4 \longrightarrow C_2H_5$$
$$C_2H_3 + C_2H_4 \longrightarrow C_4H_7$$

This is consistent with the finding that, in the presence of oxygen, the only product observed was acetylene. In the case of propylene, a similar reaction mechanism can easily be constructed.

The amount of each hydrocarbon observed in both radiolyses leveled off over the mole fraction of 4×10^{-4}. If this is due to the complete quenching of excited nitrogen molecules, the life-time of excited nitrogen molecules in liquid nitrogen can be estimated by using Eq. (I). The obtained value is about 10^{-8} sec. This is very much smaller than that estimated as the life-time in the gas phase. This is obviously another subject which needs to be investigated.

Radiolysis of Methylcyclohexane. II. The Effect of Cumene on Hydrogen Formation from γ-Irradiated Methylcyclohexane

Toyoaki KIMURA Kenji FUEKI and Zen-ichiro KURI

Department of Synthetic Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya

(Received May 1, 1969)

The effect of cumene on the hydrogen yields from methylcyclohexane γ-irradiated at 100, 20, -72, -120 and -196°C has been investigated. Cumene did not compete with N_2O for capturing electrons in methylcyclohexane and the yield of thermal H atoms in methylcyclohexane, determined by use of ethylene as an H atom scavenger, was smaller than the decrease in hydrogen yield in methylcyclohexane-cumene systems. Therefore, the decrease in hydrogen yield in methylcyclohexane-cumene systems can be ascribed mainly to positive charge transfer from methylcyclohexane to cumene. Further, the evidence of charge transfer from methylcyclohexane to cumene was found by the optical absorption method. The effect of cumene on the hydrogen yield from methylcyclohexane was similar in the temperature range from 100 to -196°C, especially at high cumene concentration. The effect of an electron scavenger at high concentrations was also examined with *n*-butyl chloride. In the present work, we have found that although the effect of a positive ion scavenger on the hydrogen yield from methylcyclohexane in the liquid state differs little from that in the glassy state, the effect of electron scavengers on the former differs considerably from that on the latter.

In a previous paper[1] we have reported the effects of temperature and electron scavengers on the hydrogen yield from γ-irradiated methylcyclohexane. We have shown that both in the liquid and glassy states the neutralization of a positive ion and an electron leads to the formation of a hydrogen molecule,

$$MCH \text{ -}\!\!\wwarrow\!\!\rightarrow MCH^+ + e^- \quad (1)$$

$$MCH^+ + e^- \longrightarrow H_2 \quad (2)$$

and that the efficiency of electron scavenging by solutes in the glassy state differs considerably from that in the liquid state. Some workers[2,3] showed that the yields of scavengable electrons in hydrocarbon glasses were lower than those in liquid hydrocarbons, and that they are at most 1.6 (G unit).[2] At present, the reason for this is not clear, but the following reasons may be considered; (1) the separation distances of positive ions and thermalized electrons in glasses are shorter than those in liquids, (2) positive ions may play a part in neutralization processes, for instance, in glasses charge transfer from positive ions to neutral molecules occurs rapidly and initial charge recombination is increased. Therefore it is of interest to know the behavior of positive ions both in liquid and glassy hydrocarbons.

Hitherto, studies of positive ions have been undertaken in several ways; observation of optical absorption spectra,[4] measurements of HD formed from solutions containing deuterated compounds such as ND_3 and C_2H_5OD as proton acceptors,[5,6] measurements of methane produced from solutions containing neopentane,[7] and observation of changes in product distribution by addition of ammonia.[8] These methods, however, are not necessarily useful for our purpose, because we can observe only positive ions surviving after a large fraction of ion pairs have neutralized, and both deuterated ammonia and deuterated ethanol are not sufficiently soluble in methylcyclohexane glass at -196°C for a major fraction of positive ions to be scavenged. Also, neopentane cannot be used to scavenge a large fraction of positive ions, since ionization potential of neopentane (10.35 eV) is higher than that of methylcyclohexane (9.85 eV).

In this work we have used cumene as a positive ion scavenger. The reasons are that cumene is soluble at any concentration in the methylcyclohexane glass at −196°C, the hydrogen yield from cumene is low (described later), and the ionization potential of cumene (8.69 eV) is lower than that of methylcyclohexane. Positive charge transfer from alkanes to olefins and aromatics and the subsequent decrease in hydrogen yields have been reported.[9,10] Thus it can be expected that cumene will scavenge the methylcyclohexane positive ion and suppress hydrogen formation.

$$MCH^+ + \text{Cumene} \longrightarrow MCH + \text{Cumene}^+ \quad (3)$$

$$\text{Cumene}^+ + e^- \longrightarrow H_2 \text{ (low yield)} \quad (4)$$

Here we report the thermal H atom yield from γ-irradiated methylcyclohexane in the liquid and glassy states, determined by use of ethylene as an H atom scavenger, and the effect of cumene on the hydrogen yield at various temperatures. In addition to these results we will show evidence for positive charge transfer from methylcyclohexane to cumene by the optical absorption method and discuss primary processes in the radiolysis of methylcyclohexane in the liquid and glassy states.

Experimental

The experimental procedure was almost the same as that described earlier.[1] Cumene was Nakarai guaranteed reagent and purified by distillation prior to use. *s*-Butyl chloride was Tokyo Kasei guaranteed reagent and was passed through a silica gel column after distillation. Tokyo Kasei guaranteed *n*-butyl chloride was passed through a silica gel column and fractionally distilled through 1.2 m long column filled with small cylindrical hollow glass packing. The purity of *n*-butyl chloride thus obtained was 99.8%. In the methylcyclohexane-cumene system, γ-irradiations were performed at 100, 20, −72, −120, and −196°C. Irradiations of samples at 100°C were performed in a Dewar filled with boiling water. In measurements of optical absorption spectra, samples were degassed in a glass tube and transferred in a rectangular quarz cell (10 mm × 5 mm), and sealed off. Irradiations were carried out at −196°C in the dark. The dose was usually 1.19×10^{19} eV/g. Optical absorption measurements were made on a Hitachi EPU-2 spectrophotometer.

Results

The hydrogen yields from pure methylcyclohexane, cumene, and *n*-butyl chloride irradiated at various temperatures and irradiation doses are listed in Table 1. The hydrogen yields from methylcyclohexane-ethylene systems irradiated at 20 and −196°C are shown in Fig. 1. The decrease in hydrogen yield is about 1.0 G in the liquid state and 0.5 G in the glassy state.

Table 1. Hydrogen yields from pure methylcyclohexane (MCH), cumene, and *n*-butyl chloride (*n*-BuCl) at various temperatures and doses

Sample	Irradiation temp. °C	$G(H_2)$	Dose eV/g
MCH	100	5.4	6.51×10^{19}
MCH	20	4.9	2.93×10^{20}
MCH	−72	4.5	2.60×10^{20}
MCH	−120	4.5	6.51×10^{19}
MCH	−196	4.4	2.60×10^{20}
Cumene	100	0.19	6.51×10^{19}
Cumene	20	0.19	2.93×10^{20}
Cumene	−196	0.11	2.60×10^{20}
n-BuCl	−196	0.92	2.60×10^{20}

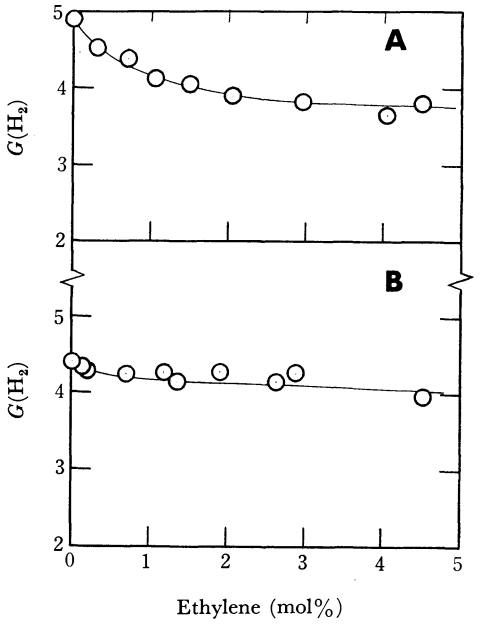

Fig. 1. Hydrogen yields from γ-irradiated methylcyclohexane-ethylene systems. (A), at 20°C; (B), at −196°C
Dose = 2.93×10^{20} eV/g

To see whether cumene scavenges an electron to form cumene anion, we have examined the nitrogen and hydrogen yields from methylcyclohexane solutions containing 3 mol % of N_2O together with various concentrations of cumene. These results are shown in Fig. 2. Though the experimental data are somewhat scattered because of the variation in the volume above the liquid surface in irradiation cells, the nitrogen yield is not affected by the presence of cumene. Moreover, it was found in γ-irradiated 3MP glasses containing biphenyl at −196°C, the yield of biphenyl anions was not affected by the

Dose=2.93×10^{20} eV/g

presence of cumene in much higher concentrations than that of biphenyl.[11] Therefore it is concluded that cumene does not scavenge electrons.

The hydrogen yields from methylcyclohexane-cumene systems irradiated at 100, 20, −72, −120, and −196°C are shown in Fig. 3.

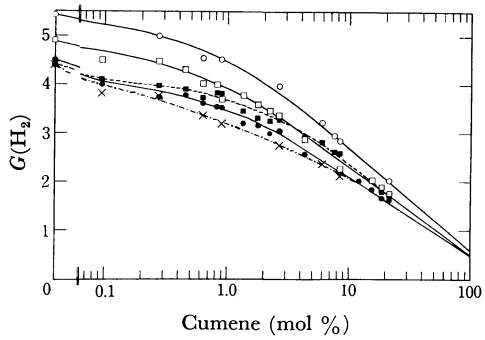

Fig. 3. Hydrogen yields from methylcyclohexane-cumene systems.
(a) —○— irradiated at 100°C (Dose=6.51×10^{19} eV/g)
(b) —□— irradiated at 20°C (Dose=2.93×10^{20} eV/g)
(c) —●— irradiated at −72°C (Dose=2.60×10^{20} eV/g)
(d) ---×--- irradiated at −120°C (Dose=6.51×10^{19} eV/g)
(e) ---■--- irradiated at −196°C (Dose=2.60×10^{20} eV/g)

These G values were obtained based on the energy absorbed only in methylcyclohexane. It can be seen from the data in Table 1 that the contribution of hydrogen formation from cumene by the direct effect of radiation is at most ~1% of the total hydrogen even at the highest cumene concentration studied, 21.5 mol 1%. Comparing the hydrogen yields from methylcyclohexane-cumene systems (Fig. 3) with those from methylcyclohexane-ethylene systems (Fig. 1), we see that the decrease in hydrogen yield in the former cannot be explained only by H atom scavenging by cumene because H atom scavenging is a minor process for the suppression of hydrogen formation, especially in the glassy state at −196°C, as shown in Fig. 1. The experimental curves (Fig. 3) which represent the hydrogen yield *vs.* cumene concentration are very similar to each other, practically at high cumene concentrations. The hydrogen yields at −72 and −120°C (Fig. 3. c and d) are somewhat lower than those at 20 and −196°C (Fig. 3. b and e). This may be partly due to inaccuracy in the evaluation of the energy absorbed in cooling agents.

Though the effect of cumene on the hydrogen yields in the liquid state at 20°C is practically the same as that in the glassy state at −196°C (Fig. 3. b and e), the effect of electron scavengers on the former is considerably different from that on the latter.[1] Therefore, in the present work we have extended the study of the effect of electron scavengers in the glassy state to higher concentrations than before.[1] For this purpose we have examined the hydrogen yield from methylcyclohexane glass with *n*-butyl chloride as an electron scavenger, since it has been found that *n*-butyl chloride is soluble at any concentration in methylcyclohexane glass at −196°C. The results are shown in Fig. 4 together with the previous data[1] for comparison. The values were obtained based on the energy absorbed only in methylcyclohexane. The observed hydrogen yield at the highest concentration of *n*-butyl chloride (26.8 mol %) is 2.8 G, which contains the hydrogen yield from *n*-butyl chloride by 0.33. Since the observed decrease in hydrogen yield at the highest concentration of *n*-butyl chloride is 1.6 G,

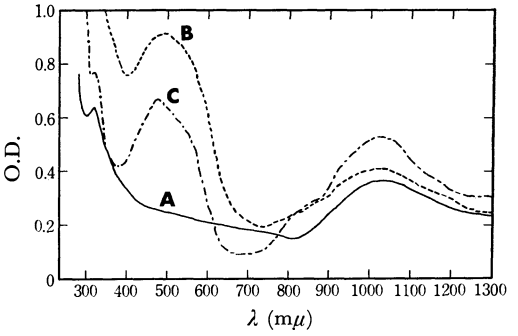

Fig. 5. Optical absorption spectra of (A) methyl cyclohexane containing 3 mol % N_2O and 3.5 mol % cumene after γ-irradiation (Dose$=1.19\times10^{19}$ eV/g); of (B) *s*-butyl chloride containing 7.9 mol % cumene after γ-irradiation (Dose$=2.38\times10^{19}$ eV/g); of (C) the same sample as (B) after photobleaching with visible light from a tungsten lamp at -196°C.

the corrected decrease, that is the scavenged electron yield, is estimated to be 1.9 G.

The optical absorption spectra of γ-irradiated methylcyclohexane glass containing cumene and N_2O, and of γ-irradiated *s*-butyl chloride glass containing cumene are shown in Fig. 5. The spectrum of methylcyclohexane glass containing 3 mol % of N_2O and 3.5 mol % of cumene has an absorption maximum at 1050 mμ (Spectrum A), which resembles that of toluene cation.[4] The spectrum of *s*-butyl chloride containing 7.9 mol % of cumene also has an absorption maximum at 1050 mμ. When γ-irradiated *s*-butyl chloride-cumene sample is photobleached with visible light from a tungsten lamp, the absorption spectrum changes from spectrum (B) to spectrum (C) and the 1050 mμ band increases in intensity. Thus, the 1050 mμ band can be assigned to the cumene cation. The dependence of the optical density at 1050 mμ on the cumene concentration in methylcyclohexane is shown in Fig. 6. The result is similar to that on toluene in 3MP glass[4] and indicates that the cumene cation is produced by charge transfer from methylcyclohexane to cumene.

Dose$=1.19\times10^{19}$ eV/g.

Discussion

The decreased hydrogen yield in methylcyclohexane-ethylene systems can be ascribed to thermal H atom scavenging by ethylene.[12] The decrease in hydrogen yield in the liquid state (1.0 G) is twice that in the glassy state (0.5 G), as shown in Fig. 1. It should be noted that the difference between the hydrogen yields of pure liquid methylcyclohexane irradiated at 20°C and of pure glassy methylcyclohexane at -196°C is 0.5 G. As we reported previously,[1] these results seem to suggest the following mechanism:

at room temperature

$$H_{thermal} + MCH \longrightarrow H_2 + MCH\cdot \quad (1.0G) \quad (5)$$

at -196°C

$$H_{thermal} + MCH \not\longrightarrow H_2 + MCH\cdot \quad (6)$$

$$H_{thermal} + H_{thermal} \longrightarrow H_2 \quad (0.5G) \quad (7)$$

Thermal H atoms abstract H atoms from solvent molecules to produce hydrogen molecules (1.0 G), but they are unable to abstract H atoms at -196°C and recombine with one another to produce hydrogen molecules (0.5 G).

Since cumene does not compete with N_2O for capturing electrons (Fig. 2), the decrease in hydrogen yield in methylcyclohexane systems (Fig. 3) cannot be attributed to electron scavenging by cumene. *s*-Butyl chloride matrix is widely used for trapping cation species.[4] Photobleaching of γ-irradiated *s*-butyl chloride-cumene glass causes the intensity of the 1050 mμ band to increase. This phenomenon is interpreted in terms of positive charge transfer from *s*-butyl chloride to cumene. It is known that the *s*-butyl chloride cation has an absorption maximum at 540 mμ[13] and can be excited by visible light to migrate over many molecules by resonant charge transfer.[14] The optical absorption measurements clearly demonstrate the formation of cumene cations in methylcyclohexane-cumene systems. It can also be seen from Fig. 6 that cumene cations are not produced by the direct ionization of cumene, but by charge transfer from methylcyclohexane to cumene. Thus, it may be said that the decrease in hydrogen yield in methylcyclohexane-cumene systems is mainly due to charge transfer from methylcyclohexane to cumene and partly due to thermal H atom scavenging by cumene.

Extrapolation of the curves in Fig. 3 to 100% cumene concentration gives hypothetical *G* values

12) W. A. Cramer and G. J. Piet, *Trans. Faraday Soc.*, **63**, 1402 (1967).
13) T. Shida and W. H. Hamill, *J. Chem. Phys.*, **44**, 2375 (1966).
14) W. F. Louwrier and W. H. Hamill, *J. Phys. Chem.*, **72**, 3878 (1968).

for hydrogen formation based on the energy absorbed only in methylcyclohexane, where all the effects of cumene on the radiolysis of methylcyclohexane are assumed to be completed. It should be noted that (1) the curves are very close to each other, and (2) the hypothetical hydrogen yields at 100% cumene are approximately the same (0.5—0.7 G). To interpret the results, two different effects of cumene are considered: H atom addition to cumene at low cumene concentrations and charge transfer to cumene at high concentrations.[9] Thus at high cumene concentrations the curves are interpreted to indicate positive ion scavenging curves at each irradiation temperature. One of the most notable features in the curves is that they differ little from each other in the temperature range from 100°C to −196°C. It is certain that in the glassy state at −196°C the mechanism of charge migration is resonant charge transfer. Since the curve of positive ion scavenging in the liquid state differs little from that in the glassy state, charge transfer in the liquid state may possibly be resonant. According to Freeman's calculation,[15] more than 10 mol % of scavenger is required to scavenge positive ion completely. Assuming the number of molecules surrounding a positive ion is six, it is shown that 13 mol % of scavenger is required for scavenger molecule to be adjacent to a positive ion. Therefore, it is difficult to discern between charge transfer by resonance and that by diffusional collision. Further study is needed to establish the charge transfer mechanism in liquid.

The hypothetical hydrogen yields at 100% cumene do not coincide with the hydrogen yields from pure cumene, as is seen from Table 1, and are tentatively considered to be the hydrogen yields from directly excited methylcyclohexane molecules:

$$MCH \rightsquigarrow MCH^* \longrightarrow H_2 \qquad (6)$$

The decrease in hydrogen yields in Fig. 4 is assumed to be equal to the yields of scavenged electrons. This interpretation is reasonable especially in the case of methylcyclohexane. It has been proposed by many workers that Eq. (2) holds in the radiolysis of liquid hydrocarbons, but some workers have shown by ESR studies that charge neutralization does not lead to decomposition of hydrocarbon lgasses at −196°C,[3] although others have shown by product analysis studies that Eq. (2) holds even in the glassy state at −196°C.[1,16] In the previous work on methylcyclohexane,[1] we have shown that the scavenged electron yield is equal to the decrease in hydrogen yield at −196°C as well as 20°C. Further, the hydrogen yield from pure methylcyclohexane irradiated at 20°C is not so different from that at −196°C. Thus, Eq. (2) seems to be valid at −196°C as well as 20°C, and we could evaluate by the decrease in hydrogen yield both the scavenged electron and the scavenged positive ion yield in methylcyclohexane.

As already described, the efficiency of electron scavenging in liquids differs considerably from that in glasses at −196°C (Fig. 4), though the efficiency of positive ion scavenging in liquids scarcely differs from that in glasses at −196°C (Fig 3). Further, the yield of scavenged electrons in methylcyclohexane-*n*-butyl chloride glasses at −196°C is at most 1.9 G at the highest concentration of *n*-butyl chloride where a *n*-butyl chloride molecule exists adjacent to a positive ion. Therefore, assuming the total ion-pair yield of methylcyclohexane is ~4, we can say that more than half of the electrons canont be scavenged at such a high solute concentration. To explain these experimental facts, we are forced to state as follows; a significant fraction of charge transfer in glasses will be completed before electrons ejected from molecules by radiation are thermalized. Since molecules in a glass at −196°C are not allowed for translational motions, charge transfer must be resonant. Hamill has suggested that resonant charge transfer is a very fast process.[14] Our results are consistent with the following mechanism: positive ions transfer their charge to solute molecules or trapping sites of the matrix before ejected electrons are thermalized, and then thermalized electrons return to positive ions or are scavenged by electron scavengers. One of the causes for the scavenged electron yield in glasses to be less than half of the total ejected electrons may be the shorter separation distances between trapped positive ions and thermalized electrons in glasses. However, it is not so easy to give a theoretical explanation for this reasoning.

We have found that the scavengable electron yield in glasses is ~2G. If this value is used in the previous calculation of electron scavenging in methylcyclohexane-iodobenzene glasses,[1] the experimental points fit well in the calculated curve without the assumption of aggregation of iodobenzene molecules at −196°C. Since positive ions do not move after electrons are thermalized, the previous calculation will be valid except for uncertainty in the initial ion-pair yield assumed in glasses.

(Received May 1, 1969)

A modification of the Archibald method for determining the molecular weight of a polydisperse sample in ideal and non-ideal solutions is developed in this paper. A reliable value of the weight-average molecular weight is obtained from the plot of an apparent weight-average molecular weight against the centrifugal time rather than against the amount of the solute sedimented from the meniscus. This fact is explained on the assumption of a fractionation effect of the solute caused by the centrifugal potential.

The sedimentation equilibrium method, one of the most reliable procedures for the molecular-weight determination of a polymer, is based on the strict thermodynamical treatment, but the time required for the attainment of the equilibrium is, in general, very long.

Archibald[1] has suggested that the molecular weight of a polymer can be determined from the data obtained during the approach to the sedimentation equilibrium for a monodisperse sample in an ideal solution.

For the system of a monodisperse sample in a non-ideal solution, Fujita and Inagaki[2,3] have derived a relationship according to which the apparent weight-average molecular weight of the solute at the meniscus at a given time is corrected to the value of that at zero time.

For a polydisperse sample in ideal and non-ideal solutions a weight-average molecular weight can be, in principle, determined in the same way, but the apparent weight-average molecular weight calculated at a given time must be extrapolated to zero time for the determination of the weight-average molecular weight of the sample.[1] It was shown in the experiments for the polydisperse sample in non-ideal solutions that the value of the apparent weight-average molecular weight of the sample at each centrifugal time at the meniscus, $M_{(app)}(t)$, does not change linearly with time, but that the extrapolated value at the meniscus to zero time is usually larger than that at the bottom of the cell.[4-7] According to the other reports, the values of $M_{(app)}(t)$ at the meniscus and the bottom of the cell vary approximately linearly with time for some cases of polydisperse samples in non-ideal solutions, and these values give the same intercept at zero time.[2,8,9] The purpose of this paper is to find out, experimentally, a suitable procedure for the extrapolation of the $M_{(app)}(t)$ of a polydisperse sample to the starting condition, and to obtain a reliable value for the molecular weight.

Experimental

Materials. Poly-α-methylstyrene 17*4 (PαMST-17, $\bar{M}_w = 37 \times 10^4$), poly-α-methylstyrene 18*4 (PαMST-18,

$\bar{M}=59\times10^4$), and polystyrene NBS705*5(PST-NBS705, $\bar{M}=19\times10^4$) were used as samples with a narrow molecular-weight distribution. PαMST-mixt, which is a 1 : 1 mixture in weight of PαMST-17 and PαMST-18, and polystyrene SM1*6 (PST-SM1, $\bar{M}_w=30\times10^4$) were used as the polydisperse samples.

Solvents. Cyclohexane was repeatedly washed with a sodium hydroxide solution and with water after being treated with a mixture of sulfuric acid and nitric acid; then it was distilled twice and fractionally distilled after being dried over calcium chloride and metallic sodium. The physical constants were as follows: bp 80.8°C, n_D^{20} 1.4264, d^{38} 0.7619 g/ml.

Toluene was repeatedly washed with sodium hydroxide and water after being treated with sulfuric acid. It was dried over calcium chloride and then distilled fractionally. The physical constants were as follows: bp 110.8°C, d^{30} 0.8579 g/ml.

Butanone was distilled after being treated with potassium permanganate; then it was distilled fractionally after being dried over sodium sulfate. The physical constants were as follows: bp 79.4°C, d^{25} 0.7986 g/ml.

Ultracentrifugation. The measurements were made with a Hitachi Analytical Ultracentrifuge, UCA-1, equipped with a schlieren optical system. A double-sector cell was used. The experimental conditions in this study are summarized in Table 1. The values of the partial specific volume, $\bar{v}$, the density of the solvent, ρ, and the refractive index increment, dn/dC, used in this experiment are also listed in Table 1. The concentration in the cell was determined in accordance with the Klainer and Kegeles method.[10]

Results and Discussion

Determination of $M(t)$. $M(t)$, a weight-average molecular weight at each centrifugal time, was calculated by the following equation:[1]

$$M(t) = \{RT/(1-\bar{v}\rho)\omega^2\}(1/C_m x_m)(dC/dx)_m \qquad (1)$$

where R is the gas constant, T is the absolute temperature, $\bar{v}$ is the partial specific volume of the solute, ρ is the density of the solvent, ω is the angular velocity of the rotation, x_m is the distance from the axis of rotation to the meniscus or to the bottom of the cell, C_m is the concentration of the solute at the meniscus or the bottom, and $(dC/dx)_m$ is the concentration gradient at the meniscus or the bottom.

The schlieren pattern at the bottom of the cell was so indistinct that it was impossible to determine the concentration gradient. Therefore, only the results obtained at the meniscus will be discussed in this report.

In the calculation of $M(t)$ at the meniscus by Eq. (1), the value of $(1/C_m x_m)(dC/dx)_m$ was obtained by extrapolating a plot of log $(1/Cx)(dC/dx)$ against a given point in the cell, x, to the meniscus.[2]

The values of $M(t)$ obtained were plotted against time, t; the value extrapolated to $t=0$ gives the weight-average molecular weight of the solute at zero time, $M(t=0)$. The centrifugal time was calculated as follows; one-third of the time before the rotor attained its final speed was added to the time which elapsed after the operational speed was reached.[19]

The Results for Ideal Systems. The results of experiments for ideal systems are summarized in Table 2, where the value of $\Delta M(t)/\Delta t$ shows the

magnitude of the slope in the plot of $M(t)$ against t. A typical plot of $M(t)$ against t is shown in Fig. 1 for three samples of PαMST in the theta solvent.

The data for ideal systems in Table 2 and Fig. 1 show that: (1) the values of $M(t)$ vary linearly with the time (though it has no theoretical basis), and (2) the plots have a negative slope.

The measured value of the molecular weight, at the meniscus, of a monodisperse solute in an ideal solution should be independent of the centrifugal time. When the time dependence of $M(t)$ observed in the sample of an ideal system is supposed to be caused by the sedimentational fractionation of the solute molecules at the meniscus, the more heterogeneous the solute is, the more negative the time dependence to be expected for $M(t)$. In the present study, it is consistent with the above expectation that $M(t)$ for PαMST-mixt in the theta solvent shows a negative time dependence, and that

C_0: Initial concentration of the solute

the magnitude of its time dependence is larger than that of either PαMST-17 or PαMST-18 in the theta solvent. A distinct negative time dependence of PαMST-17 and PαMST-18 in an ideal solution, whose molecular-weight distribution is fairly narrow, suggests the strong sensitivity of this method to sample heterogeneity. The larger gradient of the plot of $M(t)$ against t for PαMST-18 in cyclohexane than that for PαMST-17 in cyclohexane is concluded on the basis of a comparison of the sedimentation patterns for the two samples. Both samples show the schlieren pattern with a leading minor peak of the second component; the area under the minor peak in PαMST-18 in cyclohexane is a little larger than that in PαMST-17 in cyclohexane.[12]

It seems appropriate to use amounts of the solute sedimented from the meniscus, ΔC_m and $\Delta C_m/C_0$, as variables in the analysis of $M(t)$ to obtain $M(t=0)$. A typical plot of $M(t)$ against ΔC_m is shown in Fig. 2-a for PαMST-18 in the theta solvent. The plot shows a downward-curving line for a solution of a given initial concentration. When the

fractionation of the solute by the sedimentation is independent of C_0, the plots of $M(t)$ against $\Delta C_m/C_0$ for the different values of C_0 will fall on a master curve because the molecular-weight distributions of the solute at the meniscus for the different concentrations may be expected to be identical for the same value of $\Delta C_m/C_0$. Figure 2-b shows a typical plot of $M(t)$ against $\Delta C_m/C_0$ for PαMST-18 in the theta solvent. This plot also gives curved lines for each C_0 value, though the lines are close to each other. It might be reasonable to assume that the fractionation of the solute at the meniscus does not always proceed regularly in the order of the molecular weight, but that the hydrodynamic interactions between the solute molecules are influenced by the initial concentration of the solute under the conditions used in this experiment.

The Results for Non-ideal Systems. For a non-ideal system the value of $M(t)$ calculated from Eq. (1) is an apparent weight-average molecular weight, $M_{(app)}(t)$, because the value depends on C_0. The results for non-ideal systems are summarized in Table 3. The gradient of the plot of $M_{(app)}(t)$ against t decreases slightly with an increase in C_0 at the same rotor speed, as is shown in the systems of PαMST-18 in toluene, PST-SM1 in butanone, and PST-SM1 in toluene. All of the plots for PST-SM1 show negative slopes; moreover, the slopes become small in magnitude in the order of the cyclohexane, the butanone, and the toluene solutions. The plot of $M_{(app)}(t)$ against t for PST-NBS705 in toluene shows a positive slope, while that for PαMST-18 in toluene shows either a positive slope or a negative one. A positive time dependence in a non-ideal system, such as PST-NBS705 in toluene and PαMST-18 in toluene, is expected from the theory of Fujita and Inagaki[2] for the sample of a sufficiently narrow molecular-weight distribution. It may be concluded from the results in this study that the time dependence of $M_{(app)}(t)$ in a non-ideal system becomes smaller with an increase in C_0. This result shows that the fractionation effect of the solute during sedimentation is superposed on the thermodynamic non-ideality of the solution.

For a monodisperse sample in a non-ideal solution, the following equation was given by Fujita and Inagaki:[2]

$$M_{(app)}(t) = M_{(app)} + M^2\{B_{11}+(\bar{v}/M)\}\Delta C_m + (\text{higher terms in } \Delta C_m) \quad (2)$$

where $M_{(app)}$ is the apparent molecular weight of the solute (it is independent of time), M is the molecular weight of the solute, B_{11} is the parameter for thermodynamic interaction between the solutes, and $\bar{v}$ is the partial specific volume of the solute. Generally speaking, the value of ΔC_m depends on time and takes a positive value. Equation (2) suggests a linear relation between $M_{(app)}(t)$ and ΔC_m for a monodisperse solute by neglecting the higher terms. Nakazawa and Inagaki[3] reported that the plot of $M_{(app)}(t)$ against ΔC_m has a linear relation for a monodisperse solute in a non-ideal solution, as is to be expected from Eq. (2), and concluded that the effect of the rotor speed on the plot of $M_{(app)}(t)$ against t can be eliminated by the plot of $M_{(app)}(t)$ against ΔC_m. Consequently, $M_{(app)}$ is obtained more satisfactorily when $M_{(app)}(t)$ is extrapolated to $\Delta C_m=0$ than when it is extrapolated to $t=0$. The plot of $M_{(app)}(t)$ against ΔC_m for PST-NBS705 in toluene is shown in Fig. 3, where it shows a positive slope and a straight line,

as may be expected from Eq. (2). However, the value of B_{11} obtained from the slope depends on the initial concentration and the rotor speed; this finding suggests that the effect of the fractionation of the solute is fairly large, even on this sample with a narrow molecular-weight distribution.

The plot of $M_{(app)}(t)$ against ΔC_m for PST-SM1 in butanone is shown as a typical example for a non-ideal polydisperse system in Fig. 4. The plot is approximately a straight line showing a negative slope. However, the observed values of $M_{(app)}(t)$ were localized in a limited range of ΔC_m, so the values of $M_{(app)}$ obtained by the extrapolation might be considered to be more ambiguous than that shown on the plot of $M_{(app)}(t)$ against t.

The weight-average molecular weight of the sample is determined from the intercept on the plot of $1/M_{(app)}$ against C_0, where $M_{(app)}$ is the value obtained by the plot of $M_{(app)}(t)$ against t. Figure 5 shows typical plots of $1/M_{(app)}$ against C_0. For an ideal system the reciprocals of M obtained by the extrapolation of the plot of $M(t)$ against t are independent of C_0 as was expected. The reciprocals of $M_{(app)}$ for a polydisperse solute in a non-ideal solution, such as PST-SM1 in butanone and PST-SM1 in toluene, show a dependence on C_0 with an upward curvature; this finding agrees with that reported by Toyoshima and Fujita.[20] On the

other hand, the plot of $M_{(app)}$ against C_0 for the sample of a narrow molecular-weight distribution in a non-ideal solution shows that the contribution of a third term to the virial expansion of Eq. (2) can be neglected. The values of M_w obtained by this method are summarized in Table 4; the values agree with those in literature.

The authors wish to express their hearty thanks to Professor Mitsuru Nagasawa of Nagoya University for his kind help in supplying the samples. They also wish to express their hearty thanks to Dr. Takahide Saito of Tokyo Kyoiku University for his many helpful discussions, and to Miss Yasuko Nishibe and Miss Makiko Muraki for their assistance in the experimental work.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 3099—3105 (1969)

The Crystal and Molecular Structure of the Sodium Salt of Xanthine

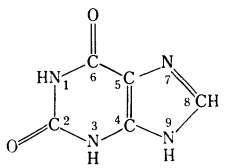
Hiroshi MIZUNO, Takaji FUJIWARA and Ken-ichi TOMITA

Faculty of Pharmaceutical Sciences, Osaka University, Toyonaka, Osaka

(Received May 6, 1969)

The crystals of sodium salt of xanthine, $C_5H_3N_4O_2Na \cdot 4H_2O$, are monoclinic with four molecules in a unit cell of dimensions; $a=7.31$, $b=19.52$, $c=7.17$ Å, $\beta=100.0°$, space group $P2_1/c$. The structure has been determined by application of the sign relationship $S(hkl)S(h'k'l') \sim S(h+h', k+k', l+l')$ from $(hk0)$ intensity data and refined by three-dimensional least-squares methods. The positions of the hydrogen atoms were determined by a three-dimensional difference Fourier analysis, and it was confirmed that deprotonation took place at the position of the imino N(3)H of the xanthine molecule. Each Na^+ cation is surrounded by six water molecules and each xanthine anion participates in ten hydrogen bonds, forming a close-packed system.

Xanthine, 2,6-dioxypurine, is well known as a



metabolic intermediate related to the common bases in nucleic acids. In man, the end product of purine metabolism is uric acid, and xanthine oxydase, an enzyme found in the liver, is capable of oxydizing xanthine to uric acid. Xanthine is a purine base which is not common in ribonucleic acid or deoxyribonucleic acid, but the deamination of guanine results in xanthine base, and this base is still able to pair with cytosine by two hydrogen bonds. Therefore the deamination of guanine by nitrous acid cannot be mutagenic, while adenine or cytosine deaminated by nitrous acid is lethal.

Its sodium salt was crystallized as the tetrahydrate from a ethanol-water solution, and this crystal structure was investigated by X-ray method. It is of particular interest to study the nature of the hydrogen bond between xanthine and water molecules, to determine the predominant resonance forms of the xanthine anion and also to investigate the environment around the sodium ion.

Experimental

The sample of the sodium salt of xanthine was purchased from the Nakarai Chemicals Ltd. (Kyoto), and recrystallized by slow evaporation of a ethanol-water solution at room temperature. The obtained crystals were in the form of colorless needles elongated along the c axis. Weissenberg photographs around the c axis demonstrated that the crystals were twins consisting of two components, in which only the a axis has different directions rotating 20.0° about the b axis, and which are united about a twin plane (100). Crystallographic data obtained from measurements of rotation, Weissenberg and precession photographs around the c axis are listed in Table 1.

Partial three-dimensional intensity data ($l=0$ to 5) with Ni-filtered Cu$K\alpha$ radiation were collected by the multiple film method using the equi-inclination Weissenberg camera. A needle-shaped crystal about 0.15×0.15 mm in cross-section was used. The crystals being twins as mentioned above, the reflection of each component was easily separable from that of the other, and the intensity was estimated by visual comparison with a caribrated scale. 1516 reflections were recorded, 1175 of which had measurable intensities. Lorentz and

TABLE 1. CRYSTAL DATA

$c=7.17\pm0.02$ Å
$\beta=100.0\pm0.5°$
$Z=4$
μ (for Cu$K\alpha$) $=18.0$ cm^{-1}
$D_m=1.64$ g/cm^3
$D_c=1.62$ g/cm^3

polarization corrections were applied, but no further corrections were made to the intensities, which were then converted to the absolute scale by means of the usual averaging process.

Structure Determination

For the reflections of appropriately large unitary structure factors (U) in centrosymmetric space groups, the sign relations

$$S(hkl)S(h'k'l') = S(h+h',\ k+k',\ l+l') \quad (1)$$

$$S(hkl) = S\{\sum_{h'k'l'} S(h'k'l')S(h+h',\ k+k',\ l+l') \quad (2)$$

are applicable, where $S(hkl)$ is the sign of $U(hkl)$.[1-3] The root-mean-square value (σ) for the unitary structure factors of this crystal was equal to

$$\sigma = \{\sum_j Z_j^2/(\sum_j Z_j)^2\}^{1/2} = 0.116$$

where Z_j is the number of electrons in the jth atom. This value seems to be suitable for the application of a direct method described by Zachariasen.[3]

A sharpened Patterson synthesis was previously calculated with the three-dimensional data. Many peaks on the Patterson sections at $W=0$ and $W=1/4$, and the two strongest reflections, (002) and (004), indicated that the xanthine anions were approximately parallel to the (001) plane. It was, therefore, to be expected that the approximate crystal structure might be revealed by the Fourier projection on (001) with only the signs of large structure factors.

For those reflections which lie within the range of $|U(hk0)|\geq 1.5\sigma=0.174$, Eq. (1) was used to determine the signs. 17 out of 132 reflections fell in this category, where the signs of two structure factors were chosen arbitrarily in order to fix the origin. The signs of remaining structure factors for $|U(hk0)|\geq 0.100$, were determined by Eq. (2). Thus the signs of 44 reflections were finally determined from Eqs. (1) and (2), but of which 7 reflections, all with the low magnitude of U, were later shown to be incorrect.

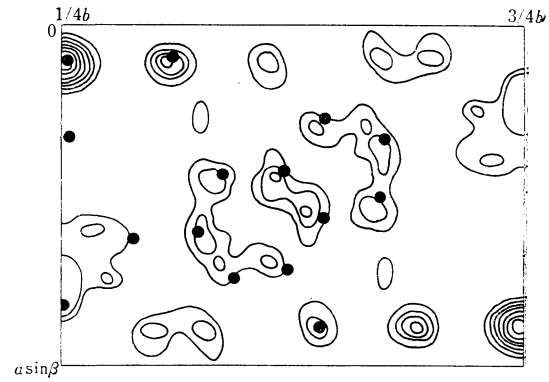

Fig. 1. First Fourier projection on (001) calculated with the signs of 44 reflections which were determined by the direct method. The black circles show the final atomic positions. One of the water oxygen atom is hidden by another one ($x=0.11$, $y=0.37$).

The first electron density projection on (001) calculated with the signs of 44 reflections is shown in Fig. 1, and there appeared significant peaks to be the purine ring atoms across a center of symmetry. Using the phases based on these peak positions, a second electron density map was calculated with all the observed ($hk0$) data, which showed the peaks of two carbonyl oxygen atoms and water oxygen atoms.

Succesive Fourier approximations by superimposing two water oxygen atoms O(5) and O(6) at $x=0.11, y=0.37$ along the c axis indicated a reasonable agreement between the observed and calculated amplitudes. At this stage the discrepancy factors, $R=\Sigma||F_o|-|F_c||/\Sigma|F_o|$, was 0.30 for ($hk0$) reflections. Because of the overlap, however, no further refinement of the structure on the projection was attempted.

An initial set of z coordinates was derived by considering the packing of the xanthine anions. Thus a three-dimensional Fourier synthesis was carried out with signs based on the phases of the xanthine ring atoms, and five peaks were newly and immediately identified; one peak was supposed to be the sodium ion in view of the peak height, and the others to be the water oxygen atoms. The second three-dimensional Fourier map calculated with the phases of all the non-hydrogen atoms showed the whole structure more clearly, and R-factor was now dropped to 0.26.

The positional parameters thus obtained, together with isotropic temperature factors, initially set to $B=3.0$ Å^2, were used as starting parameters for five cycles of block-diagonal least-squares refinement, and at the end of these cycles, the R-factor was

1) W. Cochran, *Acta Cryst.*, **5**, 65 (1952).
2) D. Sayre, *ibid.*, **5**, 60 (1952).
3) W. H. Zachariasen, *ibid.*, **5**, 69 (1952).

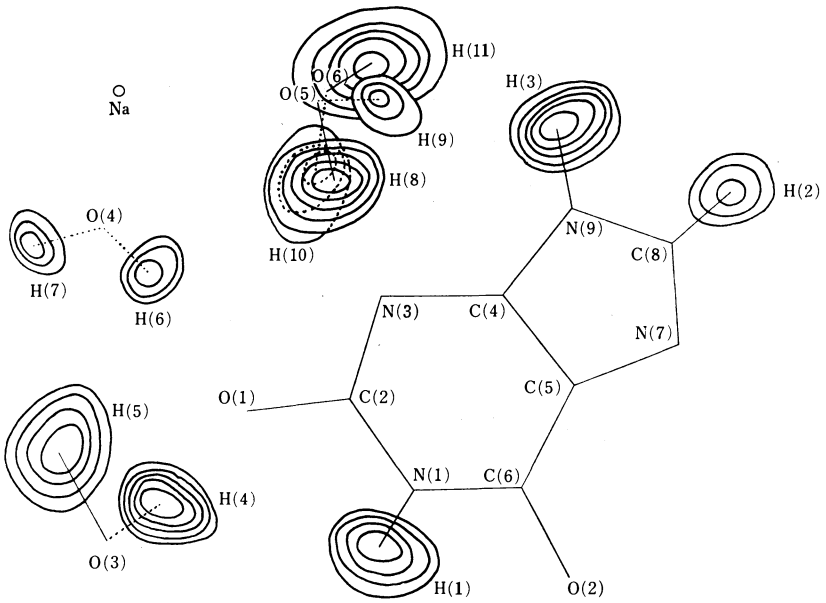

Fig. 2. A projection along the c axis of sections of a difference Fourier map for the location of hydrogen atoms. Contours are at interval of 0.1 e.Å^{-3}, starting with the 0.2 e.Å^{-3} contour.

reduced to 0.13. Anisotropic temperature factors in the form of

$$\exp[-(B_{11}h^2+B_{22}k^2+B_{33}l^2+B_{12}hk+B_{13}hl+B_{23}kl)]$$

were now used for all the non-hydrogen atoms. In the last few cycles, the contribution of the hydrogen atoms except H(7) were introduced to the calculation, and the coordinate of each hydrogen atom was located assuming the C–H, N–H and O–H distances to be 1.08, 1.03 and 1.00 Å, respectively, and also each hydrogen atom was given a temperature factor equal to the final isotropic value of the covalently bonded carbon, nitrogen or oxygen atom, but none of these parameters was refined. The R-factor at the end of the refinement was 0.11 for all observed reflections.

A three-dimensional difference Fourier synthesis was then calculated, where only H(7) was excluded for structure factor calculation. As illustrated in Fig. 2, locations of all the hydrogen atoms are clearly shown.

The final atomic coordinates and thermal parameters are listed in Tables 2 and 3. The observed and calculated structure factors are listed in Table 4. Some discrepancies between F_0 and F_c of low-order reflections may be due to absorption and

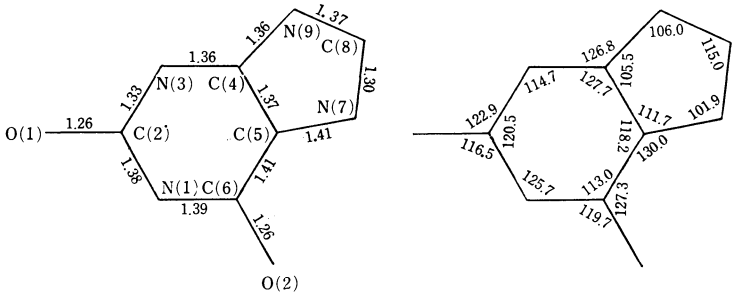

Fig. 3. Bond lengths and angles of xanthine anion.

extinction effects.

All the numerical computations were carried out on the NEAC 2203, NEAC 2206 and the NEAC 2200-model 500 Computors in the Computation Center of Osaka University. The used programs are SFFR for the three-dimensional Fourier synthesis, HBLS IV for the least-squares and DAPH for the bond lengths and angles written by Tamaichi Ashida, and the others by the authors.

Description of the Structure and Discussion

The intramolecular bond lengths and angles are listed in Table 5 and also shown in Fig. 3. The angle C(2)-N(3)-C(4)=114.7°, suggests that a hydrogen atom is not attached to N(3) in the six-membered ring, since Singh's survey[4] has shown that when an extra-annular hydrogen is attached to a nitrogen atom in a six-membered ring, the internal ring angle is 125.3°, whereas it is 116.3° when there is no hydrogen atom attached to the nitrogen atom. It may, of course, be expected that a lone pair electron of nitrogen atom gives rise to a stronger repulsion than a bonding pair. The fact that the difference Fourier map (Fig. 2) reveals no hydrogen peak at the N(3) position supports the compatibility of this empirical rule.

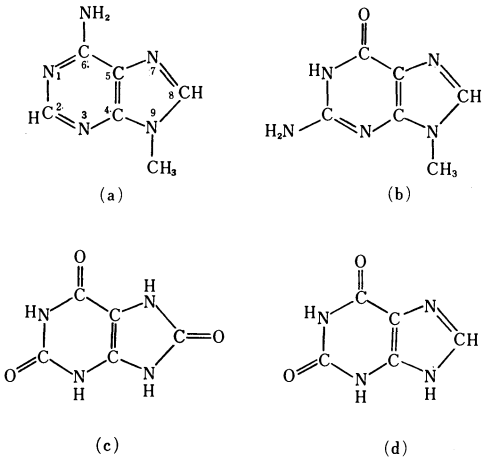

Fig. 4. Purine derivatives.

It is also probable that the reasonable position of the imidazole hydrogen atom is at the N(9) rather than at the N(7) in consideration of the hydrogen H(3) peak position on the difference Fourier map (see Fig. 2).

The C(2)-N(3) bond of 1.33 Å is in good agreement with the C(2)-N(3) bond distances of 1.322 Å found in 9-methyladenine[5] and 1.33 Å in 9-methylguanine hydrobromide;[6] however it is shorter than that of 1.382 Å found in uric acid,[7] indicating that this bond has double bond character as shown in 9-methyladenine(a) or in 9-methylguanine hydrobromide(b) rather than single bond character in uric acid(c), though the essential difference in structure between xanthine(d) and uric acid is the only atom attached to C(8), a hydrogen atom in the former and a carbonyl oxygen atom in the latter (see Fig. 4).

The C(2)-O(1) and C(6)-O(2) bond distances are both equal to 1.26 Å and are significantly longer than the standard double bond distance of 1.20 Å. These results suggest the resonance forms (I), (II) and (III) in Fig. 5 as predominant. These three resonance forms have a common feature, that is, the negatively charged O(1), O(2) or N(3) forms two or three hydrogen bonds (as seen in Fig. 6a) to the surrounding water molecules which have the induced dipolar character, suggesting that resonance forms (I), (II) and (III) contribute extra electrostatic energy to these hydrogen bonds in this crystal structure. It is of considerable interest that the nitrogen N(3) acting as hydrogen acceptor participates in two hydrogen bonds with water molecules as clearly seen in Figs. 6a and 6b.

The best plane through the xanthine ring atoms, as calculated by the least-squares method, is defined by the equation

$$0.04230x-0.18440y-0.98194z-3.39443=0.$$

Fig. 5. Resonance forms.

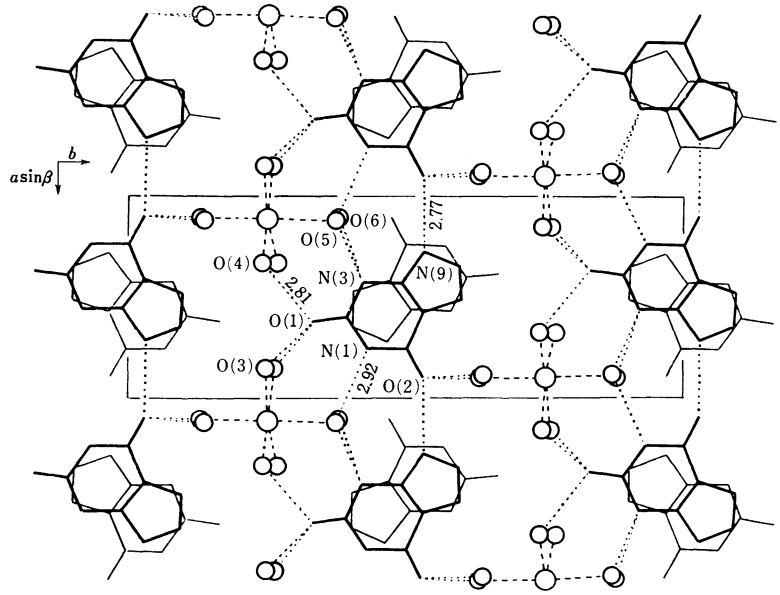

Fig. 6a. The crystal structure viewed down the *c* axis.

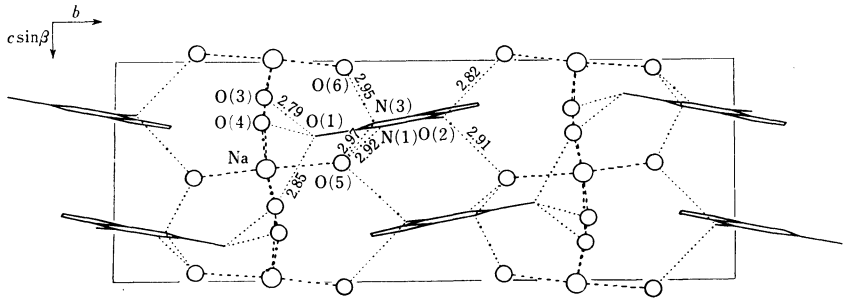

Fig. 6b. The crystal structure viewed down the *a* axis.

The average deviation of the eleven atoms from the plane is 0.01 Å which is within the errors in atomic positions. The molecular plane is inclined at an angle of 11° to the (001) plane. The van der Waals distances between adjacent molecular planes related by the center of symmetry are all nearly 3.5 Å.

A sodium ion is coordinated to six water oxygen atoms: O(3′), O(3″), O(4), O(4′), O(5) and O(6′). The O-Na-O angles range from 84.5 to 97.0°, and the Na-O distances range from 2.31 to 2.69 Å with a mean value of 2.45 Å, forming an approximately regular octahedron (see Table 6). These data are in good agreement with those of an earlier report for six-coordinate sodium compounds.[8]

The sodium-oxygen coordination polyhedrons are joined together by the shared edges O(3′)-O(3″) and O(4)-O(4′), forming a polymer-like chain parallel to the *c* axis by the continuous octahedron repeat. On the other hand, xanthine anions are stacked parallel to the *c* axis, and surrounded by these polymer-like chains.

The possible twinning operation of this compound is now presumable from its molecular arrangement in crystal as shown in Fig. 6a. The contact distances between molecules at the twinning boundary are reasonable, provided the additional *b*-glide plane perpendicular to *a**-axis is considered to be the symmetry operation of the space group $P2_1/c$.

All the water molecules may stabilize the crystal lattice in two ways, that is, by coordinating to the sodium ion as above mentioned, and by linking xanthine anion through hydrogen bonds. The lengths and arrangement of hydrogen bonds can be seen in Fig. 6 and Table 7. Seven out of the eight water hydrogen atoms form hydrogen bonds, but only the remaining hydrogen H(7) does not participate in any hydrogen bonds as occasionally seen in crystalline hydrates, for example in $MgSO_4 \cdot 4H_2O$.[9]

All the water molecules lie in the electrostatic fields of the surrounding ions; the positively charged Na^+, and the negatively charged O(1), O(2) and N(3) of xanthine anion. Therefore it seems that the orientation of each water molecule depends mainly upon the electrostatic interactions between the induced dipole of water molecule and the surrounding ions, and in this case, the hydrogen bonds are essentially electrostatic.

We wish to express our thanks to the staff of the Computation Center of Osaka University. Thanks are also due to Dr. Tamaichi Ashida for permission to use the computor programs. Finally, the authors are grateful to emeritus Prof. Tokunosuke Watanabé and Prof. Shuzo Seki for their valuable advice and discussion throughout the course of this work.

The Structure-Stability Relationship of the Metal Ion Complexes of Unsaturated Compounds. V. Stabilities of the Silver-Ion Complexes of Some *cis*-Stable Olefins

Tadashi OKUYAMA and Takayuki FUENO

Faculty of Engineering Science, Osaka University, Toyonaka, Osaka

and Junji FURUKAWA

Department of Synthetic Chemistry, Kyoto University, Sakyo-ku, Kyoto

(Received May 6, 1969)

The silver-ion complexation equilibria of a few *cis*-stable olefins have been investigated in an aqueous phase at 25°C. The *trans* isomers of β-chlorovinyl ethyl ether and 1,2-dichloroethylene were found to have greater equilibrium constants than the corresponding *cis* isomers. It was concluded that the relative stabilities of parent olefin isomers play an exclusive role determining their relative complexation abilities.

The stability of the silver ion-olefin complexes in relation to the structure of the olefins has been investigated by several groups of workers[1-9] and discussed in terms of steric, strain, and electronic effects. The electronic effect was examined from the influence of substituents on the argentation equilibria of benzene,[2b] styrene,[7] and ethylene.[8] As for the steric and strain effects, various aliphatic[1,5,6] and alicyclic olefins[3,5] as well as some alkynes[4,5] have been investigated.

Some of the above investigations include several geometrical isomer pairs of alkenes, in which the greater complexation abilities of *cis* isomers have been interpreted in terms of the effects of steric hindrance and strain relief.[1d,5,6] We have previously studied similar complexations of a variety of *cis*- and *trans*-alkenyl alkyl ethers and found that the *cis* isomers form more stable complexes with the silver ion than do the corresponding *trans* isomers.[9] It was suggested that the greater complexation abilities of the *cis* isomers be due to their relative instability at the ground state. Although the origin of this is rather ambiguous as yet, it may be conceivable that, in cases where the instability is ascribable to the steric strain of the crowded *cis* substituents, the relief of strain on complexation would be a factor responsible for the greater stability of the complexes of *cis* isomers. However, such an interpretation of the effects of geometrical isomerism seems to be biased because all the olefins treated so far have been those that are known to be more stable in the *trans* form.

The present study will treat the silver-ion complexation of a few *cis*-stable olefins with particular interest in the relative stabilities of the complexes formed from *cis* and *trans* isomers. The *trans* isomers have proved to form more stable complexes in the present cases. This finding provides a favorable counterpart to the previous interpretation and supports the concept that the ground-state stability of the olefins is a major factor governing the effect of geometrical structure of olefins on stabilities of their silver-ion complexes.

Experimental

Materials. *cis*- and *trans*-β-chlorovinyl ethyl ethers (CVE) were obtained as described previously.[10] *cis*- and *trans*-1, 2-dichloro- (DCE) and 1,2-dibromoethylenes (DBE) were purchased and distilled. Cyclohexane, toluene, silver nitrate and potassium nitrate were of the best commercial grade.

Procedure. The equilibrium constants, K, for the formation of the silver-ion complexes in the aqueous phase

$$Ag^+ + M \rightleftarrows AgM^+, \quad K = [AgM^+]/[Ag^+][M] \quad (1)$$

were measured at 25°C by the solubility method in the same manner as described previously.[7] The volumes of the olefins and the aqueous phase were 1 and 10 m*l*, respectively.

The concentrations of olefins in the aqueous phase were determined by gas chromatography after extraction with cyclohexane. Five-hour shaking of an aqueous phase (5 m*l*) with cyclohexane (1 m*l*) was sufficient to complete the extraction of an olefin.[7] Cyclohexane used here contained 2 vol% toluene as an internal standard for the gas-chromatographic determination. A Shimadzu model GC-2C gas chromatograph was used with a column packed with polyethylene glycol (for DCE and DBE) or apiezon grease L (for CVE). It was found by calibration that the half-height width method fully sufficed for linearly correlating the obtained peak area to the olefin concentration.

Results

Solubility experiments were undertaken in the dark, and during that time no appreciable side reaction was observed. The solubilities of the isomeric pairs of β-chlorovinyl ethyl ether (CVE), 1,2-dichloroethylene (DCE) and 1,2-dibromoethylene (DBE) in aqueous $AgNO_3$-KNO_3 solutions are listed in Table 1. The experiments for DBE and CVE were conducted with the mixture of isomers, and the concentrations of respective isomers were determined separately. It was confirmed that such an expedience introduced no serious error into the K-values.[11] The composition of isomers in the organic phase was assumed to be invariant during the equilibrium experiments, as the amount of the substrate transferring from the organic to the aqueous phase was only of the order of 1% of the total olefin used.

The equilibrium constants, K, were calculated by the least squares treatment of the solubility data according to the equation[7]

$$K = ([M]-[M]_0)/[Ag^+][M]_0 \quad (2)$$

where $[M]_0$ is the olefin concentration in the aqueous phase at $[Ag^+]=0$. The equilibrium leading to the formation of the 2 : 1 complex, Ag_2M^{2+}, was ignored since its contribution was immaterially small.

The equilibrium constants, K, calculated from Eq. (2) for the isomeric olefins are given in Table 2, together with the related data available in the literature. Although the K values for the disubstituted polar olefins studied here are very small, the differences between the respective geometrical isomers are certainly significant. The *trans* isomers of CVE and DCE have greater K values than their *cis* isomers (**1** and **2**). This finding is the

11) The solubilities of pure *cis*-CVE were 3.63, 4.34 and 5.06×10^{-2} mol/*l* for the silver ion concentrations of 0.00, 0.60 and 1.00 mol/*l*, respectively. These data lead to the equilibrium constant $K=0.39$ *l*/mol, which is in fair agreement with $K=0.32$ *l*/mol obtained from the experiments with the mixture of *cis*- and *trans*-CVE.

first demonstration that *trans* isomers of some α,β-disubstituted ethylenes can form more stable silver-ion complexes than the corresponding *cis* isomers. On the other hand, the K value of *trans*-DBE is comparable in magnitude with that of the corresponding *cis* isomer (**3**).

Discussion

The different abilities of geometrical isomers in forming complexes with the silver ion have already been reported for several alkenes[1d,5,6] and alkenyl alkyl ethers.[9] In all these cases, the *cis* isomers have greater equilibrium constants than the corresponding *trans* isomers, as shown in Table 2 (**4** and **5**). Such effects of the geometrical isomerism on the stabilities of the complexes have been interpreted in terms of strain effects.[1d,5,6] That is, the strain due to the group repulsions present in the *cis* isomers may be relieved on the formation of the complexes, which largely contributes to the stability of the complexes of *cis* isomers.

However, the concept of the strain relief effect is clearly inapplicable to the *cis*-stable olefins, because such a strain, if present, should be of minor importance. In fact, *cis* isomers of CVE and DCE, which were found to be more stable than the respective *trans* isomers,[12,13] have proved to form less stable complexes than do their *trans* isomers. On the other hand, all of the previous studies reporting the greater complexation abilities of *cis* isomers have been confined to the *trans*-stable olefins, where the strain may destabilize the *cis* isomers. In the case of DBE (**3**), in which both isomers are known to have nearly equal stabilities at the ground state, the K value of the *cis* isomer is only a little greater than that of the *trans* isomer. This result also accords with the expectation from the stability of the parent isomeric olefins. Thus, a more generalized idea might be that the isomers of lesser stability in the ground state lead to the more stable complexes. In other words, any structural difference between *cis* and *trans* isomers is relieved by the loosening of the olefinic double bonds on complexation, and hence the ground-state stability determines the stability of the complexes formed. In this sense, therefore, the term "stabilization effect" would be of more general use than the customary term "strain effect."

In conclusion, the relative stabilities of the silver-ion complexes of geometrical isomers are determined primarily by the relative stabilities of parent isomeric olefins. The less stable isomers, whether they are *cis* or *trans* and whatever the origin of their relative stabilities may be, have greater ability for the silver-ion complexation than their isomeric partners which are more stable.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 3109—3115 (1969)

Group Interactions in Polyelectrolytes. II. Kinetics of Alkaline Hydrolysis of Polymethyl Acrylate

Hiroshi KAWABE and Masaya YANAGITA

The Institute of Physical and Chemical Research, Yamato-machi, Saitama

(Received May 9, 1969)

The second-order rate constant of the alkaline hydrolysis of polymethyl acrylate in an aqueous acetone solution decreases as the reaction proceeds. The plot of the logarithmic term of the second-order rate equation against the reaction time is divided into four lines; this suggests that the reaction proceeds in four steps. The rate equation of the reaction can be derived by assuming that the reactivity of ester groups is electrically affected mainly by a few neighboring hydrolyzed groups. The kinetic behavior is compared with the titration data of polyacrylic acid; the sets of data can be correlated through a simple equation containg two constants, k_0, the intrinsic rate constant, and pK_0, the intrinsic ionization constant.

Kawabe and Yanagita[1] studied the kinetics of the reaction of chloromethylated polystyrene with *n*-butylamine and di-*n*-butylamine in dioxane; they found that the apparent rate constant computed by the simple second-order rate equation decreased continuosly as the reaction proceeded, and that the plot of the logarithmic term in the equation against the reaction time was divided into two straight lines. The kinetics could be expressed by the rate equation of a two-step reaction derived by assuming two distinct reactivities of chloromethyl groups, depending on their environments.

In the present study, the above procedure of plotting the logarithmic term against the time has been applied to the published kinetic data of the alkaline hydrolysis of polymethyl acrylate;[2] it has been thus revealed that the reaction in a 29% (v/v) aqueous acetone solution proceeds in four steps. The rate equation for this reaction has been derived by assuming that the reactivity of the ester group on the macromolecule is electrostatically affected mainly by a few already-hydrolyzed groups situated within relatively short distance. The derived equation has first been examined in the alkaline hydrolysis of model compounds, such as dimethyl succinate and triethyl citrate. The results obtained by the application of the equation to polymethyl acrylate has then been discussed in relation to the titration data of polyacrylic acid.

Experimental

Materials. The polyacrylic acid used for the titration was prepared by the alkaline hydrolysis of polymethyl acrylate. One hundred grams of methyl acrylate containing 3 g of benzoyl peroxide were added, drop by drop, to boiling methyl ethyl ketone over the period of an hour, and then the solution was stirred for five hours. The solution was then poured into petroleum ether to precipitate polymethyl acrylate, which was dried in a vacuum oven, dissolved in acetone, and again precipitated in water. The purified polymer was hydrolyzed with sodium hydroxide in an aqueous acetone solution according to the procedure described in the literature.[2] The dry sodium salt of polyacrylic acid was dissolved in water and converted to polyacrylic acid by passing the solution through a column of Dowex-50 (X-8) in hydrogen form.

Titration of Polyacrylic Acid. An aqueous solution of polyacrylic acid (0.05 equiv/*l*) was titrated with a 0.1N sodium hydroxide solution at 25°C; the pH of the solution was measured by means of a Beckman Model G pH meter.

Alkaline Hydrolysis of Dimethyl Succinate and Triethyl Citrate. Alkaline hydrolyses of dimethyl succinate and teiethyl citrate were carried out in water and in a 32% (v/v) aqueous ethanol solution respectively, both containing a slight excess of sodium hydroxide. During the course of this reaction, the temperature was kept constant to ±0.1°C. The rate of hydrolysis was followed, according to the usual method, by the removal of aliqots at appropriate intervals of time, pouring them into water containing an excess of hydrochloric acid, and titrating them with 0.1N sodium hydroxide.

When a large excess of sodium hydroxide (about ten times as much as the moles of the ester group) was used as a hydrolyzing agent, it interfered with the precise determination of the percentage of hydrolysis in the usual method. Sodium ions in the solution, however, could be effectively removed by the use of Dowex-50. It was ascertained by preliminary tests that sodium ions in an aqueous solution containing succinic acid or citric acid, and also excess sodium hydroxide, could be removed practically at once and completely

1) H. Kawabe and M. Yanagita, This Bulletin, **41**, 1518 (1968).

2) I. Sakurada, Y. Sakaguchi and S. Fukui, *Kobunshi Kagaku (Chem. High Polymers Japan)*, **13**, 355, 361, 408 (1956).

within 45 sec by stirring the solution in the presence of Dowex-50 (X-8, 50—100 mesh) in hydrogen form, and also that the esters were not hydrolyzed, at least during the first 10 min. In the kinetic runs in which a large excess sodium hydroxide was used, portions of the reaction mixture were poured into water containing Dowex-50, which had previously been half neutralized, and the mixture was stirred for a few minutes. After the resin had then been removed, the solution was titrated with 0.1N sodium hydroxide. This method was tentatively applied to a run in which accurate determination by the usual method was possible; both methods produced the same results.

Rate Equations

The rate equation for a polymer reaction which proceeds in two steps has already been derived, in a previous paper,[1] by assuming two distinct reactivities of reactive groups, depending on their environments, and by rearranging the polymer reaction for a reaction between a low-molecular compound with two reactive groups and a reagent. If it is assumed, in a polymer reaction which proceeds in more than two steps, that any step of the reaction is controlled by two reactivities, the rate equation of the reaction can be similarly derived by considering the reaction of a low-molecular compound with a few reactive groups and a reagent, as is illustrated below:

$$\underset{(\mu_{n-1})}{X_{n-1}Y_{\sigma-(n-1)}} \xrightarrow{k_n} \underset{(\mu_n)}{X_nY_{\sigma-n}} \xrightarrow{k_{n+1}} \underset{(\mu_{n+1})}{X_{n+1}Y_{\sigma-(n+1)}}$$

where X represents a changed group in a compound, and Y, an unchanged one; the suffix indicates the number of the group, in which σ is the total number of the group. The relationship among the concentrations are:

$$\mu_0 = M - x_1 = (b/\sigma) - x_1 \quad (1)$$

$$\mu_n = x_n - x_{n+1} \quad (2)$$

where M is the initial concentration of the compound; μ_0 and μ_n, the concentrations of the unchanged compound and the partially-changed one, n groups of which have been changed at time t; b, the initial concentration of the group, and x_1 and x_n, the concentrations of the first and nth changed groups respectively at time t.

By assuming the bimolecular mechanism for the individual reaction of each group, the over-all rate of the above reaction with σ rate constants is given by:

$$dx/dt = \sum_{n=1}^{\sigma} dx_n/dt = (a-x)\sum_{n=1}^{\sigma}(\sigma-n+1)k_n\mu_{n-1} \quad (3)$$

where a is the initial concentration of a reagent and where x is the change in the concentration of a reagent or the concentration of the changed group at time t; k_n is the rate constant of the elementary reaction, *i.e.*, the reaction of the nth group. When it is assumed in any step of the reaction that its main part is practically composed of two elementary reactions at most, the rate can be formulated for the nth step by introducing $\mu_{n-2}\simeq 0$ and $\mu_{n+1}\simeq 0$ into Eq. (3) and by then combining Eq. (3) with Eq. (4):

$$x_{n-1} \simeq b/\sigma, \quad x_n \simeq x - b(n-1)/\sigma \quad (4)$$

Thus, Eq. (3) becomes:

$$dx/dt = (a-x)[\{(\sigma-n+1)nk_n-(\sigma-n)(n-1)k_{n+1}\}b/\sigma - \{(\sigma-n+1)k_n-(\sigma-n)k_{n+1}\}x] \quad (5)$$

Upon integration, Eq. (5) yields:

$$k_n = \frac{\ln[(1-\alpha)/(1-A\beta/B)] - \ln[(1-\chi_{n-1}/a)/(1-A\chi_{n-1}/Bb)]}{(Aa-Bb)(t-\tau_{n-1})} \quad (6)$$

where τ_{n-1} is the time and χ_{n-1} is the value of x at a point where $x_{n-1}\simeq b/\sigma$; $\alpha(=x/a)$ is a fractional conversion of a reagent, and $\beta(=x/b)$ is that of the reactive group. A and B are:

$$\begin{cases} A = (\sigma-n+1) - (\sigma-n)k_{n+1}/k_n \\ B = [(\sigma-n+1)n - (\sigma-n)(n-1)k_{n+1}/k_n]/\sigma \end{cases}$$

When $\sigma=2$, k_1 and k_2 are given as follows:

$$k_1 = \frac{1}{[(2-k_2/k_1)a-b]} \ln \frac{1-\alpha}{1-(2-k_2/k_1)\beta} \quad (7)$$

$$k_2 = \frac{1}{(a-b)(t-\tau_1)}\left(\ln\frac{1-\alpha}{1-\beta} - \ln\frac{1-\chi_1/a}{1-\chi_1/b}\right) \quad (8)$$

These equations are the same as those which have been derived directly for the two-step reaction in the previous paper,[1] in which the over-all course of the reaction with a large excess of reagent was also expressed by the equation:

$$\beta = 1 - \frac{k_1-k_2}{2k_1-k_2}e^{-2k_1at} - \frac{k_1}{2k_1-k_2}e^{-k_2at} \quad (9)$$

When $\sigma=3$, Eq. (6) also yields three equations to determine k_1, k_2, and k_3. In the case with a large excess of reagent, the over-all kinetics can be expressed by a combination of two simple rate equations, each of which is derived on the assumption that the rate is cotrolled mainly by two rate constants in some range of β. If the reaction in the range of β, *i.e.*, 0—2/3, is assumed to be controlled by k_1 and k_2, Eq. (3) is simplified to:

$$dx/dt = a[k_1b - (3k_1-4k_2)x_1 - 2k_2x] \quad (10)$$

and x_1 is given by:

$$x_1 = -(1-e^{-3k_1at})b/3 \quad (11)$$

Upon integration, Eq. (10) becomes:

$$\beta = \frac{2}{3} - \frac{(3k_1-4k_2)}{3(3k_1-2k_2)}e^{-3ak_1t} - \frac{k_1}{3k_1-2k_2}e^{-2ak_2t} \quad (12)$$

Similarly, in the 1/3—1 range of β, the following equations can be derived:

$$dx/dt = a[(2k_2+k_3)b/3 - 2(k_2-k_3)x_2 - k_3x] \quad (13)$$

$$x_2 = (1-e^{-2k_2a(t-t_{1/3})})b/3 \quad (14)$$

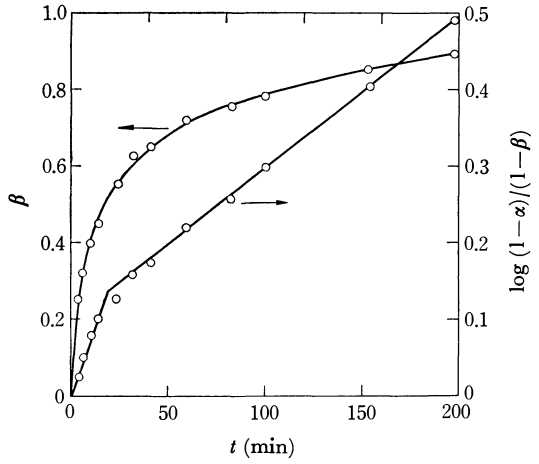

Fig. 1. Alkaline hydrolysis of dimethyl succinate in water at 10°C. (Run A)

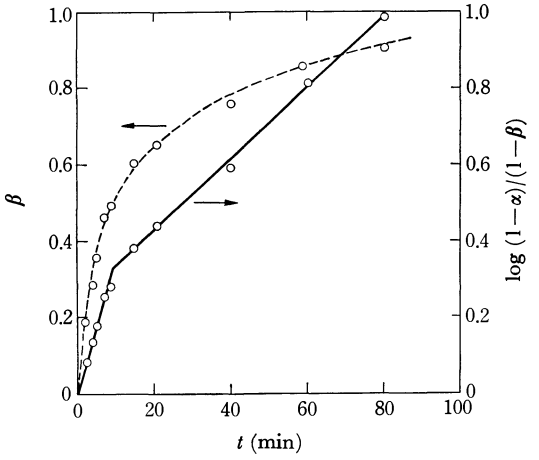

Fig. 2. Alkaline hydrolysis of dimethyl succinate in water containing a large excess of sodium hydroxide at 4.5°C. (Run B)

Upon integration, Eq. (13) then yields:

$$\beta = 1 - \frac{2(k_2-k_3)}{3(2k_2-k_3)}e^{-2k_2a(t-t_{1/3})} - \frac{2k_2}{3(2k_2-k_3)}e^{-k_3a(t-t_{1/3})} \quad (15)$$

where $t_{1/3}$ is the time, when β is 1/3.

Results and Discussion

Alkaline Hydrolysis of Dimethyl Succinate. The results obtained in the alkaline hydrolysis of dimethyl succinate in an aqueous solution are shown in Figs. 1 and 2. The apparent rate constant, k_{app}, computed by Eq. (16) decreases as the reaction proceeds:

$$k_{app} = \frac{1}{(a-b)t}\ln\frac{b(a-x)}{a(b-x)} = \frac{2.303}{(a-b)t}\log\frac{1-\alpha}{1-\beta} \quad (16)$$

Table 1. Rate constants of alkaline hydrolysis of dimethyl succinate

Run	Temp. °C	Concn. (10^{-2} mol/l) a	Concn. (10^{-2} mol/l) b	k_1 l/mol min	k_2 l/mol min	$\log(k_1/k_2)$
A	10	1.93	1.41	4.92	0.880	0.75
B	4.5	3.38	0.26	3.63	0.684	0.73

where a and b are the initial concentrations of sodium hydroxide and the ester group, and where α and β are their fractional conversions, respectively. Plots of the logarithmic term of Eq. (16) against the time, which are shown in the figures, consist of two straight lines which intersect nearly at $\beta=0.5$, in accordance with the two-step reaction mechanism. The rate constants calculated by means of Eqs. (7) and (8) are shown in Table 1. Since a large excess of sodium hydroxide was used for the run B, the over-all course of reaction can be expressed by Eq. (9), using k_1 and k_2 values listed in Table 1. The calculated values are in good agreement with the observed values, as may be seen in Fig. 2, where the dotted line and the circles show the calculated and the observed values respectively.

Since the numerical difference between k_1 and k_2 is based on the electrostatic effect of the first hydrolyzed group in the reaction of the second group, the electrostatic free energy of activation, $\Delta F_{el}^{\neq}$, is given by:

$$\Delta F_{el}^{\neq} = 2.303\boldsymbol{R}T\log(k_1/k_2) \quad (17)$$

where T is the temperature of the reaction. On the other hand, the electrostatic free energy of ionization, ΔF_{el}^{i}, of succinic acid is given by:

$$\Delta F_{el}^{i} = 2.303\boldsymbol{R}T'(pK_2-pK_1-\log 4) \quad (18)$$

$$\Delta F_{el}^{i} = \boldsymbol{N}e^2/Dr \quad (19)$$

where T' is the temperature of the titration; pK_1 and pK_2 are negative logalithms of the ionization constants at the first and second ionization steps respectively; D is the effective dielectric constant, and r is the distance between the two ionizable groups. If the two electrostatic free energies are equal, a simple correlation between the titration and kinetic data may be established; the distance between the groups may also be estimated on the basis of the kinetic data by means of the above equations. On the basis of the dissociation constant data,[3] the pK_1 and pK_2 values of succinic acid at 10°C are found to be 4.246 and 5.649 respectively. By the use of Eqs. (17) and (18), $\log(k_1/k_2)$ is calculated to be 0.80; this is quite close to the kinetically-obtained values, which are given in Table 1. Furthermore, if D is assumed to

( ) shows less accurate measurement.

be 81, a reasonable value of 4.4 Å can be calculated for r by the use of Eqs. (17) and (19).

Alkaline Hydrolysis of Triethyl Citrate. The alkaline hydrolysis of triethyl citrate in a 32% aqueous ethanol solution was carried out at 10°C; an example of the kinetic runs is graphically shown in Fig. 3. The plot of the logarithmic term of Eq. (16) against the time is divided into three lines, which intersect nearly at $\beta=1/3$ and $\beta=2/3$; this indicates that the reaction proceeds in three steps. The experimental results are summarized in Table 2, where k_n' is the approximate value of the rate constant of the nth step, estimated by:

$$k_n' = [2.303/(a-b)]\times[\Delta\log\{(1-\alpha)/(1-\beta)\}/\Delta t] \quad (20)$$

The corrected value of the rate constant, k_n, has been calculated according to Eq. (6), assuming $\sigma=3$. An average value of k_2, 6.05×10^{-1} l/mol·min, is used for the calculation of k_1.

The reaction was also carried our by using a large excess of sodium hydroxide and the observed values were compared with those calculated by means of Eqs. (12) and (15). In Fig. 4 the circles represent the observed values, while the full and dotted lines are obtained by means of Eqs. (12) and

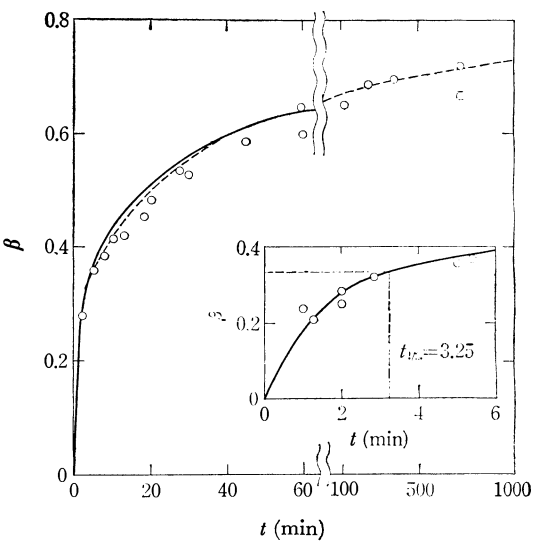

Fig. 4. Alkaline hydrolysis of triethyl citrate in 32% aqueous ethanol solution containing a large excess of sodium hydroxide at 10°C. ($a=3.38\times10^{-2}$, $b=3.04\times10^{-3}$ mol/l)

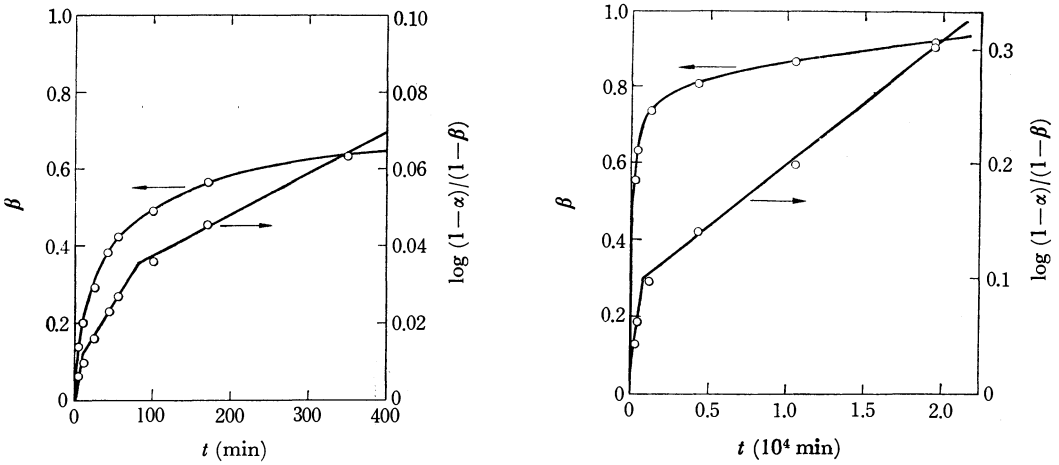

Fig. 5. Alkaline hydrolysis of polymethyl acrylate in 29% aqueous acetone solution at 55°C.[2] ($a=8.22\times10^{-2}$, $b=7.41\times10^{-2}$ mol/l)

(15) respectively, where the rate constants are: $k_1=7.93$, $k_2=6.05\times10^{-1}$, and $k_3=6.46\times10^{-3}$ l/mol·min. The fairly good agreement between the two values in the figure may show the correctness of the application of the rate equations to a reaction which proceeds in more than two steps.

Application of the Rate Equations to the Alkaline Hydrolysis of Polymethyl Acrylate. When an ester of polymeric acid is hydrolyzed in an alkaline solution, the apparent rate constant computed by Eq. (16) decreases as the reaction proceeds[2,4] as a result of the electrostatic effect of the hydrolyzed groups fixed on the macromolecule. If the reactivity of the ester group is mainly affected by a few hydrolyzed groups situated a relatively short distance apart, the k_n' given by Eq. (20) will remain almost constant over a relatively wide range, forming a step of the reaction, because it is expected that the environment of the reactive group will remain unchanged for some time and that the reaction will proceed discontinuously.

The value of $\log[(1-\alpha)/(1-\beta)]$, calculated on the basis of the kinetic data of the alkaline hydrolysis of polymethyl acrylate[2] in a 29% aqueous acetone solution, are plotted aginst the reaction time in Fig. 5. The four straight lines in this figure, which intersect nearly at $\beta=1/4$, 2/4, and 3/4, suggest that the reaction proceeds in four steps. The corresponding four rate constants have been calculated by Eq. (6), assuming $\sigma=4$. The results are summarized in Table 3, where k_n' is the approximate value of the rate constant estimated by means of Eq. (20).

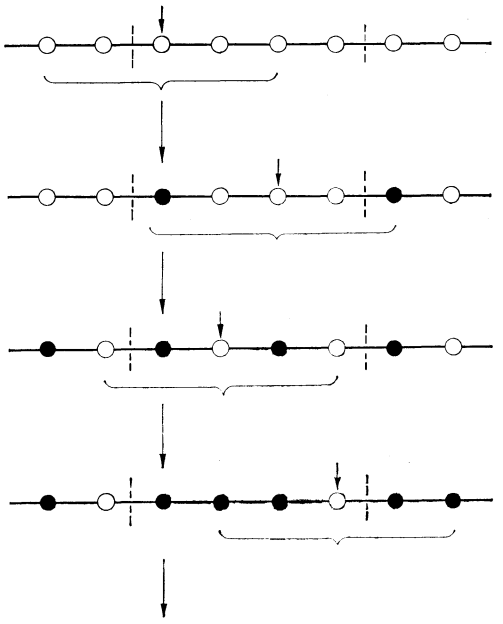

Fig. 6. Illustration of the four-step hydrolysis of polymethyl acrylate.

Table 3. Rate constnts of alkaline hydrolysis of polymethyl acrylate

n	k_n' l/mol min	k_n l/mol min	$\log(k_0/k_n)$
1	3.99×10^{-1}	8.02×10^{-1}	0.405
2	1.40×10^{-1}	1.66×10^{-1}	1.09
3	3.07×10^{-2}	4.04×10^{-2}	1.70
4	3.31×10^{-3}	3.31×10^{-3}	2.79

If it is assumed that the hydrolysis of the ester group is mainly affected by the electrical charge of the first and second neighboring groups, the electrical environment of the reactive group is considered to change in the four steps illustrated in Fig. 6, where the white and black circles represent ester and hydrolyzed groups respectively and where

4) A. Katchalsky and J. Feitelson, *J. Polymer Sci.*, **13**, 385 (1954).

the arrows indicate reacting groups. The electrostatic free energy of the activation of the nth reaction is given by:

$$(\Delta F_{el}^{*})_n = 2.303\boldsymbol{R}T\log(k_0/k_n) \quad (21)$$

where k_0 is the intrinsic rate constant. Since this energy is also given, on the basis of the above assumption, by summing up that shown in Eq. (19), the following relation is obtained:

$$\log(k_0/k_n) = (\boldsymbol{N}e^2/2.303\boldsymbol{R}TD)\sum_i(z_i/\bar{r}_i) \quad (22)$$

where z_i is the number of the electrical charge in the ith group apart from the reacting group (z_i= 0, 1 or 2, i=1 and 2) and where $\bar{r}_i$ is the average distance between the reacting group and the ith group, which is defined by:

$$1/\bar{r}_i = \sum_j(X_{i,j}/r_{i,j}) \quad (23)$$

where j is related to the steric configuration of the ith group and where X is the mole fraction ($\sum_j X_{i,j}$= 1). On the basis of the assumption illustrated in Fig. 6, three equations can be obtained:

$$\begin{cases} \log(k_0/k_2) = A(1/\bar{r}_2) \\ \log(k_0/k_3) = A(1/\bar{r}_1) \\ \log(k_0/k_4) = A(1/\bar{r}_1+1/\bar{r}_2) \end{cases}$$

where $A=2\boldsymbol{N}e^2/2.303\boldsymbol{R}TD=5.53$ (T=328, D= 80). By using the value of the rate constant in Table 3, the equations are solved to give:

$\bar{r}_1$=3.23 Å, r_2 = 5.07 Å, k_0 = 2.04 l/mol min

As the alkaline hydrolysis of polymethyl acrylate proceeds, the polymer chain stretches as a result of the charges formed on the polymer; the partly-hydrolyzed polymer may exhibit a planar zigzag structure, at least in the vicinity of reacting group. On the basis of the above assumption, two kinds of j (in Eq. (23)) may be defined; firstly, j=1, when both groups are situated sterically on the same side of the plane of zigzag, and secondly, j=2, on the opposite side. Then $X_{1,2}=1-X_{1,1}$. By introducing the two values $r_{1,1}$=2.6Å and $r_{1,2}$=4.3Å, which are estimated on the basis of the length and angles of the bonds, and the kinetically-determined value, $\bar{r}_1$=3.25Å, into Eq. (23), $X_{1,1}$ is found to be 0.5_0; this suggests that an atactic polymethyl acrylate exhibits a sterically random struture.

The relation given in Eq. (18) may be generalized in the formula given by Eq. (24) provided that a polybasic acid with σ carboxylic acid groups ionized in σ steps:

$$(\Delta F_{el}^{i})_n = 2.303\boldsymbol{R}T'[\mathrm{p}K'-\mathrm{p}K_0-\log(n/\sigma-n+1)] \quad (24)$$

where $(\Delta F_{el}^{i})n$ represents the electrostatic free energy at the nth step of ionization; K_0, the intrinsic dissociation constant of the acidic group, and K_n', the dissociation constant of the group at the nth step. If it is assumed, by analogy to the alkaline hydrolysis of polymethyl acrylate, that the ionization of polyacrylic acid is mainly affected by a few ionized groups on the polymer, $(\Delta F_{el}^{i})n$ is also given by $(\boldsymbol{N}e^2/D)\sum_i(z_i/\bar{r}_i)$. The comparison of Eq. (21) with Eq. (24) leads to the relation:

$$\log(k_0/k_n)=(T'/T)[\mathrm{p}K_n'-\mathrm{p}K_0-\log\{n/(\sigma-n+1)\}] \quad (25)$$

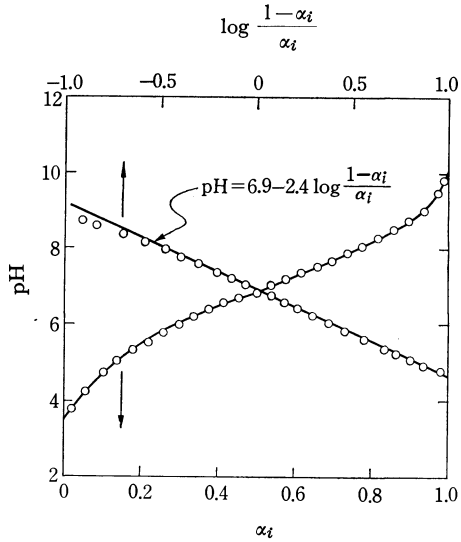

Fig. 7. Titration of polyacrylic acid with sodium hydroxide in the absence of salt.

TABLE 4. $\mathrm{p}K_0$ OF POLYACRYLIC ACID CALCULATED BY THE KINETIC DATA

n	$\mathrm{p}K_n'$	$\log[n/(5-n)]$	$(T/T')\log(k_0/k_n)$	$\mathrm{p}K_0$
2	6.40	−0.18	1.20	5.38
3	7.39	0.18	1.87	5.34
4	8.61	0.60	3.07	4.93

An aqueous solution of polyacrylic acid was titrated with a sodium hydroxide solution in the absence of added salt; the titrated data are represented in Fig. 7, in which the straight line represents the modified Henderson-Hasselbach relation,[5] $\mathrm{pH}=\mathrm{p}K_a-n'\log[(1-\alpha_i)/\alpha_i]$, where α_i is the degree of ionization. These data are in accordance with those given by Gregor and Frederic.[6] By assuming a four-step ionization for polyacrylic acid, $\mathrm{p}K_0$ may be estimated by using Eq. (25) in terms of the kinetic data. The results of the calculation are given in Table 4, where the pH values at α_i=3/8, 5/8, and 7/8 are used as the $\mathrm{p}K_n'$ values, because $\mathrm{p}K_n'$ is, by definition, equal to pH at the half-ionization point in each ionization step.

The fairly good constancy of the calculated value of $\mathrm{p}K_0$ suggests that both the alkaline hydrolysis of

5) A. Katchalsky and P. Spitnik, *J. Polymer Sci.*, **2**, 432 (1947).

6) H. P. Gregor and M. Frederic, *ibid.*, **32**, 451 (1957).

polymethyl acrylate in an aqueous solution and the ionization of polyacrylic acid are controlled by the same electrostatic effect of the charged group on the polymer, and that the ionization of polyacrylic acid can be explained approximately in terms of the four-step ionization concept.

The authors wish to express their thanks to Mr. T. Katayama for his helpful assistance in carrying out the measurements.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 3115—3118 (1969)

Measurement of Negative Ions Formed by Electron Impact. V. Negative Ion Mass Spectra and Ionization Efficiency Curves of Negative Ions of *m/e* 16, 25 and 41 from Tetrahydrofuran

Satoru TSUDA, Akira YOKOHATA and Michihiro KAWAI

Department of Chemistry, Faculty of Engineering, Hiroshima University, Senda-machi, Hiroshima

(Received May 19, 1969)

The negative ion mass spectra of tetrahydrofuran, with an emphasis on their relative abundances to the positive ions under 80 eV and 40 eV electron energies, and the ionization efficiency (IE) curves of *m/e* 16(O^-), *m/e* 25(C_2H^-) and *m/e* 41(C_2HO^-) ions to the extent of 40 eV electron energies were measured. The electron impacts of 80 eV and 40 eV gave almost the same distribution of *m/e* for negative ion mass spectra. The relatively strong peaks were observed at *m/e* 24(C_2^-) ions for 80 eV and *m/e* 14(CH_2^-) ions for 40 eV, besides the commonly strong peaks of *m/e* 25(C_2H^-), *m/e* 16(O^-) and *m/e* 41(C_2HO^-) ions. The comparison of the yield of C_2H^- ions with that of $C_3H_6^+$ gave the values 9.4×10^3 and 2.7×10^4 for $C_3H_6^+/C_2H^-$ at 80 eV and 40 eV electron energies, respectively. The reaction schemes expected to occur at each onset observed in the IE curves were also discussed. It is of interest to note that C_2H^- ions are not obtained in the range of low energy of electrons, but become observable at ~23.5 eV.

Recently, several studies have been reported on the measurement of negative ion mass spectra by the electron impact method.[1-6] However, they were made for a limited number of compounds, and data for the ionization efficiency curves of negative ions are very limited.[7-9] The role of negative ions is attracting increasing attention in the field of radiation chemistry. Compounds containing oxygen atom are of special interest. Warman,[10] Rzad[11] and Henz[12] have pointed out the occurrence of the negative ion-molecule reactions containing O^- ions.

This work was extended to tetrahydrofuran (C_4H_8O). Recently, the importance[13] of negative ions was suggested on the radiolysis of tetrahydrofuran-nitrous oxide system, but we haven't any informations about negative ions from tetrahydrofuran. In this paper negative ion mass spectra from tetrahydrofuran, with emphasis on their relative abundances to the positive ions, and the ionization efficiency (IE) curves of *m/e* 16 (O^-), *m/e* 25 (C_2H^-) and *m/e* 41 (C_2HO^-) ions are reported. There seem to be few papers so far on this subject.

Experimentals

Experiments were performed on a Hitachi RMU-6D mass spectrometer equipped with T-2M ion source having a rhenium filament. The ion detection circuit consisted of a ten stage electron multiplier and of a Faraday collector. The experimental condition was as follows: total emission=20 μA, accelerating voltage =3.6 kV and electron multiplier voltage=2.5 kV. The correction method of electron energy scale was the same as that used previously.[14] The sample was of reagent grade.

Results and Discussion

Negative Ion Mass Spectra. Table 1 shows the relative abundances of negative ions at 80 eV and 40 eV electron energies. The electron impacts of 80 eV and 40 eV gave almost the same distribution of *m/e* for negative ion mass spectra. The spectra obtained are shown as follows; *m/e* 12 (C^-), *m/e* 13 (CH^-), *m/e* 14 (CH_2^-), *m/e* 15 (CH_3^-), *m/e* 16 (O^-), *m/e* 17 (OH^-), *m/e* 24 (C_2^-), *m/e* 25 (C_2H^-), *m/e* 26 ($C_2H_2^-$), *m/e* 29 ($C_2H_5^-$), *m/e* 36 (C_3^-), *m/e* 37 (C_3H^-), *m/e* 38 ($C_3H_2^-$), *m/e* 40 (C_2O^-),*1 *m/e* 41 (C_2HO^-),*1 *m/e* 42 ($C_2H_2O^-$) and *m/e* 43 ($C_2H_3O^-$), in which parent ion ($C_4H_8O^-$) was not detected. Since their data were taken at a pressure of 10^{-6} mmHg in the source, the possibility of ions induced by ion-molecule reactions would be ruled out.

Table 1. Relative abundances of negative ions (normalized to $[C_2H^-]=100$)

m/e	Probable negative ion	Relative abundances 80 eV	40 eV
12	C	3.0	1.0
13	CH	14.8	15.0
14	CH_2	10.9	28.3
15	CH_3	trace	—
16	O	55.5	63.4
17	OH	4.2	12.7
24	C_2	29.9	8.4
25	C_2H	100.0	100.0
26	C_2H_2	2.4	4.3
29	C_2H_5	0.7	2.3
36	C_3	8.8	3.3
37	C_3H	4.5	3.3
38	C_3H_2	1.9	8.3
40	C_2O	6.6	14.0
41	C_2HO	27.7	86.7
42	C_2H_2O	trace	2.3
43	C_2H_3O	5.39	21.7

The relatively strong peaks were observed at *m/e* 24 (C_2^-) ions for 80 eV and *m/e* 14 (CH_2^-) ions for 40 eV, besides the commonly strong peaks of *m/e* 25 (C_2H^-), *m/e* 16 (O^-) and *m/e* 41 (C_2HO^-) ions.

The reason for the absence of fragment ions such as $x=4$ at CH_x^-, $x=3$, 4 and 6 at $C_2H_x^-$, $x=3$—8 at $C_3H_x^-$, $y=4$ at C_y^-, $z=1$, 3 and 4 at C_2O^-, $u=1$—4 at CH_uO^-, $u=4$ at $C_2H_uO^-$, $u=1$—6 at $C_3H_uO^-$, and $u=1$—8 at $C_4H_uO^-$ is not well known. As described by MacNeil and Thynne,[15] however, they may be explained from the size, symmetry and bonding of the molecule, or the electron affinity of each radical. Ferguson *et al.*[16] reported the geometrical considerations for

△ *m/e* 41 (C_2HO^-)

negative ion processes but their discussions are only made for a few simple molecules.

The most intense peak was observed at C_2H^- ions. The situation is quite similar to acetylene, ethane, *n*-butane and *n*-butyl alcohol.[1] This finding seems to show that C_2H^- ion is relatively stable and its electron affinity is relatively high.

A relatively large change in their relative abundances with electron energies (80→40 eV) was found at C^-, CH_2^-, OH^-, C_2^-, $C_2H_5^-$, C_3^-, $C_3H_2^-$, C_2HO^- and $C_2H_3O^-$ ions. This would be interpreted by electron energy dependency of cross section of the reaction (ion pair formation) which governs the formation of each ion.

Figure 1 shows the negative ions mass spectra at 80 eV and 40 eV electron energies, in relation to the positive ion mass spectra.

The comparison of the yield of C_2H^- ions with that of $C_3H_6^+$ ions (the most intense peak among the positive ions) gave $C_3H_6^+/C_2H^- \simeq 9.4\times10^3$ and 2.7×10^4 at 80 eV and 40 eV electron energies, respectively.

IE Curves. Figure 2 shows the IE curves of O^-, C_2H^- and C_2HO^- ions to the extent of 40 eV.

O^- Ions. It can be understood that three processes contribute to their formation. The first process appears at ~5.8 eV, the second process at ~7.7 eV*[2] and the third process at ~20.9 eV. The shape of IE curves suggests the dissociative capture process and ion pair formation.

The onset of ~5.8 eV would be interpreted with reaction (1), because it gives a reasonable value of ~3.64 eV[17] for D(RC–O),*[3] by combining 5.8 eV with EA(O)=1.47 eV.[18]

$$C_4H_8O + e^- \rightarrow C_4H_8 + O^- \quad (1)$$

Then, $\Delta H_f(C_4H_8O) = -2.2$ eV[19] and $\Delta H_f(O^-) = 1.09$ eV[20] result in $\Delta H_f(C_4H_8) \simeq 2.51$ eV.*[4]

For the second and third processes, the following reactions may be assigned.

$$C_4H_8O + e^- \rightarrow C_4H_8^* + O^- \quad (2)$$

$$C_4H_8O + e^- \rightarrow C_4H_7 + H + O^- \quad (3)$$

$$C_4H_8O + e^- \rightarrow C_4H_7^+ + H + O^- + e^- \quad (4)$$

However, the appearance potential (~5.8 eV) of reaction (1) and C–H bond energy (4.3 eV[15]) would give a value of ~10.1 eV for the appearance of reaction (3) which is inconsistent with ~7.7 eV. Thus, reaction (3) is excluded. Although speculative because of unknown value of C_4H_8,* reaction (2) appears to fit the second process.

On the other hand, the formation of reaction (4) requires a higher energy than reaction (3)—energy to be required for at least ionizing C_4H_7. The appearance potential of ~20.9 eV gives $IP(C_4H_7) \approx$ 10.8 eV, which seems a little too large to be accepted.[21] However, a small allowance of the kinetic energy of fragment ions at AP≈20.9 eV acts for $IP(C_4H_7)$ toward its decrement. Hence, the assignment of reaction (4) for the third process would be reasonable.

C_2H^- Ions. It is characteristic that C_2H^- ions are not obtained in the range of low energy and become observable at electron energy of ~23.5 eV. Probably, ion pair formation would responsible for this onset value.

C_2HO^- Ions. These ions show the typical dissociative electron capture process in the range of electron energies from ~6.2 to ~10 eV. Appearance potential of ~21.9 eV seems to correspond to ion pair formation.

For each onset value of these ions the reactions (5), (6) and (7) may be expected.*[5] However, their exact determination is difficult, because of difficulty of the assignment of ΔH_f values which is due to the unknown structure of negative ions and radicals produced.

For C_2H^- ions;

$$C_4H_8O + e^- \rightarrow C_2H^- + C_2H_4O^+ + H_2 + H + e^- \quad (5)$$

*2 Since the tailing due to the 1st process might be overlapped with the appearance of the 2nd process, the exact determination of appearance potential of the 2nd process is difficult. In this work, the minimum values in the IE curves have been discussed as by Schulz (G. J. Schulz, *Phys. Rev.*, **113**, 816 (1959)).

19) R. C. Cass, S. E. Fletcher, C. T. Moltimer, H. D. Springall and C. T. White, *J. Chem. Soc.*, **1958**, 1406.

20) S. Tsuda, A. Yokohata and M. Kawai, to be published.

*4 The structure of C_4H_8 shown in reaction (1) is not well known. It is probably in the form of tetramethylene.

21) R. R. Bernecker and F. A. Long, *J. Phys. Chem.*, **65**, 1565 (1961).

*5 There are other possibilities too.

For C_2HO^- ions;

$$C_4H_8O + e^- \rightarrow C_2HO^- + C_2H_5 + H_2 \quad (6)$$

$$\rightarrow C_2HO^- + C_2H_4^+ + H + H_2 + e^- \quad (7)$$

It should be emphasized that the main negative ionic species to be considered on the radiolysis of tetrahydrofuran are not parent ions but *m/e* 25 (C_2H^-), *m/e* 41 (C_2HO^-) and *m/e* 16 (O^-) ions.

The Electronic Structures of Glycine in the Isolated State and in Water

Akira IMAMURA, Hiroko FUJITA and Chikayoshi NAGATA

Biophysics Division, National Cancer Center Research Institute, Tsukiji, Chuo-ku, Tokyo

(Received May 20, 1969)

The electronic structures of glycine have been calculated for the dipolar-ion form and the neutral form by means of the CNDO method. The relative stability of both the dipolar-ion form and the neutral form in the gas state was reproduced by our calculation. The geometry of the glycine was also reproduced by the CNDO method, indicating the validity of our calculation. In addition, the relative stability of the two tautomeric forms of glycine was proved to be independent of its geometrical modifications. The experimental fact that the dipolar-ion form is more stable than the neutral form in an aqueous solution was well explained by the calculation of the interaction energy between the solute and the solvent.

Glycine is the simplest α-amino acid and constitutes the backbone of the protein, namely, polypeptide. Therefore, the electronic structure of glycine is of interest since the general features of the electronic structures of the amino acid and the backbone of protein can be derived from that of glycine.

Glycine is well known to exist as a dipolar ion in water and crystal, and, on the other hand, to exist in the neutral form in the isolated state.[1] Therefore, the interaction between glycine and water makes the dipolar-ion form more stable than the neutral form.

The electronic structures of various α-amino acids have already been calculated by Del Re's method;[2] a good parallelism between the electron densities of the proton and the NMR chemical shift[3] was found. Moreover, the dissociation constants of α-amino acids were found to be correlated with the calculated energy differences between the dissociated and non-dissociated forms.[4] Recently, the CNDO method was developed by Pople *et al.*;[5,6] it has proved to be very useful for the prediction of the electronic structures of many organic molecules, especially polar molecules, in the ground state.[7,8]

In the present paper, the total electronic energies of glycine in its neutral and dipolar-ion forms were calculated by the CNDO method.[5,6] The most stable geometry of glycine obtained by the calculations agrees well with the results of X-ray diffraction.[9,10] Moreover, the relative stabilities of the neutral form and of the dipolar-ion form were calculated in water and in gas, and the solvent effect considered.

a) in eV.

Methods

The calculations were carried out in the framework of the extended Hückel method developed by Hoffmann[11] and the CNDO/2 method developed by Pople *et al.*[5,6] All the parameters included in these methods are collected in Table 1; these values are the same as those usually employed. In the CNDO method the total energy is the sum of the total electronic and core-repulsion energies. The core-repulsion energy was calculated by the following equation:

$$E_{\text{core rep.}} = \frac{1}{2}\sum_{A}\sum_{\substack{B \\ (\neq A)}} \frac{Z_A Z_B e^2}{R_{AB}} \qquad (1)$$

where R_{AB} is the distance between the atoms A and B and where Z_A is the effective nuclear charge on the atom A. In order to carry out the population analysis by the CNDO method, the molecular orbitals on the CNDO basis were transformed to those on the Slater function basis by using the overlap matrix. Then the new set of the molecular orbitals thus obtained was employed to calculate the total electron densities using the population analysis[12] which was also employed in the extended Hückel method.

The convergency of the iteration procedure in the CNDO method was checked against the total electronic energy; that is, if the ratio of the total electronic energy to the energy difference between the former iteration and the present one was less than 10^{-6}, the convergency was considered to be accomplished. The usual number of the iteration was eight or nine.

Results and Discussions

The Electronic Structures of Glycine in the Neutral and the Dipolar-ion Forms. The electronic structures of glycine in the neutral and the dipolar-ion forms were calculated by the extended Hückel[11] and CNDO/2 methods.[5,6] The geometries of glycine assumed[9,10] are indicated in Fig. 1, while the total energies obtained are listed in Table 2. As is shown in Table 2, the extended Hückel method predicts that the dipolar-ion form will be more stable than the neutral form, in

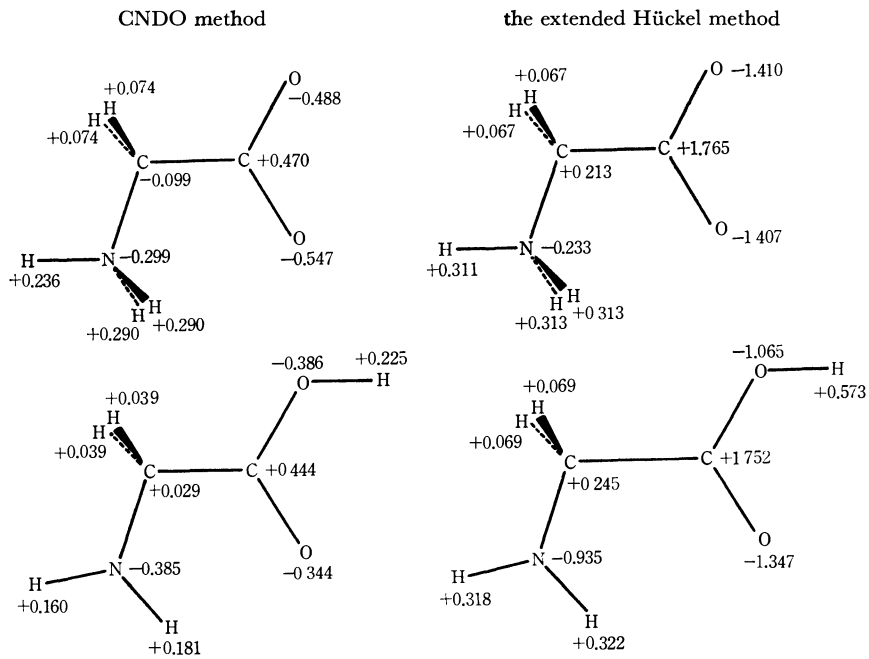

Fig. 2. The electron distribution of glycine calculated by CNDO and the extended Hückel methods.

agreement with the previous calculation;[13] on the contrary, the neutral form is indicated to be more stable by the CNDO method. This discrepancy between the two methods may be attributable to the explicit neglect of the electron-electron repulsion in the extended Hückel method. The above-mentioned inference was supported by the electron distributions of glycine calculated by the two methods; that is, the electron distributions calculated by the extended Hückel method deviate from neutral more than those calculated by the CNDO method, as is shown in Fig. 2. In other words, the electron densities of glycine calculated by the extended Hückel method exaggerate its polar nature too much; for example, the oxygen net negative charges in glycine exceed one, and the net positive charge of one of the carbons is approximately two, because of the neglect of the explicit effect of electron-electron repulsion. Glycine in water or in the solid state is well known to exist as a dipolar ion.[1] However, glycine in the isolated state, namely, in the gas state, is in the neutral form;[1] this is in accordance with the results calculated by the CNDO method.

The Geometry of Glycine in the Dipolar-ion Form. In order to investigate the validity of the CNDO method for such a polar molecule as glycine and estimate the variation in the total energy with the bond lengths and the bond angles, the calculations were carried out for various geometries of the molecule in order to establish the energy minimum. First of all, the energy dependences upon the C–C and C–N bond lengths were investigated, with the other geometrical parameters fixed as indicated in Fig. 1. The calculated results are listed in Table 3. In Table 3-A, the C–C bond length is fixed at 1.52 Å, while the C–N bond lengths range from 1.20 to 1.60 Å. Thus we obtain the energy minimum at 1.43 Å. Therefore, in Table 3-B the C–N bond length is fixed at three points, namely at 1.39, 1.43, and 1.47 Å, and the energy dependences upon the change in the C–C bond length was investigated. In the table, the energy minimum was found at the C–C bond length of 1.48 Å for all C–N bond lengths. That is to say, equilibrium C–C and C–N bond lengths were determined independently of each other. The equilibrium bond lengths calculated were approximately in accordance with the data obtained by X-ray diffraction analysis; that is, from X-ray diffraction analysis the C–C bond length was determined as 1.52 Å,[9,10] and for the C–N bond two different values, of 1.47[10] and 1.39 Å,[9] have been given by different authors. With regard to the bond angle, the energy variation with the angle between the C–C and C–N bonds was calculated, fixing the C–C bond at 1.48 Å and the C–N bond at 1.43 Å. In this case, the bond angle between the two C–H bonds was changed in harmony with the alteration of the CCN bond angle; that is, the directions of the four bonds were determined in order to construct four orthonormally-hybridized

orbitals for any values of the bond angle. The total energies calculated at various angles between the C–C and C–N bonds are listed in Table 4. The energy minimum was found at the tetrahedral configuration, which agrees fairly well with the experimental data of 112°[9] and 118.8°.[10] Moreover, the variation in the energy with the change in the angle is so small that the determination of the equilibrium bond angle is probably very difficult. Judging from this fact, the small discrepancy between the calculated bond angle and the observed one is possibly not serious. The last geometrical parameter investigated was the rotational angle around the C–C bond, with the C–C bond length of 1.48, with the C–N bond length of 1.43 Å, and with a tetrahedral configuration of the central carbon. The results in Table 5 indicate that the planar configuration is most stable. From X-ray diffraction analysis, glycine has been shown to deviate slightly from the planar configuration.[9,10] On the whole, the geometry of glycine predicted by means of the CNDO method is in good agreement with the experimental results. In addition, the energy change of the molecule with the alterations in the geometry is rather small. Therefore, it is quite impossible to expect the reversion of the relative stability of the neutral and the dipolar-ion forms by means of the variation in the geometry.

The Electronic Structure of Glycine in Water. As has already been mentioned, glycine exists in the dipolar-ion form in water, but in the neutral form in gas.[1] These facts suggest that the interaction between glycine and water stabilizes the dipolar-ion form more than the neutral form. The exact calculation of the interaction energy between the solute and the solvent is quite impossible because of the diversity of the relative conformations of glycine and water in solution. The interaction energy can be estimated roughly, however, by such a simple model as the cavity in a dielectric solution.[14] The alternative approach is treatment by

14) For example, H. Fröhlich, "Theory of Dielectrics," The Clarendon Press, Oxford (1958), Chap. 2.

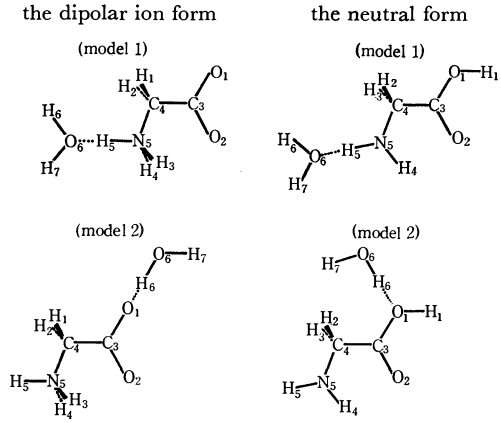

Fig. 3. The models of the hydrogen bond between glycine and water.

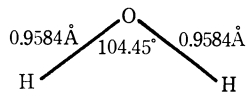

Fig. 4. The geometry of water.

the molecular orbital theory, in which the representative relative conformations of the solute and the solvent are tentatively assumed and in which the calculation is carried out for the conformation thus assumed. In this method, however, only a part of the interaction energy can be obtained; in other words, the molecular orbital approach can be used only to estimate the order of magnitude of the interaction energy. From this point of view, it is of interest to calculate the stabilization energies of the hydrogen bonds between water and glycine in the dipolar-ion form or in the neutral form in order to estimate the magnitude of the solvent effect. Although the stabilization energy by the hydrogen-bond formation is a part of the interaction energy, its contribution to the energy may reasonably be the main one; thus, this treatment can be employed for the rough estimation of the interaction energy. The models of hydrogen bonds calculated are shown in Fig. 3. The model 1 in Fig. 3 had already been accepted for the study of the protolysis kinetics of amino acid analogs.[15] The geometry of water is shown in Fig. 4. The total energies calculated by the CNDO method are listed in Table 6 for the model system of the hydrogen bonds with various intermolecular distances. For any models, the energy minimum was obtained between the intermolecular distances of 2.4 and 2.7 Å; this is in good agreement with the results obtained by means of the X-ray diffraction method used on usual hydrogen bonds. It is noteworthy that the stabilization energies by hydrogen-bond formation in the dipolar-ion form are greater than those in the neutral form by about 0.3 eV. Since many hydrogen-bond formations and other types of interaction between glycine and water can be expected in a water solution, the differences in the stabilization energies calculated are large enough to change the relative stability of the neutral and the dipolar-ion forms of glycine. In other words, the dipolar-ion form of glycine is more stable than the neutral form in water, probably because of such a solute-solvent interaction as the hydrogen bonds.

Stabilization energy	0.22	0.27

The electron densities obtained by the population analysis for various intermolecular distances are listed in Table 7. From this table, the charge transfer between water and glycine in the dipolar-ion form may be found to be larger than those in the neutral form, corresponding to the relative magnitudes of the stabilization energies. More remarkable is the fact that the charge redistribution by the hydrogen-bond formation occurs predominantly not between molecules, but within molecules; this is in good agreement with the non-empirical calculation of the hydrogen bond between water molecules[16] and the CNDO calculation of the dimer of the formic acids.[17] Moreover, when hydrogen bonds are formed, the proton-accepting

oxygen becomes more negative, and the hydrogen-bonding proton, more positive; this is in contrast with the other atoms, the charge of which does not change considerably except in the case of a few atoms adjacent to the hydrogen bond. Therefore, the mutual electrostatic interaction can be considered to determine predominantly the charge redistribution of the molecule by the hydrogen-bond formation. The electronic structures at the intermolecular distance of 2.0 Å show a characteristic feature; that is, the charge distribution of the molecules at 2.0 Å is quite different from that at 2.5 Å because of the strong solute-solvent interaction; this is parallel with the sudden increase in the total energy indicated in Table 6.

Effect of Halogens and Oxygen on the Emission of Thermal Positive Ions from the Tungsten Surface*1

Kumasaburo KODERA, Yoshifumi KITA,*2 Isao KUSUNOKI, Hiroshi KISHI and Atsuhiro SAKIYAMA

Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto

(Received May 20, 1969)

The effect of chlorine, bromine, and oxygen on the emission of thermal positive ions from tungsten filaments has been studied. When a tungsten filament is heated in a vacuum, positive ion emission is always observed, and it cannot be removed completely by flashing the filament at high temperatures. This background ion emission increases greatly in halogen or oxygen. Main positive ions are K^+ and Na^+. The increase cannot be explained by the increase of the work function of tungsten by the formation of adsorbed layer of halogen or oxygen atoms. It is ascertained that the tungsten surface reacts with these gases and the reaction products evaporate as neutral particles. As the reaction proceeds, tungsten surface is removed successively and alkali metal atoms in the bulk are exposed to the surface and contribute to the positive ion emission.

For the measurement of the intensity of an alkali metal beam, surface ionization on a hot tungsten filament is usually utilized. This is an excellent method for the measurement of the alkali metal beam, because, in spite of the high ionization efficiency, it does not ionize residual gases in the vacuum system. However, even after the filament is flashed for a long time, background positive ion emission cannot be removed completely. The background positive ion emission increases markedly when halogen or halide molecules strike the filament. Sometimes this increase amounts to more than a hundred times the original background emission, and causes serious trouble in an experiment with halogen or halide crossed beam. Birely, Wilson, and Herschbach[1] have alluded to this phenomenon, but so far no detailed study has been published.

Hendrick, Phipps, and Copley[2] have studied the effect of halogens on the ionization of alkali metal atoms on a tungsten surface. They studied the ionization of potassium halide molecular beams on a tungsten filament and discussed the presence of potassium halide or halogen layer on the surface. Metlay and Kimball[3] studied the effect of fluorine molecules on the surface ionization of alkali metals on a tungsten surface and concluded that a stable fluorine layer was formed which increased the work function of the tungsten. Zmbov[4] found the increase of ionization efficiency of Mg and Al atomic beams on the tungsten surface when the filament was exposed to a stream of halogen molecules, and explained the fact by the increase of the work function of the tungsten. However, nothing is stated in his paper on the increase of the background ion emission. As a mass spectrometer was used for the detection of the ions, even if the background emission increased, it would not give any trouble so far as the background ions were different from Mg or Al.

In all these papers the increase of the ionization efficiency of the atoms hitting the surface was described, and the increase of the work function of the tungsten by the formation of an adsorbed layer of the halogen or alkali halide was assumed to be the cause of the increase. For the ionization of potassium, instead of Mg or Al in the case of Zmbov, the work function of even a clean tungsten surface is higher than the ionization potential of potassium. Therefore, according to the Saha-Langmuir equation, considerable part of potassium atoms which hit a tungsten surface should be ionized, and the large increase of the positive ion emission could not be expected.

The present study was undertaken to clarify the cause of the increase of the positive ion emission from the tungsten surface in halogen or oxygen atmosphere.

Spark lonization source

Fig. 2. Spark ion source.

Experimental

A diode tube shown in Fig. 1 was used to measure the increase of the total positive ion emission from a tungsten filament in halogen gas.

A Mattauch-Herzog type double focussing mass spectroscope was used for the analysis of impurities in tungsten filaments and for the identification of thermally emitted positive ions and neutral particles evaporated from the tungsten surface. Ilford Q-2 plates were used for the detection of the ions, and relative intensity of the ions was determined from the density of the lines on the plate by means of a microdensitometer.

For the analysis of the tungsten filament, bundles of about ten pieces of the filament each were fixed to the sample holder electrodes as shown in Fig. 2, and intermittent radio frequency voltage was applied between the electrodes for spark discharge ionization.

For the identification of thermal ions, the tungsten filament was fixed between the electrodes and heated by electric current. Halogen gases were introduced into the ion source through a glass tube from the outside. The end of the glass tube was drawn into a nozzle and placed just behind the filament as shown in Fig. 3 (a). Negative ions were also detected by reversing both the acceleration potential and the magnetic field.

To analyze neutral particles which evaporate from the filament, electron impact ionization by electrons emitted from the sample filament itself was utilized. 75 V was applied between the filament and the first slit to accelerate the electrons to ionize the neutral particles. The ions produced were accelerated and drawn into the analyzer by the negative potential applied on the second and the third slits as shown in Fig. 3 (b).

Two different samples of tungsten filament were used for the experiments, one of them was an ordinary doped filament of 0.13 mm diameter, and the other was a 0.18 mm diameter filament not doped with alkali. The latter was supplied from Matsushita Electronics Corporation.

The chemicals for the experiments were used without any treatment: Cl_2 and O_2, Takachiho Chemical Industry, pure: Br_2, Nakarai Chemicals, extra pure: K, Merck, extra pure.

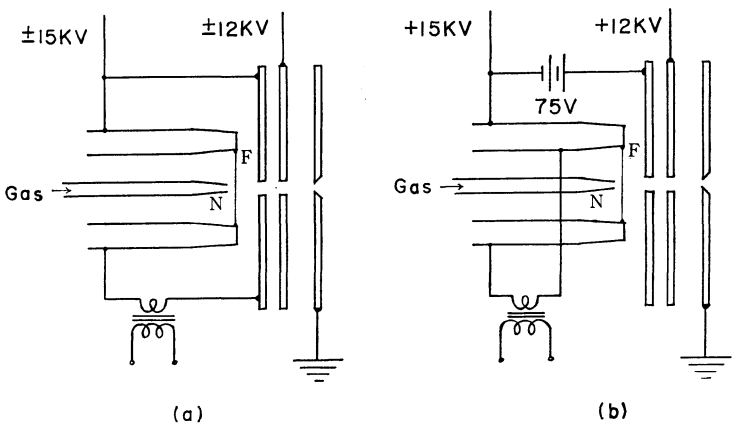

Fig. 3. (a) Surface ionization source with gas inlet nozzle, (b) electron bombardment source with gas inlet nozzle.

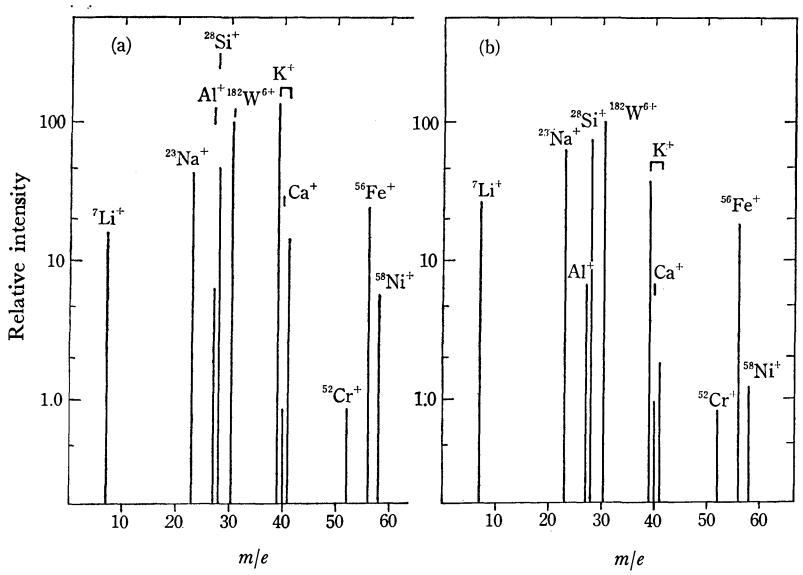

Fig. 4. Impurity spectra of tungsten filaments, (a) doped filamement, (b) undoped filament.

Results

Analysis of Impurities in the Tungsten Filaments. Mass spectra obtained by the spark discharge are shown in Fig. 4. (a) shows the result with the doped filament, and (b) shows that of the undoped filament. Both filaments contain K, Na, Li, Al, Si, Ca, Fe, Ni, and Cr as impurities. There is some difference in the quantitative distribution of these impurities between the two samples, but the difference is not remarkable. Therefore, it was found that unless a filament is manufactured particularly free of alkali metals, even an undoped filament contains some amount of alkali metal. As no precaution to remove surface contamination was taken before analysis, the impurities may include the surface contamination. Although a large difference of impurities was not observed between both filaments, after flashing, the background positive ion emission from the undoped filament was smaller than that of the doped one.

Total Positive Ion Emission. The total positive ion emission from the heated filament in vacuum and in halogen gas was measured by the diode tube shown in Fig. 1. The tungsten filament used here was the doped one. Before the measurement, the filament was flashed at about 2000°C for 30 min in a vacuum of 1×10^{-6} Torr. After the positive ion emission attained a constant value at a certain temperature, chlorine was introduced about 5×10^{-3} Torr by Pirani gauge, and then pumped out after a few minutes. The total positive ion emission during the procedure is shown in Fig. 5.

At the instant of introduction of chlorine, the positive ion emission increased for a moment and then decreased rapidly, but the final amount was greater than that before the introduction of the chlorine. When the chlorine was pumped out, the positive ion emission again decreased rapidly until it reached a value which was smaller than that before the introduction.

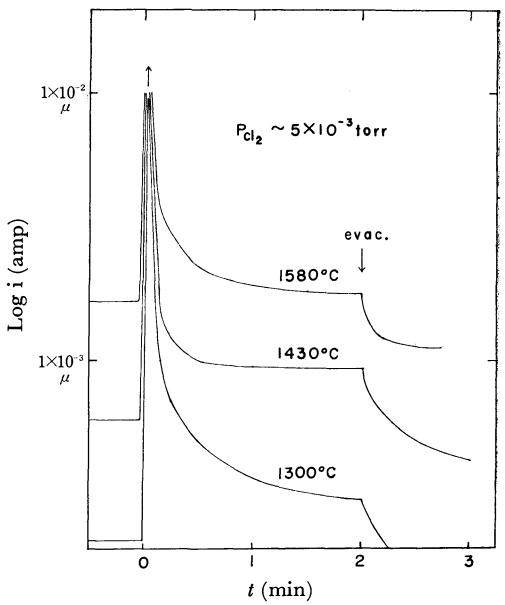

Fig. 5. Behavior of total positive ion emission in chlorine.

From these results, it was concluded that the positive ion emission in the chlorine is greater than that before the introduction and the increased background emission is greater at higher filament temperature.

Mass Spectroscopic Analysis of Thermally Emitted Ions. The thermally emitted ions from the tungsten filament were mass analyzed using the ion source shown in Fig. 3 (a). The doped filament was used for this purpose. Main ions observed were K^+ and Na^+. Quantity of the total ions measured by a monitor electrode of the mass spectroscope was larger by a hundred times in chlorine than in a vacuum.

Figures 6, 7, 8, and 9 show mass spectra of emitted positive ions. Figure 6 shows the spectra with and without chlorine under the same exposure time. In chlorine, intensity of K^+ increased greatly, and Cr^+, Ca^+, Fe^+, Cl^+ and Cl_2^+ were also observed. In Fig. 7, the effect of bromine for the same exposure is given. In bromine, emission of K^+ and Na^+ increased, and Al^+, Si^+, Cr^+, Mn^+, Fe^+, Co^+, Ni^+, Br^+, and Br^{2+} were observed.

Negative ions formed by surface ionization were also examined, but only Cl^- and Br^- were detected.

In Fig. 8, the emission from the doped filament in oxygen and in a vaccum is compared. In oxygen, emission of K^+ and Na^+ increased greatly as in chlorine and bromine. Difference in the

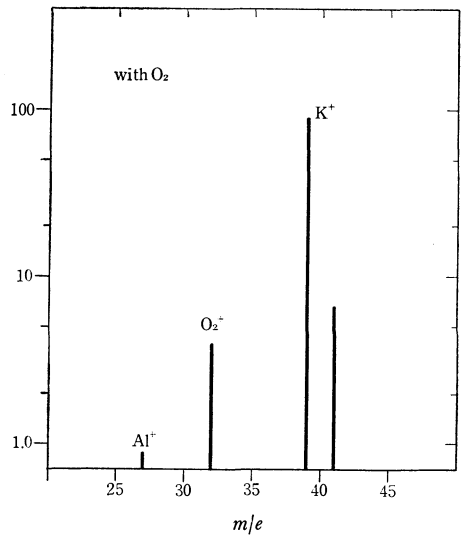

Fig. 9. Surface ionized ions from an undoped filament in oxygen.

emission in oxygen and in halogen is that no metal ions other than a small amount of Al^+ was observed in case of the former. With doped filament shown in Fig. 9, O_2^+ was detected. In both cases O^+ was out of the range of detection, and it is not certain that this ion was emitted or not. In some cases Rb^+ was found in oxygen but it was not possible to conclude under what condition Rb^+ emission could be detected, because the number of runs in oxygen was not enough. In runs with chlorine and bromine, Rb^+ was out of the range of detection.

In the above experiments, no ion of the reaction product of tungsten and halogen or oxygen were found. Therefor, it is expected that tungsten halides or oxides formed evaporate as neutral particles.

Identification of Neutral Particles by Mass Spectroscopy. Mass spectrum of neutral particles formed in chlorine is shown in Fig. 10. Ions of tungsten atoms, tungsten oxides, tungsten chlorides, and tungsten oxychlorides were observed. The detected species are W^+, WO^+, WOH^+, WO_2^+, WCl^+, WO_2Cl^+, WCl_2^+, $WOCl_2^+$, $WO_2Cl_2^+$, WCl_3^+, $WOCl_3^+$, ($WO_2Cl_3^+$), WCl_4^+, and WCl_5^+. Thus, it is confirmed that the chlorine reacted with the tungsten filament and products formed evaporated as neutral particles.

In Fig. 11, neutral particles formed in oxygen are shown. WO^+ and WO_2^+ were found in addition to W^+, but not WO_3^+.

Discussion

By the experiment of the thermal emission, Cl^+, Br^+, Cl_2^+, Br^{2+}, and O_2^- were found. As these atoms or molecules have higher ionization potentials than the electron affinity of tungsten or oxidized tungsten, it is impossible to assume that these ions were formed by the surface ionization from the standpoint of the Saha-Langmuir equation. A more probable explanation is that these ions were formed by the ion impact of chlorine, bromine or oxygen molecules around the filament, because increased positive ions (mainly alkali metal ions) could be accelerated sufficiently by the ion acceleration potential of 15 keV to ionize these molecules.

In the neutral particles evaporated from the

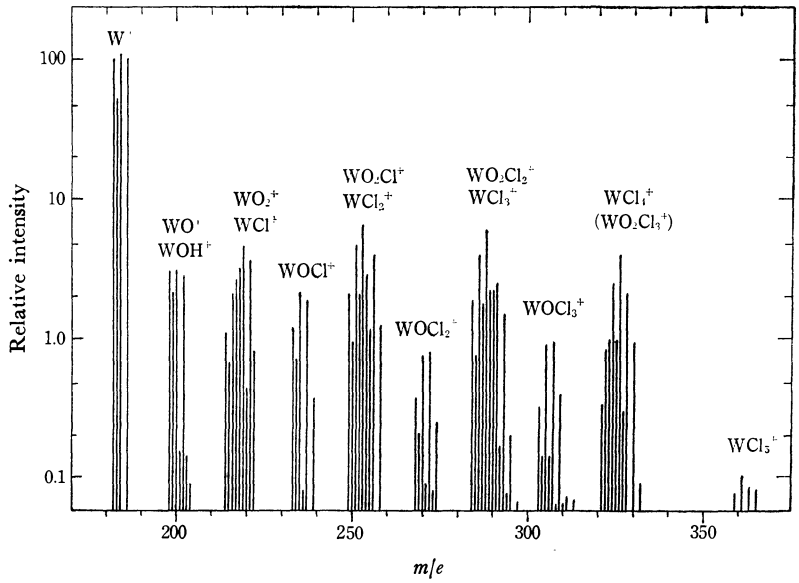

Fig. 10. Mass spectrum of neutral particles from a doped filament in chlorine.

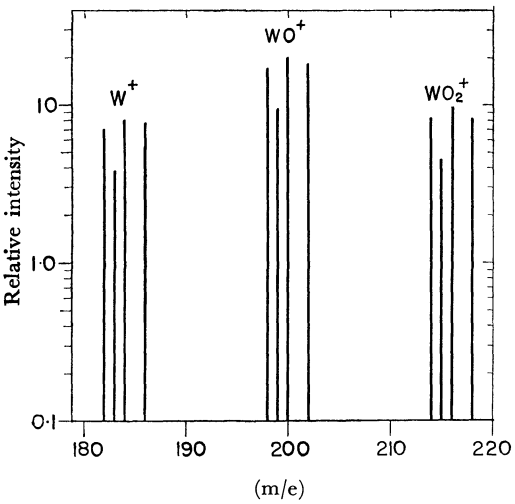

Fig. 11. Mass spectrum of neutral particles from a doped filament in oxygen.

filament in chlorine, many oxygen containing compounds were found. The origin of the oxygen should be traced. Probable sources of oxygen are the residual oxygen or water vapor in the ion source chamber, impurity in the chlorine, and the oxygen contained in the tungsten filament.

During the runs, vacuum in the ion source chamber was about 3×10^{-6} Torr and the amount of oxygen in the compounds was comparable with that of chlorine, so it is difficult to attribute the source of the oxygen entirely to the residual gas. However, there might be some contribution of the water vapor, because some hydroxy compound was seen in the mass spectrum. Impurity in the chlorine is not probable either, bacause pure sample was used and gas inlet system was evacuated carefull before the introduction of chlorine.

During the process of manufacture of tungsten filament, there are many chances that oxides are mixed. For this experiment, doped filament was used. In the process of doping, K, Na, Si, and Al are added to the tungsten powder in the form of salts. These salts are converted into oxides during the manufacturing procedure. Since the filament contains oxygen and impurities in approximately equivalent amount, it may be considered the most probable source of the oxygen.

In oxygen, W^+, WO^+, and WO_2^+ were observed as mentioned above. Berkowitz-Mattuck *et al.*[5] studied the reaction of oxygen with heated tungsten surface. They heated a piece of tungsten plate from the back by thermal radiation and electron bombardment from a W-Re filament placed behind it. A stream of oxygen from a nozzle was applied against the heated surface and neutral particles evaporated from the surface was introduced into the ion source of a mass spectrometer before any collision had occurred in the gas phase and were ionized by electron impact and mass analyzed. Oxides produced at the temperature region of 1500—2600° K were studied. Main oxides found were WO_2 and WO_3. At high temperatures WO_2 was more abundant than WO_3, but no WO was found. They proved that WO_2 was not a fragmentation product of WO_3. In a run under oxygen pressure of 7.2×10^{-4} Torr, the amount of WO_3 was

5) J. B. Berkowitz-Mattuck, A. Büchler, J. L. Engelke and S. N. Goldstein, *J. Chem. Phys.*, **39**, 2722 (1963).

maximum at 1875° K and that of WO_2 was maximum at 2200° K. At 2600° K, almost no WO_3 was seen.

As the sample filament was used as an electron emitter in the present experiment, the filament temperature was considerably high. The filament temperature could not be measured, but it might be considerably higher than 2600° K considering from the heating current. At this temperature, existence of lower oxides WO may be probable. Existence of WO^+ has been observed by Bennighoven[6] and Rybalko, Kalot, and Fogel',[7] although their experiments were somewhat different from the present ones. In these studies, oxidized tungsten surface was bombarded by Ar^+. W^+, WO^+, WO_2^+, and WO_3^+ were found by Benninghoven, and in addition ot these oxides, many other oxides were found by Rybalko *et al.*

It should be noticed that the ions observed under the electron bombardment might come from the first slit surface where the tungsten compounds might deposit while the filament was heated in the gases. But the existence of the deposit also indicates that some neutral tungsten compounds were evaporated from the filament.

It is difficult to attribute the unusual increase of positive ion emission from the heated tungsten surface in chlorine, bromine, and oxygen to the increase of the work function of tungsten by adsorbed halogen or oxygen, because, as mentioned above, the ionization efficiency of potassium on clean tungsten surface should be high and no great increase of the positive ion emission can be expected. However, for the emission of metal ions other than alkali metals, the increase of the work function may be responsible. Therefore, an entirely different mechanism should be considered.

When halogen is introduced around the tungsten filament, it reacts with the tungsten surface and tungsten halides and oxyhalides will evaporate as the reaction products. By the evaporation of these products, alkali metal atoms contained in the bulk of the tungsten are exposed to the surface and emitted as positive ions. In Fig. 5, it is seen that, when chlorine is introduced, the positive ion emission increased for the moment and decreased rapidly again. This means there is a concentrated layer of alkali metal atoms at the filament surface, and removal of the surface by the reaction causes the sudden increase of the positive ion emission. When the filament is heated at high temperatures, alkali metal atoms inside the bulk diffuse towards the surface and evaporate. The difference between the diffusion rate and the evaporation rate will build a concentrated layer of alkali metal atoms just under the surface. After the concentrated layer of alkali metal atoms are removed by the reaction, rate of the emission of the positive ions is controlled by the corrosion rate of the tungsten by chlorine. But without chlorine, the emission rate is controlled by the diffusion rate of alkali metal atoms in the bulk of the tungsten.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 3131—3134 (1969)

On the Viscosity of Liquid Oligotrifluorochloroethylene

Naosato Yoshida, Shuichi Hamada and Toshiaki Shirai

Department of Chemistry, Faculty of Science, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo

(Received May 22, 1969)

The viscosities and densities of liquid oligotrifluorochloroethylene were measured over a molecular-weight range from 820 to 1090 at temperatures from 40°C to 100°C. The temperature-dependences of the viscosities did not show an Arrhenius-type variation, but were extremely adaptable in the WLF equation; *i. e.*, a viscoelastic behavior was shown under the present experimental conditions. The apparent activation energies, ΔH_a, for the viscous flow of the liquid samples were comparatively large and increased with an increase in the number-average molecular weight. The logarithm of the viscosity, $\log \eta$, varied linearly with the logarithm of the number-average molecular weight, $\log \eta = A \log M_n + B$. The slopes, A, of the linear relationships were estimated to be 11.0, 10.4, 9.3, and 8.4 at 50, 60, 70, and 80°C respectively. The values of the slopes, A, were very much larger than unity in the case of usual organic polymers below the critical values of the molecular weight, and they decreased with an increase in the temperature.

Polytrifluorochloroethylene is a chain polymer with only fluorine and chlorine atoms on the side of the carbon chain, and so the lone-pair electrons surrounding the chain molecules may be expected to have effects on their physical properties. In many respects, polytrifluorochloroethylene has peculiar properties compared with those of usual organic polymers; for example, its thermal and chemical stabilities are unusual. Though a highly-polymerized trifluorochloroethylene is a rigid plastic material and is insoluble in many solvents,[1] the trifluorochloroethylene oligomers are oily, grease-like, and wax-like at room temperature, and they are soluble in various solvents. In this work, the properties of the liquid oligomers will be studied in order to establish those of polytrifluorochloroethylene.

Experimental

Materials. The Daifloil No. 20 and No. 50, which were obtained from the Daikin Kogyo Company, were used as the samples of oligotrifluorochloroethylene.

The precipitation method was employed to fractionate the oligotrifluorochloroethylene using an acetone and water as the solvent and the precipitant respectively. A suitable quantity of water was added to an acetone solution of the sample, and the mixture was stirred at about 30°C. The precipitates were dissolved by again heating the mixture about 55°C, and then the mixture was allowed to stand for about 5 hr at 30°C. The fractionated precipitates were separated, and then a great quantity of methanol was added to them in order to separate the precipitates easily. The precipitates were decanted repeatedly with methanol and were dried at 30°C *in vacuo*. The number-average molecular weights of the fractionated oligotrifluorochloroethylene were estimated to be from 820 to 1090 by the cryoscopic method, using a benzene as the solvent.

Procedure. The viscosities and the densities of the liquid samples were measured at temperatures from 40°C to 100°C in the manner described in a previous paper.[2]

The viscosity, η_θ, at the tilting angle, θ, of the Ubbelohde-type viscometer was calculated by the following equation:

$$\eta_\theta = A_\theta \rho t$$

where A_θ, ρ, and t are the parameter of the viscometer, the density of the liquid sample, and the efflux time respectively. The parameter, A_θ, of the viscometer was estimated by measuring the efflux time of the standard liquid of a known viscosity at 30°C and at various tilting angles, θ. The viscosities, η_θ, of the liquid samples were measured at several tilting angles. The densities of the liquid samples were measured with the U-type densimeter described in a previous paper.[2] The viscosities and densities of the liquid samples were measured at specified temperatures within an accuracy of ± 0.01°C in thermostated baths of silicone oil and water.

The linear expansion coefficient of the densimeter was 7.95×10^{-7}°C^{-1} over the temperature range from 30°C to 50°C, while those of the liquid oligotrifluorochloroethylene were calculated to be about 3×10^{-4}°C^{-1} over the temperature range from 40°C to 100°C. Therefore, the expansion of the densimeter was negligible compared with that found with the liquid samples.

Results

The thermal degradation of the oligotrifluorochloroethylene was considered to result from heating

2) S. Hamada, N. Yoshida and T. Shirai, This Bulletin, **42**, 1025 (1969).

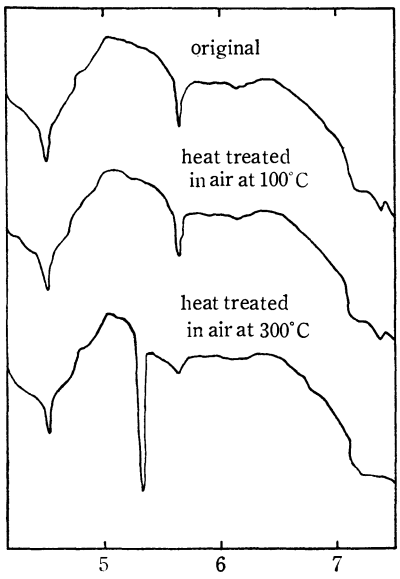

Fig. 1. IR spectra of original and heat-treated samples.

in the atmosphere.[3] Figure 1 shows the IR spectra of the sample with the molecular weight of 1090. A sharp absorption band assigned to an acid fluoride group at 5.31 μ coming from the thermal degradation was not observed in the sample heated at 100°C for 10 hr, as is shown in Fig. 1. Therefore, the measurements were carried out below 100°C, since the influence of the thermal degradation was considered to be negligible under these conditions.

The Viscosities of the Liquid Oligotrifluorochloroethylene. The viscosities, η_θ, of the liquid samples at several tilting angles were measured at temperatures from 40°C to 100°C. Table 1 shows the viscosities, η_θ, of the fractionated sample with the number-average molecular weight of 1090 at 70, 85, and 100°C, and at several tilting angles, θ_n.

The tilting angles, θ_n, represent the relative angles of the capillary of the viscometer to the vertical line, and they increase with an increase in the subscript, n; the difference between θ_5 and θ_1 is 45°. The viscosities, η_θ, were nearly constant regardless of the variation in θ_n, *i. e.*, the variation in the rate of shear. The viscosities of the other fractionated liquid samples showed the same appearance as that of the sample, $M_n=1090$. Therefore, liquid oligotrifluorochloroethylene are considered to behave as a Newtonian liquid under these experimental conditions.

Table 1. Dependence of viscosities on tilting angles

Tilting angle, θ_n	Viscosities, η_θ, poise		
	70°C	85°C	90°C
θ_1	11.8_1	4.03_1	
θ_2	11.8_0	4.03_1	1.61_0
θ_3	11.8_1	4.03_9	1.60_9
θ_4		4.03_0	
θ_5	11.8_0	4.02_9	

Table 2. Viscosities of oligotrifluorochloroethylene

Molecular weight, M_n	Viscosities, η, poise						
	40°C	50°C	60°C	70°C	80°C	90°C	100°C
820	6.43	3.04	1.51				
860	10.78	4.73	2.33	1.42	0.717		
870	15.81	6.65	3.15	1.88	0.916		
890	22.39	9.18	4.23	2.13	1.17	0.698	
1010		29.53	12.61	5.90	2.98	1.63	
1030		40.52	16.60	7.52	3.77	2.01	1.14
1050		55.90	21.62	9.49	4.61	2.44	1.36

1090			27.45	11.81	5.64	2.94	1.61

The viscosities of the fractionated liquid samples are given in Table 2.

The Temperature-dependences of the Viscosities. The temperature-dependences of the viscosities, η, did not show an Arrhenius-type variation under these conditions. Therefore, the temperature-dependences of the viscosities, η were treated with the WLF equation, $\log a_T=-C_1^0(T-T_0)/(C_2^0+T-T_0)$.[4]

Figure 2 shows the relationships between $(T-T_0)$ and $(T-T_0)/\log a_T$. The shift factors, a_T, which were expressed to be $\rho_0\eta T_0/\rho\eta_0 T$, were calculated

on the basis of a voluntary fixed temperature, T_0, because the glass-transition temperatures, T_g, of the fractionated samples were not known. The linear relationship shown in Fig. 2 makes it obvious that the temperature-dependences of the viscosities were extremely adaptable in the WLF equation. Therefore, the viscoelastic behavior was shown in the viscous flow of the liquid samples over the temperature range from 40°C to 100°C. The WLF parameters, C_1^0 and C_2^0, were estimated on the basis of T_0 from the linear relationships in Fig. 2, while the apparent activation energies, ΔH_a, for the viscous flow were estimated from the following equation:

$$\Delta H_a = 2.303 R C_1^0 C_2^0 T^2/(C_2^0 + T - T_0)^2$$

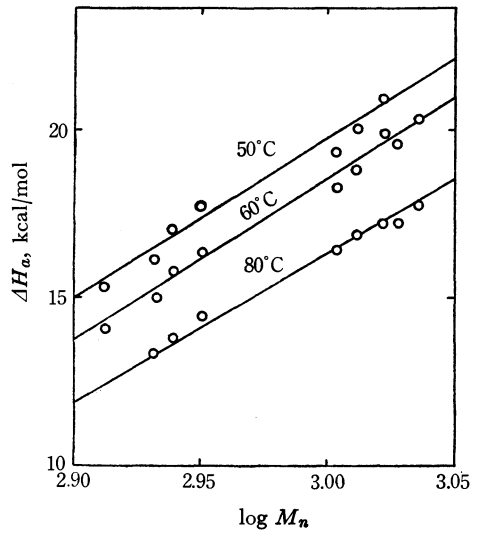

Fig. 3. Dependence of apparent activation energy for viscous flow on log M_n.

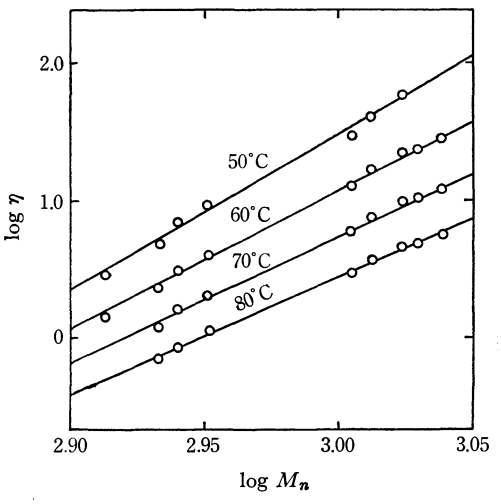

Fig. 4. Dependence of log η on log M_n.

Figure 3 shows the dependence of ΔH_a on the molecular weight. The apparent activation energy, ΔH_a, for the viscous flow increased linearly with an increase in the logarithm of the molecular weight, log M_n.

The Molecular-weight Dependences of the Viscosities. The dependences of the viscosities on the molecular weight are shown in Fig. 4. The logarithm of the viscosity, log η, varied linearly with the logarithm of the number-average molecular weight, log M_n. The linear relationships at the specified temperatures could be expressed as follows:

$$\log \eta = A \log M_n + B^{5)}$$

The slopes, A, of the linear relationships were very much larger than unity at lower temperatures, unlike the case of usual organic-polymers below the critical values of the molecular weights, and they decreased with an increase in the temperature, as is shown in Table 3.

Table 3. Slopes, A, of linear relationships

Temp., °C	50	60	70	80
A	11.0	10.4	9.3	8.4

Discussion

The relationship between the viscosity and the free volume is satisfactorily described by the Doolittle equation:[6,7]

$$\ln \eta = \ln P + Q(v - v_f)/v_f$$
$$= \ln P + Q/f$$

where P and Q are the empirical constants; v, the specific volume; v_f, the free volume, and f, the fraction of the free volume. The fraction of the free volume, f, at T is expressed as follows:

$$f = f_g + \alpha_f (T - T_g)$$

where f_g is the fraction of the free volume at T_g, and α_f, the thermal expansion coefficient of the free volume. All the oligotrifluorochloroethylenes used in the study are quite small in number-average molecular weight; $M_n \leq 1090$. In general, the melting points of the lower-molecular-weight oligomers rise remarkably with an increase in the molecular weight; also, their glass-transition temperatures, T_g, are considered to show a tendency similar.[8] Particularly the glass-transition temperatures of the oligotrifluorochloroethylene rise remark-

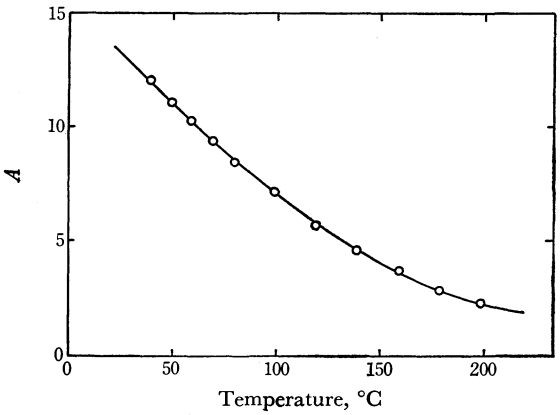

Fig. 5. Temperature dependence of slope, A, of linear relationship.

ably as the molecular weights increase; in fact, the states of the samples at room temperature depend notably on the molecular weight. They are all oily, grease-like, and wax-like, in spite of the small range of molecular weight (from 820 to 1090).

Thus, since a large dependence of the fraction of the free volume, f, on the molecular weight at specified temperatures may be expected, the viscosity will rise remarkably with an increase in the glass-transition temperature in the lower-molecular-weight range. The slopes, A, of the linear relationships in Table 3, which indicated the dependences of the viscosities on the molecular weights, show large values at lower temperatures. The large values of A are caused by the large dependence of the fraction of the free volume on the molecular weight. Though the slopes, A, were very much larger than unity at the lower temperatures, they gradually decreased as the temperature was elevated; they were considered finally to approach a certain value, A_0, as is shown in Fig. 5. The values, A, above 100°C were calculated from the WLF equation. The decrease of A with an increase in the temperature is caused by the decrease in the dependence of the fraction of the free volume on the molecular weight as the temperature is elevated.

Large dependences of the viscosities on the molecular weights have also been reported for the oligostyrene and oligoisobutylene.[5,9] For example, the A values of the oligoisobutylene over the molecular-weight range from 530 to 2190 were estimated to be 5.45, 3.08, and 1.75 at 0, 30, and 217°C respectively.

The liquid organic-chain polymers, in general, show comparatively small values of the apparent activation energies for the viscous flow, though they increase with an increase in the bulk of the side chains.[10] The comparatively large values of ΔH_a for oligotrifluorochloroethylene, with no branched chain, are considered to be caused by a high rotational barrier about carbon-carbon bonds which is to be attributed to the lone-pair electrons of fluorine and chlorine atoms.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 3135—3140 (1969)

Infrared Study of Rotational Isomers of *meso*- and *racemic*-2,3-Dibromobutane

Kazuyoshi IIMURA

Department of Chemistry, Faculty of Science, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo

(Received June 4, 1969)

The infrared spectra of *meso*- and *racemic*-2,3-dibromobutanes in solution and in gaseous states were obtained in the study of the rotational isomers. The occurrence of three rotational isomers was confirmed for both *meso*- and *racemic*-isomers. The quantitative estimation of the equilibrium concentrations of the rotational isomers was also made in various solvents. The energy difference between the rotational isomers was determined by measuring the temperature-dependence of the absorption intensities of ν(C–Br) vibrations.

In our infrared investigation of *meso*- and *racemic*-2,3-dichlorobutanes,[1] it has been shown that three rotational isomers exist for both *meso*- and *racemic*-isomers, and that the equilibrium concentrations change depending upon the solvent dielectric constants.

In the present study the infrared spectra of *meso*- and *racemic*-2,3-dibromobutanes, the molecular structures of which are analogous to those of *meso*- and *racemic*-2,3-dichlorobutanes, will be observed, and the conformational equilibria of the rotational isomers in solvents of different dielectric constants and the energy difference between the rotational isomers in the gaseous state will be investigated.

The existence of three rotational isomers for both *meso*- and *racemic*-isomers has been established by studies of the Raman spectra[2] and of the nuclear magnetic resonance (NMR).[3,4] However, in these investigations, no quantitative spectroscopic estimation of the conformational equilibria in various solvents, or of the difference in energy between the rotational isomers were made. In the recent NMR investigation of *meso*-2,3-dibromobutane reported by Deb,[5] the energy difference between the rotational isomers was determined to be 1.0 kcal/mol. However, this value seems too small compared with that of 1,2-dibromoethane.

Experimental

The *meso*- and *racemic*-2,3-dibromobutanes (hereafter abbreviated as *meso*- and *racemic*-DBB respectively) were prepared by the addition of bromine to *trans*- and *cis*-butene-2 (Matheson Co.; purity, 99.8%) at −15—−18°C. The materials were distilled, and the fractions with boiling points of 73.0—75.0°C/55 mmHg for the *meso* isomer and of 77.0—79.0°C/60 mmHg for the *racemic* isomer were collected (reported boiling points: *meso*, 74—74.2°C/50 mmHg; *racemic*, 75.6°C/50 mmHg[6]). The NMR spectra of the materials were completely identical with those observed by Bothner-By and Naar-Colin[3] and by Anet.[4] A gas-chromatographic analysis indicated also that the purity is more than 99% for both isomers. The infrared spectra were recorded mainly for the region of 800—400 cm^{-1} using a Hitachi EPI-2 double-beam spectrophotomer with a KBr prism. Spectral observation was also made in the region of the NaCl prism for reference. In measuring the solution spectra, the absorption due to the solvent was compensated for by a variable-thickenss cell filled with the solvent. The gas-phase spectra were obtained using a gas cell with an optical path-length of 7 cm and with a heating device.

Results and Discussion

ν(C-Br) Bands and Rotational Isomers. As Fig. 1 shows, it is possible for three rotational isomers to exist in both *meso*- and *racemic*-DBB. The conformations of the rotational isomers are designated by T, G, or G′, indicating whether the carbon chains are located *trans* or *gauche*. As for the *meso*-isomer, MG and MG′ are mirror images of each other and are not different in their infrared spectra.*1

The ν(C–Br) vibrations for bromine attached to the secondary carbon atom are usually observed in the region of 620—520 cm^{-1}; they appear at different frequencies depending upon the conformational

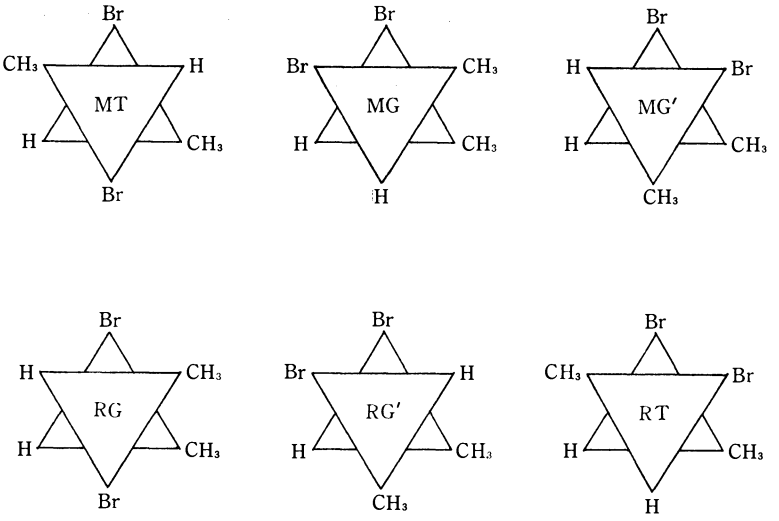

Fig. 1. The posible conformations of rotational isomers.

structures of the rotational isomers.[7,8] Figure 2 shows the infrared spectra of *meso*- and *racemic*-DBB in the pure liquid state. The strong band at 552 cm^{-1} and the weaker band at 600 cm^{-1} of *meso*-DBB, and the two strong bands at 561 and 543 cm^{-1} of *racemic*-DBB, can be assigned to the ν(C-Br) vibrations. The absorption band at 635 cm^{-1} of *meso*-DBB and those at 648 and 632 cm^{-1} of *racemic*-DBB are found somewhat apart from the ν(C-Br) region. However, these absorption bands can safely be assigned to the ν(C-Br) vibrations, because the infrared spectra in the NaCl region of *meso*- and *racemic*-DBB correspond fully to those of *meso*- and *racemic*-2,3-dichlorobutanes respectively[9] and because the frequencies of these absorption bands are too low to be assigned to the CH_3 rocking vibrations. The frequencies associated with the skeletal bending modes occur, in general, below 500 cm^{-1}. The bands at 466 cm^{-1} of *meso*-DBB and at 444 cm^{-1} of *racemic*-DBB are assigned to these modes. The weak band at 502 cm^{-1} of *racemic*-DBB is perhaps due to the skeletal bending mode.

We have calculated the dipole moment of the rotational isomers by means of the method proposed by Miyagawa.[10] The values thus calculated are listed in Table 1. In accounting for the difference in dipole moment, it can be said that the population of the rotational isomers in solution changes because it is affected by a reaction field induced by the solvent molecules.[11] The assignment of ν(C-Br) bands to each of the rotational isomers, therefore, becomes possible if we measure the intensity change of these bands in a different solvent, because a

change in the intensity will result from a change in the population. Figure 3 gives the solvent-effect for the intensity of the ν(C-Br) bands.

In the solution spectra of *meso*-DBB, the intensities of the bands at 635 and 600 cm^{-1} increase, and that of the band at 552 cm^{-1} decreases, as the dielectric constant of the solvent increases from 1.89 (*n*-hexane) to 37.5 (acetonitrile). At the same time it is noted that the positions of the ν(C-Br) bands shift downward in their frequencies by *ca.* 2—6 cm^{-1}.*2 According to Watanabe *et al.*,[11] when a molecule of the dipole moment, μ, in the gaseous state is transferred from the vacuum into the solvent medium of a dielectric constant, ε, the potential energy is lowered by:

$$Er = (\varepsilon-1)\mu^2/(2\varepsilon+1)a^3 \quad (1)$$

where a is the radius of the solute molecule. In view of the above findings, the population of the polar rotational isomer may be expected to become dominant in the solvent of the larger dielectric constant, since the values of a can be considered to be not very different for each rotational isomer. The two bands at 635 and 600 cm^{-1} can, therefore, be assigned to the ν(C-Br) vibrations arising from the polar MG, and the band at 552 cm^{-1}, to that arising from the nonpolar MT, the population of which would be expected to decrease in the polar solvent. As MT has a center of symmetry, only one ν(C-Br) vibration is possible in an infrared absorption; this is related to the antisymmetric stretching vibration of the C-Br bonds. The band at 552 cm^{-1} must be due to the antisymmetric ν(C-Br) vibration.

*2 A downward shift of absorption frequencies is also noted for *racemic*-DBB; hence, hereafter for convenience the frequencies of the absorption bands will be given by those observed in the pure liquid spectra.

On the other hand, two ν(C-Br) vibrations may be expected from MG, since this conformation has no center of symmetry. The two bands at 635 and 600 cm^{-1} correspond exactly to these vibrations. In the Raman spectrum of liquid *meso*-DBB,[2] an intense band at 632 cm^{-1} and a weaker band at 600 cm^{-1} are found in the ν(C-Br) region. Since the ν(C-Br) vibrations of MG are active for both Raman and infrared spectra, these two bands, the frequencies of which coincide exactly with those of the infrared bands, are considered to have arisen from MG. However, the intense Raman band at 632 cm^{-1} possibly involves the Raman active symmetric ν(C-Br) vibration of MT. It is very probable that no Raman band is found near 550 cm^{-1} because the infrared band at 552 cm^{-1} is a Raman-inactive antisymmetric ν(C-Br) vibration.

As is evident from Fig. 3, the intensity change in the ν(C-Br) band of *racemic*-DBB depending with the solvent is also remarkable. Two ν(C-Br) vibrations are possible in the infrared absorption for each of the three rotational isomers of *racemic*-DBB, which have no center of symmetry. The bands at 632 and 561 cm^{-1}, the intensities of which decrease with an increase in the solvent dielectric constant, can be assigned to the ν(C-Br) vibrations of the less polar RG. On the other hand, the 648 and 543 cm^{-1} bands may be ascribed to the ν(C-Br) vibrations of polar RG′ or RT, since their intensities increase as the dielectric constant of solvent increases. It is noted, however, that the solvent-effect on the intensity change of the 648 cm^{-1} band is different from that on that of 543 cm^{-1} band; that is, the increase in the relative intensity of the 648 cm^{-1} band in the polar solvent is remarkable in comparison with that of the 543 cm^{-1} band. By taking account of the facts that the potential energies of RG′ and RT in the gaseous state are almost the same order in magnitude, and that both are higher than that of RG by approximately 1.5 kcal/mol, as will be described below, the population of the most polar RG′ may be expected to become dominant in the acetonitrile solvent over that of RT. Therefore, the bands at 648 and 543 cm^{-1} may be considered to arise from RG′ and RT respectively. This assignment is also in accord with the experimental finding that the position of the ν(C-Br) vibration *trans* to a C-C bond appears usually at a frequency higher than that *trans* to a C-H bond.[7,8] Although a residual ν(C-Br) vibration must be expected for both RG′ and RT, no bands except the 648 and 543 cm^{-1} bands are found in the ν(C-Br) region. The absence of bands cannot be explained at present.

Taufene *et al.*[2] have found three Raman bands, at 633, 563, and 540 cm^{-1}, for *racemic*-DBB in the liquid state; they have ascribed them to RG, RG′, and RT respectively. The assignment of the former two bands is the reverse of our interpretation. It

can be seen, however, that the most intense band is found at 567 cm^{-1} in the infrared spectrum of *racemic*-DBB in the gaseous state (see Fig. 4). Judging from the electron diffraction investigation by Stevenson and Schomaker,[12] where they have shown that the *trans* conformation for the bromine atoms predominates in the gaseous state, the very intense 567 cm^{-1} band, which corresponds to the 563 cm^{-1} band in the Raman spectrum, must be assigned to the ν(C-Br) vibration arising from RG. The weaker bands at 651 and 547 cm^{-1} appearing in the infrared spectrum of the gaseous state may be ascribed to RG′ and RT respectively, both of which are relatively small in population.

Energy Difference between the Rotational Isomers in the Gaseous State. As Fig. 4 shows, the bands appearing at 646, 607, and 559 cm^{-1} of *meso*-DBB correspond to those at 635, 600, and 552 cm^{-1} respectively in the liquid state. For the gaseous *racemic*-DBB, the bands corresponding to those at 648, 561 and 543 cm^{-1} of the liquid state are observed at 651, 567, and 547 cm^{-1} respectively.

As Fig. 5 shows the relations of the logarithmic values of the intensity ratios for the ν(C-Br) bands in the gaseous state against 1/T were found to be linear. From the slope of the straight lines, the energy differences in the gaseous state are found to be:

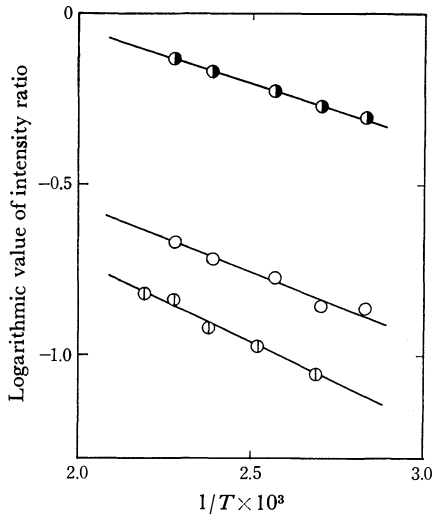

Fig. 5. Relations of the intensity ratio of ν(C-Br) bands against $1/T$ in the gaseous state.
◑: log (D_{547}/D_{567}) of *racemic*-DBB
○: log (D_{651}/D_{567}) of *racemic*-DBB
◫: log (D_{646}/D_{559}) of *meso*-DBB

$$\Delta E^{gas}_{MG\text{-}MT} = 2.2 \text{ kcal/mol}$$

$$\Delta E^{gas}_{RG'\text{-}RG} = 1.7 \text{ kcal/mol}$$

and;

$$\Delta E^{gas}_{RT\text{-}RG} = 1.5 \text{ kcal/mol}$$

by means of a previously-reported method.[1] It may be noted that the observed values of ΔE^{gas} are higher by approximately 0.5 kcal/mol than those corresponding ΔE^{gas} values for *meso*- and *racemic*-2,3-dichlorobutanes.[1] The relative behavior of chlorine and bromine substituents for ΔE^{gas}, in these cases, is in harmony with the findings for 1,2-dihalogenoethanes; *i. e.*, the values of ΔE^{gas} between the *gauche* and *trans* forms have been determined to be 1.45—1.70 kcal/mol for 1,2-dibromoethane and 1.0—1.1 kcal/mol for 1,2-dichloroethane respectively.[13,14]

The energy difference for *meso*-DBB, however, can be determined by an independent method, *e. g.*, by studing the solvent effect upon the intensity of the ν(C-Br) band. Since the MT-form has no dipole moment, its potential energy may be not subjected to any influence from the solvent dielectric constant (see Eq. (1)). The lowering in the potential energy of MG, *Er*, in the solvent of the dielectric constant, ε, can, therefore, be represented with reference to the energy differences between MG and MT in the gaseous state, ΔE^{gas}, and that in solution, ΔE^{soln}, as follows:

12) D. P. Stevenson and V. Schomaker, *J. Am. Chem. Soc.*, **61**, 3173 (1939).

13) T. Shimanouchi, H. Tsuruta and S. Mizushima, *Sci. Pap. Inst. Phys. Chem. Res. Tokyo*, **42**, 51 (1944).

14) K. Kuratani, T. Miyazawa and S. Mizushima, *J. Chem. Phys.*, **21**, 1411 (1953).

$$Er = \Delta E^{gas} - \Delta E^{soln} = (\mu^2/a^3)[(\varepsilon-1)/(2\varepsilon+1)] \quad (2)$$

In the solution, on the other hand, the ratio of the optical density of the ν(C-Br) bands can be written with reference to ΔE^{soln} as follows:

$$D_{MG}/D_{MT} = (2k_{MG}f_{MG}/k_{MT}f_{MT}) \exp(-\Delta E^{soln}/RT) \quad (3)$$

where k is the absorption coefficient and f, the partition function. Combining Eqs. (2) and (3), we thus obtain:

$$\log(D_{MG}/D_{MT}) = \log(2k_{MG}f_{MG}/k_{MT}f_{MT}) - \Delta E^{gas}/2.303RT + (\mu^2/2.303RTa^3)[(\varepsilon-1)/(2\varepsilon+1)] \quad (4)$$

At a constant temperature, the log (D_{MG}/D_{MT}) should be a linear function with $(\varepsilon-1)/(2\varepsilon+1)$. Taking the 635 cm^{-1} band to MG, and the 552 cm^{-1} band to MT, as in Fig. 6, the relation of $\log(D_{635}/D_{552})$ to $(\varepsilon-1)/(2\varepsilon+1)$ at the constant temperature of 29°C is found to be linear. This result agrees satisfactorily Eq. (4). The value of the first two terms of the right-hand equation gives -1.34 as the value of $\log(D_{635}/D_{552})$ at $(\varepsilon-1)/(2\varepsilon+1)=0$, where ε is extraporated to 1. We then have:

$$\log(2k_{MG}f_{MG}/k_{MT}f_{MT}) - \Delta E^{gas}/2.303RT = -1.34 \quad (5)$$

Assuming $f_{MG}/f_{MT}=1$,[1] and into Eq. (5) putting the value of k_{MG}/k_{MT}, which has been determined to be 0.534, as will be described below, we have found the value of ΔE^{gas} to be 1.9 kcal/mol. The value of ΔE^{gas} thus obtained is approximately the same as that obtained by measuring the temperature-change in the absorption intensity in the gaseous state.

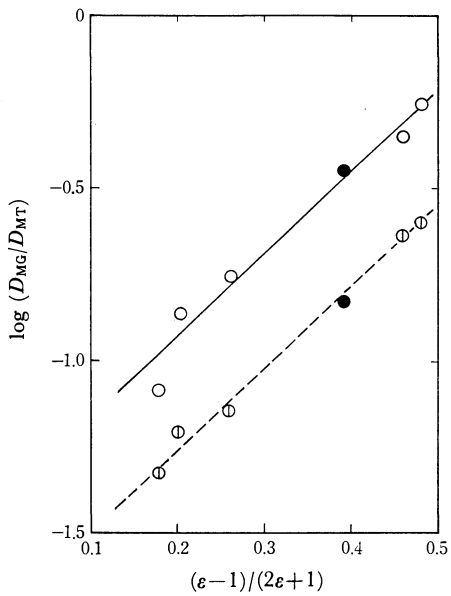

Fig. 6. Relations of log (D_{MG}/D_{MT}) against $(\varepsilon-1)/(2\varepsilon+1)$ at 29°C.
○: $D_{MG}/D_{MT}=D_{635}/D_{552}$
◑: $D_{MG}/D_{MT}=D_{600}/D_{552}$
Black circles: data for the pure liquid.

As is presented in Fig. 6, it should also be noted that the origin of the 600 cm^{-1} band seems to be same as that of the 635 cm^{-1} band, since the two lines are parallel in direction. This result gives a basis for the assignment of the 635 and 600 cm^{-1} bands to MG.

From his NMR study of *meso*-DBB, Deb[5] has found the value of ΔE^{gas} to be 1.0 kcal/mol. This value of ΔE^{gas}, however, seems to be too small as compared with the energy difference between the *gauche* and *trans* forms of 1,2-dibromoethane, for which the value of ΔE^{gas} was found to be 1.45—1.70 kcal/mol.[13,14] Since, on going from MT to MG, the number of *gauche* interactions between bulky groups, Br and CH_3, is increased from two to three, the difference in steric potential between the MG of *meso*-DBB and the corresponding *gauche* form of 1,2-dibromoethane may be larger than that between the *trans* forms of these two substances. In this case, a contribution of the electrostatic repulsion between the bromine atoms to ΔE^{gas} is considered to be approximately the same for the corresponding *gauche* and *trans* forms of these two substances. The values of ΔE^{gas} between the MG and MT may, therefore, be expected to exceed that between the *gauche* and *trans* forms of 1,2-dibromoethane.

For the gaseous *racemic*-DBB, it may be noted that the potential energies of RG′ and RT are almost the same in magnitude and that both are higher than that of RG. The same situation has been found for *racemic*-2,3-dichlorobutane, as has been reported in our previous paper.[1]

The Equilibrium Concentrations of Rotational Isomers in Various Solvents. The equilibrium concentrations of rotational isomers in various solvents were determined by measuring the intensity ratio of the ν(C-Br) bands. The ratio of the concentrations of the two rotational isomers, I and II, C_I/C_{II}, can be represented with reference to the optical densities of the ν(C-Br) bands belonging to these rotational isomers as follows:

$$C_I/C_{II} = (k_{II}/k_I)(D_I/D_{II}) \quad (7)$$

where D is the optical density and k, the absorption coefficient. In general, the determination of the k_{II}/k_I value is a little more difficult. Fortunately, in the case of liquid *meso*-DBB, the ratio of the concentration of MG to MT, C_{MG}/C_{MT}, can be calculated to be 0.667 from the observed dielectric constant and the density of the liquid.*3 Putting into Eq. (7) the C_{MG}/C_{MT}, and the observed value of D_{MG}/D_{MT}, 0.356, for the pure liquid *meso*-DBB at room temperature, we have then

*3 The value of C_{MT}/C_{MG} was calculated by a method reported in our previous paper.[1] The observed data of the dielectric constant ($\varepsilon=6.245$), the density ($d=1.7747$), and the refractive index ($n=1.5091$) at 25°C were taken from the paper of Winstein and Wood.[15]

c) Calculated from the values of $J_{AA'}$ by Deb assuming $J_T=11$ cps and $J_G=1$—2 cps.[3,4,16]
d) NMR data from the paper of Bothner-By and Naar-Colin.[3]

found the value of k_{MT}/k_{MG} to be 1.87. Using this value, the equilibrium concentrations at room temperature for *meso*-DBB in various solvents have been determined from Eq. (7), they are listed in Table 2.*4

Deb observed the NMR spectra of *meso*-DBB in various solvents and found that the vicinal coupling constant, $J_{AA'}$, between two methine protons changes depending upon the solvents.[5] From these observed $J_{AA'}$ values, we have calculated the equilibrium concentration, C_{MT}, assuming *trans* and *gauche* coupling constants of two methine protons, to be $J_T=11$ cps and $J_G=1$—2 cps respectively.[3,4,16] The agreement between the equilibrium concentrations obtained by the two different methods is satisfactory.

Table 3 gives the equilibrium concentrations of the rotational isomers of *racemic*-DBB in solution; these concentrations have been obtained by means of the method[1] we previously applied to *racemic*-2,3-dichlorobutane.*5 It may be seen that the data for the pure liquid state are in accord with those reported in the NMR investigation by Bothner-By and Naar-Colins.[3] That the increase in the population of RG′ is remarkable in the polar solvents in spite of the small effect of the solvent on the population of RT can be explained by the fact that the loss in the potential energy of RG′ under the influence of an electrostatic interaction of the solvent dipole is approximately twice that of RT.*6 A certain increase in the populations of RT may be expected in the polar solvent; at present, however, we have no good explanation for the small effect of the solvent on RT shown in Table 3.

Table 3. Equilibrium concentrations of the rotational isomers in *racemic*-2,3-dibromobutane

Solvent	D_{648}/D_{561}	D_{543}/D_{561}	$C_{RG'}$ %	C_{RG} %	C_{RT} %
n-Hexane (1.89)	0.140	1.102	6	75	19
Cyclohexane (2.02)	0.225	1.202	10	71	19
Carbon disulfide (2.64)	0.314	1.574	13	64	23
Pure liquid (5.758)	0.499	1.618	19	59	22
Cyclohexanone (18.3)	0.958	1.922	30	49	21
Acetonitrile (37.5)	1.174	1.944	34	46	20
Pure liquid[a]			20	60	20

a) NMR data from the paper of Bothner-By and Naar-Colin.[3]

The author wishes to express his hearty thanks to Professor M. Takeda of Science University of Tokyo and Professor T. Shimanouchi of The University of Tokyo for their encouragement during the progress of the work, and to M. Kawakami for his assistance.

*1 In this case we have taken the 635 cm^{-1} band to MG and the 552 cm^{-1} band to MT. When the remaining band at 600 cm^{-1} is taken to MG, the value of k_{552}/k_{600} becomes 4.48. If either band at 635 or at 600 cm^{-1} is taken for MG, the result is the same as those obtained in the determination of the equilibrium concentrations in various solvents.

16) S. Kondo, E. Tagami, K. Iimura and M. Takeda, This Bulletin, **41**, 790 (1968).

*5 The existing ratios of the rotational isomers at 80°C, $C_{RG'}/C_{RG}$ and C_{RT}/C_{RG}, were calculated from the observed energy differences, $\Delta E^{gas}_{RG'-RG}=1.7$ kcal/mol and $\Delta E^{gas}_{RT-RG}=1.5$ kcal/mol; they were found to be 0.089 and 0.118 respectively. Putting these values and the observed ratios of the optical densities at 80°C, $D_{RG'}/D_{RG}=0.139$ and $D_{RT}/D_{RG}=0.510$, into Eq. (7), the values of $k_{RG'}/k_{RG}$ and k_{RT}/k_{RG} were determined to be 1.56 and 4.32 respectively. The equilibrium concentrations were then calculated using these ratios of the absorption coefficients.

*6 Using Eq. (1), the losses in potential energies in the acetonitrile solvent ($\varepsilon=37.5$), for instance, are calculated to be 1.6 kcal/mol for RG′, 0.7 kcal/mol for RT, and 0.2 kcal/mol for RG; hence, the energy differences between the rotational isomers in the solvent become $\Delta E_{RG'-RG}=0.3$ kcal/mol and $\Delta E_{RT-RG}=1.0$ kcal/mol. In this calculation, the value of the density, 1.7836, was taken from the paper of Winstein and Wood.[15]

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 3141—3147 (1969)

Kinetics of Reactions of Amines with Alkene Oxides

P. K. SUNDARAM and M. M. SHARMA

Department of Chemical Technology, University of Bombay, Bombay 19, India

(Received August 10, 1968)

A variety of amines such as piperazine, pyrrolidine, morpholine, dialkyl amines, alkanolamines *etc.* were reacted with ethylene-, propylene-, and 1,2-butylene oxides in aqueous medium. Most of the experiments were made at 20°C. For some typical amines kinetic runs were made over a wide temperature range to obtain values of activation energy. Theoretical aspects of the reaction are discussed. It is shown that the method suggested by Swain and Scott could be used to correlate the rate constants. A close relationship exists between the relative rates of reaction of amines with CO_2, COS, CS_2 and alkene oxides.

The reaction of an amine with an alkene oxide results in the formation of an alkanolamine. The first addition to the epoxide is followed by one or more secondary additions of the epoxide to the reaction products. The reactions are:

$$R_1\text{-}\underset{\backslash O /}{CH\text{-}CH_2} + RNH_2 \rightarrow R_1CH(OH)CH_2NHR \quad (1)$$

$$R_1\text{-}\underset{\backslash O /}{CH\text{-}CH_2} + R_1CH(OH)CH_2NHR \rightarrow [R_1CH(OH)CH_2]_2NR \quad (2)$$

which may be followed by

$$R_1\text{-}\underset{\backslash O /}{CH\text{-}CH_2} + [R_1CH(OH)CH_2]_2NR + H^+ \rightarrow [R_1CH(OH)CH_2]_3N^+R \quad (3)$$

which occurs very slowly at a very late stage in the reaction.

Sharma[1] and Kothari and Sharma[2] have studied the kinetics of reactions between a variety of primary and secondary amines and CO_2, COS and CS_2 and have found close relationships in their rates of reactions *e.g.*:

$$\log_{10} k_{Am\text{-}CS_2} \approx \log_{10} k_{Am\text{-}CO_2} - 4.3 \quad (4)$$

where k is the second order rate constant. It is likely that there also exists a close relationship between the rates of reactions of amines with CO_2, COS, CS_2 and alkene oxides.

Experimental Methods, Analytical Techniques and Theoretical Aspects

Many methods have been reported in the literature for following the amine-alkene oxide reactions: the distillation method, conductivity method, dialatometric method, polarimetric method and the gas chromatographic method. Hansson[3] in his extensive series of reactions between amines and alkene oxides had adopted the "distillation method," which does not appear to be sound. Here an aliquot of the reaction mixture was taken at appropriate times and was subjected to vacuum. *n*-Octadecyl alcohol was added to the flask in which the aliquot of the reaction mixture was taken to reduce foaming on application of vacuum. It was supposed by Hansson that on application of vacuum to the aliquot of the reaction mixture, none of the reaction product (that is, the alkanolamine which was thought to be non-volatile) was lost and what was distilled off was only the relatively more volatile reactants in the reaction mixture. The material left in the flask after application of vacuum for sufficient length of time was titrated directly with a standard mineral acid. The supposition that no reaction product distilled off is not valid. Hansson had realized that some alkanolamine is likely to be lost and he therefore, applied a 'correction' factor. His method of correcting for the loss of the alkanolamine is theoretically unsound.

Known and appropriate amounts of freshly estimated epoxide[4] and amine[5] were taken separately in two 250 m*l* iodination flasks and brought to the experimental temperature in a thermostatic bath where the temperature could be controlled to ±0.05°C of the desired temperature. The reactants were mixed at a known time and aliquots of the reaction mixture were withdrawn at known intervals of time and added to sufficient quantity of dilute sulphuric acid taken in a 100 m*l* conical flask to arrest the reaction. The volatile epoxide (*i.e.* ethylene- or propylene oxide) was removed by the application of vacuum. In the case of 1,2-butylene oxide the reaction sample withdrawn was analysed immediately after adding it to sulphuric acid with the minimum lapse of time——this being necessitated due to its relative nonvolatility (bp 63.2°C/760 mmHg)

and the difficulty in removing it by the application of vacuum. In this case the analysis was carried out quickly so as to reduce to a minimum any possibility of reaction of the protonated amine with the epoxide.

Most of the reactions were studied at 20°C in aqueous medium. However, in some typical cases, experiments were made upto 40°C to obtain values of activation energy.

In most of the cases secondary amines were reacted with an epoxide and in a few cases when primary amine-epoxide reactions were studied, the relative amine concentration in the reaction mixture was taken at least four times that of the epoxide so that the secondary reactions are either obviated or reduced to a minimum. Similarly when a secondary amine is reacted with an epoxide the product of the reaction is a tertiary amine and the complications due to its reaction with another molecule of the epoxide to form a tetra-alkyl ammonium hydroxide (in the presence of a hydrogen ion from the solvent) are insignificant.

Analytical Techniques

Primary Amine-Epoxide Reactions. The analysis involving the separation of the primary amine and the product (a secondary amine) was effected by the Schiff's reaction of salicylaldehyde in 1:1 ethylene glycol, isopropanol solvent with the primary amine and the potentiometric titration of the unreacted secondary amine with hydrochloric acid in the same prescribed solvent:[6,7] The method depends upon the fact that salicylaldehyde reacts quantitatively with primary amines to form compounds of decreased basicity capable of being differentiated from the secondary amine in a non-aqueous potentiometric titration.[7]

It was found that the above method was suitable only for studying the reactions between alkene oxides and amines like cyclohexyl-, and benzylamines, the products of reactions of which had steric resistance and were likely to react sluggishly, if at all, with salicylaldehyde under normal conditons. However, this method failed to differentiate between simple amines like *n*-butylamine and its product with ethylene oxide-butylaminoethanol or that with propylene oxide, butylaminoisopropanol.

Secondary Amine-Epoxide Reactions. This involved an estimation of the secondary amine in the presence of the tertiary amine. An aliquot of the reaction mixture withdrawn in an excess of sulphuric acid was subjected to vacuum to remove the volatile epoxide. The solution was then neutralized with alkali using thymolphthalein indicator after running in 30—40 m*l* of isopropanol. An excess of CS_2 was then added to convert the secondary amine to the dithiocarbamic acid which was only 90—95 per cent complete. It was forced to completion by a standard sodium hydroxide titrant to a first blue or blue green end point. The amount of the standard sodium hydroxide titrant gave a direct measure of the secondary amine present. The reactions involved are:

$$R_2NH + CS_2 \rightarrow R_2N\overset{\overset{S}{\|}}{C}\text{-}S^- + H^+ \qquad (6a)$$

and $$OH^- + H^+ \rightarrow H_2O \qquad (6b)$$

This method of the estimation of secondary amine[8] is specific as only the secondary amine can react with carbon disulphide; the tertiary amine does not have a labile hydrogen atom to react with carbon disulphide. In this method only amines that are highly branched in the 2-position, like diisopropylamine, tertiary butylamine, *etc.* do not react quantitatively with CS_2 under the conditions used.

Materials

All the chemicals used were, in general, technical grade. The materials were purified whenever necessary and estimated before using them for experimental work.

Propylene- and 1,2-butylene oxides were obtained as liquids and were sufficiently pure to be used as such without further purification. Ethylene oxide was available in cylinders and an aqueous solution was prepared for reactions immediately prior to use. All the three epoxides were estimated prior to use in aqueous solution by Ross method[4]——by estimating the total amount of hydroxide ion liberated in the reaction between the epoxide and an excess of thio-sulphate anion in a 50 per cent aqueous acetone solution, by using a standard acetic acid solution.

Methylaminoethanol, ethylaminoethanol, butylaminoethanol and methylaminoisopropanol were synthesized by reacting the relevant epoxide and the amine; the amount of the amine being at least five times the concentration of the epoxide. The alkanolamines were recovered in aqueous solutions from the synthetic mixture (after allowing it to stand for sufficient length of time) by removing the relatively more volatile amine used, by application of vacuum.

Discussion of the Reactions

The primary reactions are:

$$R_1\text{-}\underset{\diagdown O \diagup}{CH}\text{-}CH_2 + RNH_2 \begin{cases} \nearrow R_1CH(OH)\text{-}CH_2NHR & (1) \\ \searrow R_1\underset{\displaystyle NHR}{\underset{|}{CH}}\text{-}CH_2OH & (7) \end{cases}$$

which can give rise to one or both possible isomers, with the exception of ethylene oxide or symmetrically substituted alkene oxides. In accordance with the general practice and also the rule summarized from the work of Krassusky[9] product obtained through Eq. (1) will be termed "Normal" and the one obtained through Eq. (7) as "Abnormal."

The literature pertaining to the direction of the cleavage of the substituted epoxide ring is extensive and various hypotheses to explain the observed isomer distribution have been considered by various workers. It may be summarized that the reactions between amines and alkene oxides

give predominantly the "Normal" isomer under neutral or basic conditions. Since the reactions studied here are all under basic conditions reaction (7) could be neglected.

When primary amine reactions are studied complications arise due to the consecutive and competitive reaction of the product amine with the epoxide. The same could be avoided or reduced to a minimum by taking high ratios of the amine to the alkene oxide as pointed out earlier. In the case of secondary amine the reactions become reasonably free of complications as the reaction rate of the tertiary amine product will be very small compared to the secondary amine used due to the steric inhibition.

Another important factor to be considered is the solvolysis of the epoxide. In the case of water (and even alcohol) the solvolysis does not disturb the main reaction of addition of amine to the alkene oxide as the solvolysis rates are of no significance till almost the very end of the reaction. This becomes important however, when rather slow reactions, as those between sterically hindered amines and epoxides are studied as the rate constant for the primary reactions may be affected appreciably due to the side reaction.

Results

The reactions between amines and alkene oxides were found to follow a second order rate equation:

$$\frac{dx}{dt} = k(a-x)(b-x) \tag{8}$$

giving,

$$\log_{10}\frac{(a-x)}{(b-x)} = \frac{k_2(a-b)}{2.303}t - \log_{10}\frac{b}{a} \tag{9}$$

where,

a=the initial concentration of the epoxide
and b=the initial concentration of the amine.

The values of the second order rate constants k_2 were obtained graphically by plotting $\log_{10}\frac{(a-x)}{(b-x)}$ against t, the slope of the line being $\frac{k_2(a-b)}{2.303}$. The points fell on good straight lines. A good portion usually 5—75 per cent of the reaction was followed and all the runs were done at least in duplicate. There was always a good agreement between the duplicate runs.

The rate constants for the reactions between amines and alkene oxide in water at 20°C are presented in Table 1.

In Tables 2 and 3 are presented the rate constants for the reactions of some typical amines with propylene oxide and ethylen oxide, respectively, at different temperatures along with the values of the activation energies evaluated from the slopes of the Arrhenius plots.

Table 1. Rate constants for the reactions between amines and alkene oxides in water

Temperature=20°C k_2 in l mol^{-1}min^{-1}

No.	Amine	Ethylene oxide	Propylene oxide	1,2-Butylene oxide

Discussion

The reactions of amines with alkene oxides follow a second order rate equation and follow the S_N2 mechanism, the rate being proportional to the

concentration of both the nucleophilic reagent and the substrate.[10]

The rates of the reactions of amines with the alkene oxides (see Table 1) show a close relationship. A plot of logarithms of the rate constants of the amines for one epoxide say ethylene oxide with the same parameter for another epoxide say propylene oxide shows a linear free energy relationship (see Figs. 1 and 2). The relationships are:

$$\log_{10} k_{\text{Am-Propylene oxide}} \approx \log_{10} k_{\text{Am-Ethylene oxide}} - 0.17 \quad (10)$$

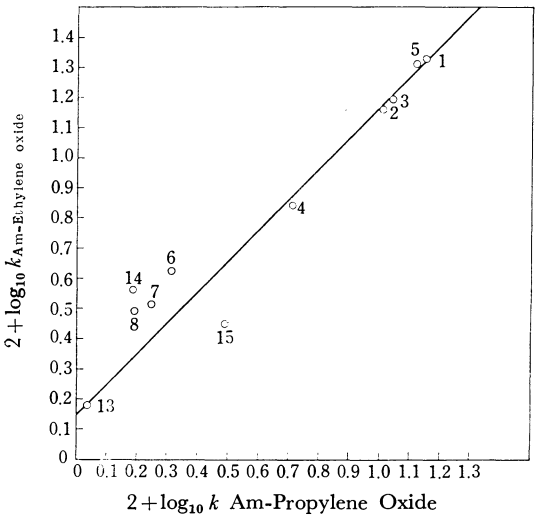

Fig. 1. Plot of rate constans of amines with ethylene oxide against rate constants for propylene oxide.

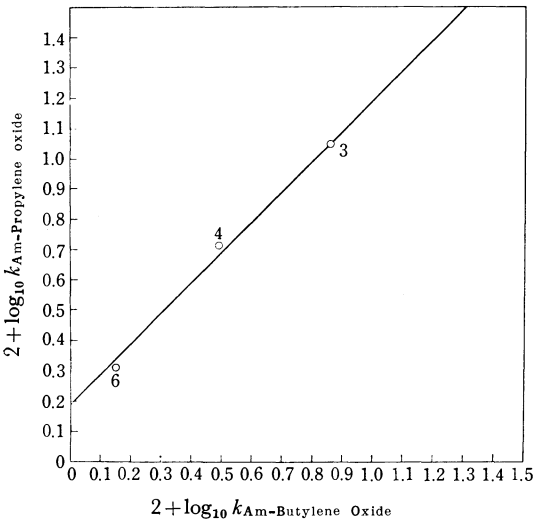

Fig. 2. Plot of rate constants of amines with propylene oxide against rate constants for 1,2-butylene oxide.

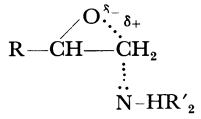
10) L. F. Fieser and M. Fieser, "Organic Chemistry," III Ed., Reinhold Publishing Corp., New York (1958), p. 337.

$$\log_{10} k_{\text{Am-Butylene oxide}} \approx \log_{10} k_{\text{Am-Propylene oxide}} - 0.19 \quad (11)$$

so that with the same amine on passing from ethylene-, propylene-, to 1,2-butylene oxide the rate goes on decreasing approximately in the ratio 1 : 0.67 : 0.44.

A similar trend has been observed in the results obtained by Hansson[11] and other workers,[12] where ethylene oxide was found to react faster than propylene oxide and epichlorohydrin even faster than ethylene oxide. This behaviour could be understood by considering the transition state

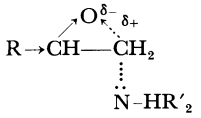


(I)

supposed to involve the attack of the nucleophile on the methylene group of the epoxide ring, with a simultaneous displacement of the ring oxygen atom in the opposite direction.[13]

The presence of the substituent R in the epoxide acts as an impediment for the approach of the reactant and hence the reaction will be slower the larger the size of this substituent R. Thus the increasing size of the alkyl substituent group in propylene oxide ($R=CH_3$) and 1,2-butylene oxide ($R=CH_3CH_2$), explains the decreasing rate of reaction.

However, if the positive inductive effect of the alkyl groups is considered simultaneously, the transition state could be represented by:



(II)

The density of electrons at the CH-carbon atom will increase due to the presence of the electron repelling group R.[14] Consequently, the demand for the electron shift from the methylene carbon atom (CH_2 carbon) will be lowered resulting in a smaller positive charge on it and a lower reaction rate. Thus the dual effect of the alkyl groups, one steric and the other polar (with a positive inductive effect) act in the same direction as to inhibit the reaction.

Similar reasoning accounts for the much higher reactivity of epichlorohydrin[12] when compared to the other epoxides. In this instance it appears

11) J. Hansson, "A Kinetic Study of the Addition of Amines to Propylene Oxide," Lindstedts. Lund (1955), and earlier papers.

12) L. Smith, S. Mattsson and S. Andersson, Lunds Univ. Arsskr., Nr. 7, 1 (N. F.) (1946).

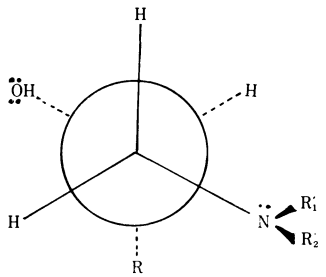
13) R. E. Parker, N. B. Chapman and N. S. Issaacs, *J. Chem. Soc.*, **1959**, 1925.

14) D. Swern, G. N. Billen and H. B. Knight, *J. Am. Chem. Soc.*, **71**, 1152 (1949).

that the increased size of the substituent in the epoxide from CH_3 (in propylene oxide) to $ClCH_2$ (in epichlorohydrin) does not have as much effect in retarding the reaction rate as the acceleration of the rate due to the negative inductive character of the chloromethyl group.

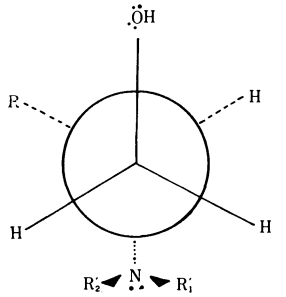
Normal and Abnormal Reactions. The attack of the epoxide by the nucleophile on the terminal methylene carbon atom (CH_2) bearing a positive charge and having less steric hindrance is much easier than the attack on the CH carbon atom. Moreover the secondary amines themselves show appreciable primary steric effects. All these factors contribute to the preferential formation of the normal rather than the abnormal products of the reactions considered.

Conformational Analysis. Conformational analysis as to the relative stabilities of the normal isomer (a) and the abnormal isomer (b) (see Fig. 3) also favours the formation of the former rather than the latter.



Normal isomer R-CH(OH)-CH_2-N$\begin{matrix}R'_1\\R'_2\end{matrix}$

(a)



Abnormal isomer R-CH-CH_2OH

N$\begin{matrix}R'_1\\R'_2\end{matrix}$

(b)

Fig. 3. Projection formulae of normal and abnormal Isomers

Of the various rotational isomers possible for the normal and the abnormal isomers (a) and (b) represent the most stable conformation in each set. The relative stabilities of the above two structures will determine as to which isomer is formed predominantly, if at all. In the formula (b) the groups R'_1 and R'_2 are situated very close to the hydrogen atoms and the conformation though not exactly, is similar to an eclipsed one. These two "almost eclipsed" interactions combined with the strong skew interaction between groups R and $\ddot{O}H$ and the probable R–R'_2 interaction make the molecule very constrained and of much higher energy content than (a) where there are two mild interactions between $\ddot{O}H$ and H, R'_1 and H, and R and $\ddot{N}$. But the sum of these interactions should be much smaller than that of (b). These indicate that the isomer (b) is under great strain and of higher energy content and hence the predominance, if not the exclusive formation of the isomer (a), in most of the reactions.

In view of the above considerations, it may be inferred that the greater the size of the alkyl group R and also the greater the branching of the chains present in the alkyl groups R'_1 and R'_2, the more difficult should be the formation of the isomer (b).

Reactivities of Heterocyclic Amines. The heterocyclic amines pyrrolidine, piperidine, *etc.* (See Table 1) react markedly faster compared to most of the amines listed. Pyrrolidine reacts with ethylene oxide about 3.5 times as fast as diethylamine and about 5 times as fast with propylene oxide. Similarly, the reactivity of morpholine (pK_a at 25°C[15]=8.36) is about 4—5 times that of diethanolamine (pK_a at 25°C[16]=8.88) though the former is the weaker base.

The structures of pyrrolidine and morpholine could be obtained from those of diethyl- and diethanolamines respectively with a little distortion and this results in the high increase in the reaction rates.

The relative rates of reactions of morpholine and diethanolamine with CO_2 and COS are about 13.5 and 20 respectively as shown by the work of Sharma.[1] Pyrrolidine reacts about 5 times as fast as diethylamine with COS.[1] The rate of reactions with CS_2 also follow a similar trend—pyrrolidine reacting about 6 times as fast as diethylamine and morpholine about 10 times as fast as diethanolamine.[2] Further at 25°C, pyrrolidine and morpholine react with 4-nitrofluoro-benzene[17] about 90 times as fast as diethylamine and diethanolamine respectively. The increased reactivity of the heterocyclic amines is due to the restriction of the free play of the alkyl groups about the nitrogen atom about the ring.

If the same analogy is applied in the case of dimethylamine and ethylenimine, it would be con-

15) H. K. Hall, Jr., *J. Am. Chem. Soc.*, **79**, 5441 (1957).
16) V. E. Bower, R. A. Robinson and R. G. Bates, *J. Res. Nat. Bur. Stand.*, **A66**, 71 (1962).
17) H. Suhr, *Ann. Chem.*, **689**, 109 (1965).

cluded that ethylenimine should be a very highly reacting species as even dimethylamine is a fast reacting compound. Some preliminary experiments showed that ethylenimine was reacting so slow as to be termed "almost inert" when compared to the other amines listed. In agreement with the above observation, the reactivity of dimethylamine with 4-nitrofluoro-benzene is seen to be 156 times as great as that of ethylenimine.[17] The "inert" character of ethylenimine is probably due to the aromaticity or electron delocalization of the three membered ring.[18] The fact that ethylenimine is a base (pK_a at 25°C[19]=8.04) even weaker than ammonia (pK_a at 25°C[15]=9.21) is also due to the same reason.

Steric and Inductive Effects. The relative rates of reactions of dimethyl-, diethyl-, di-*n*-propyl-, and di-*n*-butylamines with propylene oxide are seen to be 8.60 : 1.32 : 1.00 : 1.13. The same order of reactivity is maintained in their reactions with ethylene oxide, with a minimum in the rate in case of di-*n*-propylamine. But then to di-*n*-butylamine there is a slight but a definite increase in the rate. This may be explained by considering the simultaneous operation of two effects——the rate decreasing steric effect and the rate increasing positive inductive character of the alkyl groups attached to the amino nitrogen.

It appears that from dimethyl-, to di-*n*-propylamine the steric effect outweighs the inductive effect but from di-*n*-propyl- to di-*n*-butylamine, the effect of the increase in the inductive character is a little more than that of the increase in the size of the alkyl groups, giving rise to the observed minimum at the di-*n*-propylamine.

Amine Reactivities and pK_a Values. No correlation between the reactivities of amines with the epoxides, with the pK_a values of the amines is found.

It may be that the steric arrangements of the amines are such that the different groups attached to the amino nitrogen are not effective in preventing a hydrogen ion in combining with it in the equilibrium reaction:

$$RNH_2 + H^+ \rightleftarrows RNH_3^+ \qquad (12)$$

on which the basicity of the amine depends, but offering strong resistance to the transition state formation with a bulkier substrate like an epoxide.

The non-dependence of the basicities of the substituted ammonium ions on the steric factors is reflected in the fact that *n*-, *s*-, and *t*-butylamines have practically the same basicities (pK_a's 10.5 at 25°C[15]).

The importance of steric and inductive factors is evident from the following examples in the reactions of amines with ethylene oxide:

1) piperazine (pK_{a_1}=9.81[20]) and dimethylamine (pK_a=10.64[15]) react almost with the same velocity.

2) dimethylamine (pK_a=10.64[15]) reacts more than six times as fast as di-*n*-butylamine (pK_a=11.25[15])

3) methylaminoethanol (pK_a=9.70[21]) reacts more than three times as fast as ethylaminoethanol (pK_a=9.80[21]) and

4) morpholine (pK_a=8.36[15]) reacts more than four times as fast as diethanolamine (pK_a=8.80[16]).

Similarly with CO_2, *n*-butylamine and isobutylamine (pK_a=10.42 at 25°C[22]) show practically the same rate of reaction, but *s*-butylamine reacts at one third this rate; *t*-butylamine, where the steric factors are likely to be most important, reacts at about only a tenth of that for *n*- and isobutylamine.[1]

Similarity of Structures and Reactivities. The rate constant in the case of ethylaminoethanol (containing one ethyl and one hydroxy-ethyl groups) is about the mean of the rate constants of diethylamine (containing two ethyl groups) and diethanolamine (containing two hydroxyethyl groups). A similar relation in the case of methylaminoethanol with that of dimethyl- and diethanolamines is also seen to exist.

In the above case, the groups mentioned are similarly linked with the reaction centre both in the compounds considered for isolating the combined contribution of the polar and steric effects of each group and also in the compounds for which the estimations of the rates are made in addition to the mechanism of the reactions as well as the substrate being the same in all the cases. However, it is unlikely that general group contribution values could be assigned to various functional groups.

Swain-Scott Correlation. Plots of the values of *n*[23] the nucleophilic constants of the amines against their respective logarithms of rate constants with alkene oxides are found to give approximate linear plots (Fig. 4) showing that the nucleophilic reactivities of aliphatic amines towards varied substrates can be correlated by the four parameter equation proposed by Swain and Scott.[24] The correlation of course is not exact as indicated by the scatter of the points.

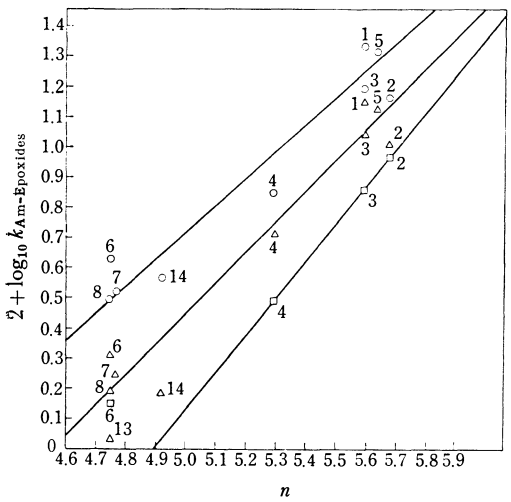

Fig. 4. Plot of logarithms of the rate constants of amines with alkene oxides against the nucleophilic constant, *n*, of the amines.
○ Ethylene oxide, △ Propylene oxide, □ 1,2-Butylene oxide

The values of *n* are found to be higher for the faster reacting amines and *vice-versa*. Thus the values of *n* are found to give the quantitative measures for the reactivities of different nucleophiles.

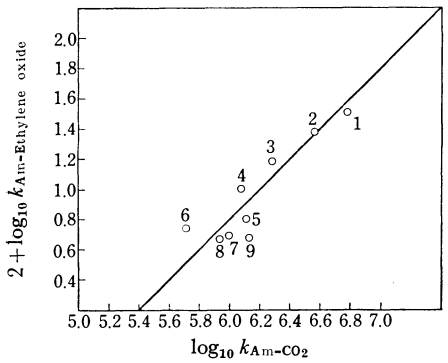

Fig. 5. Plot of rate constants of amines with ethylene oxide against rate constants for CO_2.

Linear Free Energy Relationship. An attempt was made to see whether a linear free energy relationship exists between the reactions of a variety of amines with ethylene oxide and CO_2. The values of the logarithms of the rate constants of amines with ethylene oxide at 25°C (obtained from the respective rates at 20°C using a value of activation energy of 14 kcal/g mol) were plotted against the logarithms of the rate constants of the amines with CO_2[1] at 25°C (Fig. 5). Although there is some scatter of data, the following relation is likely to hold:

$$\log_{10} k_{\text{Am-Ethylene oxide}} \approx \log_{10} k_{\text{Am-CO}_2} - 7.20 \qquad (13)$$

Conclusions

1) The rate constant for a given reaction is found to be a function of (i) steric and (ii) polar factors: (i) For a specified amine, the rate constant for ethylene oxide is significantly greater than that for propylene- and 1,2-butylene oxides; (ii) In the case of dialkylamines the rate constant decreases from dimethyl- to di-*n*-propylamine and then there is a nominal increase in the rate when higher di-*n*-alkylamines are used.

2) The "Normal" addition of amines to epoxides could be explained on the basis of conformational analysis.

3) Heterocyclic amines react faster than the other related amines probably due to structural factors.

4) For all classes of amines there is no general relationship between their basicities and rate constants.

5) In general, the rate constants for a variety of amines can be correlated by the Swain-Scott equation.

6) Linear free energy relationships exist between the rates of reactions of a variety of amines with ethylene-, propylene-, 1,2-butylene oxides, CO_2, *etc.*

Investigations on the Kinetics and Mechanism of the Reduction of Mercuric Chloride by Malic Acid, Induced by Potassium Peroxodisulphate

Krishna KUMAR and L. K. SAXENA

Chemical Laboratories, Agra College, Agra, India

(Received August 22, 1968)

The $S_2O_8^{2-}$ induced reduction of mercuric chloride by malic acid has been studied by estimating the precipitated calomel. Kinetic measurements reveal the reduction rate to be independent of the acid concenıration and first order in peroxodisulphate, but only to up an optimum concentration, whereafter further increase in inductor concentration decreases the reduction rate. A fractional order dependence in mercuric chloride concentration is encountered. The reaction is characterized by an initial of period induction. The initial rapid consumption of the acid results in lowering of the rate beyond a particular stage of the reaction. Increase of temperature and concentration of reactants is found to effect the period of induction. H^+ ions and oxygen inhibit the reduction rate. Products identified are mainly calomel, carbon dioxide and malonic acid. A chain mechanism in which radical ion chain carriers participate, has been suggested.

Induced reduction of mercuric chloride by certain organic acids was first observed by Dhar.[1] The role of the inductor (normally an oxidizing agent) in activating the acid was later investigated by Cartledge,[2] Weiss,[3] and others.[4] Kinetic investigations undertaken by Weiss led him to propose a chain mechanism based on free radical formation. Mathur and Bansal,[5] employing MnO_4^- as the inducing ion, have kinetically investigated the reduction of mercuric chloride by certain organic acids.[6] They have based the mechanisms, in the respective cases, on the formation of an intermediate complex which on decomposition furnishes the reducing radical. Mechanisms for aqueous decomposition of such manganic complexes have been cited as evidence for free radical generation in the reactant solutions.[7]

The reduction of mercuric chloride to the mercurous state by oxalic acid[8] and tartaric acid[9] induced by $S_2O_8^{2-}$ ion has also been studied kinetically by one of the authors. Kinetic measurements conducted to determine the exponents in the rate law

$$d(Hg_2Cl_2)/dt = k(HgCl_2)^x(C_2O_4^{2-})^y(S_2O_8^{2-})^z$$

showed that $x=0.5$ to 1, $y=0$, and $z=1$.
With tartaric acid the reduction was found to obey a second order rate.

From the references cited above, it is clear that the reduction of mercuric chloride employing peroxodisulphate as the inducing ion, has been investigated only in cases of oxalic and tartaric acids. However, $S_2O_8^{2-}$ induced reduction of mercuric chloride by malic acid remains hitherto uninvestigated from the viewpiont of kinetics and mechanism.

Investigations have revealed that the mechanism, consistent with the observations on induced reduction of mercuric chloride by organic acids, were mainly dependent on the acid-inductor reaction mechanism. Therefore, observations incorporated in this paper were preceded by kinetic studies on the reaction between malic acid and potassium peroxodisulphate so as to ascertain the mechanism involved therein.[10] The paper includes our results on kinetic investigations undertaken to uncover the mechanism of peroxodisulphate induced reduction of mercuric chloride by malic acid.

placed in a thermostat maintained at desired temperature. For a single kinetic run the reaction was allowed to progress for different intervals of time in different conical flasks under identical conditions of temperature and concentrations of the reactants. The kinetics was followed by estimating the amount of calomel precipitated in each flasks at desired intervals of time.

Estimation of Calomel. Calomel precipitated was filtered off through a double-walled funnel containing ice-cold water in between its walls. With this technique further reduction of mercuric chloride is prevented even during filtration. The precipitate was then washed and estimated by a standard potassium iodate solution.[11]

Estimation of Peroxodisulphate. Peroxodisulphate was also estimated during a kinetic run. Aliquot portions of the solution, usually 10 m*l* were withdrawn at intervals with a pipette plugged with wool to avoid calomel and analyzed for residual peroxodisulphate by the usual method.[12] Excess of potassium iodide removed mercuric chloride in solution, as complex. Experiments showed that the presence of this complex caused no error.

The apparent first and second order rate constants (k_1 and k_2 respectively) in mercuric chloride were calculated by the established relations. The average rate of mercuric chloride reduction between successive time intervals was calculated by the expression dx/dt, where dx is the amount of mercurous chloride (in mol l^{-1}) formed during an interval dt. Average C signifies the mean concentration of mercuric chloride, between two successive time intervals, calculated in terms of the equivalent titre volume of KIO_3 in m*l*.

Results of Rate Measurements

Preliminary experiments showed that the induced reduction of mercuric chloride by malic acid proceeds with measurable speed at 60°C and with 0.2M initial concentration of the acid. A typical set of results is shown in Table 1.

TABLE 1

The data in Table 1 shows that reduction of mercuric chloride commences after an initial period of induc- tion (3.5 min) and proceeds to about 50% in 10 hr. Figure 1 reveals that the reaction is autocatalytic for a comparatively short period of 60 min, whereafter the rate decreases continuously with time.

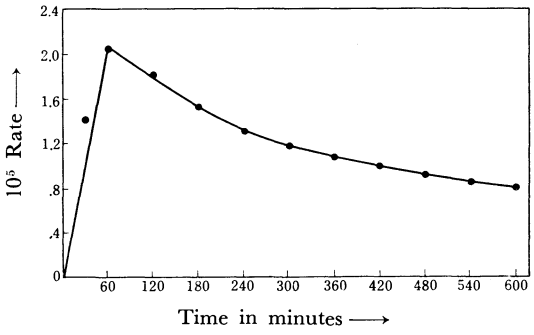

Fig. 1
Malic acid=0.2 M, $HgCl_2$=0.02 M,
$K_2S_2O_8$=0.02 M, Temp.=60°C

First and second order kinetic plots in mercuric chloride revealed marked deviations from linearity; the downward curvatures in each plot signifying the rapid fall in concentration of one of the reactants.[13] Since the reduction of mercuric chloride proceeds only to 50% and is also rapid during the initial few hours, it leads one to suspect that the acid concentration falls much below that of mercuric chloride. This could happen only if the acid is consumed rapidly during the initial stages of the run. It could also be possible that peroxodisulphate concentration may fall much below the acid concentration. But, as will be seen later, this does not happen.

In view of these observations it seems obvious that one is dealing with a complex system wherein, because of the initial rapid consumption of the acid, the reduction does not exceed 50%. This conclusion finds further confirmation from kinetic measurements with initially high acid concentration, which reveal the acid consumption to follow a similar trend. Despite the ratio (Acid)/($HgCl_2$) being kept 50 in certain experiments, we have not been able to obtain reduction of mercuric chloride beyond 50—60% in a period of 10 hr.

Dependence of the Reduction Rate on the Initial Concentration of Reactants. Table 2 records the results of a series of experiments showing the influence of the initial concentration of inductor ($K_2S_2O_8$), actor (malic acid) and acceptor ($HgCl_2$)

		0.030	1.62	4.65	0.06	1.50	0.025

on the rate of mercuric chloride reduction. In each experiment the concentrations of two reactants were kept constant and the third was varied as noted in the columns. Since the overall reduction rate changes with time (as shown in Fig. 1), the initial rate (IR) at each concentration was calculated for 120 min from the x–t curves.

The initial reduction rate is not appreciably affected over a range of 0.15M to 0.40M acid concentration which suggests the rate law to be zero order in (malic acid) (Table 2a), and the variation of rate with respect to mercuric chloride concentration can be expressed as $d(Hg_2Cl_2)/dt=k(HgCl_2)^{0.3}$ (Table 2b, Fig. 2).

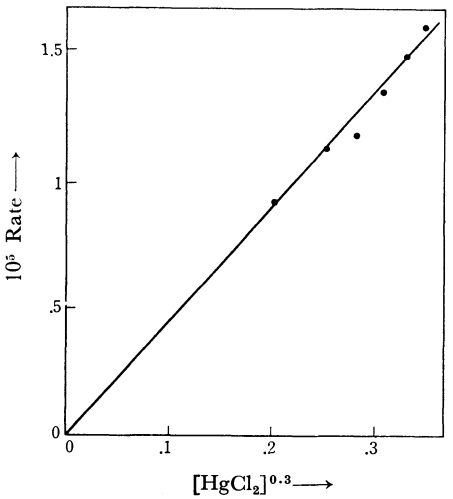

Fig. 2

Malic acid=0.1 M, $K_2S_2O_8$=0.02 M, Temp.=60°C

Scrutiny of results in Table 2(c) shows the reduction rate to be strictly of first order with respect to peroxodisulphate up to 0.03M concentration of the inductor. However, further increase in the initial concentration decreases the reduction rate.

Temperature Dependence. From Fig. 3 it can be seen that increase of temperature increases the overall reaction velocity. The mean energy and

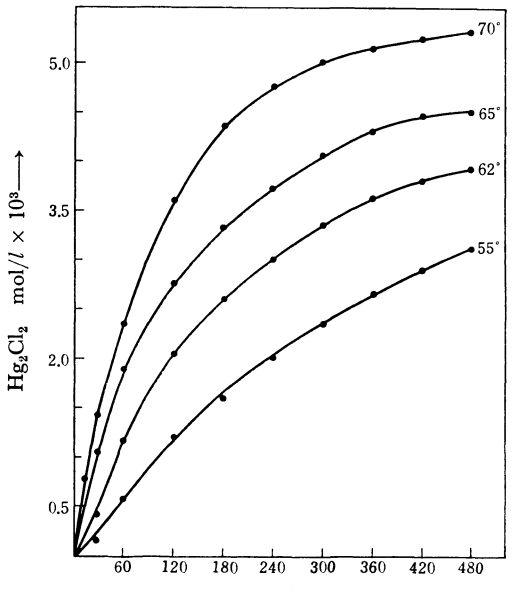

Fig. 3

Malic acid=0.1 M, $HgCl_2$=0.02 M, $K_2S_2O_8$=0.02 M

entropy of activation for the range 55—65°C were found to be 18 kcal/mol and −16 e.u., respectively. It may be pointed out that these values are merely qualitative in nature since they have been calculated from average values of the rate constants from regions exhibiting fair amount of constancy; nevertheless, their order and magnitude helps to evaluate the mechanism of the reaction.

Influence of Gases. Influence of gaseous atmosphere on the reduction rate is represented graphically in Fig. 4. In nitrogen and carbon dioxide atmospheres the reduction rate is faster; the effect of nitrogen being more than carbon dioxide under comparable conditions. Oxygen is found to exert a strong inhibitive influence.

Influence of Acids and Salts. The influence of some acids and their salts was studied to ascertain the role of specific ions on the reduction rate. The percentage reduction of mercuric chloride, in each

case, was calculated as follows:

$$\% = \frac{\text{Titre vol. of } KIO_3 \text{ in m}l}{20\ \text{m}l} \times 100$$

where 20 m*l* KIO_3 volume corresponds to the amount of Hg_2Cl_2 formed on complete reduction of 0.01M $HgCl_2$ in the reaction mixture.

From the foregoing data it may be concluded that H^+ and Cl^- ions inhibit the reduction of mercuric chloride. It appears that Cl^- ion exerts a very strong inhibitive influence. The % reduction is observed to be maximum in the presence of sodium acetate.

Rate of Peroxodisulphate Decomposition. As already mentioned in the experimental part, peroxodisulphate was also estimated. The first order plot at 0.02M concentration of the inductor, is a straight line with a slope giving, $k=4.37\times10^{-3}$ min^{-1}. It can be seen that almost 8 hr are required for the complete decomposition of peroxodisulphate.

The Period of Induction. When peroxodisulphate was added to a solution containing mercuric chloride and malic acid, the reduction of mercuric chloride to the mercurous state did not start immediately. The reduction was observed to begin after a certain time interval after the mixing of the reactants. This time interval has been termed as the period of induction.

Investigations on the induction period were divided into two parts: its dependence on (i) temperature, and (ii) reactant concentration. Results obtained showed that increase in concentration of any of the reactants decreased the period of induction. It was further observed that increase of temperature also decreased this period. Hence, it may be concluded that the induction period depends upon the concentrations of the reactants as well as on the temperature of the reaction. In view of these findings it appears that the induction period is related with the mechanism of the reduction of mercuric chloride.

Discussion

Prolonged oxidation of malic acid by peroxodisul-

phate involves its degradation to malonic acid and carbon dioxide, as revealed by our investigations described earlier.[10] The stoichiometric equation of the reaction verified by us approximates as follows:

$$2K_2S_2O_8 + \begin{matrix}CH_2COOH\\|\\CHOHCOOH\end{matrix} + H_2O$$

$$= CH_2\begin{matrix}COOH\\\diagup\\\diagdown\\COOH\end{matrix} + 4KHSO_4 + CO_2$$

(found: 2 equiv. $S_2O_8^{2-}$: 1 equiv. acid.)

When mercuric chloride is added, the evolution of carbon dioxide sets in immediately, indicative of the degradation of malic acid in this case as well. Products that have been identified are mainly mercurous chloride, malonic acid,[14] carbon dioxide and sulphuric acid. A steady decrease in pH is observed, as the induced reduction of mercuric chloride proceeds, signifying the increase in acidity of the system. Under such conditions the stoichiometry may be represented as follows:

$$2HgCl_2 + \begin{matrix}CH_2COOH\\|\\CHOHCOOH\end{matrix} + K_2S_2O_8 + H_2O$$

$$= Hg_2Cl_2 + CH_2\begin{matrix}COOH\\\diagup\\\diagdown\\COOH\end{matrix} + 2KCl + CO_2 + 2H_2SO_4$$

Malic acid alone, like oxalic and tartaric acids, does not reduce mercuric chloride even on boiling. However, addition of small amounts of peroxodisulphate activates the acid to reduce it. This clearly suggests that as a result of the interaction of malic acid and the inductor, some active substance is produced which reduces Hg^{2+} to Hg^+ state. The mere fact that the reduction commences after an initial period of induction, further lends support to this view. Evidently, the nature of this active species is related to the product of oxidation of malic acid by peroxodisulphate.

At this point it would be pertinent to refer to our investigations carried out earlier on the reaction between $S_2O_8^{2-}$ and malic acid (loc. cit.). The proposed mechanism consistent with the rate data, involves chain sequences with transient products SO_4^- and CO_2^- radicals. It has been our contention that these active transients act as chain carriers and control the mechanism of the process of reduction of mercuric chloride,[15] as has been suggested for oxalic and tartaric acid (loc. cit.).

We believe this reaction to be a free radical chain reaction for the following reasons:

1) It progresses through various successive zones;

2) Fractional order dependence in mercuric chloride concentration is encountered (Fig. 2, Table 2b);

3) The marked inhibition by oxygen implicates CO_2^- as a reactive intermediate, since oxygen is known to inhibit certain chain reactions involving CO_2^- radical;[16,17]

4) Peroxodisulphate-malate reaction is a chain reaction in itself.

A reasonable mechanism, similar to that proposed for oxalic and tartaric acids (loc.cit.) may have the gross features as given below:

Chain Initiating Sequence:

1. $S_2O_8^{2-} = 2SO_4^-$ slow

Chain Propagating Sequences:

2. $SO_4^- + \begin{matrix}CH_2COO^{2-}\\|\\CHOHCOO\end{matrix} = SO_4^{2-} + \begin{matrix}CH_2COO^-\\|\\CHOHCOO\\(\text{unstable})\end{matrix}$ fast

$$\xrightarrow{2OH} CH_2\begin{matrix}COOH\\\diagup\\\diagdown\\COOH\end{matrix} + CO_2^- + H_2O$$

3. $CO_2^- + S_2O_8^{2-} = SO_4^{2-} + SO_4^- + CO_2$ fast

Chain Terminating Sequences:

4. $CO_2^- + Hg^{2+} = Hg^+ + CO_2$ faster than 3

5. $SO_4^- + H_2O = HSO_4^- + OH$ slow

$2OH = H_2O + \frac{1}{2}O_2$ fast

6. $CO_2^- + O_2 = CO_2 + O_2^-$ slow

7. $O_2^- + H^+ = HO_2$ leading to H_2O_2 (3)

8. $CO_2^- + SO_4^- = CO_2 + SO_4^{2-}$ slow at low concs.

The primary step is characteristic of peroxodisulphate decomposition and sequences 2 and 3 have been postulated as the mechanism for the reaction between peroxodisulphate and malic acid (loc.cit.).

The chain initiation is caused by the thermal decomposition of peroxodisulphate ion which undergoes a fission on the weak O–O bond with formation of two sulphate radical ions.[18] In a recent review Wilmarth[19] has discussed at length the role of this active species. He maintains SO_4^- to be energetically capable of reacting with the organic substrate and with the solvent, though with unequal efficiencies. Accordingly, in the beginning step 2 would predominate, producing CO_2^- radical and malonic acid.

19) W. K. Wilmarth and A. Haim, Peroxide reaction mechanisms, Conference, Rhode Island, 1960.

CO_2^- being a reactive species reacts with peroxodisulphate ion, thereby regenerating SO_4^-. This could lead to a two pronged attack on malate ions (as long as steps 2 and 3 are equally fast). Our results conform to this initial rapid consumption of the acid.

CO_2^- radical also reacts with Hg^{2+} ion resulting in the precipitation of calomel by step 4. Accordingly, the initial period of induction is the time required for the thermal activation of the $S_2O_8^{2-}$ ion so as to break into SO_4^- radicals which produce CO_2^- responsible for the reduction of mercuric chloride. Increase of temperature increases the velocity of the chain initiating process, resulting in the decrease of period of induction. Similarly, increase in the concentration of either malate or $S_2O_8^{2-}$ increases the rate of SO_4^- production by step 1 or by step 2, respectively, thereby decreasing the period of induction. These conclusions are supported by our observations.

The initial auto-catalytic nature of the reduction reaction probably is a result of chain sequences 2 and 3. Due to the two pronged attack on malic acid the rate of CO_2^- production increases. This results in the reaction becoming autocatalytic in the initial stages (Fig. 1). With the progress of the reaction, however, the accumulated acid would inhibit the rate of reduction since it has been observed that H^+ ions inhibit the reduction of mercuric chloride (Table 3) by catalyzing the chain terminating sequence 5 as follows:

9. $SO_4^- + H^+ = HSO_4$

10. $HSO_4 + H_2O = HSO_4^- + OH + H^+$

$$SO_4^- + H_2O = HSO_4^- + OH \qquad (18)$$

This increases the contribution of sequence 5 to the overall chain termination, resulting in the observed rate drop after the induction period (Table 1). Sodium acetate removes H^+ ions, thereby stabilizing SO_4^- with the result that the chains are elongated (Table 3).

The proposed mechanism also accounts for the independence of the reduction rate on malic acid concentration, since step 4 of the mechanism, which governs the reduction of mercuric chloride, involves free radical CO_2^-. Its rate of production is governed by peroxodisulphate concentration. This further explains the first order dependence in peroxodisulphate in low concentration range (Table 2c). With increase in the initial peroxodisulphate concentration, the oxygen content of the system increase, making sequence 11 quite effective:

11. $O_2 + Hg^+ = Hg^{2+} + O_2^-$

Inhibition by oxygen could also occur through reaction with CO_2^- radical (seq. 6) followed by chain termination, as observed by Allen.[17] This finds support from the enhanced rate obtained by the authors working with nitrogen and carbon dioxide atmospheres which might dispel the accumulated oxygen (Fig. 4).

Appendix

$$d(Hg_2Cl_2)/dt = k_4(CO_2^-)(Hg^{2+}) \qquad (1)$$

In the stationary state of chains:

$$d(CO_2^-)/dt = k_2(SO_4^-)(Mal^{2-}) - k_3(CO_2^-)(S_2O_8^{2-}) - k_4(CO_2^-)(Hg^{2+}) - k_6(CO_2^-)(O_2) - k_8(CO_2^-)(SO_4^-) = 0 \qquad (2)$$

and

$$d(SO_4^-)/dt = 2k_1(S_2O_8^{2-}) + k_3(CO_2^-)(S_2O_8^{2-}) - k_2(SO_4^-)(Mal^{2-}) - k_5(SO_4^-) - k_8(CO_2^-)(SO_4^-) = 0 \qquad (3)$$

from 2 and 3 we have:

$$2k_1(S_2O_8^{2-}) = k_5(SO_4^-) + 2k_8(CO_2^-)(SO_4^-) + k_4(CO_2^-)(Hg^{2+}) + k_6(CO_2^-)(O_2) \qquad (4)$$

Consideration of all the termination steps 5—8 would involve a complicated rate term with various limiting-forms. It is not unlikely that one or two of these steps may be most important of all and a consideration of these would lead to a simple rate expression conforming of the experimental facts. The possibility of other steps becoming important under changed conditions is also not ruled out. However, our results can be best explained by assuming steps 6 and 8 to be insignificantly operative in the initial stages of the reaction and therefore considered negligible as compared to the propagating sequences of the proposed mechanism.
Therefore,

$$2k_1(S_2O_8^{2-}) = k_5(SO_4^-) + k_4(CO_2^-)(Hg^{2+}) \qquad (5)$$

Under these conditions, the steady-state concentration

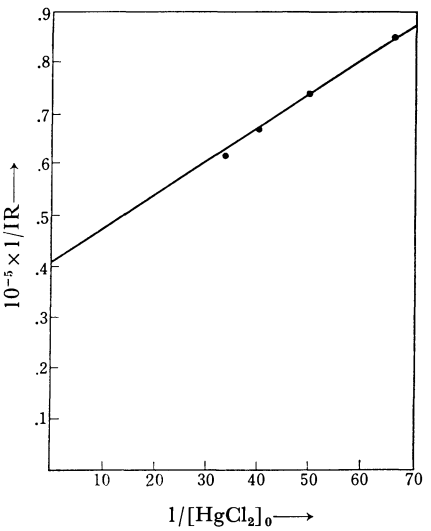

Fig. 6. Dependence of reaction rate on $HgCl_2$ concentration.
Intercept. $= 0.41 \times 10^5$ Slope $= 650$

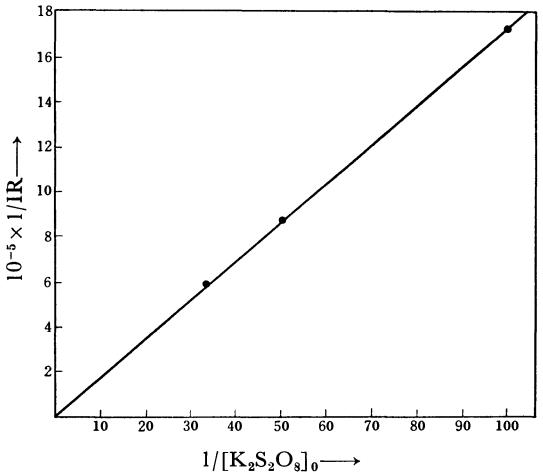

Fig. 7. Dependence of reaction rate on $K_2S_2O_8$ in low concentration range.
Slope = 1745

of SO_4^- as derived from Eq. (2) is:

$$(SO_4^-) = \frac{k_3(S_2O_8^{2-}) + k_4(Hg^{2+})}{k_2(Mal^{2-})}(CO_2^-)$$

Substituting this expression into Eq. (5), we get

$$(CO_2^-) = \frac{2k_1k_2(S_2O_8^{2-})(Mal^{2-})}{k_3k_5(S_2O_8^{2-}) + k_4k_5(Hg^{2+}) + k_2k_4(Mal^{2-})(Hg^{2+})}$$

and

$$\text{rate} = k_4(CO_2^-)(Hg^{2+}) = \frac{2k_1k_2k_4(S_2O_8^{2-})(Mal^{2-})(Hg^{2+})}{k_3k_5(S_2O_8^{2-}) + k_4k_5(Hg^{2+}) + k_2k_4(Mal^{2-})(Hg^{2+})} \quad (A)$$

On the other hand, at the outset of reaction when the stationary state is not yet attained, the rate is given by:

$$\text{rate} = 2k_1(S_2O_8^{2-})\frac{k_4(Hg^{2+})}{k_3(S_2O_8^{2-}) + k_4(Hg^{2+})} \quad (B)$$

In either case the experimental data should fit linear plots of the type

$$1/\text{rate} = a + [b/(\text{reagent})],$$

intercept and slopes of these straight lines giving the constants a and b.

Figures 6 and 7 are such plots of the data in Table 2 and the following tables record the values of rate as obtained by the use of Eq. (B):

TABLE 4. DEPENDENCE OF THE REACTION RATE ON $HgCl_2$ CONCENTRATION
(conditions same as in Table 2)

$(HgCl_2)(mol\,l^{-1})$	0.01	0.015	0.02	0.025	0.03
$10^5(min^{-1})$(obsd)	1.14	1.19	1.36	1.50	1.62
$10^5(min^{-1})$(calcd)*	0.96	1.18	1.36	1.51	1.60

* IR calculated from the relation
$1/\text{rate} = 0.41 \times 10^5 + [650/(Hg^{2+})]$

TABLE 5. DEPENDENCE OF THE REACTION RATE ON $K_2S_2O_8$ IN LOW CONCENTRATION RANGE
(conditions same as in Table 2)

$(K_2S_2O_8)(mol\,l^{-1})$	0.01	0.02	0.03
$10^5(min^{-1})$(obsd)	0.58	1.14	1.70
$10^5(min^{-1})$(calcd)*	0.57	1.14	1.71

* IR calculated from the relation
$1/\text{rate} = O + 1754/(S_2O_8^{2-})$

The observed rates compare reasonably well with those calculated from Eq. (B) (after appropriate choice of values for a and b), thus justifying the proposed reaction scheme and the rate equations derived therefrom.

The authors wish to thank Drs. C. P. Singhal and O. P. Bansal for their interest and encouragement. Thanks are due to Professor P. N. Sharma for his valuable discussion and advice given to the authors. Financial support by the U. G. C. is gratefully acknowledged.

Oscillopolarographic Behaviour of Lanthanide Ions in Potassium Iodide Solutions

Akio IWASE and Chieko YOKOYAMA

Department of Chemistry, Faculty of Science, Yamagata University, Koshirakawa-cho, Yamagata

(Received November 8, 1968)

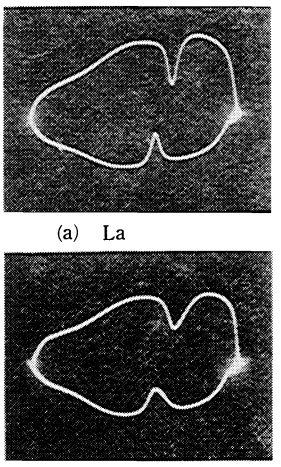
The oscillopolarographic depolarization effect of lanthanide ions in KI solutions was investigated using dropping (DME) and hanging-drop (HME) mercury electrodes. The lanthanide-ion incision depth in the $dE/dt=f(E)$ curve, measured in a 1M KI solution (pH 3.65) with a DME, was found to be much deeper than that in a 1M KCl solution. The temperature coefficient was negative for the La and Sm incision depths in the temperature range from 25° to 50°C. The incision depths of the La (pH 4.0) and Sm (pH 4.5) ions in a solution with an ionic strength of 0.7 (KCl added) were found to depend on the I^- concentration. These facts seem to show that I^- is adsorbed on DME, and that the adsorbed I^- (at -1.4 V) promotes the electrode reaction of lanthanide ions.

Treindl[1] has reported a study of the oscillopolarographic behaviour of La, Pr, Nd, and Sm ions in KI solutions. He has pointed out that, in a 0.2—1M KI (pH 6.4—6.8) solution, the position of the Q incision quotient of the $dE/dt=f(E)$ curves are 0.66, and that a reversible incision is observed. However, no systematic study of the lanthanide ions has been reported. The present authors have noted previously that the lanthanide-ion incision[2] depth measured in such supporting electrolytes as $NaClO_4$, KCl, KBr, and KSCN depends on the first ionization potential and the basicity of the lanthanides. In this study we investigated the oscillopolarographic behaviour of lanthanide ions in KI solutions; we found that their incision depths are much deeper than those in KCl solutions. This seems to indicate that the deeper incision depth is due to the I^- adsorption on the DME.

Experimental

The preparation of 0.01M lanthanide-ion solutions has been described previously.[2] All the other materials were of a reagent grade and were used without further purification. The KI solutions were prepared just before use. The pH values of the electrolyte solutions were adjusted by adding either a 0.01N HCl or 0.01N NaOH solution. All the experiments except for those shown in Figs. 6 and 7 were carried out in a constant temperature bath at 25 ± 0.1°C. Dissolved oxygen was removed by passing nitrogen gas through.

The curves, $dE/dt=f(E)$, were recorded by a manual Heyrovsky-Forejt-type oscillopolarograph, as has been described previously.[2] DME or HME was used as the polarizable electrode. The characteristics of the DME and the HME were as follows. The value of m with a mercury height of 57.6 cm was 0.936 mg/sec; the dropping time was 1.7 sec (in the 1M KI solution), and the weight of a mercury drop was 0.0058 g. An alternating-current source provided 150 V at 50 cps; a 0.23 mA current (0.12 mA for the experiment in Fig. 2) was passed through the cell. The oscillopolarogram in Fig. 1 was photographically recorded by a Polaroid-Land camera using an Iwasaki UP-7 photo-oscilloscope unit. The incision positions and the depths of the $dE/dt=f(E)$ curves were measured directly on the oscilloscope just before the mercury dropped. The values obtained are the averages of three measurements. The vertical-deflection sensitivity of the oscilloscope was 10.0 mV/cm.



(a) La

(b) Sm

Fig. 1. Typical curves of the $dE/dt=f(E)$ of the lanthanum and samarium ions in a deaerated M KI solution at pH 3.65. The concentration of lanthanide was 0.5 mM and the curves were obtained with a DME.

when the DME was used and 5.5 mV/cm when the HME was used. The horizontal deflection sensitivity was 25 mV/mm.

Results and Discussion

The $dE/dt=f(E)$ curves of La^{3+} and Sm^{3+} are shown in Fig. 1. The solutions contained 5×10^{-4}M La^{3+} (Curve a) or 5×10^{-4}M Sm^{3+} (curve b) in M KI(pH=3.65±0.05). The Q values of the cathodic and anodic incisions were 0.67 and 0.61 respectively. The values are shifted from the Q value, 0.66, of the reversible incision. The Q values for other lanthanide ions were the same as with the lanthanum. Figure 2 shows the incision

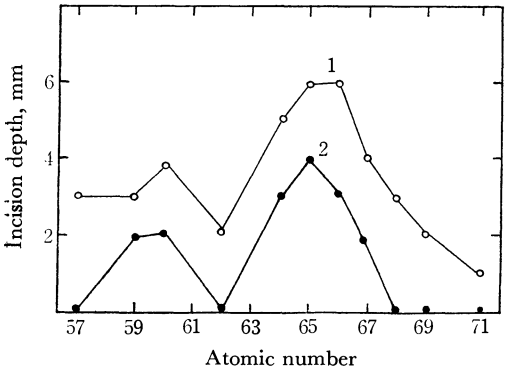

Fig. 2. Variation of the cathodic incision depth with the lanthanides in M (1) KI and (2) KCl solutions at pH 3.65±0.05. The concentration of lanthanides was 0.5 mM.

depth of the 5×10^{-4}M lanthanide solution measured in M KI (curve 1) and in M KCl (curve 2) at pH 3.65 plotted against the atomic number of the lanthanides. The vertical deflection sensitivity was 10 mV/cm for curve 1 and 2.5 mV/cm for curve 2. Curve 1 shows a deeper incision depth than does curve 2. Note that such ions as La^{3+}, Sm^{3+}, Er^{3+}, Tm^{3+}, and Lu^{3+}, which do not give any incision in M KCl (pH 3.65), show a sharp incision in M KI (pH 3.65). The difference between curves 1 and 2 can be difinitely attributed to the presence of I^-.

Therefore, the depth of this incision depends on the concentration and a.c. frequency according to the following formula:[3]

$$h = kc/(kc+4C'\omega^{1/2})$$
$$k = n^2F^2D^{1/2}/RT$$

where C' denotes the differential capacity of the mercury, and ω, the angular frequency. Moreover, the capacity-potential curves reported by Grahame[4]

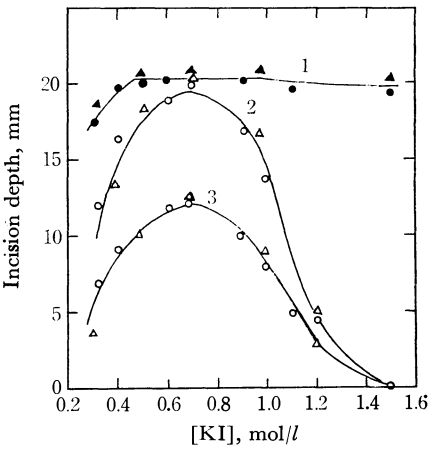

Fig. 3. Effect of potassium iodide concentration on incision depth of the lanthanum and samarium ions. The ploarizable electrode used was a DME for (2) and (3) and a HME for (1).

were the same for mercury in KI and KCl (concentrations not stated) solutions except at potentials markedly were positive than the incision potential for the lanthanide ions. Consequently, it seems that the depth of incision in Fig. 2 is mainly a function of the electrode reaction rate.

The effect of the KI concentration on the electrode reaction of the La^{3+} and Sm^{3+} ions was investigated. Figure 3 shows the incision depths of a 5×10^{-4}M lanthanide (La or Sm) solution of pH 3.65 with KI concentrations from 0.3 to 1.5 M. In this figure, curve 1 is a plot of the cathodic incision depth obtained using HME, while curves 2 and 3 are the plots of the cathodic and anodic incision depths respectively. In curve 1, the incision depth is almost constant over the KI concentration range from 0.4 to 1.0M. However, in curves 2 and 3, the incision depths show a maximum when the KI concentration is about 0.7M, and at a KI concentration of 1.5M, no incision depth was observed. On the contrary, at the KI concentrations, 1.5 and 0.7M, the incision depths in curve 1 are almost the same. It seems that KI promotes or retards the electrode reaction when the concentration is either lower or higher than 0.7M respectively. We interpret this as follows. In a 0.3—0.7M KI solution, the amount of I^- adsorbed on the electrode in the positively-polarized branch with respect to the electro-capillary maximum point, e.c.m., increases with an increase in the I^- concentration in the solution bulk. This results in an increase in the I^- remaining on the electrode surface in the desorption process in the negative polarization region, and it promotes the electrode reaction. In a 0.7—1.5M KI solution the electrode reaction rate decreases as the KI concentration increases. This effect may be attributed to the change in the potential,

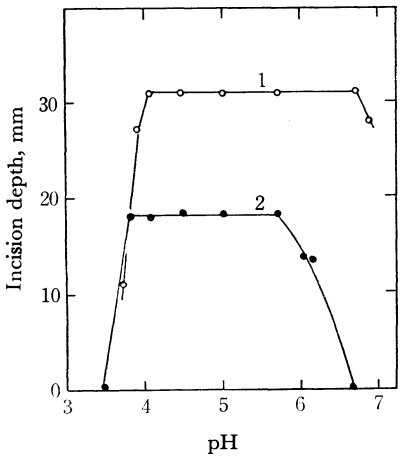

Fig. 4. Effect of pH on incision depth of (1) lanthanum and (2) samarium ions in M KI solution.

ϕ_2*1 (which becomes less negative). A similar phenomenon has been observed with Zn.[5]

Figure 4 shows the effect of the pH on the incision depths of La^{3+} and Sm^{3+} ions. Both curves 1 (La) and 2 (Sm) were measured in solutions containing M KI and 5×10^{-4}M lanthanide ions, with pH values between 3.5 and 6.8. The incision depth was independent of the pH in the region between pH 4.0 and 6.7 for La^{3+} and between pH 3.8 and 5.7 for Sm^{3+}. At higher pH values the incision depth decreased due to the hydrolysis of La^{3+} and Sm^{3+} ions, and with a decrease in pH values in the lower pH region the incision depth decreased, eventually reaching zero at pH values of about 3.5. However, at pH 3.5, a fairly deep incision was observed with the HME. It seems that the cathodic incision of lanthanides is attributable to the reduction of H^+ in hydrated water molecules[6] and that the anodic incision is attributable to the oxidation of lanthanide-halogeno hydride complexes,[7] which are formed by the hydride ions produced at the cathode. Consequently, the increase in the hydrogen-ion concentration on the electrode surface might suppress the formation of lanthanide-halogeno hydride complexes. The ratio of the incision depths of curves 1 and 2 at the plateaus is 1.7, and the depth is greater for La^{3+} than for Sm^{3+}. It is probably true that the larger the ionic size, the less the concentration of the ions in the Helmholtz layers, since the Stokes radius[8] of a Sm^{3+} ion is larger than that of a La^{3+} ion.

Figure 5 shows the relation between the incision depth and the concentrations of La^{3+} and Sm^{3+} ions. Curves 1 and 2 were measured using DME, while curves 3 and 4 were measured using HME in M KI solutions at pH 4.5. Curve 1 is linear in the range of La^{3+} concentrations ranging from 0.5 to 3×10^{-3}M, and curve 2 is linear in throughout the range measured. However, the plot of the ion concentration *versus* the incision depth shows

saturated curves for La^{3+} and Sm^{3+} when the HME is used.

The characteristic behaviour of KI, compared with that of other supporting electrolytes such as KCl or KBr, seems to be due to the adsorption of I^- on the electrode. Accordingly, we investigated the relative temperature dependence of La^{3+} and Sm^{3+}-ion incisions in the KCl and KI solutions. The results are shown in Figs. 6 (La^{3+}) and 7 (Sm^{3+}). In Fig. 6, curve 1 and curve 3 are the cathodic and anodic incisions, respectively, in 0.5M KI plus 0.2M KCl solutions, while curves 2 and 4 are the cathodic and anodic incisions respectively, in 0.7M KCl solutions. All the measurements shown in Fig. 6 were carried out at pH 4.4 in the temperature range from 25° to 50°C and with a 5×10^{-4}M La^{3+} solution. The temperature coefficient of the incision depth in the KI solutions was found to be negative, whereas it was positive in the KCl solutions. The same result was obtained for Sm^{3+} ions (Fig. 7). The concentration dependence of the incision depth was further investigated at I^- concentrations from

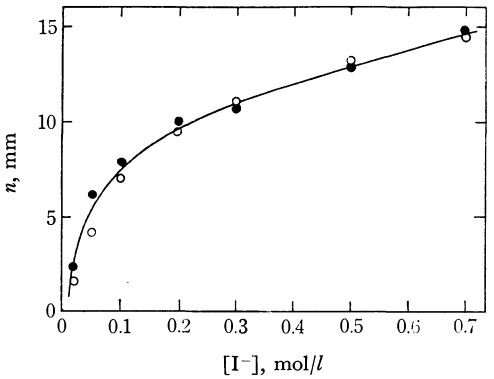

Fig. 8. Relation between the cathodic incision depth of La (pH 4.0) and Sm (pH 4.5) ions and the iodide concentration (ionic strength, 0.7).

0.02 to 0.7M, with the ionic strength kept at 0.7 with KCl. The results are shown in Fig. 8. In this figure, n is the increase in incision depth (in mm) on the addition of iodide ions. The n value increases sharply in the KI concentration range from 0.02 to 0.1M, and then it tends to slope gently above 0.1M. It may be supposed that the ionic adsorption of the I^- on the electrodes has a large effect on the electrode reaction of lanthanide ions, and that, therefore, the iodide complex is formed at the electrode surface. This assumption is also supported by the evidence of curve 1 in Fig. 2, which shows the dependence of the incision depth on the first ionization potential of lanthanides.

The incision depth of lanthanide ions increases with the following order of supporting electrolyte anions:

$$ClO_4^- < Cl^- = Br^- = SCN^- < I^-$$

There is no experimental evidence that Cl^-, Br^-, and SCN^- ions remain on the electrode surface at a negative voltage (−1.4 V). However, since these anions become strongly adsorbed at positive voltages, as is indicated by the above relation, some may remain as a lanthanide complex in the Helmholtz layer.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 3159—3165 (1969)

Polarographic Study of Metal Complexes. VIII.[1] Dicyanobis-(ethylenediamine)cobalt(III) Complex with a *cis*-Configuration[2]

Nobufumi MAKI, Kouei YAMAMOTO, Hiroshi SUNAHARA*1 and Shukichi SAKURABA

Department of Chemistry, Faculty of Engineering, Shizuoka University, Johoku, Hamamatsu

(Received November 12, 1968)

In an aqueous solution containing an excess of ethylenediamine, *i. e.*, under the conditions where the aquation is prevented, the dicyano-cobalt(III) complex, *cis*-$[Co(CN)_2en_2]NO_3$, has been found to be reduced in three steps at the dropping mercury electrode (DME). The first step, corresponding to the acceptance of one electron, represents the reduction from the cobalt(III) to the cobalt(II) state, while the second and the third step were interpreted as being due to the reduction of two kinds of the cobalt(II) species formed by the overall rearrangement of ligands in solution. One such kind of cobalt species is the binuclear tetracyanocobaltate(II) complex, $[Co(CN)_4\text{-en-}Co(CN)_4]^{4-}$, which is reduced to the metal through the cobaltate(I) complex, while the other is the cobalt(II) complexes with ethylenediamines in an equilibrium state, which are reduced directly to the metal at the DME. Namely, the second step represents the reduction from the cobalt(II) complex of the former to the cobalt(I) state, while the third step, denoting the reduction to the metal, was observed only on the dE/dt-E curve of the oscillopolarogram, but not on the current-potential curve due to the maximum wave. In the non-aqueous solution of dimethyl sulfoxide, the dicyano-cobalt(III) complex, *cis*-$[Co(CN)_2en_2]ClO_4$, undergoes the step-by-step reduction of Co(III)→Co(II)→Co(I)→Co(0), as it were, at the DME. Neither aquation nor rearrangements of ligands take place throughout reductions under these experimental conditions, that is, even in lower oxidation states of the cobalt.

The ammine and amine cobalt(III) complexes have hitherto been well known to be reduced to the metal through the hexaquocobalt(II) ions at the dropping mercury electrode (DME). Namely, this kind of reduction type is regarded as belonging to the group of the "*inert-labile*" type according to the classification of Vlček.[3]

On the other hand, the cyano-cobalt(III) complexes in general exhibit a reduction of the "*inert-inert*" type from the view-point of the lability of the complex. For example, the pentacyanocobaltate(III) complexes are reduced to the cobaltate(I) complex in one or two steps at the DME.[4,5]

The polarography of the tetracyano complexes, $Na_5[Co(CN)_4(SO_3)_2]$ and $K[Co(CN)_4en]\cdot H_2O$, proves that the tetracyanocobaltate(I) complexes can exist stably in solution during reduction when such labile ligands as ethylenediamine and SO_3^{2-} ions are present in solution in an overwhelmingly large excess.[6] The net electrode processes of the tetracyanocobaltate(III) complexes are thus simplified under these conditions.[1,6]

As for the dicyano-cobalt(III) complexes, however, the aquation and the overall rearrangement of ligands are both involved in the electrode processes. Accordingly, in the presence of an excess of ethylenediamine, only the latter appears to take place through the electrode reduction. In the present work, most of our effort was devoted to elucidating the effects of the overall rearrangement of ligands on the current-potential curves.

On the other hand, the electrode processes are ultimately simplified in dimethyl sulfoxide (DMSO), since the dicyano-cobalt(II) and cobalt(I) complexes are regarded as "*inert*"-type complexes in such a non-aqueous solvent. Hence, the polarographic behavior in DMSO will be dealt with here briefly for the sake of comparison, because such simplified processes of the electrode reaction may serve to

provide information which can then be used in interpreting more complicated processes of the polarographic reduction in an aqueous solution.

In the present paper, however, the polarographic reduction of the dicyano-cobalt(III) complex, *cis*-$[Co(CN)_2en_2]NO_3$, was dealt with mainly in an aqueous solution containing ethylenediamine.

Experimental

Apparatus. The experimental details of the measurements have been described previously.[1] The current-potential curves of the cobalt(II) complex in the presence of ethylenediamine were determined in a stream of nitrogen which had previously been passed through the same supporting electrolyte containing ethylenediamine. The current-time (t) curves were recorded on a Yanagimoto Polarovision model PE 20 equipped with a National X-Y recorder, model VR 301. The potential (E) - dE/dt curves were photographed on a Polaroscope P 576 of Kovo, Inc. The characteristics of the capillary used were as follows: m=1.81 mg/sec and t=4.43 sec (both of which values were measured in a 0.5M Na_2SO_4 solution containing 1M en), and m=1.69 mg/sec and t=4.42 sec in a 0.5M Na_2SO_4 aqueous solution only.

Materials. Twenty grams of *trans*-$[CoCl_2en_2]NO_3$,[7] were suspended in 700 m*l* of distilled water, mixed with 20 g of AgCN, and then heated on a water bath (90°C) for three hours. The color of the solution changed from green to yellow. The solution was then filtered, and the filtrate was concentrated by evaporation to one-third its former volume. When the solution was allowed to stand, silky-yellow crystals separated from the solution; these were filtered and washed with cold water, ethanol, and ether. The crude product was recrystallized from hot water.[8] Found: Co, 19.98; C, 24.49; N, 33.49; H, 5.63%. Calcd for $[Co(CN)_2en_2]NO_3$: Co, 20.10; C, 24.58; N, 33.44; H, 5.50%. The absorption spectrum in the visible and ultraviolet regions agrees with that reported by Ohkawa *et al.*[9]

The perchlorate of the complex was analogously obtained by treating *trans*-$[CoCl_2en_2]ClO_4$ (20 g) with 22 g of AgCN instead of the nitrate of the praseo salt. Found: Co, 17.90; C, 21.78; N, 25.34; H, 4.90%. Calcd for $[Co(CN)_2en_2]ClO_4$ (anhydrous): Co, 17.83; C, 21.80; N, 25.42; H, 4.88%. For making polarographic measurements in DMSO, the perchlorate of the complex is suitable; it was used since its solubility in DMSO is considerably larger than that of the corresponding nitrate.

The binuclear complex of potassium μ-ethylenediamine-bis{tetracyanocobaltate(II)} monohydrate was prepared according to the directions of Ripân *et al.*[10] Found: Co, 20.98; C, 21.22; N, 24.86; H, 1.91%. Calcd for $K_4[Co(CN)_4\text{-en-}Co(CN)_4]\cdot H_2O$: Co, 21.03; C, 21.43; N, 24.99; H, 1.80%.

Results and Discussion

The *cis*-$[Co^{III}(CN)_2en_2]^+$ ion behaves quite differently polarographically, depending upon the experimental conditions, especially on whether or not the supporting electrolyte contains an excess of ethylenediamine (en) and cyanide ions. Therefore, the electrode processes were studied and discussed in these four cases: (1) in an aqueous solution of 0.5M Na_2SO_4 only; (2) in a water solution containing 1M en and 0.5M Na_2SO_4; (3) in a water solution containing 1M en, 0.1M KCN and 0.45M Na_2SO_4, and (4) in dimethyl sulfoxide (100%) containing 0.1M $[(C_2H_5)_4N]ClO_4$.

1) In an Aqueous Solution of 0.5M Na_2SO_4 Containing No Ethylenediamine. Here the *cis*-$[Co(CN)_2en_2]^+$ ion gives rise to waves of two steps at the DME. The ratio of the height of the first wave to that of the second is approximately 1 : 2. The electrode process of the first step is of the *"inert-labile"* type and is considered to be quite similar to that of the usual ammine cobalt(III) complexes. That is, the resulting cobalt(II) complex of the *"labile"* type is broken up into several kinds of aquocobalt(II) species, which are subsequently reduced to the metal at the DME:

$$\underset{inert}{cis\text{-}[Co^{III}(CN)_2en_2]^+} \xrightarrow{e} \underset{labile}{cis\text{-}[Co^{II}(CN)_2en_2]}$$

$$\downarrow$$

$$[Co^{II}(CN)_2(OH_2)_4],\ etc. + 2en$$

$$\downarrow 2e$$

$$Co(metal) + 2CN^-.$$

but it was seen to exist in the oscillopolarogram of the Heyrovský-Forejt type: indeed, the last step was covered completely with the large maximum, which could not be suppressed with a usual surface-active agent, such as Triton X 100*2 or gelatin.

Figure 1 shows the dE/dt - E (potential) curves photographed in the presence and the absence of excess ethylenediamine. In the former case three cuts were observed on the cathodic branch of the curve: the first two cuts correspond to the reduction waves of two steps in the classical d. c. polarogram, while the last cut may correspond to the last step of the maximum, which probably represents the reduction to the metallic cobalt, since only a cut ($Co \rightarrow Co^{II}$) was noticed on the anodic branch of the curve.

On the other hand, in the latter case two cuts were seen to exist on the cathodic branch of the curve; these cuts correspond to the reductions of Co(III)→Co(II) and of Co(II)→Co(*metal*) respectively.

The limiting current of the first and the second wave is linearly related to the concentration of the complex in the range between $4\cdot10^{-4}$ and $2\cdot10^{-2}$M. The ratio of the height of the first wave to that of the second is approximately 1 : 0.5. The limiting current of each step was found to be proportional to the square root of the height of the mercury reservoir, as is shown in Table 1. The values of $i_1/\sqrt{h_{corr.}}$ are independent of the increase in mercury pressure. Accordingly, the

limiting current of both the waves is diffusion-controlled. This conclusion was also supported by the results of the analyses of *i-t* curves coupled with the temperature-dependence of the limiting currents, as will be discussed hereafter.

Figure 2 shows the dependence of the current-potential curve on the concentration of the complex. In the figure, the current scale was individually curtailed, lest the current scale should change with the concentration of the complex. The two maxima observed at higher concentrations are considered to be due to the adsorption of the complex on the DME, judging from the electrocapillary curves measured. The maxima could be suppressed in the presence of Triton X 100 more than 0.0025%, as is shown in Fig. 3.

Figures 4 and 5 show the effect of Trition X 100 on the diffusion currents of both the waves obtained at the concentration of the complex of 10^{-3} and $5\cdot10^{-3}$M. In the figure, at the steady state, *i. e.*, when Triton X 100 suppresses the maxima to exclude the adsorption of the complex on the DME, the height of the second wave is seen to become nearly a half of that of the first wave.

Figure 6 shows the effect of an excess of ethylenediamine on the current-potential curve at the 10^{-3}M complex ion. At concentrations higher than 0.007M, the single wave is seen to split into the double wave. This fact suggests that the cobalt(II) complexes formed at the first step of the reduction react with each other in the presence of excess ethylenediamine to produce two kinds of stable new species. One of the species might be the binuclear tetracyanocobaltate(II) complex, $[Co(CN)_4\text{-en-}Co(CN)_4]^{4-}$, formed partly as a result of the overall rearrangement of ligands in solution, which is reduced in two steps to the metal through the cobaltate(I) complex; the other of the cabalt(II) species is a mixture of the aquocobalt(II) complexes with ethylenediamines in an equilibrium state, with all the elements being reduced directly to the metal at the DME. That is, the reduction of the former to a cobalt(I) state takes place at -1.18 V *vs.* SCE, while the reduction of the latter to the metal is not observed because of the maximum. In short, the former is polarographically active, but the latter is apparently inactive. Consequently, the fact that the wave-height of the second step, corresponding to an apparently 1/2 electron reduction, is always a half of that of the first step can be explained in terms of the following processes of the electrode reaction:

In the previous paper,[1] the tetracyanocobaltate(I) complex, $[Co^{I}(CN)_4en]^{3-}$, was speculated to be present stably in a solution containing ethylenediamine. Furthermore, Watt *et al.*[11,12] have reported isolating two complexes, $K_3[Co^{I}(CN)_4]$ and $K_4[Co^{0}(CN)_4]$, as solids by the reduction of $K_3[Co(CN)_6]$ in liquid ammonia with metallic potassium. Therefore, it would not be out of the way to assume that such tetracyanocobaltate(I) and cobaltate(0) complexes are present in solution as intermediates in the reduction process.

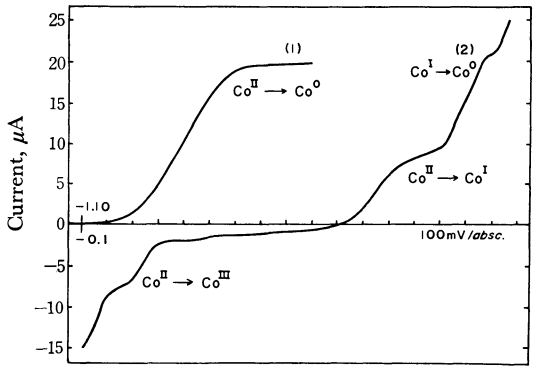

Fig. 7. The current-potential curves of the cobalt(II) complexes: (1) $[Co(OH_2)_6]^{2+}$ ion (10^{-2}M) in 0.5M Na_2SO_4 solution; Recorded from −1.10 V *vs.* SCE. (2) $K_4[Co(CN)_4\text{-en-}Co(CN)_4]\cdot H_2O$ ($5\cdot10^{-3}$M) in 0.5M Na_2SO_4 solution containing 1.5M ethylenediamine (25°C); Recorded from −0.10 V *vs.* SCE in a stream of nitrogen.

Figure 7 shows the current-potential curve for $K_4[Co(CN)_4\text{-en-}Co(CN)_4]\cdot H_2O$ obtained in a stream of nitrogen. For comparison, the two-electron reduction wave of the hexaquocobalt(II) ion is also shown in the figure. Both the curves were obtained at the same concentration of the cobalt(II). The $[Co(CN)_4\text{-en-}Co(CN)_4]^{4-}$ ion gave rise to waves of two steps: the first and the second wave, corresponding to a gain of one electron,

represent the step-by-step reduction of Co(II)→Co(I) and of Co(I)→Co(0) respectively. The half-wave potential (−1.23 V *vs.* SCE) of the first step ($Co^{II}\rightarrow Co^{I}$) is near that of the second wave for the *cis*-$[Co(CN)_2en_2]^+$ ion, as Table 2 shows. Therefore, the second step for the *cis*-$[Co(CN)_2en_2]^+$ ion may be concluded to represent the overall reduction from the binuclear tetracyanocobaltate(II) to the cobaltate(I) complex at the DME.

Figure 8 shows the temperature-dependence of the current-potential curves. The diffusion currents are linearly related with the temperature; the tangents of the lines for the first and the second wave-heights are 1.25 and 1.23% at 25°C respectively. The shape of the second wave at higher temperatures becomes more obvious than that at lower temperatures.

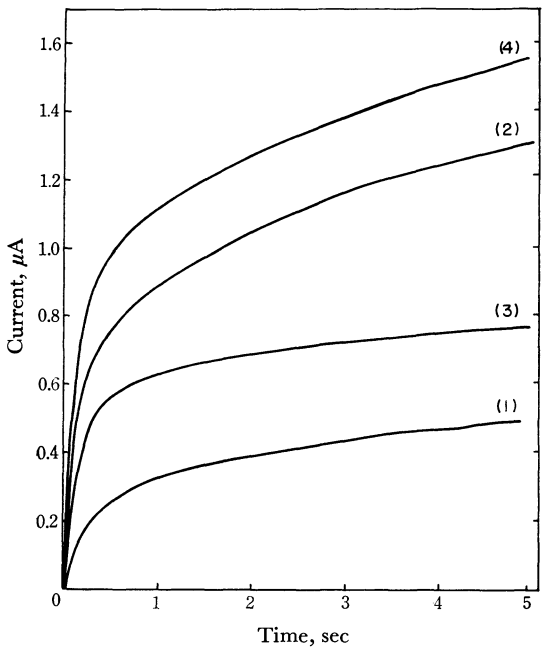

Fig. 9. The current-time curves of the *cis*-$[Co(CN)_2en_2]^+$ ion recorded during one drop growth of DME at the potentials: (1) −0.85; (2) −1.00; (3) −1.18; (4) −1.35 V *vs.* SCE.
Supporting electrolyte: 0.5M Na_2SO_4 + 1M en (25°C)

Figure 9 shows the current-time curves during a one-drop growth of DME obtained at a constant potential. The current varies with time to the powers of 0.17 and 0.19 at the potentials at which the first and the second step respectively exhibit the limiting currents. This result, combined with the above-mentioned finding in relation to the effect of the mercury head, supports the conclusion regarding the diffusion-controlled features of both the waves in a supporting electrolyte of this sort.

3) In a 0.45M Na_2SO_4 Aqueous Solution Containing 0.1M KCN and 1M Ethylenediamine. Here the *cis*-$[Co(CN)_2en_2]^+$ ion similarly gave rise to well-defined waves of two steps at the DME. The second wave-height, however, increases twice as much as that in a solution containing no excess cyanide ions, that is, in a solution containing only excess ethylenediamine. More exactly, the ratio of the wave-heights of the first and the second waves was 1 : 1.03 which had been corrected for the drop time. Undoubtedly, the cyanide ions in excess are available for producing the binuclear tetracyanocobaltate(II) complex through the rearrangement of ligands in solution.

The limiting currents of the two steps were found to be proportional to the square root of the mercury pressure on the DME; the limiting currents exhibit the diffusion-controlled feature.

In addition to these results, the d. c. polarogram of two steps for the $K_4[Co(CN)_4\text{-en-}Co(CN)_4]\cdot H_2O$ (a pale yellow crystal) dissolved in a 0.45M Na_2SO_4 solution containing both 0.1M KCN and 1M ethylenediamine agrees quite well with that of the hexaquocobalt(II) chloride dissolved in the same supporting electrolyte in the shape of the waves and in the half-wave potentials (see Table 2).

The presence of ethylenediamine in excess is essential for the existence of the $[Co(CN)_4\text{-en-}Co(CN)_4]^{4-}$ ion in water solution, but the cyanide ions in excess are not necessary; the binuclear tetracyanocobaltate(II) complex should be regarded as "*partly-labile.*"

Accordingly, the net processes of the electrode reaction presented below may be considered to be the most plausible:

$$2\ cis\text{-}[Co^{III}(CN)_2en_2]^+ \xrightarrow{2e} 2\ cis\text{-}[Co^{II}(CN)_2en_2]$$
$$\downarrow$$
$$[Co^{II}(CN)_4\text{-en-}Co^{II}(CN)_4]^{4-}$$
$$\downarrow 2e$$
$$2\ [Co^{I}(CN)_4en]^{3-}$$
$$\downarrow 2e$$
$$2\ [Co^{0}(CN)_4]^{4-}$$
$$\downarrow$$
$$2\ Co(metal)$$

in the presence of both CN^- ions and en.

Thus, all the resulting cobalt(II) species of the $[Co^{II}(CN)_2en_2]$ complex are presumed to be totally subject to the rearrangement of ligands to produce a binuclear tetracyanocobaltate(II) complex in solution; this is then reduced to the metal through the cobaltate(I) complex at the DME. Under these experimental conditions, no aquation occurs, and only the rearrangement of ligands is discerned to take place in solution.

4) In Dimethyl Sulfoxide (100%) Con-

taining 0.1M $[(C_2H_5)_4N]ClO_4$. Here the complex, *cis*-$[Co(CN)_2en_2]ClO_4$, gave rise to waves of three steps at the DME. The limiting current of each step is strictly diffusion-controlled. The diffusion currents of the first, the second, and the third wave, named from positive to negative potentials, are proportional to the concentration of the complex in the range between $5\cdot10^{-4}$ and $5\cdot10^{-3}$M. The first, the second, and the third wave, corresponding to an acceptance of one electron, represent the step-by-step reductions of Co(III)→Co(II), Co(II)→Co(I), and of Co(I)→Co(*metal*) respectively. The following processes of the electrode reaction seem to be the most plausible:[13]

$$\underset{inert}{cis\text{-}[Co^{III}(CN)_2en_2]^+} \xrightarrow{e} \underset{inert}{cis\text{-}[Co^{II}(CN)_2en_2]} \downarrow e \; \underset{inert}{[Co^{I}(CN)_2en_2]^-} \downarrow e \; Co(metal)$$

Thus, the dicyano-cobalt(III) complex is considered not to undergo any structural changes throughout the reductions and to undergo the step-by-step reductions, as it were, without disrupting the complex. In other words, neither the aquation nor the rearrangement of ligands takes place during the reductions.

Figure 10 shows the current-potential curves obtained in the four kinds of supporting electrolytes mentioned above. In the figure, the limiting currents of only three waves in a DMSO are relatively depressed to some extent compared with those of the other curves.

As far as the processes of the electrode reaction in these solutions are concerned, the processes in a DMSO are most simplified and can be best understood, an understanding of them evidently serves to provide information for interpreting more complicated processes in water solutions, since the polarographic reductions are regarded as of the "*inert-inert*" type in such a DMSO.

On the other hand, it is evident from the above-mentioned results that the dicyano-cobalt(II) complex in itself tends to be broken up and to turn into the more stable species of the tetracyanocobaltate(II) complex as a result of the overall rearrangement of ligands in a water solution containing excess ethylenediamine. The rearrangement of ligands was also observed for the other dicyanocobalt(III) complexes; for example, *cis*-$[Co(CN)_2dip_2]NO_3\cdot7H_2O$, *cis*-$[Co(CN)_2phen_2]NO_3\cdot6H_2O$, *trans*-$[Co(CN)_2en_2]NO_3$, and *trans*-$[Co(CN)_2(NH_3)_4]NO_3\cdot H_2O$. In a DMSO, even the $[Co^I(CN)_2(NH_3)_4]^-$ ion was found to be able to exist stably without disrupting the complex.

The merit of adopting a non-aqueous solvent lies not only in such a simplification of the electrode processes, but also in the stabilization of the lower oxidation states of the central metal ion from the point of view of the other side.

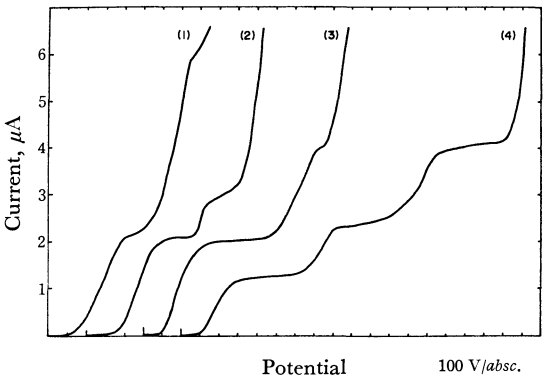

Fig. 10. The current-potential curves of the *cis*-$[Co(CN)_2en_2]^+$ ion measured at the concentration of the complex, 10^{-3}M, in the various kinds of the supporting electrolytes: (1) in 0.5M Na_2SO_4 aqueous solution only; (2) in 0.5M Na_2SO_4 aqueous solution containing 1M ethylenediamine; (3) in 0.45M Na_2SO_4 aqueous solution containing 0.1M KCN and 1M ethylenediamine; (4) in dimethyl sulfoxide (100%) containing 0.1M $[(C_2H_5)_4N]ClO_4$ (25°C). The curves, (1), (2), and (3), were recorded from −0.60 V *vs.* SCE, while the curve of (4) was recorded from −0.80 V *vs.* SCE.

13) More details in a non-aqueous solution are to be reported in the next paper of this series.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 3166—3171 (1969)

Polarographic Study of Metal Complexes. IX.[1] Halogeno- and Aquo-bis(dimethylglyoximato)amminecobalt(III) Complexes[2]

Nobufumi MAKI, Yukio ISHIUCHI and Shukichi SAKURABA

Department of Chemistry, Faculty of Engineering, Shizuoka University, Johoku, Hamamatsu

(Received January 13, 1969)

The halogeno- and aquo-bis(dimethylglyoximato)amminecobalt(III) complexes of the *trans*-[$Co^{III}X\ dg_2(NH_3)$]-type have been found to be reduced to the metal through the cobalt(I) state in a 0.5M Na_2SO_4 aqueous solution at the dropping mercury electrode (DME), where the ligand, X, denotes the ion, Cl^-, Br^-, or I^-, or the molecule, OH_2. The aquation of the halogeno complexes is found to take place more rapidly in solution in this order: $Cl^- < Br^- < I^-$. The diaquobis(dimethylglyoximato)cobalt(III) ion, $[Co(OH_2)_2dg_2]^+$, has also been ascertained to undergo a step-by-step reduction to the metal through the cobalt(I) state at the DME.

In previous papers,[3-5] the dicyanobis(dimethylglyoximato)cobaltate(III) complex, *trans*-$K[Co(CN)_2dg_2]\cdot\frac{3}{2}H_2O$, was found to be reduced down to the cobaltate(I) complex in a 0.5M Na_2SO_4 solution at the dropping mercury electrode (DME). The resulting cobaltate(I) complex was isolated as an almost black soid *in vacuo* by the reduction of a 3% sodium amalgam. The aqueous solution of the cobaltate(I) complex assumed a deep blue color.

The bis(dimethylglyoximato)diamminecobalt(III) complex, $[Codg_2(NH_3)_2]Cl\cdot 5H_2O$ (efflorescent crystals), has been reported to undergo the step-by-step reduction of Co(III)→Co(II)→Co(I)→Co(0) at the DME in a neutral Na_2SO_4 solution.[3] In connection with these complexes, the cyanobis(dimethylglyoximato)amminecobalt(III), *trans*-$[Co(CN)dg_2(NH_3)]\cdot\frac{1}{2}H_2O$,[5] has also been found to be reduced to a cobalt(0) complex through the cobalt(I) state in the same supporting electrolyte. It is of interest that this complex, with both the cyanide ion and an ammonia ion, has a configuration similar to that of cyanocobalamine (vitamin B_{12})[6] in the coordination sphere around the cobalt.

The stabilization of such lower oxidation states of the central cobalt can be interpreted as being due to the strong π-bonding character, *i. e.*, the "back donation" in the coordinate-bonds of the cyanide ions and of a pair of dimethylglyoximes with two hydrogen bonds.

The purpose of this study is to determine if the oxidation state of a cobalt(I) can be detected in a solution or not for the halogeno- and aquo-ammine complexes, in which the contribution of the π-bonding character at the fifth and the sixth ligands is regarded as being absent.

Experimental

The experimental details of the measurements have been described previously.[7] The current-time curves were recorded on a Yanagimoto Polarovision, Model PE 20, equipped with a National X-Y recorder, Model VR 301. The characteristics of the capillary used were as follows: $m=1.42$ mg/sec, $t=4.80$ sec, both measured at an open circuit in a 0.5M Na_2SO_4 water solution.

Materials. The chloro-ammine complex, $[CoCldg_2(NH_3)]$ (anhydrous) was prepared according to the directions of Tschugaeff.[8] Found: Co, 17.28; C, 28.03; N, 20.39; H, 5.21%. Calcd for $[CoCldg_2(NH_3)]$: Co, 17.25; C, 28.13; N, 20.50; H, 5.02%.

Preparation of *trans*-[Co Br $dg_2(NH_3)$]. The bromo- and iodo-bis(dimethylglyoximato)amminecobalt(III) complexes were prepared analogously to the method of Tschugaeff.[8]

Twenty grams of $[CoBr(NH_3)_5]Br_2$[9] dissolved in 400 ml of water were heated on a water bath for two hours with 12.1 g of dimethylglyoxime and 50 g of ammonium acetate. During the reaction, 15 ml of

glacial acetic acid were added to the solution in small portions. The reaction took place, evolving ammonia, to yield a brown solution. When the temperature of the solution went down, lustrous brown crystals were deposited from the solution, these were filtered and washed with cold water, ethanol and ether. The crude product was recrystallized from hot water containing acetic acid. Found: Co, 15.37; C, 24.99; N, 18.04; H, 4.64%. Calcd for [Co Br $dg_2(NH_3)$]: Co, 15.26; C, 24.89; N, 18.14; H, 4.44%.

Preparation of *trans*-[CoIdg$_2$(NH$_3$)].[10] Twenty grams of $[CoI(NH_3)_5](NO_3)_2$[11] and 50 g of ammonium acetate were dissolved in 400 m*l* of water, and the mixture was heated on a water bath with 9.5 g of dimethylglyoxime. During the reaction, 15 m*l* of acetic acid were stirred into the solution. After the solution had then been allowed to stand overnight, dark brown crystals were separated from the solution; they were filtered and washed with water, ethanol, and ether. The crude product was purified by recrystallization from hot water containing acetic acid. Found: Co, 13.54; C, 22.09; N, 16.02; H, 4.16%. Calcd for [CoIdg$_2$(NH$_3$)]: Co, 13.61; C, 22.19; N, 16.17; H, 3.96%.

Preparation of *trans*-[Co(OH$_2$)dg$_2$(NH$_3$)]OCOCH$_3$. Ten grams of [CoCldg$_2$(NH$_3$)][8] and about 6 g of wet Ag_2O were well mixed together in 50 m*l* of distilled water under ice cooling, then the mixture was allowed to stand for three hours below 0°C. The exothermic reaction took place gently to yield the hydroxo complex, [Co(OH)dg$_2$(NH$_3$)]. No smell of ammonia could be discerned during the reaction. The suspension was filtered, and the filtrate was concentrated to one-fifth its volume by evaporation *in vacuo* with a rotatory evaporator after 15 m*l* of acetic acid had been added to it. On cooling, bright yellow crystals separated from the solution; they were filtered and washed with ethanol and ether. Recrystallizations were carried out from hot water containing acetic acid. The yield was 48% of theory. The complex has no water of crystallization. Found: Co, 15.21; C, 31.11; N, 18.28; H, 5.85%. Calcd for [Co(OH$_2$)dg$_2$(NH$_3$)]OCOCH$_3$: Co, 15.38; C, 31.34; N, 18.27; H, 5.79%. The complex is soluble in water, while the corresponding salt of nitrate, [Co(OH$_2$)dg$_2$(NH$_3$)]NO_3, is insoluble in water. The absorption spectra of this and the diammine complex in the visible and ultraviolet regions are shown in Fig. 1. The first spin-allowed band is located at a longer wavelength than that of the corresponding diammine cobalt(III) complex, [Codg$_2$(NH$_3$)$_2$]Cl·5H$_2$O, though the first d–d band is hidden by the foot of the charge-transfer bands of dimethylglyoximes.

Results and Discussion

The halogenobis(dimethylglyoximato)ammineco-balt(III) complexes, [Co^{III}Xdg$_2$(NH$_3$)], gave rise to four step waves in a 0.5M Na_2SO_4 aqueous solution at the DME, where the ligand, X, is the ion, Cl^-, Br^-, or I^-. The first two steps, corresponding to a total acceptance of one electron, represent the reductions from the cobalt(III) and the aquated cobalt(III) species to a cobalt(II) state, while the following two steps represent the reduction of $Co^{II} \rightarrow Co^{I}$ and of $Co^{II} \rightarrow Co^{0}$ respectively. The waves of the second, the third, and the fourth step for halogeno complexes agree completely with those of the aquo-complex, [Co(OH$_2$)dg$_2$(NH$_3$)]OCOCH$_3$. Therefore, the aquation of the halide ligands is considered to be almost completely finished in lower oxidation states. Judging from the wave-height of the first wave, it can be said that the aquation proceeds more rapidly in a solution according to this order of the ligands: Cl<Br<I.

Figure 2 shows the current-potential curves of the halogeno- and the aquo-ammine complexes under the same experimental conditions. The two-electron reduction wave of *trans*-K[Co(CN)$_2$dg$_2$]·$\frac{3}{2}$H$_2$O under the same conditions is given for the sake of comparison. It may be seen that the total height of the first and the second steps for halogeno complexes is approximately equal to that of the first step for the aquo-complex. The ratio of the wave-heights corrected for drop time is given in Table 1.

Each of the limiting currents of the waves was proportional to the concentration of the complex in the range of $2.5 \cdot 10^{-3}$—$5 \cdot 10^{-4}$M for halogeno complexes and in the ragne of 10^{-2}—$5 \cdot 10^{-4}$M for

the aquo-ammine complex, $[Co(OH_2)dg_2(NH_3)]OCOCH_3$.

The limiting currents of the first, the second, and the third steps (named from positive to negative potentials) were found to be proportional to the square root of the mercury pressure on the DME, whereas that of the fourth step was not proportional for all the halogeno complexes, the value of $i_{1(4)}/\sqrt{h_{corr.}}$ becoming smaller with the increase in the mercury pressure. Table 2 shows the dependence of the limiting currents on the mercury pressure obtained for the chloro-ammine complex. The results for the aquo-ammine complex quite agree with the above results obtained for the waves following the second step of the halogeno-ammine complexes. Accordingly, hereafter the polarographic data for the halogeno complexes only will be described, unless otherwise stated, since the three waves following the second step of the halogeno complexes coincide completely with those of the aquo-ammine complex.

For the iodo-ammine complex, $[CoIdg_2(NH_3)]$: $2.5 \cdot 10^{-3}$M in 0.5M Na_2SO_4 containing $2.3 \cdot 10^{-3}$ % of Triton X 100.

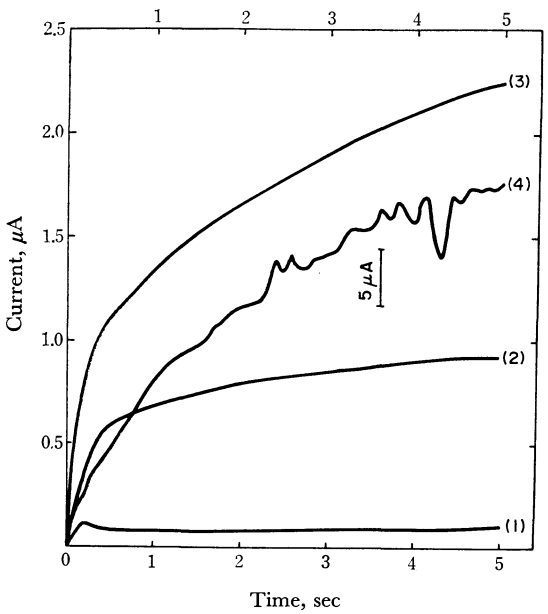

Fig. 3. The current-time curves obtained at the constant potentials.
(1) −0.40; (2) −0.85; (3) −1.15; (4) −1.33 V *vs.* SCE. Concn. of the complex: $1\cdot10^{-3}$M; Supporting electrolyte: 0.5M Na_2SO_4 soln. The current scale of the curve (4) only is curtailed, as indicated in the figure.

The temperature coefficients of the first, the second, the third, and the fourth steps were 1.2, 1.5, 2.4, and 2.5%/deg respectively at 25°C for all the halogeno complexes, and 1.5, 2.4, and 2.4%/deg respectively at 25°C for the aquo-ammine complex (in this case, the first step is absent).

Figure 3 shows the current-time curves observed during the life of a mercury drop at various potentials for the iodo-ammine complex. At the potentials of −0.85 and −1.15 V (*vs.* SCE), at which the current reaches the limiting plateaus of the second and third steps, the exponents (τ) of the drop time (t) in the Ilkovič equation, $i_d=kt^{\tau}$, were 0.21 and 0.33 respectively (25°C); the value of the former falls within 0.16—0.22, a range characteristic of diffusion-controlled values, but the value of the latter did not because of the disruption of the resulting cobalt(I) complex in solution. At the potentials of −0.40 and −1.33 V (*vs.* SCE), at which the current reaches the limiting plateaus of the first and fourth steps, the current-time curves show an abnormal shape. At the former potential, the current is quenched with time to some extent, this distinctive quenching may be attributed to the adsorption of the halogeno complex at the DME. The electrocapillary curve also indicated that the adsorption was taking place and so supported this interpretation. At the latter potential, the oscillations observed on the abnormal curve are undoubtedly connected with the time involved in the formation and adherence of the disruption species of dimethylglyoximes insoluble in an aqueous solution at the DME. In a 40% methanolic solution containing 1M LiCl, no oscillations were observed.

Thus, the limiting current of the second step only may be concluded to be strictly diffusion-controlled, whereas those of the other three steps involve, more or less, a kinetic character, though the polarographic data of the others presented above indicate the rate-determining step of the first three steps to be by diffusion.

The half-wave potentials of each of the steps for halogeno- and their related complexes are summarized in Table 3. The half-wave potentials of the waves following the second step for halogeno complexes agree approximately with those of the aquo-complex $[Co(OH_2)dg_2(NH_3)]^+$ and do not coincide with those of the diaquo-complex $[Co(OH_2)dg_2(OH_2)]^+$. Therefore, the ammonia ligand for the halogeno- and aquo-ammine complexes may be concluded not to aquate in the lower oxidation states of the cobalt in a solution.

On the other hand, Figs. 4 and 5 show the dependences of the current-potential curves on the concentration of excess ammonia in a solution for the aquo-ammine and the diammine cobalt(III)

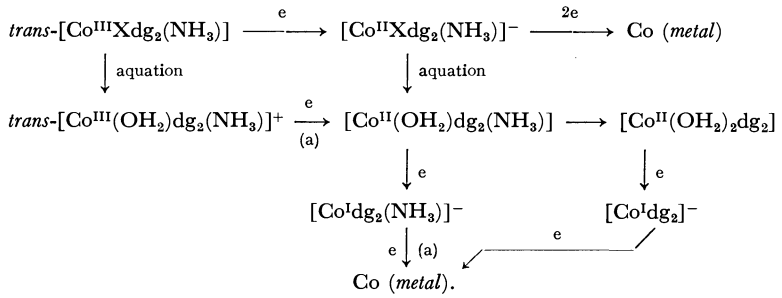
complexes respectively. In Figs. 4 and 5, the shapes of the waves for the aquo-ammine and the diammine complexes are seen to come to resemble each other with the increase in the concentration of ammonia, especially in the shapes of the last steps. This suggests that the ammine complexes tend to aquate in a solution in the absence of excess ammonia, especially in the last step of reduction

($Co^{I} \rightarrow Co^{0}$). Nevertheless, the fifth ligand of ammonia or, at least, one of ammonia ligands is not replaced with a water molecule in a neutral Na_2SO_4 solution throughout the reductions, taking account of the half-wave potentials for the diaquo-complex (see Table 3).

Accordingly, the overall processes of the electrode reaction given below may be considered to be the most plausible:



The electrode reaction in a 0.5M Na_2SO_4 solution is considered to proceed mainly along the (a) path rather than along the other paths. The contribution of the other paths, accompanied by the disruption of the cobalt(I) complexes, is considered to be one of the reasons why the limiting currents of the last two steps exhibit some kinetic character. From the view point of the electronic structure, the cobalt(I) complex might have the tetra-coordinate formula, $[Co^{I}dg_2]^-$, even in solutions.

Copper(II) Complexes of Ethylenediaminemonoacetic Acid (EDMA). A Polarographic Study of the Solution Equilibria between the Copper(II) Ion and EDMA and the Preparation of Copper(II)-EDMA Complexes

Yuki Fujii and Mutsuo Kodama

Department of Chemistry, Ibaraki University, Bunkyo-cho, Mito

(Received April 2, 1969)

In the present paper, the solution equilibria between the copper(II) ion and ethylenediaminemonoacetic acid (EDMA) were determined polarographically and, then copper(II)-EDMA complexes were prepared and characterized using ion-exchange chromatography and the visible and infrared absorption spectra. Since copper(II) ions in an EDMA solution behave reversibly in a polarographic electrolysis, the composition and the stability constants of copper(II)-EDMA complexes were determined from the dependence of the half-wave potential on the concentration of uncomplexed EDMA by employing a modification of the Deford-Hume method. The copper(II) ion was found to form complexes of 1-to-1 and 1-to-2 compositions with EDMA. Their successive formation constants, K_1 and K_2, were $2.5_2\times10^{13}$ and 1.10×10^{8} respectively. The copper(II)-EDMA complex with a 1-to-1 composition was easily isolated from an aqueous solution of pH 3.0—4.0. On the other hand, the complex with a 1-to-2 composition could be isolated in a low yield by adding ethanol from a solution containing an excess amount of EDMA in the pH range from 10.0 to 11.0. From the infrared spectra and the ion-exchange chromatographic behavior, the ethylenediaminemonoacetate ion in the complexes was concluded to function as a tridentate ligand.

The metal complexes of ethylenediamine and aminopolycarboxylic acids which derived from ethylenediamine have been studied in various aspects, but the investigations of the complexes with ethylenediaminemonoacetic acid (EDMA) as the ligand have been quite limited. In this connection, in order to understand the detailed properties of EDMA as the ligand in the complex formation reaction, it seemed that it would be worthwhile to study thermodynamically the complex formation reaction involving EDMA and to prepare and characterize the metal complexes of EDMA. In this paper, the polarographic determination of the solution equilibria between the copper(II) ion and EDMA and the preparation of copper(II) complexes of EDMA from an aqueous solution will be described. The participation of the acetate group in the complex formation was demonstrated by studying the infrared absorption spectra and by ion-exchange chromatography.

Experimental

Reagents. The ways of preparing and standardizing a standard copper(II) perchlorate solution were given previously.[1] The preparation and purification of EDMA dihydrochloride were also described in a previous paper.[2] Its purity was checked by means of C.H.N. analysis. All the other chemicals used in the polarographic measurements were of an analytical reagent grade.

Apparatus and Experimental Procedures. All the d. c. current-voltage curves were measured by using a manual polarograph similar to that of Kolthoff and Lingane.[3] The rate of the flow of mercury, m, and the drop time, t_d, of the dropping mercury electrode (DME) were 0.839 mg/sec and 3.92 sec respectively, as measured in an air-free 0.10M acetate buffer solution of pH 5.00 with an open-circuit and 70.0 cm of a mercury column at 25°C. A saturated calomel electrode used as the reference electrode has also been described previously.[4] The pH value of the solution was measured with a glass electrode pH meter (Hitachi-Horiba Model M-5). In the pH titration, a semimicroburet with a capacity of 10 ml was used. All the experimental procedures in the polarography were given previously.[4,5] Under the present experimental conditions, the maximum

of the first kind appeared in the reduction wave of the copper(II) ion in an EDMA solution. Therefore, 6×10^{-6}M LEO (polyoxyethylene lauryl ether) was added to the sample solution in order to surpress it.

All the visible absorption spectra were recorded on a Hitachi EPS-3 pen-recording spectrophotometer using water as a solvent. The infrared absorption spectra were taken on Nujol mulls between sodium chloride plates or potassium bromide disks, using a Hitachi EPI-S2 spectrometer. The magnetic susceptibility was determined by the Gouy method using powdered samples at 24°C.

Methods of Analysis. The carbon, hydrogen, and nitrogen analyses of the solid complexes were performed by the conventional combustion method using a Yanagimoto C.H.N. Corder MT-1. The copper was determined polarographically by measuring the wave-height of the copper(II) ion in an acetate buffer solution of pH 5.0 containing 20.0 mM EDMA.

Results and Discussion

Polarographic Determination of Solution Equilibria between Copper(II) Ions and EDMA. In the theoretical analysis of the polarographic data, accurate pK values of EDMA are necessary. Therefore, the pK values of EDMA were first determined by the potentiometric acid-base titration. Titration was carried out on oxygen-free sample solutions in a beaker-type cell with a water-jacket thermostatted at 25°C. The titration curve of an EDMA with a carbonate-free sodium hydroxide exhibited sharp inflections corresponding to the successive stages of neutralization (Fig. 1). The pK_2 value corresponding to the following dissociation reaction was estimated to be 6.65 from the pH value at the half-titration point.

$$H_2X^+ \overset{pK_2}{\rightleftharpoons} HX + H^+$$

The pK_1 and pK_3 values were then calculated by using the pH values at the first and second inflection points with the aid of the well-known relation (1):[6]

$$pH_i = \frac{(pK_2+pK_j)}{2} \quad (1)$$

where pH$_i$ denotes the pH at the first or second inflection point, and pK_j, the pK_1 or pK_3 value corresponding to the following proton dissociation equilibria. The estimated pK_1 and pK_3 were 2.15 and 10.15 respectively.

$$H_3X^{2+} \overset{pK_1}{\rightleftharpoons} H_2X^+ + H^+$$

$$HX \overset{pK_3}{\rightleftharpoons} X^- + H^+$$

The copper(II) ion in an EDMA solution invariably gave a single well-defined polarographic wave (Fig. 2). Its wave-height was exactly proportional to the square-root of the effective mercury pressure on the DME and to the bulk concentration of the

copper(II) ion. At pH's lower than 7.0, the log-plot analysis of the polarogram has a linear relation with a reciprocal slope falling in the range from 33 to 35 mV. A typical example is shown in Fig. 3. Therefore, it can be concluded that the copper(II) ion in the EDMA solution undergoes a two-electron reversible reduction at the mercury electrode. Consequently, the solution equilibria between the copper(II) ion an EDMA can be successfully determined by the conventional polarographic method. Since and EDMA anion has two nitrogen groups and one acetate group, it may act as a tridentate ligand. Therefore, the copper(II) ion may be expected to form the complexes with 1-to-1 and 1-to-2 compositions. If both 1-to-1 and 1-to-2 complexes are formed, the electrode reaction of the copper(II) ion at the mercury electrode can be assumed to be:

$$\begin{array}{l} CuX^{+} + nH^{+} + Hg + 2e^{-} \rightleftharpoons Cu(Hg) + H_nX^{n-1} \\ \quad\quad \uparrow\downarrow \\ \quad\quad CuX_2 \end{array}$$

where CuX^{+} and CuX_2 are copper(II)-EDMA complexes of 1-to-1 and 1-to-2 compositions and where H_nX^{n-1} means the protonated EDMA ion. Hence, the shift of the half-wave potential of the copper(II) ion due to the complex formation can be derived thermodynamically as:

$$\Delta E_{1/2} = (E_{1/2})_{Cu} - (E_{1/2})_{CuX}$$

$$= 0.0296\left[\log\left(\frac{K_1\cdot[X]_f}{(\alpha_H)_X} + \frac{K_1\cdot K_2\cdot[X]^2_f}{(\alpha_H)^2_X}\right) + \log\frac{k_{CuX}}{k_{Cu^{2+}}}\right] \quad (3)$$

where $(E_{1/2})_{Cu}$, $(E_{1/2})_{CuX}$, k_{CuX}, and $k_{Cu^{2+}}$ have their usual meanings[7] and where $(\alpha_H)_X$ and $[X]_f$ denote the (α_H) value of EDMA and the concentration of uncomplexed EDMA respectively. K_1 and K_2 are the successive formation constants of copper(II)-EDMA complexes.

Equation (3) clearly indicates that when the solution pH is kept constant, the plot of (antilog $[\Delta E_{1/2}/0.0296+\log k_{Cu^{2+}}/k_{CuX}])/[X]_f$ against $[X]_f$ will give the linear relation, the slope and the intercept of which correspond to $K_1\cdot K_2/(\alpha_H)^2_X$ and $K_1/(\alpha_H)_X$ respectively. On the other hand, if only the complex with a 1-to-1 composition is formed, the plot of antilog $[\Delta E_{1/2}/0.0296+\log k_{Cu^{2+}}/k_{CuX}]$ against $[X]_f$ should give the linear relation. These relations were examined at pH 5.0. Experiments were carried out on acetate buffer solutions containing an uncomplexed EDMA, because at this pH the system containing only uncomplexed EDMA does not have enough buffer capacity to keep the solution pH constant during the electrolysis. The linear relation shown in Fig. 4 clearly indicates that the copper(II) ion forms complexes of 1-to-1 and 1-to-2 compositions under the present experimental conditions. From the intercept and the slope of the linear relation, the K_1 and K_2 values were estimated to be $2.5_2\times10^{13}$ and 1.10×10^{8} respectively.

7.11	−0.324	+29	+24.7
7.48	−0.353	0	0
7.83	−0.384	−31	−24.0
8.01	−0.397	−44	−35.1

* No buffer reagent was used because uncomplexed EDMA can serve as a buffer reagent in this pH range.

The possible formation of a mixed ligand complex involving acetate or chloride ions could be ruled out by the fact that the half-wave potential was independent of the concentration of acetate or chloride ions, provided that the solution pH and EDMA concentration were kept constant (Table 1). If the above conclusion is correct, the dependence of the half-wave potential on the solution pH must be explained satisfactorily by using the K_1 and K_2 values thus determined. The pH dependence of the half-wave potential was calculated with the aid of Eq. (3) and compared with the observed data. The results are shown in Table 2. In acid and neutral media, the calculated values agreed well with the observed values. In a weak alkaline medium, however, the observed values are slightly larger than the calculated ones. This can be ascribed to the fact that the reversibility of the electrode reaction in a weak alkaline medium is not so complete as in acid and neutral media. This explanation could be confirmed by the value of the reciprocal slope (45 mV).

From all the above results and discussion, it can be concluded that the pK values of EDMA and K_1 and K_2 values of copper(II)-EDMA complexes thus determined are reasonable.

Characterization of Copper(II)-EDMA Complexes. Since the formation of copper(II)-EDMA complexes of 1-to-1 and 1-to-2 compositions was confirmed polarographically, we tried to prepare and characterize these complexes. Although, because of kinetic, solubility and other limitations, the predominant species in the solution can not always be separated selectively from the equilibrium mixture, for the successful preparation of metal complexes, it seems that its formation reaction in solution had better to be complete in a thermodynamic sense. Therefore, in order to find the optimum conditions for the preparation, we first calculated the fraction of the copper(II) ion present in each species of the copper(II)-EDMA complex using the pK values of EDMA and the formation constants of copper(II)-EDMA complexes with the aid of the following relations:

$$[\mathrm{Cu}]_t = [\mathrm{Cu}^{2+}] + [\mathrm{CuX}^+] + [\mathrm{CuX}_2]$$

$$[\mathrm{X}]_t = [\mathrm{X}]_f + [\mathrm{CuX}^+] + 2\cdot[\mathrm{CuX}_2]$$

$$\frac{K_1}{(\alpha_H)_X} = \frac{[\mathrm{CuX}^+]}{[\mathrm{Cu}^{2+}]\cdot[\mathrm{X}]_f}, \quad \frac{K_2}{(\alpha_H)_X} = \frac{[\mathrm{CuX}_2]}{[\mathrm{CuX}^+]\cdot[\mathrm{X}]_f}$$

Table 3. The fraction of copper(II) ion presents as each species of copper(II)-EDMA complex
Total concentration of copper(II)=0.80 M

pH	Total concentration of EDMA, M	Fraction Cu^{2+}	CuX^+	CuX_2
3.0	0.80	5.8×10^{-2}	9.41×10^{-1}	6.6×10^{-4}
4.0	0.80	2.0×10^{-3}	9.96×10^{-1}	2.0×10^{-3}
10.0	3.20	3.6×10^{-22}	9.1×10^{-9}	1.00
11.0	3.20	8.2×10^{-23}	4.3×10^{-9}	1.00

where $[Cu]_t$ and $[X]_t$ mean the total concentrations of copper(II) and EDMA respectively, and $[CuX^+]$ and $[CuX_2]$, the concentrations of copper(II)-EDMA complexes of 1-to-1 and 1-to-2 compositions. The results summarized in Table 3 clearly indicate that the copper(II) ion in the solution of pH 3.0—4.0, which is 0.80M with respect to copper(II) and 0.80M with respect to EDMA, exists predominantly in the form of CuX^+ and that the copper(II) ion in the solution of pH 10.0—11.0 containing 0.80M copper(II) and 3.20M EDMA exists only in the form of CuX_2. On the basis of the above thermodynamic information, we tried to prepare the copper(II)-EDMA complexes. The complex with a 1-to-1 composition could be prepared and isolated from the solution of pH 3.0—4.0, and that with a 1-to-2 composition, from the solution of pH 10.0—11.0 containing an excess of EDMA, as will be described below.

Preparation of Ethylenediaminemonoacetatoaquocopper(II) Chloride Monohydrate. To 50 m*l* of an aqueous solution containing 3.4 g (0.02 mol) copper(II) chloride dihydrate, about 4.2 g (0.02 mol) of EDMA·2HCl·H_2O were added. After adjusting the solution pH to 3.0—4.0 by adding a 6N sodium hydroxide solution, the mixture solution was heated on a water bath until its volume was reduced to 25 m*l*. When the resulting solution was cooled to 0°C, light blue crystals were deposited and filtered off. This crude product was then recrystallized from a 50% ethanol solution. The yield was 1.5 g (approximately 30%). Found: Cu, 24.6; C, 18.78; H, 4.87; N, 11.14%. Calcd for $[Cu(EDMA)(H_2O)]Cl\cdot H_2O$: Cu, 25.2; C, 19.04; H, 5.21; N, 11.11%.

Preparation of Bis(ethylenediaminemonoacetato)copper(II) Tetrahydrate. To 50 m*l* of an aqueous solution containing 3.4 g (0.02 mol) copper(II) chloride dihydrate, about 16.0 g (0.08 mol) EDMA·2HCl·H_2O were added. After the resulting mixture had been heated on a water bath for ten minutes, the solution pH was adjusted to 10.0—11.0 by adding a 6N sodium hydroxide solution. The mixture solution was then evaporated naturally to about 10 m*l*, whereby the sodium chloride thus deposited was filtered off. At this point, ethanol (80—100 m*l*) was added to the solution. The resulting mixture was then cooled to 0°C and allowed to stand in a refrigerator for 2—3 weeks. Dark blue crystals were obtained. The yield was about 10%. Found: Cu, 16.6; C, 26.01; H, 6.65; N, 15.41%. Calcd for $[Cu(EDMA)_2]\cdot 4H_2O$: Cu, 17.2; C, 25.97; H, 7.10; N, 15.15%.

Table 4. The visible and IR spectra of the copper(II)-EDMA complexes

Compound	λ_{max} (c/s) $\times 10^{-13}$	log ε	Carboxylate asym. str., cm^{-1}
$[Cu(H_2O)_6^{2+}]$	36.5	1.09	—
$[Cu(EDMA)(H_2O)]Cl\cdot H_2O$	44.4	1.62	1600
$[Cu(EDMA)_2]\cdot 4H_2O$	49.2	1.86	1626
EDMA·2HCl·H_2O	—	—	1730

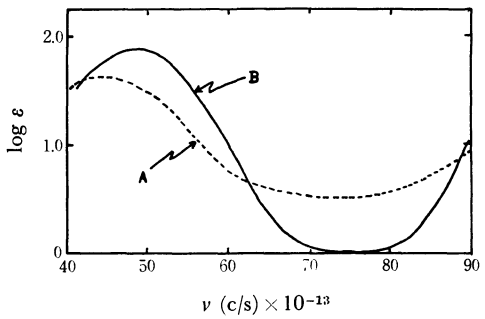

Fig. 5. Visible absorption spectra of copper(II)-EDMA complexes.
Concentration of uncomplexed EDMA = 10.0 mM
A: pH=4.0, Acetate buffer solution (0.10M), the complex with 1-to-1 composition
B: pH=7.0, The complex with 1-to-2 composition

As is shown by the visible absorption spectra in Fig. 5, the copper(II)-EDMA complexes of 1-to-1 and 1-to-2 compositions gave absorption maxima at 44.4×10^{13} and 49.2×10^{13} sec^{-1} respectively. The maxima can be regarded as the peaks due to the d–d transition. The large shift of the absorption curve to the higher energies may be a strong indication that the nitrogen groups of EDMA are coordinated to the copper(II) ion[8,9] (Table 4). Since the visible absorption study can not give any confirmative information about the participation of the acetate group in the coordination bond formation, the infrared (IR) study was carried out. The IR absorption spectrum of dark blue crystal was measured in a potassium bromide disk, but that of light blue crystal, in a Nujol-mull state. Because, in the case of light blue crystal, the color of the potassium bromide disk changed from light blue to yellow. This can be ascribed to the formation of a mixed ligand complex involving the bromide ion. As the spectral data in Table 4 show, the light blue and dark blue crystals show the strong bands of the carboxylate group at 1600 and 1626 cm^{-1} respectively. Generally, the uncoordinated $-COO^-$ group of aminopolycarboxylic acid has been observed to exhibit its characteristic band in the range from 1610 to 1580 cm^{-1}, and the –COOH group, from 1750 to 1690 cm^{-1}.[10] Therefore, the above two bands of copper(II)-EDMA

10) T. Sakaguchi and K. Ueno, "Metal Chelates," Vol. II, Nankodo, Tokyo (1963), p. 43.

complexes can probably be ascribed to the coordinated carboxylate group.

The ion-exchange chromatographic study also supports the above interpretation. In the aqueous solution of the light blue crystal (pH=4.0; concentration of uncomplexed EDMA=10.0 mM), the cation exchange regin (Dowex 50W-X8, 100—200 mesh) in the Na^+ form could capture the copper(II) ion effectively, but the anion exchange regin (Dowex 1-X8, 100—200 mesh) in the Cl^- form could not. On the other hand, in the case of the solution containing the dark blue crystal (pH=7.0; concentration of uncomplexed EDMA=10.0 mM), neither ion-exchange resin could capture the copper(II) ion. These facts clearly indicate that the copper(II) ion in the former solution exists as a positively-charged species, but in the latter solution, as a zero-charged species, suggesting the participation of the carboxylate group in the complex formation.

The possibility of the formation of the dimer structure in the crystal state could be ruled out by the magnetic susceptibility measurements (1.75 B.M. for the light blue crystal and 1.92 B.M. for the dark blue crystal).[11]

From the above results and discussion, we have concluded that the light blue crystal isolated from an acid solution is $[Cu(EDMA)(H_2O)]Cl \cdot H_2O$, corresponding to the square planar structure, and that the dark blue crystal obtained from the alkaline medium is $[Cu(EDMA)_2] \cdot 4H_2O$, corresponding to the octahydral structure.

The authors wish to thank Professor Ryokichi Tsuchiya and Dr. Eishin Kyuno of Kanazawa University and Professor Katsumi Yamamoto of Ibaraki University for their helpful suggestions. The authors also wish to thank to Professor S. Ito and his coworkers of Tohoku University for their kind help in Elemental Analyses.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 3177—3184 (1969)

The Ion Exchange of a Mixture of Er and Tm with HEDTA

Zenzi HAGIWARA and Hideo ŌKI

Faculty of Engineering, Tohoku University, Katahira-cho, Sendai

(Received April 18, 1969)

Under experimental conditions similar to those in the elution system of the rare earth with a dilute HEDTA eluant, the Er-Tm separation factor has been found in the system of HEDTA and Dowex 50W, X-8, 50—100 mesh. The values for this pair, 1.57 at 25°C and 1.63 at 60°C were in agreement with the values calculated from the stability constants of the rare earth-HEDTA chelates. Further, an equimolar mixture of Er and Tm has been eluted with a 0.015M HEDTA solution buffered with ammonium hydroxide. Under the present experimental conditions, the adsorption band of each rare earth reached a steady state after it had moved down through the hydrogen-retaining bed to a distance several times the initial band length. Several series of experimental data were used for analyses of the adsorption band from the point of view of rate theory. It was concluded that the present ion-exchange process with a HEDTA eluant was controlled by film diffusion as the rate-determining step. The plate-height values were also found to be functions of the flow rate.

In the ion-exchange separation of the rare-earth series on a commercial scale, EDTA[1] (ethylenediamine-*N,N,N',N'*-tetraacetic acid, H_4Y) and HEDTA[2] [*N'*-(2-hydroxyethyl)-ethylenediamine-*N,N,N'*-triacetic acid, H_3Ch] eluants buffered with ammonium hydroxide has been employed with marked success. In order to make a theoretical treatment of the elution system of the rare earth by HEDTA complexation, it is necessary to find an accurate separation factor for adjacent rare-earth pairs and to understand the mechanism of the separation of the rare-earth group under steady-state conditions.

In connection with the above ion-exchange

system, the formation of the H_5Ch^{2+}-band[3] during elution was studied; the adsorption isotherm was also discussed in detail. Theoretical treatments[4] of the ion-exchange column involving the rare-earth band with dilute HEDTA were made in order to clarify the elution mechanism of the rare-earth species. Further, one of the present authors previously reported the separation factors[5] for adjacent rare-earth pairs, such as Er-Tm, Dy-Ho, Y-Dy, Tb-Y, Eu-Gd and Sm-Nd, in the presence of EDTA, significant differences were then found in them between the values calculated from the stability constants of the rare earth-EDTA chelates and the measured values. Thus we arrived at the conclusion that, except in special cases, the separation factor should be measured experimentally under conditions similar to those in a practical elution system containing a mixture of rare earths.

One of the purposes in this work is to find the Er-Tm separation factor in the presence of HEDTA at different temperatures, and to use these values for analyzing the elution system involving the Er-Tm pair. Another purpose is to analyze the elution system of a rare-earth mixture under steady-state conditions so that a comparison of both dilute and concentrated eluants can be made.

Separation Factor for the Er-Tm Pair in the Presence of HEDTA

The separation factor (α) of an adjacent rare-earth pair (Ln_1-Ln_2) in the presence of a chelating agent, such as EDTA (H_4Y) or HEDTA (H_3Ch), can be estimated using the values of the stability constants of the Ln-chelates.

In the ion-exchange system involving adjacent rare-earths and HEDTA, the main exchange reaction is written by:

$$\overline{Ln_1}^{3+} + Ln_2Ch \rightleftarrows \overline{Ln_2}^{3+} + Ln_1Ch$$

where the barred symbols refer to the resin phase, and the unbarred symbols, the aqueous phase. The exchange quotient (or selectivity coefficient) is expressed by:

$$K' = \frac{[\overline{Ln_2}^{3+}][Ln_1Ch]}{[\overline{Ln_1}^{3+}][Ln_2Ch]} \tag{1}$$

where the brackets represent the concentrations of related species. In the elution system with a dilute eluant of HEDTA buffered with ammonium hydroxide, the following species are present in the aqueous phase of the rare-earth band:

$LnCh^0$, Ln^{3+}, NH_3^+, H^+, H_3Ch, H_2Ch^-, HCh^{2-}, Ch^{3-}.

Whether a chelating agent is present in the system or not, $\alpha^{Ln_1}_{Ln_2}$ is defined as the concentration ratio of the two elements:

$$\alpha^{Ln_1}_{Ln_2} = \frac{[\overline{Ln_{1T}}][Ln_{2T}]}{[\overline{Ln_{2T}}][Ln_{1T}]} \tag{2}$$

where the T's indicate the total concentrations of indicated rare earths in both phases. Since the rare earth is present as the tripositive ion in the resin, Eq. (2) is expressed in this form:

$$\alpha^{Ln_1}_{Ln_2} = \frac{[\overline{Ln_1}^{3+}][Ln_{2T}]}{[\overline{Ln_2}^{3+}][Ln_{1T}]} \tag{3}$$

Considering the presence of Ln^{3+} and $LnCh^0$ as the Ln-species, we have:

$$\alpha^{Ln_1}_{Ln_2} = \frac{[\overline{Ln_1}^{3+}]\{[Ln_2^{3+}]+[Ln_2Ch]\}}{[\overline{Ln_2}^{3+}]\{[Ln_1^{3+}]+[Ln_1Ch]\}} \tag{4}$$

Introducing $[LnCh]=K_{LnCh}[Ln^{3+}][Ch^{3-}]$ into (4), we have:

$$\alpha^{Ln_1}_{Ln_2} = \frac{[\overline{Ln_1}^{3+}][Ln_2^{3+}]\{1+K_{Ln_2Ch}[Ch^{3-}]\}}{[\overline{Ln_2}^{3+}][Ln_1^{3+}]\{1+K_{Ln_1Ch}[Ch^{3-}]\}} \tag{5}$$

In the above expressions, K_{LnCh} indicates the stability constant of LnCh and the brackets represent the molarities of the indicated species. As $[Ln^{3+}]$ is very small compared with [LnCh], we have:

$$\alpha^{Ln_1}_{Ln_2} = \frac{[\overline{Ln_1}^{3+}][Ln_2^{3+}]K_{Ln_2Ch}}{[\overline{Ln_2}^{3+}][Ln_1^{3+}]K_{Ln_1Ch}} = K^{Ln_1}_{Ln_2}\frac{K_{Ln_2Ch}}{K_{Ln_1Ch}} \tag{6}$$

When the exchange quotient, $K^{Ln_1}_{Ln_2}$, is almost equal to unity, one obtains the following approximation:

$$\alpha^{Ln_1}_{Ln_2} \cong \frac{K_{Ln_2Ch}}{K_{Ln_1Ch}} \tag{7}$$

Surls and Choppin[6] studied the ion-exchange equilibrium between Ln^{3+} and the hydrogen form of Dowex 50 using radioactive Ln-nuclides and perchloric acid; they observed no difference in the distribution coefficient ($K_d=[\overline{Ln^{3+}}]/[Ln^{3+}]$) between the adjacent rare earths. Consequently, $K^{Ln_1}_{Ln_2}$ is approximately equal to unity. According to their study, the mean K_d-values of 2.20×10^5 and 2.22×10^5 were obtained for the Er-H and Tm-H systems respectively. It can be decided from these data that K^{Er}_{Tm} is approximately equal to unity.

In the presence of HEDTA, the Er-Tm separation factor is expressed by Relation (7):

$$\alpha^{Er}_{Tm} \cong \frac{K_{TmCh}}{K_{ErCh}} \tag{8}$$

It may be said qualitatively that $\alpha^{Ln_1}_{Ln_2}$ in the system containing a chelating agent is independent of the composition of the aqueous and resin phases and

of the type of exchanger, and that the $\alpha^{Ln_1}_{Ln_2}$-value is decided only by the ratio of the stability constants of the Ln-chelates. However, it is recommended the α-values should be measured directly, for the reason described in the previous paper.[5] In the present work, the α-values were measured at 25 and 60°C using the batch method and their temperature dependency was investigated.

Experimental

1) Experimental Method for Determining the Separation Factor. *Preparation of Aqueous Phase.* Erbium and thulium were eluted separately using a 0.015M HEDTA eluant buffered with ammonium hydroxide (pH=7.5) and using a hydrogen-retaining bed with Dowex 50W, X-8, 100—200 mesh. The elution conditions were the same as those in Exp. No. 12 and 13 in the previous paper;[7] the rare-earth eluates from the exchange column were employed as the aqueous phase in the equilibrium experiments. As the composition of the Er-eluate obtained by this elution was almost identical with that of the Tm-eluate, it was very easy to prepare aqueous solutions having different ratios of Er to Tm but without any other notable change in constituents.

Preparation of the Rare Earth and Ammonium Types of Resins. By passing the load solutions, such as $ErCl_3$, $TmCl_3$ and NH_4Cl, into an ion-exchange column containing Dowex 50W, X-8, 50—100 mesh in the hydrogen form, the erbium, thulium, and ammonium types of resins were prepared.

Equilibrium Experiment. A total of about 5 g of the prepared resins was taken; for weighing, the ammonium and Ln-types of resin were taken into the required portions, so that the constituents in the resin phase would become a 0.8 equivalent fraction of the sum of $\overline{Er^{3+}}$ and $\overline{Tm^{3+}}$ and a 0.2 equivalent fraction of $\overline{NH_4^+}$. Further, the ratio*1 of Er to Tm in the resin was adjusted to give a α^{Er}_{Tm}-value of approximately 1.6, as was to be expected from the α^{Er}_{Tm}-values in Table 3. After the resin mixture (5 g) had been equilibrated with a total volume of 300 m*l* of the erbium and thulium eluates at a constant temperature of either 25°C or 60°C for 48 hr in a thermostat, the two phases were separated and analyzed.

Analytical Method. The analytical methods employed for the determination of the various species present in the two phases were the same as those given in the literature,[4] while the rare-earth mixtures were determined spectrophotometrically using a Shimadzu QR-50 spectrophotometer and a 1.00-cm cell. The samples of the rare-earth oxides obtained from the two phases were placed in a volumetric flask and dissolved with a slight excess of 1M $HClO_4$ under heating. After dilution to a definite volume, the resulting solutions were analyzed at the following wavelengths:

Rare earth	λ (mμ)	Slit width (mm)	Molecular absorption coefficient (l/mol·cm)
$ErClO_4$	379.0	0.0240	6.55
$TmClO_4$	683.0	0.0135	2.50

A 1.00-cm quartz cell was used.

2) Experimental Method of the Elution of the Er-Tm Mixture. As the experimental method[4] for the elution at 60°C has already been reported, only the outline will be given here. In the experiments, 22-mm I.D. columns made of Pyrex glass jacketed with 60-mm-I.D. columns were used. At the bottom of each column, a sintered glass disk was fixed in order to support the resin bed containing Dowex 50W, X-8, 50—100 mesh. The column was kept at a certain temperature by circulating water through the jacket columns from the thermostat. The jacket column with an equimolar mixture of Er and Tm was connected to the main column containing the hydrogen form of Dowex 50W, X-8, 50—100 mesh. The connection was made by the aid of a vinyl tube, whose outside was covered with shielding material. In elution, the HEDTA eluant (0.015M) was first passed through the pre-heater equipped with a stirrer; here the solution temperature was raised in order to remove any dissolved air. Then the eluant entered the top of the rare-earth adsorption column. The eluate from the retaining column was cooled through the condenser and collected into small fractions by means of a fraction collector. The experimental apparatus is represented in Fig. 1.

are listed in Tables 1 and 2. The α^{Er}_{Tm}-values were calculated by the use of Eq.(2):

$$\alpha^{Er}_{Tm} = [\overline{Er_T}][Tm_T]/[\overline{Tm_T}][Er_T]$$

Table 1 and 2 indicate that when the total composition of rare earths in the resin and aqueous phases shows an almost constant value [see (Er_T+Tm_T) and $(\overline{Er^{3+}}+\overline{Tm^{3+}})$], the variation in α with the Er/Tm ratio and temperature is not remarkable. The average α^{Er}_{Tm} -values were 1.57 at 25°C and 1.63 at 60°C. The stability constants of the Ln-HEDTA chelates have been found by several investigators. Introducing these data into Eq.(8), the Er-Tm separation factors were calculated as tabulated in Table 3, in which the agreement is excellent with the α^{Er}_{Tm}-values calculated from the data of Spedd-

ing[8] and Moeller.[9] The α-value calculated from the data of Powell and Mackey[10] seems, however, to be too large. In spite of measurements at different ionic strengths, the α_{Tm}^{Er}-value observed at 25°C is in good agreement with that calculated Spedding's data.[8]

Elution Results. After the break-through of rare earth, the total concentration of the rare earth in the eluate was plotted against the eluate volume. As may be seen in Fig. 2 (Exp. No. HT-2), the total amount of Er and Tm in the eluate was kept almost constant; an elution curve with a flat top for each element was obtained over a fairly wide range of eluate volume. After the rare-earth band had been moved down the hydrogen-retaining bed a distance corresponding to about 5 band lengths,*2

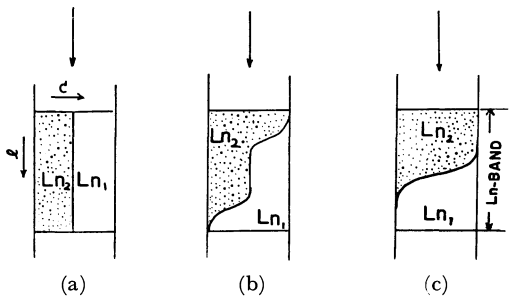

Fig. 3. Change in the composition of rare earth during the ion exchange process.

a steady state was reached. In such a steady state, the mixed rare-earth boundary with Er and Tm has a pattern with a definite gradient of composition; further progress in the separation of these species can not be expected by increasing the elution distance. The elution curves obtained under different flow rates did not differ from the elution curve shown in Fig. 2. However, tailing and channelling were increased to some degree with the increase in the flow rate.

When the rare-earth-saturated band containing equimolar adjacent rare earths (Fig. 3-a) is displaced down the hydrogen-retaining bed with the HEDTA eluant buffered with ammonium hydroxide in the beginning of the elution step, ammonium and hydrogen ions in the eluant leak through the rare-earth band until the band expands to its equilibrium band length. During this early step, Ln_1 and Ln_2 begin to be separated at the boundary, the degree of separation is gradually increased, as Fig. 3-b shows. However, the analysis of the exchange system on the basis of the rate theory seems to be difficult in this step, because complicated phenomena are still occurring in the rare-earth band, with Ln, NH_4, H, and HEDTA species included in both phases. With further progress in elution, a steady state is finally attained, as may be seen in Fig. 3-c, in which the composition of the Ln_1-Ln_2 boundary has been fixed to a definite gradeint, as has been mentioned above. Under steady-state conditions (Fig. 3-c), all the other species except the rare earths are considered to be distributed homogenously over the entire range of the band. This may be explained by the fact that, after the attainment of a steady state, the exchange system is finally fixed by the composition of the eluant itself, as has been illustrated in a previous paper.[7] In other words, when the composition of the eluant and the exchange constants related to the system are known, all the constituents in the resin and aqueous phases of each pure rare-earth band formed during elution can be calculated as functions of the eluant composition on the assumption of a true equilibrium for the ion-exchange

*2 The minimum number of displacements (v) of the mixed rare-earth band needed to carry out separation is about 2.1 using the relation of $v=(1+\varepsilon N_0)/\varepsilon$, where N_0 is the mole fraction of Er in the mixture of Er and Tm being separated, and where N_0 and ε are 0.5 and 0.63 respectively in this run. Therefore, the value of *ca.* 5 band lengths (see Table 4) is enough to realize a steady-state elution.

process. The effective separation of rare earths by ion exchange is based mainly on differences in K_{LnCh} between the lanthanons. However, these differences are not very large between the adjacent rare-earth pairs. Further, significant differences in such exchange constants as $K^{Ln}_{NH_4}$ and K^{Ln}_{H} cannot be expected between the adjacent pairs. Considering only the presence of rare earth as the cationic species in the rare-earth band, and taking only the reaction of Eq. (1) as important, the Ln_1-band can be assumed to be displaced by Ln_2(see Fig. 3-c; Ln_1=Tm and Ln_2=Er in this study).

Analysis of the Ion-Exchange System by the Rate Theory. For an elution system involving the rare earths under steady-state conditions, the analysis on the basis of the rate theory[4,11,12] is possible using the experimental data related to the mixed region with adjacent rare earths.

In the ion-exchange process, the rate of particle and film-diffusion may be expressed by the following relation.[13] For particle-diffusion control, we have:

$$\left(\frac{\partial \bar{X}_i}{\partial t}\right)_Z = \frac{\bar{D}}{0.071 r_0^2}(\bar{X}_i^* - \bar{X}_i) \tag{9}$$

and for film-diffusion control:

$$\left(\frac{\partial \bar{X}_i}{\partial t}\right)_Z = \frac{3D}{2\delta r_0}(C_i - C_i^*) \tag{10}$$

The r_0 and δ symbols indicate the radius of the resin particle and the film thickness respectively, while $\bar{D}$ and D express the self-diffusion or interdiffusion coefficient in the resin and aqueous phases. The symbol C_i represents the concentration of species i in the interstitial solution, and $\bar{X}_i$, the amount of species i in the resin per unit volume of the resin bed. The asterisks refer to equilibrium; for example, C_i^* denotes the concentration of the interstitial solution in equilibrium with $\bar{X}_i$. The symbol Z represents the distance from a reference point in the column.

From Eqs. (9) and (10), the following relations can finally be deduced. When particle diffusion is the rate-limiting step, one obtains:

$$Z(x_{Ln_2}) = H_p\left\{-\frac{1}{\alpha-1}\ln x_{Ln_2} + \frac{\alpha}{\alpha-1}\ln(1-x_{Ln_2}) + 1\right\} \tag{11}$$

where:

$$H_p = v_b r_0^2/14\bar{D}$$

For film-diffusion control, one obtains:

$$Z(x_{Ln_2}) = H_f\left\{-\frac{\alpha}{\alpha-1}\ln x_{Ln_2} + \frac{1}{\alpha-1}\ln(1-x_{Ln_2}) - 1\right\} \tag{12}$$

where:

$$H_f = 2\delta r_0 v_b \bar{X}/3DC$$

In Eqs. (11) and (12), $Z(x_{Ln_2})$ indicates the distance of the plane with a concentration of x_{Ln_2} from the gravity center of a rare-earth boundary containing Ln_1 and Ln_2, and α is the separation factor. The symbol v_b represents the linear velocity for the movement of the rare-earth band; $\bar{X}$, the total amount of species in the resin phase per unit volume of bed, and C, the total concentration of counter ions. Further, H_p and H_f indicate the plate height due to particle diffusion and film diffusion. Using Eqs. (11) and (12), the plots of x_{Ln_2} with respect to Z give the shape of the boundary in a steady state.

In particle-diffusion control, the shapes of the boundary with Ln_1 and Ln_2 are represented in Fig. 4, in which some relationships between x_{Ln_2} and Z may be seen at the α-values of 1.2, 1.5, 2, and 3 on the assumption that H_p=0.5 cm. For film-diffusion control, similar relations are represented

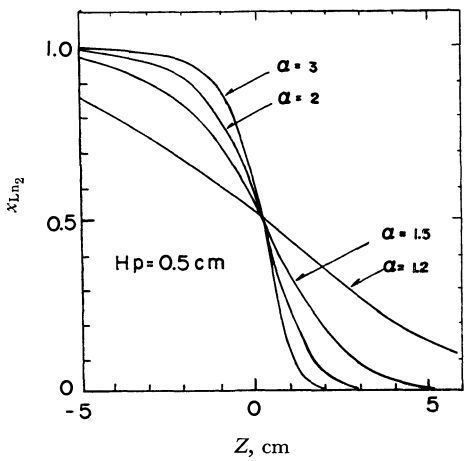

Fig. 4. Relationship between x_{Ln_2} and Z in particle-diffusion control.

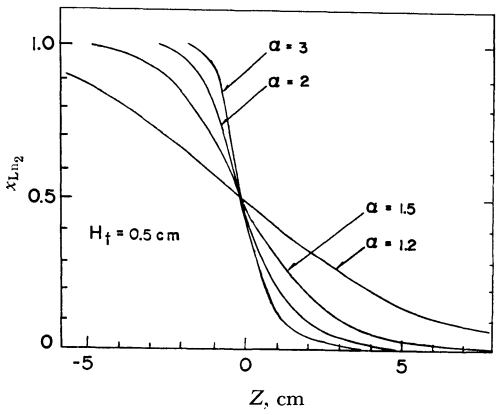

Fig. 5. Relationship between x_{Ln_2} and Z in film-diffusion control.

11) Z. Hagiwara and A. Kamei, *J. Inorg. Nucl. Chem.*, to be published.

12) Z. Hagiwara, *J. Phys. Chem.*, **73**, 3102 (1969).

in Fig. 5. As may be clear from the above figures, under steady-state conditions, the concentration gradient of the mixed region is decided by the value of either H_p or H_f as well as by the α-value, and a sharp boundary can be expected if we decrease the plate height. In general, some leakage of Ln_2 is observed in film-diffusion control and some tailing of Ln_1 in particle-diffusion control.

Employing the experimental data obtained in the elution of the Er-Tm mixture, the analysis of the overlap region in a steady state was performed on the basis of the rate theory. The following values were used as the Er-Tm separation factors in a system with HEDTA:

$$\alpha_{Tm}^{Er} = 1.57 \text{ at } 25°C;\ \alpha_{Tm}^{Er} = 1.63 \text{ at } 60°C$$

Introducing them into Eq. (12), we obtain the following equations:

for 25°C-elution:

$$Z(x_{Er}) = H_f\{-6.34 \log x_{Er} + 4.04 \log (1-x_{Er}) - 1\} \quad (13)$$

and for 60°C-elution:

$$Z(x_{Er}) = H_f\{-5.96 \log x_{Er} + 3.66 \log (1-x_{Er}) - 1\} \quad (14)$$

where $Z(x_{Er})$ indicates the distance of the plane with a concentration of x_{Er} from the gravity center of the Er-Tm overlap region. The dimensions of x_{Er} and Z are expressed in the equivalent fraction and in centimeters respectively. Further, the separation factor is assumed to be constant throughout the Er-Tm overlap zone. The plate-height contribution due to film-diffusion can be found from the cruve-fitting method using Eqs. (13) and (14); the experimental data are represented graphically in Figs. 6 and 7. As the figures show, most of the experimental data fall on the theoretical line. On the contrary, the elution results in this study cannot be explained with the aid of Eq. (11). It is obvious that the elution system of the rare earth with a dilute HEDTA, such as 0.015M as the total anionic species of HEDTA ($\widetilde{Ch}_T$) and with

a moderate crosslinked resin (X-8) is mainly controlled by film-diffusion as the rate-determining step. The plots of H_f *versus* the flow rate are shown in Fig. 8, where a linear relation may be observed. Also, the detailed values of H_f obtained in the elution at 25° and 60°C are tabulated in Table 5. The elution temperature affects the plate-height value as well as the separation factor. Since a smaller value of the plate height is obtained with an increase in the temperature, the separation efficiency in the ion-exchange process is improved by elution at high temperatures. Generally, film diffusion, particle diffusion, and particle size all contribute to the plate height. The contribution of the last two is, however, very small in the present exchange system, and film-diffusion plays the most important role for the rate-determining step. As may be seen in Table 5, the plate-height value by film diffusion at 60°C becomes smaller than that at 25°C; this is because the diffusion rates of various species in the Nernst film layer increase with a rise in the temperature.

Summary

1) The separation factors for the Er-Tm pair were found to be 1.57 at 25°C and 1.63 at 60°C in the system with HEDTA and Dowex 50W, X-8.

2) Under various experimental conditions, elutions of an equimolar mixture of Er and Tm were carried out at 25° and 60°C using a 0.015M HEDTA eluant buffered with ammonium hydroxide; a steady state was established through the rare-earth band.

3) The elution system of the rare earth under steady-state conditions was analyzed on the basis of the rate theory; the present exchange system was thereby confirmed to be controlled by film-diffusion the rate-determining step.

4) By raising the elution temperature, the separation efficiency was increased; this was because of the decrease in the plate-height value as well as because of the increase in the separation factor itself.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 3184—3189 (1969)

Nuclear Magnetic Resonance Study of Metal Complexes. I. A Conformational Analysis of D-(*l*)-Propylenediamine Chelate Rings of Diamagnetic Cobalt(III), Palladium(II) and Platinum(II) Complexes

Shigenobu YANO, Haruko ITO, Yoshio KOIKE,*1 Junnosuke FUJITA and Kazuo SAITO

Department of Chemistry, Faculty of Science, Tohoku University, Katahira-cho, Sendai

(Received May 26, 1969)

Proton magnetic resonance (PMR) spectra of tetracyano-*l*-propylenediamine cobalt(III) ion and bis(*l*-propylenediamine) platinum(II) and palladium(II) ion have been measured in deuterated water and analyzed according to Castellano and Waugh's exact analysis. The values of coupling constants clearly indicate that the *l*-propylenediamine chelate rings in these diamagnetic complexes have fixed *λ-gauche* form in aqueous solutions at room temperature.

Recent researches have shown that high resolution proton magnetic resonance spectroscopy provides useful information on the structure of a variety of organic compounds in solution, but only a few papers have reported on its application to metal

*1 Present address: Faculty of Engineering, Kanagawa University, Kanagawa-ku, Yokohama.

complexes.[1] It is known that ethylenediamine (en) and propylenediamine (pn) coordinate to various metal ions to form nonplanar *gauche* chelates. Spees *et al.*[2] measured proton magnetic resonance (PMR) spectra of various metal complexes containing ethylenediamine and propylenediamine, and showed that the ethylenediamine chelate changes its conformation rapidly from λ- to δ-*gauche* form (IUPAC, 1966) and *vice versa* in an aqueous solution at room temperature. No clear experimental evidence has been given, however, concerning the chelate conformation of propylenediamine ring in solution.

Propylenediamine chelate ring was considered to be less labile to such conformational change, because the preference for the methyl group to be equatorial to the chelate ring would make one of the conformers more stable. The energy difference between the conformers with the methyl group in the axial and the equatorial direction was estimated to be about 2 kcal/mol, and it was supposed that about ninetyfive per cent of the ligand has the methyl group equatorial even in a solution at room temperature.[3]

We have measured PMR spectra of the diamagnetic complexes, $K[Co(CN)_4(l\text{-pn})]$, $[Pt(l\text{-pn})_2]Cl_2$ and $[Pd(l\text{-pn})_2]Cl_2$ and obtained significant information on the conformation of the *l*-propylenediamine chelate ring.

Experimental

Preparation of the Complexes. *Potassium Tetracyano-l-propylenediamine Cobalt(III) Dihydrate* $K[Co(CN)_4(l\text{-pn})]\cdot 2H_2O$. A mixture containing 5.0 g of $K_3[CoI(CN)_5]$[4] and 1.5 g of *l*-propylenediamine in 50 m*l* of water was warmed on a water bath at 80°C until the color changed to yellow. The solution was cooled, filtered, and evaporated to almost dryness under reduced pressure at 60°C. The residue was treated with 100 m*l* of absolute methanol and filtered. The crude complex was precipitated by adding 95% ethanol to the filtrate, filtered off, washed with absolute ethanol and ether. The product was recrystallized from methanol solution by adding 95% ethanol.

Found: C, 27.62; H, 4.60; N, 26.44%. Calcd for $C_6H_{12}N_6O_2KCo$. C, 26.91; H, 4.52; N, 26.90%.

Other complexes used in this work were the lots prepared in our previous work.[5]

Measurements. Proton magnetic resonance spectra of $K[Co(CN)_4(l\text{-pn})]$, $[Pt(l\text{-pn})_2]Cl_2$ and $[Pd(l\text{-pn})_2]Cl_2$ were recorded with Varian A-60, T-60 and HA-100 spectrometers. The spectra of $K[Co(CN)_4(l\text{-pn})]$ and $[Pt(l\text{-pn})_2]Cl_2$ were obtained in deuterated water and in a mixture of pyridine and deuterated water. The spectra of $[Pd(l\text{-pn})_2]Cl_2$ were measured in deuterated water. Sodium trimethylsilylpropanesulfonate (Na-TMS) was used as an internal reference. In all the solvents, hydrogen atoms of the amino groups were deuterated rapidly and only the C–H resonance was observed. Diamagnetic contributions of the complex and the solvent on the chemical shifts have not been corrected. To facilitate the analysis of spectra, nuclear magnetic double resonance technique was used; *i.e.* the methyl signal was decoupled to give a simpler ABC pattern with HA-100 spectrometer. All the measurements were made at about 39°C.

The coupling constants, the chemical shifts and the intensities were calculated with a HITAC 5020 electronic computer at the University of Tokyo. The Fortran program for Castellano and Waugh's[6] exact analysis was kindly supplied by Dr. J. Cavanaugh at Research Department, Socony Mobil Oil Company, Inc., Paulsboro, New Jersey, U.S.A. to whom our sincere thanks are due.

Results and Discussion

The spectra of $K[Co(CN)_4(l\text{-pn})]$ in deuterated water are shown in Fig. 1. Whenever amino group hydrogens are deuterated, propylenediamine $ND_2CH(CH_3)CH_2ND_2$ should give an $ABCX_3$ pattern. One sharp doublet and one triplet were observed at about 1.25 and 2.38 ppm, respectively. That the splitting (J=6.0 cps for the doublet and 12.3 cps for the triplet) is not affected by the outer magnetic field strength indicates that these splittings are brought about by the spin-spin coupling. The doublet is safely assigned to the methyl signal, and its integrated intensity is three times as large as that of the triplet. In the lower field, complicated signals appear in the region from 2.80 to

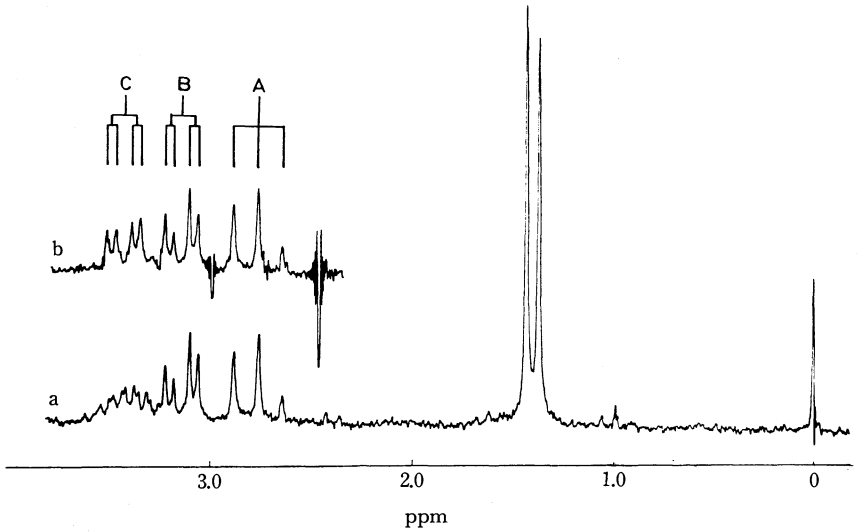

Fig. 2. 100 MHz PMR spectrum of K[Co(CN)$_4$(*l*-pn)] in pyridine-D_2O mixed solvent (a) and the double resonance spectrum irradiated on the methyl signal (b).

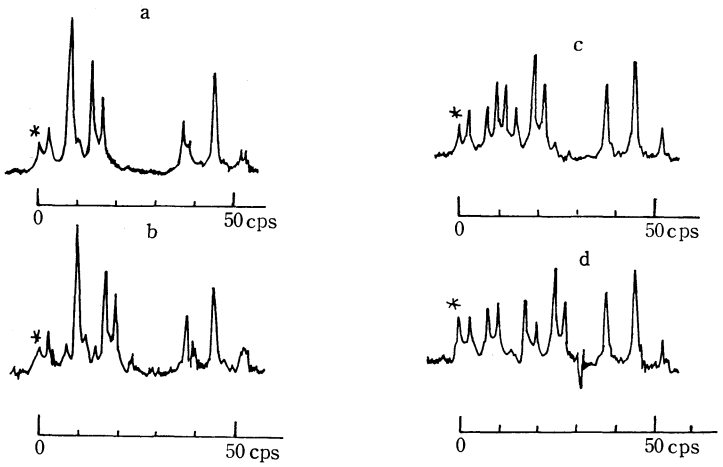

Fig. 3. The methine and methylene part of 100 MHz PMR double resonance spectra irradiated on the methyl signal of K[Co(CN)$_4$(*l*-pn)] in pyridine-D_2O mixed solvents (Chemical shifts from * peak). Approximate ratios (by volume) of pyridine to water are as follows; (a) 0, (b) 0.231, (c) 0.455 and (d) 0.600

3.20 ppm. The integrated intensity ratio of these signals to that of the doublet is two thirds. Although the signal of methine proton appears usually at a lower field than those of methylene protons, the spectra are too complicated to be analyzed further. Thus we used the nuclear magnetic double resonance technique. Irradiation at 1.25 ppm (the region of the methyl signal) made the signals from 2.80 to 3.20 ppm region less complicated, as shown in Fig. 1-b. Conversely, irradiation at the lower region of the complicated signals (3.10 ppm) converted the methyl doublet into a single sharp peak. This indicates that the signals at the lower region of the complicated part correspond to the methine proton. The double resonance spectrum obtained on irradiation at the methyl region should consist of ABC or ABB′ pattern, which gives rise to fifteen lines including three combination bands. However, the signals arising from methylene and methine group overlap with each other to make the analysis of spectrum still difficult.

The PMR spectra of K[Co(CN)$_4$(*l*-pn)] in pyridine-D_2O mixed solvents irradiated in the methyl signal region are shown in Fig. 2. With increase in the amount of pyridine, the whole signal shift to a lower field and the complicated part splits into two quartets as shown in Fig. 3. The higher field quartet is shifted to a lower field to a

less extent as compared with the other quartet. The extent of splitting of these groups of signals remains unchanged with the change in molar ratio of pyridine to water. Since coupling constants are not affected by changing solvents, these quartets were considered to be brought about by the spin-spin coupling. We denote tentatively the triplet, the higher quartet and the lower quartet A, B and C, respectively. Their integrated intensities are equal.

All the experiments described above lead to the assignment that A and B are due to protons of CH_2 group and C to that of CH group (Fig. 2). On the basis of these eleven lines of the spectra in aqueous pyridine solutions, we have calculated the coupling constants, the chemical shifts and the intensities, according to Castellano and Waugh's exact analysis[6] (Tables 1 and 2).

Two possible conformers can exist when *l*-propylenediamine coordinates to a metal, *λ-gauche* and *δ-gauche* form with the methyl group equatorial and axial to the chelate ring, respectively (Fig. 4). The *λ-gauche* form can provide three kinds of coupling: a *geminal*, a *trans* and a *gauche*. On the other hand, the *δ-gauche* form gives two different kinds of coupling: one *geminal* and two *gauche*. Karplus,[7] Lemieux and Lown,[8] and Abraham and Mclauchlan[9] calculated theoretical values of vicinal coupling

	Experimental	Theoretical	
J_{trans} (CA)	12.4	11.0	16.1
J_{gauche} (BC)	4.4	2.0	4.0
J_{gem} (AB)	−12.4	13.2	13.4

constants, which are dependent on the dihedral angle between two vicinal CH bonds. Barfield and Grant[10] calculated the *geminal* coupling constants for methane derivatives on the basis of the valence bond approach. These values are shown in Table 3.

The coupling constant J_{AB}(−12.4 cps) is undoubtedly for *geminal*, because A and B are the signals of methylene protons. The constants J_{BC} and J_{AC} are, therefore, of vicinal coupling. Of these, J_{BC} (4.4 cps) is in good agreement with the theoretical value of the *gauche* coupling constant.

TABLE 4. CALCULATED CHEMICAL SHIFTS AND SPIN-SPIN COUPLING CONSTANTS (in cycle/sec) OF $[Pd(l\text{-pn})_2]Cl_2$ IN DEUTERATED WATER AND $[Pt(l\text{-pn})_2]Cl_2$ IN PYRIDINE-DEUTERATED WATER

	Chemical shifts			Coupling constants		
	C	B	A	AB	BC	CA
$[Pd(l\text{-pn})_2]Cl_2$	−33.3	4.3	29.0	−12.5	4.2	9.9
$[Pt(l\text{-pn})_2]Cl_2$	−30.2	−0.3	30.5	−12.3	4.3	10.0

The constant J_{AC} is 12.4 cps and agrees well also with the theoretical *trans* coupling constant. These results indicate that the *l*-propylenediamine chelate ring has a *λ-gauche* form, and that A and B are due to the axial and the equatorial proton, respectively. The coupling constants J_{AC} and J_{AB} must have accidentally coincided with each other.

The large difference of the chemical shifts between the methylene protons may also support fixed *λ-gauche* form of the *l*-propylenediamine chelate ring. On the basis of the above assignment the axial proton gives a signal at a higher field than the equatorial proton does. This is consistent with the observation for substituted cyclohexanes.[11]

The PMR spectra of $[Pt(l\text{-pn})_2]Cl_2$ in deuterated water and in a mixture of pyridine and deuterated water, and $[Pd(l\text{-pn})_2]Cl_2$ in deuterated water are shown in Figs. 5, 6 and 7. These spectra are not significantly different from that of $K[Co(CN)_4(l\text{-pn})]$, except that the difference of the chemical shift between B and C protons is large enough to be distinguished without use of the solvent effect. In these cases twelve lines are observed and all the coupling constants J_{AB}, and J_{BC} and J_{AC} have different values as shown in Table 4. On these results, we conclude that the *l*-propylenediamine chelate rings in these complexes have also fixed *λ-gauche* form under the given conditions.

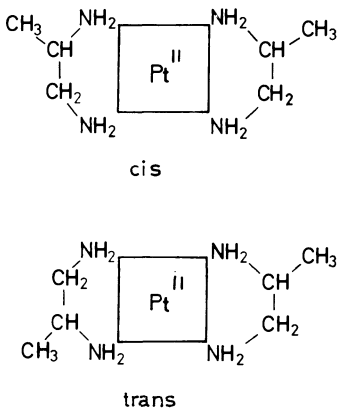

Fig. 8. Two geometrical isomers for square planar $[Pt(l\text{-pn})_2]^{2+}$ ion.

Two geometrical isomers are possible for bis-*l*-propylenediamine complex of a planar type shown in Fig. 8. The chemical environment for protons should be different between these two isomers. Such a difference, however, would be too small[1] to be detected by the present spectrometer.

In Table 2 are listed the values of observed and calculated intensities. They seem to agree with each other satisfactorily, to support our assignments.

The authors thank the Ministry of Education for Grant in aid.

Tautomerism in 3-Substituted-2,4-pentanediones and Their Copper Chelates

Minoru TANAKA, Toshiyuki SHONO and Koichiro SHINRA

Department of Chemical Technology, Faculty of Engineering, Osaka University, Yamadakami, Suita

(Received may 29, 1969)

Seventeen 3-substituted-2,4-pentanediones were synthesized. The effect of substituents in the position 3 on the tautomeric equilibria, *i. e.*, keto-, *cis*-enol- and *trans*-enol-forms, has been investigated by nuclear magnetic resonance spectroscopy. It has been found that the percentage of each tautomer depends upon the electronic and steric effects of the substituents. The relative intensity of intramolecular hydrogen bonds in these compounds was evaluated from both the NMR and IR data. It has been found from the half-wave potential data of polarographic reduction and the Cu–O stretching frequencies of 16 copper chelates of 3-substituted-2,4-pentanediones that the relative stability of the chelate decreases with an increase in the electron-withdrawing effect of the substituents.

In recent years, NMR spectroscopy has been frequently used for the study of β-dicarbonyls, especially for keto-enol tautomerism and hydrogen bonding. Burdett and Rogers examined the NMR spectra of β-diketones and β-keto esters, determined their equilibrium constants[1] and discussed the solvent effect[2] on the chemical shifts and on the tautomeric equilibrium. Lowe and Ferugson[3] studied the direction and the percentage of the enolization of several substituted benzoylacetones by infrared, ultraviolet, and NMR spectroscopy and found that the benzoylacetones were enolized toward the carbonyl close to the phenyl group. Lintvedt and Holtzclaw studied the position of the methylene proton and enolic proton resonance peaks of several substituted 1,3-diketones with respect to the electronic effects[4] of the groups substituted in the position 1 or 3 and the correlation between the position of this enolic proton resonance peak and the thermodynamic formation constants[5] of the 1,3-diketone metal chelates. They reported that, with a greater electron-releasing effect of the substituents, the hydrogen bond became stronger as the electron density on the oxygen increased. The enolic proton resonance peak was shifted toward a lower field, and the stability of the chelates was increased.

In a previous paper the tautomeric equilibria of six 3-alkylated-2,4-pentanediones[6] were reported; they had been studied using NMR spectroscopy. In this paper seventeen 3-substituted-2,4-pentanediones will be investigated in order to establish the substituent effect on the tautomerism and on the intramolecular hydrogen bond. The relative stability of these sixteen copper chelates was, further, checked by infrared spectroscopy and by polarography.

Experimental

Preparation of 3-Substituted-2,4-pentanediones and Copper Chelates. The 3-substituted-2,4-pentanediones were prepared by the established methods, references for which are listed in Table 1. The copper chelates were prepared by adding an ethanol solution of 3-substituted-2,4-pentanedione to an excess aqueous solution of cupric acetate, except in the case of bis[3-nitro-2,4-pentanediono]copper. The analytical data are shown in Table 2.

NMR Spectroscopy. The NMR spectra were obtained on a JNM-3H-60 spectrometer at 60 Mcps. All the samples were run in carbon tetrachloride. The sample concentration was 2 mol/*l*. The chemical shift values are reported in cps from internal tetramethylsilane.

Polarography. The polarograms for copper chelates were recorded using a Yanagimoto Model P-8 polarograph. Each sample solution was 10^{-3} mol/*l* with respect to the chelate, 0.1 mol/*l* with respect to potassium nitrate as the supporting electrolyte, and 1.6 g/*l* with respect to Tween-80 as the maximum suppressor. The chelate, supporting electrolyte and maximum suppressol-

isopropyl and *s*-butyl groups have no *cis*-enol form. In the case of a methyl substituent, *cis*-enol and keto forms have been found. Substitution with *n*-propyl, *n*-butyl, and isobutyl groups showed *cis*- and *trans*-enol forms and the keto form. Substituents with an inductive effect different from alkyl groups as well as bulky substituents were introduced. Table 3 summarizes the chemical shift values of the enolic proton and the methine proton in the keto form, and the percentage of each tautomer obtained from the corresponding signal intensity. Table 3 shows that the substitution of carbethoxy, cyano, or benzoyl groups in the position 3 of 2,4-pentanedione results in a considerable increase in the *cis*-enol tautomer, while in the case of alkyl, acetoxy, and methoxy substituents, an increase of

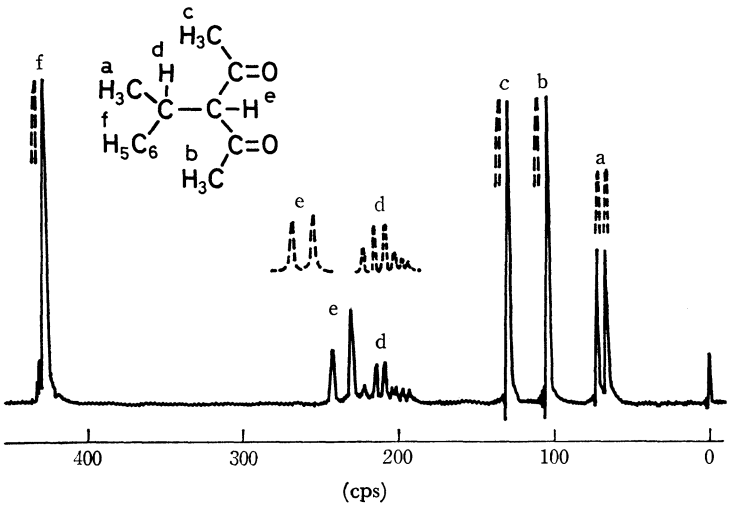

Fig. 1. NMR spectra for 3-(α-phenylethyl)-2,4-pentanedione in CCl_4 (solid line) and in *d*-DMSO (broken line).

the keto tautomer is found. Though many factors influence the keto-enol tautomeric equilibrium, the results in Table 3 can be qualitatively explained in terms of both the electronic and steric factors of the substituent. The electron density in the vicinity of the methine proton must be decreased by the substitution of electronegative groups in the position 3. The enol tautomer will, then, be more stabilized. Among keto-, *cis*-enol-, and *trans*-enol-forms, the steric hindrance between acetyl methyl groups and the 3-substituent is the largest in the *cis*-enol tautomer. The percentage of the *cis*-enol tautomer was found to decrease with an increase in the bulkiness of the substituent in the position 3. In the absence of steric hindrance, the *cis*-enol tautomer is more stabilized than the *trans*-enol tautomer by an intramolecular hydrogen bond.[1,10] The combination of the electronic and steric effects mentioned presumably influences the tautomeric equilibrium. In fact, substitution with electron-withdrawing groups, such as carbethoxy, cyano, and benzoyl groups, results in a considerable increase in the *cis*-enol tautomer. In the case of electron-releasing groups, such as alkyl, acetoxy, and methoxy, the keto tautomer increases reversely. It should be sterically impossible for 2,4-pentanediones substituted with isopropyl anb *s*-butyl groups to take the *cis*-enol form. The presence of only small amounts of the *trans*-enol form in the cases of *n*-propyl, *n*-butyl, and isobutyl substituents is presumably the result of steric hindrance, which is even larger in isopropyl and *s*-butyl groups (see Table 3). The α-phenylethyl group, which is bulkier than the isopropyl and *s*-butyl groups, was introduced in the position 3. The NMR spectrum of 3-(α-phenylethyl)-2,4-pentanedione is shown in Fig. 1. In the case of the carbon tetrachloride solution (see Fig. 1, solid line), three signals, corresponding to three protons, appear at 69 cps as a doublet, and at 104 cps and 130 cps as a singlet. Phenyl proton resonance occurs at 428 cps. The signals corresponding to the two methine protons appear in the 210—236 cps region. Using *d*-dimethyl sulfoxide as the solvent, these signals can be separated into two signals with the same intensity (*cf.* the broken line) *i.e.*, the multiplet centered at 210 cps and the doublet, at 263 cps. An examination of this spectrum leads to the conclusion that this compound has only the keto form, and no *cis*- and *trans*-enol forms, because of its great bulky substituent. The same results have been reported in the case of 3-(*t*-butyl)-2,4-pentanedione.[11]

Intramolecular Hydrogen Bond. As Table 3 shows, the *cis*-enol OH protons show considerable variations in chemical shift and all are at a very low applied magnetic field, indicating the presence of intramolecular hydrogen bonds in these compounds. With an increase in the strength of this hydrogen bond, the carbonyl stretching vibration is shifted to a lower frequency.[12,13] The *cis*-enol OH proton chemical shift values are plotted *vs.* the carbonyl stretching frequencies in Fig. 2. It is

found that, with an increase in the strength of the hydrogen bond, the *cis*-enol OH proton resonance signal is shifted toward a lower field.

Copper Chelates of 3-Substituted-2,4-pentanediones. The polarograms and infrared spectra of sixteen 3-substituted-2,4-pentanedione copper chelates were recorded in order to investigate their relative stability. Lintvedt *et al.*[14] reported that the reduction potential should be a function of the electronic density on and around the copper atom. The reduction potential becomes more negative as the chelate becomes more stable, because the stability of the chelate increases with an increase in the electron density near the copper ion. Much information concerning the nature of coordinate bonds and chelate rings has been obtained from the infrared spectroscopy of 2,4-pentanedione metal chelates.[15,16] Especially, the metal-oxygen stretching modes appearing in the 700—250 cm^{-1} region may directly provide information on the relative strength of coordinate bonds. Table 4 shows the half-wave potential data of the polarographic reduction, the copper-oxygen stretching frequencies, and the carbonyl stretching frequencies of copper chelates. A plot of the half-wave potentials *vs.* the copper-oxygen stretching frequencies (Fig. 3) shows that the chelate with a more negative half-wave potential tends to show a higher copper-oxygen stretching frequency. Namely, in the case of copper chelates reduced more easily when substituted with electron-withdrawing substituents, such as nitro, cyano, and benzoyl groups, coordinate bonds become weaker because the electron density near the copper atom decreases. The chelates with a higher frequency of the copper-oxygen stretching vibration also tend to show a lower carbonyl stretching frequency. The electronic effect of the substituent thus affects the electron density on the copper atom. This proves the delocalization of π-electrons in the chelate ring. Murakami *et al.*[17] have studied the delocalization of π-electrons for 2,4-pentanedione metal chelates substituted in the position 3 with phenyl and benzyl derivatives.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 3195—3198 (1969)

A New Monoclinic Phase of Cerium Orthovanadate ($CeVO_4$)

Masahiro YOSHIMURA and Toshiyuki SATA

Research Laboratory of Engineering Materials, Tokyo Institute of Technology, Ookayama, Meguro-Ku, Tokyo

(Received June 2, 1969)

A new monoclinic phase of cerium orthovanadate, $CeVO_4$(H), was found during the course of oxidation of pseudo-perovskite $CeVO_3$ below 400°C. It has been confirmed to crystallize in the huttonite-type structure (C_{2h}^5—$P2_1/n$), that of $LaVO_4$. The lattice parameters were determined to be:

$$a_0 = 6.98\text{Å},\ b_0 = 7.22\ \text{Å},\ c_0 = 6.76\ \text{Å},\ \beta = 105°02',\ V = 328\ \text{Å}^3 \text{ and } Z = 4.$$

This phase was metastable, and exothermally transformed into a known stable $CeVO_4$ (tetragonal zircon-type, D_{4h}^{19}-$I4_1/amd$) above 400°C, releasing a small amount of oxygen. From magnetic, chemical and thermogravimetric analyses, the valences of cerium ion and vanadium ion in $CeVO_4$-(H) seem to be tripositive and pentapositive respectively, but V^{4+} ion is mixed in zircon-type $CeVO_4$; $CeVO_4$(Z).

It has been reported[1-7] that all rare earth (except La) orthovanadates are isostructural with xenotime which has the tetragonal zircon-type structure (D_{4h}^{19}-$I4_1/amd$), while $LaVO_4$ is isostructural with monazite, the monoclinic huttonite-type structure (C_{2h}^5-$P2_1/n$). The polymorphism of $LnMO_4$ (Ln= lanthanide, M=P, As, V, Nb, Ta, *etc.*) was studied in view of crystallographic interest. Stubican and Roy[3] investigated the phase transition of rare earth vanadates and arsenates under high pressure, but gave no description on the polymorphism of $CeVO_4$.

Several researchers[5-7] reported that zircon-type $CeVO_4$, represented as $CeVO_4$(Z), was prepared by the reaction between Ce^{3+} salts or oxide and V_2O_5 in an inert atmosphere taking the instability of Ce^{3+} into consideration. However, this consideration seems unnecessary.

During the course of study on the valence states of ions in cerium vanadium double-oxides, a new monoclinic huttonite-type phase of $CeVO_4$, represented as $CeVO_4$(H), was found as a metastable phase. In this paper, the formation of $CeVO_4$(H) and its characteristic properties are presented in relation to those of $CeVO_4$(Z).

Experimental

Materials are ceria for optical use (CeO_2 contents 99.99%) and a guaranteed grade NH_4VO_3 or V_2O_5 which was obtained by decomposition of NH_4VO_3 at 500°C for 12 hr in air. The reaction processes were traced by the ordinary TGA and DTA methods programmed 5°C/min under various atmospheres. The reaction products were identified by means of powder X-ray diffraction ($CuK\alpha_1$=1.5405 Å).

Samples for X-ray powder diffraction were obtained as follows: $CeVO_4$(H), prepared by oxidation of $CeVO_3$ at 370°C for 8 hr in air. $LaVO_4$ and $CeVO_4$(Z) prepared by heating equimolar mixtures of V_2O_5 and La_2O_3 or CeO_2 at 800°C for 4 hr.

Their magnetic susceptibilities were measured with a torsion-type magnetobalance (Shimadzu MB-II) at temperatures between 77 and 1000°K.

Results and Discussion

Contrary to expectation, the formation of $CeVO_4$ from component salts is represented by the equation,[8]

$$CeO_2 + \tfrac{1}{2}V_2O_5 \longrightarrow CeVO_4 + \tfrac{1}{4}O_2, \qquad (1)$$

because CeO_2, instead of Ce_2O_3, is obtained by the thermal decomposition of Ce(III) salts under usual conditions.[9] This reaction is different from those of the formation of other lanthanide orthovanadates:

$$\frac{1}{2}Ln_2O_3 + \frac{1}{2}V_2O_5 \longrightarrow LnVO_4. \quad (2)$$

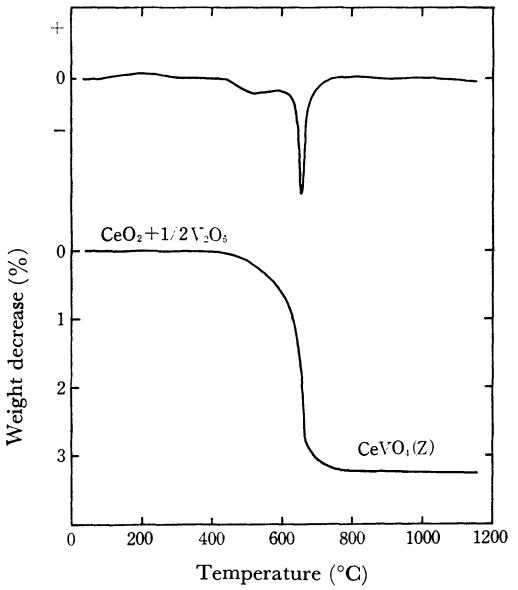

Fig. 1. DTA and TGA curves for the reaction (1).

TGA and DTA curves for the reaction (1) in air are shown in Fig. 1. The same results were also obtained in argon atmosphere. As shown in Fig. 1, the reaction starts above 400°C releasing oxygen, and is completed at about 800°C. The sharp endothermic peak at 655°C near the eutectic temperature[10] of V_2O_5 and YVO_4 suggests that the reaction is accelerated by the formation of liquid phase. The reaction product was dark purplish brown and identified to be the tetragonal zircon-type $CeVO_4$ by means of X-ray analysis. The lattice parameters were calculated to be $a_0=$ 7.400 Å and $c_0=6.497$ Å. The observed weight decrease (3.230%) was larger than the calculated value (3.041%) according to raection (1). This indicates that the real composition of $CeVO_4$(Z) is not stoichiometric $CeVO_{4.000}$ but $CeVO_{3.968}$. A further discussion on $CeVO_4$(Z) will be presented in a next paper.[11]

$CeVO_4$ was also obtained by the oxidation of $CeVO_3$ which has a pseudo-perovskite structure.[12] This reaction is given by the following equation:

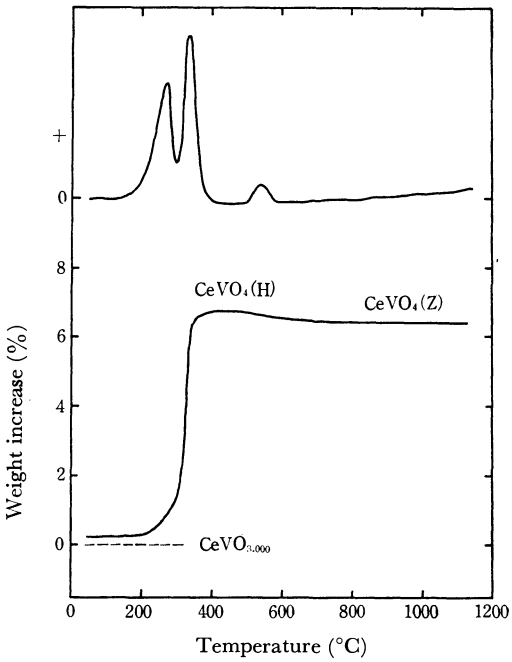

Fig. 2. DTA and TGA curves for the reaction (3). Starting compound, $CeVO_{3.030}$, was prepared by the reaction that equimolar mixture of component oxides was heated at 1200°C for 10 hr in hydrogen atmosphere.

$$CeVO_3 + \frac{1}{2}O_2 \longrightarrow CeVO_4. \quad (3)$$

The TGA and DTA results of this reaction are given in Fig. 2. Two exothermic peaks at 280°C and 330°C seems to be caused by the oxidation of $CeVO_3$. However, no intermediate compound such as $Ce_2V_2O_7$ was found. The same behavior was observed in the case of the oxidation of perovskite $LaVO_3$ into $LaVO_4$. Thus it is reasonable that the valency of cerium ion remained trivalent and only that of vanadium ion changed from trivalent to pentavalent during the course of this reaction. When the oxidation of $CeVO_3$ took place below 400°C, $CeVO_4$(H) was obtained. It was brownish yellow and identified to be isostructural with $LaVO_4$, huttonite-type (C_{2h}^5-$P2_1/n$). X-Ray powder data of $CeVO_4$(H) are given in Table 1 in comparison with $LaVO_4$. The difference in the cell volume corresponds to that in ionic radii; $Ce^{3+}=1.07$ Å, $La^{3+}=1.14$ Å.

The transition of $CeVO_4$(H) to $CeVO_4$(Z) was exothermic, gradually releasing oxygen gas, as shown in Fig. 3. This gives rise to the increase of lattice symmetry and cell volume. The third peak at about 540°C in Fig. 2 corresponds to this transition.

Magnetic studies on $CeVO_4$ (Fig. 4) demonstrate

that both $CeVO_4$(H) and $CeVO_4$(Z) showed paramagnetic behavior following the Curie-Weiss law, $\chi=C/(T+\theta)$, above 100°K, where χ is molar magnetic susceptibility, C, the Curie constant, T, the absolute temperature, and θ, the Weiss constant. The correction of diamagnetism was made using the value given by Selwood.[13]

Some results of magnetic and chemical analyses for $CeVO_4$(H) and $CeVO_4$(Z) are summerized in Table 2. The effective magnetic moment, 2.51 μ_B for $CeVO_4$(H), indicates that the valence states are almost tripositive for cerium ion and pentapositive for vanadium ion respectively, since this value is fairly smaller than the theoretical value of 2.54 μ_B for free Ce^{3+} ion. On the contrary, the value of 2.58 μ_B would indicate that a small quantity of V^{4+} coexists with V^{5+} in $CeVO_4$(Z) and the magnetic moment obtained is caused by both Ce^{3+} and V^{4+}. TGA, chemical analysis and color support the results.

$CeVO_4$(H) could not be detected during the course of the reaction (1). It was observed that $CeVO_4$(H) transformed into $CeVO_4$(Z) after being kept at 400°C for 20 hr or at 450°C for 8 hr. The reverse transition, $CeVO_4$(Z)→$CeVO_4$(H), could not be observed. Even treatments under high-pressure oxygen (P_{O_2}=500—1000 atm, temperature 350—500°C, 2—40 hr) gave no change on $CeVO_4$(Z). From these results, it seems that $CeVO_4$(H) is a metastable phase and $CeVO_4$(Z) a stable phase.

The authors wish to thank Mr. Y. Shibazaki, Professor M. Koizumi and Assistant Professor S. Kume of the Osaka University, Osaka, for experiments and comments on the high-pressure oxygen treatments.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 3198—3203 (1969)

Chemical and Spectral Study of 6- and 7-Nitro-2-Methyl, 2-Benzyl, 2-Styryl and 2-(1-Phenylstyryl)-3*H*-4-Ketoquinazolines and Their 3-Me and 3-Ph Derivatives

R. K. THAKKAR and S. R. PATEL

Department of Chemistry, Sardar Patel University, Vallabh Vidyanagar, Gujarat State, India

(Received September 5, 1968)

6- and 7-Nitro-2-benzyl-3*H*-4-ketoquinazolines and their 3-Me and 3-Ph derivatives were prepared by condensing the 6-nitro (III) and 7-nitro (XII) derivatives of -4*H*-3,1-benzoxazin-4-one with ammonia, methylamine and aniline, respectively. The compounds III and XII were formed on refluxing 5- and 4-nitro-*N*-phenylacetylanthranilic acids with acetic anhydride. 6- and 7-Nitro-2-benzyl-3*H*-4-ketoquinazolines (IV and XIII) were also prepared by condensing 5- and 4-nitro-*N*-phenylacetylanthranilic acids with formamide, respectively, in very low yields. The compounds IV and XIII yielded the corresponding 2-benzoyl derivatives on oxidation and the corresponding 2-(1-phenylstyryl) derivatives on reaction with benzaldehyde. 6- and 7-Nitro-2-styryl and 2-(1-phenylstyryl)-3*H*-4-ketoquinazolines were not oxidized by alkaline permanganate. UV spectra of these compounds have been studied.

Quinazoline has proved to be a very stable ring-system. Unlike quinoline and isoquinoline, a quinazoline does not undergo a ring-cleavage when subjected to an oxidation reaction which normally brings about such a cleavage. Simple quinazoline yields 4-ketoquinazoline on oxidation.[1] 2-Methyl-3-phenyl-3,4-dihydroquinazoline affords 2-methyl-3-phenyl-4-ketoquinazoline on oxidation with alkaline permanganate.[2] 2-Methyl-3*H*-4-keto-quinazoline remains unchanged on treatment with this reagent.[1]

Patel and coworkers have reported that 2-benzyl and 2-(1-phenylstyryl)-3*H*-4-ketoquinazolines on oxidation yield 2-benzoyl-3*H*-4-ketoquinazoline, but 2-styryl-3*H*-4-ketoquinazoline remains uneffected.[3] 2-(1-Phenylstyryl)-3*H*-4-ketoquinazoline was formed on condensing 2-benzyl-3*H*-4-ketoquinazoline with benzaldehyde.[4] In continuation of this, the syntheses and the study of the oxidation reactions of various 6- and 7-nitro-2-R-3*H*-4-ketoquinazoline derivatives were undertaken. UV spectra of these compounds have been studied with a view to studying the spectra-structure correlation. Because of the interesting aspect of the tautomeric behaviour of 6- and 7-nitro-3*H*-4-ketoquinazolines, their

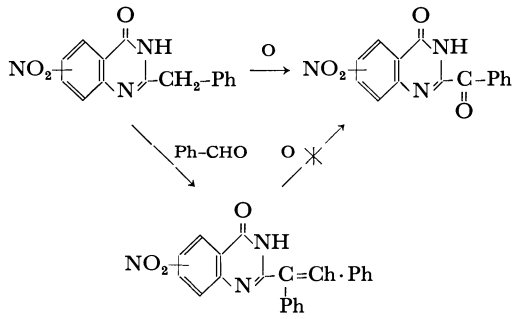
spectra were compared with those of the corresponding 3-methyl and 3-phenyl derivatives which have fixed amide-structures. With this aim in view, the 3-methyl and 3-phenyl derivatives of 6- and 7-nitro 2-benzyl-3*H*-4-ketoquinazolines were also prepared.

5-Nitro-*N*-phenylacetylanthranilic acid (II) was formed on reaction of 5-nitroanthranilic acid (I) with phenylacetyl chloride. 6-Nitro-2-benzyl-4*H*-3,1-benzoxazin-4-one (III), synthesized by refluxing II with acetic anhydride, afforded 6-nitro-2-benzyl-3*H*-4-ketoquinazoline (IV) on reaction with liquid ammonia at 100°C. The compound IV was also synthesized in about 15% yield by condensing II with formamide following the modified Niementowski 4-ketoquinazoline synthesis.[5] Patel has reported that condensation of 5-nitro-*N*-acetylanthranilic acid with formamide yields a mixture of 6-nitro-3*H*-4-ketoquinazoline and its 2-methyl derivative, while its condensation with acetamide affords pure 6-nitro-2-methyl-3*H*-4-ketoquinazoline.[6] The condensation of 6-nitro-2-benzyl-4*H*-3,1-benzoxazin-4-one III with methylamine and with aniline at 100°C afforded 6-nitro-2-benzyl-3-methyl and 3-phenyl-4-ketoquinazolines (V and VI) respectively.

6-Nitro-2-methyl-3*H*-4-ketoquinazoline was not oxidized on treatment with alkaline permanganate at 100°C. 6-Nitro-2-benzyl-3*H*-4-ketoquinazoline (IV) on oxidation with alkaline potassium permanganate at 100°C afforded 6-nitro-2-benzoyl-3*H*-4-ketoquinazoline (VII) in very low yield.



Chart

Most of the original compound (IV) was recovered unchanged. The same product (VII) was also formed in good yield when the oxidation of IV was carried out with selenium dioxide in isoamyl alcohol. The oxidation reaction of IV leading to the formation of a ketone is a characteristic property of a benzylic methylene group. Selenium dioxide has been reported to be a specific oxidizing agent for an alkyl group attached to an *ortho* or a *para* position to ring-nitrogen of a heterocyclic system.[7] 6-Nitro-2-methyl-3*H*-4-ketoquinazoline (VIII) on reaction with benzaldehyde afforded the corresponding 2-styryl derivative (IX). Compound IV likewise afforded 6-nitro-2-(1-phenylstyryl)-3*H*-4-ketoquinazoline (X) on reaction with benzaldehyde. Both 2-styryl (IX) and 2-(1-phenylstyryl) (X) derivatives did not undergo oxidation reaction when treated with alkaline permanganate solution at 100°C even on prolonged heating with excess of the reagent. As indicated previously, 2-(1-phenylstyryl)-3*H*-4-ketoquinazoline is reported to be oxidized to the corresponding 2-benzoyl derivative on treatment with permanganate in acetone solution in cold.

7-Nitro-2-benzyl-4*H*-3,1-benzoxazin-4-one (XII), formed on treating 4-nitro-*N*-phenylacetylanthranilic acid (XI) with boiling acetic anhydride, afforded 7-nitro-2-benzyl-3*H*-4-ketoquinazoline (XIII) and their 3-methyl (XVIII) and 3-phenyl (XIX) derivatives on reaction with ammonia, methylamine and aniline solutions, respectively. The compound (XIII) was also formed on condensing 4-nitro-*N*-phenyl acetylanthranilic acid (XI) with formamide in about 23% yield. Compound XIII was oxidized by heating it with a large excess of alkaline permanganate solution at 100°C for twenty four hours to 7-nitro-2-benzoyl-3*H*-4-ketoquinazoline (XIV) in very poor yield. Most of compound XIII was recovered from precipitated manganese dioxide on extracting it with boiling acetone. Compound XIV was formed in very good yield on oxidation of XIII with selenium dioxide in isoamyl alcohol solution. 7-Nitro-2-methyl-3*H*-4-ketoquinazoline (XV) and its 2-benzyl analog (XIII) on reaction with benzaldehyde afforded 7-nitro-2-styryl-3*H*-4-ketoquinazoline (XVI), and 7-nitro-2-(1-phenylstyryl)-3*H*-4-ketoquinazoline (XVII). Both these 2-styryl (XVI) and 2-(1-phenylstyryl) (XVII) derivatives were not oxidized on treatment with alkaline permanganate solution at 100°C. Even 7-nitro-2-methyl-3*H*-4-ketoquinazoline was not oxidized by the same reagent.

These results suggest that owing to the presence of the nitro group, the permanganate oxidation reaction of nitro-substituted 2-benzyl-3*H*-4-ketoquinazolines becomes difficult and that of the correspondingly substituted 2-(1-phenylstyryl)-3*H*-4-ketoquinazoline is completely prevented. The fact that the presence of a nitro group makes oxidation reaction of so-substituted compound difficult is well known.[8]

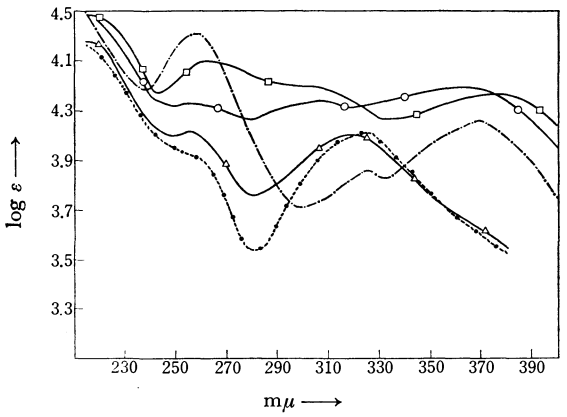

Fig. 1

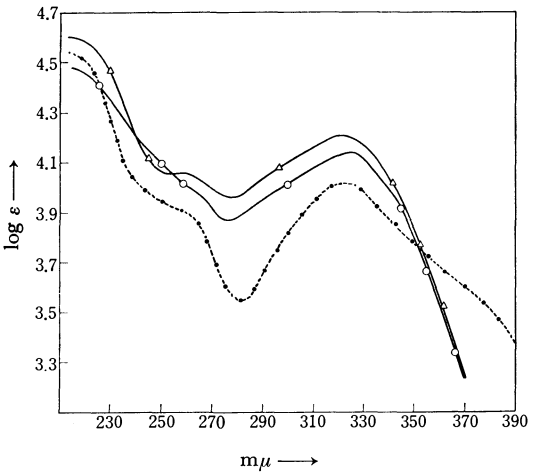

Fig. 2

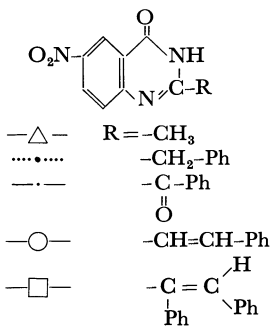

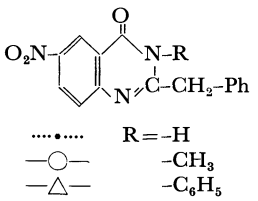

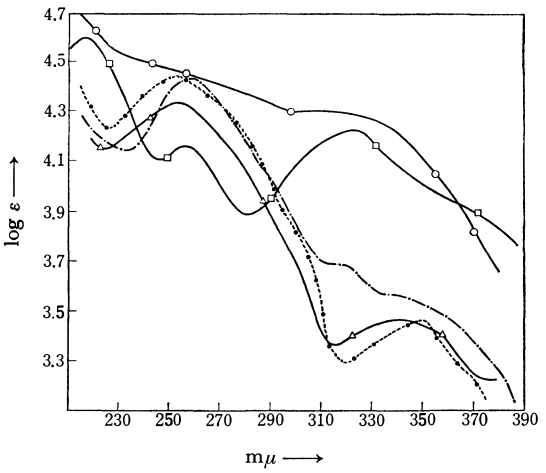

Fig. 3

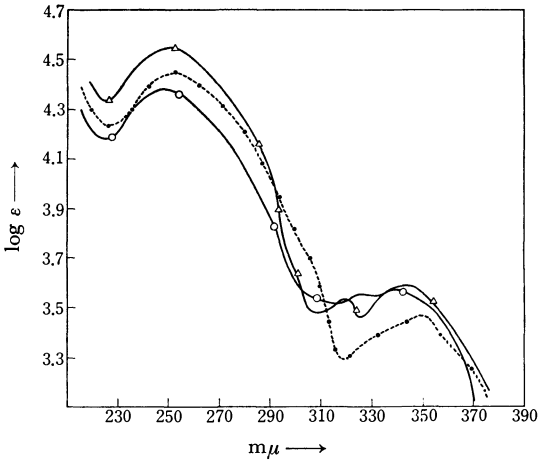

Fig. 4

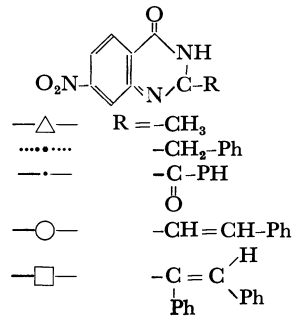

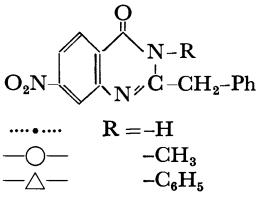

The ultraviolet spectra of the compounds described in this communication have been studied on Beckmann DU Spectrophotometer in ethanol solution. The sepctral data have been reported in Table 1 and the spectral curves have been shown in Figs. 1—4. 2-Alkyl-3*H*-4-ketoquinazoline normally exhibits a three band spectrum characteristic of a bicyclic aromatic hydrocarbon with the only difference that the long wavelength band does not show a much finer structure.[9] The spectra of all the 2,3-disubstituted 6- and 7-nitro-4-ketoquinazolines described in the present communication comprise only two bands. They have been designated as β and *para* bands.[10] The disappearance of the long wave length α band in the spectrum of the nitrosubstituted 2-alkyl-3*H*-4-ketoquinazoline seems most probably due to the presnece of the nitro group which is known to be a very strong chromophore.

The β and *para* bands in the spectrum of 6-nitro-2-methyl-3*H*-4-ketoquinazoline appear at 255 mμ (log ε=4.02) and 320 mμ (log ε=4.01) (Fig. 1). The corresponding bands appear at relatively longer wavelengths ($\Delta\lambda\approx+5$ mμ) in the spectrum of 6-nitro-2-benzyl-3*H*-4-ketoquinazoline (IV). In the spcctrum of 6-nitro-2-benzoyl-3*H*-4-ketoquinazoline (VII) the β band is much more intense (log ε=4.41) and the *para* band appears at a much longer wavelength, 370 mμ (log ε=4.06), than the corresponding bands in the spectrum of its parent compound, 6-nitro-2-benzyl-3*H*-4-ketoquinazoline (IV). This seems to be due to the -C-Ph group acting as a strong chromophore.
O

Attachment of a styryl group in 2-position increases the length of the conjugated system. This is reflected in the spectrum of 6-nitro-2-styryl-3*H*-4-ketoquinazoline (IX) which exhibits a strong absorption over the whole of the spectrum range with the value of log ε ranging around the value of 4.0. In the spectrum of 6-nitro-2(1-phenylstyryl)-3*H*-4-ketoquinazoline (X) the short wavelength β band is slightly stronger probably owing to an extra phenyl group while the long wavelength *para* band is somewhat weaker than the corresponding band in the spectrum of its 2-styryl compound (IX). Similar differences in the spectral trends have been observed in the spectra of stilbene and α-phenylstibene by Suzuki.[11] According to this author, the difference in the spectral trend is due to the fact that all the three phenyl groups in α-phenylstilbene are not accomodated in a strain-free planar configuration around the ethylenic bond, but have

9) J. B. Koepfli, J. F. Mead and J. A. Brockman, *J. Am. Chem. Soc.*, **71**, 1048 (1949).

11) H. Suzuki, This Bulletin, **33**, 389 (1960).

been possibly tilted slightly away from the main plane. By analogy 6-nitro-2-(1-phenylstyryl)-3*H*-4-ketoquinazoline (X) may be supposed to have a similar configuration for the quinazolone moiety and the two phenyl groups around the styryl double bond. Had only the α-phenyl group been tilted away from the main plane and the other two groups left remaining in the same plane, the spectra of 2-(1-phenylstyryl) and 2-styryl compounds would have probably been almost exactly the same in the long wavelength part of their spectra. The spectra of 6-nitro-2-benzyl-3*H*-4-ketoquinazoline (IV), and its 3-methyl and 3-phenyl derivatives (V and VI) exhibit mainly the same trends (Fig. 2). The β and *para* bands in the spectra of both the 3-methyl and 3-phenyl compounds (V and VI) appear respectively at almost the same positions as, but more intense than, the corresponding bands in the spectrum of their parent 3*H* compound (IV). The spectral similarity is an indication of the fact that compound IV exists mostly in the amide-form like its 3-methyl and 3-phenyl derivatives (V and VI) which have fixed keto-structures.

The ultraviolet spectra of 7-nitro-2-methyl-3*H*-4-ketoquinazoline (XV) and its 2-benzylanalog (XIII) comprise only two bands (Fig. 3). The β band appears near about 255 mμ but is more intense in the spectrum of XIII than that in the spectrum of XV; the *para* band appears round about 350 mμ in the spectra of both these compounds. The spectrum of the 7-nitro-2-benzoyl compound (XIV) also comprises two bands; its long wavelength *para* band is almost featureless and is more intense than the corresponding band in the spectrum of XIII in the region beyond 310 mμ as expected, owing to the presence of the 2-benzoyl group acting as a stronger chromophore. The UV spectrum of 7-nitro-2-styryl 3*H*-4-ketoquinazoline (XVI) exhibits a strong absorption over a range from 210 to 323 mμ with log ε value decreasing slowly from 4.7 to 4.2; the only feature in the spectrum of XVI seems to be a broad shoulder near about 323 mμ, beyond which the intensity of absorption decreases comparatively more rapidly. The broadening, the increased intensity and the disappearance of the fine structure of the constituent bands are the usual effects of increased conjugation which in this case is due to the presence of styryl group in 2-position. The spectrum of 7-nitro-2(1-phenylstyryl)-3*H*-4-ketoquinazoline (XVII) exhibits an arm at 261 mμ (log ε=4.59) and a peak at 256 mμ (log ε=4.16) and a broad band at 256 mμ (log ε=4.16) and a broad band at about 323 mμ (log ε=4.23). However the intensity of all the bands in the spectrum of the 7-nitro-2-(1-phenylstyryl) compound (XVII) is less than that of the corresponding bands in the spectrum of its parent compound (XVI) almost over the whole spectral range. It seems to be due to the steric effect exerted by the α-phenyl group which would not allow all the three groups to remain in a strain-free planar configuration. The spectra of 7-nitro-2-benzyl-3-methyl and phenyl (XVIII and XIX) derivatives are very closely similar to that of their parent compound (XIII) (Fig. 4), indicating that XIII exists mostly in the keto-form.

Experimental

5-Nitro-*N*-phenylacetylanthranilic Acid (II). The compound was prepared by heating 5-nitroanthranilic acid (2.58 g) with phenylacetyl chloride (4.2 g) in dry benzene (20 m*l*) containing a drop of pyridine for two hours. Excess of benzene was removed by steam distillation and the residual solid product was collected, washed with hot water and crystallized from a mixture of chloroform and benzene (2 : 1) in white long needles, mp 187—189°C. Yield: 2.5 g.

Found: N, 9.40%. Calcd for $C_{15}H_{12}O_5N_2$: N, 9.33%.

4-Nitro-*N*-phenylacetylanthranilic Acid (XI). The compound was prepared as described above from 4-nitroanthranilic acid and crystallized from aqueous ethanol in white needles, mp 206—208°C.

Found: N, 9.28%. Calcd for $C_{15}H_{12}O_5N_2$: N, 9.33%.

6-Nitro-2-benzyl-4*H*-3,1-benzoxazin-4-one (III). A mixture of 5-nitro-*N*-phenylacetylanthranilic acid (0.660 g) and acetic anhydride (1.5 m*l*) was refluxed for forty five minutes. The solution was clarifide with activated charcoal, filtered hot and cooled to room temperature to give yellowish crystalline solid. It was filtered and washed with dry petroleum ether, mp 177—179°C. Yield: 0.550 g.

Found: N, 9.85%. Calcd for $C_{15}H_{10}O_4N_2$: N, 9.92%.

7-Nitro-2-benzyl-4*H*-3,1-benzoxazin-4-one (XII). The compound was synthesised from 4-nitrophenylacetylanthranilic acid (0.5 g) and acetic anhydride as described above in the form of yellowish white needles, mp 125—126°C. Yield: 0.390 g.

Found: N, 9.82%. Calcd for $C_{15}H_{10}O_4N_2$: N, 9.92%.

6-Nitro-2-benzyl-3*H*-4-ketoquinazoline (IV). 6-Nitro-2-benzyl-4*H*-3,1-benzoxazin-4-one (0.550 g) was suspended in liquid ammonia and heated for three hours at 100°C. The reaction mixture was acidified and the solid product was stirred in dilute bicarbonate solution. The residual solid was then filtered, washed and crystallized from glacial acetic acid (carbon) in pale yellow crystalline solid, mp 258—260°C. Yield: 0.405 g.

Found: N, 15.02%. Calcd for $C_{15}H_{11}O_3N_3$: N, 14.95%.

7-Nitro-2-benzyl-3*H*-4-ketoquinazoline (XIII). The compound was prepared as described above from 7-nitro-2-benzyl-4*H*-3,1-benzoxazin-4-one (0.380 g). It was crystallized from ethanol (carbon) in white cottony needles, mp 262—264°C. Yield: 0.315 g.

Found: N, 14.85%. Calcd for $C_{15}H_{11}O_3N_3$: N, 14.95%.

6-Nitro and 7-Nitro-2-benzyl-3*H*-4-ketoquinazolines (IV and XIII) by Modified Niementowski Method. A mixture of 4- or 5-nitro-*N*-phenylacetylanthranilic acid (1.3 g) and formamide (2.0 g) was heated to 160—165°C for two hours. The solid product was powdered and stirred in bicarbonate solution,

filtered, and washed with water. It was crystallized from glacial acetic acid. Yield 22.9% for the 7-nitro isomer and 15.5% for 6-nitro isomer, respectively. They were compared (mixed mp) with corresponding products prepared by an alternate method describeed earlier.

6-Nitro-2-benzyl-3-methyl-4-ketoquinazoline (V). The compound was formed on heating a suspension of 6-nitro-4*H*-3,1-benzoxazin-4-one (0.350 g) and methylamine (2.0 m*l*; 10%) for an hour on a water bath. The dark orange coloured solution was decomposed with dilute hydrochloric acid (10 m*l*) and the solid product was collected, washed with bicarbonate solution and crystallized from ethanol (carbon) in white amorphous powder, mp 180—182°C. Yield: 0.275 g.

Found: N, 14.13%. Calcd for $C_{16}H_{13}O_3N_3$: N, 14.25%.

7-Nitro-2-benzyl-3-methyl-4-ketoquinazoline (XVIII). The compound was prepared from 7-nitro-2-benzyl-4*H*-3,1-benzoxazin-4-one (0.4 g) and methylamine and was crystallized from ethanol (carbon) in light amorphous powder, mp 155—158°C. Yield: 0.330 g.

Found: N, 13.78%. Calcd for $C_{16}H_{13}O_3N_3$: N, 14.25%.

6-Nitro-2-benzyl-3-phenyl-4-ketoquinazoline (VI). The compound was prepared by reacting 6-nitro-2-benzyl-4*H*-3,1-benzoxazin-4-one (0.4 g) with 20% alcoholic solution of aniline (3.0 m*l*). It was crystallized from glacial acetic acid in yellowish white plates, mp 231—233°C. Yield: 0.365 g.

Found: N, 11.92%. Calcd for $C_{21}H_{15}O_3N_3$: N, 11.76%.

7-Nitro-2-benzyl-3-phenyl-4-ketoquinazoline (XIX). The compound was synthesised from 7-nitro-2-benzyl-4*H*-3,1-benzoxazin-4-one (0.5 g) and aniline. The product was crystallized from ethanol (carbon) in silvery plates, mp 171—173°C. Yield: 0.420 g.

Found: N, 11.69%. Calcd for $C_{21}H_{15}O_3N_3$: N, 11.76%.

6-Nitro-2-styryl-3*H*-4-ketoquinazoline (IX). A suspension of 6-nitro-2-methyl-3*H*-4-ketoquinazoline (0.3 g) in freshly distilled benzaldehyde (2 m*l*) was heated for an hour at 180°C. The reaction mixture was steam distilled to remove excess benzaldehyde. The brownish orange product was collected, treated with bicarbonate solution and crystallized (carobn) from glacial acetic acid in orange yellow powder, mp 322—323°C. Yield: 0.405 g.

Found: N, 14.20%. Calcd for $C_{16}H_{11}O_3N_3$: N, 14.33%.

7-Nitro-2-styryl-3*H*-4-ketoquinazoline (XVI). The compound was synthesised from 7-nitro-2-methyl-3*H*-4-ketoquinazoline (0.420 g) and benzaldehyde (2.0 m*l*). The product was crystallized from glacial acetic acid in light yellow powder, mp 298—300°C. Yield: 0.575 g.

Found: N, 13.96%. Calcd for $C_{16}H_{11}O_3N_3$: N, 14.33%.

6-Nitro-2-(1-phenylstyryl)-3*H*-4-ketoquinazoline (X). The compound was prepared from 6-nitro-2-benzyl-3*H*-4-ketoquinazoline (0.570 g). The product was crystallized from glacial acetic acid in yellowish short needles, mp 274—276°. Yield: 0.600 g.

Found: N, 11.59% Calcd for $C_{22}H_{14}O_3N_3$: N, 11.41%.

7-Nitro-2-(1-phenylstyryl)-3*H*-4-ketoquinazoline (XVII). The compound was prepared from 7-nitro-2-benzyl-3*H*-4-ketoquinazoline and benzaldehyde. The brownish sticky mass was dissolved in a minimum amount of acetone and the acetone extract was poured in dilute bicarbonate solution and left overnight at room temperature. The solid product was collected, washed and crystallized from aqueous ethanol in light yellow short needles, mp 242—244°C. Yield: 98.5%.

Found: N, 11.18%. Calcd for $C_{22}H_{14}O_3N_3$: N, 11.41%.

7-Nitro-2-benzoyl-3*H*-4-ketoquinazoline (XIV). The compound was formed on, oxidation of 7-nitro-2-benzyl-3*H*-4-ketoquinazoline by the following two methods.

a) Oxidation with Alkaline Permanganate. 6-Nitro-2-benzyl-3*H*-4-ketoquinazoline (1.0 g) was suspended in a mixture of sodium hydroxide solution (5.0 m*l*; 4%) and potassium permanganate solution (50.0 m*l*; 2%). The reaction mixture was heated on a boiling water bath for six hours with continuous stirring. As the violet colour disappeared, extra permanganate (1.0 g) was added and heating was continued for two more hours. Excess permanganate was destoryed by adding required amount of ethanol to the hot reaction mixture. The latter was then filtered hot and the precipitates were washed with boiling water. The combined filtrate was concentrated and acidified with acetic acid. The product which separated was collected and crystallized from ethanol in pale yellow short needles, mp 235—237°C. The precipitated manganese dioxide was extracted with boiling acetone. Acetone was evaporated to dryness to give a major portion of the unreacting original compound (XIII).

Found: 13.96%. Calcd for $C_{15}H_9O_4N_3$: N, 14.23%.

b) Oxidation with Selenium Dioxide. A mixture of 7-nitro-2-benzyl-3*H*-4-ketoquinazoline (0.6 g) and selenium dioxide (0.6 g) in isoamyl alcohol (15.0 m*l*) was refluxed for fifteen hours. The yellowish brown solution was filtered hot and the residual solid was washed with a minimum amount of hot isoamyl alcohol. The combined filtrate was steam distilled to remove isoamyl alcohol. The residual brownish yellow product was collected, washed and crystallized from ethanol (charcoal) in light yellow short needles, mp 235—237°C.

Found: N, 14.12%. Calcd for $C_{15}H_9O_4N_3$: N, 14.23%.

6-Nitro-2-benzoyl-3*H*-4-ketoquinazoline (VII). The compound was formed on oxidation of 6-nitro-2-benzyl-3*H*-4-ketoquinazoline by the two methods described above. In the permanganate oxidation reaction major part of the starting substance (IV) was recovered unchanged. The product was crystallized from ethanol in yellowish white tiny needles, mp 230—233°C.

Found: N, 14.15%. Calcd for $C_{15}H_9O_4N_3$: N, 14.23%.

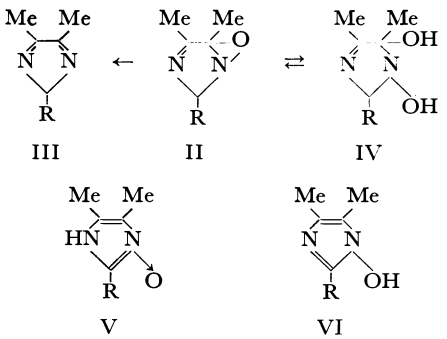
(Received October 14, 1968)

The reaction of α-dione monoximes with aldehydes and ammonia affords a general and facile synthetic route to 1-hydroxyimidazoles. By selection of the starting materials substituents can be readily introduced into the 2,4 and/or 5 positions of the imidazole ring which is formed *via* the intermediacy of a *gem*-aminoalcohol. The reactions of the *N*-hydroxyl function are discussed.

In a study of cellulosic fiber-polymer interactions[4,5] we have been concerned with the synthesis of imidazoles[6–9] and other polyaza heterocycles suitable for the attachment of vinylic moieties having differing reactivity ratios.[10] Thus, although 4(5)-vinylimidazole has been described,[11–15] the procedure is not amenable to facile variation and this alkene does not readily copolymerize with a wide range of monomers.[13] Our attention was thus directed to the fact that almost exactly half a century ago Diels discovered[15] that when aldehydes (RCHO) and butane-2,3-dione monoxime (I) are shaken with aqueous ammonia, a clan of compounds is formed by the elimination of two moles of water. Their reductive conversion into trisubstituted imidazoles (III) and their reversible hydrolysis to products considered to be the diols (IV) led[16] to their formulation as II.



III II IV

V VI

Although the synthesis of the somewhat labile oxaziridine ring system has been achieved[17,18] by several, usually oxidative, procedures, its generally limited stability in alkaline solutions and its apparent ease of formation in this alkaline condensation suggested that a re-examination of this group of products was merited.

Repetition of the prescribed procedure smoothly afforded II in good yield. Examination of this compound then disclosed (for R=Ph) that IV is a simple hydrate of II and that the transformations

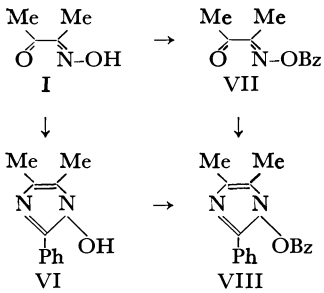
of IV into II and II into IV can readily be effected by crystallization from anhydrous and aqueous solvents respectively. The transition IV→II can also be realized by melting. The representational inadequacies of the general formula II were further underscored by the ultraviolet absorption spectrum of the congener (II, R=Me) originating from acetaldehyde which exhibited an absorption maximum at 2240 Å (ε=8800). This is indicative of the di-unsaturation of an imidazole ring and further clarification of the alleged structure II (with R=Me) resulted from a scrutiny of its nuclear magnetic resonance spectrum in chloroform solution. This contained three singlets (τ= 8.02, 7.77 and −3.33 ppm) corresponding to a pair of closely similar methyl groups, a single different methyl group and a very polar proton. These facts are in accord with a general hydroxylamine formulation (VI) and its hydrate as the corrected versions of the structure of these condensation products previously represented as II and IV respectively. A more recently suggested formulation of these products as *N*-oxides (V) and their hydrates[19] could be discounted in favor of the hydroxylamine representation because the condensation product, with R=phenyl, is amphoteric (pK_A 9.41, pK_B 9.36) and because its derived benzoate forms a well defined hydrochloride salt which of course requires the presence of a basic center. Final definitive chemical evidence eliminating the *N*-oxide alternative (V) was secured by replacing butane-2,3-dione monoxime (I) in the condensation reaction with its *O*-benzoate (VII).[20] The product isolated was also a benzoate (VIII) and was identical with that afforded by direct benzoylation of the condensation product originating from butane-2,3-dione monoxime itself. The moderate yield of VIII provided by the *O*-benzoate (VII) can be attributed to the diminution in the nucleophilic character of the oxime nitrogen occasioned by the attached benzoyloxy group.



With structure VI established, many of the previously recorded transformations of these compounds are obviously inadequately formulated and this situation is remedied by the clarifications summarized in Table 1. The evolution of carbon dioxide and the isolation of diphenylurea from the reaction of phenyl isocyanate with IV[16] is further substantiation of the hydrate structure. It is to be emphasized that the hydrates are the usual reaction products isolated and these can easily be mistaken[24] for the parent hydroxylamine.

Table 1. Reformulated derivatives of 1-hydroxy-2-phenyl-4,5-dimethylimidazoles originally prepared by Diels and Salomon[15]

Derivatizing reagent	Formula	Reaction product mp °C	Structure
EtOOCNCO	$C_{15}H_{17}N_3O_4$	80	PhNCO	$C_{18}H_{17}N_3O_2$	140	CH_3COCl	$C_{13}H_{15}N_2O_2Cl$	148	EtNCO	$C_{14}H_{17}N_3O_2$	116	PhCOCl	$C_{18}H_{17}N_2O_2Cl$	162	
Another objective of this research was to begin an assessment of the generality and scope of this synthetic route to 1-hydroxyimidazoles, a class of compounds not previously explicitly recognized although the corresponding 1-hydroxybenzimidazoles[21] are known and noted for their physiological action and the closely related *N*-oxides have been described.[22–28]

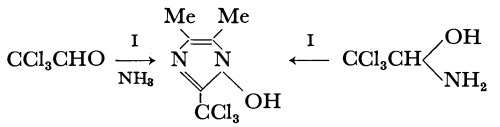
1-Hydroxy-2-phenylphenanthrimidazole***	Colorless needles[c,e]	280—282	34	$C_{21}H_{14}N_2O$	9.0	8.9

* The 13 compounds appearing in this Table were similarly prepared and were dehydrated before crystallization from anhydrous solvents.

** Crystallization solvents: [a] acetone, [b] dioxan, [c] ethanol, [d] hexane, [e] dimethylformamide.

*** The hydrate[24] has mp 235—238°C.

Since the formation of these 1-hydroxyimidazoles probably requires the genesis of an aldehyde-ammonia intermediate as the initial step, a wide variety of aldehydes should be capable of participation in this cyclization with butane-2,3-dione monoxime. This is indeed the case and the properties of the 2-substituted 1-hydroxyimidazoles obtained from various aldehydes are collected in Table 2. The participation of the aldehyde ammonia intermediate was confirmed by the formation of the same 1-hydroxyimidazole (IX) from trichloroacetaldehyde (X) and also directly from 1-amino-2,2,2-trichloroethanol (XI)[29] without the use of aqueous ammonia.



X IX XI

The versatility of this synthetic route to 1-hydroxyimidazoles can also be further extended by replacement of the aliphatic α-dione monoxime (I) with the monoximes of aromatic diketones such as benzil or *o*-phenanthraquinone. These variations permit the introduction of polymerizable moieties of various types in positions 2, 4 and 5 of the imidazole ring.

Experimental

General Preparation of 1-Hydroxyimidazoles. An equimolecular solution of the aldehyde and the dione monoxime in the minimum amount of ethanol (95%) or dioxan was treated at room temperature with aqueous ammonia (*d*, 0.88; 80 m*l*/mol of dione monoxime) when an exotherm was usually noted. The temperature was not allowed to rise above 60°C and the reaction mixture was allowed to stand overnight before collecting and crystallizing the product which had separated.

1-Benzoyloxy-2-phenyl-4,5-dimethylimidazole (VIII). a) A solution of 1-hydroxy-2-phenyl-4,5-dimethylimidazole (0.859 g, 3.4 mmol) in dioxan (200 m*l*) was heated with benzoyl chloride (0.63 g, 5 mmol) at 80—100°C for 10 min. After the addition of a suspension of sodium bicarbonate (0.34 g) in dioxan (100 m*l*) the reaction mixture was shaken for 10 min, allowed to stand for 5 days at room temperature, warmed to 50°C for 10 min and filtered. The cooled filtrate deposited needles (1.0 g) which were recrystallized from dioxan to give the benzoate (VIII) as needles (0.79 g), mp 163—165°C, which showed an IR absorption maximum at 1730 cm^{-1}.

Found: N, 9.2%. Calcd for $C_{18}H_{16}N_2O_2$: N, 9.6%.

b) A mixture of benzaldehyde (3.8 g, 0.036 mol) and aqueous ammonia (*d*, 0.88; 1.8 g, 0.03 mol) in dioxan (200 m*l*) was treated with butane-2,3-dione monoxime benzoate[20] (6.8 g, 0.04 mol, mp 111—113°C) and allowed to stand overnight. The material which had separated was crystallized from dioxan to afford the product as needles (0.5 g), mp 163—165°C, which showed no mp depression when mixed with VIII prepared in a). IR spectra of the two products were superimposable.

Found: N, 9.2%. Calcd for $C_{18}H_{16}N_2O_2$: N, 9.6%.

1-Hydroxy-2-trichloromethyl-4,5-dimethylimidazole (IX). a) A solution of trichloroacetaldehyde (2.94 g,

29) R. Schiff, *Ber.*, **10**, 167 (1877).

0.02 mol) and butane-2,3-dione monoxime (2.02 g, 0.02 mol) in dioxan (6 m*l*) was treated at room temperature with aqueous ammonia (*d*, 0.88, 1.6 m*l*) and allowed to stand overnight. Recrystallization of the separated material from acetone-hexane afforded the product as white needles (0.89 g, 18% yield), mp 175—180°C (dec).

Found: N, 12.10%. Calcd for: $C_6H_7N_2OCl_3$: N, 12.20%.

b) A solution of 1-amino-2,2,2-trichloroethanol (1.64 g, 0.01 mol) and butane-2,3-dione monoxime (1.01 g, 0.01 mol) in ethanol-dioxan (1 : 1, 4 m*l*) was allowed to stand overnight, the material which had separated was recrystallized from acetone-hexane to yield white needles (0.6 g, 14% yield), mp 178—182°C (dec.). This product showed no mp depression when mixed with IX prepared in a). IR spectra of the two products were superimposable.

Found: N, 12.15%. Calcd for $C_6H_7N_2OCl_3$: N, 12.20%.

Financial aid (to T.F.) was provided by the Undergraduate Research Participation Program of the National Science Foundation. One of us (K.A.) thanks the Kansai Paint Co. for support during a study leave.

(Received December 12, 1968)

A study of the polymerizations and copolymerizations of α-methoxyacrylonitrile(MeOAN) and methyl α-methoxyacrylate(MeOA) has been made. These monomers were homopolymerized with a radical initiator at 60°C, but did not give any polymer with such ionic catalysts as $BF_3O(C_2H_5)_2$ and C_6H_5MgBr at 0°C. From the radical copolymerizasions of these monomers with styrene at 60°C, their Q and e values were determined to be as follows:

$Q = 0.72$, $e = 0.40$ for MeOAN

$Q = 0.47$, $e = 0.04$ for MeOA

These monomers were also copolymerized with acrylonitrile, and the copolymerization parameters were determined.

In previous papers, it was pointed out that some α-substituted acrylate monomers, such as methyl α-cyanoacrylate[1] and alkyl α-phenylacrylate,[2] showed remarkably higher copolymerization reactivities than the respective unsubstituted monomers, such as methyl acrylate, acrylonitrile, and styrene. Similar enhanced reactivities of the monomers upon the introduction of some α-substituents have also been observed in the reported copolymerization data.[3]

By using these copolymerization data, we recently found that α-substituents of acrylonitrile and acrylic esters contributed additively to the values of e and $\log Q$ in the following equations, (1) and (2):[4]

$$e_{CH_2=C\langle^{X}_{Y}} = e_{CH_2=C\langle^{H}_{Y}} + 2.4\sigma_X = e_{CH_2=C\langle^{X}_{H}} + 2.4\sigma_Y \quad (1)$$

$$\log Q_{CH_2=C\langle^{X}_{Y}} = \log Q_{CH_2=C\langle^{H}_{Y}} + (\log Q_{CH_2=C\langle^{X}_{H}} - \log Q_{CH_2=CH_2}) = \log Q_{CH_2=C\langle^{H}_{Y}} + \Delta\log Q_X$$

or

$$\log Q_{CH_2=C\langle^{X}_{Y}} = \log Q_{CH_2=C\langle^{X}_{H}} + (\log Q_{CH_2=C\langle^{H}_{Y}} - \log Q_{CH_2=CH_2}) = \log Q_{CH_2=C\langle^{X}_{H}} + \Delta\log Q_Y \quad (2)$$

where X represents the methoxy, methyl, hydrogen, chloro, bromo, acetoxy, carboalkoxy, and cyano groups, and Y cyano and carboalkoxy groups.

In the course of studying the effect of the α-substituents of vinyl monomers on their radical reactivities, α-methoxy acrylonitrile (MeOAN) and methyl α-methoxyacrylate (MeOA) were prepared and copolymerized with styrene and acrylonitrile. The present paper will describe the results thus obtained. Since it has been generally known that some 1,1-disubstituted ethylenic monomers, especially α-substituted styrenes, have low ceiling temperatures,[5] the homopolymerizabilities of these monomers will also be described in this study.

Experimental

Preparations of Monomers. The MeOAN monomer was prepared by the method described by Baker[6] through the following reaction path:

$$CH_3CHO + CH_3OH + HCl \longrightarrow CH_2CHOCH_3 \quad (Cl)$$

$$\xrightarrow{Br_2} CH_2(Br)\text{-}CH(Br)OCH_3 \xrightarrow{CuCN} CH_2(Br)\text{-}C(CN)\text{-}OCH_3$$

$$\xrightarrow{\text{Pyridine}} CH_2{=}C(CN)COCH_3 \text{ (MeOAN)}$$

The resulting MeOAN monomer was purified by fractional distillations under reduced pressure: bp 32—33°C/22 mmHg. (lit,[6] 32.5°C/23 mmHg), n_D^{20} 1.4155, d_4^{15} 0.942.

Found: C, 58.23; H, 6.13%. Calcd for C_4H_5NO: C, 57.83; H, 6.07%.

The MeOA monomer was also obtained as follows:

$$CH_2(Br)\text{-}CH(CN)OCH_3 \xrightarrow[HCl]{CH_3OH} CH_2(Br)\text{-}CH(OCH_3)\text{-}C(OCH_3){=}NH\cdot HCl \xrightarrow{H_2O}$$

$$CH_2(Br)\text{-}CH(COOCH_3)OCH_3 \xrightarrow{\text{Piperidine}} CH_2{=}C(COOCH_3)COCH_3 \text{ (MeOA)}$$

The resulting MeOA monomer was also purified by fractional distillation: bp 52.5—53.0°C/11 mmHg. (lit,[6] 51.5—52.0°C/11 mmHg), n_D^{20} 1.4347 (lit,[6] 1.4316), d_4^{15} 1.068.

Found: C, 51.65; H, 6.98%. Calcd for $C_5H_8O_3$: C, 51.72; H, 6.90%.

Other Reagents. The styrene and acrylonitrile were purified by ordinary methods and were distilled under reduced pressure before use. The α,α'-azobisisobutyronitrile(AIBN) was recrystallized from ethanol. The benzene, methylene chloride, and toluene were used after purification by ordinary methods.

Radical Polymerizations and Copolymerizations. The required amounts of the monomer, AIBN, and the solvent were charged into a polymerization ampoule. After it had then been degassed by a freezing and thawing method, the ampoule was sealed off under a vacuum.

The polymerizations and copolymerizations were carried out at 60°C under shaking. After polymerization for a given time, the content of the ampoule was poured into a large amount of mehanol (the homopolymer of MeOAN and copolymers) or diethyl ether (the homopolymer of MeOA) to precipitate the polymer. The resulting copolymers with styrene and with acrylonitrile were purified by the reprecipitation method from benzene-methanol and dimethylformamide-methanol systems respectively.

The compositions of the copolymers were calculated from their carbon or nitrogen content, and the monomer reactivity ratios were determined by the Fineman-Ross[7] and curve-fitting methods.

Ionic Polymerizations. The cationic polymerizations of these monomers were carried out by the use of boron trifluoride diethyl etherate in methylene chloride at 0°C. The anionic polymerizations were performed with phenylmagnesium bromide in toluene at 0°C. After a given polymerization time, the reaction mixture was poured into a large excess of methanol or diethyl ether.

Results and Discussion

Homopolymerizations of MeOAN and MeOA. The results of the homopolymerizations of MeOAN and MeOA monomers with radical and ionic initiators are shown in Table 1.

From Table 1, it can be seen that these monomers were homopolymerized only by the AIBN initiator

Table 1. Homopolymerizations of MeOAN and MeOA monomers

Monomer	(ml)	Initiator (g)	Solvent (ml)	Temp. (°C)	Time (hr)	Yield (%)
MeOAN	0.6	AIBN, 0.0023	C_6H_6, 1.0	60	150	8.9

	84.1	9.33	6.4	—	60.53	76.4

* In the copolymericaztions of MeOAN and MeOA, the concentrations of AIBN were kept constant at 4.63×10^{-3} and 5.06×10^{-3} mol/l, respectively.

under the present conditions. However, their rates were quite low compared with those of the respective unsubstituted monomers, acrylonitrile and methyl acrylate. Between the two monomers, the homopolymerizability of MeOA was larger than that of MeOAN. This tendency was identical to that observed in the radical homopolymerizabilities for α-methyl substituted monomers, such as methacrylonitrile and methyl methacrylate. It was also obvious that these monomers have ceiling temperatures higher than 60°C.

Although these monomers have both an electron-donating methoxy substituent and an electron-withdrawing cyano or carbomethoxy substituent, they were not found to give any homopolymer with cationic and anionic catalysts ($BF_3O(C_2H_5)_2$ and C_6H_5MgBr respectively) at 0°C.

Copolymerizations of MeOAN and MeOA with Styrene. Table 2 shows the results of the radical copolymerizations of MeOAN and MeOA (M_1) with styrene (M_2) at 60°C.

From Table 2, the rate of copolymerization was found to decrease with an increase in the concentration of MeOAN or MeOA in the feed-monomer mixture. The monomer-copolymer composition curves are shown in Fig. 1.

The copolymerization parameters (r_1, r_2, Q_1 and e_1) were determined to be as follows:

for MeOAN (M_1)-styrene (M_2):
$r_1 = 0.35$, $r_2 = 0.53$, $Q_1 = 0.72$, $e_1 = 0.40$

for MeOA (M_1)-styrene (M_2):
$r_1 = 0.51$, $r_2 = 1.10$, $Q_1 = 0.47$, $e_1 = 0.04$

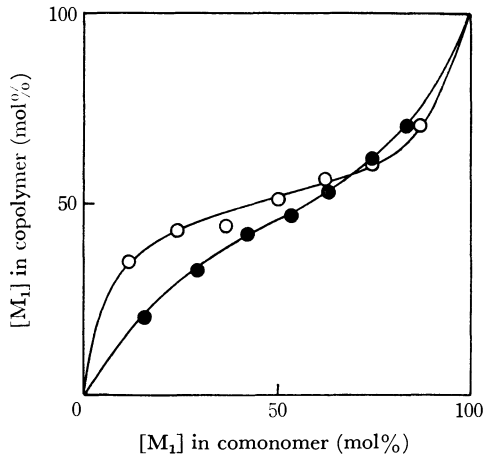

Fig. 1. Monomer-copolymer composition curves for MeOAN (M_1)-styrene(M_2) (○) and MeOA(M_1)-styrene(M_2) (●) at 60°.

where the Q_1 and e_1 values were calculated by assuming that the Q_2 and e_2 values were 1.0 and −0.80 respectively.

The values of e_1 and Q_1 obtained for MeOAN and MeOA were then compared with those calculated from Eqs. (1) and (2). When the values of e and log Q for acrylonitrile and methyl acrylate used were $e=1.20$ and log $Q=-0.22$, and $e=0.60$ and log $Q=-0.38$ from the literature,[3] and when those of Δ log Q and σ for the methoxy substituent used were 0.06 and −0.27, as reported in a previous paper,[4] the following values of Q_1 and e_1 were obtained:

for MeONA: $Q_1 = 0.69$, $e_1 = 0.49$

for MeOA: $Q_1 = 0.48$, $e_1 = -0.11$

It was clear that the Q_1 and e_1 values calculated from Eqs. (1) and (2) were in agreement with those obtained in this experiment; the validity of the above equations was thus confirmed.

Copolymerizations of MeOAN and MeOA with Acrylonitrile. The results of the radical copolymerizations of these monomers (M_1) with acrylonitrile (M_2) are shown in Table 3, while the resulting copolymer composition curves are indicated in Fig. 2.

The following copolymerization parameters were obtained:

for MeOAN (M_1)-acrylonitrile (M_2):
$r_1 = 1.93$, $r_2 = 0.37$, $Q_1 = 0.83$, $e_1 = 0.61$

for MeOA (M_1)-acrylonitrile (M_2):
$r_1 = 0.30$, $r_2 = 0.15$, $Q_1 = 0.48$, $e_1 = -0.56$

where the Q_1 and e_1 values were calculated by assuming that $e_2 = 1.20$ and $Q_2=0.60$ for acrylonitrile.

Contrary to the results of the copolymerizations with styrene, the relative reactivities ($1/r_2$) of these monomers toward a polyacrylonitrile radical were

	50.0	5	13.7	7.75	52.4
	63.0	5	11.6	6.39	58.9
	75.0	5	8.8	5.53	63.3
	87.0	5	5.4	3.83	72.9

* In the copolymerizations of MeOAN and MeOA, the concentrations of AIBN were kept constant at 5.47×10^{-3} and 5.00×10^{-3} mol/l, respectively.

found to be greater than those of the respective unsubstituted monomers of acrylonitrile and methyl acrylate, probably because of the electron-donating nature of the methoxy group. It was also noted that the e_1 value for MeOA obtained from the copolymerization with acrylonitrile was not in agreement with that obtained with styrene.

Although the Q and e values for α-substituted acrylonitriles and acrylic esters obtained from the copolymerizations with styrene were in agreement with those calculated from Eqs. (1) and (2), those

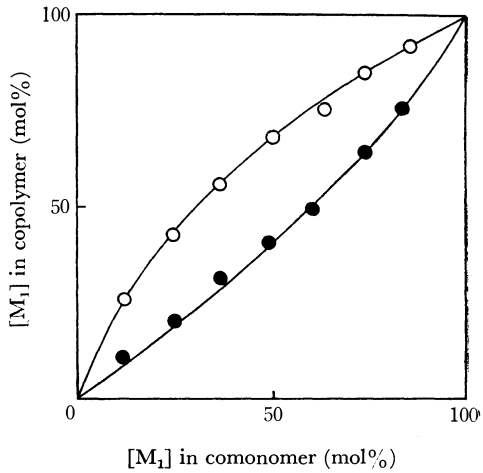

Fig. 2. Monomer-copolymer composition curves for MeOAN(M_1)-acrylonitrile(M_2)(○)and MeOA (M_1)-acrylonitrile(M_2) (●) at 60°C.

obtained from the copolymerizations with acrylonitrile did not agree. In Table 4, the Q_1 and e_1 values of several α-substituted acrylonitriles and acrylic esters calculated from the copolymerizations with styrene and with acrylonitrile are summarized. In this table, the negative e_1 values of α-substituted acrylic esters carrying the electron-donating methyl and methoxy groups are noted; their e_1 values are not those with would be predicted from Eq. (1). However, no such abnormal behavior was found in the copolymerizations of α-substituted acrylonitriles, and Eqs. (1) and (2) were valid for the copolymerization with acrylonitrile.

The effects of electron-donating α-substituents on the relative reactivities of α-substituted vinyl monomers toward a polyacrylonitrile radical will be discussed in detail in a subsequent paper.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 3211—3215 (1969)

Crystalline Terpolymer of Formaldehyde, Carbon Dioxide, and *N*-Phenylethylenimine

Tsutomu KAGIYA and Kōzō NARITA
Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

and Masatsune KONDO
Sumitomo Chemical Co., Ltd., Takatsuki

(Received March 14, 1969)

Formaldehyde, carbon dioxide, and *N*-phenylethylenimine were allowed to terpolymerize by means of dimethyl ether acetate to give a crystalline solid terpolymer, melting at 178—265°C, with the composition of: CH_2O: 70—95, CO_2: 0.5—5, C_8H_9N: 5—25 mol%. The content of *N*-phenylethylenimine in the terpolymer thus obtained increased with the content of the imine in the feed, and that of carbon dioxide in the terpolymer, with the content of the imine in the feed, the lowering of the polymerization temperature, and the polymerization time. The infrared spectrum of the terpolymer showed the characteristic peaks of $-(-CH_2OCH_2O-)-$, $-(-\overset{\overset{O}{\|}}{OCO}-)-$ and $-(-\underset{\underset{C_6H_5}{|}}{N}CH_2CH_2-)-$. The mechanism of the terpolymerization was proposed on the basis of these results.

Recently, the copolymerizations[1] of formaldehyde with olefins or with various aldehydes have been studied. No paper on the copolymerization of carbon dioxide as a monomer has, however, been reported.

The present authors have previously studied formaldehyde polymerization in a liquid carbon dioxide solution.[2] During the course of their study, the authors found that the crystalline terpolymers of formaldehyde, carbon dioxide, and *N*-phenylethylenimine were produced by dimethyl ether acetate.

In this paper, the sturcture and the physical properties of the terpolymer will be determined, and the mechanism of the terpolymerization will be discussed.

Experimental

Materials. The formaldehyde in liquid carbon dioxide was prepared by means of the two-step method reported previously.[2] Eighteen hundred grams of paraformaldehyde, 1000 g of polyethylene glycol (a degree of polymerization of about 10), and 1.8 mol of calcium carbonate were put into a 3000 m*l* decomposer, and then the mixture was heated at from 110 to 160°C under a carbon dioxide stream (flow rate: 160 m*l*/min). The mixture of formaldehyde and carbon dioxide was passed through two tubes cooled at −20°C and then liquefied in the monomer reservoir at −78°C. The *N*-phenylethylenimine was prepared according to the method of the literature[3] from *β*-bromoethylaniline hydrobromide; it was dried over sodium sulfate and fractionated twice before use (bp 70—70.5°C/13 mmHg). Commercial carbon dioxide was dried through two drying tubes packed with phosphorus pentoxide. The dimethyl ether acetate was prepared by the reaction[4] of monochloromethyl ether with potassium acetate; it was then purified by distillation (bp 117—118°C). The toluene, acetonitrile, and formic acid were purified in the usual way.

Polymerization Procedure. A 30 m*l* stainless steel autoclave or a 20 m*l* glass ampule was used as the reaction vessel. The vessel was degassed *in vacuo* and cooled at −198°C. Then, measured quantities of the catalyst and *N*-phenylethylenimine were put into the autoclave, and then a carbon dioxide solution of formaldehyde (about 60 wt%) or liquid formaldehyde was introduced. In the experiment using the glass ampule, a measured quantity of the organic solvent containing the catalyst, *N*-phenylethylenimine, and liquid formaldehyde was put into the ampule. The vessel was kept standing for the definite time at a constant temperature. After the reaction, the unreacted formaldehyde

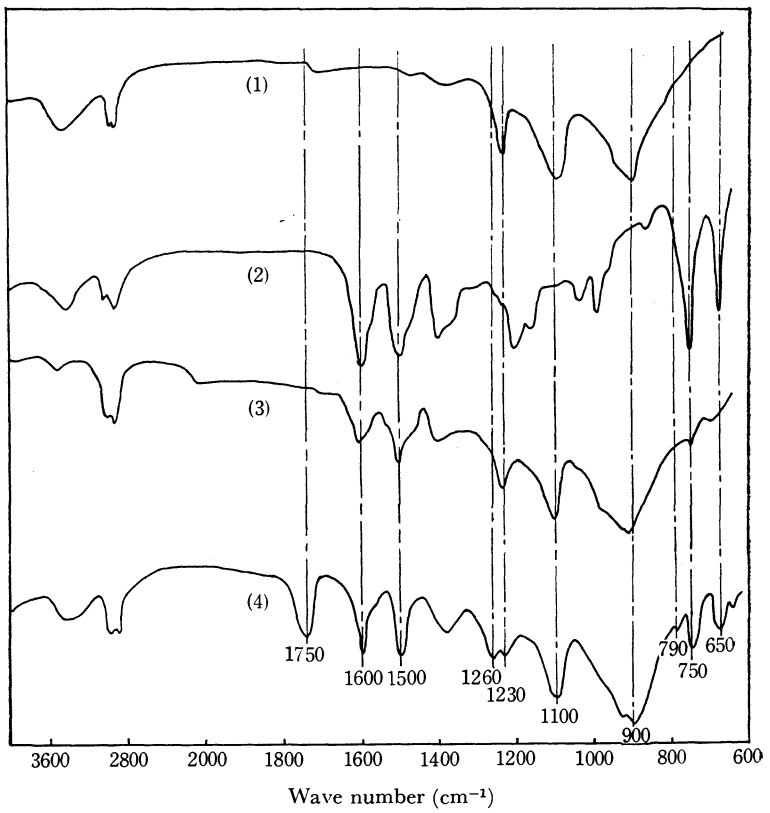

Fig. 1. Infrared spectra of: (1) poly-formaldehyde; (2) poly-*N*-phenylethylenimine; (3) copolymer of formaldehyde and *N*-phenylethylenimine; (4) terpolymer of formaldehyde, carbon dioxide, and *N*-phenylethylenimine.

and carbon dioxide were purged out, and the polymer was washed with cooled diethyl ether, dried *in vacuo* at room temperature, and weighed.

Analysis. The composition of the terpolymer was determined by elementary analysis. The specific viscosity measurement of the solution containing 0.5 g of the polymer in 100 m*l* of *p*-chlorophenol containing 2% α-pinene was carried out with the aid of an Ostwald viscometer at 60°C. The melting point of the polymer was visually determined in a nitrogen atmosphere in an electric heater. The infrared spectrum was obtained by using the potassium bromide pellet technique on a Japan Spectroscopic infrared spectrometer, Model DS-402G, with a sodium chloride prism. The X-ray diffraction diagram was recorded with a powder camera on a Shimadzu X-ray difractometer, Model GX-3B, employing Ni-filtered CuK_α radiation and standard techniques. The differential thermograms were obtained by using sandwiches with α-alumina powder as a diluent under an argon atmosphere on a Shimadzu differential thermal apparatus, Model DT-10, equipped with a platinum cell.

Results and Discussion

Terpolymerization of Formaldehyde, Carbon Dioxide, and *N*-Phenylethylenimine. The results of the terpolymerization of formaldehyde, carbon dioxide, and *N*-phenylethylenimine are shown in Table 1. Formaldehyde, being unable to copolymerize with carbon dioxide, was allowed to terpolymerize with carbon dioxide and *N*-phenylethylenimine in the presence of dimethyl ether acetate to give a white powdery polymer, which was soluble in *p*-chlorophenol, *m*-cresol, and dimethylformamide, and insoluble in diethyl ether, acetone, ethanol, chloroform, and toluene. The melting points of the terpolymers were 178°C to 265°C, between those of poly-*N*-phenylethylenimine (285—292°C) and poly-formaldehyde (*ca.* 170°C).

As is shown in Table 1, the *N*-phenylethylenimine content of the terpolymer increased with the imine content of the feed, and that of carbon dioxide in the terpolymer increased with the imine content of the feed, the lowering of polymerization temperature, and the polymerization time. The yield of the terpolymer increased with a rize in the reaction temperature.

Structure of the Terpolymer. The infrared spectrum of the resulting polymer showed the characteristic absorptions at 1230, 1100, and 900 cm^{-1} based on the acetal linkage (formaldehyde unit); at 1600, 1500, 750, and 690 cm^{-1} based on the benzene nucleus (*N*-phenylethylenimine unit), and at 1750, 1260, 1040, and 790 cm^{-1} based on the carbonate linkage (carbon dioxide unit) (Fig. 1). In addition, the infrared spectra of the polymers obtained by the polymerization of formaldehyde or *N*-phenylethylenimine in the presence of carbon dioxide and the copolymer of formaldehyde and *N*-phenylethylenimine in the absence of carbon dioxide are shown in Fig. 1. It is found that none of these polymers has the structure of the carbonate group -(-OCO-)-.

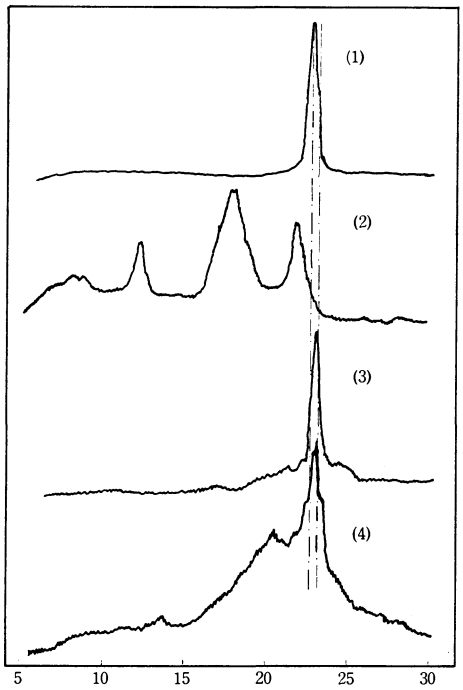

Fig. 2. X-Ray diffraction diagrams of: (1) poly-formaldehyde; (2) poly-*N*-phenylethylenimine; (3) copolymer of formaldehyde and *N*-phenylethylenimine; (4) terpolymer of formaldehyde, carbon dioxide, and *N*-phenylethylenimine.

Table 2. Characteristic peaks of X-ray diffraction diagrams of the polymers

	2θ (°)
Poly-formaldehyde	22.6
Poly-*N*-phenylethylenimine	8.3(s), 12.0, 18.0, 21.8
Copolymer of formaldehyde and *N*-phenylethylenimine	23.0, 24.2(s)
Terpolymer	13.5(s), 20.8(b), 23.0

(s) means small peak. (b) means broad peak.

X-Ray diffraction diagrams of the terpolymer (carbon dioxide 2.5 mol%, *N*-phenylethylenimine 23.6 mol%), the poly-*N*-phenylethylenimine, and poly-formaldehyde are shown in Fig. 2. The characteristic peaks (2θ) of these polymers are listed in Table 2. The X-ray diffraction diagram of the terpolymer displayed the main characteristic peak and a broad shoulder. The main characteristic peak of the terpolymer is the same as that of the copolymers of *N*-phenylethylenimine and formaldehyde, but a little different from the characteristic peaks of poly-formaldehyde and poly-*N*-phenyl-

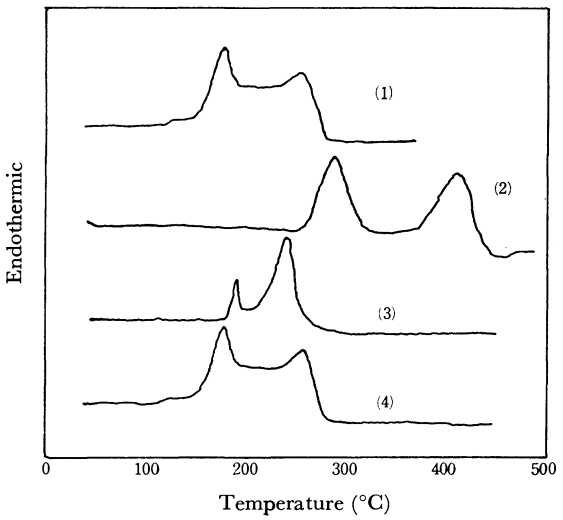

Fig. 3. Differential thermograms of: (1) polyformaldehyde; (2) poly-*N*-phenylethylenimine; (3) copolymer of formaldehyde and *N*-phenylethylenimine; (4) terpolymer of formaldehyde, carbon dioxide, and *N*-phenylethylenimine.

ethylenimine. On the other hand, the broad shoulder of the terpolymer is not different from the characteristic peaks of the above three polymers. It follows that the X-ray diagram indicates that the polymer from the three components contains a part of the block of the characteristic sequence of the terpolymer. In view of the relative half-value width, it may be concluded that the terpolymer is partially crystalline. Figure 3 shows a differential thermogram of the terpolymer (carbon dioxide 3.6 mol%, *N*-phenylethylenimine 6.7 mol%) in comparison with those of both homopolymers and those copolymers. The endothermic peak corresponds to the melting point of neither homopolymer, but a new peak of the terpolymer was observed.

Mechanism of the Terpolymerization. On the basis of the results shown in Table 1 and 3, the following reaction mechanism of the terpolymerization of formaldehyde, carbon dioxide, and *N*-phenylethylenimine by dimethyl ether acetate can be proposed.

Since formaldehyde was homopolymerized in the presence of carbon dioxide (Expt. No. 1 in Table 3), the reaction of formaldehyde with the propagating species of $-OCH_2^{\delta+}-OOCCH_3^{\delta-}$ (Eq. (1)) really occurs. On the other hand, from the fact that *N*-phenylethylenimine was hardly allowed to polymerize at all by dimethyl ether eacetate (Expt. No. 2 in Table 3), the reaction of *N*-phenylethylenimine with the propagating species of $-NCH_2CH_2^{\delta+}-OOCCH_3^{\delta-}$ (C_6H_5) is negligible in this polymerization.

On the other hand, formaldehyde was allowed to copolymerize with *N*-phenylethylenimine in

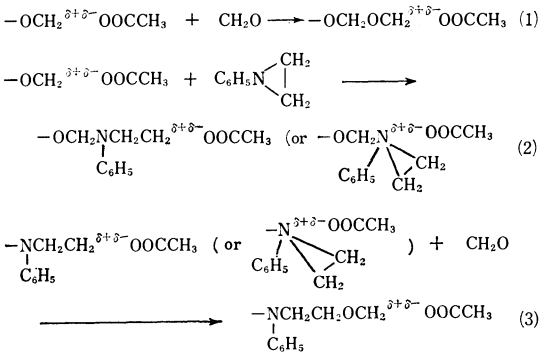
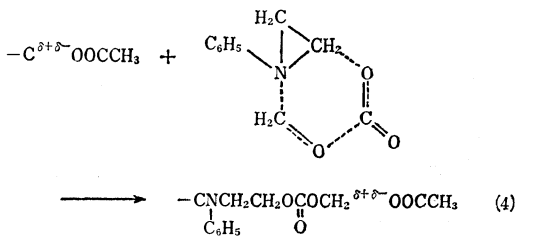
organic solvents by dimethyl ether acetate (Expts. No. 4, 5, 6, and 7 in Table 3). Therefore, both the reactions of *N*-phenylethylenimine with the propagating species of $-OCH_2{}^{\delta+\delta-}OOCCH_3$ (Eq. (2)) and of formaldehyde with the propagating species of  (Eq. (3)) may occur. From the results of both Expt. No. 2 in Table 1 and Expt. No. 1 in Table 3, it may be supposed that the rate of the propagation of reaction (1) is larger than that of reaction (2). On the basis of these results, the following elementary reactions may be proposed:



Further, carbon dioxide was allowed by dimethyl ether acetate to react only with formaldehyde in the presence of *N*-phenylethylenimine to give a terpolymer. The infrared spectrum of the terpolymer showed the existence of $-(-OCH_2OCH_2-)-$, $-(-NCH_2CH_2-)-$, and $-(-OCO-)-$. Therefore, it may be considered that the existence of carbon dioxide in this terpolymer is caused by the attack of the complex of formaldehyde, carbon dioxide, and *N*-phenylethylenimine on the propagating species of $-CH_2{}^{\delta+\delta-}OOCCH_3$ as follows:



The low carbon dioxide content (0.5—5 mol%) in the terpolymer indicates that the equilibrium constant of the reaction (4) is very small. This quantitative mechanism is consistent with the experimental results. A detailed study of the mechanism of this type of terpolymerization is now being carried out and will be reported on in a subsequent paper.

The authors wish to express their gratitude to Professor Kenichi Fukui for his helpful suggestions and to Mr. Hiroshi Hatta for his assistance in carrying out the experiments.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 3216—3220 (1969)

The Reaction of Carboxylic Acids and Hydrocarbons in a Silent Electric Discharge. II. The Reactions of Ethylene with Methyl Acetate and with Acetic Anhydride*1

Teruo HIRAKI

Institute of Commodities, Faculty of Economics, Kagawa University, Takamatsu

(Received March 19, 1969)

The present study was undertaken in order to ascertain the difference, if any, in the chemical behavior of methyl acetate and acetic anhydride submitted to a silent discharge between that in the presence and that in the absence of ethylene. (1) In the reaction of methyl acetate without ethylene, the main products were methanol, diacetyl, liquid hydrocarbons, formaldehyde, methane, carbon dioxide, carbon monoxide, and hydrogen. Although the methanol yield was almost the same, regardless of the presence or absence of ethylene, the yields of the hydrocarbons, all the carbonyl compounds, and of *n*-butyl acetate increased in the presence of ethylene. The great quantity of methanol produced might indicate that C–OCH_3-bond breaking in the methyl acetate occurs preferably upon the discharge. (2) With acetic anhydride, on the other hand, acetaldehyde, acetone, ethyl acetate, ethyl methyl ketone, diacetyl, hydrocarbons, carbon monoxide, carbon dioxide, and hydrogen were obtained as the main products. The yields of acetone and diacetyl decreased remarkably in the presence of ethylene, while the yields of hydrocarbons, ethyl methyl ketone, *n*-butyl methyl ketone, and of *n*-butyl acetate increased. The $CH_3COO\cdot$ and $CH_3CO\cdot$ radicals are thought to be the main intermediates in this reaction. The formation of *n*-butyl acetate and of *n*-butyl methyl ketone in the presence of ethylene can be explained on the basis of the telomerization of ethylene initiated by these radicals.

In the previous paper,[1] the reaction between acetic acid and ethylene by a silent discharge was studied. The α-C-alkylation which has been known to take place in the reaction[2,3] of a saturated organic acid with ethylene in the presence of benzoyl peroxide at 70—80°C did not occur when there was the discharge. Instead, the formations of ethyl and *n*-butyl acetates and of carbonyl compounds (acetone, ethyl methyl ketone, *etc.*) were observed in the discharge reaction. These observations were explained in terms of the telomerization of ethylene initiated by the $CH_3COO\cdot$ and $CH_3CO\cdot$ radicals which were formed from CH_3COOH under the discharge.

One of the purposes of the present study was to ascertain whether the $CH_3COO\cdot$ and $CH_3CO\cdot$ radicals are formed as the main intermediate also in the decompositions of methyl acetate and acetic anhydride under a silent discharge, and to check whether or not a similar telomerization occurs under the present reaction conditions.

*1 The major part of these research results were presented at the 21st Annual Meeting of the Chemical Society of Japan, Osaka, April, 1968.

Experimental

Materials. The methyl acetate was purified by washing it with a 10% sodium chloride solution three times, refluxing it over quick lime, and then distilling it through a column. The acetic anhydride was purified by column distillation *in vacuo* after it had been allowed to stand for 2—3 days with a small amount of sodium. Commercial ethylene was used without purification. No impurity was found in these reagents by gas-chromatographical analysis. For the analyses of methyl acetate and acetic anhydride and of ethylene, a 3-m column of DEGS (diethylenglycol succinate) and a 3-m column of activated charcoal respectively were used at 100°C.

Apparatus and Procedure. All the experiments were performed in a flow system. The apparatus and the procedure were similar to those previously reported.[1]

Analysis of the Products. The non-condensable gases produced were identified by comparing their retention times on gas chromatography with those of authentic samples. (Columns of activated charcoal, hexamethylphosphoramide, and molecular sieve-13X were used.) The gaseous products were not determined quantitatively.

The condensable products were confirmed not only by gas chromatography (columns; tricresyl phosphate, DEGS, PEG-6000, and silicon DC-550 at 120°C; carrier gas: He), but also by the formation of their derivatives. Thus, ethyl methyl ketone, obtained as a fraction boiling at 80—82°C, and acetone (bp 56—

57°C) were converted into their semicarbazones,*[2] the melting points of the derivatives being 146—146.5°C and 186.5—187°C respectively. They showed no depression in their melting points when mixed with authentic specimens. The quantitative analysis of the liquid products was performed by gas chromatography (column: a 3-m column of PEG-6000 and a 3-m column of DEGS, at 120°C).

Results and Discussion

When the discharge reactions of methyl acetate or acetic anhydride with ethylene were carried out in a Pyrex tube of the Siemen type under the conditions shown in Table 1 (helium was used in the case of the reaction without ethylene), a large number of compounds were obtained in every run. Among these, the identified compounds are summarized in Table 2. The percentage compositions of products shown in this table are the averages of three experiments; the fluctuations in the yields of these compounds were less than 1%.

I. The Reaction of Methyl Acetate. *Influence of Ethylene on the Discharge Reaction of Methyl Acetate.* As may be seen from Experiments No. 21 and 22 in Table 2, a large number of compounds were formed along with methanol, the major product in the reaction of methyl acetate with ethylene; acetaldehyde, diacetyl, ethyl methyl and methyl vinyl and *n*-butyl methyl ketones, *n*-propyl and *n*-butyl acetates, liquid hydrocarbons, formaldehyde, C_1—C_4-hydrocarbons, carbon dioxide, carbon monoxide, and hydrogen were all detected.

Most of these compounds were also formed in the silent discharge-induced reaction of methyl acetate without ethylene (Exp. No. 20). However, the distribution of the products was different from that in the reaction without ethylene: (1) While the methanol yield was scarcely affected at all by the presence of ethylene, the yields of all the carbonyl compounds and acetates increased in the presence of ethylene. (2) The propylene, *n*-butane, 1-butene, and 1,3-butadiene in the gaseous products were formed only in the presence of ethylene. (3) Influences of the molar ratio of ethylene to methyl acetate on the conversion efficiency (percentage of grams of the reaction product per grams of methyl acetate used) and the products pattern were not recognized in the region of the ratios from 0.6 : 1 to 0.9 : 1.

The increase in methyl vinyl ketone in the presence of ethylene may be due to the combination of a $CH_3CO\cdot$ radical with a vinyl radical, which has been reported to be formed from ethylene in the electrical discharge.[4] The formation of acetylene, 1-butene, and 1,3-butadiene also supports the idea of the formation of the intermediate vinyl radical. On the other hand, the formation of *n*-butyl methyl ketone and *n*-butyl acetate in the presence of ethylene suggests telomerization of ethylene involving the $CH_3CO\cdot$ and $CH_3COO\cdot$ radicals.

The Assumed Radicals and the Reaction Scheme. It is believed that most of the products in the discharge-induced reaction can be explained on the basis of known free redical processes. Since many

Gaseous products****: Methane, Ethane, Acetylene, Propane, Propylene, Butane, 1-Butene, 1,3-Butadiene, Carbon monoxide, Carbon dioxide, Hydrogen, and Formaldehyde.

* The conversion efficiency was given by (grams of reaction product per grams of methyl acetate or acetic anhydride used) × 100.

** The yields of each compound produced were given by (grams of each compound per grams of total liquid product) × 100.

*** Ethyl acetate might has been produced, but this product could not be identified because of interference by a large peak of methanol.

**** Formaldehyde was only obtained in the reaction of methyl acetate, and also hydrocarbons higher than C_3 were not obtained in Exp. Nos. 20 and 30.

workers[5] have reported that the extent of the formation of ionized molecules in the discharge reaction is very small, the possible ion-molecule reactions which might explain the products will not be considered in this discussion.

Primary Processes. The possible homolytic cleavage of methyl acetate can be shown as follows:

$$CH_3COOCH_3^* \rightarrow CH_3CO\cdot + \cdot OCH_3 \quad (I)$$

$$\rightarrow \cdot CH_2COOCH_3 + H\cdot \quad (II)$$

$$\rightarrow CH_3\dot{C}OOCH_2 + H\cdot \quad (III)$$

$$\rightarrow CH_3COO\cdot + \cdot CH_3 \quad (IV)$$

$$\rightarrow \cdot CH_3 + \cdot COOCH_3 \quad (V)$$

$$\rightarrow 2\cdot CH_3 + CO_2 \quad (VI)$$

where $CH_3COOCH_3^*$ denotes a methyl acetate excited by the discharge.

The high yield of methanol in the reaction of methyl acetate without ethylene by the silent discharge indicates that Step I is the most probable primary process. This cleavage has been proposed as a major process in the radiolysis of methyl acetate also.[6]

Rust *et al.*[7] have shown that the dissociation of the $\cdot OCH_3$ radicals formed in the vapor-phase decomposition of methyl *t*-butyl peroxide ($Me_3C\cdot O\cdot O\cdot Me$) in the presence of cyclohexene was no more than 0.2%; 99.8% of the radical produced was converted into methanol. Evidence for the stability of $\cdot OCH_3$ radicals has also been reported by Shteen *et al.*[8] On the other hand, the presence of carbon monoxide in the gaseous products indicates that another radical in Step I, $CH_3CO\cdot$, immediately decomposed, as has been proposed to be the case in photolysis[9] and radiolysis.[6] As a result, the yields of carbonyl compounds may be low. Thus, at least to some extent, process I may be written:

$$CH_3COOCH_3^* \rightarrow \cdot CH_3 + CO + \cdot OCH_3$$

Although the presence of hydrogen in the gaseous products may be good evidence for the occurrence of processes II and III, the formation of the $\cdot CH_2COOCH_3$ radical (process II) is apparently of minor importance in view of the fact that no

7) F. F. Rust, F. H. Seibold and W. E. Vaughan, *ibid.*, **72**, 338 (1950).

8) Shteen *et al.* have shown that the stability of $\cdot OCH_3$ radicals may be due to the geometrical configuration of H and O in the radical and to the endothermic dissociation process of the radicals; N. YA Shteen, N. YA Chernyak, V. L. Antonovskii and A. F. Revzin, *Zh. Fiz. Khim.*, **28**, 240 (1954).

methyl propionate and butyrate were obtained.

It can be thought that carbon dioxide, ethane, and methane are formed *via* three processes, IV, V, and VI. The IV and V processes have previously been proposed in radiolysis.[6]

Secondary Reactions. The possible ways of the production of methanol are thought to be as follows:

$$\cdot OCH_3 + CH_3COOCH_3 \rightarrow CH_3OH + R\cdot \quad (1)$$

$$2\cdot OCH_3 \rightarrow CH_3OH + HCHO \quad (2)$$

Wijnen has reported that methanol production *via* reaction (1) occurs mainly in the photolysis of CH_3COOCH_3 over the temperature range from 29 to 217°C,[9] and that a similar tendency is observed also in the photolysis of i-$C_3H_7OOCC_2H_5$ at 29—65°C.[10] From the above data, most of the methanol here can be thought to be formed through reaction (1).

The methanol yield was almost the same both in the presence and in the absence of ethylene. This might indicate that most of the methoxy radicals abstract the hydrogen atom from methyl acetate rather than add to the ethylene (little or no ethyl methyl ether or butyl methyl ether was obtained). Rust *et al.*[7] have also shown that $\cdot OCH_3$ radicals add to cyclohexene scarcely at all.

The formations of methyl vinyl ketone and n-butyl acetate in the presence of ethylene are thought to occur *via* the following reactions:

$$CH_3CO\cdot + \cdot CH{=}CH_2 \rightarrow CH_3COCH{=}CH_2 \quad (3)$$

$$CH_3COO\cdot + CH_2{=}CH_2 \rightarrow CH_3COOCH_2\dot{C}H_2 \quad (4)$$

$$CH_3COOCH_2\dot{C}H_2 + CH_2{=}CH_2 \rightarrow CH_3COO\dot{C}_4H_8 \quad (5)$$

$$CH_3COO\dot{C}_4H_8 + CH_3COOCH_3 \rightarrow CH_3COOC_4H_9 + R\cdot \quad (6)$$

Some of the $CH_3CO\cdot$ or $CH_3COO\cdot$ radicals (though most of these radicals may decompose immediately) may react on a vinyl radical and/or ethylene. The possibility that these reactions occur in a silent discharge has been discussed in connection with the reaction of acetic acid with ethylene previously studied.[1]

Comparison with Radiolysis. The products that were obtained in the decomposition of the methyl acetate excited by the silent discharge were similar to those obtained in the rediolysis;[6] Ausloos and Trumbore have shown that the G-values of the gaseous products are 2.14 (H_2), 1.76 (CH_4), 0.43 (C_2H_6), 2.68 (CO), 1.10 (CO_2), and 0.034 (CH_3OCH_3), and that methanol is the major liquid product.

Interestingly, however, the γ-ray-induced reaction of methyl formate with ethylene[11] has been found to produce the esters, $H(CH_2CH_2)_n COOCH_3$ (n=6.9 on the average), which were not formed by the discharge reaction.

II. The Reaction of Acetic Anhydride. *Influence of Ethylene Addition on the Discharge Reaction of Acetic Anhydride.* As may be seen from Experiments No. 31 and 32 in Table 2, the main liquid products in the silent discharge-induced reaction of acetic anhydride with ethylene were acetaldehyde, acetone, ethyl methyl and n-butyl methyl ketones, diacetyl, and ethyl, n-propyl and n-butyl acetates. The gaseous products were C_1—C_4-hydrocarbons, carbon dioxide and monoxide, and hydrogen.

Most of these compounds were also obtained in the reaction without ethylene (Exp. No. 30), but the distribution of the products was different from that in the reaction without ethylene; also, it was influenced by the molar ratio of the reactants: (1) The highest yields of acetone and diacetyl were in the absence of ethylene; the yields of these products decreased almost linearly with a rise in the ratio of the ethylene to the acetic anhydride concentration. Especially, the acetone yield decreased remarkably at a high ratio. (2) In the presence of ethylene, the yield of ethyl methyl ketone increased. Further, n-butyl acetate and n-butyl methyl ketone, which were not formed in the reaction without ethylene, were obtained; their yields increased slightly with an increase in the ratio of the ethylene to the acetic anhydride concentration.

These results suggest that, in the presence of ethylene, most of the $CH_3CO\cdot$ radicals which did not decompose add to ethylene rather than recombine with the methyl radical. The production of n-butyl acetate in the presence of ethylene may be good evidence for the formation of the $CH_3COO\cdot$ radical as an intermediate.

The Reaction Occurring in the Silent Discharge. The discharge-induced reaction of acetic anhydride is presumed to be chiefly a radical reaction, also. Thus, on the basis of the products, the assumed radicals and a part of the postulated reaction scheme may be formulated as follows:

$$(CH_3CO)_2O^* \rightarrow CH_3CO\cdot(A) + CH_3COO\cdot(B) \quad (7)$$

$$\rightarrow 2\cdot CH_3(C) + CO_2 + CO \quad (\text{or } C_2H_6 + CO_2 + CO) \quad (8)$$

$$\rightarrow 2\,CH_3CO\cdot + \cdot O\cdot(D) \quad (9)$$

where $(CH_3CO)_2O^*$ represents the acetic anhydride excited by the discharge.

The evidence for the occurrence of the A and B radicals in this reaction system has been already

discussed. Moreover, the presence of carbon monoxide and dioxide in the gaseous products may be clear evidence of the production of the excited $CH_3CO\cdot$ and $CH_3COO\cdot$ radicals, which decompose before taking part in any reactions. It has been demonstrated by many workers[9,12,13] that these radicals are rather unstable. Thus, the reactions (7) and (8) are thought to be the most probable primary processes.

The Mechanisms of the Formations of n-Butyl Acetate and n-Butyl Methyl Ketone. The one-to-two adducts, such as *n*-butyl acetate and *n*-butyl methyl ketone, were obtained in the reaction of acetic anhydride with ethylene under the silent discharge. The formation of these telomers may be presented as follows:

$$R\cdot + CH_2{=}CH_2 \rightarrow RCH_2\dot{C}H_2 \quad (10)$$

$$RCH_2\dot{C}H_2 + CH_2{=}CH_2 \rightarrow R(CH_2)_3\dot{C}H_2 \quad (11)$$

$$R(CH_2)_3\dot{C}H_2 + AH \rightarrow R(CH_2)_3CH_3 + A\cdot \quad (12)$$

where R· represents a $CH_3COO\cdot$ or $CH_3CO\cdot$ radical and where AH is any hydrogen donor (most AH's are probably the hydrocarbons produced).

Comparison with Pyrolysis. Szwarc and Murawski[14] have shown that the thermal decomposition of acetic anhydride is not a radical reaction, but a "molecular" process, because equimolecular amounts of ketene and acetic acid are obtained in the pyrolysis of acetic anhydride in a stream of toluene vapor. However, the possibility of this process is not thought to be important in the present study because such products were not obtained.

This difference in reaction paths is not surprising. It has been proposed by Thomas *et al.*[4] that there are essential differences between thermal activation and electrical activation. In the former energy must be put into the entire aggregation of molecules, but in the latter the electron collides with the bonding electrons.

The author wishes to express his thanks to Professor Tamon Matsuura, Hiroshima University, and to Professor Kazuaki Kawamoto, Kagawa University, for their kind advice.

Solvent Effects in the Oxidation of Hydrocarbons. I. Chain Initiation by Azobisisobutyronitrile

Etsuo NIKI, Yoshio KAMIYA and Nobuto OHTA

Department of Fuel Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received March 26, 1969)

The effects of solvents on the rate of decomposition and the efficiency of radical production by AIBN were studied by measuring the rate of evolution of nitrogen from AIBN and the inhibition time in the oxidation of tetralin. The rates of decomposition of AIBN were larger in aromatic solvents than in aliphatic solvents. The efficiency of AIBN was found to depend more on the viscosity of the medium than on the polarity of the solvents. The requirements for the determination of the inhibition time are discussed.

Azobisisobutyronitrile (AIBN) is one of the most widely used initiators for the radical reactions such as autoxidation and polymerization. The mechanism for the initiation by AIBN has been thoroughly studied by numerous investigators and confirmed to proceed by the following equations, where brackets indicate pairs of radicals which have not been separated by diffusion.[1)]

$$\mathrm{AIBN} \xrightarrow{k_i} [2(CH_3)_2(CN)C\cdot] + N_2 \quad (1)$$

$$[2(CH_3)_2(CN)C\cdot] \xrightarrow{k_c} (CH_3)_2C(CN)-C(CN)(CH_3)_2 + \text{disproportionation products} \quad (2)$$

1) C. E. Boozer, G. S. Hammond, C. E. Hamilton and J. N. Sen, *J. Am. Chem. Soc.*, **77**, 3233 (1955).

$$[2(CH_3)_2(CN)C\cdot] \xrightarrow{k_d} 2(CH_3)_2(CN)C\cdot \xrightarrow{O_2} \text{initiate chains} \quad (3)$$

It is known that the efficiency of the radical production by the thermal decomposition of AIBN, which can be expressed as $e=k_d/(k_c+k_d)$, is smaller than unity. This phenomenon has been explained as being due to the geminate recombination of demethylcyanomethyl radical in the solvent cage to from tetramethylsuccinonitrile and the disproportionation product, ketenimine. The solvent effects on the decomposition of AIBN have been studied by several investigators,[2] but a definite conclusion has not yet been obtained. In the course of our study on the solvent effects in the autoxidation of hydrocarbons, the effects of solvents in the initiation step by AIBN had to be elucidated. The rate of decomposition and the efficiency of radical production of AIBN were studied in the various solvents.

Theoretical

The mechanism of the autoxidation of hydrocarbons in the liquid phase at moderate temperature under sufficient oxygen pressure is represented as follows.

$$RH \rightarrow R\cdot \qquad R_i = 2ek_i[AIBN] \quad (4)$$

$$R\cdot + O_2 \rightarrow RO_2\cdot \quad (5)$$

$$RO_2\cdot + RH \xrightarrow{k_p} ROOH + R\cdot \quad (6)$$

$$RO_2\cdot + RO_2\cdot \xrightarrow{k_t} \text{non-radical products} + O_2 \quad (7)$$

When the inhibitor IH is added to the system, the following fast termination step replaces the normal termination reaction (7).

$$RO_2\cdot + IH \xrightarrow{k_{inh}} ROOH + I\cdot \quad (8)$$

$$RO_2\cdot + I \xrightarrow{\text{fast}} ROOI\cdot \quad (9)$$

In this case, the values of ek_i can be obtained by measuring the inhibition time, t_{inh}, using the equation[1]

$$t_{inh} = n[IH]/R_i = n[IH]/2ek_i[AIBN], \quad (10)$$

where n represents the number of peroxy radicals which are scavenged by each inhibitor molecule.

This inhibition method is useful not only for determination of the rate or efficiency of intiation but also for comparing the activities of various inhibitors for polymers, oils, *etc.* It is important to confirm the validity and accuracy of this technique. The two reactions (7) and (8) are competitive and Eq. (10) is applicable only when reactions (8) and (9) replace completely reaction (7). The ratio of the rate of reaction (8) to that of (7) is given by

$$\frac{V_8}{V_7} = \frac{k_{inh}[IH][RO_2\cdot]}{2k_t[RO_2\cdot]^2} = \frac{k_{inh}[IH]}{2k_t[RO_2\cdot]} \quad (11)$$

where V_8 and V_7 represent the rates of reactions (8) and (7) respectively. The steady state treatment for the elementary steps (4), (5), (6), (7), (8) and (9) gives the concentration of the peroxy radical as

$$[RO_2\cdot] = \{-k_{inh}[IH] + (k_{inh}^2[IH]^2 + 2k_tR_i)^{1/2}\}/2k_t \quad (12)$$

Substitution of Eq. (12) into Eq. (11) yields

$$\frac{V_8}{V_7} = \frac{1}{-1+\{1+4ek_ik_t[AIBN]/k_{inh}^2[IH]^2\}^{1/2}} \quad (13)$$

Therefore, the importance of reactions (8) and (7) in the specific reaction system is determined by the value of $[AIBN]/[IH]^2$, and the contribution of reaction (8) decreases with the increase in this value.

Table 1. Contribution of the two termination steps in the oxidation of tetralin at 70°C with 1.00×10^{-2}M AIBN

[IH] M	[AIBN]/[IH]	$[AIBN]/[IH]^2$ M^{-1}	V_8/V_7	Percent of reaction (8)
5.00×10^{-3}	2.0	4.0×10^2	292	99.7
2.00×10^{-3}	5.0	2.5×10^3	48.3	98.0
1.00×10^{-3}	10	1.0×10^4	12.3	92.5
5.00×10^{-4}	20	4.0×10^4	3.40	77.3
2.00×10^{-4}	50	2.5×10^5	0.782	43.9
1.00×10^{-4}	100	1.0×10^6	0.311	23.7
1.00×10^{-5}	1000	1.0×10^8	0.0250	2.45

IH: 2,6-di-*t*-butyl-4-methylphenol

In Table 1 are summarized the calculated values of V_8/V_7 for the oxidation of tetralin at 70° with 1.00×10^{-2}M of AIBN at various concentrations of 2,6-di-*t*-butyl-4-methylphenol (BMP), a well known inhibitor. n was assumed to be 2.0.[3] The value of k_t was taken as 8.0×10^6 *l*/mol/sec, k_{inh} as 7.0×10^3 *l*/mol/sec, e as 0.65, and k_i as 3.96×10^{-5} sec^{-1}, respectively, from literature values.[4] Table 1 shows how the relative contribution of the termination reaction (8) decreases with the decreases in the concentration of the inhibitor. When the relative importance of the termination reaction (7) is not small enough, Eq. (10) is not applied and the value of ek_i thus measured may be unreliable.

TABLE 2. REQUIRED CONCENTRATIONS OF THE INHIBITOR IN THE OXIDATION OF TETRALIN, α-METHYLSTYRENE AND CUMENE AT 70°C, $V_8/V_7 \geqq 40$

[AIBN] M	[IH]≧, M ([AIBN]/[IH]≦) Tetralin	α-Methylstyrene	Cumene
1.00×10^{-1}	5.74×10^{-3} (17.4)	3.04×10^{-3} (32.9)	5.28×10^{-4} (189)
4.00×10^{-2}	3.63×10^{-3} (11.0)	1.92×10^{-3} (20.8)	3.33×10^{-4} (120)
2.00×10^{-2}	2.57×10^{-3} (7.78)	1.36×10^{-3} (14.7)	2.36×10^{-4} (84.7)
1.00×10^{-2}	1.81×10^{-3} (5.52)	9.62×10^{-4} (10.4)	1.67×10^{-4} (59.9)
1.00×10^{-3}	5.74×10^{-4} (1.74)	3.04×10^{-4} (3.29)	5.28×10^{-5} (18.9)

IH: 2,6-*t*-butyl-4-methylphenol

As is clear from Eq. (13), the relative importance of reaction (8) depends also on the value of k_t, *i. e.*, on the hydrocarbons. In Table 2 are shown the calculated concentrations of the inhibitor required to make the value of V_8/V_7 larger than 40, corresponding to 97.5% termination by inhibitor, in the oxidation of tetralin ($k_t=8.0\times10^6$ *l*/mol/sec), α-methylstyrene ($k_t=1.0\times10^6$ *l*/mol/sec), and cumene ($k_t=3.0\times10^4$ *l*/mol/sec) at 70°C with various concentrations of AIBN. The values of k_{inh} for the oxidation of α-methylstyrene and cumene were taken as 4.7×10^3 and 1.6×10^3 *l*/mol/sec, respectively, from the fact that the relative reactivities of tetralylperoxy, α-methylstyrylperoxy and cumylperoxy radicals are in the ratios of 4.5 : 3.0 : 1.0.[4] Table 2 suggests that the required concentration of the inhibitor is largely dependent on the hydrocarbons and the concentration of the initiator.

As described above, the concentrations of AIBN and the inhibitor used in the determination of the inhibition time should be carefully chosen in order to satisfy the above requirements and to obtain accurate and reasonable data. These important conditions seem to have been overlooked until now, and the inhibition time has been determined with an insufficient amount of inhibitor.

Results and Discussion

The rate constant for the unimolecular decomposition of AIBN was determined by measuring the rate of nitrogen evolution. The inhibition time was measured in the oxidation of tetralin using 2,6-di-*t*-butyl-4-methylphenol (BMP) as an inhibitor assuming that 2 radicals reacted with one molecule of inhibitor.[3]

Equation (10) suggests that the inhibition time is proportional to the concentration of the inhibitor and inversely proportional to the concentration of AIBN. Figure 1 shows that the inhibition time in

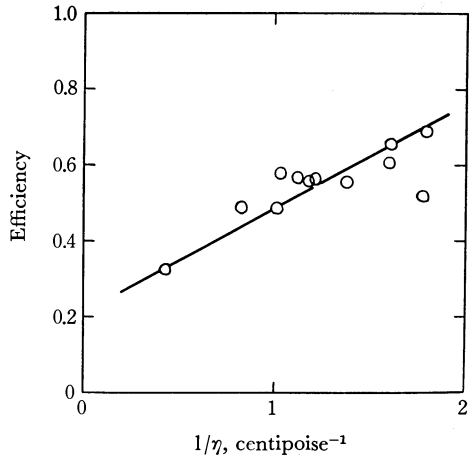

Fig. 2. Plots of efficiency of AIBN as a function of viscosity of the solution.

the oxidation of tetralin in chlorobenzene solvent is inversely proportional to the concentration of AIBN. In addition, Table 3 indicates that the inhibition time is proportional to [IH]/[AIBN]. Since all the solvents used in this study were found to be really inert under the reaction conditions employed here and since sufficient amount of inhibitor was used in the measurement, it may be said that Eq. (10) applies for solvents other than chlorobenzene.

The inhibition time in the oxidations of tetralin in various solvents with added AIBN and BMP is summarized in Table 4. The values of ek_i calculated from Eq. (10), the measured rate constant for the decomposition of AIBN, and calculated efficiency of chain initiation are also included in Table 4. Both k_i and e were reproducible within an experimental error of about 5%. The results indicate that both k_i and e are dependent on the reaction medium. The rate of decomposition of AIBN differs by a factor of 1.54, and is a little higher in an aromatic than in an aliphatic solvent. The efficiency of initiation differs by a factor of 2.10 ranging from 0.33 to 0.69. It depends mostly on the viscosity of the oxidizing solution and is a nearly linear function of the reciprocal of the viscosity, as shown in Fig. 2. Such a correlation has been observed in other systems.[5] However, there is also some contribution to this efficiency from the dielectric constant of the solution: the three solvents that give the greatest positive deviations from the indicated line, nitrobenzene, acetophenone, and diethyl maleate, also have the highest dielectric constants, and in the same order. *n*-Decane, which gives the greatest negative deviation, has the lowest dielectric constant.

Table 5. Inhibition time, rate constant for decomposition and efficiency of AIBN in the oxidation of tetralin in chlorobenzene at 70°C, [AIBN]=0.100M, [BMP]=6.00×10^{-3}M

[Tetralin] M	D	η centipoise	t_{inh} sec	$ek_i\times10^5$ sec^{-1}	$k_i\times10^5$ sec^{-1}	e
7.35	2.657	0.9869	2935	2.02	4.22	0.483
5.88	3.086	0.8424	2650	2.26	4.04	0.559
4.41	3.509	0.7238	2410	2.49	4.47	0.557
2.94	4.017	0.6257	2290	2.62	4.33	0.605
1.47	4.440	0.5568	2140	2.82	4.10	0.668

The effect of dilution by chlorobenzene was also studied. As shown in Table 5, the effect of medium change on k_i is less than the experimental error, and e is approximately a linear function of the reciprocal of the viscosity (Fig. 2).

Experimental

Tetralin and various solvents used were the same as in the previous paper.[6] AIBN and 2,6-di-*t*-butyl-4-methylphenol were recrystallized from methanol several times.

The inhibition time was determined by performing the oxidation of tetralin in a variety of solvents with added inhibitor under atmospheric pressure of oxygen in a constant pressure closed system. The rates of decomposition of AIBN in the various solvents were determined by measuring the rate of nitrogen evolution using a buret connected to the constant closed system under atmospheric pressure of nitrogen. Oxygen which might possibly interfere with the accurate measurement of the nitrogen evolution was carefully eliminated from the system. The viscosity was measured at 70°C with a modified Ostwald viscometer.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 3224—3229 (1969)

Solvent Effects in the Oxidation of Hydrocarbons. II. Oxidations of Tetralin in Various Solvents

Etsuo NIKI, Yoshio KAMIYA and Nobuto OHTA

Department of Fuel Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received March 26, 1969)

The rates of oxidation of 1.47M tetralin in a variety of solvents at 70°C in the presence of 1.00×10^{-2}M AIBN varied by a factor of 2.9, ranging from 6.39×10^{-6} mol/*l*/sec in *n*-decane to 1.84×10^{-5} mol/*l*/sec in nitromethane. The rate of oxidation was dependent on the composition of the solution as well as the kinds of solvents. It was found that the solvents affected the initiation step approximately as much as they affected the propagation and/or temination step. The rate of initiation by AIBN was mainly dependent on the viscosity of the medium, while that of propagation and termination was mainly determined by the dielectric constant of the medium. The correlation between log $(k_p/(2k_t)^{1/2})$ and $(D-1)/(2D+1)$ was discussed, where k_p and k_t are the rate constants for propagation and termination steps, respectively, and D is the dielectric constant of the medium, under conditions where the complication caused by the selective solvation could be excluded.

Although it was once accepted that the solvent effects in the reactions of free radicals and atoms are small in contrast to the ionic reactions, it is known nowadays that the solvent affects both the rate and the course of the free radical reactions.[1,2] The solvent effects in the autoxidation of hydrocarbons, a typical example of the reaction by a free radical mechanism, have been studied by several investigators. Zaikov[3-6] studied the oxidation of methyl ethyl ketone in benzene and acetic acid solutions by varying the compositions of the reactant and the solvents, and found that the rates of oxidation and the rate constants could be well correlated with Kirkwood equation[7]

$$\log(\text{rate or rate constant}) = a(D-1)/(2D+1)+b \quad (1)$$

where D is the dielectric constant of the medium, and a and b are constants. Hendry and Russell,[8] and Howard and Ingold[9] studied the oxidation of several hydrocarbons in a number of solvents and found that the rates of oxidation increased with the increase in the dielectric constants of the solvents. They suggested that the dipolar transition state was involved in the propagation step and the contribution of the solvation at this stage enhanced the rates of propagation and oxidation. They also suggested that the solvation is greater at the ground state than at the transition state in the termination step, which decreased the rate of termination and increased the rate of oxidation.[8]

Since then, several papers concerning the solvent effects on the autoxidation of hydrocarbons have been presented and the correlation between the rates of oxidation and the dielectric function, $(D-1)/(2D+1)$, has been discussed.[10-12]

However, two important problems have been overlooked. One is the variation of the dielectric constant with temperature and the other is the difference between the bulk dielectric constant and the microscopic dielectric constant. In particular, the microscopic dielectric constant in the immediate vicinity of a reactant particle and the existence, extent, and nature of selective solvation have received little attention. This paper deals with the study on the solvent effects in the oxidation of tetralin taking the problems mentioned above into consideration. Tetralin was chosen as the oxidant since its oxidation mechanism is now well established,

and in addition its oxidation rate is greater than those of other hydrocarbons. This is advantageous for studying the oxidation of dilute solutions.

Results and Discussion

The autoxidation of tetralin in a variety of solvents at 70°C initiated by azobisisobutyronitrile (AIBN) were carried out in order to estimate the solvent effects on the rates of oxidation. The results are summarized in Table 1. The observed rates of oxygen absorption were corrected for nitrogen evolved from AIBN and for oxygen absorbed and evolved in the initiation and termination steps respectively, the correction factor being $R_i(1/e-1)/2$ where R_i is the rate of initiation and e is the efficiency of AIBN for radical production.[13] Table 1 indicates that the rates of oxidation of 1.47M tetralin in 35 solvents studied differ by a factor of 2.9, ranging from 6.39×10^{-6} mol/l/sec in n-decane to 1.84×10^{-5} mol/l/sec in nitromethane.

The rates of oxidation are dependent on the composition of the solutions as well. The effects of dilution on the rates of oxidation of tetralin in eight inert solvents, n-decane, butyl stearate, butyric acid, anisole, chlorobenzene, diethyl maleate, acetophenone and nitrobenzene, are summarized in Table 2. The rate of oxidation of tetralin is

Table 2. Effects of dilution in the oxidation of tetrlin in various solvents[a]
70°C, [AIBN] = 1.00×10^{-2}M

Tetralin, M	6.61	5.88	4.41	2.94	1.47	0.668

Nitrobenzene	4.16	4.02	3.19	2.45	1.34	0.614

a) The rate of oxidation of pure tetralin under the same reaction conditions was 3.95×10^{-5} mol/l/sec.

given by the following equation:

$$-dO_2/dt = k_p(2k_t)^{-1/2}[RH]R_i^{1/2} = k_p(ek_i/k_t)^{1/2}[RH][AIBN]^{1/2} \quad (2)$$

where k_i is the rate constant for the unimolecular decomposition of AIBN, and k_p and k_t are the rate constants for the following propagation and termination steps respectively.

$$RO_2\cdot + RH \xrightarrow{k_p} ROOH + R\cdot$$

$$RO_2\cdot + RO_2\cdot \xrightarrow{k_t} \text{tetralone} + \text{tetralol} + O_2$$

Equation (2) implys that the rate of oxidation of tetralin is strictly first with respect to tetralin concentration at a constant initiator concentration. However, plots of the rates of oxidation in Table 2 as a function of tetralin concentration always show some curvature and, as shown in Fig. 1, the values of $k_p(ek_i/k_t)^{1/2}$ calculated from Eq. (2) varies monotonously with the tetralin concentration.

That the rates of oxidation of tetralin are dependent on the nature of the solvents is more clearly established by oxidation in the binary inert solvents media. The rates of oxidation of tetralin in the binary solvents are shown in Fig. 2. A deviation from linearity is again observed for each system, and it is interesting that the curves in nitrobenzene - *n*-decane and nitrobenzene - chlorobenzene systems are convex upward, while that in nitrobenzene-acetophenone system convex downward.

Data in literature and in this work indicate that the rate of oxidation of hydrocarbon increases, as a whole, with the increase in the dielectric constant of the medium. However, with regard to the correlation between the rate of oxidation and the dielectric function, $(D-1)/(2D+1)$, some are satisfactory but others are not. In Fig. 3 are shown the plots of the rates of oxidation of tetralin in Table 1 against the dielectric function of the solvents. Fugure 3 shows that the solvents evidently affect the rates of oxidation but the correlation predicted from Eq. (1) is not applicable.

As shown in Eq. (2), the rate of oxidation is determined by k_p, k_t, e, and k_i at constant concentration of hydrocarbon and initiator. The solvent may affect some or, more probably, all of the above mentioned four constants. The kinetic data for the oxidation of 1.47M tetralin in the various solvents are summarized in Table 3 together with the physical properties of the media measured at 70°C.[14,15] As shown in Table 3, the values of $k_p(ek_i/k_t)^{1/2}$, $(ek_t)^{1/2}$, and $k_p/(2k_t)^{1/2}$ range from 4.35×10^{-5} to 9.12×10^{-5} $l^{1/2}$/mol$^{1/2}$/sec (by a factor of 2.1), from 3.46×10^{-3} to 5.31×10^{-3} sec$^{-1/2}$ (by a factor of 1.5), and from 7.73×10^{-3} to 1.23×10^{-2} $(l$/mol/sec$)^{1/2}$ (by a factor of 1.6), respectively. Thus, in the oxidation of tetralin initiated by AIBN, the solvents give an effect about as much in the initiation step as in the propagation and/or termination step. As discussed in the preceding paper,[15] the

a) Pure tetralin.
b) Dielectric constant of the solution containing 20 vol% tetralin and 80 vol% solvent measured at 70°C.[14]
c) Viscosity of the solution measured at 70°C.[15]
d) Density of the pure solvent at 70°C.
e) Molecular weight of the solvent.

value of k_i was larger in the aromatic solvent than in the aliphatic solvent and that of e was dependent more on the viscosity of the solution rather than its polarity. But the solvent affected e more than k_i and the rate of initiation by AIBN was mainly dependent on the viscosity of the medium.

Before discussing the correlation between $\log(k_p/((2k_t)^{1/2})$ and $(D-1)/(2D+1)$, the error involved in the measurement should be examined. The rates of oxidation of tetralin in various solvents were fairly good in reproducibility. The largest negative and positive deviations from the lines in Fig. 1 are those for the oxidation of 4.41M tetralin in nitrobenzene and 0.668M tetralin in diethyl maleate, the deviations being about 6%. It may be said that the experimental error involved in most of the measurements is within 5%. On the other hand, the values of e and k_i were reproducible within an experimental error of 5%. The physical constants determined for the media may be more accurate. Thus we could say that the results obtained in this work are accurate within an experimental error of 5% and 10% for the worst.

Now we should like to discuss the correlation between $k_p/k_t^{1/2}$ and the dielectric function. If the solvent effects on the propagation and termination[16] steps may be attributed to the solvation of the solvents at the transition state and/or ground state as proposed by Hendry and Russell,[8] and Howard and Ingold,[9] and if both k_p and k_t are expressed in terms of the dielectric function, $(D-1)/(2D+1)$, as in Eq. (1), then logarithm of $k_p/k_t^{1/2}$ should be proportional to $(D-1)/(2D+1)$. In the meantime, tetralin acts not only as a reactant but also as a solvent. The solution has been regarded as a medium of uniform dielectric constant. However, this assumption is not valid when one of the solvents solvates more preferentially than the others. Such a preferential, or selective, solvation has been observed in some cases.[18] In this case, the bulk dielectric constant of the medium is not important, but the microscopic dielectric constant in the immediate vicinity of a reactant particle may be the more important factor in determining the extent of solvation. Although the bulk dielectric constant can be measured, the microscopic dielectric constant can not be measured easily, and the extent of the selective solvation is hard to evaluate from the

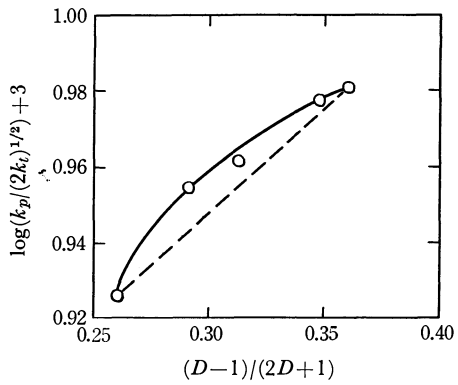

Fig. 4. Plots of $\log(k_p/(2k_t)^{1/2})$in the oxidation of tetralin in chlorobenzene against the dielectric function, 70°C.

16) It is known that the viscosity of the medium has significant effect on the bimolecular interaction of the tertiary peroxy radicals.[17] However, the bimolecular interaction of the tetralylperoxy radicals at 70°C may be all terminating and no free tetraloxy radical should be produced. Therefore, the viscosity of the solution may have little effect on the termination step in the oxidation of tetralin.

conventional kinetic study. If the selective solvation does exist, then the plot of $\log(k_p/(2k_t)^{1/2})$ as a function of $(D-1)/(2D+1)$ should give a curve convex upward. In Fig. 4 is shown the plot of $\log(k_p/(2k_t)^{1/2})$ in the oxidation of tetralin in chlorobenzene, calculated from $k_p(ek_i/k_t)^{1/2}$ and ek_i measured for each mixture,[15] against the dielectric function calculated from the measured dielectric constants of the media at 70°C.[14] The curve is indeed convex upward, but the curvature is small and it is difficult to measure the extent of selective solvation. Although the problem of selective solvation is interesting and important itself, it complicates the situation and it is desirable to disregard the problem discussing the correlation between the rate constant and the dielectric function. One possible approach so as to reduce the effect of selective solvation may be the oxidation of the very dilute reactant in a large excess of solvent. However, the lower the concentration, the smaller the rate of oxidation and the shorter the kinetic chain length, and the radical produced from the initiator may also participate in the terminating reactions, complicating the over-all kinetics.[19] The most suitable method may be the extrapolation to the infinite dilution of the reactant by the solvent. In Fig. 5 is shown the plot of $\log(k_p/(2k_t)^{1/2})$, calculated from $k_p(ek_i/k_t)^{1/2}$ and ek_i extrapolated to the infinite dilution, against the dielectric function of the neat solvent at 70°C. A fairly good linear correlation between the two functions is observed, although $\log(k_p/(2k_t)^{1/2})$ for the aromatic solvents, especially for acetophenone, is somewhat smaller than expected.

Powling and Bernstein[20] introduced the function of $d(D-1)/M(2D+1)$, where d and M are density and molecular weight of the solvent respectively, on the study of the heats of tautomerization of several substances in a variety of solvents on the assumption that the radii of the reactants and the transition state are dependent on the molar volume of the solvent. The plot of $\log(k_p/(2k_t)^{1/2})$ at the infinite dilution against $d(D-1)/M(2D+1)$, however, gave a poorer correlation than that against $(D-1)/(2D+1)$.

In addition to the general dielectric effect some specific interactions between the solute and the solvent such as hydrogen bonding, π-complex and charge transfer complex formations may also participate, to some extent, in the solvent effects. It has been known that the peroxy radical forms hydrogen bonding with the hydroxy group such as water, acid and alcohol. Hendry and Russell[8] observed that the rates of oxidation of cyclohexene and cumene in acetic acid were smaller than anticipated, and they interpreted this as being due to the decrease in the reactivity of the hydrogen-bonded peroxy radical. In the present study, however, the rates of oxidation of tetralin in fatty acids were not small. This might be because although such a hydrogen bonding, if any, would decrease the rate of propagation, it would also decrease the rate of termination. Such a phenomenon was observed experimentally by Zaikov.[5] The formation of π-complex was observed for chlorine atom and alkoxy radical,[1] but this π-complexing may not be so important for the peroxy radical since the electron affinity of the peroxy radical may be smaller than chlorine atom and alkoxy radical.[21] In any event, if the peroxy radical forms complex with the solvent and desolvation is necessary for both propagation and termination steps, both k_p and k_t values are expected to decrease and the effect of complex formation on the over-all rate or on $k_p/(2k_t)^{1/2}$ may in part be cancelled.

In summary, in the oxidation of tetralin initiated

20) J. Powling and H. J. Bernstein, *J. Am. Chem. Soc.*, **73**, 1815, 4353 (1951).

21) The speculation that the π-complex formation between the tetralylperoxy radical and the aromatic solvents should give smaller values for $k_p/(2k_t)^{1/2}$ than expected in Fig. 5 may be ruled out. Because, if so, the decrease should be in the order, anisole>chlorobenzene>nitrobenzene>acetophenone, as predicted by the electron density at the aromatic ring. However, this is not the case as is clear from Fig. 5. This does not necessarily deny the π-complex formation of the peroxy radical, and the information on this complex formation may be obtained by studying the products distribution in the various solvents.

by AIBN the solvents affect approximately as much the initiation step as the propagation and/or termination step. The effects of solvents on the initiation step are mainly determined by the viscosity of the medium, while those on the propagation and/or termination step are mainly dependent on the dielectric constant of the medium.

Experimental

Materials used were the same as in the preceding papers.[14,15] All of the solvents were found to be oxidation resistant under the experimental conditions employed here. Oxidation was performed under atmospheric pressure of oxygen and the oxygen uptake was measured periodically in a constant pressure closed system. Satisfactory and reproducible straight line was obtained.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 3229—3233 (1969)

On the Oxidation of Guaiazulene*1,*2

Kazuko KOHARA

Kōnan Chemical Industry Co., Ltd., Nakagawachō, Takatsuki, Osaka

(Received March 26, 1969)

Guaiazulene was oxidized with potassium permanganate and with selenium dioxide according to the Treibs procedure. An acidic and a neutral crystalline compounds obtained from the permanganate oxidation in acetone were identified by means of UV, IR, and NMR spectrum measurements as 4-methyl-7-isopropylazulene-1-carboxylic acid and 1-formyl-4-methyl-7-isopropylazulene respectively. It was also confirmed that the selenium dioxide oxidation of guaiazulene in acetone gave 3-formylguaiazulene and 3,3′-diguaiazulenylacetone, the chemical structure of which had already been established by Treibs.

In 1957, Treibs[1] reported that guaiazulene (GA) was oxidized in acetone with pulverized potassium permanganate to yield small amounts of an acidic compound, A, and also that the oxidation with selenium dioxide gave compounds B and C. According to the results of the elemental analyses and the visible absorption spectrum measurements, he proposed the structural formula; 2,3-dihydroxyguaiazulene (I), 1-formyl-4-methyl-7-isopropylazulene (II), and 3,3′-diguaiazulenylacetone (III)[2] for the compounds A, B, and C respectively.

In the present work the oxidation of GA was carried out by Treibs procedure in order to prepare these three compounds as reference substances for the thin-layer chromatographic study of the photooxidation of GA.[3] By the selenium dioxide oxidation of GA, compounds B and C were obtained as has been described by Treibs;[1,2] in the case of permanganate oxidation, another neutral compound, D, was obtained together with an acidic compound,

A. The present results of the IR and NMR spectra measurements of these compounds revealed that compounds A, B, and D should correspond to the structures 4-methyl-7-isopropylazulene-1-carboxylic acid (IV), 3-formylguaiazulene (V) and 1-formyl-4-methyl-7-isopropylazulene (II) respectively, and that compound C is III, as was determined by Treibs and Vogt.

Experimental

Measurements. The NMR data were obtained on a Japan Optics Lab. JNM-3H-60 spectrometer using tetramethylsilane as an internal standard. The infrared absorption spectra were recorded on a Shimadzu model IR-27 infrared spectrophotometer. The ultraviolet and visible absorption measurements were carried on a Jasco model ORD/UV-5 recording spectrophotometer.

The plates for thin-layer chromatography were prepared with silica gel G (Merck) and developed with ethyl acetate - *n*-hexane (15 : 85).

Oxidation of GA with Potassium Permanganate. To a solution of 10.0 g of GA in 1000 m*l* of acetone containing 60 m*l* of water, 25 g of powdered potassium permanganate were added in small portions at room temperature. The reaction mixture was then filtered to separate manganese dioxide. By evaporating off the acetone from the filtrate under reduced pressure, a blue, oily product was obtained.

Purification of 4-Methyl-7-isopropylazulene-1-carboxylic Acid (IV). The ether solution of the blue, oily product was extracted with a 2% sodium hydroxide solution, and the alkaline layer was then acidified with hydrochloric acid and extracted again with ether. The deep-red-colored ether extract was washed with a dilute sodium bicarbonate solution and then with water, and dried. The evaporation of ether gave 0.3 g of the acidic compound, A, as red needle crystals, mp 169°C. It was recrystallized from petroleum ether, mp 171°C, and was identified as IV, as will be shown later. Found: C, 78.03; H, 7.18%. Calcd for $C_{15}H_{16}O_2$: C, 78.92; H, 7.07%. Visible: λ_{max} 532, 565, 620 mμ. IR: 1628 cm^{-1} for C=O, 2550 cm^{-1} for O-H (Nujol). Tlc: R_f=0.15 (red).

Methyl 4-Methyl-7-isopropylazulene-1-carboxylate (VI). A tenth of a gram of IV was dissolved in 2 m*l* of anhydrous methanol containing a small amount of sodium. To this solution 0.4 g of methyl sulfate was added, drop by drop, under cooling with ice. The mixture was then poured into water and extracted with ether. The ether solution was dried on sodium sulfate and evaporated to give a red oil. The red oil was purified by chromatography through a silica gel column (Wako gel C-200) with ethyl acetate - *n*-hexane (15 : 85). Found: C, 78.99; H, 7.61%. Calcd for $C_{16}H_{18}O_2$: C, 79.31; H, 7.49%. Visible: λ_{max} 536, 574, 627 mμ. IR: 1692 cm^{-1} for C=O (CCl_4). Tlc: R_f=0.46 (red).

Isolation of 1-Formyl-4-methyl-7-isopropylazulene (II). A neutral oil obtained by the permanganate oxidation was chromatographed on silica gel. About 5.5 g of unreacted GA was eluted with petroleum ether, while several kinds of colored compounds (red, yellowish-green, blue, *etc.*) remained on the column. They could be eluted separately with ethyl acetate - *n*-hexane (15 : 85). A tenth of a gram of the red compound, D, which spotted at R_f=0.52 on a thin-layer was purified by repeated elution chromatography with ethyl acetate - *n*-hexane (15 : 85) on a silica-gel column. Thus, 0.05 g of dark red crystals, mp 60—61°C, was obtained. Found: C, 84.44 H, 7.67%. Calcd for $C_{15}H_{16}O$: C, 84.87; H, 7.60%. Visible: λ_{max} 535, 580 (shoulder), 630 mμ. IR: 1645 cm^{-1} for C=O, 2790, 2700 cm^{-1} for aldehydic C-H (CCl_4). Tlc: R_f=0.52 (red). 2,4-DNP, mp 265—266°C. Found: C, 64.49; H, 5.03; N, 14.20%. Calcd for $C_{21}H_{20}O_4N_4$: C, 64.27; H, 5.14; N, 14.28%.

Oxidation of GA with Selenium Dioxide. A solution of 7 g of SeO_2 in 50 m*l* of water was added, drop by drop, to a solution of 15 g of GA in 1000 m*l* of acetone under ice cooling; the mixture was allowed to stand for 24 hr at room temperature. Meanwhile, the solution changed green from blue. After the neutralization of the mixture with solid sodium carbonate, the solvent was distilled off and the residue was extracted with cyclohexane. A carbonyl compound, C, and a small quantity of an aldehyde, B, were obtained by repeated chromatography with benzene on a silica gel column. Only a small amount of GA was recovered at that time.

3-Formylguaiazulene (V). Compound B (0.1 g) was recrystallized from ethanol as brownish-red crystals, mp 84—86°C. Found: C, 85.14; H, 7.94%. Calcd for $C_{16}H_{18}O$: C, 84.92; H, 8.02%. Visible: λ_{max} 568 mμ IR: 1630 cm^{-1} for C=O, 2680 cm^{-1} for aldehydic C-H (CCl_4). Tlc: R_f=0.28 (brownish-red). 2,4-DNP, mp 181°C. Found: C, 64.82; H, 5.32; N, 13.88%. Calcd for $C_{22}H_{22}O_4N_4$: C, 65.01; H, 5.46; N, 13.79%.

3,3'-Diguaiazulenylacetone (III). Compound C (3.8 g) was recrystallized from *n*-hexane as blue needle crystals, mp 196°C. Found: C, 88.13; H, 8.32%. Calcd for $C_{33}H_{38}O$: C, 87.95; H, 8.50%. Visible: λ_{max} 622, 675 mμ. IR: 1705 cm^{-1} for C=O (Nujol). Tlc: R_f=0.59 (blue).

Results and Discussion

Structure of Acidic Compound A. Treibs[1] proposed the structure I for an acidic compound, A, in view of the position of the visible absorption maximum of compound A and the formation of guaiazulene dimethyl ether-2,3 (compound E) by treating compound A with methyl sulfate.

In the present work, however, a broad absorption of ν_{O-H} near 2550 cm^{-1} (Nujol) and an intense absorption of a hydrogen-bonded carbonyl at 1628 cm^{-1} were found in the infrared spectrum of compound A. Furthermore, the treatment of compound A with methyl sulfate led to the disappearance of the ν_{O-H} absorption and the shift of the $\nu_{C=O}$ absorption to a higher frequency in CCl_4. Moreover, compounds A and E were found to have the visible absorption maximum at 532 and 536 mμ in *n*-hexane respectively (Fig. 2). Hence, it was deduced that the acidic compound, A, should be a carboxylic acid and that compound E should be the methyl ester of compound A.

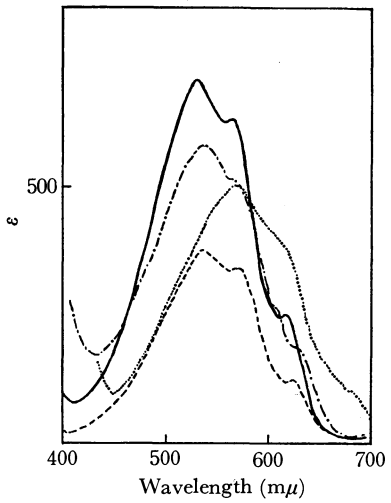

Fig. 2. The visible absorption spectra of compound A(IV)(——), B(V)(·····), D(II)(·-·-) and E(VI)(------) in *n*-hexane.

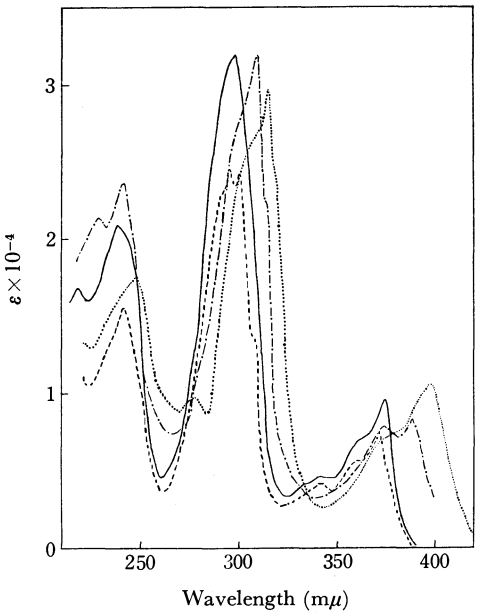

Fig. 3. The ultraviolet absorption spectra of compound A(IV)(——), B(V)(·····), D(II)(·-·-) and E(VI)(------) in *n*-hexane.

The NMR spectra of compounds A and E are shown in Fig. 4. In comparison with the assignment of the NMR spectrum of GA, which had already been reported,[4] it was found that the signal corresponding to one of the two methyl groups of GA disappeared in the spectrum of compound A and that the two signals due to ring protons, H_2 and H_8, shifted considerably to a lower magnetic field compared with those of GA. Those results have lead the present author to conclude that the methyl group in the 1-position was oxidized to a carboxyl group. The signals of ring protons can be assigned as is shown in Fig. 4-a. As the signal at 7.14 ppm, which was not assigned to the ring proton, remains unchanged upon deuterium exchange, it may be assigned to the peak of a proton of $CHCl_3$ in the solvent $CDCl_3$. The signal to be assigned to an acidic proton was not found in Fig. 4-a; this is presumably because of the disappearance of the signal by shifting to a lower magnetic field or by a spectral broadening of the peak. The NMR spectrum of compound E indicated the

presence of an ester methyl (3.89 ppm), a ring methyl (2.84 ppm), and five ring protons which are in just the same positions as those of the carboxylic acid, A. Besides, the chemical shifts of the ester methyl and ring protons (H_2 and H_3) in compound E are in good agreement with those of the methyl 4-methylazulene-1-carboxylate isolated by Meuche *et al.*[5] from natural Moose. From the results above mentioned, it may be deduced that the structures of compounds A and E should correspond to 4-methyl-7-isopropylazulene-1-carboxylic acid (IV) and methyl 4-methyl-7-isopropylazulene-1-carboxylate (VI) respectively. The absorption maxima in the visible region of these compounds satisfy the Plattner rule.[6]

Structure of Compound D. The dark red crystal (mp 60—61°C) obtained from a neutral portion of the reaction mixture in the permanganate oxidation is a new substance which had not been isolated by Treibs or by others. The visible absorption spectrum of compound D showed a maximum at 535 mμ, which shifted by 70 mμ to a shorter wavelength as compared with that of GA at 605 mμ. The UV spectrum of compound D (Fig. 3) showed a maximum at 390 mμ corresponding to carbonyl. The infrared spectrum of compound D also indicates a strong $\nu_{C=O}$ absorption at 1645 cm^{-1} and ν_{C-H} (aldehydic) absorptions at 2790 and 2700 cm^{-1} (CCl_4). In the NMR spectrum of compound D (Fig. 5-a), a methyl proton signal in the 1-position of GA vanished and an aldehydic proton[7,8] appeared at 10.12 ppm. The ring protons are assigned as indicated in the figure from the coupling constants. From these results, it may be concluded that compound D is 1-formyl-4-methyl-7-isopropylazulene (II). It has also been clarified by thin-layer chromatography that this aldehyde is gradually oxidized in CCl_4 to give a carboxylic acid (IV). This structure is also supported by the fact that the absorption maxima of the compound D at 535, 580, and 630 mμ are closely similar to those of lactaroviolin[9—12] at 538, 577, and 633 mμ.

Structure of Compound B. Treibs has reported that an aldehyde, mp 88.5—89.5°C, obtained by the selenium dioxide oxidation of GA corresponds to formula II. As is shown in Fig. 5-b, however, the NMR spectrum of this aldehyde, mp 84—86°C, obtained by the present author showed that two methyl groups and one isopropyl group remained as they were in GA. An aldehydic proton signal[7,8] was found at 10.34 ppm. The formyl group should be situated in the 3-position of the azulene ring, since four ring protons were assigned to H_2, H_5, H_6, and H_8, as is indicated in Fig. 5-b. The R_f value of tlc and the UV, visible, IR, and NMR spectra of compound B were in good agreement with those of 3-formylguaiazulene obtained by means of the formylation of GA,[13] and

The Reaction of Carbon Suboxide with Alicyclic Diketones and with Phenols. Formation and Structure of Pyrone Derivatives

Akira Omori, Noboru Sonoda, Yuzo Uchida and Shigeru Tsutsumi

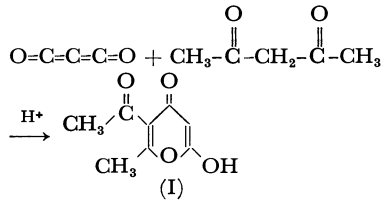
Department of Chemical Technology, Faculty of Engineering, Osaka University, Suita, Osaka

(Received April 7, 1969)

The reactions of carbon suboxide with alicyclic diketones and with phenols were found to give various pyrone derivatives. From the reaction of 5,5-dimethyl-1,3-cyclohexanedione, 4-hydroxy-7,7-dimethyl-5,6,7,8-tetrahydro-2*H*-benzo[*b*]pyran-2,5-dione (II) was produced in the presence of a sulfuric acid catalyst. However, the reaction with 1,2-cyclohexanedione gave the malonic acid diester (III), and the formation of corresponding pyrone was not observed. The reaction of phenols with carbon suboxide gave only esters of malonic acid in the presence of the sulfuric acid catalyst, whereas cyclization to coumarin derivatives occurred on the presence of aluminum trichloride, in addition to the formation of the esters. The structure of the pyrone derivatives and the possible reaction mechanism were discussed.

The reaction of carbonyl compounds with carbon suboxide has been reported by several workers.[1-3] The reaction between carbon suboxide and benzaldehyde was reported to give the benzalmalonic acid benzylidenester,[1] whereas the reaction of carbon suboxide with some ketones produced dipyrone derivatives.[2,3]

In a recent publication,[4] we have reported the reaction of carbon suboxide with acetylacetone in the presence of a sulfuric acid catalyst to produce 3-acetyl-6-hydroxy-2-methyl-4-pyrone (I), (1) while the reaction with aliphatic-1,3-diketones affords dipyrone derivatives.



(1)

(I)

In the present paper, we wish to report on the reaction for the formation of various pyrone derivatives by the reaction of carbon suboxide with alicyclic diketones and with phenols, which have an enol functional group(>C=C(OH)–) in their molecular structure.

Results and Discussion

Reaction of Cyclohexanedione Derivatives. Pyrone (II) was prepared in a 44% yield by the reaction of carbon suboxide with 5,5-dimethyl-1,3-cyclohexanedione at 0—5°C in the presence of a catalytic amount of sulfuric acid (2). However, by the reaction with 1,2-cyclohexanedione, only the malonic acid diester (III) was isolated in a 41% yield under similar conditions (3). In the reaction of 1,4-cyclohexanedione, the dione was recovered almost completely.

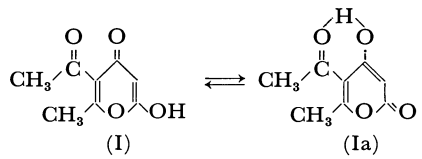
(3)

The pyrone structure of II was confirmed by a study of infrared, ultraviolet, and NMR spectra. The ultraviolet spectrum of II showed two bands, at 232 mμ (log ε, 4.27) and 270 mμ (log ε, 4.13), which were closely similar to those of 5-acetyl-4-hydroxy-6-methyl-2-pyrone (Ia) [225 mμ (log ε, 4.00) and 261 mμ (log ε, 3.91)],[4] characteristic absorptions of the pyrone ring. The infrared spectrum of II in both KBr and a chloroform solution showed a band at 3000 cm^{-1} which suggested the presence of hydrogen bonding, and one at 1742 cm^{-1} due to the carbonyl stretch of α-pyrone. However, the infrared spectrum[4] of I in KBr showed bands at 2600 cm^{-1} (strong hydrogen-bonded ν-OH) and at 1660 cm^{-1} (νC=O of γ-pyrone), but in a chloroform solution they were at 3000 cm^{-1} (hydrogen-bonded ν-OH) and 1739 cm^{-1} (νC=O of α-pyrone). Therefore, I is considered to have a γ-pyrone structure (I) in the solid phase and α-pyrone structure (Ia) in the liquid phase.



Additionally, the hydroxy proton shifts of the NMR spectrum of II in a deuteriochloroform solution were independent of the concentration, as is shown in Table 1.

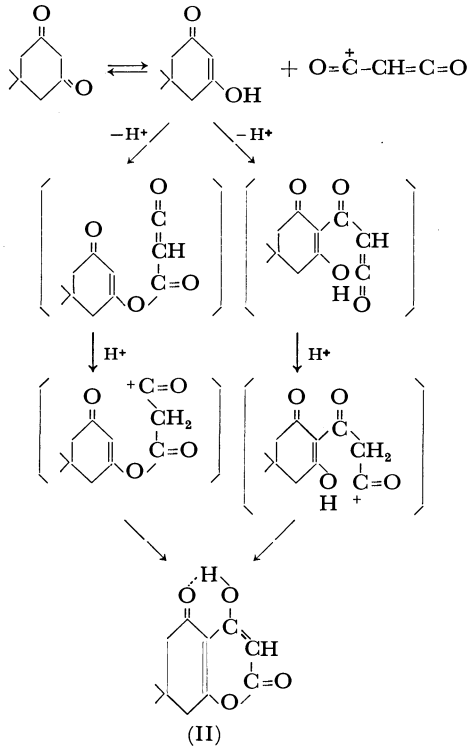
Table 1. Influence of concentrtion on OH shifts*

Concentration	τ Value of OH-proton
1.1%	−1.58
2.5	−1.60
4.5	−1.62

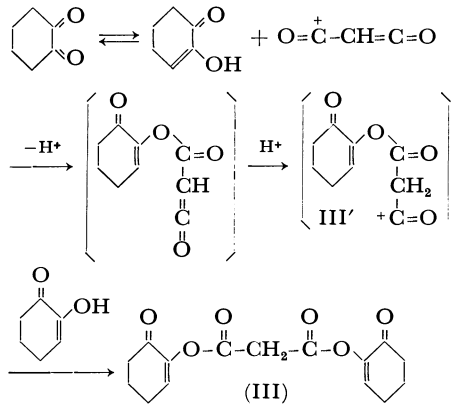
* In $CDCl_3$ Solution at 25°C.

In contrast with the pyrone (I) from acetylacetone, this evidence suggested the α-pyrone structure for the pyrone (II), which had a strong intramolecular hydrogen bond, in both the solid phase and the liquid phase. The structure of III was established by analyses of the infrared, ultraviolet, and NMR spectra. The ultraviolet spectrum of III showed bands at 230 mμ (log ε, 4.27) and 304 mμ (log ε, 2.57) which were similar to the characteristic absorption bands reported for α,β-unsaturated ketone. The infrared and NMR spectra were consistent with those of the malonic acid diester (III).

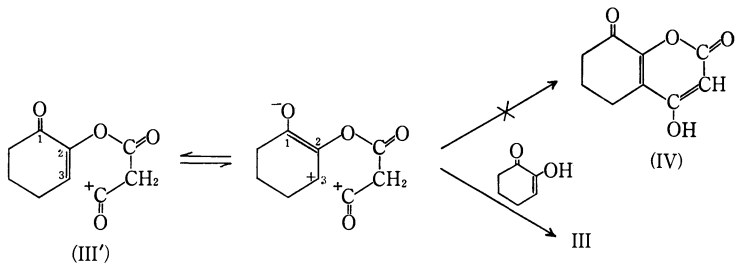
Two pathways for the formation of the pyrone (II) may be worthy of consideration. The first of these may be C-acylation of the enol of dione with protonated carbon suboxide; the alternative pathway may involve the O-acylation as the initial step (Scheme I). However, in the case of 1,2-cyclohexanedione, the formation of the diester(III) of malonic acid indicates that O-acylation occurred preferentially (Scheme II). Therefore, in the case of 1,3-cyclohexanedione, the reaction path may also include O-acylation mainly rather than C-acylation.



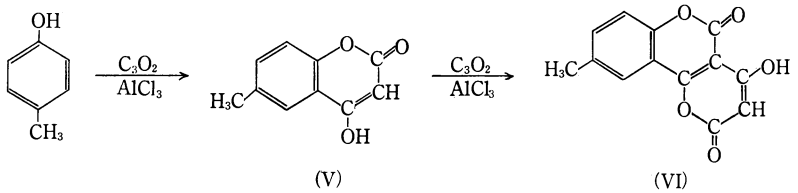
Scheme I



Scheme II



(4)



(5)

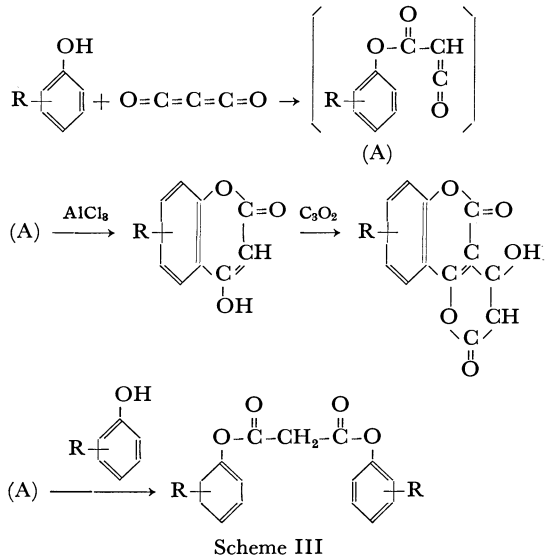
To account for the formation of pyrone(II), a reaction process is proposed which involves an electrophilic attack on the C-2 position by the acyl cation (Scheme I). In the case of the reaction with 1,2-dione, the presence of an electron-withdrawing carbonyl group at the C-1 position in the intermediate (III′) would deactivate the C-3 position toward electrophilic attack (4); consequently, the cyclization to pyrone (IV) is not likely.

Reaction of Phenols. The reaction of carbon suboxide with phenols in the presence of a sulfuric acid catalyst gave only diphenyl malonate derivatives, and no cyclization to coumarin derivatives was observed. However, it was confirmed that, in the presence of aluminum trichloride, the reaction of phenols produced coumarins to some extent at low temperatures. In the case of *p*-cresol, 4-hydroxy-6-methyl-coumarin (V) was obtained in an 8.5% yield in tetrachloroethane plus traces of 4-hydroxy-9-methyl-2*H*,5*H*-pyrano[3,2-*c*]benzo[*b*]-pyran-2,5-dione (VI) and di-*p*-tolyl malonate (5).

The structure of V and VI was confirmed by comparison with an authentic sample or by analyses of the infrared and ultraviolet spectral data. The ultraviolet spectrum of VI showed two bands, at 261 mμ (log ε, 4.16) and 351 mμ (log ε, 4.02), which were closely similar to those reported for 4-hydroxy-7-methyl-2*H*,5*H*-pyrano[3,2-*c*]pyran-2,5-dione[4] [270 mμ (log ε, 3.81) and 330 mμ (log ε, 3.76)], while the infrared spectrum of VI showed bands at 3150 cm^{-1} (-OH), 1745, 1695 cm^{-1} (C=O of lactone, and 1520 cm^{-1} (C=C of dipyrone).

m-Cresol reacted with carbon suboxide to give two isomers, 4-hydroxy-7-methyl-coumarin (VII) and 4-hydroxy-5-methyl-coumarin (VIII); the ratio of the two isomers was determined by the ultraviolet spectrum analysis. The results obtained by the reaction of phenols are shown in Table 2.

The table shows that tetrachloroethane is a better solvent than nitrobenzene for the formation of 4-hydroxy-coumarins. The reaction process for the formation of 4-hydroxy-coumarins may include cyclization to 4-hydroxy-coumarins through an intermediate (A); the further reaction of 4-hydroxy-coumarins with carbon suboxide yielded the pyrono-coumarins (Scheme III).



Scheme III

Experimental

Preparation of Carbon Suboxide. Carbon suboxide was prepared by the pyrolysis[5] of diacetyltartaric anhydride at about 700°C; it was trapped at −78°C in a bath of dry ice-methanol and purified by distillation from trap to trap. The identification of carbon suboxide was established by the preparation of malonanilide by the reaction of carbon suboxide with aniline.

4-Hydroxy-7,7-dimethyl-5,6,7,8-tetrahydro-2*H*-benzo[*b*]pyran-2,5-dione (II). To a solution of carbon suboxide (1.65 g, 0.024 mol) in dry ether (60 m*l*)

and THF (75 m*l*), 5,5-dimethyl-1,3-cyclohexanedione (3.75 g, 0.024 mol) and conc. sulfuric acid (0.02 m*l*) were added at −78°C. The reaction mixture was maintained at 0—5°C for 7 days. The solids (2.4 g, 44%) were then separated on a filter; subsequent recrystallization from ethyl acetate gave the compound II; mp 138—139°C; ν_{max} (KBr and $CHCl_3$) 3000 (broad ν-OH), 1742 (C=O), 1670 (C=O), 1570 (C=C) cm^{-1}; λ_{max}^{EtOH} 232 (log ε, 4.27), 270 (log ε, 4.13) mμ: NMR ($CDCl_3$) τ 8.81 (s, 6H, $-CH_3$), 7.52 (s, 2H, $-CH_2-$), 7.28 (s, 2H, $-CH_2-$), 4.49 (s, H, >C=CH-); enolic -OH group (by $FeCl_3$ test). Found: C, 63.66; H, 5.90%; mol wt ($CHCl_3$ osmotic method), 203. Calcd for $C_{11}H_{12}O_4$: C, 63.45; H, 5.81; mol wt, 208.2.

Bis(6-oxo-1-cyclohexenyl) Malonate (III). To a solution of carbon suboxide (1.2 g, 0.018 mol) in dry ether (100 m*l*), 1,2-cyclohexanedione (4.2 g, 0.038 mol) and conc. sulfuric acid (0.05 m*l* were added at −78°C. The reaction mixture was maintained at 25°C for 1 day. The solids (2.1 g, 41%) were then separated on

a filter; subsequent recrystallization from ethanol gave the compound II; mp 80—81°C; ν_{max}^{KBr} 1760 (C=O), 1685 (C=O), 1650 (C=C) cm^{-1}; λ_{max}^{EtOH} 230 (log ε, 4.27), 304 (log ε, 2.57) mμ; NMR ($CDCl_3$) τ 7.9 (m, 4H, $-CH_2-$), 7.5 (m, 8H, $-CH_2-$), 6.3 (s, 2H, $-\overset{O}{\overset{\|}{C}}-CH_2-\overset{O}{\overset{\|}{C}}-$), 3.4 (t, 2H, $-CH=C\langle$). Found: C, 62.40; H, 5.34%; mol wt (benzene cryoscopic method), 298. Calcd for $C_{15}H_{16}O_6$: C, 61.64; H, 5.52%; mol wt, 292.

4-Hydroxy-coumarin and 4-Hydroxy-2*H*,5*H*-pyrano[3,2-*c*]benzo[*b*]-pyran-2,5-dione. To a solution of phenol (6.1 g, 0.06 mol) in tetrachloroethane (130 m*l*) we added a solution of carbon suboxide (4.4 g, 0.06 mol) in carbon disulfide (20 m*l*) at −44°C under nitrogen; then a solution of $AlCl_3$ (17.3 g, 0.12 mol) in tetrachloroethane (140 m*l*) was stirred into this reaction mixture drop by drop over a period of 2 hr. The reaction mixture was maintained at −44——30°C for 9 hr, at 0°C for 10 hr, and at 25°C for 12 hr, and was then poured into ice water. A solid thus deposited was extracted with a saturated sodium bicarbonate solution, and the solution was acidified. From the non-soluble materials thus separated were isolated ethanol-soluble crystals and non-soluble crystals. The recrystallization of the former from ethanol gave 4-hydroxy-coumarin (0.02 g, 0.2%); mp 203—205°C. From ethanol-non-soluble crystals, 4-hydroxy-2*H*,5*H*-pyrano[3,2-*c*]benzo-[*b*]pyran-2,5-dione (0.13 g, 0.9%) was isolated by crystallization from acetone; mp 241—243°C (decomp.); ν_{max}^{KBr} 3250 (-OH), 1750 (C=O), 1695 (C=O), 1550 (C=C) cm^{-1}; λ_{max}^{EtOH} 260.5 (log ε, 4.19), 339 (log ε, 4.03) mμ; enolic -OH group (by $FeCl_3$ test). Found: C, 62.52; H, 2.71%. Calcd for $C_{12}H_6O_5$: C, 62.62; H, 2.63%. From the tetrachloroethane layer, diphenyl malonate (164—168°C/3.5 mmHg) was obtained; yield 2.3 g (28%).

4-Hydroxy-6-methyl-coumarin (V) and 4-Hydroxy-9-methyl-2*H*,5*H*-pyrano[3,2-*c*]benzo[*b*]pyran-2,5-dione (VI). To a solution of *p*-cresol (8.7 g, 0.08 mol) in tetrachloroethane (150 m*l*) there was added a solution of carbon suboxide (5.5 g, 0.08 mol) in carbon disulfide (20 m*l*) at −44°C under nitrogen; a solution of $AlCl_3$ (21.6 g, 0.16 mol) in tetrachloroethane (130 m*l*) was then stirred into this reaction mixture drop by drop over a period of 2 hr. By treating the reaction mixture as has been described above for the case of phenol, 4-hydroxy-6-methyl-coumarin (V) (1.2 g, 8.4%; mp 247—249°C) and VI (0.1 g, 0.5%; mp 241—243°C (decomp.)) were obtained; ν_{max}^{KBr} 3160 (OH), 1740 (C=O), 1695 (C=O), 1570 (C=C) cm^{-1}; λ_{max}^{EtOH} 261(log ε, 4.16), 351 (log ε, 4.02) mμ. Found: C, 63.90; H, 3.25%. Calcd for $C_{13}H_8O_5$: C, 63.94; H, 3.30%. From a similar organic layer, 1.87 g (16%) of di-*p*-tolyl malonate (181—185°C/3.0 mmHg) was obtained.

4-Hydroxy-8-methyl-coumarin and 4-Hydroxy-7-methyl-2*H*,5*H*-pyrano[3,2-*c*]benzo[*b*]pyran-2,5-dione. To a solution of *o*-cresol (7.0 g, 0.06 mol) in tetrachloroethane (150 m*l*) there was a solution of carbon suboxide (4.4 g, 0.06 mol)in carbon disulfide (20 m*l*) at −44°C under nitrogen; then a solution of $AlCl_3$ (17.3 g, 0.12 mol) in tetrachloroethane (130 m*l*) was stirred into this reaction mixture drop by drop over a period of 2 hr. By treating the reaction mixture as has been described above for the case of phenol, 4-hydroxy-8-methyl-coumarin (0.98 g, 8.6%; mp 231—233°C) and 4-hydroxy-7-methyl-2*H*,5*H*-pyrano[3,2-*c*]-benzo[*b*]pyran-2,5-dione (0.04 g, 0.2%; mp 229—231°C) were obtained; ν_{max}^{KBr} 3220 (-OH), 1740 (C=O), 1715 (C=O), 1570 (C=C) cm^{-1}; λ_{max}^{EtOH} 264 (log ε, 4.23), 348 (log ε, 4.05); Found: C, 64.46; H, 3.19%. Calcd for $C_{13}H_8O_5$: C, 63.94; H, 3.30%. From a similar organic layer, 1.66 g (18%) of di-*o*-tolyl malonate (180—190°C/4.5 mmHg) were obtained.

4-Hydroxy-7-methyl-coumarin (VII) and 4-Hydroxy-5-methyl coumarin (VIII) and 4-Hydroxy-8-methyl- or 4-Hydroxy-10-methyl-2*H*,5*H*-pyrano-[3,2-*c*]benzo[*b*]pyran-2,5-dione (IX). To a solution of *m*-cresol (8.7 g, 0.08 mol) in tetrachloroethane (150 m*l*) there was added a solution of carbon suboxide (5.5 g, 0.08 mol) in carbon disulfide (20 m*l*) at −44°C under nitrogen; then a solution of $AlCl_3$ (21.6 g, 0.16 mol) in tetrachloroethane (170 m*l*) was stirred into this reaction mixture drop by drop over a period of 2 hr. By treating the reaction mixture as has been described above for phenol, VII (1.2 g, 8.6%; mp 214—216°C) and VIII (0.8 g, 5.7%; mp 221—223°C) were obtained. The ratio of the two isomers was determined by the UV spectrum analysis. IX (0.1 g, 0.5%.) was obtained in addition to the two isomers; mp 218—220°C; ν_{max}^{KBr} 3090 (-OH), 1755 (C=O), 1690 (C=O), 1565 (C=C)cm^{-1}; λ_{max}^{EtOH} 266 (log ε, 4.15), 339 (log ε, 4.10) mμ. Found: C, 64.22; H, 3.33%. Calcd for $C_{13}H_8O_5$: C, 63.94; H, 3.30%. From a similar organic layer, 3.91 g (34%) of di-*m*-tolyl malonate (180°C/4.0 mmHg) were obtained.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 3238—3242 (1969)

Characterization and Some Reactions of Peroxy-*trans*-crotonic Acid[1a)]

Ryo Yoshizawa and Takashi Inukai[1b)]

The Central Research Laboratories, Chisso Corporation, Kamariya, Kanazawa-ku, Yokohama

(Received April 14, 1969)

Peroxy-*trans*-crotonic acid was prepared from dicrotonyl peroxide by alkaline cleavage and isolated for the first time in a crystalline state, mp 41—42°C. It was characterized by NMR and IR spectra, and its stability briefly tested. Reaction with dimethyl sulfide gave a quantitative yield of crotonic acid. Its pK_a in water at 25°C was 8.2. Second order rate constants of reaction with crotonaldehyde in benzene (Table 4) were measured: E_a, 13.3 kcal/mol; log A(l/mol sec), 5.3; $\Delta S^{\neq}$, −36 eu/mol. Detection of a possible intermediate, a peracid-aldehyde complex X, was attempted by means of NMR but evidence for it was not obtained.

Peroxycrotonic acid, first prepared by Fichter and Rosenzweig[2)] in an impure liquid form, has remained unidentified, although it has been reasonably assumed to be identical with, and appeared in chemical literature as, the peroxidic intermediate of vapor phase[3)] and liquid phase[4)] autoxidation of crotonaldehyde. Recently some infrared absorption bands were ascribed to the peroxycrotonic acid that was believed to be formed transiently in the course of autoxidation of crotonaldehyde.[5)]

We wish to describe the preparation, characterization, and some reactions of peroxy-*trans*-crotonic acid.

Results and Discussion

Peroxycrotonic acid was prepared from dicrotonyl peroxide by cleavage with sodium methoxide. It is necessary to handle the alkaline solution of the peracid quickly and in the cold, as in the preparation of peroxybenzoic acid,[6,7)] in order to get satisfactory results. Peroxycrotonic acid forms colorless needle crystals which melt at 41—42°C with slow decomposition and flash vividly in free flames. The crystals are stable against fairly strong mechanical shock. In crystalline state the peracid could be stored for longer than one year at −70°C without appreciable deterioration, while at 0—5°C the loss of peroxidic oxygen amounted to 0.5, 4.9, and 14% after periods of 38, 55, and 82 days, respectively. In benzene solution (0.45M) at 30°C the decrease of the iodometric titre was about 1.7% per day in the first week, indicating that its stability is greater[8)] than that of peroxybenzoic acid[7)] under the same conditions.

8) The comparison is only tentative since peracid stability is easily influenced by contamination of metallic impurities.

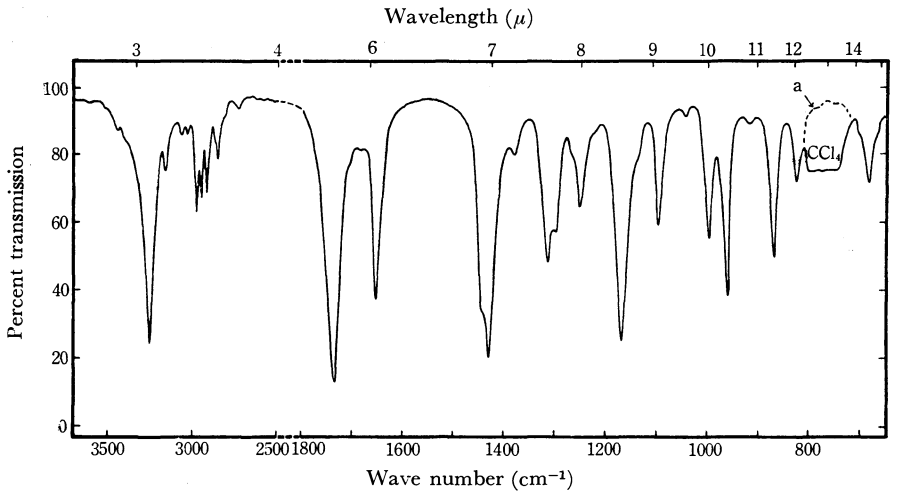

Fig. 1. Infrared absorption spectrum of peroxy-*trans*-crotonic acid in CCl_4: 650—2000 cm^{-1}, 1.0 mol/*l*, 0.025 mm optical length: 2000—4000 cm^{-1}, 0.25 mol/*l*, 0.1 mm optical length. Solvent absorptions are compensated, except in the region 720—810 cm^{-1} where the peracid has no absorption bands in CS_2 solution (curve a), by adjusting the optical length of CCl_4 reference.

Peroxycrotonic acid can be identified by the following observations, 1) the wt% of its peroxidic oxygen agrees with the calculated value, 2) it is quantitatively converted to crotonic acid by reduction with dimethyl sulfide, and 3) its NMR and IR spectra are consistent with the assigned structure.

The NMR parameters are listed, together with those for dicrotonyl peroxide and crotonic acid as authentic references, in Table 1.

The infrared absorption spectrum and the tentative assignment[9] of the principal bands are shown in Fig. 1 and Table 2, respectively. Many of the absorption bands agree with those reported by Deglise and Lemaire[5] for the peroxycrotonic acid intermediate of the autoxidation of crotonaldehyde (Table 2), supporting identity of the substance.

The pK_a of peroxycrotonic acid in water at 25°C (pH of half neutralization) was found to be 8.15. When correction for ionic strength was made, it was calculated to be 8.21. However, it should be noted that pK_a determination of peroxyacids by the acidimetric titration method cannot be accurate since the compounds are unstable.[10] As an example of the present determinations, 15% of the initial peroxidic activity had been lost when pH determination at half neutralization point was finished (in about 15 min at 25°C). Although the pK_a value should be taken as approximate, it is comparable with those of some other peracids as shown in Table 3. The difference in acid strength of a peroxyacid and the parent carboxylic acid is around 3.4 in pK_a units on the average.[11]

The rate of reaction of peroxycrotonic acid with crotonaldehyde in benzene solution forming two moles*1 of crotonic acid was measured by iodometric determination of the remaining peracid. The rate followed the second order kinetics, first order in both reactants, with no induction period within experimental error (Fig. 2). The decrease of the rate caused by the addition of 1,3,5-trinitrobenzene, a stronger inhibitor of radical chain reaction,[12] was real, but to an extent that would permit us to neglect the induced decomposition of the peracid in evaluation of the rate data (Table 4). The least-squares treatment of the Arrhenius equation afforded the following parameters of activation: E_a, 13.3±0.5 kcal/mol; log A (*l*/mol sec), 5.3±0.5

9) For the basis of the assignment see Ref. 5, as well as W. V. F. Brooks and C. M. Haas, *J. Phys. Chem.*, **71**, 650 (1967); D. Swern and L. S. Silbert, *Anal. Chem.*, **35**, 880 (1963); and R. Kavcic, B. Plesnicar and D. Hadzi, *Spectrochim. Acta*, **23A**, 2483 (1967).

(in the absence of trinitrobenzene): and E_a, 13.5± 0.1 kcal/mol; log A (l/mol sec), 5.4±0.1 (in the presence of trinitrobenzene).[13]

From these results we could regard the reaction as a simple bimolecular reaction, where a highly ordered alignment of the reactants in the transition state is implied by the small pre-exponential factor A ($\Delta S^{\neq} = -36$ eu/mol) comparable to that of the Diels-Alder reactions.

Further considerations as to the course of the reaction seem to be required. It is known that peracetic acid and acetaldehyde react to form an isolable complex, "AMP" (X: R=CH_3),[14] which

13) The attached ranges are limits of 95% confidence of the regression analysis.

eventually transforms to two moles of acetic acid. Similar intermediates have been shown spectrometrically in the peroxyheptanoic acid - heptaldehyde[15] and peroxycrotonic acid - heptaldehyde[5] cases. In the cases of peroxybenzoic acid - benzaldehyde and peroxycrotonic acid - crotonaldehyde pairs, however, direct search by infrared spectrometry for the intermediate, X, turned out to be negative,[5,15,16] although X (R=phenyl) was assumed as an intermediate from kinetic studies.[17] Whether

X can accumulate to a detectable concentration or not depends evidently on the ratio of rates of steps i and ii of the particular system under investigation. In an extreme case the structure X can be a representation of the transition state of a single step reaction.

An attempt to detect X (R=CH_3CH=CH–) by NMR was made. As an example, a solution of peroxycrotonic acid (2M) and crotonaldehyde (2M) in methyl acetate was stored at 0°C for 76 hr to accomplish a half conversion of the reactants and the NMR spectrum was taken. No extra absorption, other than those from the reactants and crotonic acid, were observed. A critical examination of the spectrum in order to find an upper limit of the steady state concentration of X did not give a definite conclusion, but it seems that X very probably does not exist in a considerable concentration. This result is in accord with the conclusion by Deglise and Lemaire[5] based on infrared spectroscopic studies.

The contrast between the behavior of saturated aldehydes and the α,β-unsaturated and aromatic aldehydes with regard to the intermediacy of X is ascribed partly to the reduced rate of step i in the latter, because of the loss of conjugative stabilization of the carbonyl group in transforming into hemi-acetal structure X. The effect of unsaturation to the rate of step ii cannot be predicted. From failure to detect X it is inferred that step i is slower than step ii, if X is an unstable intermediate in contrast to the transition state. However, the possibility that a rapid equilibrium between the reactants and X, together with step ii, may give an undetectable steady state concentration of X, cannot be ruled out.[18]

Experimental[19]

Dicrotonyl peroxide was prepared by the method of Tuerck[20] and was purified by recrystallization from petroleum ether; mp 41.3—42.3°C, lit mp 40—41°C,[20] mp 41°C.[2] The peroxidic oxygen as determined by the iodometric titration for dibenzoyl peroxide[6] was 97.9% of the theoretical.

Preparation of Peroxycrotonic Acid. A solution of 17.0 g (0.10 mol) of dicrotonyl peroxide in 70 m*l* of chloroform was placed in a round bottomed flask equipped with a loosely fitted thermometer, and was cooled in a dry ice-acetone bath. To this solution (at *ca.* −65°C) was added an ice cold methanolic sodium methoxide solution, prepared from 2.4 g (0.105 g atom) of sodium and 20 m*l* of absolute methanol, in less than 1 min with swirling. The flask was vigorously shaken in the bath for several seconds and was transferred into an ice-salt bath (−5°C) in which it was vigorously shaken for 4 min.[21] The solution was immediately poured onto 250 g of water containing chopped ice in a separatory funnel, the sodium peroxycrotonate extracted quickly into the aqueous layer, and the chloroform discarded. After washing with two successive 50 m*l* portions of cold chloroform, the aqueous solution was admixed with 50 m*l* of chloroform and 120 g of 5% aqueous sulfuric acid, and the peroxycrotonic acid was extracted with three further 50 m*l* portions of cold chloroform. The combined chloroform extracts were washed twice with water, dried with anhydrous sodium sulfate, and the chloroform was evaporated in a vacuum by a water aspirator to obtain 10 g of white solid of crude peroxyacid as residue. The solid was recrystallized from 100 m*l* of petroleum ether, bp 40—60°C, to obtain fine needles. After storing overnight in a refrigerator, the crystals, 4.5 g, were collected by suction filtration under dry atmosphere: mp 41—42°C. Further crops, 1.4 g, were obtained from the filtrate: total yield, 57.8% of the theory. When the petroleum ether suspension of the peroxyacid is stored in a refrigerator for a week, massive crystals which are easier to handle are obtained.

In a run of smaller scale (0.02 mol) the alkaline cleavage reaction was carried out in an ice bath with similar yield of the product.

The purity of the specimen was determined to be nearly 100% by the iodometric titration or the wt % of the peroxidic oxygen was found to be 15.57%: Calcd for $C_4H_6O_3$, 15.67%.

Reaction with Dimethyl Sulfide. Dimethyl sulfide, 1.0 m*l*, was added dropwise to 1 m*l* of ethyl acetate solution of 0.0450 g of peroxycrotonic acid in a dry ice-acetone bath. After standing in a refrigerator for 1 hr the solution was treated with a slight excess of ethereal diazomethane at −70°C, and was kept overnight at this temperature. The methyl crotonate formed was determined to be 96—99% of theory by quantitative glpc analysis using ethylbenzene as the internal standard. Esterification with diazomethane at 0°C gave erratic results presumably because of the pyrazoline formation.[22]

Kinetic Measurements.[23] A 200 m*l* two-mouthed

18) When this mechanism is adopted the net forward rate of step i should mean the rate of step i of the foregoing description.

19) Melting points are corrected. NMR spectra were taken using a Varian A-60A spectrometer. IR spectra were recorded on a Nihon Bunko Model DS-402G double-beam grating spectrophotometer. A Hitachi-Horiba glass electrode pH meter type M-5, calibrated with pH standard solutions, was used for pH determinations.

20) K. H. W. Tuerck, U. S. Pat. 2379390 (1945); *Chem. Abstr.*, **39**, 4620 (1945).

21) In a few runs in which this procedure was allowed to continue for about 10 min, very poor results were obtained.

22) a) A. Ledwith and D. Parry, *J. Chem. Soc.*, *C*, **1966**, 1408. b) T. V. Van Auken and K. L. Rinehard, Jr., *J. Am. Chem. Soc.*, **84**, 3736 (1962).

23) Commercial crotonaldehyde was dried with anhydrous calcium sulfate and rectified under nitrogen stream; bp 42°C/83 mmHg. Benzene was purified by treatment with concentrated sulfuric acid, dried with calcium chloride, and was distilled from sodium wire.

flask, fitted with a gas-inlet and a stopper, was flushed with dry nitrogen and 50 m*l* of a benzene solution of crotonaldehyde was added and thermostated. While a slow stream of nitrogen, saturated with benzene vapor, was bubbled through the solution, a 50 m*l* benzene solution of peroxycrotonic acid was added to start the reaction, and the system was stoppered under a slight pressure of nitrogen. After appropriate time intervals an aliquot of 10 m*l* was taken out into a flask containing 2 g of potassium iodide, 45 m*l* of water, 5 m*l* of acetic acid, 10 m*l* of chloroform, and a few pieces of dry ice. The liberated iodine was immediately titrated with a standard sodium thiosulfate solution: the end-point was sharp.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 3242—3244 (1969)

Homolytic Chlorination of Aliphatic Compounds. II.[1] Photochlorination of Aliphatic Nitriles

Masanori Kosugi, Kohji Takeuchi and Toshihiko Migita

Department of Chemistry, Gunma University, Kiryu, Gunma

(Received April 16, 1969)

Acetonitrile, propionitrile, *n*-butyronitrile and pivalonitrile were photochlorinated competitively at 40°C in the presence of an appropriate chlorinated ethane, and relative amounts of the chlorinated products were determined by v.p.c. From the results the relative reactivities of C-H bonds toward hydrogen abstraction by chlorine atom were estimated. A linear free energy relationship was observed between σ^* value of X and the reactivity of CH_3–X toward chlorination (X: –CN, $-CH_2CN$, $-CH_2CH_2CN$, $-CMe_2CN$). This indicates that cyano group will affect the reactivities of these C-H bond through its inductive effect.

Orientation of photochlorination of saturated aliphatic nitriles has been studied by Bruylants *et al.*[2] In order to investigate the effect of cyano group on the reactivities of aliphatic chains toward chlorination, we have estimated relative reactivities of acetonitrile, propionitrile, *n*-butyronitrile and pivalonitrile.

Nitriles and the standard substrate were competitively photochlorinated in carbon tetrachloride. The reaction mixture were analyzed for chlorinated products by v.p.c. method. Since a large excess of the substrate was used, the relative reactivities of R_1H and R_2H can be calculated from the molar ratio of R_1Cl and R_2Cl by the equation

$$\frac{k_2}{k_1} = \frac{[R_2Cl]}{[R_1Cl]} \times \frac{[R_1H]_0}{[R_2H]_0},$$

where k_2/k_1 is the ratio of the rate constants for R_2H and R_1H, $[R_2H]_0$ and $[R_1H]_0$ are the initial concentrations of the substrates, and $[R_2Cl]$ and $[R_1Cl]$ are the molar amounts of the chlorinated products. The relative reactivities of C–H bonds were calculated by correcting the relative rate constants for the statistic factors. Unit reactivity was assigned to one of the six available hydrogen atoms of 2,2-dichloropropane. Results are summarized in Table 1.

Table 1. Relative reactivities* of nitriles at 40°C

CH_3——CMe_2CN			
2.7			

* The values are relative to the raeactivity of a C-H bond of 2,2-dichloropropane and average of four runs.

The relative reactivity of acetonitrile toward photochlorination reported by Russell[3] is ten times higher than that we obtained. However, our value is considered to be more plausible. Russell estimated the relative reactivities from the amounts of substrates consumed by competitive reactions. In this technique, considerably high conversions are required. In such circumstances, acetonitrile seems to undergo consecutive chlorination and triazine derivatives formation as shown in the

1) Part I: T. Migita, M. Kosugi and Y. Nagai, This Bulletin, **40**, 920 (1967).

3) G. A. Russell, *J. Am. Chem. Soc.*, **80**, 4997 (1958).

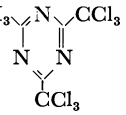
following equations.[4,5]

$$CH_3CN + Cl_2 \xrightarrow{slow} (CH_2ClCN)HCl$$

$$(CH_2ClCN)HCl + Cl_2 \xrightarrow{fast} (CHCl_2CN)HCl + HCl$$

$$(CHCl_2CN)HCl + Cl_2 \xrightarrow{fast} (CCl_3CN)HCl + HCl$$

$$CH_3CN + 2\,CCl_3CN \xrightarrow{HCl}$$



We obtained a considerable amount of 2-methyl-4,6-di-trichloromethyl-1,3,5-triazine in the photo-induced chlorination of acetonitrile at a high conversion. Since acetonitrile is consumed not only by chlorination but also by triazine formation, it would be possible that the relative reactivity obtained from the amount of acetonitrile consumed gives an overestimated value. In our method, such consecutive chlorination might lead us to underestimate the reactivity of acetonitrile, since relative reactivities were derived from the relative amounts of the monochlorinated products. However, the conversion was so small (less than 10%) that the possibility of underestimation due to the consecutive reaction may be negligible.

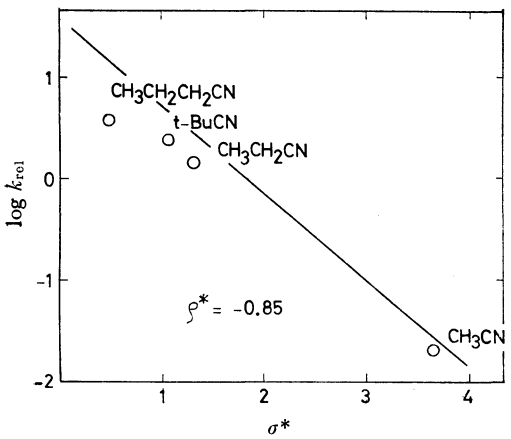


Fig. 1. Hammett plot for CH_3–X. 40°C.

* Estimated by the following relations:
$\sigma^*(CH_2CHCl_2) = 1/2.8\,\sigma^*(CHCl_2)$
$\sigma^*(CMeCl_2) = \sigma^*(CHCl_2) + \sigma^*(Et)$.
Ref. 7, p. 592.

The orientation patterns of chlorination of propionitrile and *n*-butyronitrile were in good agreement with those obtained by Bruylants *et al.*,[2] except for α-position of *n*-butyronitrile. In our experiments formation of α-chloro-*n*-butyronitrile (at least 3—4% of total chlorinated products) was recognized. The structure of the product was derived from its NMR spectra.

As previously reported,[1,6] a linear free energy relationship was found to exist between the reactivities of methyl hydrogen of CH_3–X and Taft's σ^* constants[7] for the substituents X (X: CH_3, CH_2Cl, $CHCl_2$, CCl_3, CH_2CMe_3, CH_2CH_2Cl, CH_2CHCl_2, CH_2CCl_3, CMe_3, CMe_2Cl, $CMeCl_2$). The straight line in Fig. 1 represents Hammett's relationship we obtained previously,[6] ρ^* value being −0.85. As shown in Fig. 1, the same relationship can approximately hold for the chlorina-

tion of the nitriles, when σ^* constants noted in Table 2 are used.

It is quite reasonable that reactivities of β- or γ-C–H bonds of nitriles are represented by Hammett's equation, since a cyano group will affect the reactivities of these C–H bonds through its inductive effect. However, it is noteworthy that the relationship holds even in reactivities of α-C–H bonds. This may indicate that resonance stabilizing effect of a cyano group on an intermediate radical $\dot{R}CHCN$ hardly enhances the reactivity of α-C–H bonds of RCH_2CN.

$$R\text{-}\dot{C}H\text{-}C{\equiv}\overline{N} \longleftrightarrow R\text{-}CH{=}C{=}\overline{\dot{N}}\cdot$$

Experimental

Materials. Acetonitrile and propionitrile (commercial materials) were treated with activated silica gel chromatographically and refluxed over phosphorus pentoxide and then rectified through a Vigreux column. The boiling points were 81°C and 97°C, respectively. *n*-Butyronitrile and pivalonitile were prepared by the dehydration of the corresponding acid amide.[8] The boiling points were 118°C and 105°C, respectively. All the materials were shown by v.p.c. analysis to be pure.

Reaction Products. Monochlorinated products were collected by v.p.c. method and their structures were derived from their NMR spectra. The NMR data are given in Table 3.

2-Methyl-4,6-di-trichloromethyl-1,3,5-triazine was isolated from the chlorination mixture of acetonitrile.[5] Mp 94—95°C. NMR 7.0 (H singlet). Found: C, 22.28; H, 1.18%. Calcd for $C_6H_3N_3Cl_6$: C, 21.84; H, 0.92%.

Competitive Chlorination Procedure. The chlorination procedure has already been described.[1] Analysis of the chlorination products were performed by v.p.c. method employing a 1.5 m Carbowax 20M 25% column. Competitive experiments were carried out on the mixtures of nitriles with an appropriate chloroethanes in carbon tetrachloride solution. The reactivities of C–H bonds of nitriles relative to that of 2,2-dichloropropane were calculated from the data thus obtained on the basis of the reactivity values of chloroethanes.[1]

Since acetonitrile has much lower reactivity than 2,2-dichloropropane, competitive experiments with 2,2-dichloropropane have difficulties in gas chromatographical analysis for determination of reliable relative rates. Acetonitrile was made to compete with 1,1,1-trichloroethane. The rate factor was calculated as,

$$f\left(\frac{MeCN}{MeCCl_2Me}\right) = f\left(\frac{MeCN}{MeCCl_3}\right) \times f\left(\frac{MeCCl_3}{MeCCl_2Me}\right).$$

The results of competitive experiments are shown in Table 4.

Sugars Containing a Carbon-phosphorus Bond. I. Photochemical Addition of Diethyl Thiophosphonate to Unsaturated Sugars

Kazuo KUMAMOTO, Hiroshi YOSHIDA, Tsuyoshi OGATA and Saburo INOKAWA*1

Department of Synthetic Chemistry, Faculty of Engineering, Shizuoka University, Johoku, Hamamatsu

(Received April 26, 1969)

Sugars containing a carbon-phosphorus bond were synthesized by the photochemical addition of diethyl thiophosphonate to unsaturated sugars. By UV illumination from a high-pressure mercury lamp in the presence of diethyl thiophosphonate, D-glucal gave 1,5-anhydro-2-deoxy-2-(diethyl thiophosphonate)-D-glucit; 3-deoxy-1,2;5,6-di-*O*-isopropylidene-α-D-*erythro*-hex-3-enose gave 1,2;5,6-di-*O*-isopropylidene-3-deoxy-3-(diethyl thiophosphonate)-α-D-glucofuranose and 1,2;5,6-di-*O*-isopropylidene-3-deoxy-3-(diethyl thiophosphonate)-α-D-galactofuranose (4:1 mol ratio); 6-*O*-benzyl-5-deoxy-1,2-*O*-isopropylidene-α-D-*xylo*-hexofuran-5-enose gave 6-*O*-benzyl-5-deoxy-5-(diethyl thiophosphonate)-1,2-*O*-isopropylidene-α-D-glucofuranose and 6-*O*-benzyl-5-deoxy-5-(diethyl thiophosphonate)-1,2-*O*-isopropylidene-α-L-idofuranose (2:5 or 5:2 mol ratio), and 5-deoxy-1,2-*O*-isopropylidene-3-*O*-methyl-α-D-xylofuranose-4-ene gave 5-deoxy-5-(diethyl thiophosphonate)-1,2-*O*-isopropylidene-3-*O*-methyl-α-D-xylofuranose.

Recently, a large number of sugars with sulfur and nitrogen atoms directly connected to the carbon chain have been synthesized and investigated not only with regard to their chemical properties, but also with regard to their biological activities. These sugars represent a potentially important area of sugar chemistry.[1] However, sugars with a phosphorus atom connected to the carbon chain are little-known. Exploration of the phosphorus sugars may be expected to provide information leading to another important new area of sugar chemistry.

In order to prepare the phosphorus sugars,[2] an investigation of the addition of diethyl thiophosphonate (DETP) to unsaturated sugars was undertaken. The results will be reported here. As the unsaturated sugars, D-glucal [1], 3-deoxy-1,2; 5,6-di-*O*-isopropylidene-α-D-*erythro*-hex-3-enose [2], 6-*O*-benzyl-5-deoxy-1,2-*O*-isopropylidene-α-D-xylo-hexofuran-5-enose [3], and 5-deoxy-1,2-*O*-isopropylidene-3-*O*-methyl-α-D-xylofuranose-4-ene [4] were used. The structures of the products were determined by studying the NMR spectra and by elementary analyses. The stereoselectivity of the radical addition will also be described.

Experimental

The infrared spectra were measured on a Hitachi-Perkin-Elmer 337 spectrophotometer. The nuclear magnetic resonance spectra were at 60 Mc on a Hitachi-Perkin-Elmer R-20 spectrometer, using tetramethylsilane as the internal reference. The thin-layer chromatograms were run on a silica-layer G[3] using various mixtures of ethyl acetate and petroleum ether, and phosphorus compounds were detected by spraying the plates with a cobalt chloride solution[4] and then heating them. The gas chromatograms were run on Yanagimoto GCG-3D gas chromatograph with a stainless column (2 mm×2 m) packed with Apiezon Grease M[5] (20 wt % on Celite 545 of 40—60 mesh, using H_2 as the carrier gas (100 ml/min) at 200°C. The UV source was a 100-W Halos PIH-100 (high-pressure mercury lamp). Periodic sampling and examination by thin-layer chromatography permitted the determination of the most suitable irradiation times for the preparative runs.

Materials. The D-glucal [1] was prepared by the method of Roth and Pigman;[6] mp 57—59°C. The 3-deoxy-1,2;5,6-di-*O*-isopropylidene-α-D-*erythro*-hex-3-enose [2] was prepared by the method of Schmidt;[7] mp 108—110°C. The 6-*O*-benzyl-1,2-*O*-isopropylidene-α-D-*xylo*-hexofuran-5-enose [3] was prepared by the

method of Gramera and Whistler[8]; mp 113°C. The 5-deoxy-1,2-*O*-isopropylidene-3-*O*-methyl-α-D-xylofuranose-4-ene [4] was prepared by the method of Inokawa *et al.*;[9] bp 80°C/7 mmHg. The diethyl thiophosphonate [DETP] was prepared by the method of Krawiechi and Michalski;[10] bp 73—75°C/14 mmHg, λ_{max} 252 mμ, ε_{max} 162.

1,5-Anhydro-2-deoxy-2-(diethyl thiophosphonate)-D-glucit [5]. A solution of 5 g of [1] and 10 m*l* of DETP in 70 m*l* of dioxane in a reaction vessel was irradiated internally for 10 hr with a high-pressure mercury UV lamp (100 W) under a nitrogen atmosphere with stirring. The solution was then concentrated *in vacuo*; the residue was washed with petroleum ether and recrystallized from ethanol-petroleum ether to give, in a 90% yield(9.5 g), colorless needles of [5]; mp 93—95°C, $[\alpha]_D^{16}$ +23.4° (*c* 10, chloroform).

Found: C, 39.74; H, 7.04%. Calcd for $C_{10}H_{21}O_6PS$: C, 39.99; H, 7.06%.

The acetate; mp 93—95°C (from petroleum ether), $[\alpha]_D^{16}$ +62.5 (*c* 10, chloroform). The ^{1}H NMR data (carbon tetrachloride) were as follows: τ 4.50 (one-proton quartet, $J_{2,3}$=9.0 Hz, $J_{3,4}$=9.0 Hz, $J_{3,P}$=15 Hz, H_3), 5.06 (one-proton triplet, $J_{3,4}$=9.0 Hz, H_4), 5.4—6.7 [nine-proton multiplets, $H_{1,1',5,6'}$, (P-O-CH_2-)$_2$], 6.35 (one-proton multiplet, $J_{1,2}$=4.0 Hz, $J_{1',2}$=9.0 Hz, $J_{2,P}$=25 Hz, H_2), 7.8—7.9 [nine-proton singlets, (CH_3CO)$_3$], and 8.7 [six-proton triplets, (P-O-C-CH_3)$_2$].

1,2;5,6-Di-*O*-isopropylidene-3-deoxy-3-(diethyl thiophosphonate)-α-D-glucofuranose [6] and 1,2;5,6-di-*O*-isopropylidene-3-deoxy-3-(diethyl thiophosphonate)-α-D-galactofuranose [7]. A mixture of 3 g of [2], 6 m*l* of DETP, and 6 m*l* of dioxane in a quartz tube was irradiated for 15 hr from a high-pressure mercury UV lamp (100 W) at a distance of about 3 cm under a nitrogen atmosphere. The mixture was then concentrated *in vacuo*; the residue was dissolved in ether, washed with water, dried over magnesium sulfate, and concentrated *in vacuo* to give an oil. The fractional vacuum distillation of the resulting oil gave, in a 42% yield (2.0 g), a pale yellow oil, a mixture of [6] and [7]; bp 175—177°C/2 mmHg.

Found: C, 48.74; H, 7.61%. Calcd for $C_{16}H_{29}O_7PS$: C, 48.46; H, 7.38%.

This mixture was separated into [6] and [7] by gas chromatography. The mol ratio of [6] and [7] in the mixture was 4 to 1. The product (retention time, 62 min) gave [6], $[\alpha]_D^{16}$ −4.6° (*c* 21, chloroform). The ^{1}H NMR data (carbon tetrachloride) were as follows: τ 4.4 (one-proton doublet, $J_{1,2}$=4.0 Hz, H_1), 5.2 (one-proton multiplet, $J_{3,4}$=2.8 Hz, $J_{4,5}$=4.9 Hz, $J_{4,P}$=14.0 Hz, H_4), 5.5—6.3 [eight-proton multiplets, $H_{2,5,6,6'}$, (P-O-CH_2-)$_2$], 7.3 (one-proton multiplet, $J_{2,3}$=7.0 Hz, $J_{3,4}$=2.8 Hz, $J_{3,P}$=16.0 Hz, H_3), and 8.4—8.9 [eighteen-proton multiplets, C(CH_3)$_2$, (P-O-C-CH_3)$_2$]. The product (retention time, 78 min) gave [7]; $[\alpha]_D^{16}$ −9.3° (*c* 6, chloroform). The ^{1}H NMR data (carbon tetrachloride) were as follows: τ 4.3 (one-proton doublet, $J_{1,2}$=4.0 Hz, H_1), 5.1 (one-proton quartet, $J_{4,5}$=3.5 Hz, $J_{4,P}$=9.0 Hz, H_4), 5.4—6.4 [eight-proton multiplets, $H_{2,5,6,6'}$, (P-O-CH_2-)$_2$], 7.3 (one-proton quartet, $J_{2,3}$=5.0 Hz, $J_{3,P}$=16.0 Hz, H_3], and 8.5—8.8 [eighteen-proton triplets, C(CH_3)$_2$, (P-O-C-CH_3)$_2$].

6-*O*-Benzyl-5-deoxy-5-(diethyl thiophosphonate)-1,2-*O*-isopropylidene-α-D-glucofuranose [8] and 6-*O*-benzyl-5-deoxy-5-(diethyl thiophosphonate)-1,2-*O*-isopropylidene-α-L-idofuranose [9]. A mixture of 1.8 g of [3], 2 m*l* of DETP, and 4 m*l* of dioxane in a quartz tube was irradiated for 5 hr from a high-pressure mercury UV lamp (100 W) at a distance of about 3 cm under a nitrogen atmosphere. The solution was then concentrated *in vacuo*; the residue was dissolved in ether, washed with water, dried over magnesium sulfate, and concentrated *in vacuo* to give an oil. The high-vacuum distillation of the resulting oil gave, in a 55% yield (1.6 g), a pale yellow oil, a mixture of [8] and [9], bp 120—125°C/10^{-3}—10^{-4} mmHg, in company with small amounts of impurities. The mixture was separated into [8] and [9] by thin-layer chromatography using a solvent of ethyl acetate and petroleum ether (1 : 1 v/v). The mol ratio of [8] and [9] in the mixture was 2 to 5 or 5 to 2. The product of R_f 0.6 showed $[\alpha]_D^{16}$ +32° (*c* 17, chloroform). The ^{1}H NMR data (carbon tetrachloride) were as follows: τ 2.7 (five-proton singlet, C_6H_5), 4.2 (one-proton doublet, $J_{1,2}$=4.0 Hz, H_1), 5.5 (two-proton singlet, CH_2Ph), 5.5—6.5 [nine-proton multiplets, $H_{2,3,4,6,6'}$, (P-O-CH_2-)$_2$], 6.8 (one-proton singlet, OH), 7.6 (one-proton multiplet, H_5), and 8.5—9.0 [twelve-proton multiplets, C(CH_3)$_2$, (P-O-C-CH_3)$_2$]. The product of R_f 0.5 showed $[\alpha]_D^{16}$ −13° (*c* 17, chloroform). The ^{1}H NMR data (carbon tetrachloride) were as follows: τ 2.8 (five-proton singlet, C_6H_5), 4.3 (one-proton doublet, $J_{1,2}$=4.0 Hz, H_1), 5.6 (two-proton singlet, CH_2Ph), 5.6—6.5 [nine-proton multiplets, $H_{2,3,4,6,6'}$, (P-O-CH_2-)$_2$], 6.7 (one-proton singlet, OH), 7.5 (one-proton multiplet, H_5), and 8.5—8.8 [twelve-proton multiplets, C(CH_3)$_2$, (P-O-C-CH_3)$_2$].

5-Deoxy-5-(diethyl thiophosphonate)-1,2-*O*-isopropylidene-3-*O*-methyl-α-D-xylofuranose [10]. A mixture of 2.5 g of [4], 5 m*l* of DETP, and 5 m*l* of dioxane in a quartz tube was irradiated for 40 hr from a high-pressure mercury UV lamp (100 W) at a distance of about 3 cm under a nitrogen atmosphere. The mixture was then concentrated *in vacuo*; the residue was dissolved in ether, washed with water, dried over magnesium sulfate, and concentrated *in vacuo* to give an oil. The vacuum distillation of the resulting oil gave, in a 95% yield, a colorless oil; bp 149°C/2 mmHg, $[\alpha]_D^{20}$ −23.2° (*c* 10, carbon tetrachloride).

Found: C, 45.86; H, 7.51%. Calcd for $C_{14}H_{25}O_6PS$: C, 45.88; H, 7.36%. The ^{1}H NMR data (carbon tetrachloride) were as follows: τ 4.3 (one-proton quartet, $J_{1,2}$=4.0 Hz, H_1), 5.6 (one-proton doublet, partially overlapping with H_4; H_2), 4.5—6.2 [five-proton multiplets, partially overlapping with H_3; H_4, (P-O-CH_2-)$_2$], 8.2 (one-proton doublet, partially overlapping with (P-O-CH_2-)$_2$; $J_{3,4}$=1.6 Hz, H_3), 7.6 (two-proton quartet, $J_{4,P}$=16 Hz, H_4), 8.5, 8.8 [six-proton singlets, overlapping with (P-O-C-CH_3); C(CH_3)$_2$], and 8.7 [six-proton triplets, overlapping with C(CH_3)$_2$; (P-O-C-CH_3)$_2$].

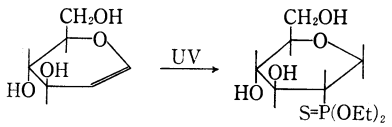
Results and Discussion

According to Pudovik and Konovalova,[11] the radical addition of diethyl thiophosphonate (DETP) to olefins affords a carbon-phosphorus bond. Also, Lehmann has made it clear that the radical addition to an enolic sugar derivative occurs at the β-position[12] to a hydroxyl group. When [1] is exposed to UV radiation in the presence of DETP, a reaction takes place, with the formation of one major product, as is indicated by thin-layer chromatography. The concentration on the solution gave, in a good yield, a solid residue. After recrystallization from ether-petroleum ether, this product was identified as 1,5-anhydro-2-deoxy-2-(diethyl thiophosphonate)-D-glucit [5]. The structure of this product was established by elementary analysis and by a study of the NMR spectrum of its acetate. The coupling constants,[13] $J_{1,2}=4.0$ Hz, $J_{1',2}=9.0$ Hz, and $J_{2,3}=9.0$ Hz, show that a diethyl thiophosphonate group is in an equatorial conformation.



[1] [5]

The compound [2] was exposed to UV radiation in the presence of DETP: the solution was then concentrated *in vacuo* to give, in a good yield, an oil, a mixture of two major products. After purification by vacuum distillation and separation by gas chromatography, they were identified as 1,2; 5,6-di-*O*-isopropylidene-3-deoxy-3-(diethyl thiophosphonate)-α-D-glucofuranose [6] and 1,2; 5,6-di-*O*-isopropylidene-3-deoxy-3-(diethyl thiophosphonate)-α-D-galactofuranose [7]. The structures of these two products were established by elementary analyses and by studies of the NMR specta. It was generally accepted[14] that the *endo*-side of [2] was sterically strongly hindered by the 1,2-*O*-isopropylidene group. Therefore, the diethyl thiophosphonate group should be on the *exo*-side at the C-3 position. The fact that, in these NMR spectra, the coupling constant,[15] $J_{3,4}$, is 2.8 Hz for [6] and practically zero for [7] shows that [6] has the configuration of 1,2-*O*-isopropylidene-α-D-glucofuranose, while [7] has that of 1,2-*O*-isopropylidene-α-D-galactose. The mol ratio of [6] and [7] in the product was 4 to 1.

The compound [3] was exposed to UV radiation in the presence of DETP; the solution was then concentrated *in vacuo* to give an oil containing two major products, as indicated by thin-layer chromatography. After purification by high-vacuum distillation and separation by thin-layer chromatography, these products were identified as 6-*O*-benzyl-5-deoxy-5-(diethyl thiophosphonate)-1,2-*O*-isopropylidene-α-D-glucofuranose [8]*2 and 6-*O*-benzyl-5-deoxy-5-(diethyl thiophosphonate)-1,2-*O*-isopropylidene-α-L-idofuranose [9].*2 The structure of these products were established by a study of the NMR spectra. The NMR spectra of these two products are very similar and shown that the number of hydrogen atoms at the carbon-bearing phosphorus is one. The optical rotations differed by $+32°$ and $-13°$ respectively. However, from the present results, it seems to be difficult to identify either of the two products as [8] or [9]. The mol ratio of the two products was 5 to 2.

The compound [4] was exposed to UV radiation in the presence of DETP; the solution was then concentrated *in vacuo* to give, in an almost quantitative yield, an oil containing one product, as indicated by thin-layer chromatography. After vacuum distillation, this product was identified as 5-deoxy-

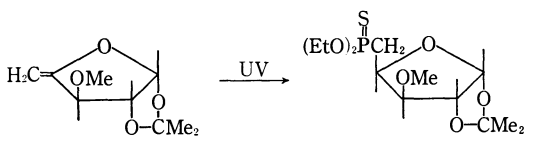
*2 The product still contained a small amount of impurities.



[4] [10]

5-(diethyl thiophosphonate)-1,2-*O*-isopropylidene-3-*O*-methyl-α-D-xylofuranose [10]. The structure of this product was established by elementary analysis and by a study of the NMR spectrum. The coupling constant, $J_{3,4}=1.6$ Hz, in the NMR spectrum and the finding that the photochemical addition of benzyl mercaptan to [4] gave only one product, 5-benzylthio-5-deoxy-1,2-*O*-isopropylidene-3-*O*-methyl-α-D-xylofuranose,[9] show that [10] has the configuration of xylofuranose.

The results described above are summarized in Table 1.

The authors express their sincere thanks to Professor R. L. Whistler of Purdue University for his continued interest in this work and to Professor S. Kunichika of Kyoto University for carrying out elementary analyses. They are also grateful to Hashimoto Kaseikogyo, Ltd. for supplying them silver fluoride.

One-Electron Reduction of Carbonium Ions. II. Reduction of the Tropylium Ion and the Triphenylmethyl Cation with Metallic Powders and Metallic Ions*1

Kunio OKAMOTO, Kôichi KOMATSU and Haruo SHINGU

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Yoshida, Sakyo-ku, Kyoto

(Received April 28, 1969)

The reaction of tropylium fluoroborate in an aqueous solution has been carried out at room temperature with powders of various metals (Mg, Al, Mn, Zn, Cr, Fe, Cd, Co, Ni, Sn, Pb, Sb, Cu, Hg, and Ag) under heterogeneous conditions and with several metallic ions (Cr(II), Ti(III), Sn(II), Cu(I), Fe(II), Fe(III), Hg(I), Hg(II), and Ag(I)) in a homogeneous solution. All these reagents, except Ag, Fe(III), Hg(I), Hg(II), and Ag(I), reduce with ease the tropylium ion to give the tropyl radical, which then rapidly couples to bitropyl; their reducing powers, estimated by comparing the yields of bitropyl under the same reaction conditions, correlate with their oxidation electrode potentials and oxidation-reduction potentials. The ferric ion, the mercurous ion, the mercuric ion, and the silver ion afforded no bitropyl, but only an oxidation product of the tropylium ion, *i.e.*, benzaldehyde. Silver powder gives neither a reduction nor an oxidation product under these reaction conditions. The reduction has also been carried out in an acetonitrile solution, and the reducibility of tropylium fluoroborate with powders of Zn, Fe, Ni, Sb, Cu, and Ag has been compared with that of triphenylmethyl fluoroborate under heterogeneous conditions. Both the tropylium ion and the triphenylmethyl cation are smoothly reduced by Zn, Fe, Ni, Sb, and Cu in this solvent. The tropylium ion, however, is not reduced by silver powder, while the triphenylmethyl cation is reduced to the triphenylmethyl radical. This greater reducibility of the triphenylmethyl cation is consistent with what could be anticipated from the data of half-wave potentials, ionization potentials, and H.M.O. calculation reported with respect to these two carbonium ions.

Although the reactivity scale of carbonium ions in a one-electron reduction in the gaseous phase has araised much theoretical interest in association with the ionization potential of organic radicals to carbonium ions,[1] relatively little attention has been devoted to the reducibility scale in solutions, and the range of carbonium-ion structures investigated is quite small. Heretofore, the tropylium ion[2] and the triarylcyclopropenyl[3] and polyarylmethyl cations[2c-4] have been reported to be carbonium ions whose reducibilities in the liquid phase have been determined by a polarographical method[2,3] and by the measurement of the reversible-electrode reduction potentials of the solutions of carbonium ions and the corresponding redicals.[4] Thus, a systematic investigation into the reducibility scale in solution for other carbonium ions with a wide range of structures should be of considerable interest. However, preliminary to a systematic scrutiny of the carbonium-ion structure, the exploration of simple reducing agents with a wide range of applicability is needed because of the restricted applicability of the electrochemical measurements.[2-4]

As for the reducing agents of the carbonium ions, Conant and his collaborators[5] first demonstrated that the vanadous ion reduces serveal stable polyarylmethyl cations. There have since been employed such reductants as the chromous ion,[6] zinc,[7]

ferrocene,[8] tetraphenyl-*p*-xylylene,[9] the dinegative ion of cyclooctatetraene,[10] carbazole,[11] phenylenediamine,[11] the triphenylmethyl radical,[12] and others.[13] Among these reducing agents we chose various metals and low-valent metallic ions with the idea that these reducing agents would show various degrees of reducing power, which would correlate with their oxidation electrode potentials and oxidation-reduction potentials, and that a spectrum of the percentage yields of the reduction products would reflect the intrinsic reducibility of the carbonium ion concerned. In this paper we will report on the results of the reduction of the tropylium ion and of the triphenylmethyl cation with these reductants in aqueous and in acetonitrile solutions and will discuss the applicability of the spectrum of the radical yields as a measure for estimating the reducibility of the respective stable carbonium ions.

Reduction of the Tropylium Ion in an Aqueous Solution with Metallic Powders. A 0.1N solution of tropylium fluoroborate in 0.1N hydrochloric acid[14] was treated with various metallic powders at room temperature for ten minutes. As Doering and Knox[7] found in zinc-dust reduction, most of the metals examined (see Table 1) were found to reduce the tropylium ion to bitropyl readily. As Table 1 shows, magnesium, aluminum, manganese, zinc, iron, cadmium, cobalt, tin, lead, and antimony afforded bitropyl in fairly good yields, whereas the yield of bitropyl was poor in the cases of chromium (1%), nickel (0.4%), copper (0.2%), and mercury (0.03%). In each reduction only the unchanged tropylium ion was identified as an organic compound other than bitropyl, and a good material balance (>94%) was obtained. Since these reductions were carried out under heterogeneous conditions and with metals of various grain sizes, the percentage yields of bitropyl might not exactly reflect the intrinsic reducing powers of these metals. However, an examination of the standard oxidation electrode potentials of these metals reveals that there exists a correlation between the spectra of the values of the bitropyl yield and of the oxidation electrode potentials of these metals; that is, under these reduction conditions the reducibility of the tropylium ion seems to correspond to the values of the oxidation electrode potential between those of mercury and silver, *i. e.*, −0.789 and −0.799 V.

Table 1. The reduction of the tropylium ion in the aqueous solution with metallic powders at 21—31°C[a]

Metal (mesh)	Oxidation potential[b] (V)	Bitropyl Yield (%)	Tropylium ion, unchanged[e] (%)
Mg (200—250)	2.37	92	3.2
Al (200—250)	1.66	99	0.0
Mn (>400)	1.18	98	1.8
Zn (>400)	0.763	100	0.0
Cr (200—250)	0.74	1.0	99
Fe (200—250)	0.440	20	79
Cd (>200)	0.403	26	73
Co (>250)	0.277	94	0.0
Ni (>400)	0.250	0.4[d]	95
Sn (>400)	0.136	100	0.0
Pb (200—250)	0.126	60	41
Sb (200—250)	−0.212	5.4	94
Cu (200—250)	−0.521	0.2[d]	95
Hg (liq.)[c]	−0.789	0.03[d]	99
Ag (≷200)	−0.799	0.0[d]	99

a) Except when otherwise noted, all reactions were conducted with about 15 molar equivalents of metallic powder under an atomosphere of nitrogen for ten minutes, aqueous hydrochloric acid (0.1N) being used as the solvent. Initial concentration of tropylium fluoroborate was 0.100N.
b) W. M. Latimer, "Oxidation Potentials," Prentice-Hall (1952).
c) The reaction was carried out for 30 min with 50 molar equivalents of mercury, aqueous nitric acid (0.1N) being used as the solvent.
d) Estimated by t.l.c. analysis.
e) Determined by UV spectrophotometry.

Reduction of the Tropylium Ion in an Aqueous Solution with Low-Valent Metallic Ions. An aqueous 0.1N hydrochloric acid solution of tropylium fluoroborate (0.1N) was treated with about three equivalents of various metallic ions at room temperature under an atmosphere of nitrogen. As is shown in Table 2, bitropyl was readily obtained as the sole product in the reductions with chromous[15] and titanous ions, whereas it was obtained in poor yields in the reduction with stannous, cuprous, and ferrous ions. However, the mercurous ion, which oxidation-reduction potential is the lowest among the ions examined,

afforded no detectable amounts of bitropyl, but an oxidation product of the tropylium ion, *i. e.*, benzaldehyde,[16,17)] in the 35% yield. Furthermore, in this reaction the mercurous ion was reduced to metallic mercury by the tropylium ion. The formation of benzaldehyde due to the oxidation of the tropylium ion was also observed in the reaction with mercuric, ferric, and silver ions in yields of 46, 9.3, and ~1% respectively (Table 2). Thus, as in the case of metallic powder reduction under heterogeneous conditions, the correlation between the reducing power of low-valent metallic ions, as measured by the use of the yields of bitropyl, and of the oxidation-reduction potential of these metallic ions seems to be fairly good; in Table 2 it is clearly demonstrated that the tropylium ion in an aqueous solution can be reduced by the ions with oxidation-reduction potentials with values higher than that of the ferrous ion, and that under these reaction conditions the oxidation-reduction potential of the tropylium ion seems to be just between those of ferrous and mercurous ions, *i. e.*, −0.771 and −0.920 V.

Reduction of the Tropylium Ion and the Triphenylmethyl Cation in an Acetonitrile Solution with Metallic Powders. Since it has been demonstrated for the tropylium ion that its reducibility can be estimated by the use of a spectrum of bitropyl yields in the reduction with various metallic powders, the reducibility of the other carbonium ion was examined by the use of this method. Among the other carbonium ions the triphenylmethyl cation was chosen as a representative carbonium ion, which is stable in an acetonitrile solution. For purposes of comparison, the tropylium ion was reduced also in an acetonitrile solution. In each reduction the respective carbonium ions were allowed to react with 15 molar equivalents of various metallic powders under exactly the same reaction conditions as those employed in the experiments with the tropylium ion in an aqueous solution.

The spectrum of the yields of the reduction product is shown in Table 3, along with the values for the oxidation-electrode potentials of metals and the half-wave potentials of the respective metallic ions in an acetonitrile solution.

In an acetonitrile solution the triphenylmethyl cation was smoothly reduced by zinc dust to the triphenylmethyl radical, which was identified as triphenylmethyl peroxide and a minor amount of benzophenone after its oxidation by air. Similarly, the tropylium ion in acetonitrile was readily reduced by zinc dust to bitropyl, as was observed in an aqueous solution. Iron powder and copper powder also reduced each carbonium ion with ease. It is of interest to note that the yield of bitropyl in copper reduction increased from 0.2% in an aqueous solution (Table 1) to 100% in acetonitrile (Table 3). This dramatic increase in the yield may be a reflection of an intrinsic increase in the reducing power of copper in acetonitrile, as is shown by the relatively higher values of the oxidation-electrode potential of the metal and the half-wave potential of the ion (Table 3), values which

16) It is reported that the tropylium ion is oxidized to benzaldehyde by bromine in absolute alcohol,[17)] by dilute aqueous permanganate,[17)] by chromic acid in acetic acid,[7)] and by silver oxide in water.[7)]

are closely related to the stabilization of the cuprous ion caused by the strong solvation by the acetonitrile molecules (see the references cited in Table 3).

As has been shown in an aqueous solution, nickel and antimony, which have relatively lower oxidation-electrode potentials, were found to have low reducing powers in acetonitrile for each carbonium ion, this being shown in the low yields of the reduction product from each carbonium ion (Table 3).

Silver did not show any reducing power to the tropylium ion under these reaction conditions; this is a result similar to that observed in an aqueous solution (Tables 1 and 3). In contrast to this, the triphenylmethyl cation was easily reduced by silver powder, indicating that this cation is more reducible than the tropylium ion (Table 3).

The ready reducibility of the triphenylmethyl cation observed in these experiments is consistent with the following reactivity sequence of these two cations: (a) the half-wave potentials of the tropylium ion and the triphenylmethyl cation, measured in methylene dichloride by direct-current polarography, are estimated to be −0.45 and −0.135 V respectively,[2c)] showing the ready reducibility of the latter cation; (b) the ionization potentials of tropyl and triphenylmethyl radicals in the gaseous phase are determined to be 6.60 and 7.25 eV[18)] respectively, indicating that the former radical is more easily transformed into the tropylium ion (in other words, the tropylium ion is less reducible). The loss of delocalization energy resulting when the tropylium ion is converted to the tropyl radical is calculated to be $-0.45\,\beta$ (from the simple H.M.O. theory),[19)] whereas between the triphenylmethyl cation and radical there exists no difference in delocalization energy. When we assume that the reducibility of the cation is governed by the difference in the electronic stabilization (delocalization) energy between the carbonium ion and the corresponding radical, this reslut of calculation is also consistent with the ready reducibility of the triphenylmethyl cation.

20) The infrared and the ultraviolet spectra were obtained from Shimadzu models, an IR-27 spectrometer and a UV-50M spectrometer respectively.

fluoroboric acid. Tropilidene was prepared by the reaction of a large excess of benzene with diazomethane in the presence of cuprous bromide as a catalyst, according to the method of Müller and Fricke.[22] Triphenylmethyl fluoroborate was prepared by the reaction of triphenylcarbinol with aqueous fluoroboric acid in propionic anhydride, according to the method of Dauben *et al.*[23] Acetonitrile was refluxed over phosphorus pentoxide and distilled; bp 80.8—81.2°C. For all the inorganic reagents, except silver powder, commercial materials were used as received. Metallic silver was prepared by the reduction of silver nitrate with saccharose, as has been described by Brauer,[24] while metallic copper employed was the electrolytically-prepared material supplied by the E. Merck Co.

The Reduction of the Tropylium Ion in an Aqueous Solution with Metallic Powders. The results are shown in Table 1; the details of the procedure are illustrated in the following description of a representative run with metallic iron.

The Reduction of the Tropylium Ion in an Aqueous Solution with Iron. In a 50-m*l*, round-bottomed flask equipped with a magnetic stirring bar, a thermometer, and a nitrogen inlet and outlet, 0.399 g of tropylium fluoroborate (2.24 mmol) was dissolved in 22.4 m*l* of 0.1N aqueous hydrochloric acid to give a clear, colorless solution. To the stirred solution of the tropylium ion there was then added a 1.865-g portion of iron powder (200—250 mesh) (33.4 mg atom) under an atmosphere of nitrogen at 30.8°C. The reaction temperature immediately rose by 1.1°C and remained almost constant for 10 min. The reaction mixture was then filtered and washed with three 5-m*l* portions of 0.1N aqueous hydrochloric acid and with five 10-m*l* portions of ether. The amount of the unchanged tropylium ion in the aqueous layer was estimated from the ultraviolet absorbance of the tropylium ion ($\lambda_{max}^{0.1NHCl}$ 219 and 275 mμ); 79.4% of the charged ion. The organic layer was washed once with 40 m*l* of 5% aqueous sodium carbonate and twice with 40 m*l* of 10% aqueous sodium chloride, dried over magnesium sulfate, concentrated by distillation, and evaporated *in vacuo* to give 0.0407 g of bitropyl (0.224 mmol, 20.0% yield), identified by the superimposability of the infrared spectrum on that of the authentic sample.

The Reduction of the Tropylium Ion in an Aqueous Solution with Low-Valent Metallic Ions. The results are shown in Table 2; the details of the procedure are illustrated in the following description of a run which affords a small amount (<1% yield) of the reduction product.

The Reduction of the Tropylium Ion in an Aqueous Solution with Ferrous Chloride. In a 50-m*l*, round-bottomed flask equipped with a magnetic stirring bar, a thermometer, a rubber serum bottle cap, and a nitrogen inlet and outlet, 0.322 g of tropylium fluoroborate (1.81 mmol) was dissolved in 6.0 m*l* of 0.1N aqueous hydrochloric acid and then kept under an atmosphere of nitrogen. The aqueous solution of ferrous chloride was prepared by dissolving 1.067 g of $FeCl_2 \cdot 4H_2O$ (5.37 mmol) in 12.1 m*l* of 0.1N aqueous hydrochloric acid. The ferrous chloride solution was added with a syringe through the rubber serum cap to a stirred solution of tropylium fluoroborate. A specific change in neither the color nor reaction temperature was observed. The solution was stirred under nitrogen at 18.0—20.0°C for two hours and then extracted with three 20-m*l* portions of ether. The amount of the unchanged tropylium ion was determined from the ultraviolet absorbance (*vide supra*) of the aqueous layer (102% of the charged tropylium ion). The organic layer was washed with a 40-m*l* portion of 5% aqueous sodium carbonate and with two 50-m*l* portions of 10% aqueous sodium chloride, and was then dried over magnesium sulfate. The dried ethereal solution was concentrated and evaporated *in vacuo* to give 0.0027 g of a colorless oil, which was shown to be a mixture of bitropyl, benzaldehyde, and other minor components by a study of the infrared spectrum. The t.l.c. analysis of the oily product with the authentic bitropyl showed that the bitropyl content was *ca.* 38 wt% of the oil; 0.0055 mmol, 0.6% yield, based on the charged tropylium ion.

The Reduction of the Tropylium Ion and the Triphenylmethyl Cation in an Acetonitrile Solution with Metallic Powders. The results are shown in Table 3; the reaction of the tropylium ion with the metallic powder was carried out at room temperature for 10 min under nitrogen and worked up in a manner similar to that described above. The details of the procedure in the reaction of the triphenylmethyl cation are illustrated in the following description of a representative run with metallic iron.

The Reduction of the Triphenylmethyl Cation in an Acetonitrile Solution with Iron. In a 50-m*l*, round-bottomed flask equipped with a magnetic stirrer, a thermometer, and a nitrogen inlet and outlet there was placed a 0.504-g portion of triphenylmethyl fluoroborate (1.53 mmol). In a stream of nitrogen 15.3 m*l* of acetonitrile was added, and a clear, orange colored solution was obtained by magnetic stirring; the initial concentration of the triphenylmethyl cation was 0.100N. To the stirred solution there was then added a 1.299-g portion of iron powder (150—250 mesh) (23.3 mg atom) under an atmosphere of nitrogen at 20.5°C. The reaction temperature rose by 4.1°C within two minutes and remained almost constant for the rest of the reaction time. With the increase in the temperature, it was observed that a white precipitate appeared and was dispersed throughout the reaction vessel. After the reaction time of 10 min, 10-m*l* portions of water and ether were added to the reaction mixture with continuous stirring in order to stop the reaction by the hydrolysis of the unchanged cation. The reaction mixture was filtered and washed with three 10-m*l* portions of ether in a stream of nitrogen. Air was then bubbled into the pale yellow organic layer. A white precipitate was formed with the simultaneous disappearance of the yellow color of the solution. This precipitate was filtered, washed with ether, and dried at 60°C under reduced pressure (5 mmHg) to give 0.272 g of white, powdery crystals, identified as triphenylmethyl peroxide by the superimposability of the infrared spectrum; 0.524 mmol, 68.6% yield. The organic layer of the

Intermolecular Hydrogen Bond Involving a π Base as the Proton Acceptor. VI. Hydrogen Bonding of Phenols and Naphthols to Aromatic Hydrocarbons. Entropy Anomaly and the Role of Charge-Transfer

Zen-ichi Yoshida and Nobuyuki Ishibe*

Department of Synthetic Chemistry, Kyoto University, Yoshida, Sakyo-ku, Kyoto

(Received April 30, 1969)

Using a series of alkylphenols and naphthols as the proton donors, the hydrogen bond shifts and the association constants of hydrogen-bonded complexes involving methyl benzenes, naphthalene, and phenanthrene as the proton acceptors have been determined from the infrared spectra in carbon tetrachloride. The frequency shifts ($\Delta\nu$) of the hydroxyl stretching vibration and the free energy changes ($-\Delta F$) for complex formation increase with decreasing pK_a of the proton donors. Linear correlation between $-\Delta F$ and $\Delta\nu$ are obtained for each proton donor interacting with methyl benzenes. The entropy anomaly discovered previously was confirmed. Charge-transfer arguments of Basila and co-workers are reconsidered for the hydrogen-bonded systems involving a π base as the proton acceptor.

Recently, there has been increasing evidence for hydrogen bond formation involving olefins and aromatics as the proton acceptors,[1,2] and this has been quantitatively studied by several investigators.[3–5] A good linear correlation of pK_a *vs.* the hydrogen-bonded frequency shift exists for many compounds of entirely different functional types.[1] Recently we have developed such a correlation for the hydrogen bonding of 4-substituted-2,6-xylenols to mesitylene.[6]

The purpose of this paper is to confirm (A) the existence of this correlation through methyl benzenes, naphthalene, and phenanthrene as the proton acceptor and (B) the correlation between the association constants and $\Delta\nu$. Another objective is to show the importance of charge-transfer type contributions[7] to hydrogen bond which are revealed from the results of infrared spectroscopic measurements.

Experimental

The OH stretching absorption spectra were scanned on a Shimadzu IR 600 (high precision grating spectrophotometer) with spectral slit width 1.5 cm^{-1} in the region of 3 μ. The cells had an optical path length of 0.2 cm, and were equipped with NaCl windows. The

a) Literature values are summarized in Ref. 5a and 5b.

concentration of phenols and naphthols in carbon tetrachloride was kept below 0.015—0.010 mol/*l* to avoid self-association of the proton donor. Concentration of π bases ranged from 0.2 to 4 mol/*l*. All measurements were carried out at average room temperature of 26°C. Two peaks were observed on all spectra, as is well-known in hydrogen-bonded systems.[8] A previously described procedure was employed for calculating the equilibrium constants and the apparent integrated molar absorption intensities of the OH···π complexes and for analyzing the infrared spectra to obtain the hydrogen-bonded frequency shifts.[5a]

All materials used were commerciall products and purified by the usual methods.

Results

In the presence of aromatic hydrocarbons, the spectra of the hydroxyl stretching vibration of alkylphenols and naphthols in carbon tetrachloride were seen as doublets. Table 1 summarizes: (A) Shifts of ν_{OH} of alkylphenols and naphthols due to interaction with the added π base ($\Delta\nu$); (B) free energy change, $-\Delta F$, due to 1 : 1 hydrogen bond complex formation; and (C) apparent integrated molar absorption coefficient, A^b, of the bonded OH bond.

Discussion

Effect of the pK_a of proton donors on $\Delta\nu$ and $-\Delta F$: The previous works with *t*-BuOH,[2c] pyrrole,[9] and phenol[5a,10] as proton donors showed

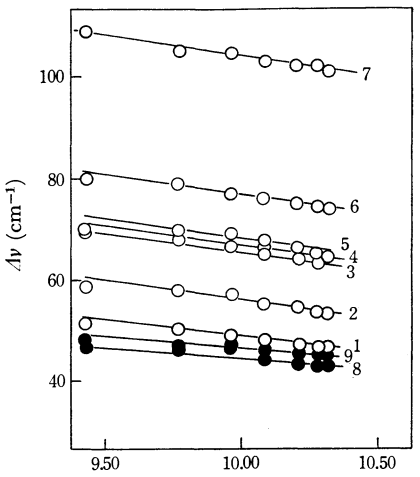

Fig. 1. Relationship between $\Delta\nu$ and pK_a of the proton donors. Numbers correspond to the π bases listed in Table 1.

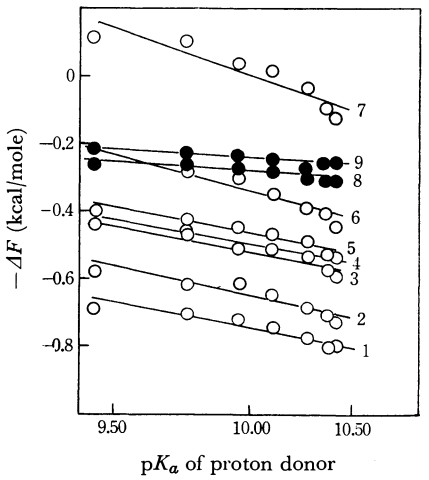

Fig. 2. Plots of $-\Delta F$ *vs.* pK_a of the proton donors. Numbers correspond to the π bases listed in Table 1.

a regular increase of $\Delta\nu$ with a number of methyl groups on the benzene ring. We have observed a similar increase using different proton donors. The linear correlation between $\Delta\nu$ and the pK_a of proton donors[11] (Fig. 1) is in agreement with the relation observed for ordinary hydrogen bonds involving lone pair electrons on oxygen and nitrogen atoms.[12,13] The slopes of all lines in Fig. 1 are virtually the same. The pK_a in aqueous solution of the proton donors includes both the enthalpy and entropy terms. The linear relationships, therefore, indicate that the proton donors used in this study have the same effect on $\Delta\nu$ when each infrared frequency shifts are measured in a solvent (CCl_4) different from water; consequently, one might conclude that the base strength of a series of π bases can be obtained by using a proton donor as reference. The "$\Delta\nu$" becomes a convenient measure for the base strength, as pointed out by Arnett.[1]

As shown in Fig. 2, when the free energy changes of hydrogen bond formation ($-\Delta F$) are plotted against the pK_a values of the proton donors, linear correlations are obtained for each π base except *p*-*t*-butylphenol (pK_a 10.31 at 26°C) and α-naphthol (pK_a 9.43 at 26°C) as the proton donor. While

11) The titration curve of various proton donors in water was obtained by using the automatic potentiometric titration method at 26°C. The slopes of observed curves were so steep that the break point in the curve could not be determined precisely as in the case of carboxylic acids. The dissociation constants were, therefore, determined at the point where the observed curve meets the theoretical one.

13) R. Denger, A. Gilchirst, J. Pegg, J. Smith, T. Thompson and L. Sutton, *J. Chem. Soc.*, **1955**, 3889; J. Gordon, *J. Org. Chem.*, **26**, 738 (1961).

the slope of the lines for methyl benzenes increases with basicity ($-\Delta F$) of the proton acceptors,[14] the slopes for phenanthrene and naphthalene are very small, in spite of the high $-\Delta F$ values. In contrast, the dependence of $\Delta\nu$ on the pK_a values of the proton donor is essentially the same for these polycyclic compounds as it is for the methyl benzenes (Fig. 1). This observation can be interpreted by assuming a large entropy effect. By comparing the $\Delta\nu$- and $-\Delta F$-values for each of the proton donors, a larger entropy effect with the polycyclic compounds than with the methyl benzenes is confirmed. This entropy anomaly has been reported in the hydrogen bonding of phenol with aromatic π base.[5a,15]

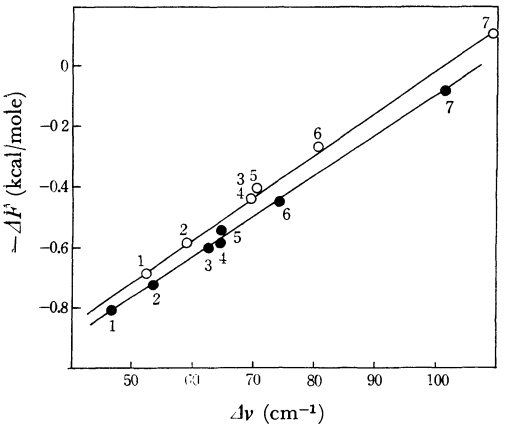

Fig. 3. Plots of $-\Delta F$ *vs.* $\Delta\nu$ for the α-naphthol- and *p-t*-butylphenol-methylbenzene systems. ○ : α-Naphthol, ● : *p-t*-Butylphenol. Numbers correspond to the π bases listed in Table 1.

Linear correlations between $-\Delta F$ and $\Delta\nu$ were obtained for each proton donor (even for *p-t*-butylphenol and α-naphthol as shown in Fig. 3) interacting with methyl benzenes. The value of the slopes was 0.014 ± 0.001 kcal/mol·cm^{-1}. This value agrees with the one obtained by Joesten and Drago[16] for thermodynamic measurements of the phenol adducts.

On the role of charge transfer: The possibility of detecting experimentally the role of charge-transfer involving π electrons from the proton acceptor to the proton donors has been anticipated.[17] The arguments of Basila, Saier, and Cousins[2c] is based on quantitative infrared spectroscopic studies of *t*-butyl alcohol-methyl benzene complexes. Their observed deviations for benzene, ethyl benzene, and mesitylene, when compared with other π bases, were not well explained. Although they consider 1 : 2 as well as 1 : 1 complexes involving these three π bases, the reexamination of their experiments proved that the deviations were due to the use of cells which were too long (15 mm).[5b] For these reasons, it seems best to reconsider their arguments.

The first argument for the importance of charge-transfer in hydrogen bonding is the linear relationship between ionization potential of the proton acceptor, I_D, and the frequency function, $\nu^f/\Delta\nu$:

$$I_D = C_1 \times (\nu^f/\Delta\nu)^{1/2} + C_2$$

where ν^f is the stretching frequency of the free OH. According to the Puranik-Kumar equation,[18] based on Mulliken's second-order perturbation theory for loose 1 : 1 complexes,[19] the plot of I_D *vs.* $(\nu^f/\Delta\nu)^{1/2}$ should be a straight line for a series of related proton acceptors with a given proton donor. Figure 4 shows the plots for phenol-aromatic hydrocarbon complexes as well as those for phenol-olefin complexes.[20] The methyl benzenes

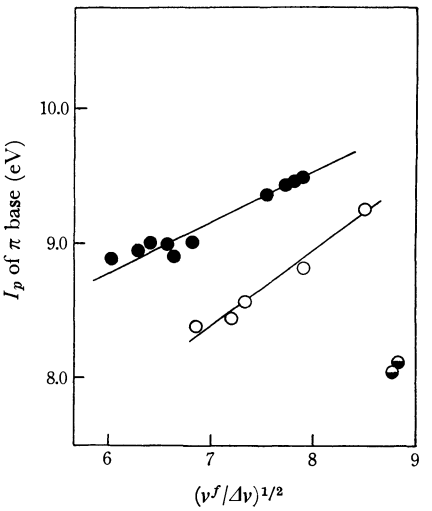

Fig. 4. Correlation between the ionization potential of π bases and $(\nu^f/\Delta\nu)^{1/2}$. ●, olefins; ○, Methylbenzene; ◒, Polyacenes.

fit the straight line. The same relations were obtained with other proton donor-aromatic hydrocarbon complexes. A linear correlation was also obtained for phenol-olefin complexes, although

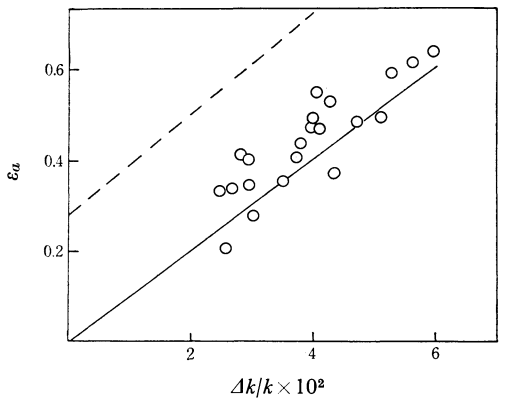

Fig. 5. Plots of the added effective nuclear change ε_a *vs.* the relative change in force constant $\Delta k/k$. The solid line is the one expected from the model discussed in the text and the dashed one is the one reported by Person *et al.* Ref. 23).

some of the ionization potentials of the olefins[21] used in this plot were not determined experimentally.[22] Naphthalene and phenanthrene both show large deviations from the correlation line found for the methyl benzenes; this implies that the polycondensed aromatics fit another line. This could be expected from the fact that the parameters C_1 and C_2 involve terms such as (1) overlap integral between the molecular orbital of the proton acceptor molecule and that of the negative ion of the proton donor molecule, and (2) polarity of the proton donor orbital.

The second argument of Basila and co-workers[2c] is based on the linear relation between ε_a, the added effective charge on the oxygen atom of the OH group due to the hydrogen bonding, and $\Delta k/k$, the relative change of the force constant of the OH stretching vibration due to hydrogen bonding. This correlation, proposed by Person and co-workes,[23] is based on the "van der Waals interaction-charge-transfer" resonance model, (a)↔(b),

for some charge-transfer complexes. Figure 5 shows the result of this plot for complexes with

$$\underset{\text{(a)}}{\text{A–H}\cdots\cdots\text{B}} \longleftrightarrow \underset{\text{(b)}}{\text{A}^-\cdots\cdots(\text{H–B})^+}$$

α-naphthol, phenol, and *p-t*-butylphenol. It should be noted that the plots are between the line obtained by Person *et al.* and the theoretical line obtained by assuming that the structures (a) and (b) would be equally important (*i. e* $\Delta k/k=0.50$, $\varepsilon_a=4.8$).

As additional evidence, Fig. 6 shows the plots of $\Delta\nu$ *vs.* the increment of the apparent absorption coefficient of the OH stretching band due to hydrogen bond formation, ΔA, for complexes where β-naphthol, phenol, and *p-t*-butylphenol are the proton donors. In the hydrogen bonding with lone-pair electrons Huggins and Pimentel[24] found a much larger ratio of $\Delta A/\Delta\nu$ (dashed line in Fig. 6). Since ΔA is a measure of the increased polarity of the OH group due to hydrogen bonding, Fig. 6 suggests that not only electrostatic interactoins but also charge-transfer interactions are important.

The results of three different treatments lead to the same conclusion, that is, charge-transfer from the proton acceptor to the vacant antibonding orbital of the proton donor plays an important role in the hydrogen bonding with π electrons.

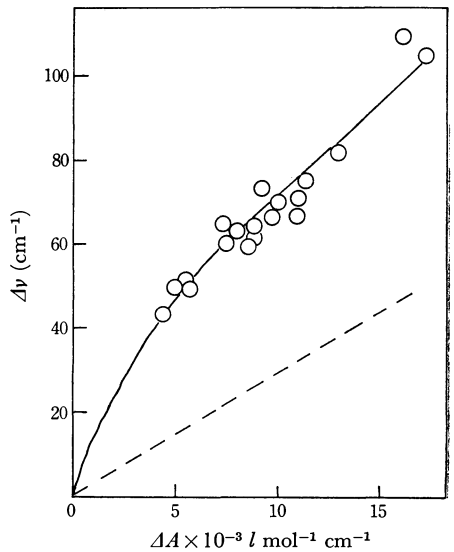

Fig. 6. Plots of $\Delta\nu$ *vs.* the difference between the integrated molar absorption intensity of the hydrogen bonded OH band and that of the free one. The dashed line is the one obtained by Huggins and Pimentel (Ref. 24).

Intermolecular Hydrogen Bond Involving a π Base as the Proton Acceptor. VII. Substituents and Steric Effects in the Hydrogen Bonding of 2,6-Xylenols to Mesitylene

Zen-ichi YOSHIDA, and Nobuyuki ISHIBE*1

Department of Synthetic Chemistry, Kyoto University, Yoshida, Sakyo-ku, Kyoto

(Received April 30, 1969)

Hydrogen bonding of 4-substituted-2,6-xylenols to mesitylene has been investigated by measurement of the hydroxyl stretching vibration. A linear relationship between the electronic effects of *para* substituents (Hammett σ_p constant) and the frequency shifts of the hydroxyl stretching vibration was obtained. A similar correlation was also observed with the free energy change associated with the formation of the hydrogen-bonded complex. The thermodynamic sutdies on the hydrogen bonding of 2,6-xylenol and phenol with both mesitylene and acetonitrile demonstrated the steric effect of 2- and 6-methyl groups on hydrogen bond formation. The free energy change for hydrogen bond formation with 2,6-xylenols as the proton donor was lower than with phenol. This is explained in terms of both entropy and enthalpy factors.

Many workers have investigated the substituent effects of proton donors such as phenols on the intramolecular hydrogen bond[1] and reported that usually there was a correlation between the electronic effects of substituents and the frequency shifts of hydroxyl stretching vibration due to hydrogen bond formation. Recent studies of the substitutent effects on the intermolecular hydrogen bond[2] show that the proton donors having typical substituents auch as nitro, acetyl, or alkoxyl groups are subject to self association.[3] This phenomenon is explained in terms of the proton accepting ability of these substituentents. In order to resolve this experimental difficulty, the sterically hindered phenols were used as the proton donor[2] because they are less associated than the simple hydroxyl compounds.[4-6]

Singh and Rao[2a] reported that in the hydrogen bonding of *para* substutited-2,6-di-*t*-butylphenols with tetrahydrofuran neither the equilibrium constantsnor the values of frequency shifts show a linear relationship with the Hammett σ_p constants. Both values of pK_a[7] and OH stretching vibration[8,9] in the infrared are, however, correlated with σ_p. The substituent effects of the proton donor on weak hydrogen bonding involving benzenes as a π base have not been investigated. We report the effect in the system of the 4-substituted-2,6-xylenols and mesitylene by measurement of the stretching frequencies of the OH group. In order to reveal whether the decrease of the equilibrium constant is due to the steric effect of 2- and 6-methyl groups on the enthalpy change and/or on the entropy change, the thermodynamic measurements of hydrogen bonding of phenol and 2,6-xylenol with both mesitylene and acetonitrile were carried out. These experiments are important because there is some discrepancy in the explanation of the smaller frequency shifts and free energy changes in hydrogen bonding of the hindered phenols to various proton acceptors involving a lone pair electron.[2a,5]

Experimental

Materials. Carbon tetrachloride as a solvent, mesitylene and acetonitrile as the proton acceptors, and phenol as a proton donor were purified by known methods.[10] 4-Substituted-2,6-xylenols were prepared by known methods.[9] The details of the preparative method were reported previously.[9]

Determination and Analysis of Spectra. All spectra of the hydroxyl stretching vibration, ν_{OH}, were obtained with a double pass grating infrared spectrophotometer JASCO DS-402G. The scanning conditions for determination of the spectra were the same as in the previous report.[11] Two liquid cells of 2 and 10 mm thickness (window material: NaCl), were used. Concentration ranged from 0.001 to 0.04 mol/*l* for the proton donors and from 1.5 to 4 mol/*l* for mesitylene. The cells were placed in a thermostated air-bath[12] to adjust the sample to an appropriate temperature. Analysis of the spectra and calculation of the equilibrium constants have been described previously.[13]

When thermodynamic values were estimated from a linear plot of log K *vs.* $1/T$, concentrations of free phenol and 2,6-xylenol were corrected. This was necessary because the integrated absorption intensities of phenol[14] and 2,6-xylenol in the absence of base depend not only on their concentration but also on temperature. In the range of -10 to 50° C the integrated molar absorption intensities of phenol[14] and 2,6-xylenol (A_p and A_x, *l*/mol cm) (whose band shape are assumed to be represented by Lorentzian function) correlate with the sample temperature (T) as follows:

$$A_p = 18200 - 26.50 \times T$$

$$A_x = 13700 - 18.09 \times T$$

Results

The OH stretching frequency of 4-substituted-2,6-xylenols (ν^f), the frequency shifts ($\Delta\nu$), the relative frequency shifts ($\Delta\nu/\nu^f$), and the free energy changes for hydrogen bonding between 4-substituted-2,6-xylenols and mesitylene are summarized in Table 1. The thermodynamic values of hydrogen bonding of phenol and 2,6-xylenol to both mesitylene and acetonitrile are given in Table 2. The values of frequency shifts in the hydrogen bond involving mesitylene remain constant with the change of concentration of π base and the temperature. In the case of acetonitrile, however, they depend not only on the concentration of acetonitrile[15] but also on the temperature. The frequency shifts decrease with increase of temperature.[14] This behavior could be explained as a specific solvent effect (dipole-dipole interaction).[16]

Discussion

Steric Effects on Hydrogen Bonding. A linear relationship was obtained in a plot of pK_a values of unhindered phenols (alkylphenols and naphthols) *vs.* the free energy changes for hydrogen bond of these phenols to mesitylene.[17] If this correlation also holds in the hydrogen-bonded system involving 2,6-xylenol as the proton donor, the value for $-\Delta F$ is expected to be -0.60 kcal/mol when the pK_a of 2,6-xylenol is 10.58.[18] This value is much larger than the observed one of -0.94 kcal/mol. Introduction of alkyl groups to the 2 and 6 positions of phenol causes a decrease of the equilibrium constant in the hydrogen bond with a lone pair electron in amides,[5] ethers,[2a,4a] ketones,[2a,6a] nitro compounds,[2a] and other compounds.[2a] A similar decrease ($-\Delta F$) was also found in the hydrogen bond interaction with the delocalized π electrons of mesitylene. Introduction of the methyl groups (into phenol) causes a decrease of $-\Delta F$ value, which is larger in the hydrogen bond with acetone and acetonitrile than with mesitylene. The differences in $-\Delta F$ are about 0.8 kcal/mol with mesitylene (Table 2). Table 2 shows that the hydro-

a) These values are measured at 25°C.
b) Ref. 6a. These values were obtained at 23°C.

gen bond energy and the frequency shift are much smaller in hydrogen bond of acetonitrile with 2,6-xylenol than with phenol, but the entropy change ($\Delta S°$) increases with introduction of methyl substituents into phenol. Mesitylene behaves in a similar way, although the entropy changes for these proton donors are nearly equal.

Our results are consistent with those of Takahashi and Li[5] who studied hydrogen bonding in amides. However, our results are not consistent with those of Singh and Rao[2a] who reported that the enthalpies of hydrogen bonding are nearly equal for both phenols and hindered phenols. The thermodynamic values reported here should be more accurate than those of Singh and Rao,[2a] because the dependence of the intensity of ν_{OH} of the free phenol on the sample temperature was considered in the calculation of the equilibrium constant. These authors[2a] stated that the increase in barrier height in the double minimum potential with increasing bulkiness of the substituent could be used to explain both the invariance of the enthalpies and the decrease of the frequency shifts in the hydrogen-bonded system involving the hindered phenols. They assumed there is little or no variation of the distance, $R_{x\cdots y}$, in the hydrogen bond X–H···Y. A more reasonable explanation is that $R_{x\cdots y}$ increases with the bulkiness of the alkyl substituents of the proton donors; therefore, the enthalpies decrease with introduction of the methyl substituents to 2 and 6 positions of phenol. As expected from this consideration, the frequency shift of the hydrogen bond between 2,6-xylenol and mesitylene is less than the values calculated from the $\Delta\nu - pK_a$ relationship,[17] where the steric effects were not detected. This decrease is, therefore, explained by the larger distance $R_{x\cdots y}$ and the higher OH stretching frequency of 2,6-xylenol.[9] Qualitatively this could be supported by the correlation between the frequency shift and the X···Y bond distance in the hydrogen-bonded solid.[19] The values of entropy changes support these considerations; the steric effect of the methyl substituent causes an increase of $R_{x\cdots y}$ in the hydrogen-bonded complex so that to some extent the rotational and vibrational movement of the complex is less restricted. The same trend apparently occurs in the complex involving acetonitrile as the proton acceptor. For mesitylene the entropy change in both phenol and 2,6-xylenol are nearly equal. $R_{x\cdots y}$ in the hydrogen-bonding of phenol with acetonitrile may be shorter than in the case of phenol with mesitylene. When the methyl groups are introduced into phenol, there seemingly occurs a greater increase of $R_{x\cdots y}$ with acetonitrile than with mesitylene, resulting in the differences in entropy changes mentioned above. It should be noted that the entropy anomaly observed in the hydrogen bonding of phenol with aromatic hydrocarbons[13] was obtained in the hydrogen-bonded system involving the hindered phenols.

From these considerations, steric effects on hydrogen bonding could influence not only the enthalpy but also the entropy changes associated with the formation of the hydrogen-bonded complex. Although a large steric effect was not observed in hydrogen bonding of phenol with di-*t*-butyl ether and di-*t*-butyl sulfide,[20] it is interesting that introduction of bulky groups into the proton donor causes a steric effect.

Substituent effects on hydrogen bonding: From Table 1 it is clear that both the frequency shifts and the free energy changes increase with enhance-

ment of the proton donating ability of the 4-substituents in 2,6-xylenols. A similar trend was also observed in some other hydrogen bonded systems, *e.g.* alkyl phenols-aromatic hydrocarbons,[17] alcohols-diethyl amine or -ethyl ether.[21] As shown in Fig. 1, both the relative frequency shift, $\Delta\nu/\nu^f$,[22] and the free energy change vary linearly with the Hammett σ_p constants.[23] In these plots the best linear relationship was obtained when σ_p[23] was used for the substituent constants of nitro and acetyl groups. This suggests the coplanarity of the OH group of 2,6-xylenols with the benzene ring in the hydrogen-bonded complexes, as well as in free 2,6-xylenols.[9] In the hydrogen bond between *para* substituted-2,6-di-*t*-butylphenols and tetrahydrofuran, however, neither the equilibrium constants nor the frequency shifts vary linearly with the Hammett σ constants.[28] This discrepancy cannot be explained adequately, but in the latter system, steric interaction of the *t*-butyl groups with the hydrogen atom of tetrahydrofuran causes bending of the OH group out of the plane of the benzene ring.

The slope of $\Delta\nu/\nu$ *vs.* pK_a for the hydrogen bonding of 2,6-xylenols with mesitylene is smaller than that of phenols with mesitylene.[17] The slope of $\Delta\nu/\nu$ *vs.* Hammett σ constant for the hydrogen bonding of 2,6-xylenols with mesitylene is larger than that of the intramolecular hydrogen bonding of 2-hydroxylbiphenyl derivatives.[24] The OH stretching frequencies of 4-substituted-2,6-xylenols are higher than those of the corresponding phenols,[17] so that the transmission of electronic effects of *para* substituents to the reaction center becomes more difficult in the hydrogen-bonded complexes with 4-substituted-2,6-xylenols than those with phenols. In the intramolecular hydrogen bonding of 4 (or 5)-substituted-2-hydroxylbiphenyls, the electronic effects of the substituent transmit the the reaction center not only through the benzene ring involving the OH group but also through the other ring because of conjugation between the two aromatic nuclei. The substituent effects on the OH group, therefore, cancel each other, thereby reducing the slope in the relationship $\Delta\nu/\nu^f$ *vs.* Hammett σ constants.

It is concluded that investigation of the hydrogen bond involving the hindered phenols might present interesting information about the transition states involving the hydrogen bond.

Intermolecular Hydrogen Bond Involving a π Base as the Proton Acceptor. IX. Hydrogen Bonding of Phenol to Monoolefins

Zen-ichi YOSHIDA and Nobuyuki ISHIBE

Department of Synthetic Chemistry, Faculty of Engineering, Kyoto University, Yoshida, Sakyo-ku, Kyoto

(Received April 30, 1969)

The π hydrogen bonding between phenol and monoolefins has been studied by examining the OH stretching vibration spectra of phenol in the presence of monoolefins. From comparison of the hydrogen bond shifts, it has been shown that the basicity of the aliphatic olefins toward phenol increases with the increasing alkylsubstitution on the double bond carbon. The endocyclic olefins are more basic than $RCH{=}CH_2$ and $RCH{=}CHR'$ where R and R′ represent alkyl groups. The equilibrium constants for complex formation with olefins were smaller than those with aromatic hydrocarbons. The steric effects on the hydrogen bond complex with aliphatic and endocyclic olefins have been discussed.

In relation to the various proposed conformations of olefin carbonium ions[1] the investigation of the hydrogen bonds involving olefins as the base is of interest, since hydrogen bonding could be the first step of the proton transfer.[2] Several examples are found in literatures.[3-6] The effect of structure (but not of strain) of base upon hydrogen bonding has been studied by West[5] and Kuhn and Bowman.[6] However, the influences of structure and strain of base on the hydrogen bonding have not been studied so far. The present paper describes the infrared data on hydrogen bonding of phenol with straight, branched and cycloolefins. The frequency shifts of the hydroxyl stretching vibration of phenol and the free energy changes due to complex formation were found to be strongly affected by the structure of the olefins. These variations are explained in terms of steric strain and electronic effects.

Experimental

Materials. 1-Olefins were prepared by pyrolysis of the methyl esters of the corresponding alcohols at 470—515°C under nitrogen atmosphere.[7,8] Cyclopentene and cycloheptene were prepared by dehydration[9,10] of the cycloalcohols obtained by hydrogenation[11] of the ketones.[12,13] The other materials were commerical products and purified by the usual methods, special care being taken to remove all traces of water. Their purity was confirmed by gas chromatography, using Apiezon L or β,β'-bispropionitrile ether columns.

Measurements and Analysis of Spectra. Hydroxyl stretching vibration spectra of phenol were recorded on a Double Pass High Precision Spectrophotometer of Japan Spectroscopic Co. A pair of 0.10 cm cells equipped with NaCl windows were used for double path operations. The concentration of olefins were 1—7 mol/*l* and that of phenol 0.01—0.02 mol/*l* in carbon tetrachloride. The detailed conditions for measuring the ν_{OH} spectra of phenol have been described previously.[14] The analysis of the observed spectra was carried out by use of the Lorentz equation[15] as mentioned in previous papers.[14-16] The equilibrium constants were calculated according to a previous paper.[14]

Results and Discussion

The hydroxyl stretching vibration spectra of phenol in the presence of olefins were all doublets as shown in Fig. 1 for the system of phenol-1-pentene. The hydrogen bond shifts, $\Delta\nu$, and the free energy changes for the complex formation, $-\Delta F$, are summarized in Table 1. Generally the half width of the bonded OH band for olefins was larger than that for aromatic hydrocarbons[14] with similar frequency shifts. For example, the hydrogen bond shifts are nearly equal for 1-octene and *m*-xylene, but the half widths of the bonded OH band were 73 cm^{-1} and 39 cm^{-1}, respectively.

From Table 1 it is apparent that for a given type of olefin, such as a monosubstituted ethylene, the hydrogen bond shifts are nearly constant, but they are strongly affected by the number and the position of alkyl groups attached to the double bond carbon, in the order $RCH{=}CH_2(A) < RCH{=}CHR'$ (B) $< \begin{matrix} R \\ R' \end{matrix}\!\!>C{=}CH_2(C)$, where R and R′ are alkyl groups. This trend is interpreted in terms of an increase in the electron density of the double bond with an increase in the total inductive effect due to alkyl-substitution as ascertained in the case of phenol-alkylsubstituted benzenes system.[16] Since the frequency shift is a good measure of the base strength of the proton acceptor,[17-19] the result obtained for aliphatic olefins means that alkyl-substitution at the double bond carbon increases its base strength toward the phenolic proton. This order corresponds well with West's results,[5] but the frequency shift (particularly for 1-olefins) in our investigation was about 1—13 cm^{-1} smaller than those of West. The effect of alkyl substitution on the frequency shift is also expected from the ionization potentials of olefins, the ionization potential of branched aliphatic olefins being smaller

than those of the linear ones.[20,21] The importance of charge-transfer in hydrogen bond interaction has been suggested by many workers,[22] and it has been demonstrated[19,23] that a linear correlation between the ionization potential of the aromatic donor and $(\nu_f/\Delta\nu)^{1/2}$ is observed. Such correlation was also obtained for phenol and olefins system as shown in Fig. 2.

Table 1 shows that the free energy change, $-\Delta F$, in π hydrogen bond formation increases with the frequency shifts. Accordingly, the more basic the proton acceptor, the easier the complex formation. In contrast, these $-\Delta F$ values are smaller than those obtained for aromatic hydrocarbons as the proton acceptors. For example, while the frequency shifts for mesitylene and 4-methyl-2-pentene are about the same, $-\Delta F$ for the latter (−1.03 kcal/mol) is much (*i. e.* −0.30 kcal/mol) smaller than that for the former. The plot of $-\Delta F$ *vs.* $\Delta\nu$ (Fig. 3) shows that $-\Delta F$ depends strongly on the type of the π base; monoolefins behave as a distinct group from polycondensed aromatics and alkylbenzenes. According to our previous considerations,[14,16] the entropy decrease for the phenol monoolefin interactions is the largest. In charge-transfer complexes involving alkylbenzenes and olefins as the electron donor, however, the formation constants as well as the entropy changes are nearly equal.[24] This suggests that degrees of freedom of movement of the electron acceptor molecule should be much smaller in the case of π hydrogen bond interactions involving

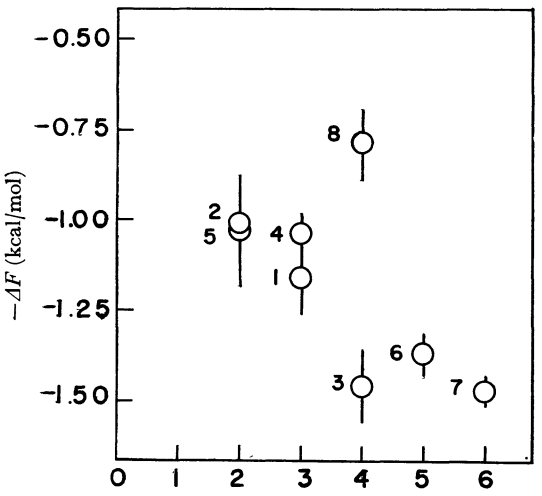

Fig. 4. Dependence of lenght of the carbon chain adjacent to olefinic double bond on $-\Delta F$. Numbers correspond to those listed in Table 1.

olefins as the electron donor than in the case of typical charge-transfer complexes. It can be seen from Table 1 that the increasing length of the alkyl group attached to the double bond carbon causes a decrease of $-\Delta F$. This trend is significant in the α-olefin series, where $-\Delta F$ decreases with the increasing length of the alkyl group while the frequency shifts being nearly constant (See Fig. 4). This could be due to steric hindrance. The steric hindrance has also been observed in the Ag^+-olefin complex formation.[25]

From a comparison of $-\Delta F$ values of the hydrogen bonded complexes with those of the Ag^+-olefin complexes it is shown that the branched olefins give more stable complexes for the hydrogen bond formation, and less stable complexes for the argentation than in the case of α-olefins. This opposite relation of basicity of the alkyl-substituted olefins toward phenolic proton and Ag^+ might be explained in terms of π (for the π hydrogen bonding) and σ complex-formations (for the argentation). If this is correct, the phenolic proton approaches the π electron cloud of olefin along the z axis, assuming that the olefin molecule lies on the xy plane with the y axis passing through the carbon atom of the double bond.[1b] The steric hindrance (Fig. 4) in such configuration of the π hydrogen bond complex could be explained as follows. The carbon chain of the alkyl groups adjacent to the double bond could freely rotate in solution. Since the aliphatic olefins used in this work have *trans*-form, judging from their boiling points, the saturated carbon chain has a considerable rotational freedom around the carbon-carbon single bonds. Accordingly, the length of the alkyl group would control the stability of π hydrogen bonded complex.

Table 2 shows that endocyclic olefins are more basic than RCH=CHR′ where R and R′ are alkyl groups, though the ring size of the endocyclic olefins has an effect on the value of $\Delta\nu$. The decreasing order of $\Delta\nu$ and $-\Delta F$ is the following: cyclohexene>cycloheptene≈*cis*-cyclooctene>cyclopentene. This result differs from the order of the equilibrium constants for Ag^+-complexes involving the endocyclic olefins as the electron donor.[26] If the linear Badger-Bauer relationship[27] between $-\Delta H$ and $\Delta\nu$ is correct, the effects of variations in ring size on $-\Delta F$ may be attributed to differences in ring strain, resulting from deformations and hydrogen-hydrogen repulsion with the endocyclic olefins. If we assume that the steric strain of cycloolefins is correlated with the distortion of the C=C–C bond angle, the differences in $\nu_{C=C}$ for cyclohexene and other cycloolefins will be a measure of the steric strain.[28] Table 2 shows that the smaller the $\Delta\nu_{C=C}$ value, the easier the formation of π hydrogen bond complexes. Namely, in π hydrogen bond ring strain does not appear to lead or facilitate deformation strain of the π orbital for complex formation as observed in the argentation of the cycloolefins.[26] This would suggest that the hydrogen bonded complexes are π complexes, while the Ag^+-complexes would be of the σ type.

Table 2. Stretching frequency of carbon-carbon double bond $\nu_{C=C}$ for cycloolefins, and change of free energy in the phenol-cycloolefins system

Cycloolefin	$\nu_{C=C}$[a] (cm^{-1})	$\Delta\nu_{C=C}$ (cm^{-1})	$-\Delta F$ (kcal/mol)

Nitroalkenylferrocene. III.[1] Condensation Reaction of Acetylferrocene Using Lewis Acid and Cyclic Amine

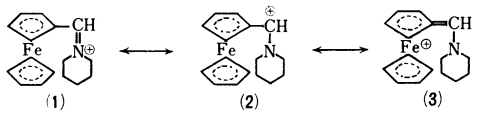
Hiromichi KONO, Mikio SHIGA, Izumi MOTYOAMA and Kazuo HATA

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya-ku, Tokyo

(Received May 9, 1969)

Acetylferrocene reacted with nitromethane and morpholine in the presence of titanium(IV) chloride to give a Mannich base, 2-ferrocenyl-2-morpholino-1-nitropropane (**7**), whose sodium salt (**8**) was then converted to 2-ferrocenyl-1-nitropropene (**9**) by acidifying it with hydrochloric acid. In the presence of aluminum chloride in place of titanium(IV) chloride, acetylferrocene as well as 1,1′-diacetylferrocene dimerized to form α,β-unsaturated ketone, (**10**) or (**11**).

In a previous paper[2] it has been reported that a condensation reaction of formylferrocene with nitroalkane and cyclic amine gave a Mannich base through an intermediacy involving an immonium ion-carbonium ion resonance[3] participated with ferrocene nuclei.



(1) (2) (3)

The fact that the Mannich base was the main product indicates that the carbonium-ion structure (**2**) is the most favorable and that it is predominantly attacked by a carbanion generated from nitroalkane.

However, neither acetylferrocene nor benzoylferrocene reacted under similar conditions. In these cases it can be assumed that the methyl or phenyl group on a carbonyl carbon may sterically prevent the formation of enamine. The procedure reported by White and Weingarten[4] for the preparation of enamines from sterically-hindered ketones in the presence of Lewis acid was applied to the condensation of acylferrocene with nitroalkane, using titanium(IV) chloride as the condensing agent. By this procedure, acetylferrocene reacted with morpholine to give an enamine when a solution of titanium(IV) chloride in benzene was added to a benzene solution of acetylferrocene and an excess of morpholine. A part of the enamine thus formed was isolated as a perchlorate, which then crystallized in fine, dark red scales. In the IR spectrum of the perchlorate, a characteristic absorption band of the $-C=\overset{+}{N}-$group was observed at 1613 cm^{-1}.[5] When nitromethane was added to the reaction mixture containing the enamine, 2-

5*1	2.2	10.0	1.5	5	1.2 (56.7)	0.55 (25.0)
6*2	2.2	10.0	1.5	20	1.3 (61.3)	0.58 (26.0)

*1 2.0 g of acetic acid was added after the condensation reaction had been over.
*2 15 g of acetic anhydride was added after the condensation reaction had been over.

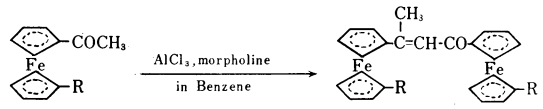
ferrocenyl-2-morpholino-1-nitropropane (**7**), mp 156—158°C, was obtained as orange crystals. When the Mannich base (**7**) was converted into its sodium salt (**8**) by sodium methoxide and then acidified with dilute hydrochloric acid, 2-ferrocenyl-1-nitropropene (**9**) was almost quantitatively obtained as violet crystals, mp 120—122°C.

The formation of an enamine from benzoylferrocene by a similar procedure was also proved by the isolation of its perchlorate. Nevertheless, no product was isolated from the reaction of the enamine with nitromethane. It is considered that the enamine from benzoylferrocene is far less reactive than that from acetylferrocene because of both the electronical stabilization and the steric hindrance by a phenyl group on it. Probably, a positive charge on the carbon atom bonded with a nitrogen atom in the enamine will be largely delocalized by the aid of the phenyl group attached to the carbonium ion; hence, the electrophilic nature of the enamine will be much reduced.

The IR spectrum of the nitroolefin (**9**) has an olefinic absorption band at 1606 cm^{-1} and characteristic asymmetric and symmetric nitro-stretching bands at 1508 cm^{-1} and 1320 cm^{-1} respectively. It is very interesting that the olefinic absorption band of 2-ferrocenyl-1-nitropropene (**9**) is 22 cm^{-1} lower than that of 2-ferrocenyl-1-nitroethylene, while that of 1-ferrocenyl-2-nitropropene, which is an isomer of **9**, is 24 cm^{-1} higher than that of 2-ferrocenyl-1-nitroethylene.[1] This observation suggests that the ethylenic bond of 2-ferrocenyl-1-nitroethylene may be much polarized *in situ*.

The NMR spectrum of **9** shows a singlet peak for methyl protons at τ 7.47, two singlet peaks at τ 5.82 and τ 5.48 for unsubstituted and substituted ferrocene ring protons respectively, and a singlet for vinyl proton at τ 2.69.

When aluminum chloride was used as a catalyst instead of titanium(IV) chloride, acetylferrocene dimerized in the presence of morpholine to form a self-condensation product, 1,3-diferrocenyl-2-buten-1-one (**10**), which had previously been reported to be formed from acetylferrocene by the reaction with potassium *t*-butoxide or sodium hydride.[6,7] By a similar reaction, 1,1′-diacetylferrocene also gave 1,3-bis(1′-acetylferrocenyl)-2-buten-1-one (**11**) in a moderate yield. Such a self-condensation reaction never occurs when only morpholine or aluminum chloride is used alone. The reaction conditions and the yields are listed in Table 1.



(**10**) R=H; (**11**) R=$COCH_3$

The reaction seems to proceed through an aldol condensation-type mechanism, and aluminum chloride may promote the polarization of the carbonyl group of acetylferrocene and facilitate the attack of a nucleophile on it. The yield of **10** increased upon the addition of acetic acid, acetic anhydride, or acetyl chloride after the primary condensation reaction was over. The acid was expected to be effective at the stage of the elimination of water molecule from the aldol-type condensation product[8] (Table 1, Exps. No. 5 and 6).

The IR spectrum of **11** has two kinds of carbonyl absorption bands, at 1664 cm^{-1} (acetyl group) and at 1644 cm^{-1} (α,β-unsaturated ketone), and an olefinic absorption band at 1597 cm^{-1}. The NMR spectra of the unsaturated ketones, (**10**) and (**11**), are presented in Table 2. The NMR spectrum of **10** shows the presence of three kinds of peaks for the substituted ferrocene ring protons, at τ 5.19, 5.40, and 5.54, with the relative intensities of 2, 2, and 4 respectively. The signals at τ 5.19 and 5.40

Table 2. The NMR spectra of α,β-unsaturated ketones (τ-value, in $CDCl_3$)

	1,3-Diferrocenyl-2-buten-1-one (**10**)		1,3-Bis(1′-acetylferrocenyl)-2-buten-1-one (**11**)	
	τ-Value	Relative intensities	τ-Value	Relative intensities
Ferrocene ring protons				
Unsubstituted	5.81 (s)	5		
	5.84 (s)	5		
Substituted	5.19 (t)	2	5.23 (m)	6
	5.40 (t)	2	5.24 (m)	2
	5.54 (m)	4	5.50 (t)	8
Vinyl proton	3.27 (s)	1	3.38 (s)	1
Allylic methyl protons	7.44 (m)	3	7.49 (s)	3
Acetyl methyl protons			7.64 (s)	6

were assigned to α-protons to the carbonyl and olefinic substituents on the ferrocene rings respectively, and the signal at τ 5.54, to β-protons on the substituted ring. In the NMR spectrum of **11**, the signals at τ 5.23 and 5.34 were assigned to α-protons to the carbonyl and olefinic substituents respectively, and the signal at τ 5.50, to β-protons on the ferrocene ring.

Experimental

2-Ferrocenyl-2-morpholino-1-nitropropane (7). A solution of titanium(IV) chloride (3.5 g) in benzene (10 m*l*) was added, drop by drop, to a stirred solution of acetylferrocene (4.4 g) and morpholine (10 g) in benzene (20 m*l*) which had previously been cooled in an ice bath. In a little while, a yellowish-brown solid appeared to form a suspension in the reaction mixture. The suspension was stirred for 4 hr at room temperature, and then nitromethane (5 g) was added. After the reaction mixture had been stirred for another 16 hr, it was filtered and the residue on the filter was repeatedly washed with ether. The filtrate and the washing were combined and concentrated under reduced pressure at room temperature. From the concentrated solution 2-ferrocenyl-2-morpholino-1-nitropropane (**7**) was obtained as orange needles (0.58 g, 8.4%); mp 156—158°C. IR (KBr): 2850—3000 ($-CH_2-$), 1557 (NO_2) and 1105 cm^{-1} (C–O–C).

Found: C, 57.41; H, 6.42; N, 7.63%. Calcd for $C_{17}H_{22}N_2O_3Fe$: C, 57.03; H, 6.14; N, 7.82%.

A part of the yellowish-brown solid which separated in the initial reaction was dissolved in water to give a deep red solution. On the treatment of the aqueous solution with $NaClO_4$, dark red crystals of perchlorate were isolated. IR spectrum: 1613 cm^{-1} ($-C=\overset{+}{N}-$ group).

2-Ferrocenyl-1-nitropropene (9). Following the procedure described in a previous report,[1] 2-ferrocenyl-2-morpholino-1-nitropropane (0.13 g) was treated with sodium ethoxide in ethanol and then with dilute hydrochloric acid to afford 2-ferrocenyl-1-nitropropene (**9**), mp 120—122°C. The chromatographic purification of the nitroolefin (**9**) was carefully done because of its instability on alumina. IR (CCl_4): 1606 (C=C), 1508 (asym. NO_2) and 1319 cm^{-1} (sym. NO_2). NMR (in $CDCl_3$): τ 7.47 (singlet, 3H), 5.82 (singlet, 5H), 5.48 (singlet, 4H), 2.69 (singlet, 1H).

Found: C, 58.29; H, 5.08; N, 5.17%. Calcd for $C_{13}H_{13}NO_2Fe$: C, 57.59; H, 4.79; N, 5.16%.

1,3-Diferrocenyl-2-buten-1-one (10). (a) To a stirred mixture of 8.3 g (0.06 mol) of aluminum chloride and 50 m*l* of anhydrous benzene cooled in an ice bath there was added, drop by drop, a solution of 11.4 g (0.05 mol) of acetylferrocene and 22 g (0.25 mol) of morpholine in 70 m*l* of anhydrous benzene under an atmosphere of nitrogen. After the addition had been completed, the mixture was stirred for another 20 hr at room temperature. At the end of the reaction, the deep red reaction mixture was poured into water and the aqueous layer was extracted with benzene. The organic layer thus obtained was washed thoroughly with water and dried over anhydrous magnesium sulfate. The removal of the solvent left 8.8 g of an oil, which was then chromatographed on alumina with *n*-hexane-benzene (1 : 1). The first fraction gave 4.5 g of acetylferrocene, and the second fraction gave 4.3 g (39.2%) of 1,3-diferrocenyl-2-buten-1-one (**10**), which was recrystallized from methanol to yield fine, deep red crystals; mp 122—124°C (lit 123—124°C[7]). IR (KBr): 1638 (C=O) and 1585 cm^{-1} (C=C).

(b) A mixture of acetylferrocene (2.2 g, 0.01 mol), morpholine (10 g, 0.11 mol), and aluminum chloride (1.5 g, 0.01 mol) in anhydrous benzene (30 m*l*) was treated similarly. After it had been stirred for 18 hr at room temperature, 15 g (0.15 mol) of acetic anhydride was added, drop by drop, to the reaction mixture under ice cooling; the resulting reaction mixture was stirred for another 2 hr at room temperature. The treatment of the reaction mixture much as in the procedure (a) gave 0.58 g of acetylferrocene and 1.3 g (61.3%) of 1,3-diferrocenyl-2-buten-1-one (**10**).

1,3-Bis(1′-acetylferrocenyl)-2-buten-1-one (11). A reaction was carried out in the same way as has been described in the case of the procedure (a) above by using 1,1′-diacetylferrocene (1.20 g, 0.005 mol), morpholine (7.0 g, 0.08 mol), aluminum chloride (1.2 g, 0.001 mol), and anhydrous benzene (40 m*l*). After it had been stirred for 20 hr, the reaction mixture was poured into ice water and the aqueous layer was extracted with benzene. The organic layer was washed with water and dried over anhydrous magnesium sulfate. After the solvent had been removed by a rotatory evaporator, the deep red oily residue was carefully chromatographed on alumina with *n*-hexane, benzene and chloroform successively as the elution solvents. The first fraction, eluted with *n*-hexane-benzene, gave diacetylferrocene (0.7 g), while the second fraction, eluted with chloroform, gave a deep red oil which was then rechromatographed with *n*-hexane-benzene (1 : 2) to give 0.2 g (17%) of 1,3-bis(1′-acetylferrocenyl)-2-buten-1-one (**11**) as an oil. An analytical sample of **11** was obtained by repeated chromatography of the oily product on alumina. IR (liquid film): 1664 and 1644 (C=O), 1576 cm^{-1} (C=C).

Found: C, 63.94; H, 5.18%. Calcd for $C_{28}H_{26}O_3Fe$: C, 64.45; H, 4.98%.

The authors are indebted to Mr. Kisaburo Yamazaki and his group of the Central Research Laboratory, Yamanouchi Pharmaceutical Co., Ltd., for their measurement of the NMR spectra.

Nitroalkenylferrocene. IV.[1] Preparation of 1-Ferrocenyl-2-iodo-2-nitroethylene and Configurations of Several Nitroalkenylferrocenes

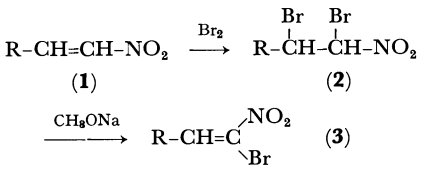
Hiromichi KONO, Mikio SHIGA, Izumi MOTOYAMA and Kazuo HATA

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya-ku, Tokyo

(Received May 19, 1969)

A new method of synthesizing 1-ferrocenyl-2-iodo-2-nitroethylene (**6**) was presented, whereas 1-ferrocenyl-2-halo-2-nitroethylene could not be prepared by the usual method, involving the direct halogenation of the nitroolefin. The iodonitroethylene (**6**) was prepared by the reaction of the sodium salt of 1-ferrocenyl-2-nitroethylene with iodine or with potassium iodide. This procedure proved to be useful for introducing various groups on the α-carbon of the nitroethylene. The stereochemistry of nitroalkenylferrocenes, including some previously reported ones, was discussed on the basis of their spectral data.

In the course of study of the reactions of nitroalkenyl-ferrocenes, it has been found that a sodium salt (**5**) which was obtained when 1-ferrocenyl-2-nitroethylene (**4**) was treated with sodium methoxide reacted directly with iodine to give 1-ferrocenyl-2-iodo-2-nitroethylene (**6**). The usual method[2] for the synthesis of α-halonitroethylene (**3**) from α-nitroethylene (**1**) through dibromide (**2**) was found to be unsuccessful when applied to 1-ferrocenyl-2-nitroethylene (**4**). The reaction of **4** with bromine gave no dibromide, but the ferrocene nuclei was largely decomposed, even at −65°C in the presence of bromine.



On the other hand, 1-ferrocenyl-2-iodo-2-nitroethylene (**6**) was easily obtained in a 30% yield when the sodium salt (**5**) was treated with iodine in dry ether under an atmosphere of nitrogen and then treated with aqueous sodium thiosulfate. The sodium salt (**5**) also reacted with mercury(II) chloride in the presence of excess sodium methoxide to give a brownish sodium salt (**7**). The brownish salt (**7**), on treatment with dilute hydrochloric acid, was easily converted into 1-ferrocenyl-2-chloromercuri-2-nitroethylene (**8**), which separated as a blue solid. The structure of **8** was assumed on the basis of its IR spectrum: an olefinic absorption band at 1588 cm^{-1}, an asymmetrical NO_2 stretching band at 1480 cm^{-1}, and a pair of symmetrical NO_2 stretching bands at 1290 cm^{-1} and 1282 cm^{-1}. The results of elemental analyses also support the structure.

When **8** was stirred with iodine and potassium

2) B. Priebs, *Ann.*, **225**, 342 (1884); W. E. Parham and J. L. Bleasdale, *J. Am. Chem. Soc.*, **73**, 4664 (1951).

iodide in dioxane containing a trace of water, 1-ferrocenyl-2-iodo-2-nitroethylene (**6**) was obtained in a 32% yield after the treatment of the crude product with aqueous sodium thiosulfate. The reaction of **8** with iodine was carried out in several kinds of solvents; the results are summarized in Table 1. The chloromercuri compound (**8**) was easily decomposed to the nitroolefin (**4**) and mercury(II) chloride by the action of concentrated hydrochloric acid. The identity of the decomposition product with the starting nitroolefin (**4**), which has been prepared by the condensation of formylferrocene with nitromethane using a base catalyst,[3] was proved by the coincidence of their IR spectra.

Table 1. Iodination of 1-ferrocenyl-2-chloromercuri-2-nitroethylene (**8**) (at 0°C)

8 (g)	**8** (mol)	Iodinating reagent	(g)	Solvent	Reaction time (hr)	Yield of **6** (%)
15	0.03	I_2	11.1	THF (200 m*l*)	20	19
15	0.03	I_2	11.1	CH_2Cl_2 (200 m*l*)	20	24
15	0.03	I_2	11.1	CCl_4 (200 m*l*)	20	26
15	0.03	I_2 KI	11.1 5	Dioxane (200 m*l*) H_2O (2 drops)	20	32

When **8** was stirred in acetic acid, a small amount of violet oil was obtained, together with the nitroolefin (**4**) as the main product. The minor product was too unstable to be thoroughly purified, and it easily decomposed into formylferrocene. The IR spectrum indicated the presence of acetoxy group (1758 cm^{-1} and 1200 cm^{-1}), as well as nitro group (1502 cm^{-1} (asym. NO_2) and 1325 cm^{-1} (sym. NO_2)). Accordingly, 1-ferrocenyl-2-acetoxy-2-nitroethylene (**9**) was tentatively proposed as the structure of this compound. The same compound (**9**) was also obtained by the reaction of **6** with copper(II) acetate.

Infrared Spectra and Configuration of Nitroalkenylferrocenes. Although various nitroalkenylferrocenes have been synthesized in our laboratory,[1,3,4] no discussion of the geometric relationship between nitro and ferrocenyl groups has yet been undertaken becasue of the difficulty of isolating their geometric counterparts. Recently, however, Watarai *et al.*[5] have shown that the geometric relationship between nitro and phenyl groups in nitrostyrene and the related compounds could be determined by means of their IR spectra. According to their rule, the absorbance of the symmetrical NO_2 stretching absorption band is smaller than that of the asymmetrical one in the case of the cis isomer, while the former is equal to or larger than the latter in the case of the trans isomer. Because of the close structural resemblance of 1-ferrocenyl-2-nitroethylene to β-nitrostyrene, it is quite reasonable to assume that this empirical rule would be applicable to the system of 1-ferrocenyl-2-nitroethylene and would give a strong suggestion regarding its stereochemistry. Thus, the IR spectra of several 1-ferrocenyl-2-nitroalkenes were measured in CCl_4. All the results are summarized in Table 2. By comparing the absorbances of the symmetrical and asymmetrical NO_2 stretching absorption bands with each other, it is evident that the absorbance of the former band considerably exceeds that of the latter in all the compounds listed in Table 2. Therefore, the configuration of these nitroalkenes can be concluded to be trans, according to the Watarai rule.

Table 2. IR spectra of nitroalkenylferrocenes (cm^{-1}, in CCl_4)

Compound	C=C (ε)	Asym. NO_2 (ε)	Sym. NO_2 (ε)
Fc-CH=CH-NO_2*1 (**4**)	1628 (388)	1518 (285)	1343 (350) 1331 (649)
Fc-CH=C(CH_3)NO_2*1	1652 (283)	1512 (496)	1324 (386) 1313 (1038)
Fc-CH=C(C_2H_5)NO_2*1	1645 (331)	1512 (457)	1323 (512) 1303 (328)
Fc-CH=CINO_2 (**6**)	1596 (492)	1523 (371)	1302 (1294) 1287 (552)
Fc-C(CH_3)=CH-NO_2*2	1606 (332)	1508 (476)	1344 (291) 1320 (980)

*1 Ref. 3 *2 Ref. 1

A similar conclusion can be derived from the results of the NMR spectra of these compounds. The $J_{\alpha\beta}$-value of the olefinic protons in **4** (12.5 cps) corresponds to that of *trans*-olefin, and the chemical shifts of the olefinic β-protons in the other nitroolefins[3,4] were almost the same as that of 1-ferrocenyl-2-nitroethylene (**4**).

Jensen *et al.*[6,7] have reported that mercuri-

olefins are replaced by a cationoid reagent with the retention of the configuration, but not by a radical reagent.

1-Ferrocenyl-2-chloromercuri-2-nitroethylene (**8**) was easily converted to *trans*-1-ferrocenyl-2-nitroethylene (**4**) by the action of hydrochloric acid. According to Jensen's observation, the compound **8** is considered to have a trans configuration with respect to ferrocenyl and nitro groups. A similar consideration can be applied to the compound **6**, which was prepared by the reaction of **8** with iodine and potassium iodide.

Careful examination of the stereochemistry using a molecular structure model reveals that the cis form may bring about a considerable steric strain in the molecule because of a steric interaction between nitro and ferrocenyl groups.

As was expected from this consideration, *cis*-1-ferrocenyl-2-iodo-2-nitroethylene could be obtained neither from the reaction of 1-ferrocenyl-2-chloromercuri-2-nitroethylene with iodine under radical conditions nor from the attempted isomerization of the trans isomer by UV irradiation in CCl_4.

Some interesting phenomena have been observed in the symmetrical NO_2 stretching absorption bands of the nitroalkenylferrocenes. All the nitroolefins studied here have doubly-split absorption bands in the range of 1287—1343 cm^{-1}. The positions and the relative intensities of the split bands depend on the substituents on the double bond of nitroolefin, as well as on the state in which the IR spectra were observed, as is shown in Fig. 1 and Table 2. Such splitting in the symmetrical NO_2 stretching absorption band has never been observed in the benzene analogs. Therefore, it seems to be attributable to a certain influence of the ferrocenyl group on the nitro group. However, no simple explanation of the splitting is possible at present.

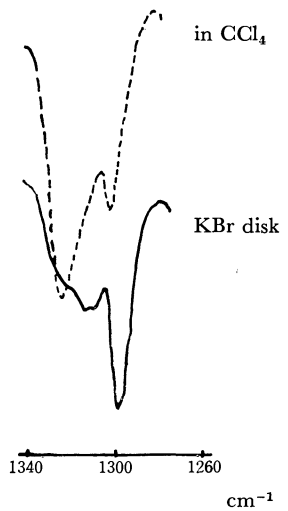

Fig. 1. The symmetrical NO_2 stretching absorption bands of $FcCH=C(C_2H_5)NO_2$.

Experimental

1-Ferrocenyl-2-chloromercuri-2-nitroethylene (8). To 10.8 g (0.041 mol) of finely-powdered 1-ferrocenyl-2-nitroethylene in 20 m*l* of absolute methanol, there were slowly added, at 0°C, 10.8 g (0.2 mol) of sodium methoxide which had been freshly prepared from absolute methanol and sodium metal. Subsequently, 20.2 g (0.075 mol) of finely-powdered mercury(II) chloride were added to the mixture with stirring. In a little while, the sodium salt of the chloromercuri compound (**7**) precipitated as a brown solid. An additional 5.4-g portion (0.1 mol) of sodium methoxide was added, and the reaction mixture was stirred for a while. Then, the mixture was poured into 500 m*l* of 20% hydrochloric acid and stirred for half an hour. A blue solid was collected on a filter, washed three times with methanol, and dried in a desiccator under reduced pressure. The finely-powdered material was then stirred in 100 m*l* of chloroform for half an hour in order to remove the unreacted starting material. After filtration, 19.5 g (96% yield) of **8** were obtained as a pale blue solid.

Found: C, 25.26; H, 2.31; N, 2.56%. Calcd for $C_{12}H_{10}FeNO_2HgCl$: C, 29.26; H, 2.03; N, 2.84%.

Repeated elemental analyses failed to give good results owing to the difficulty of purification.

1-Ferrocenyl-2-iodo-2-nitroethylene (6). (a) Into 15 g (0.03 mol) of 1-ferrocenyl-2-chloromercuri-2-nitroethylene (**8**) in 200 m*l* of dioxane, a solution of iodine (11.1 g) and potassium iodide (5 g) in 200 m*l* of dioxane containing two drops of water was slowly added with stirring at 0°C. After having been stirred for 20 hr, the reaction mixture was poured into a solution of 30 g of sodium thiosulfate in 200 m*l* of water; then the mixture was stirred for another hour. Subsequently, the mixture was extracted with ether, and the solution was washed with aqueous sodium thiosulfate and dried over anhydrous magnesium sulfate. After the removal of the solvent, the residue was chromatographed on Florisil using a mixture of benzene and *n*-hexane (1 : 3) as the solvent. The first fraction gave blue needles of 1-ferrocenyl-2-iodo-2-nitroethylene (**6**) (3.7 g, 32% yield), mp 139—141°C, after recrystallization from methanol. NMR spectra (in $CDCl_3$): τ 5.70 (5H, unsubstituted ring H, singlet), 5.28 (2H, substituted ring H, triplet), 4.91 (2H, substituted ring H, triplet), and 1.22 (1H, vinyl H, singlet).

Found: C, 37.02; H, 2.49; N, 3.62%. Calcd for $C_{12}H_{10}FeNO_2I$: C, 37.59; H, 2.61; N, 3.65%.

(b) To a solution of 5.14 g (0.02 mol) of 1-ferrocenyl-2-nitroethylene in 100 m*l* of dry ether, 3 g (0.05 mol) of sodium methoxide were added at 0°C under an atmosphere of nitrogen. After the reaction mixture had been decolored, a solution of 13 g (0.05 mol) of iodine in 200 m*l* of dry ether was added, drop by drop, to the stirred mixture within an hour. After it had then been stirred for 2 hr, the solution was let stand overnight. Then the reaction mixture was treated in the way described for the procedure (a). After the removal of the solvent from the dried ethereal solution thus obtained, the residue was repeatedly extracted with a mixture of benzene and *n*-hexane (1 : 1). The residue, obtained from the extracts by the removal of the solvent, was chromatographed on Florisil using a mixture of

benzene and *n*-hexane (1 : 3). The first fraction gave 2.3 g (30.2% yield) of **6**.

1-Ferrocenyl-2-acetoxy-2-nitroethylene (9). (a) 1-Ferrocenyl-2-iodo-2-nitroethylene (**6**) (0.5 g, 0.002 mol) dissolved in 3 m*l* of dioxane was added to a mixture of 20 m*l* of ethanol and 20 m*l* of water containing 1.5 g of copper(II) acetate, and then the mixture was heated at 90°C for 4 hr. At the end of the reaction, the hot reaction mixture was poured into 100 g of ice water and the product was extracted with ether. The extracts were shaken with 5% hydrochloric acid, and then washed with water and dried over anhydrous magnesium sulfate. After the removal of the solvent, the residue was chromatographed on Florisil with benzene to afford 1-ferrocenyl-2-nitroethylene (**4**). Further elution with chloroform afforded crude **9** (90.1 mg, 18% yield) as a blue violet oil which contained a small amount of formylferrocene. Formylferrocene is considered to be produced by the decomposition of the unstable product (**9**) during elution, although the chromatographic column was covered with aluminum foil in order to prevent the decomposition of the product by light.

(b) 1-Ferrocenyl-2-chloromercuri-2-nitroethylene (**8**) (10 g) was added to 20 m*l* glacial acetic acid, and the mixture was heated at 95°C for 3 hr. At the end of the reaction, the reaction mixture was poured into 200 m*l* of water. The precipitate was collected by filtration and washed with water. The product was then dissolved in 30 m*l* of benzene and dried over anhydrous magnesium sulfate. The benzene solution, treated much as in the procedure (a), afforded 0.3 g (5% yield) of **9**.

Spectral Measurements. The infrared spectra were measured in carbon tetrachloride using a 0.52-mm rock salt cell on a Hitachi EPI-G2 grating infrared spectrometer.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 3273—3277 (1969)

β-Ferrocenyl-α,β-unsaturated Ketones. I. Condensation Reactions of Formylferrocene with Ketones

Hiromichi KONO, Mikio SHIGA, Izumi MOTOYAMA and Kazuo HATA

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya-ku, Tokyo

(Received May 19, 1969)

The condensation reaction of formylferrocene with simple aliphatic and alicyclic ketones, as acetone, ethyl methyl ketone, isobutyl methyl ketone, and cyclohexanone, in the presence of piperidine as a condensing agent afforded seven kinds of β-ferrocenyl-α,β-unsaturated ketones. The geometric configurations of the unsaturated ketones were discussed on the basis of their NMR spectra, and the influences of the ferrocenyl group on the π-π* transition bands in their UV spectra were also discussed.

It is widely known[1] that formylferrocene, like aromatic aldehydes, undergoes a variety of condensation reactions and thereby serves as an important starting material for the syntheses of many ferrocene derivatives. A Knoevenagel-type or aldol-type condensation[2] with a compound having a reactive methylene group under the influence of a base catalyst affords a ferrocene derivative with an unsaturated group conjugated with the ferrocene nucleus. Base-catalyzed condensations of formylferrocene or 1,1′-diformylferrocene with acetone have been reported by Boichard *et al.*[3] and by Osgerby and Pauson.[4] However, little has been reported on the condensation of formylferrocene with other simple aliphatic ketones.

A cyclic amine proved to be a very useful catalyst for the condensation of formylferrocene with nitroalkane.[5] In the present investigation, seven kinds of β-ferrocenyl-α,β-unsaturated ketones were prepared by the condensation of formylferrocene with various ketones, such as acetone, cyclohexanone, ethyl methyl ketone, and isobutyl methyl ketone, in the presence of piperidine, which was also found to be the most effective catalyst for such condensations.

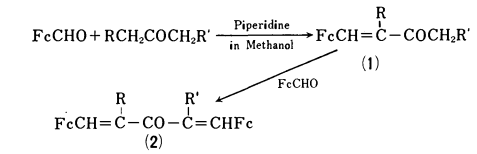
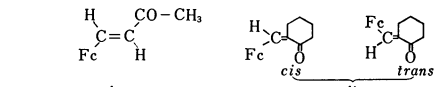
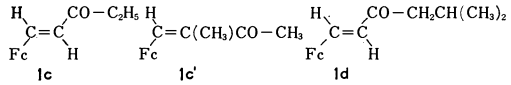
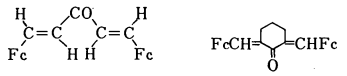
Results and Discussion

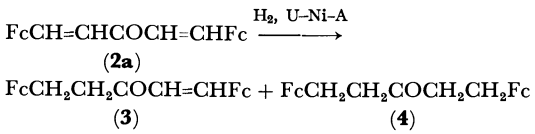
The α,β-unsaturated ketones obtained in the present study were five 1 : 1 adducts (from 1 mol of formylferrocene and 1 mol of ketone) (**1a–d**) and two 2 : 1 adducts (from 2 mol of the aldehyde and 1 mol of ketone) (**2a,b**).











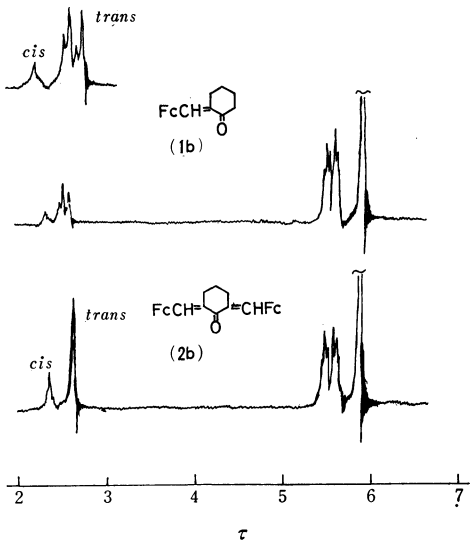


Fig. 1. NMR spectra of **1b** and **2b** in $CDCl_3$ (60 Mc).

The hydrogenation of 1,5-diferrocenyl-1,4-pentadien-3-one (**2a**) with Urushibara nickel A[6] proceeded step-by-step and afforded 1,5-diferrocenyl-1-penten-3-one (**3**) and 1,5-diferrocenyl-3-pentanone (**4**).

The NMR spectral data of the β-ferrocenyl-α,β-unsaturated ketones obtained here are listed in Table 1, together with those of vinylferrocene.

Representative NMR spectra of **1b** and **2b** are shown in Fig. 1. The UV spectra of some of these unsaturated ketones are listed in Table 2, together with those of the related compounds.

When symmetrical ketones, such as acetone and cyclohexanone, were employed, considerable quantities of 2 : 1 adducts (**2a** and **2b**) were obtained as by-products besides the 1 : 1 adducts (**1a** and **1b**). On the other hand, unsymmetrical ketones, such as ethyl methyl ketone and isobutyl methyl ketone, gave 1 : 1 adducts (**1c**, **1c′**, and **1d**) exclusively.

A well-known reaction of this type is the Claisen-Schmidt condensation[7] with aromatic aldehydes. Benzaldehyde condenses with acetone under acidic conditions to form dibenzylideneacetone predominantly, whereas under basic conditions the main product is benzylideneacetone, accompanied by dibenzylideneacetone as a minor product.

It is known that ethyl methyl ketone suffers an enolization-controlled reaction mainly on the methyl side rather than on the ethyl side under basic conditions.[8] The same tendency was observed in the present experiments. Ethyl methyl ketone condensed with formylferrocene to afford **1c** as the main product and **1c′** as a minor product, while isobutyl methyl ketone afforded **1d** as the sole product. These observations indicate that steric hindrance against an electrophilic attack on the α-carbon to the carbonyl group of the ketone is apparently an important factor in the orientation of these condensation reactions.

Assignment of the Geometrical Configuration of the α,β-Unsaturated Ketone. The geometrical configurations of the α,β-unsaturated ketones were determined in terms of the coupling constants between the vinyl protons. As is shown in Table 1, α- and β-protons of the vinyl group gave respective doublet peaks, corresponding to an AB pattern. The coupling constant of the vinyl protons was 16 cps in the cases of **1a**, **1c**, and **1d**, and 15.5 cps for **2a**. The magnitude of the coupling constant reveals these α,β-unsaturated ketones to have trans configurations, in which ferrocenyl and carbonyl groups are on opposite sides of the double bond.[9] In this connection, it has been pointed out that the coupling constant of trans vinyl protons is 17 cps for vinylferrocene itself and 12.5 cps for *trans*-1-ferrocenyl-2-nitroethylene.[5]

The compound **1b** gave complex signals due to the β-vinyl proton in the range from τ 2.26 to 2.60, as is shown in Fig. 1. In the trans isomer of this compound, in which the ferrocenyl group is on the side opposite to that of the carbonyl group, a signal of the vinyl proton is expected to appear in a higher field, because of an anisotropic effect of the carbonyl group on the same side, than that of the cis isomer. Further, the splitting of the former is expected, considering a long-range coupling with a methylene group situated trans to the vinyl proton. Therefore, a quartet in the higher field, centered at about τ 2.52, was assigned to the vinyl proton of the trans isomer, whereas a broad signal centered at about τ 2.30 was assigned to that of the cis isomer. On the basis of the relative intensities of these signals, the trans : cis ratio in **1b** was determined to be about 8 : 1.

The compound **2b**, which contains two exo-double bonds in the molecule, showed the signals of the vinyl protons at τ 2.59 and 2.33 as two singlets. The former, in the higher field, was assigned to the trans vinyl proton for the same reason as has been described for **1b**, and the latter was assigned to the cis. No such long-range coupling as was observed in *trans*-**1b** was observed in *trans*-**2b**, probably because of a conformational change in the cyclohexanone ring caused by the two exo-double bonds.

Ultraviolet Spectra. The UV spectra of **1a**, **1c**, **1c′**, and **2a** were observed in 95% ethanol and

9) L. M. Jackman, "Applications of Nuclear Magnetic Resonance Spectroscopy in Organic Chemistry," Pergamon Press, London (1959), p. 85.

are summarized in Table 2, together with those of some related ferrocene derivatives. The strongest absorption bands, at 305—308 mμ, in the spectra of **1a**, **1c**, and **1c'** can be assigned to the π–π* transition band of the α,β-unsaturated ketone conjugated with the ferrocene nucleus, while the corresponding absorption bands of nitroalkenylferrocenes appear at about 325 mμ.[10] As the π–π* transition band of methyl vinyl ketone has been reported to appear at 219 mμ (ε=3600),[11] the replacement of a vinyl hydrogen by a ferrocenyl group causes a remarkable shift of this band to a longer wavelength (305 mμ). Such a large bathochromic shift (85 mμ) by a ferrocenyl group has also been observed in the nitroalkene series.[10]

The UV spectrum of ferrocene has been discussed in detail by Scott and Becker,[12] who assigned the two long wavelength bands at 325 and 440 mμ to *d–d* type transitions, with some mixing with ring orbitals. In the cases of **1a**, **1c**, and **1c'**, both of these long wavelength bands, due to the *d–d* type transitions, appeared in the longer-wavelength region, namely, at about 370 and 480 mμ respectively.

In the spectrum of **2a**, the π–π* and *d–d* type transition bands exhibited larger bathochromic shifts and appeared at 340, 402, and 527 mμ respectively.

However, such a large bathochromic shift as that observed in the π–π* transition band cannot simply be explained in terms of conjugation of the α,β-unsaturated ketone with the ferrocene ring. It will be necessary to consider the interaction of the non-bonding *d*-orbitals of the metal in the ferrocene nucleus with the π-orbital of the side chain on the ferrocene ring.

Further work on this subject is now in progress, and a more detailed discussion will be presented in the near future.

Experimental

General Procedure for the Preparation of β-Ferrocenyl-α,β-unsaturated Ketones. A solution of formylferrocene (1 mol) and a ketone (2 mol) in methanol was left to stand for 2—4 days in the presence of piperidine (2 mol) at room temperature. After the subsequent removal of the solvent under reduced pressure, a deep red residue was dissolved in benzene; then the benzene solution was washed repeatedly with water and dried over anhydrous magnesium sulfate. The benzene solution was concentrated under reduced pressure and then chromatographed on alumina using a mixture of benzene-hexane (1 : 1) as a sovlent. The isolated products were identified by means of the NMR, IR, and UV spectra and elemental analyses.

4-Ferrocenyl-3-buten-2-one (1a) and 1,5-Diferrocenyl-1,4-pentadien-3-one (2a). The condensation product from the reaction of formylferrocene and acetone was chromatographed on alumina. The first fraction gave **1a** in a 78.9% yield. The product was recrystallized from petroleum ether to afford a deep red powder, mp 84—85°C (lit mp 86°C[3]). IR (in CCl_4): 3100, 1689, 1666, 1619, 1601, 1359, 1251, 1186, 1108, 1043, 1028, 998 and 964 cm^{-1}.

Found: C, 67.25; H, 5.70%. Calcd for $C_{14}H_{14}OFe$: C, 66.18; H, 5.52%.

The second fraction gave **2a** in a 4.3% yield; it was recrystallized from benzene-hexane (1 : 1) to afford reddish-orange leaflets, mp 203—204°C. IR (in CCl_4): 3100, 1665, 1649, 1614, 1104, 1090, 1037, 1024 and 995 cm^{-1}.

Found: C, 65.89; H, 4.81%. Calcd for $C_{25}H_{22}OFe_2$: C, 66.71; H, 4.89%.

2-(Ferrocenylmethylene)cyclohexanone (1b) and 2,6-Bis(ferrocenylmethylene)cyclohexanone (2b). The condensation product from formylferrocene and cyclohexanone was chromatographed on alumina. From the first fraction, **1b** was obtained, on recrystallization from benzene-hexane (1 : 1), as deep red powder, mp 110—112°C, in a 70.4% yield. IR (in CCl_4): 3080, 2920, 1677, 1585, 1309, 1239, 1137, 1100, 1040 and 991 cm^{-1}.

Found: C, 69.79; H, 6.16%. Calcd for $C_{17}H_{18}OFe$: C, 69.35; 6.11%.

The second fraction gave **2b**; it was then recrystallized from petroleum ether-benzene (1 : 1) to give deep red needles, mp 163—165°C, in a 12% yield. IR (in CCl_4): 3100, 2940, 1666, 1604, 1304, 1273, 1240, 1158, 1136, 1101, 1037 and 991 cm^{-1}.

Found: C, 69.20; H, 5.55%. Calcd for $C_{28}H_{26}OFe_2$: C, 68.60; H, 5.30%.

1-Ferrocenyl-1-penten-3-one (1c) and 4-Ferrocenyl-3-methyl-3-buten-2-one (1c'). 1-Ferrocenyl-1-penten-3-one (**1c**) was obtained as a first fraction from the chromatographic separation of the crude product, which had been obtained by the reaction of formylferrocene and ethyl methyl ketone. The recrystallization of **1c** from petroleum ether gave a deep red powder, mp 101—102°C, in a 41.2% yield. IR (in CCl_4): 3100, 2900, 1688, 1665, 1621, 1606, 1350, 1100 and 1025 cm^{-1}.

Found: C, 68.00; H, 6.20%. Calcd for $C_{15}H_{16}OFe$: C, 67.20; H, 5.95%.

A small amount of another product was isolated from the second fraction as reddish-orange needles, mp 162—164°C. It was found to be 4-ferrocenyl-3-methyl-3-buten-2-one (**1c'**) by means of a study of the IR, UV, and NMR spectra and by elemental analysis. IR (in CCl_4): 3110, 2900, 1682, 1658, 1604, 1107, 1038 and 1000 cm^{-1}. NMR (in $CDCl_3$): τ 8.45—8.80 (methyl), 5.82 (unsubstituted ring), 5.40—5.60 (substituted ring) and 2.53 (vinyl).

Found: C, 67.83; H, 6.64%. Calcd for $C_{15}H_{16}OFe$: C, 67.20; H, 5.95%.

1-Ferrocenyl-5-methyl-1-hexen-3-one (1d). The repeated chromatographic purification of the crude product from isobutyl methyl ketone afforded **1d**. Recrystallization from *n*-hexane gave reddish orange needles, mp 31—32°C, in a 54.2% yield. IR (in CCl_4):

Catalytic Hydrogenation of 1,5-Diferrocenyl-1,4-pentadien-3-one (2a). Dienone **2a** (1.1 g) dissolved in 10 m*l* of dioxane was placed in a hydrogenating vessel together with 0.5 g of Urushibara nickel A and vigorously shaken with hydrogen for 7 hr at atmospheric pressure and at 24°C. After the catalyst had been removed by filtration, the filtrate was poured into water; the aqueous layer thus obtained was extracted with ether. The extract was washed with water and dried over anhydrous magnesium sulfate. The removal of the solvent under reduced pressure gave 1.2 g of a red oil; this oil was then subjected to chromatographic separation on alumina using benzene-hexane (1 : 1). The first fraction afforded 0.4 g of a yellow solid which was recrystallized from *n*-hexane to give 1,5-diferrocenyl-3-pentanone (**4**) as greenish-yellow needles, mp 110—111°C. IR (in CCl_4): 3100, 2900, 1710, 1475, 1440, 1413, 1362, 1110, 1090, 1043, 1027 and 1003 cm^{-1}. NMR (in $CDCl_3$): τ 7.39 (methylene), 5.94 (substituted ring), 5.89 (unsubstituted ring).

Found: C, 65.62; H, 5.44%. Calcd for $C_{25}H_{26}OFe_2$: C, 66.12; H, 5.73%.

From the second fraction, 0.2 g of a solid was obtained. Recrystallization from benzene afforded 1,5-diferrocenyl-1-penten-3-one (**3**) as reddish-orange plates, mp 113—114°C. IR (in CCl_4): 3100, 1690, 1660, 1621, 1604, 1355, 1215, 1180, 1107, 1093, 1045, 1030 and 1000 cm^{-1}.

Found: C, 66.02; H, 5.30%. Calcd for $C_{25}H_{24}OFe_2$: C, 66.41; H, 5.31%.

The authors wish to express their thanks to Professor Michio Kobayashi, Tokyo Metropolitan University, for his kind advice regarding the identification of the geometrical configuration. Thanks are also due to Mr. Kisaburo Yamazaki and his group of the Central Research Laboratory, Yamanouchi Pharmaceutical Co., Ltd., for the measurement of the NMR spectra and to Mr. Takeo Akiyama, Sophia University, for the measurement of the UV spectra.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 3277—3284 (1969)

Reactions of Alkyltropylium Ions with a Base[1]

Tetsuo NOZOE,[2] Kazuko TAKAHASHI and Hiroshi YAMAMOTO[3]

Department of Chemistry, Faculty of Science, Tohoku University, Katahira-cho Sendai

(Received May 13, 1969)

On the reaction with a base (*e.g.*, aqueous sodium hydroxide), isopropyl- and methyl-tropylium ions afforded cycloheptatrienyl polymers with an alkylene bridge, such as IIIa and IIIb, while the *t*-butyltropylium ion gave a mixture of 3- and 4-*t*-butyltropone, which was then transformed to 4- and 5-*t*-butyltropolone (VIIIa and IX). The bromination of VIIIa with 3 mol of bromine in methanol gave 3,7-dibromo-4-*t*-butyl-2-methoxy-2,3-dihydrotropolone (XIIa). On the heating of the adduct (XIIa) at 130°C, 7-bromo-4-*t*-butyltropolone (XIa) was formed.

It has been reported that the tropylium ion reacts with phenols,[4] aromatic amines,[5] and arylmagnesium halides[6] to give arylcycloheptatrienes, the dehydrogenation products of which, aryltropylium ions, are very stable in an aqueous solution or in the solid state. Upon the treatment of aryl-(such as phenyl- or *p*-methoxyphenyl)-tropylium ions with alkali, followed by the disproportionation reaction,[7,8] aryltropones have been

obtained. Tropylium ions carrying alkyl side chains have also been studied to some extent.[9,10] However, a more detailed investigation of alkyltropylium ions would be desirable, because the ions could be precursors of alkyltropones and alkyltropolones,[7,8,11] which mostly cannot be prepared

by the direct alkylation of tropone or tropolone. In view of these points, our intense interest was focused on the reaction of alkyltropylium ions with the base.

7-Isopropylcycoheptatriene[12] (Ia), prepared in a good yield by the reaction of ethoxycycloheptatriene with isopropylmagnesium bromide, was kept at 175°C for 1.5 hr in order to cause a thermal isomerization of the double bonds.[13-15] The intramolecular 1—5 H shift of Ia gave an isomeric mixture of 3-, 1- and 7-isopropylcycloheptatriene in the ratio of 6 : 3 : 1. The positions of the isopropyl group and the ratio of the products were determined on the basis of the NMR spectral data (*cf.* Table 1). The mixture was treated with phosphorus pentachloride to afford the isopropyltropylium ion (IIa) ($X=\frac{1}{2}PtCl_6$). The spectral data of IIa, recorded in the Experimental section, were consistent with the structure. Although the cation (IIa) was very stable in an acidic medium, it changed to a colorless amorphous powder on treatment with a base such as aqueous sodium hydroxide or sodium bicarbonate, and no isopropyltropyl alcohol or isopropyltropone (IVa) was detected. The powder contained virtually no oxygen atoms (on the evidence of elemental analysis), and the infrared (IR) spectrum showed no hydroxy, carbonyl, or ether bands. The NMR spectrum (in CCl_4) had three, very broad signals at τ 3.55, 4.15, and 4.90 typical of a cycloheptatrienyl system and two broad signals at 8.5 and 8.8. The ratio of the intensities of the down- and the up-field signals was approximately 5 : 7. These spectral data, together with the unusual broadness of the signals and the possible modes of formation of the compound (see below), suggested that it was a polymer and that it most likely had the structure IIIa.

When 7-methylcycloheptatriene[9] (Ib) was heated at 170°C for 3.5 hr, a mixture of 3- and 1-methylcycloheptatriene was obtained in the ratio of 1 : 2 (from the NMR spectrum). The treatment of the mixture with phosphorus pentachloride gave the methyltropylium ion[9] (IIb) ($X=\frac{1}{2}PtCl_6$), which was very stable in the solid state and in a strongly acidic aqueous solution. However, a weakly acidic (pH 3—5) or neutral solution of IIb gradually turned orange and finally yielded a colorless, amorphous powder. The formation of the material was also demonstrated, but in a better yield, when an aqueous solution of IIb was treated with sodium

hydroxide, but the reaction was accompanied by the formation of a trace (1%) of methyltropone[16] (IVb) as the by-product (ν_{max} 1630, 1590 cm^{-1}). The main product was shown by the IR spectrum to possess methine, methylene, and cycloheptatriene groups, but no hydroxy nor carbonyl group, although all bands were very broad (*cf.* Experimental section). The spectral evidence presumably verifies the structure IIIb for the compound.

The formation of the poylmers IIIa and IIIb could reasonably be explained in terms of the attack of a hydroxide anion on the α-hydrogen atom, H_A, in the formula A, rather than on the seven-membered ring; thus, the heptafulvene-type compound B could be formed as an intermediate. It is at present uncertain on which site of the cycloheptatriene ring the polymerization reaction takes place, but the products are considered to be a mixture of the alkylated cycloheptratiene polymers with an alkylene bridge at the 3,7 and 2,7 positions, assuming that the negatively-charged carbon (C-8) in the formula B, instead of a hydroxide anion,[17] attacks the 4- or 3-position of the seven-membered ring of another molecule (a steric repulsion would prevent the 2—8 polymerization). The fact that the methyltropylium ion (IIb) required a stronger acidic medium than IIa to keep the cation stable indicated that the stability of the two alkyltropylium ions, IIa and IIb, dependend on the acidity of the medium. A similar phenomenon had been observed in aliphatic alkenyl cation systems.[18]

A B

When the isopropyltropylium ion (IIa) was allowed to react with dimethylamine, a mixture of 1-, 2- and 3-isopropyl-7-dimethylaminocycloheptatriene (Va) was formed. By the same reaction with monomethylamine, a mixture of 1-, 2-, and 3-isopropyl-7-methylaminocycloheptatriene (Vb) was obtained. Although the methyltropylium ion (IIb) gave no clear substance, it was noteworthy that, upon treatment with alkylamines, the cation IIa did not undergo a polymerization reaction but instead afforded the *N*-alkylaminocycloheptatriene derivatives. A similar treatment of IIa with methanolic sodium bicarbonate, however, mostly afforded the polymer IIIa.

These observations led us to a further study of the *t*-butylcycloheptatrienium ion (IIc) which has no acidic hydrogen atom at the α-position of the substituent. Upon the heating of 7-*t*-butylcycloheptatriene (Ic), prepared in a good yield by the reaction of 7-ethoxycycloheptatriene with *t*-butyl magnesium chloride, at 175°C for 2 hr, a mixture of 7-, 3-, 1- and 2-*t*-butylcycloheptatriene was obtained in the ratio of 1 : 2.2 : 10 : 2 (from NMR). The subsequent dehydrogenation of the mixture with phosphorus pentachloride in carbon tetrachloride gave the stable cation, IIc ($X=\frac{1}{2}PtCl_6$). A considerable amount of 7- and 1-*t*-butylcycloheptatriene was recovered unchanged in the above reaction, indicating that the hydride abstraction from the sterically-hindered 7-position of the cycloheptatriene seemed to be relatively difficult. The treatment of the cation IIc with sodium hydroxide afforded an oily stuff, di-(*t*-butyl-cycloheptatrienyl) ether, which was then converted with a trace of acid into the tropone (IVc) and the cycloheptatriene (VIc). The IR band of IVc observed at 1623 cm^{-1} was attributed to the carbonyl group. A broad peak due to the ring protons appeared at τ 3.1 in the NMR spectrum (in CCl_4). Although IVc showed a sharp singlet due to the *t*-butyl group at τ 8.72 and gave one 2,4-dinitrophenylhydrazone, mp 182—184°C it was assumed to be a mixture of 3- and 4-*t*-butyltropone, because two spots (R_f 0.7, 0.6) appeared on an alumina thin-layer plate in a ratio of *ca.* 2 : 1 (benzene-ethyl acetate, 20 : 1, as the solvent). The moiety, VIc, was concluded to be a nearly equivalent amount of a mixture of 1-, 2-, and 3-*t*-butylcycloheptatriene, considering the presence of three methylene signals at τ 7.78 (d), 7.88 (t), and 7.91 (t), and three singlets of approximately the same intensities due to *t*-butyl groups at 8.83, 8.87, and 8.90 in the NMR spectrum (in CCl_4). The treatment of a methanolic solution of IIc with sodium bicarbonate gave a 1 : 1 mixture of 2- and 3-*t*-butyl-7-methoxycycloheptatriene (Vc), the structures of which were derived from the NMR spectrum (see Experimental section). No polymerized hydrocarbon similar to IIIa and IIIb was produced on the treatment of the cation IIc with the base.

The two *t*-butyltropolones, VIIIa and IX, were successfully synthesized by treating the tropone (IVc) with hydrazine hydrate, followed by the hydrolysis of the resulting aminotropone mixture (VII) with alcoholic potassium hydroxide. The tropolone (VIIIa) readily gave the sodium salt as yellow crystals with aqueous sodium carbonate, while the tropolone (IX) formed hardly any salt under the same conditions. Thus, IX could be extracted from the above basic layer with chloroform or ether; the separation and purification of VIIIa and IX from the crude mixture were effectively achieved by repetition of the above procedure. The yields of VIIIa and IX from the tropone mixture (IVc) were 40 and 1% respectively. The IR spectrum of VIIIa showed absorption bands at 3226 and 1610 cm^{-1} typical of the hydroxy and carbonyl group of tropolones. The ring protons of VIIIa appeared in the NMR spectrum as a doublet (1H) at τ 2.61 (J=1.5 Hz) and as a multiplet (3H) at 2.90, as may be expected for 4-substituted tropolone systems. The assignment of the signals is shown in the table. The structure was confirmed by the degradation of the tosyl ether (X) to 3-*t*-butylbenzoic acid on refluxing in alcoholic potassium hydroxide.

The minor product mentioned above was proved to be 5-*t*-butyltropolone[19] (IX), by taking account of the A_2B_2-octet signal centerrd at τ 2.57 ($J_{ab}=J_{a'b'}$=11.0, $J_{aa'}$=1.2, $J_{bb'}\simeq 0$ Hz) in the NMR spectrum (*cf.* the table). The hydroxyl and

19) T. Nozoe, H. Kishi and A. Yoshikoshi, *Proc. Japan Acad.*, **27**, 149 (1951).

carbonyl absorption bands appeared at 3247 and 1616 cm^{-1} respectively. The ultraviolet spectra of both VIIIa and IX are recorded in the Experimental section. When phenyl- and *p*-methoxyphenyl-tropolone were synthesized from the corresponding aryltropylium ions by the procedure described above, the relative ratio of 4- and 5-arylsubstituted tropolone was about 3 : 1.[4d,7] The present study, however, showed that the 4-substituted tropolone (VIIIa) was produced in a much larger amount than the 5-substituted compound (IX); the reason for this we have not yet made clear. Nevertheless, this procedure would seem to be a useful approach for the synthesis of 4-*t*-butyl-tropolone.

In order to examine the steric influence of the bulkier alkyl group of VIIIa, the bromination of VIIIa and 4-isopropyltropolone (VIIIb)[20] was carried out in order to compare their reactivities. When one mole of bromine in methanol was used, VIIIa was shown to give 7-bromo-4-*t*-butyltropolone (XIa) on the evidence of the elemental analysis and the spectral data (*cf.* table and the Experimental section). The treatment of VIIIa with 3 mol of bromine in the same solvent, however, afforded a non-aromatic addition product (XIIa) the structure of which was derived from the IR (3367, 1667 cm^{-1}: non-tropolone ring) and the NMR (see table) spectra. On refluxing in ethanol, the methoxy group of XIIa was replaced by an ethoxy group, giving the adduct (XIIb). On the other hand, VIIIb mainly afforded the dibromo derivative[21] (XIb) on the bromination of 3 mol in methanol.

The possibility of the removal of methanol from the adduct (XIIa) to yield a dibromotropolone (XIc) similar to XIb was then examined. Although XIIa mostly remained unchanged at 80°C/1 mmHg (3 hr), it was unexpectedly converted to the monobromotropolone (XIa) upon heating at 130°C for 20 min. This suggested that a large steric repulsion between the *t*-butyl group and the bromine atom on C-3 of the compound XIIa prevented the formation of the more sterically-hindered dibromotropolone (XIc) but, upon heating, facilitated the removal of the bromine atom to give XIa. The steric effect of a *t*-butyl group in seven-membered aromatics appeared to be remarkable; it is now being examined in detail.

Experimental

Materials for the analyses were dried over P_2O_5 at about 20°C/20 mmHg overnight. The NMR spectra were obtained with a Varian A-60 spectrometer, operating at 25°C and 60 Mc/sec, with tetramethylsilane (τ 10) as the internal standard.

7-Isopropylcycloheptatriene (Ia). A mixture of 68.9 g of isopropyl bromide and 200 m*l* of dry ether was slowly stirred into 13.6 g (1 equiv.) of magnesium over a 2.5 hr period at such a rate that the mixture was gently refluxed; then it was stirred for a further 30 min. A solution of 61.1 g (0.8 eqiuv.) of 7-ethoxycycloheptatriene[15] in 100 m*l* of dry ether was stirred in over a 1.5 hr period and then stirring was continued for another hour. Into the mixture cooled with an ice bath there was stirred, 500 m*l* of cold 2N hydrochloric acid over a 30 min period. The reaction mixture was extracted with ether, and the ether was washed with cold water and dried over $MgSO_4$. After the solvent had been evaporated, the residue was distilled to give 48.1 g (80%) of a colorless oil, Ia; bp 82—86°C/42 mmHg. The specimen for the analysis was distilled at 74°C/33 mmHg.

Found: C, 89.72; H, 10.46%. Calcd for $C_{10}H_{14}$: C, 89.49; H, 10.51%. ν_{max}^{neat} 2967, 2919, 2833, 1445, 1385, 1368, 1193, 1164, 950, 799, 743, 704 and 685 cm^{-1}.

7-Methylcycloheptatriene (Ib). This was obtained from methylmagnesium iodide and 7-ethoxycycloheptatriene by the above procedure in a 71% yield (bp 63°C/80 mmHg).

7-*t*-Butylcycloheptatriene (Ic). This was similarly made from *t*-butylmagnesium chloride and 7-ethoxycycloheptatriene as a colorless oil. (55% yield); bp 95—98°C/45 mmHg.

Found: C, 89.37; H, 10.83%. Calcd for $C_{11}H_{16}$: C, 89.12; H, 10.88%. ν_{max}^{neat} 2994, 2941, 2857, 1464, 1389, 1366, 1250, 1208, 1190, 1011, 952, 852, 741 and 703 cm^{-1}.

Thermal Isomerization of the Cycloheptatrienes (Ia, b, c). The substance was heated in a sealed tube at a given temperature (±0.5°C), and then purified by distillation. When 12 g of Ia were heated at 175°C for 1.5 hr, and then distilled, 11 g of a mixture consisting of 3-, 1-, and 7-isopropylcycloheptatriene (6 : 3 : 1) was obtained as a colorless oil; bp 78—79°C/37 mmHg.

Found: C, 89.79; H, 10.43%. Calcd for $C_{10}H_{14}$: see above.

The heating of 18.3 g of Ic at 175°C for 2 hr, followed by distillation, gave 17.5 g of a mixture of 7-, 3-, 1-, and 2-*t*-butylcycloheptatriene (1 : 2.2 : 10 : 2) as a colorless oil; bp 88—89°C/37 mmHg.

Found: C, 89.40; H, 10.69%. Calcd for $C_{11}H_{16}$: see above.

Isopropyltropylium Ion (IIa). Into a suspension of 3.3 g of phosphorus pentachloride (2.1 equiv.) in 25 m*l* of anhydrous carbon tetrachloride there was stirred a solution of 1.00 g of the above thermally-isomerized isopropylcycloheptatriene mixture in 5 m*l* of carbon tetrachloride. After the mixture had been stirred for 7 hr and then set aside overnight at room temperature, the precipitate was filtered off in a dry box, dried over P_2O_5 *in vacuo*, and poured into 1 m*l* of cold acetonitrile. To the solution, after clarification by filtration, there was added, drop by drop, a saturated solution of $H_2PtCl_6 \cdot 6H_2O$ in acetonitrile, giving 1.00 g (40%) of IIa (as the hexachloroplatinate) as yellow prisms; mp 164°C (decomp.).

Found: C, 35.93; H, 3.94; Pt, 29.55%. Calcd for $C_{10}H_{13} \cdot 1/2PtCl_6$ C, 35.63; H, 3.89; Pt, 28.94%. λ_{max}^{MeCN}

Methyltropylium Ion (IIb). This was obtained by the same procedure as above in a 37% yield as a brownish yellow crystalline powder; mp 160°C (blackened).

Found: C, 32.58; H, 3.23; Pt, 32.57%. ν_{max}^{KBr} 3012, 1522, 1486, 1449, 1359, 1282, 1235, 1164, 1027, 979, 965, 867 and 727 cm^{-1}. $\delta_{CF_3CO_2H}$ 3.31 (s; Me), 9.08 (s; 6H).

***t*-Butyltropylium Ion (IIc).** This was similarly prepared. The hexachloroplatinate isolated in a 38% yield was in the form of pale orange needles; mp 181°C (decomp.).

Found: C, 37.32; H, 4.28; Pt, 27.67%. Calcd for $C_{11}H_{15}\cdot 1/2PtCl_6$: C, 37.63; H, 4.31; Pt, 27.78%. λ_{max}^{MeCN} 272, 346 sh mμ. ν_{max}^{KBr} 2976, 2933, 1595, 1570, 1522, 1490, 1439, 1385, 1292, 1067, 1056, 947, 820, and 770 cm^{-1}.

The Reaction of IIa with Sodium Bicarbonate. Five grams of the thermally-isomerized isopropylcycloheptatriene was treated with 16.1 g (2.1 equiv.) of phosphorus pentachloride in 110 m*l* of carbon tetrachloride according to the above procedure. After 7 hrs' stirring at room temperature, 50 m*l* of ice water was stirred into the cooled mixture. After 10 mins' stirring at 0°C, the contents were separated and the aqueous layer was quickly washed with 10 m*l* of cold chloroform. Solid sodium bicarbonate enough to give pH 5—6 was stirred into the cooled aqueous layer, and then the mixture was stirred for 30 min, and then basified by the addition of further sodium bicarbonate (pH 8). The contents turned orange during this basification. The sodium chloride precipitated was filtered off and washed with chloroform. The filtrate was extracted with chloroform, and the combined extract was dried over anhydrous K_2CO_3. The evaporation of the solvent below 25°C (bath) under reduced pressure left 3.23 g of a viscous orange oil, which gradually solidified on being set aside at room temperature. The material dissolved in benzene reprecipitated in methanol for purification (three times), giving IIIa as a white amorphous solid (65% yield); mp 150—154°C.

Found: C, 88.05; H, 8.59%. ν_{max}^{KBr} 2985, 2924, 2833, 2577, 1456, 1376, 1357, 1214 w, 1183 w, 830, 794 and 727 cm^{-1}. The basification of the aqueous solution of IIa with cold 5N sodium hydroxide produced the same polymer.

The Reaction of IIb with Sodium Hydroxide. An aqueous solution of IIb, prepared from 3.5 g of the above isomerized methylcycloheptatriene and 15.1 g of phosphorus pentachloride, was alkalized with 8N sodium hydroxide (pH 9) and subjected to the same treatment as above; this gave a viscous orange liquid. Two purifications of the oil by reprecipitation from benzene-methanol gave IIIb as a pale yellow amorphous solid (57% yield); mp above 260°C. ν_{max}^{KBr} 3030, 2924, 2857, 1439, 1389, 763, 730 and 712 cm^{-1} (All the bands were very broad.).

The combined filtrate of the above purification was evaporated, and the residue, dissolved in benzene, was passed through an alumina column. The evaporation of the benzene-elute under reduced pressure gave 30 mg of a yellow oil which was assumed, from its IR spectrum (1630 and 1590 cm^{-1}), to be a mixture of the methyltropones (IVb) (1% yield). The oil was refluxed with 40 mg of 2,4-dinitrophenylhydrazine in 20 m*l* of ethanol (with a trace of hydrochloric acid) for 10 min. The precipitate was then collected and recrystallized from benzene, giving 30 mg of reddish-brown plates; this substance was considered to be the 2,4-dinitrophenylhydrazone of IVb, mp 230—232°C.

Found: C, 56.93; H, 3.98; N, 18.06%. Calcd for $C_{14}H_{12}N_4O_4$: C, 56.00; H, 4.03; N, 18.66%.

The Reactions of IIa with Alkylamines (Va and Vb). a) An aqueous solution of IIa, prepared from 20 g of the thermally-treated isopropylcycloheptatriene and 65.3 g of phosphorus pentachloride, was added, drop by drop, into 169 g of an ice-cooled and stirred 40% aqueous solution of dimethylamine. After having been stirred for 2 hr, the mixture was extracted with ether; the extract was evaporated under reduced pressure, and then distilled, giving a mixture of 1-, 2-, and 3-substituted Va as a yellow oil (72% yield); bp 66—67°C/1.3 mmHg.

Found: C, 81.60; H, 10.89; N, 8.23%. Calcd for $C_{12}H_{19}N$: C, 81.30; H, 10.80; N, 7.90%. ν_{max}^{neat} 2959, 2865, 2829, 2786, 1464, 1458, 1385, 1366, 1304, 1277, 1217, 1174, 1153, 1103, 1064, 1042, 1013, 1001, 911, 898, 878, 867, 839, 798, 768, 755 and 731 cm^{-1}. τ_{CCl_4} 8.97 (d, J 6.6 Hz; *i*-Pr), 8.89 (d, J 6.6 Hz; *i*-Pr), 8.86 (d, J 6.6 Hz; *i*-Pr), 8.22 (m; J 6.6 Hz; H-7), 7.74 (s; NMe_2), 7.45 (m; *i*-Pr-methine), 4.80, 4.02, 3.51 (m; ring protons).

b) The similar treatment of IIa with an excess 30% aqueous solution of methylamine gave Vb as a yellow oil (35% yield); bp 70—71°C/3 mmHg.

Found: C, 80.68; H, 10.27; N, 8.03%. Calcd for $C_{11}H_{17}N$: C, 80.92; H, 10.50; N, 8.58%. ν_{max}^{neat} 2950, 2857, 2778, 1456, 1445, 1377, 1359, 1311, 1290, 1181, 1136, 1100, 1028, 996, 921, 827, 800, 762 and 726 cm^{-1}. τ_{CCl_4} 8.97 (d, J 6.6 Hz; *i*-Pr), 8.90 (d, J 6.6 Hz; *i*-Pr), 8.87 (d, J 6.6 Hz; *i*-Pr), 8.3 (m; H-7), 7.62 (s, N-CH_3), 7.46 (m; *i*-Pr), 4.77, 4.08, 3.80 (m; ring protons).

The Reaction of IIc with Sodium Hydroxide: Formation of *t*-Butyltropone (IVc) and *t*-Butylcycloheptatrienes(VIc). A solution of IIc in 100 m*l* of water, prepared from 7.43 g of an isomerized mixture of Ic and 20.1 g (2.1 equiv.) of phosphorus pentachloride as has been described above was slowly stirred into 60 m*l* of cold 33% aqueous sodium hydroxide under ice-cooling, and then the stirring was continued for 30 more min. The precipitate was then filtered off and washed with chloroform. The filtrate was extracted with chloroform, and the combined extract, washed with cold water and dried over $MgSO_4$, was evaporated at 20°C/20 mmHg, affording an oily stuff. The NMR spectrum (in CCl_4) showed *t*-butyl signals as singlets at τ 8.83, 8.90, and 8.92 and an H-7 signal as a multiplet at 6.57, indicating that the oil was a mixture of di-(1-, 2- and 3-*t*-butylcycloheptatrienyl)ether. It was set aside overnight at room temperature with 0.2 m*l* of conc. hydrochloric acid, and then extracted with benzene after the addition of cold dilute aqueous sodium bicarbonate. The extract was washed with cold water and dried over $MgSO_4$. After the evaporation of the solvent under reduced pressure, the residue was distilled, giving VIc as a colorless oil (52% yield), bp 27—29° C/0.7 mmHg, and IVc as a yellow oil (61%), bp 104—106°C/0.7 mmHg.

Found for IVc: C, 80.28; H, 8.87%. Calcd for

$C_{11}H_{14}O$: C, 81.44; H, 8.70%. ν_{max}^{neat} 2941, 1623, 1567, 1520, 1471, 1362, 1333, 1235, 1208, 988, 902, 864, 833, 790, 740, 711 and 684 cm^{-1}. It did not give a picrate.

2,4-Dinitrophenylhydrazone of IVc. A mixture of 58 mg of IVc and 71 mg of 2,4-dinitrophenylhydrazine was refluxed for 1 hr in 2 m*l* of ethanol with a trace of concentrated hydrochloric acid. The precipitate was then filtered off and recrystallized from ethanol, giving dark brown needles; mp 182—184°C.

Found: C, 60.24; H, 5.03; N, 16.17%. Calcd for $C_{17}H_{16}N_4O_4$: C, 59.64; H, 5.30; N, 16.37%.

2- and 3-*t*-Butyl-7-methoxycycloheptatriene (Vc). To 150 m*l* of a cold aqueous solution of IIc, made by the treatment of 5.0 g of an isomerized mixture of Ic with 13.5 g of phosphorus pentachloride, there was added 15 m*l* of methanol, and then 40 g of sodium bicarbonate, drop by drop under ice-cooling. The contents were stirred at 0°C for a further 30 min, and then extracted with ether. The extract was washed with cold water, dried over anhydrous K_2CO_3, and distilled, giving 1.79 g (30%) of Vc as a colorless oil, bp 64—69°C/2.5 mmHg, and 0.3 g (12%) of IVc as a yellow oil, bp 105—107°C/1.8 mmHg.

Found for Vc: C, 80.36; H, 9.46%. Calcd for $C_{12}H_{18}O$: C, 80.85; H, 10.18%. ν_{max}^{neat} 2959, 1475, 1460, 1387, 1374, 1361, 1252, 1205, 1135, 1122, 1109, 1080, 991, 829, 799, 764, 743 and 725 cm^{-1}. τCCl, 8.90 (s; *t*-Bu),*1 8.83 (s; *t*-Bu),*1 6.91 (m; 2H), 6.68 (s; OMe),*2 6.67 (s; OMe),*2 4.65 (m; 4H), 4.03 (m; 3H), 3.49 (m; 3H); the two couples of the singlets (*1,2) had approximately the same intensity, showing that Vc was a 1 : 1 mixture of the 2- and 3-substituted cycloheptatriene.

4- and 5-*t*-Butyltropolone (VIIIa, IX). A mixture of 5.84 g of the above tropone (IVc) and 9.05 g (4 equiv.) of 80% hydrazine hydrate was refluxed in 50 m*l* of ethanol for 6 hr. To the residue freed from the solvent there was added 50 m*l* of cold water, and then the mixture was extracted with benzene. The extract was evaporated at 20°C/15 mmHg, leaving 6.24 g (86%) of the crude 2-amino-*t*-butyltropone (VII) as a reddish-brown tar (ν_{max}^{neat} 3348, 3311, 2950, 1592, 1513, 1473, 1429, 1364, 1333, 1263, 949, 901, 792, 761 and 710 cm^{-1}). Without purification, this was dissolved in 350 m*l* of ethanol and 50 m*l* of 6N potassium hydroxide and refluxed for 10 hr. Most of the solvent was removed at below 60°C under reduced pressure; a saturated aqueous solution of sodium carbonate and ether was then added to the residue. After the mixture had been stirred for 30 min at room temperature, the precipitate, the sodium salt of 4-*t*-butyltropolone (mp>290°C), was collected and washed with ether. The precipitate, dissolved in 25 m*l* of water, was brought to pH 2—3 with 2N sulfuric acid, and the freed tropolone was extracted with ether. This procedure was repeated 3—4 times until the band at 11.9 μ in the IR spectrum of the sodium salt disappeared, giving 2.5 g of the free acid (VIIIc) (in 40% overall yield from the tropone mixture) as yellowish-brown needles, mp 33—34°C, after recrystallization from light petroleum (<60°C).

Found: C, 74.34; H, 7.91%. Calcd for $C_{11}H_{14}O_2$: C, 74.13; H, 7.97%. λ_{max}^{MeOH} mμ (log ε): 240 (4.23), 325 (3.52), 349 (3.45). ν_{max}^{neat} 3226, 2959, 1610, 1543, 1497, 1477, 1429, 1391, 1366 w, 1348 w, 1299 sh, 1269, 1252, 1199, 943, 916, 893, 825, 756 br, 741 br and 714 br cm^{-1}. VIIIc turned green (aq. layer) and reddish brown (benzene layer) when treated with ferric chloride.

The filtrate and the ether washing obtained by the above sodium carbonate treatment were combined, and the ether was evaporated under reduced pressure. The residue, after filtration, was extracted with chloroform, and the extract (dried over Na_2SO_4) was evaporated. The residue, which crystallized on standing, was washed with a small amount of light petroleum (<60°C); the insoluble part was sublimed at 80—100°C/1 mmHg, giving IX as pale yellow prisms, mp 102—104°C.

Found: C, 74.12; H, 7.98%. Calcd for $C_{11}H_{14}O_2$: see above. λ_{max}^{MeOH} mμ (log ε): 234.5 (4.48), 245 sh (4.40), 250 sh (4.27), 323 (4.04), 3.51 (3.87), 3.67 (3.78). ν_{max}^{KBr} 3247, 2959, 1616, 1555, 1471, 1449, 1427, 1376, 1279, 1248, 1214, 1200, 1085, 869, 856, 822, 764 and 704 cm^{-1}.

3-*t*-Butylbenzoic Acid. Into an ice-cooled solution of 0.50 g of VIIIa dissolved in 4 m*l* of pyridine there was slowly stirred, 0.70 g (1.3 equiv.) of *p*-toluenesulfonyl chloride; then the mixture was stirred for 5 hr at 0°C. The mixture was poured into 15 m*l* of ice water and, after stirring, extracted with chloroform. The dried extract (over $MgSO_4$) was freed from the solvent, leaving a reddish-orange oil which was presumably a mixture of 4- and 6-*t*-butyl-2-tosyloxytropone (X). The oil, dissolved in 15 m*l* of ethanol and 15 m*l* of 20% aqueous potassium hydroxide, was heated under reflux for 1 hr. The ethanol was removed under reduced pressure, and the aqueous solution was brought to pH 2—3 with cold 6N sulfuric acid at 0°C. The mixture was extracted with ether; the evaporation of the dried extract (over $MgSO_4$) at 20°C *in vacuo* left a reddish liquid. The benzene solution (3 m*l*) of the oil was shaken with 5 m*l* of 10% aqueous sodium bicarbonate. The aqueous layer was brought to pH 2 with cold 6N sulfuric acid; the precipitate was recrystallized from light petroleum (<50°C), giving 0.17 g (35%) of the benzoic acid as colorless prisms, mp 132—133°C (lit[22] 127°C).

(Found: C, 74.13; H, 7.90%.) ν_{max}^{KBr} 2941, 2632, 2525, 1670, 1590, 1570, 1470, 1433, 1405, 1355, 1297. 1282, 1255, 1172, 1134, 1078, 957 br, 820, 746, 720 and 695 cm^{-1}. τ_{CCl_4} 8.62 (s; *t*-Bu), 3.61 (t, *J* 7.5 Hz; H-5), 3.39 (dt, *J* 7.2, 1.5 Hz; H-4), 3.07 (dt, *J* 7.2, 1.5 Hz; H-6), 2.87 (t, *J* 1.5 Hz; H-2), −3.00 (s; OH).

7-Bromo-4-*t*-butyltropolone (XIa). Into a solution of 0.30 g of VIIIa in 4 m*l* of methanol there was stirred, drop by drp at 0°C, 0.33 g (1.2 equiv.) of bromine dissolved in 1 m*l* of methanol. After having been stirred at 0°C for 4 hr and then set aside overnight, the mixture was evaporated under reduced pressure, leaving a yellow powder. Recrystallization from ethanol gave 0.30 g (69%) of the bromotropolone as yellow plates, mp 75—75.5°C.

Found: C, 51.90; H, 5.29%. Calcd for $C_{11}H_{13}O_2Br$: C, 51.38; H, 5.10%. λ_{max}^{MeOH} mμ (log ε): 256 (4.30), 331 (3.48), 367 (3.48), 379 (3.50). ν_{max}^{KBr} 3226, 2933, 1603, 1575, 1538, 1466, 1441, 1387, 1362, 1351, 1289, 1214, 1190, 1109, 941, 928, 903, 848, 839, 794. 776, 746 br and 722 cm^{-1}.

3,7-Dibromo-4-*t*-butyl-2-methoxy-2,3-dihydrotropolone (XIIa). The tropolone VIIIa was treated with 3 equiv. moles of bromine under the above conditions; the recrystallization of the product from benzene-

22) A. Baur, *Ber.*, **24**, 2832 (1891).

light petroleum (<50°C) gave the adduct (XIIa) as colorless needles (89%), mp 120—127°C (gradually decomp.).

Found: C, 39.13; H, 4.46%. Calcd for $C_{12}H_{16}O_3Br_2$: C, 39.17; H, 4.37%. ν_{max}^{KBr} 3367, 2933, 1667, 1558, 1456, 1351, 1189, 1147, 1110, 1070, 1063, 1046, 1004, 895, 840, 825, 787 and 742 cm^{-1}.

3,7-Dibromo-4-*t*-butyl-2-ethoxy-2,3-dihydrotropolone (XIIb). A solution of 0.80 g of XIIa in 5 m*l* of ethanol was refluxed for 5 min; after the solvent had then been removed, the residue was recrystallized from ethanol, giving 0.60 g (73%) of the ethanol adduct (XIIb) as pale yellow needles, mp 84.5—85.5°C.

Found: C, 41.45; H, 4.85%. Calcd for $C_{13}H_{18}O_3Br_2$: C, 40.87; H, 4.75%. λ_{max}^{EtOH} mμ (log ε): 240 (3.83), 348 (3.57). ν_{max}^{KBr} 3413, 2941, 2857, 1658, 1613, 1555, 1466, 1453, 1385, 1370, 1351, 1323, 1152, 1115, 1087, 1063, 1048, 1014, 899, 885, 851, 828, 792 and 740 cm^{-1}.

Bromination of 4-Isopropyltropolone (VIIIb) in Methanol. To an ice-cooled and stirred solution of 0.30 g of VIIIb in 5 m*l* of methanol there was added 0.96 g (3.0 equiv.) of bromine dissolved in 1 m*l* of methanol. After 2 hrs' stirring, the mixture was set aside overnight and then poured onto ice and extracted with ether. The ether extract was dried, the solvent was evaporated at room temperature, and the residue was recrystallized from methanol, affording 0.19 g of pale green needles (mp 130—133°C undepressed on admixture) identified from the IR and NMR spectra with an authentic specimen of 3,7-dibromo-4-isopropyltropolone (XIb). On the evaporation of the recrystallization filtrate, 0.12 g more of XIb (crude) was obtained from the residual fraction forming the sodium salt with saturated aqueous sodium bicarbonate. The IR spectrum of the fraction (*ca.* 0.15 g), which did not give any sodium salt with alkali, showed a hydroxy band at 3448 and carbonyl bands at 1686 and 1730 cm^{-1}, suggesting the presence of an additional bromine product, but the structure had not yet been made clear.

7-Bromo-4-*t*-butyltropolone (XIa) from 3,7-Dibromo-4-*t*-butyl-2-methoxy-2,3-dihydrotropolone (XIIa). The XIIa adduct (20 mg) was heated at 130°C for 20 min under ordinary pressure. The resulting oil was then purified by sublimation at 80°C/1.5 mmHg, followed by sodium salt formation; this gave 11 mg of colorless crystals. The IR and NMR spectra were identical with those of XIa.

We wish to thank Professor K. Takase (of this department) for helpful discussions, Dr. C. T. Chang (National Taiwan University) for his experimental work in the isolation of 5-*t*-butyltropolone, and Mr. E. Kirii (of this department) for the preparation of the *N*-alkylamino-isopropylcycloheptatrienes.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 3284—3288 (1969)

Stereochemical Studies of Monoterpene Compounds. VII.[1] Conformational Study of 4-Hydroxymenthones by Temperature-dependent Circular Dichroism[2]

Tsuyoshi SHISHIBORI, Takayuki SUGA, Satoru WATANABE and Tamon MATSUURA

Department of Chemistry, Faculty of Science, Hiroshima University, Hiroshima

(Received May 14, 1969)

The conformational analysis of a stereoisomeric pair of 4-hydroxymenthones, (1R:4R)-(−)-4-hydroxymenthone (**1**) and (1R : 4S)-(+)-4-hydroxyisomenthone (**2**), was made by means of temperature-dependent circular dichroism. It was demonstrated that α-hydroxyketone (**1**) exists in the conformational equilibrium: **1a**⇄**1b**; the conformer **1a** exists predominantly in a nonpolar medium, whereas the conformer **1b** is more stable than **1a** in a polar medium. On the other hand, the other isomer, (**2**), exists preferentially in the state of the conformer **2b** in either a polar or a nonpolar solvent. The results were interpreted in terms of the competition of the steric factor and intramolecular hydrogen-bonding.

The measurement of circular dichroism (CD) at different temperatures has been found very useful for investigating the conformational equilibrium in a flexible cyclohexanone structure.[3] α-Hydroxycyclohexanones represent interesting examples because, in addition to a possible ring-

conformational equilibrium, intramolecular hydrogen-bonding between the hydroxyl and the carbonyl groups can be expected. The room-temperature ORD and CD curves of 4-hydroxymenthones in several solvents[4] have been interpreted in terms of these effects. The temperature-dependent CD spectra may be expected to furnish further insight into the interplay of conformational, solvational, and hydrogen-bonding effects in 4-hydroxymenthones. This paper will deal with the conformational analysis of (1R : 4R)-(−)-4-hydroxymenthone (**1**), (1R:4S)-(+)-4-hydroxyisomenthone (**2**), and (1R:4R)-(+)-4-acetoxymenthone (**3**) by means of the temperature-dependent CD

Results and Discussion

The temperature-dependent CD data of compounds **1** and **2** and of the acetate (**3**) of **1** are summarized in Table 1.

(1R : 4R)-(−)-4-Hydroxymenthone (**1**) and (1R:4S)-(+)-4-hydroxyisomenthone (**2**) can exist in two interconvertible chair conformations, **1a** and **1b**, and **2a** and **2b**, respectively. On the basis of steric requirements only, it can be predicted that the conformer **1b** will be energetically favored. However, the conformer **1a** can be stabilized by hydrogen-bonding between the carbonyl and the hydroxyl groups, so a clear-cut evaluation of the difference between the relative energies of **1a** and **1b** is difficult. On the other hand, the conformer **2b** in the conformational equilibrium **2a**⇄**2b** can be predicted to be energetically favored on the basis of steric requirements; also, it can be stabilized by an intramolecular hydrogen bond.

The variable-temperature CD measurements of compounds **1** and **2** afforded a convincing assignment for the preferred conformation. According to the octant rule,[5] the conformers **1a** and **2a**

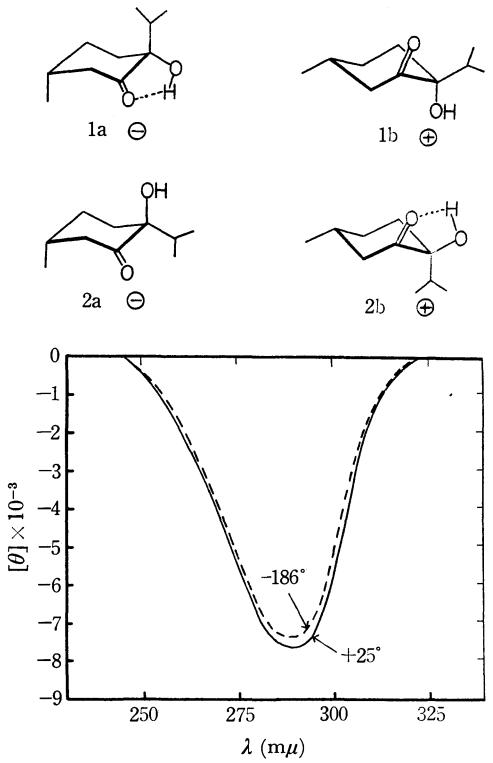

Fig. 1. Circular dichroism curves of (1R:4R)-(−)-4-hydroxymenthone (**1**) in MI at +25 and −186°C.

should exhibit a negative Cotton effect and the conformers **1b** and **2b** a positive one.

(1R : 4R)-(−)-4-Hydroxymenthone (1). As is shown in Fig. 1 and Table 1, the CD curves of **1** in MI solvent[6] and decalin exhibit a negative Cotton effect, and the rotational strength of **1** is almost temperature-independent over the range from 25°C to −186°C in a MI solvent and 25°C to −74°C in decalin. These phenomena observed in CD curves are distinct from those of (−)-

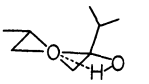
6) MI solvent is composed of methylcyclohexane-isopentane in the ratio 1 : 3 by volume.

menthone[7] and 2-oxo-1-*p*-menthanol,[8] either of which shows a strong temperature-dependence. The negative Cotton effect implies that **1** exists in the **1a** conformation, while the temperature-independence of the rotational strength suggests the conformational homogeneity of **1a** in such a nonpolar solvent as MI and decalin.

The infrared spectrum of **1** in carbon tetrachloride showed only a concentration-independent band at 3495 cm^{-1} resulting from an intramolecular hydrogen-bond between the hydroxyl and the lone-pair electrons on the carbonyl oxygen atom.[9] This indicates that **1** exists in the conformation **1a**, only in which the OH···O=C-type intramolecular hydrogen bond is possible.

A deductive calculation of the conformational energy on the basis of the steric factor shows that the conformer **1a** would be energetically less favored by *ca.* 1.7 kcal/mol[10] than would be **1b** in the conformational equilibrium **1a**⇄**1b**. However, the conformer **1a** can be stabilized by intramolecular hydrogen-bonding between the carbonyl and the hydroxyl group (a saving of *ca.* 2—5 kcal in terms of energy). The results of the variable-temperature CD and the infrared spectral measurements show that the conformer **1a** is stabilized by the intramolecular hydrogen-bonding energy, which is sufficient to overcome the instabilization due to the steric repulsion between groups and atoms.

At a high temperature the strength of the negative CD curve of **1** in decalin was decreased (Table 1). This means that at a high temperature the hydrogen-bonded form of **1a** would be diminished with an increase in the amounts of the nonbonded conformer, **1b**, and/or of the positively-rotating conformer, **1c**, of the twist form.



1c

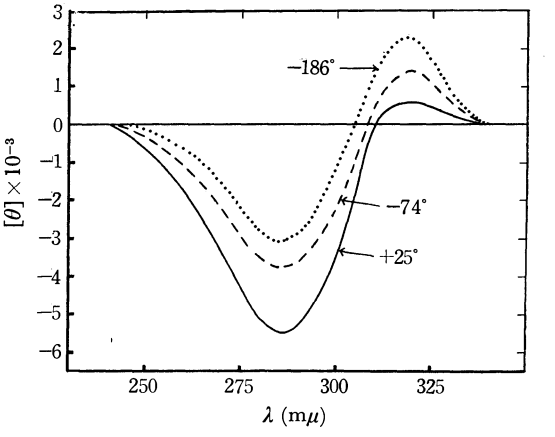


Fig. 2. Circular dichroism curves of (1R:4R)-(−)-4-hydroxymenthone (**1**) in EPA at +25, −74, and −186°C.

In the EPA solvent,[13] **1** exhibits a multiple-Cotton-effect CD curve (Fig. 2). The double-humped Cotton effects arising from $n\rightarrow\pi^*$ transitions in a saturated ketone can be explained in terms of solvational equilibria[14] and/or conformational equilibria. If a solvational equilibrium were solely responsible for the double-humped Cotton effect observed in **1**, the short-wavelength CD band could be attributed to the solvational species, and the long-wavelength band, to the unsolvated form. If this were the case, the apparent rotational strength of the blue-shifted band would increase at lower temperatures. Actually, the opposite result was obtained in EPA (Fig. 2).

The CD data were favorably explained on the basis of a conformer equilibrium as follows. According to the octant rule,[5] the negative CD band at a short wavelength may be attributed to the conformer **1a**, and the red-shifted positive band, to the conformer **1b**. These assignments are also in agreement with the following findings: an equatorial hydroxyl group adjacent to the carbonyl group causes a blue-shift of the ORD curve peak, whereas an axial hydroxyl group results in a red-shift. If the CD band assignment is accepted, the enlargement of the long-wavelength band at lower temperatures indicates that the conformer **1b** is energetically favored in a polar solvent, EPA.

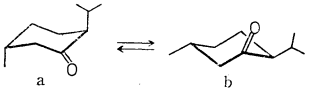
10) A free energy difference ($-\Delta G$) for the equilibrium



a b

a⇄b of menthone was estimated by Richborn[11] to be 2.4 kcal/mol based on the menthone-isomenthone isomerisation. Assuming ΔG of the hydroxyl group adjacent to the carbonyl to be −0.7 kcal/mol,[12] the free energy difference for the equilibrium la⇄1b is estimated *a priori* to be *ca.* 1.7 kcal/mol.

14) Ref. 3, p. 329.

Such a result may be interpreted in terms of the competition of the steric factor and intramolecular hydrogen-bonding. In hydrocarbon solvents, the stabilization due to the intramolecular hydrogen-bonding overcomes the steric repulsion, as has been described above. However, the stabilizing intramolecular hydrogen bond will be broken in the polar solvent, so that the steric requirements mainly dominate the conformation of **1**. Therefore, the sterically-favored conformer, **1b**, is preferred in EPA.

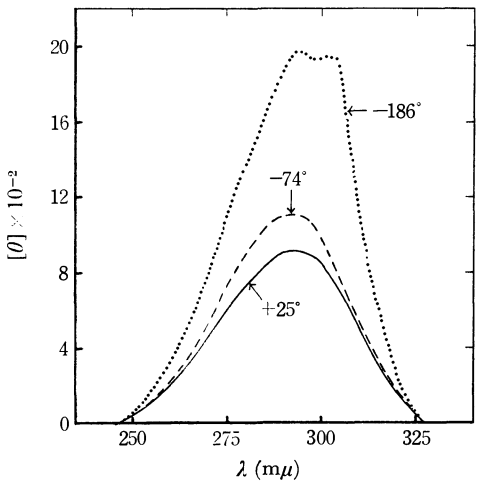

Fig. 3. Circular dichroism curves of (1R:4R)-(+)-4-acetoxymenthone (**3**) in EPA at +25, −74, and −186°C.

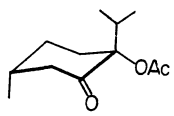
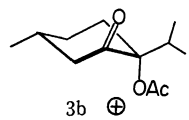
(+)-4-Acetoxymenthone. The variable-temperature CD curves of (+)-4-acetoxymenthone (**3**), the acetylated compound of **1**, gave further support to the above deduction. The CD curve (Fig. 3) of **3** in EPA showed a weak positive Cotton effect and an increase in strength upon the lowering of the temperature. This implies that the positively-rotating conformer **3b** is preferred. Since the stabilization due to the intramolecular hydrogen-bonding is absent in the acetylated compound **3**, the conformer **3b** is energetically favored by the



3a ⊖



3b ⊕

steric requirements. If one bears in mind that the conformational energy of the hydroxyl group[12] in **1** is comparable with that of the acetoxyl group in **3**, the stabilizing intramolecular hydrogen bond can be found to contribute to the conformational preference of **1a** in a nonpolar solvent.

(1R : 4S)-(+)-4-Hydroxyisomenthone (2). The CD curves of **2** in decalin and MI (Table 1) and in EPA (Fig. 4) show a positive Cotton effect, with

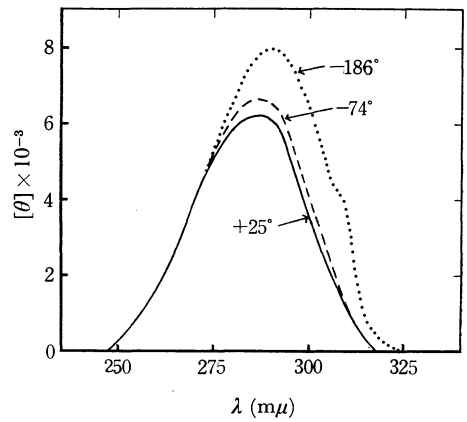


Fig. 4. Circular dichroism curves of (1R:4S)-(+)-4-hydroxyisomenthone (**2**) in EPA at +25, −74, and −186°C.

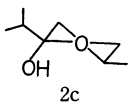
only a single maximum at room temperature. The increase in the rotational strength upon a change to lower temperatures in EPA and MI indicates that the positive rotating conformer, **2a**, is the more stable in either a polar or nonpolar medium. This behavior in CD curves is similar to that of (+)-isomenthone.[7] The infrared spectra of **2** in carbon tetrachloride showed only a concentration-independent band at 3495 cm^{-1} resulting from an intramolecular hydrogen bond between the hydroxyl and the carbonyl groups. The stabilization due to the intramolecular hydrogen bond contributes to the preference of the conformer **2b**. On the basis of steric requirements, the conformer **2b** can also be predicted to be energetically favored by *ca.* 1.9 kcal/mol.[15] more than **2a**. The results of the low-temperature CD curves are in agreement with the above proposal.

The CD curves of **2** in decalin showed a decrease in rotational strength upon a change to higher temperatures (Table 1). This suggests that the less stable conformer in the conformational equilibrium of **2** would not be the twist form **2c**, which would be highly positive, but the negatively-rotating chair form **2a**.



2c

15) The conformational energy ($-\Delta G$) of the methyl group situated at β-position to the carbonyl is estimated to be *ca.* 1.8 kcal/mol,[11b] and of the isopropyl group adjacent to carbonyl to be *ca.* 0.6 kcal/mol.[11b] Assuming ΔG of the hydroxyl group adjacent to the carbonyl group to be −0.7 kcal/mol, the free energy difference for the equilibrium 2a⇄2b is estimated deductively to be *ca.* 1.9 kcal/mol.

Experimental

Materials. (1R : 4R)-(−)-4-Hydroxymenthone (**1**), (1R : 4S)-(+)-4-hydroxyisomenthone (**2**), and (1R : 4R)-(+)-4-acetoxymenthone (**3**) are the same as were prepared in a previous paper[4] of this series.

Spectral Measurements. The IR spectra in the hydroxyl-stretching region were measured with a Perkin-Elmer Model 621 Grating Infrared Spectrometer at 25°C. A sodium chloride absorption cell, 20 mm long, was used; the concentration of the solution was 0.005 mol/*l*, at which the association of the solute is negligible. The CD curves were obtained by a Japan Spectroscopic Co., Ltd., automatically-recording spectropolarimeter, Model ORD/UV-5, equipped with a circular dichroism attachment. The low- and high-temperature CD curves were obtained by the same spectrometer, using low- and high-temperature CD cells[16] designed and constructed by the authors. All the measurements were performed using spectrograde or purified solvents, a 10 mm cell, and *c* 0.1. The volume contraction of the solvents was corrected.

Kinetic Studies of Solvolysis. XVI.*1 Phenolysis of *cis*- and *trans*-4-*t*-Butylcyclohexyl *p*-Toluenesulfonates. Rates and Product Distribution

Kunio Okamoto, Seiki Saitô and Haruo Shingu

Department of Hydrocarbon Chemistry, Faculty of Engineering Kyoto University, Sakyo-ku, Kyoto

(Received May 15, 1969)

The rates of the phenolysis of *cis*- and *trans*-4-*t*-butylcyclohexyl *p*-toluenesulfonates have been measured in the presence of equimolar amounts of triethylamine in phenol, phenol-benzene (3 : 1 by wt), and phenol-benzene (1 : 1 by wt) solvents. At 75°C, the axial isomer, *i.e.*, the *cis* tosylate, phenolyzes more rapidly in the phenol-benzene mixture (1 : 1 by wt) than the equatorial isomer, *i.e.*, the *trans* tosylate, by a factor of 3.08; this factor is not far from the axial-equatorial rate ratios observed in other hydroxylic solvents,[2] indicating that phenol is a typical solvolytic solvent. Under the same reaction conditions as the rate measurements, the equatorial tosylate yields *t*-butylcyclohexene (72.5%), *t*-butylcyclohexyl phenyl ether (9.4%), predominantly inverted (*cis*-4-*t*-butylcyclohexyl) phenyl ether, and *t*-butylcyclohexylphenol (4.4%), whereas the axial tosylate yields *t*-butylcyclohexene (87%) and the phenyl ether (8.7%), largely inverted (*trans*-4-*t*-butylcyclohexyl) phenyl ether, but containing increasing amounts of retained (*cis*-4-*t*-butylcyclohexyl) and and rearranged (*trans*-3-*t*-butylcyclohexyl) ethers; the rest is a mixture of *t*-butylcyclohexylphenols (1.6%). The composition percentages of the retained phenyl ether obtained from the two tosylates, *i.e.*, 20.4% for the *cis* tosylate and 12.9% for the *trans* tosylate, indicate the highest extents of retention for phenol among those known for any other hydroxylic solvents.[3] The initially added *t*-butylcyclohexenes exert no influence on the olefin or on the phenyl ether composition, whereas triethylammonium and diethylammonium *p*-toluenesulfonates, when added initially, enhance the phenolysis rate and exert a small but definite influence on the composition of the phenyl ether. The hypothesis of the hydrogen-bridged cation,[2] proposed in order to explain the enhanced rate of the *cis* isomer and in order to elucidate the retained solvolysis product, has been questioned by a consideration of the mechanism on the basis of the results of this phenolysis.

In previous studies[1] of the retentive solvolysis, it has been demonstrated that phenol is a notable

solvent in which the S_N1 solvolysis of optically-active α-phenylethyl chloride gives a partially-retained phenyl ether. However, for the systems other than α-phenylethyl, it was not clear whether or not such retentive phenolysis is common. Therefore, it is obviously desirable to have more information about the structural factors of the substrate with regard to the retention of the configuration in phenolysis. As one of works of this line, we have considered it of interest to extend the rate and the product studies to the 4-*t*-butylcyclohexyl system, because this system has a rigid conformation fixing the *t*-butyl group in the equatorial position; also, the kinetic[2] and the product analysis[2,3] data have already been made available for various solvents other than phenol. In this paper we will describe our findings on the rate and the products in the phenolysis of *cis*- and *trans*-4-*t*-butylcyclohexyl *p*-toluenesulfonates in the presence of triethylamine, and will discuss the bearing of the results on the characteristics of phenol as an ionizing solvent and as a retentive solvent.

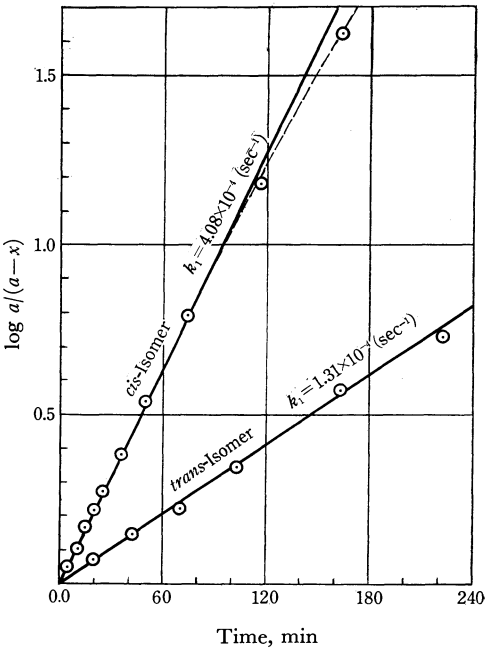

Fig. 1. First-order plots for phenolysis of *cis*- and *trans*-4-*t*-butylcyclohexyl *p*-toluenesulfonates in the presence of triethylamine in 50 wt% phenol-benzene solvent at 75.0°C.

Results and Discussion

Phenolysis Rates of *cis*- and *trans*-4-*t*-Butylcyclohexyl *p*-Toluenesulfonates in the Presence of Triethylamine. The phenolysis of *cis*- and *trans*-4-*t*-butylcyclohexyl *p*-toluenesulfonates was carried out in phenol-benzene solvents at 75°C and the rate constants were determined titrimetrically. In spite of the presence of equimolar amounts of triethylamine, the *trans* tosylate displayed good first-order behavior, whereas the first-order plot for the *cis* tosylate shows a downward drift after about 80% completion (Fig. 1). Initially-added triethylammonium *p*-toluenesulfonate gave rise to a small rate enhancement for both tosylates (Table 1), probably due to the normal salt effect.[4]

There is a decided trend towards markedly enhanced rates in solvents with higher phenol contents; at 75°C for the *trans* tosylate a one and half-fold increase in the phenol concentration gave rise to rate enhancement by a factor of three (Table 1).

In Fig. 2 the solvolysis rates of 4-*t*-butylcyclohexyl *p*-toluenesulfonates in phenol-benzene (1 : 1 by wt), phenol-benzene (3 : 1 by wt), phenol, acetic acid,[2] formic acid,[2] and ethanol[2] at 75°C are plotted on a logarithmic scale against the *Y* scale of Grunwald and Winstein.[5,6] There is a general tendency towards higher rates in solvents of higher *Y* values, but the proportionality is far from exact. This result is not unexpected if one considers that the rate measured for the *t*-butylcyclohexyl system might not reflect the true ionization rate of the system (*vide infra*).

The *cis* tosylate, *i. e.*, the axial isomer, phenolyzed more rapidly than the *trans* (equatorial) tosylate by a factor of 3.08 in phenol-benzene (1 : 1 by wt) at 75°C, indicating, as far as the axial-equatorial rate ratio is concerned, that the phenolic solvent[7] is not specifically different from such other solvents as formic acid, acetic acid, and ethanol, in which the axial tosylate solvolyzes more rapidly than the equatorial isomer by factors of 2.51, 2.85, and 3.05 respectively (Table 1).

In the extreme that the higher rate of the axial over the equatorial tosylate is attributed only to steric acceleration caused by the higher initial

state energy of the axial isomer, the rate enhancement for the axial isomer is calculated to be a factor of 2.1 at 75°C, since a reliable value for the energy difference in ΔF between the two isomers has recently given as 0.515 kcal/mol.[8]

The gap between the calculated (2.1) and the observed factor (2.51—3.08) can be ascribed to the lowering of the free energy for the transition state of the axial isomer; the value is estimated to be about 0.12—0.27 kcal/mol (Fig. 3).

As regard to the elucidation of this decrease in the free-energy of the transition state for the *cis* tosylate, the neighboring hydrogen participation hypothesis has prevailed, especially in the cases of the 4-*t*-butylcyclohexyl[2,9] and 3-cyclohexyl-2-butyl[10] systems. However, it seems difficult to deduce the formation of a bridged ethylene-protonium-ion-type intermediate[2] on the basis of such a small stabilization of the transition state.[11]

11) The question of the existence of a hydrogen-bridged cation intermediate for the solvolysis of the 4-*t*-butylcyclohexyl system will be the subject of a subsequent publication.

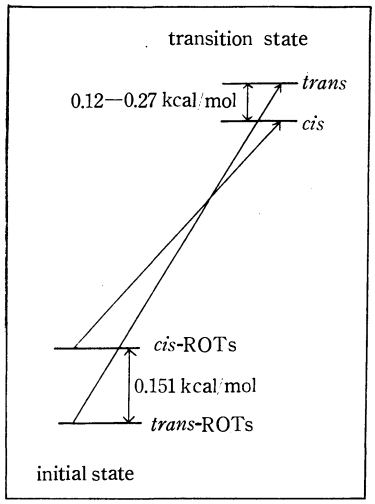

Fig. 3. Free-energy diagram for the solvolysis of *cis*- and *trans*-4-*t*-butylcyclohexyl *p*-toluenesulfonates.

Products of Phenolysis of *cis*- and *trans*-4-*t*-Butylcyclohexyl *p*-Toluenesulfonates in the Presence of Triethylamine. The products of phenolysis were investigated for both *trans*- and *cis*-4-*t*-butylcyclohexyl *p*-toluenesulfonates in a 50 wt% phenol-benzene solvent containing equimolar amounts of triethylamine at 75°C. The reaction mixture was worked up in the usual manner and then chromatographed over silica gel, giving *t*-butylcyclohexenes (a mixture of 4-, 3- and 1-*t*-butyl isomers), *t*-butylcyclohexyl phenyl ethers (a mixture of *cis*-4-, *trans*-4-, *cis*-3- and *trans*-3-*t*-butylcyclohexyl isomers), and a mixture of *t*-butylcyclohexylphenols. After the run with added triethyl- or diethylammonium *p*-toluenesulfonate had been conducted up to about 75% completion, the reaction mixture was treated with sodium naphthalene in tetrahydrofufan in order to cleave the unchanged tosylate into *t*-butylcyclohexanols; then, from the reaction mixture *t*-butylcyclohexanols,[12] *t*-butylcyclohexyl phenyl ethers and *t*-butylcyclohexylphenols were separated by elution chromatography.

The compositions of *t*-butylcyclohexenes and *t*-butylcyclohexyl phenyl ethers were determined by GLC; in some cases the latter mixture was separated into two components by means of TLC prior to the GLC analysis. The analysis scheme for the composition of *t*-butylcyclohexyl phenyl ethers is as follows:

ROPh —(t.l.c., silica gel)→ (*trans*-4- and *cis*-3-ROPh) —(g.l.c.)→ *trans*-4-ROPh + *cis*-3-ROPh

ROPh —(t.l.c., silica gel)→ (*cis*-4- and *trans*-3-ROPh) —(g.l.c.)→ *cis*-4-ROPh + *trans*-3-ROPh

12) A mixture of *cis*-4-, *trans*-4-, *cis*-3-, and *trans*-3-*t*-butylcyclohexanols; the analysis of the composition will be described in a subsequent paper.

ROPh —(g.l.c., Apiezon grease, 200°C)→ *trans*-3-ROPh + (*cis*-3- and *cis*-4-ROPh) + *trans*-4-ROPh (three peaks)

The composition of *t*-butylcyclohexanols, separated as a fraction of chromatography, was not analyzed.

Much as with the trend observed for other solvents,[3] the main product of the phenolysis for both tosylates is a mixture of *t*-butylcyclohexenes. The yield (%) of olefin formed from the equatorial (*trans*) tosylate is not far below that obtained from the axial (*cis*) tosylate (Table 2); this seems also a general tendency for the 4-*t*-butylcyclohexyl system irrespective of the nature of the solvent employed (*cf.* Ref. 3 and Table 2).

a) Ref. 3.

Since olefin formation from the equatorial (*trans*) tosylate cannot be attributed to a usual E2-type anti-elimination,[13] the production of so much olefin from the equatorial isomer may indicate the contribution of a considerable amount of *cis*-*syn*-elimination in the El or S_Ni ion-pair intermediate.[14]

13) J. Sicher, J. Závada and M. Pánková, *Chem. Commun.*, **1968**, 1147.

14) For *cis*-elimination *via* the carbonium-ion intermediate for the deamination of *cis*-4-*t*-butylcyclohexylamine and *trans*-2-decalylamine, see, respectively, G. Lamaty, C. Tapiero and R. Wylde, *Bull. Soc. Chim. France*, **1968**, 2039, and T. Cohen and A. R. Daniewski, *J. Am. Chem. Soc.*, **91**, 532 (1969).

The composition of the olefin formed in phenol is compared with that in acetic acid[3] in Table 2; the compositions for the two solvents are quite similar. Besides 4-*t*-butylcyclohexene, there exists a small amount of rearranged olefins in the cases of both solvents, indicating the presence of rearranged ion-pair intermediates during the solvolysis.

The substitution products for both tosylates are composed of a major proportion of *t*-butylcyclohexyl phenyl ether and a minor amount of *t*-butylcyclohexylphenol; among the isomers of the phenyl ether, the inverted ether is the predominant component, the rest being the retained and the rearranged or isomerized ether (Table 2). This trend has also been found in the distribution of substitution products for acetolysis[3] (Table 2) and other solvolyses.[3]

However, the composition percentage of the retained phenyl ether in phenolysis for both tosylates is the highest among those of the retained products in other solvents.[3] This probably means that the front-side attack of the phenol molecule may play an important part in increasing the retentive course for the substitution; the fact that, even in the phenolic solvent, the yield of the retentive product never exceeds that of the inverted product for 4-*t*-butylcyclohexyl system is in marked contrast to the α-phenylethyl system, for which the retentive course is predominant in the phenolic solvents.[1]

As has been observed in the cases of other solvents,[2,3] in the phenolic solvent a substantial quantity of rearranged products is also present in the substitution products; the proportions of 3-*t*-butylcyclohexyl phenyl ethers are 24.6% from the *cis* tosylate and 17.9% from the *trans* tosylate.

Since initially-added *t*-butylcyclohexenes did not exert any influence on the composition of olefins and phenyl ethers for both tosylates within essentially the experimental error of analysis (Table 3), the possibility of the formation of rearranged products *via* a proton addition to a stable molecule of *t*-butylcyclohexene can be eliminated. This course is illustrated in Fig. 4.

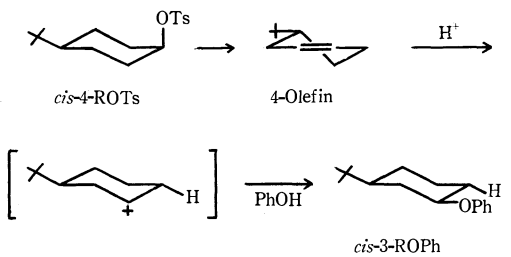

Fig. 4. 1,2-Rearrangement *via* *t*-butylcyclohexene.

The initial addition of the *p*-toluenesulfonate anion in the form of triethyl- or diethyl-ammonium salt, which is also produced as the phenolysis proceeds, has a small but definite influence on the composition of the phenyl ether (Table 4).

d) The yield was not determined.

A thorough explanation of the variation in the composition with an increase in the concentrations of the *p*-toluenesulfonate anion would be difficult because of the presence of at least four probably interconvertible ion-pair intermediates, corresponding to the four substitution products. However, it can be conservatively pointed out that the retained substitution need not be derived by only a front-side attack of a molecule of phenol, but may also be produced by the isomeric intermediate. For instance, the *cis* ion-pair intermediate may be formed by an internal rotation of the *t*-butyl cyclohexyl cation from the *trans* ion-pair intermediate; consequently, starting from the *trans* tosylate, the retained substitution product may also be produced *via* a double inversion course, following the course illustrated in Fig. 5.

Thus, conceivably there exists a possibility of the accumulation of isomerized or rearranged tosylates during the phenolysis of the 4-*t*-butylcyclohexyl system by means of the internal return of the isomerized or rearranged intermediate or by an inversive attack of the *p*-toluenesulfonate anion on the unrearranged intermediate.

The downward drift of the first-order plot for

a) In phenol-benzene (1:1 by wt) solvent at 75.0°C.
b) Instead of $Et_3NH^+OTs^-$, $Et_2NH_2^+OTs^-$ was used.
c) The yield or composition was not determined.

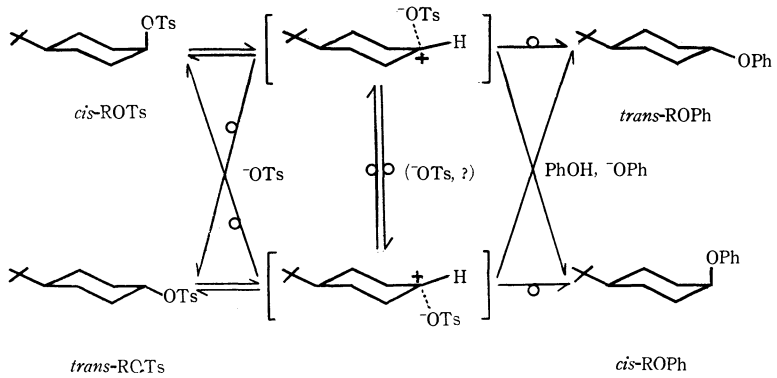

Fig. 5. Possible courses for the formation of retained 4-*t*-butylcyclohexyl phenyl ethers in phenolysis.

the *cis* tosylate, illustrated in Fig. 1, might be due to the accumulation of the *trans* tosylate, which is phenolyzed slower than the *cis* isomer.

On the basis of these considerations of the course for the retained products, the necessity of the hypothesis of a hydrogen-bridged cation intermediate[2)] for the 4-*t*-butylcyclohexyl system, proposed as an explanation of the formation of the retained substitution product, may well be questioned, as it may also be questioned on the basis of the rate data presented above. Further discussion of this problem will be the subject of a subsequent paper.

Experimental[15)]

Materials. ***trans*-4-*t*-Butylcyclohexanol** was obtained from the hydrogenphthalate of a mixture of 4-*t*-butylcyclohexanol, which had itself been prepared by means of the catalytic hydrogenation of *p*-*t*-butyl-

15) The melting points are not corrected. The microanalyses were done by the Microanalytical Center, Kyoto University. The infrared spectra were determined with a Shimadzu Model IR-27 spectrophotometer. All the gas-liquid chromatographical studies were made with a Shimadzu Model GC-2B dual-column gas chromatograph.

phenol, employing the same reaction conditions as those of the hydrogenation of *p*-isopropylphenol.[16]

p-*t*-Butylphenol (30 g, 0.20 mol) was hydrogenated using 1.6 g of a Raney nickel catalyst (W-2)[17] and 41 ml of absolute ethanol as a solvent in a 300-ml autoclave at 150°C for five hours (initial hydrogen press, 100 kg/cm^2). The catalyst was removed by filtration and washed with ethanol. The combined ethanol solutions were evaporated to dryness to give 31.0 g of 4-*t*-butylcyclohexanol (97% yield, mp 62—68°C); the infrared spectrum of the carbon tetrachloride solution showed no absorptions in the aromatic regions.

Several crystallizations of the hydrogenphthalate and subsequent saponification afforded *trans*-4-*t*-butylcyclohexanol; mp 80.1—81.1°C (lit, mp 81—82°C,[2] 80—80.5°C[18] and 82°C[19]).

***cis*-4-*t*-Butylcyclohexanol** was obtained by the elution chromatography of a mixture of 4-*t*-butylcyclohexanols; this mixture had been prepared by the reduction of 4-*t*-butylcyclohexanone with Raney nickel (W-2)[17] in ethanol. *cis*-4-*t*-Butylcyclohexanol, obtained by chromatography over alumina (Nakarai 200), melted at 81—82°C (lit, mp 82—83°C,[2] 82.5—83.5°C[20] and 83—83.5°C[19]).

4-*t*-Butylcyclohexanone was prepared following the method of Winstein and Holness[2]; the chromic acid oxidation of a mixture of 4-*t*-butylcyclohexanols in acetic acid gave 4-*t*-butylcyclohexanone in an 82% yield. This ketone melted at 48—50°C (lit, mp 47.5—48.5°C[2] and 49—50°C[21]) and boiled at 85—86°C/7 mmHg (lit, bp 90—92°C/9 mmHg[2] and 106—108°C/19 mmHg[21]).

The Tosylate of *trans*- and *cis*-4-*t*-Butylcyclohexanols was prepared according to the usual Tipson procedure.[22] *trans*-4-*t*-Butylcyclohexyl *p*-toluenesulfonate melted at 88.5—89.5°C (lit, mp 89.4—90.0°C[2] and 89—90°C[23]). *cis*-4-*t*-Butylcyclohexyl *p*-toluenesulfonate melted at 78—79°C (lit, mp 79—80°C[2] and 78—79°C[23]).

3-*t*-Butylcyclohexanone was prepared by means of the reaction of 2-cyclohexen-1-one with *t*-butylmagnesium chloride using a modification of the method of Whitmore and Pedlow[24]: oxidation of cyclohexene with chromium trioxide in acetic acid gave 2-cyclohexen-1-one (27% yield); bp 64—65°C/20 mmHg, n_D^{20} 1.4870 (lit, bp 65—66°C/20 mmHg[2] and 67°C/25 mmHg,[24] n_D^{25} 1.4824,[2] n_D^{20} 1.4879[24]). The Grignard reaction of 2-cyclohexen-1-one with *t*-butylmagnesium chloride in the presence of cuprous chloride[25] gave 3-*t*-butylcyclohexanone (39% yield); bp 69—72°C/4 mmHg, n_D^{25} 1.4601 (lit, bp 92—95°C/10 mmHg[2] and 96—98°C/20 mmHg,[24] n_D^{25} 1.4611,[2] n_D^{20} 1.4615[24]).

***cis*-3-*t*-Butyl- and *trans*-3-*t*-Butylcyclohexanols** were prepared in good yields by the reduction of 3-*t*-butylcyclohexanone with, respectively, lithium aluminum hydride[2] and Raney nickel in ethanol.[2] Each alcohol was purified by several recrystallizations of the hydrogenphthalate and by subsequent saponification. *trans*-3-*t*-Butylcyclohexanol melted at 64—66°C (lit, mp 48—49°C,[2] 48°C[3] and 64°C[3]), and *cis*-3-*t*-butylcyclohexanol melted at 41—43°C; bp 105—106°C/10 mmHg, n_D^{25} 1.4670 (lit,[2] mp 40—41°C, bp 103°C/10 mmHg, n_D^{25} 1.4660).

***cis*-3-*t*-Butyl- and *trans*-3-*t*-Butylcyclohexyl *p*-Toluenesulfonates** were prepared according to the method of Tipson.[22] *cis*-3-*t*-Butylcyclohexyl *p*-toluenesulfonate melted at 58—59°C (lit, mp 58—59.5°C[2]). *trans*-3-*t*-Butylcyclohexyl *p*-toluenesulfonate melted at 44—45°C (lit, mp 33—35°C[2]).

4-*t*-Butylcyclohexene was prepared by means of the E2 reaction of *cis*- or *trans*-4-*t*-butylcyclohexyl *p*-toluenesulfonate with sodium phenoxide in acetone at 80°C for 20.9 hr (for the reaction of the *cis*-tosylate) or 17.3 hr (for the *trans*-tosylate). After working up in the usual way, the residual oily material was chromatographed over silica gel (Nakarai, No. II-A. 100—200 mesh). 4-*t*-Butylcyclohexene was eluted by using *n*-hexane as an eluant (see the section describing the preparation of *cis*-4-*t*-butylcyclohexyl phenyl ether).

3-*t*-Butylcyclohexene was prepared by treating 3-bromocyclohexene with *t*-butylmagnesium chloride. The bromination of cyclohexene with *N*-bromosuccinimide, following the method of Ziegler *et al.*,[26] gave 3-bromocyclohexene, bp 71—73°C/29 mmHg, in an 81% yield. The 3-bromocyclohexene was treated with *t*-butylmagnesium chloride by the method of Goering *et al.*[27] to produce 3-*t*-butylcyclohexene, bp 68.5—69°C/29 mmHg, n_D^{25} 1.4579, in a 50% yield (lit, bp 170.5°C/746 mmHg,[27] n_D^{25} 1.4568[27]).

Triethylammonium *p*-Toluenesulfonate and Diethylammonium *p*-Toluenesulfonate were prepared by dissolving slight excess of the corresponding amine and *p*-toluenesulfonic acid (Nakarai reagent-grade, monohydrate) in acetone; then, after the evaporation of the acetone and the excess of amine, the ammonium salts were dried to a constant weight *in vacuo* at 90—100°C.

Sodium Phenoxide was prepared from metallic sodium and phenol in dry toluene. A solution with a slight excess of phenol in toluene was mixed with metallic sodium, and then refluxed. The sodium phenoxide was filtered out, washed with benzene, and then dried *in vacuo* to a constant weight at 100—110°C.

The benzene, phenol, triethylamine, acetone, dimethylformamide, and tetrahydrofuran (each of a reagent grade) were dried and purified by fractional distillation; bps 80.2—80.5°C, 181—182°C, 56.5—56.7°C, 151.5—153°C, and 66.7—66.9°C respectively. The naphthalene (reagent grade) was used without further purification.

***cis*-4-*t*-Butylcyclohexyl Phenyl Ether.** A solution of 3.10 g (0.15 mol) of *trans*-4-*t*-butylcyclohexyl *p*-

toluenesulfonate in 67 m*l* of an acetone solution of sodium phenoxide (0.396M) was sealed in an ampoule, and then the ampoule was kept at 80°C for 17.3 hr. To the reaction mixture there were then added 120 m*l* of water, 70 m*l* of benzene, and 23 g of sodium chloride. The water layer was extracted several times with benzene, and the combined benzene solutions were washed with a 10% aqueous sodium chloride solution. After drying over anhydrous magnesium sulfate, the benzene solution was concentrated in a rotatory evaporator to give 9.68 g of a brown oil. A part of the brown oil (6.21 g) was chromatographed over 100 g of silica gel (Nakarai, No. II-A. 100—200 mesh). The column was eluted successively with *n*-hexane, *n*-hexane-benzene (4 : 1 by vol), and benzene. The fractions 1—22, obtained using *n*-hexane, gave 342 mg of 4-*t*-butylcyclohexene (37.3% yield); bp 49—50°C/14 mmHg, n_D^{20} 1.4597, n_D^{30} 1.4569 (lit, bp 65—66°C/20 mmHg,[2] n_D^{20} 1.4583,[2] 1.4581[28] and 1.4587[29]). The fractions 24—30, obtained using *n*-hexane-benzene (4 : 1 by vol), gave 465 mg of *cis*-4-*t*-butylcyclohexyl phenyl ether (30.2% yield); bp 88—90°C/0.13 mmHg, n_D^{30} 1.5093.

Found: C, 82.88; H, 10.34%. Calcd for $C_{16}H_{24}O$: C, 82.70; H, 10.41%.

The fractions 31—40, obtained using benzene, gave 90.9 mg of 4-*t*-butylcyclohexylphenol.

***trans*-4-*t*-Butylcyclohexyl Phenyl Ether.** *trans*-4-*t*-Butylcyclohexyl phenyl ether was prepared by the reaction of *cis*-4-*t*-butylcyclohexyl *p*-toluenesulfonate with sodium phenoxide in acetone at 80°C for 20.9 hr. The *trans*-ether was separated as has been described in the case of the *cis*-ether; it melted at 71—72°C after recrystallization from *n*-hexane.

Found: C, 82.96; H, 10.50%. Calcd for $C_{16}H_{24}O$: C, 82.70; H, 10.41%.

***trans*-3-*t*-Butylcyclohexyl Phenyl Ether.** *trans*-3-*t*-Butylcyclohexyl phenyl ether was prepared by treating *cis*-3-*t*-butylcyclohexyl *p*-toluenesulfonate with sodium phenoxide in dimethylformamide at 90°C. A mixture of 3.10 g (0.01 mol) of *cis*-3-*t*-butylcyclohexyl *p*-toluenesulfonate and 100 m*l* of a solution of sodium phenoxide (0.215M) in dimethylformamide was kept at 90°C for 17 hr in a glass-stoppered, round-bottomed 200-m*l* flask. After 900 m*l* of water had been added to the reaction mixture, the mixture was extracted with 100-m*l* portions of ether. The ether extracts were washed successively with a 10% aqueous sodium chloride solution, a 10% aqueous sodium hydroxide solution, and a 10% aqueous sodium chloride solution until the washings became neutral to litmus. After drying over anhydrous magnesium sulfate, the ether was removed by rotatory evaporation to give 1.70 g of a brown oil as a residue; this was chromatographed using an elution column packed with 50 g of silica gel (Nakarai, No. II-A. 100—200 mesh). The column was eluted successively with *n*-hexane, *n*-hexane-benzene (7 : 3 by vol), and benzene, 20-m*l* portions being taken. The fractions 1—7, obtained using *n*-hexane, gave 615 mg of *t*-butylcyclohexene (46.7% yield); bp 64°C/18 mmHg. Analysis by GLC indicated two components with retention times of 22.3 min (authentic 3-*t*-butylcyclohexene, 22.7 min) and 25.6 min (authentic 4-*t*-butylcyclohexene, 25.5 min). The fractions 8—16, obtained using *n*-hexane-benzene (7 : 3 by vol), gave 612 mg of *trans*-3-*t*-butylcyclohexyl phenyl ether (26.4% yield); bp 105°C/0.3 mmHg, n_D^{20} 1.5110, n_D^{30} 1.5091.

Found: C, 82.74; H, 10.59%. Calcd for $C_{16}H_{24}O$: C, 82.70; H, 10.41%.

The fractions 21—28, obtained using benzene, gave 63 mg of 3-*t*-butylcyclohexylphenol.

***cis*-3-*t*-Butylcyclohexyl Phenyl Ether.** *cis*-3-*t*-Butylcyclohexyl phenyl ether was prepared by treating *trans*-3-*t*-butylcyclohexyl *p*-toluenesulfonate with sodium phenoxide in dimethylformamide at 90°C for 16.5 hr. The *cis*-3-ether was separated in a manner similar to that described in the case of the *trans*-3-ether; bp 105°C/0.3 mmHg (27.1% yield).

Found: C, 82.72; H, 10.52%. Calcd for $C_{16}H_{24}O$: C, 82.70; H, 10.41%.

Gas-Liquid Chromatography of *t*-Butylcyclohexyl Derivatives. *A) Analysis of t-Butylcyclohexenes.* A complete separation was achieved on a column (5 m) packed with 30 wt% polyethylene glycol 6000 on selite 545 (Yanagimoto Co.), at 80°C using hydrogen as the carrier gas (60 m*l*/min). Analysis was carried out using peak-height and half-width measurements. The retention times of the three olefins are summarized in Table 5.

Table 5. Retention times of *t*-butylcyclohexenes

	1-*t*-Butyl-cyclohexene	3-*t*-Butyl-cyclohexene	4-*t*-Butyl-cyclohexene
Retention time (min)	20.1[a]	22.7	25.5

a) The retention time of the first peak which was showed by g.l.c. examination for the mixture of *t*-butylcyclohexenes, prepared by treating 4- or 3-*t*-butylcyclohexene with *N*-lithioethylenediamine in ethylenediamine solution at 100—110°C for 3 hr. It had been confirmed by Campbell *et al.* (N. C. G. Campbell, J. R. P. Clark, R. R. Hill, P. Oberhänsli, J. H. Parish, R. M. Southan and M. C. Whiting, *J. Chem. Soc., B*, **1968**, 349) that this first peak corresponds to 1-*t*-butylcyclohexene.

B) Analysis of t-Butylcyclohexyl Phenyl Ethers. All the gas-liquid chromatographical studies of the isomeric *t*-butylcyclohexyl phenyl ethers were made at 200°C (column and detector temperature). A coiled column was made of 4-mm-i. d. × 2-m annealed copper tubing packed with 20% apiezon grease L on neosorb NC (60—80 mesh: Nishio Co.). Hydrogen was used as the carrier gas (50 m*l*/min). Benzene solutions (15—25 μ*l*) of *t*-butylcyclohexyl phenyl ethers (5 wt%) were then injected. The retention times of the four ethers are summarized in Table 6. It was difficult to separate the *cis*-4- and *cis*-3-isomers.

Table 6. Retention times of *t*-butylcyclohexyl phenyl ethers

	trans-3	*cis*-3	*cis*-4	*trans*-4
Retention time (min)	15.4	17.9	17.9	22.3

28) J. H. Simous and A. C. Meunier, *ibid.*, **65**, 1269 (1943).

29) J. Sicher, F. Sipos and M. Tichy, *Collect. Czech. Chem. Commun.*, **26**, 837 (1961).

Thin-Layer Chromatography of *t*-Butylcyclohexyl Phenyl Ethers. A mixture of the *cis*-4-ether and *cis*-3-ether, the separation of which was not successful by means of GLC, was separated by TLC on silica gel GF 254 (E. Merck, Darmstadt) using *n*-hexane - benzene (9 : 1 by vol) as the developing solvent, the spots being detected by means of a UV lamp. In this case, we did not succeed in separating a mixture of the *trans*-4- and *cis*-3-(equatorial) isomers or the *trans*-3- and *cis*-4-(axial) isomers. The R_f values of the *t*-butylcyclohexyl phenyl ethers are listed in Table 7.

Table 7. R_f values of *t*-butylcyclohexyl phenyl ethers

	trans-3	*cis*-3	*cis*-4	*trans*-4
R_f Value	0.54—0.66	0.41—0.51	0.56—0.66	0.35—0.46

On the basis of these results, it can be concluded that the composition of a mixture of four ethers could be analyzed according to the analysis scheme presented above.

Rate Measurements. *A) Solvolysis in a Phenol-benzene Mixture.* A sealed-ampoule technique was employed. The reaction mixture was prepared by mixing a weighed amount of the tosylate and the solution of triethylamine (of a known concentration) in a phenol-benzene mixture at room temperature. Each ampoule contained 1 m*l* of an aliquot of the reaction mixture. The thermostat was controlled to ±0.05 at 75°C. After reaction for appropriate lengths of time, the content of the ampoule was run into acetic acid. The unchanged triethylamine was titrated with a 0.05N perchloric acid solution in acetic acid, with crystal violet as the indicator. The infinity titers were determined after at least ten half-lives. The rate constant was calculated graphically by a plot of $\log a/(a-x)$ against the time. The rate data are shown in Table 1.

B) Solvolysis in Phenol. A weighed amount of *trans*-4-*t*-butylcyclohexyl *p*-toluenesulfonate and an aliquot of a solution of a known concentration of triethylamine in melted phenol were placed in a measuring flask placed in a thermostated bath kept at 75.0±0.05°C. At appropriate time intervals, aliquot portions (1.000 m*l*) were pipetted into 5 m*l* of cold acetic acid; the solutions were then titrated according to the method described in section A. The rate constant was calculated from the first-order rate equation by a graphical method, the results being illustrated in Table 1.

Phenolyses of *cis*- and *trans*-4-*t*-Butylcyclohexyl *p*-Toluenesulfonates in a 50 wt% Phenol-Benzene Solvent in the Presence of Triethylamine. The results of the phenolyses of *cis*- and *trans*-4-*t*-butylcyclohexyl *p*-toluenesulfonates in a 50 wt% phenol-benzene solvent are summarized in Table 2. The details of the procedures can be illustrated by the following description of the phenolysis of *trans*-4-*t*-butylcyclohexyl *p*-toluenesulfonate.

A weighed amount (65 m*l*) of a 50 wt% phenol-benzene mixture containing triethylamine (0.106M) was preheated in a glass-stoppered, round-bottomed 100-m*l* flask at 75±0.05°C for 20 min; then *trans*-4-*t*-butylcyclohexyl *p*-toluenesulfonate (1.989 g) was added in one portion. After 18.7 hr (13 half-lives), the reaction mixture was diluted with 120 m*l* of ether and extracted with five 50-m*l* portions of a 10% aqueous sodium hydroxide solution. The organic layer was washed successively with 50 m*l* of a 10% aqueous sodium chloride solution, two 50-m*l* of a 10% aqueous hydrochloric acid solution, and three 50-m*l* portions of a 10% aqueous sodium chloride solution until the washings became neutral to litmus. The ether solution was then dried with anhydrous magnesium sulfate and the solvent removed by fractional distillation to give *ca.* 1 g of an oily material; this material was chromatographed using an elution column packed with 25 g of silica gel (Nakarai, No. II-A. 100—200 mesh). The column was eluted successively with *n*-hexane, *n*-hexane - benzene (7 : 3 by vol), and benzene, 20-m*l* portions being taken.

The fractions 2—5, obtained using *n*-hexane, gave 642 mg of *t*-butylcyclohexene (bp 68—69°C/29 mmHg; 72.5% yield); this substance showed, when submitted to GLC, three peaks with retention times of 20.0 min (authentic 1-*t*-butylcyclohexene, 20.1 min), 22.3 min (authentic 3-*t*-butylcyclohexene, 22.7 min), and 25.9 min (authentic 4-*t*-butylcyclohexene, 25.5 min). The composition analysis was carried out by peak-height and half-width measurements, giving the following results: 1-olefin, 0.6%; 3-olefin, 4.1%; 4-olefin, 95.3%. The fractions 9—17, obtained using *n*-hexane - benzene (7 : 3 by vol), gave 137 mg of *t*-butylcyclohexyl phenyl ether (9.4% yield). The GLC of this material showed three peaks, with retention times of 15.6 min (authentic *trans*-3-ether, 15.4 min), 18.4 min (a mixture of *cis*-3- and *cis*-4-ethers), and 22.3 min (authentic *trans*-4-ether, 22.3 min). The analysis by peak-height and half-width measurements gave 12.8%, 74.3% and 12.9% for the respective peaks. Then, the rest of the resulting phenyl ether was separated by TLC on a silica-gel layer (GF 254 E. Merck, 1 mm), using *n*-hexane - benzene (9 : 1 by vol) as the developing solvent; the spots were detected by means of a UV lamp. A mixture of the phenyl ethers (A) (*cis*-4+*trans*-3) was extracted from the layer of the R_f=0.54—0.66 by the use of benzene; another mixture of the phenyl ethers (B) (*cis*-3+*trans*-4) was similarly collected from the layer of the R_f=0.37—0.50. These ether mixtures were submitted directly to the GLC; from each mixture (A or B), two peaks were observed. The retention times were 15.4 min (authentic *trans*-3-ether, 15.4 min) (15.6%) and 18.2 min (authentic *cis*-4-ether, 17.9 min) (84.4%) for A, and 17.8 min (authentic *cis*-3-ether, 17.9 min) (30.7%) and 22.3 min (authentic *trans*-4-ether, 22.3 min) (69.3%) for B. From these results, the composition of the resulting *t*-butylcyclohexyl phenyl ether was calculated to be as follows: *trans*-3-ether, 12.8%; *cis*-3-ether, 5.1%; *cis*-4-ether, 69.2%; *trans*-4-ether, 12.9%. The fractions 20—36, obtained using benzene, gave 64.3 mg of *t*-butylcyclohexylphenol (4.4% yield); the infrared spectrum in chloroform had characteristic bands in the hydroxylic regions: ν_{max} 3700 cm^{-1} and 3500 cm^{-1}, due to nonbonded OH and bonded OH respectively. No attempt was made to determine the composition of this *t*-butylcyclohexylphenol.

The Phenolyses Conducted in the Presence of Added *t*-Butylcyclohexene. The results of the phenolyses of *cis*- and *trans*-4-*t*-butylcyclohexyl *p*-toluenesulfonates in 50 wt% phenol-benzene, in the presence of added *t*-butylcyclohexene and triethylamine at 75°C are summarized in Table 3.

A weighed amount of a 50 wt% phenol-benzene

solvent, containing triethylamine and *t*-butylcyclohexene, was preheated in a glass-stoppered flask at 75°C for 20 min. The products were isolated and separated in a manner similar to that described in the preceding section. The composition analyses of the olefin and the phenyl ether were conducted by GLC and by the combined use of GLC and TLC respectively, as has been described above.

Phenolyses Conducted in the Presence of Added Triethylammonium or Diethylammonium *p*-Toluenesulfonate. The results of the phenolyses of *cis*- and *trans*-4-*t*-butylcyclohexyl *p*-toluenesulfonates in a 50 wt% phenol-benzene solvent in the presence of initially-added triethylamine and triethylammonium (or diethylammonium) *p*-toluenesulfonate at 75.0°C are shown in Table 4. The following description of the phenolysis of *cis*-4-*t*-butylcyclohexyl *p*-toluenesulfonate in the presence of triethylamine and triethylammonium *p*-toluenesulfonate will serve to illustrate the details of the procedure.

A two-necked, round-bottomed 200-m*l* flask, placed in a dry box, was charged with 120 m*l* of a 50 wt% phenol-benzene solvent containing 0.105M triethylamine, and 3.31 g of triethylammonium *p*-toluenesulfonate (0.101M). Then the mixture was preheated at 75.0± 0.05°C for 20 min. To this mixture there was added a 3.69-g portion of *cis*-4-*t*-butylcyclohexyl *p*-toluenesulfonate (0.0990M), and then the reaction vessel was kept in a thermostated bath for 57 min. The reaction mixture was cooled in an ice bath to room temperature. The titration of 1 m*l* of an aliquot with a standard 0.05N perchloric acid solution in acetic acid, using crystal violet as the indicator, showed that phenolysis proceeded up to 75.5% completion.

A 200-m*l* portion of ether was added to the reaction mixture; the ether solution was extracted with seven 50-m*l* portions of a 20% aqueous sodium hydroxide solution which had been cooled in ice water. The ether layer was washed with a 10% aqueous hydrochloric acid solution and a 10% aqueous sodium chloride solution successively, and then dried over anhydrous magnesium sulfate. The dried ether solution was concentrated using an efficient fractionating column; during this period the bath temperature was kept below 55°C. The residual benzene solution was concentrated in a rotatory evaporator equipped with an ice-sodium chloride trap to give *ca.* 1.9 g of a colorless liquid as the residue and *ca.* 45 m*l* of a condensate in the trap. The colorless residual liquid was then condensed further under 4 mmHg at 50°C in a rotatory evaporator equipped with a dry ice-methanol trap. A wet, pale yellow crystal (0.982 g) was recovered as the residue, and in the trap 0.906 g of a colorless liquid condensed. This liquid was analyzed by GLC (5-m column, 30% PEG 6000 on selite 545 at 80°C; the same analytical conditions as that of olefin). There were observed four peaks with retention times of 1.9 min (benzene), 20.6 min (authentic 1-*t*-butylcyclohexene, 20.1 min) (a trace), 22.7 min (authentic 3-*t*-butylcyclohexene, 22.7 min) (1.2%), and 26.7 min (authentic 4-*t*-butylcyclohexene, 25.5 min) (98.8%).

The recovered pale yellow crystal, which was a mixture of phenolysis products other than olefin, was treated with sodium naphthalene in tetrahydrofuran in order to cleave the unchanged tosylate into the corresponding alcohol. In a 100-m*l* four-necked flask, equipped with a mechanical stirrer, a thermometer, a dropping funnel and a calcium chloride tube, there were successively placed 1.62 g (0.0127 mol) of naphthalene, 38 m*l* of purified THF and 0.280 g of metallic sodium, which had been cut in small pieces, under a nitrogen atmosphere and at room temperature. The mixture was stirred for 1 hr to produce a dark green solution of sodium naphthalene. Then the reaction vessel was cooled in an ice bath, and a solution of 0.800 g of pale yellow crystal in 8 m*l* of THF was added to the sodium naphthalene solution over a period of 0.8 min (reaction temperature, 0—4°C). The sodium naphthalene solution was then immediately decomposed by the addition of aqueous THF. The reaction mixture was treated with 50 m*l* of water and 15 g of sodium chloride. The water layer was extracted with three 20-m*l* portions of ether, and the combined ether extracts were washed with a 10% aqueous sodium chloride solution and then dried with anhydrous magnesium sulfate. The ether was removed by means of a rotatory evaporator to give 2.0 g of a crystalline material, which was chromatographed using an elution column packed with 60 g of silica gel (Nakarai, No. II-A. 100—200 mesh). The column was eluted successively with *n*-hexane, *n*-hexane-benzene (1 : 1 by vol), benzene, *n*-hexane-ether (9 : 1 by vol), and *n*-hexane-ether (4 : 1 by vol), 50-m*l* portions being taken. The fractions 1—12, obtained using *n*-hexane, gave 1.39 g of naphthalene. The fractions 14—17, obtained using *n*-hexane-benzene (1 : 1 by vol), gave 191.3 mg of *t*-butylcyclohexyl phenyl ether (11.6% yield), contained in the phenolysis products (it was confirmed by means of a control experiment that *t*-butylcyclohexyl phenyl ether was not affected during the cleavage reaction). The composition of the resulting *t*-butylcyclohexyl phenyl ether was determined following the analysis scheme described above: *trans*-4-ether, 60.9%; *cis*-4-ether, 19.5%; *cis*-3-ether, 7.5%; *trans*-3-ether, 12.1%. The fractions 20—22, obtained using benzene, gave 34.4 mg of *t*-butylcyclohexylphenol (2.1% yield), the infrared spectrum of which in chloroform had characteristic bands at 3700 cm^{-1} and 3500 cm^{-1}. No attempt was made to determine the composition of this material.

The fractions 33—36, obtained using *n*-hexane-ether (9 : 1 by vol), gave *t*-butylcyclohexanone, while the fractions 37—50, obtained using *n*-hexane-ether (4 : 1 by vol), gave *t*-butylcyclohexanol (products of the cleavage reaction). The details of the analyses of these materials will be reported in a subsequent paper.

Phenolytic Rearrangement and Isomerization of *cis*- and *trans*-4-*t*-Butylcyclohexyl *p*-Toluenesulfonates in a Phenol-Benzene Solvent*1

Kunio Okamoto, Seiki Saitô and Haruo Shingu

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received May 15, 1969)

As the first examples of solvolytic *cis-trans* isomerization and 1,2-rearrangement for the 4-*t*-butylcyclohexyl system, phenolytic *cis-trans* (or *trans-cis*) isomerization and 1,2-rearrangement have been found for *cis*- and *trans*-4-*t*-butylcyclohexyl *p*-toluenesulfonates in the phenol-benzene (1 : 1 by wt) solvent at 75.0°C. The tosylate, recovered after a 75% completion of the S_N1 phenolysis of the *cis*-4-tosylate, was composed of small amounts of the *trans*-4-tosylate (1%) and the *cis*-3-tosylate (11%), besides 88% of the starting *cis*-4-tosylate, clearly indicating occurrence of both the *cis-trans* isomerization and the 1,2-rearrangement of the starting *cis*-4-tosylate. In a similar fashion, starting from the *trans*-4-tosylate, small amounts of the *cis*-4-tosylate (0.7%) and the *trans*-3-tosylate (2.6%) were recovered from the tosylate after the S_N1 phenolysis was 75% complete. On the basis of the results of an examination into the influence of the added tosylate anion on the extent of isomerization and of rearrangement, it has been suggested that the *cis-trans* or *trans-cis* isomerization results largely from the external S_N2-like attack of the tosylate anion on the S_N1 ion-pair intermediate and partly as a consequence of the rotation of the *t*-butylcyclohexyl cation within the ion-pair intermediate, whereas the 1,2-rearrangement proceeds through an intramolecular 1,2-shift of hydrogen within the 4-*t*-butylcyclohexyl cation.

After the initial work of Winstein and Holness,[1] the solvolytic reactions of 4-*t*-butylcyclohexyl *p*-toluenesulfonates have been investigated by several other workers.[2-4] In these solvolyses, *t*-butylcyclohexene was the major product, while minor amounts of substitution, products were obtained as side products; as a general trend, both the olefin and the substitution product contained a considerable amount of rearranged isomers. In view of the formation of so many rearranged products, we have previously suggested[4] the possibility of the accumulation of rearranged tosylates during the course of the solvolysis of a *t*-butylcyclohexyl tosylate, since the isomerized or rearranged solvolysis intermediate, which produced an isomerized or rearranged product, will also give an isomerized or rearranged tosylate by the course of return.

In this paper, we will report on the results of the examination of such a possibility for the phenolytic *cis-trans* isomerization and the 1,2-rearrangement of *cis*-4- and *trans*-4-tosylates, and will discuss the implications of the results with the structure of the ion-pair intermediate for this system.

Results and Discussion

Recovery and Analysis of the Mixture of *t*-Butylcyclohexyl *p*-Toluenesulfonates. The phenolyses of *cis*- and *trans*-4-*t*-butylcyclohexyl *p*-toluenesulfonates were conducted in the presence of triethylamine in a 50 wt% phenol-benzene solvent at 75°C up to 75% completion. After washing with dilute aqueous sodium hydroxide and the subsequent condensation of the organic layer under reduced pressure at room temperature, the residue was treated with sodium naphthalene in THF in order to cleave the tosylate and obtain the corresponding *t*-butylcyclohexanol. The mixture of *t*-butylcyclohexanols was isolated by elution chromatography, and the composition was assayed according to the following scheme:

*1 Presented at the 18th Symposium on the Organic Reaction Mechanism, Kyoto, October, 1967 (Abstract, p. 81) and at the 21st Annual Meeting of the Chemical Society of Japan, Osaka, April, 1968 (Abstract, Part III, p. 2034).

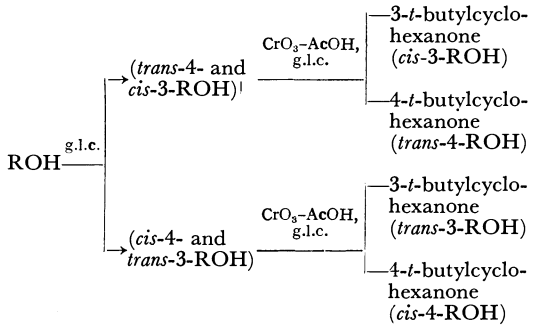
4) K. Okamoto, S. Saitô and H. Shingu, This Bulletin, **42**, 3288 (1969).



First, the mixture was separated by GLC into two fractions, *i. e.*, a mixture of the *trans*-4- and *cis*-3-alcohols and a mixture of *cis*-4- and *trans*-3-alcohols; then each fraction was oxidized by means of chromium trioxide in acetic acid, giving a mixture of 3- and 4-*t*-butylcyclohexanones, which was then assayed by GLC.

The reductive cleavage of the tosylates with sodium naphthalene was first reported by Closson, Wriede and Bank[5] as an almost ideal procedure for obtaining the alcohols without isomerization. However, the data for the *t*-butylcyclohexyl system have not been made available. Therefore, we examined the degree of isomerization for the *cis*-4-, *trans*-4-, *cis*-3-, and *trans*-3-tosylates in a series of experiments with the authentic tosylates; the results are summarized in Table 1.

From the *trans*-4- and *cis*-3-tosylates obtained under the reaction conditions shown in Table 1, the *t*-butylcyclohexanol contained no isomerized alcohols, whereas the *cis*-4- and *trans*-3-tosylates afforded the respective alcohols contaminated with a small quantity of isomerized alcohols, even though the cleavage was conducted at −1—2°C. The percentage of isomerization observed in the control experiments of *cis*-4- and *trans*-3-tosylates was used as a correction factor for the analysis of the tosylate mixture recovered from the phenolytic products.

Composition of the Tosylate Recovered from the Reaction Mixture for the Phenolysis of *cis*-4-*t*-Butylcyclohexyl *p*-Toluenesulfonate. The phenolysis of *cis*-4-*t*-butylcyclohexyl *p*-toluenesulfonate was carried out in the presence of an equimolar amount of triethylamine in a 50 wt% phenol-benzene solvent at 75°C up to 75% completion. A mixture of the phenolysis products and the unchanged tosylate was isolated from the phenolysis mixture, then cleaved with sodium naphthalene in THF, and subsequently separated into *t*-butylcyclohexanol and the phenolysis products by elution chromatography. The phenolysis products were not affected under the cleavage conditions.[6] The mixture of *t*-butylcyclohexanols was assayed following the scheme described above.

As is summarized in Table 2, the cleavage reaction of the recovered tosylate afforded the corresponding alcohol in a fairly good yield; the *t*-butylcyclohexanol was composed of a large portion (88—89%) of the *cis*-4-alcohol and small amounts of the *cis*-3-alcohol (10%) and the *trans*-4-alcohol (1%). This result clearly indicates that, during the phenolysis of the *cis*-4-tosylate in a phenol-benzene solvent, *cis-trans* isomerization and 1,2-rearrangement did occur.

In a previous paper[4] we reported that, during this phenolysis, the first-order plot gave a slight downward drift after 80% completion. In view of the fact that the solvolysis rates of the *cis*-3- and *trans*-4-tosylates are lower than those of the *cis*-4-tosylate,[1,4] this downward drift may be attributed to an accumulation of the less reactive tosylates in the unchanged tosylate with the progress of the

reaction.

In order to obtained further information about the mechanism, the phenolysis was conducted in the presence of added triethyl- or diethyl-ammonium *p*-toluenesulfonates; the composition of the tosylate thus recovered was then compared with that observed in the absence of added alkylammonium salt. In Fig. 1 the percentages of *trans*-4- and *cis*-3-tosylates in the recovered tosylate are plotted against the effective concentrations of the *p*-toluenesulfonate anion, which are defined as the sum of the concentration of the added alkylammonium tosylate and one half of the concentration of the tosylate anion liberated until the interruption of the phenolysis.

The amount of the *trans*-4-tosylate in the recovered tosylate increases linearly with an increase in the effective concentration of the tosylate anion in the reaction medium, and, within the range of experimental error, there seems to exist no isomerized tosylate in the absence of the added tosylate anion. In other words, the *cis-trans* isomerization of the *cis*-4-tosylate seems to proceed almost entirely *via* the intermolecular course including the attack of the tosylate anion on the ion-pair S_Ni intermediate, although the possibility of the intramolecular course including the rotation of the carbonium ion

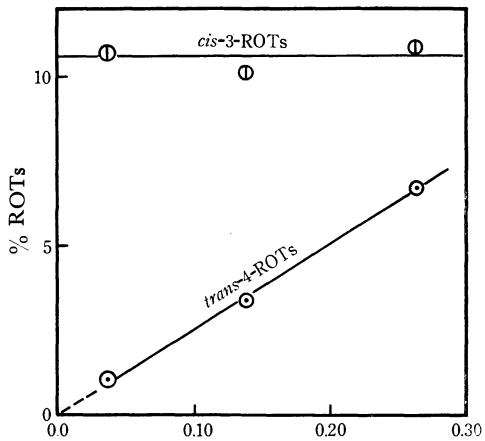

Fig. 1. The percentages of *cis-trans* isomerization and 1,2-rearrangement in the recovered tosylate for the phenolysis of *cis*-4-*t*-butylcyclohexyl *p*-toluenesulfonate in 50 wt% phenol-benzene solvent in the presence of triethylamine at 75°C.

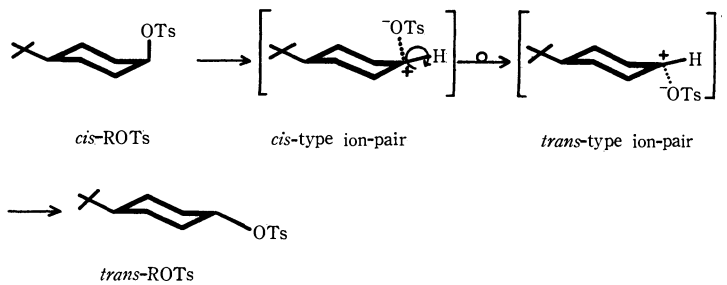
in the ion-pair intermediate can not be entirely eliminated (*vide infra*).

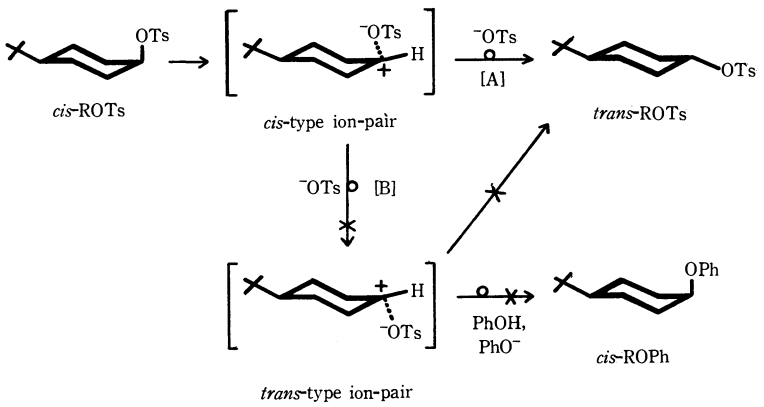
The intramolecular course is illustrated below without considering its reversibility:



cis-ROTs *cis*-type ion-pair *trans*-type ion-pair

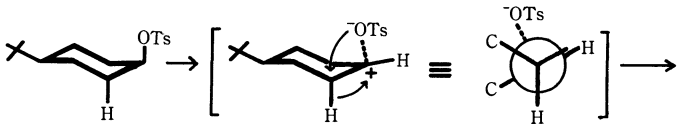
trans-ROTs

As for the intermolecular course, two pathways are possible: one is a direct return of the *cis*-type ion-pair intermediate to the *trans*-tosylate (Course A), and the other is the return *via* the *trans*-type ion-pair intermediate produced by the S_N2-like attack of the tosylate anion on the *cis*-type intermediate (Course B). These two courses may be illustrated as follows:



If the concentration of the *trans*-type ion-pair intermediate were increased with the increase in the S_N2-type attack of the tosylate anion on the *cis*-type intermediate (Course B), the portion of *cis*-4-*t*-butylcyclohexyl phenyl ether in the concomitant phenolysis products would also be increased. However, this is not the case; rather, the percentage of the *cis*-4-ether is slightly diminished with the increase in the added $Et_3NH^+OTs^-$.[7] Therefore, the possibility of the B course *via* the *trans*-type intermediate may be excluded.

In contrast to the *cis-trans* isomerization, the 1,2-rearrangement of the *cis*-4-tosylate seems to be little affected by the added tosylate anion (Fig. 1). This clearly indicates that the rearrangement is almost intramolecular in nature. Thus, the rearrangement conceivably proceeds *via* the exchange of the positions of the axial tosylate group and the axial neighboring hydrogen, as is illustrated below:



cis-4-ROTs

cis-3-ROTs

As has been mentioned in the previous paper,[4] since the initially-added *t*-butylcyclohexene does not exert any influence on the composition of the olefin product or of the phenyl ethers in the concurrent phenolysis, the possibility of 1,2-rearrangement *via* a proton addition to a stable molecule of *t*-butylcyclohexene can be eliminated. This course is as follows:

cis-4-ROTs

cis-3-ROTs

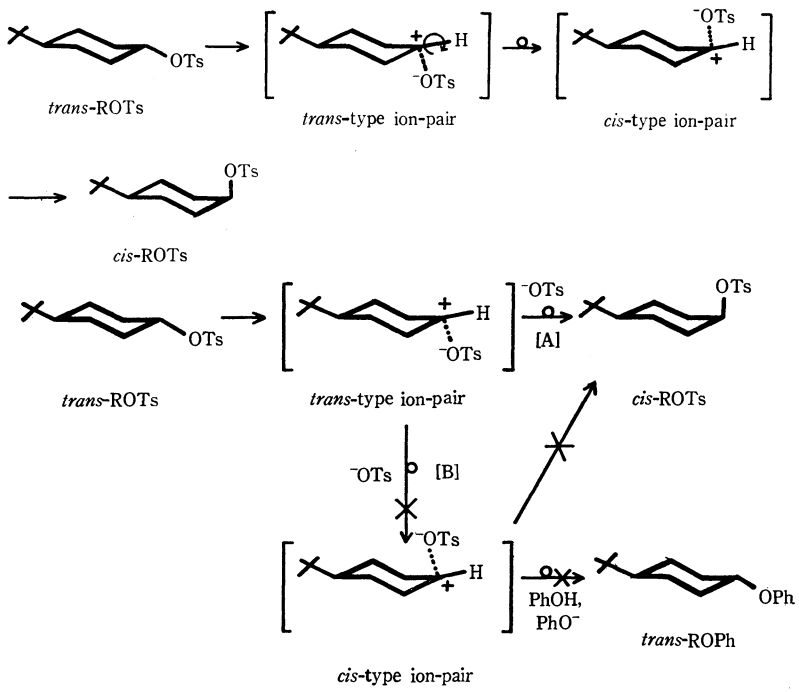
a) The phenolysis was conducted in phenol-benzene (1:1 by wt) solvent at 75°C. Initial concentrations are 0.099—0.10M for ROTs and 0.105—0.109N for Et_3N (see Table 4 in Ref. 4).
b) Analyzed by the phenolysis of the sample for the cleavage reaction; the phenyl ethers contained in the sample were not affected under the cleavage condition.
c) Based on the recovered tosylate.

Composition of the Tosylate Recovered from the Reaction for the Phenolysis of *trans*-4-*t*-Butylcyclohexyl *p*-Toluenesulfonate. The phenolysis of *trans*-4-tosylate was conducted in the presence of an equimolar amount of triethylamine in a 50 wt% phenol-benzene solvent at 75°C up to 75% completion. In a manner similar to that in the case of the *cis*-tosylate, *t*-butylcyclohexanol was isolated from the reaction mixture of the cleavage reaction of the recovered tosylate; it was assayed following the scheme described above.

As is shown in Table 3, the *t*-butylcyclohexanol was composed of a large amount (97%) of the *trans*-4-alcohol, derived from the starting *trans*-4-tosylate, and small amounts of the *cis*-4-alcohol (0.7%) and the *trans*-3-alcohol (2.6%). This indicates that, in a fashion similar to that in the case of the *cis*-4-tosylate, *trans-cis* isomerization and 1,2-rearrangement occur during the phenolysis of *trans*-4-tosylate, although the extent of isomerization and of rearrangement is smaller when compared with the case of the *cis*-4-tosylate.

The percentages for the isomerization and the rearrangement are set against the effective concentrations (*vide supra*) of the tosylate anion in the reaction medium in Fig. 2.

The extents of the *trans-cis* isomerization are not much affected by the increase in the effective concentrations of the tosylate anion, and there seems to exist a definite, though small, amount of *trans-cis* isomerization even in the absence of the tosylate anion. Therefore, it is conceivable that, for the *trans-cis* isomerization, there exist both the intramolecular and the intermolecular courses and that the latter course becomes predominant with the increase in the concentration of the tosylate anion. These courses are illustrated below.



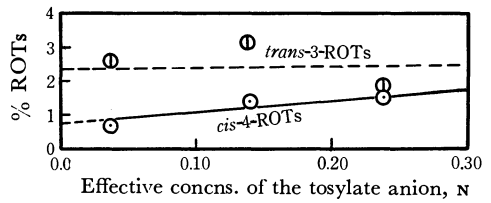


Fig. 2. The percentage of *trans-cis* isomerization and 1,2-rearrangement in the recovered tosylate for the phenolysis of *trans*-4-*t*-butylcyclohexyl *p*-toluenesulfonate in 50 wt% phenol-benzene solvent in the presence of triethylamine at 75°C.

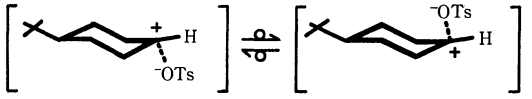
As has been mentioned above, the intramolecular course for the *cis-trans* isomerization of the *cis*-tosylate was not observed within the range of experimental error. However, in view of the existence of the intramolecular course in the *trans-cis* isomerization, the intramolecular course should exist also in the case of the *cis*-tosylate isomerization, judging from the microscopic reversibility, as is shown below:



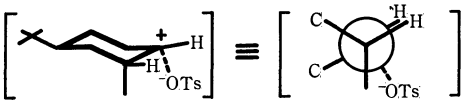
trans-type ion-pair *cis*-type ion-pair

Therefore, the apparent absence of the intramolecular course for the *cis-trans* isomerization may be attributed to the relative rapidity of the rate of the intermolecular isomerization, *i.e.*, the rate of attack of the tosylate anion on the *cis*-type ion-pair, as compared with the rate of intermolecular isomerization, *i.e.*, the rate of the internal rotation of the 4-*t*-butylcyclohexyl cation in the *cis*-type ion-pair intermediate.

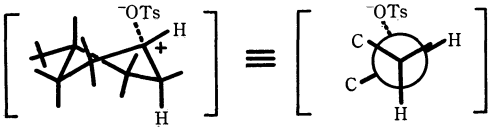
In view of the fact that the portions of *trans*-4-*t*-butylcyclohexyl phenyl ether in the products of the concomitant phenolysis decrease with an increase in the concentration of the added tosylate anion,[6] it is conceivable that the concentration of the *cis*-type ion-pair intermediate does not increase with the increase in the added tosylate anion. Consequently, the course to the *cis*-4-tosylate *via* the *cis*-type ion-pair intermediate (Course B) may be excluded.

The extent of 1,2-rearrangement for the *trans*-tosylate changes non-linearly with the increase in the effective concentration of the tosylate anion, this being shown in Fig. 2. A thorough interpretation of this trend would be difficult. However, there seems to exist no definite tendency of increase with the increase in the concentration of the tosylate anion. Consequently, we may conceive this 1,2-rearrangement to be intramolecular in nature.

Since the tosyl-group and the neighboring equatorial hydrogen atom are in the *syn*-position in the chair conformation of the ion-pair intermediate from the *trans*-4-tosylate, it seems to be rather difficult for them to exchange their positions with each other, this being illustrated as follows:



However, if a twist boat conformation is assumed for the *t*-butylcyclohexyl cation, as was first suggested in the case of the solvolysis in 50% aqueous ethanol by Shiner and Jewett,[2] a facile exchange of the two groups would be achieved because of their *anti*-position. This is illustrated as follows:



As in the case of the *cis*-tosylate, the initially added *t*-butylcyclohexenes exerted little influence on the composition of the olefin product or of the phenyl ethers in the concomitant phenolysis.[4] Thus, the possibility of 1,2-rearrangement *via* a proton addition to a stable molecule of *t*-butylcyclohexene can be excluded for the *trans*-tosylate.

The results presented in this paper clearly suggest the possibility of the solvolytic rearrangement or isomerization of the 4-*t*-butylcyclohexyl system in a solvent other than phenol. The details of the examination of the other solvents will be reported in a succeeding paper.

Experimental[8]

Materials. The *t*-butylcyclohexanols (*cis*-4, *trans*-4, *cis*-3 and *trans*-3), *t*-butylcyclohexyl tosylates (*cis*-4, *trans*-4, *cis*-3 and *trans*-3), 3- and 4-*t*-butylcyclohexanones, and triethylammonium and diethylammonium tosylates were synthesized as described in a previous paper.[4] Benzene, phenol, triethylamine, and tetrahydrofuran (each of a reagent grade) were dried and purified by fractional distillation: benzene, bp 80.2—80.5°C; phenol, bp 181—182°C; triethylamine, bp 89—89.8°C; tetrahydrofuran, bp 66.7—66.9°C. The naphthalene (reagent grade) was used without further purification.

Gas-liquid Chromatography of *t*-Butylcyclohexanols. The gas-liquid chromatography of isomeric *t*-butylcyclohexanols was performed on a 2 m×4 mm copper-tubing column packed with 30 wt% PEG 6000 on selite (80—100 mesh) at 150°C, and the hydrogen flow rate was adjusted to 60 ml/min; benzene solutions (15—25 μl) of *t*-butylcyclohexanols (5—10 wt%) were injected. Retention times: *cis*-4-OH, 18.0 min; *trans*-4-OH, 20.5 min; *cis*-3-OH, 20.3 min; *trans*-3-OH, 17.9 min. We could not separate the mixture of the *trans*-4- and

8) The melting points are not corrected. The infrared spectra were determined with a Shimadzu Model IR-27 spectrophotometer. All the GLC studies were made with a Shimadzu Model GC-2B dual-column gas chromatograph.

cis-3- (equatorial) isomers or the mixture of the *trans*-3- and *cis*-4- (axial) isomers under these conditions.

Gas-liquid Chromatography of *t*-Butylcyclohexanones. A mixture of 3- and 4-*t*-butylcyclohexanones was separated on a 2-m column packed with 30% PEG 6000 on selite at 110°C, using hydrogen as the carrier gas (70 ml/min). Benzene solutions (40—50 μl) of ketones (5 wt%) were injected. The retention times of the 3- and 4-*t*-butylcyclohexanones were 51.9 min and 56.8 min respectively; calibration was carried out with ketones of known compositions.

Analysis of *t*-Butylcyclohexanols. Mixtures of the *cis*-4- and *trans*-3-alcohols and of the *trans*-4- and *cis*-3-alcohols were separated gas-chromatographically, using a 5-m column and two liquid-nitrogen traps; then each fraction was converted into a mixture of 3- and 4-ketones by treating it with chromium trioxide in acetic acid according to the method of Winstein and Holness.[1] This 3- and 4-ketone mixture was gas-chromatographically analyzed. The calibration was performed by the oxidation of mixtures of the respective alcohols of known compositions.

The Cleavage of *t*-Butylcyclohexyl *p*-Toluenesulfonates into the Parent Alcohols Using Sodium Naphthalene in Tetrahydrofuran. *A) Cleavage of trans-4-t-Butylcyclohexyl p-Toluenesulfonate.* In 100-ml four-necked flask, equipped with a mechanical stirrer, a thermometer, a dropping funnel and a calcium chloride tube, there were placed successively 3.42 g (0.0267 mol) of naphthalene, 84 ml of THF, and 0.580 g of matallic sodium, which has been cut in small pieces, all under a nitrogen atomosphere at room temperature. The mixture was then stirred for 1 hr to produce a dark green solution of sodium naphthalene.

To this sodium naphthalene solution there was added a solution of 1.30 g (0.0042 mol) of the *trans*-4-tosylate in 7 ml of THF at 0°C through a dropping funnel over a period of 1 min. Then, the sodium naphthalene solution was immediately decomposed by the addition of aqueous THF. The reaction mixture was treated with 100 ml of water and 30 g of sodium chloride. The water layer was extracted with three 50-ml portions of ether, and the combined ether extracts were washed with 10% aqueous sodium chloride solution and then dried over anhydrous magnesium sulfate. The ether solution was concentrated to give 4.0 g of a crystalline material, which was chromatographed over 100 g of silica gel (Nakarai, No. II-A. 100—200 mesh). The column was eluted successively with benzene, *n*-hexane-ether (9 : 1 by vol), *n*-hexane-ether (4 : 1 by vol), and *n*-hexane-ether (1 : 1 by vol), 25-ml portions being taken. The fractions 3—8, obtained using benzene, gave 3.07 g of naphthalene. The fractions 9—16, obtained using *n*-hexane-ether (9 : 1 by vol), did not give anything. The fractions 17—24, obtained using *n*-hexane-ether (4 : 1 by vol), gave 162 mg of a viscous oil the infrared spectrum of which exhibited a strong absorption at 1060 cm^{-1}; no attempt was made to characterize this material further. The fractions 25—31, obtained using *n*-hexane-ether (4 : 1 by vol), gave 67.1 mg of an oily material. The evaporation of this material under 4 mmHg at 80°C gave, in a dry-ice-methanol trap, 4-*t*-butylcyclohexanone (20.6 mg, 3.2% yield; mp 46—49°C; mp 48—51°C on admixture with an authentic sample of 4-*t*-butylcyclohexanone; the infrared spectrum was identical with that of an authentic sample of 4-*t*-butylcyclohexanone). The infrared spectrum of the remaining high-boiling material was identical with that of the viscous oil given by the preceding fractions 17—24. The fractions 48—57, obtained using *n*-hexane-ether (1 : 1 by vol), gave 630 mg of *trans*-4-*t*-butylcyclohexanol (96.4% yield). The GLC analysis of the alcohol of the fraction 48 (27.4 mg) indicated one peak with a retention time of 21.1 min (an authentic *trans*-4-alcohol, 20.5 min). The results of this run are listed in Table 1, along with the results of other runs under different reaction conditions.

B) Cleavage of cis-4-t-Butylcyclohexyl p-Toluenesulfonate. To a sodium naphthalene solution in THF, prepared from 1.50 g (0.0116 mol) of naphthalene, 40 ml of THF, and 0.270 g (0.0116 mol) of metallic sodium, there was added a solution of 0.602 g (0.00194 mol) of the *cis*-4-tosylate in 3 ml of THF at −1—3°C over a period of 0.5 min. Working-up in the usual way gave a residual crystalline material (1.5 g), which was then chromatographed over 50 g of silica gel (Nakarai, No. II-A. 100—200 mesh). The column was eluted successively with benzene, *n*-hexane-ether (4 : 1 by vol), and *n*-hexane-ether (3 : 2 by vol), 25-ml portions being taken. The fractions 1—5, obtained using benzene, 1.39 g of naphthalene. The fractions 12—17, obtained using *n*-hexane-ether (4 : 1 by vol), gave 126.3 mg of a viscous oil from which, by means of the working-up described in section A, 4-*t*-butylcyclohexanone (19.0 mg, 6.4% yield) was collected in the trap. The fractions 18—29, obtained using *n*-hexane-ether (3 : 2 by vol), gave 289.3 mg of 4-*t*-butylcyclohexanol (94.4% yield). Analysis of the alcohol of the fraction 25 by GLC showed one peak corresponding to *cis*-4-*t*-butylcyclohexanol. Analysis of the combined alcohol fractions from 26 to 29 by GLC showed two peaks, corresponding to *cis*- and *trans*-4-*t*-butylcyclohexanol respectively. The percentage of the *trans*-4-alcohol produced during the cleavage reaction of the *cis*-4-tosylate was calculated to be 1.70% of the total alcohol. The results of the cleavage reactions of *cis*-4-tosylate under various reaction conditions are summarized in Table 1.

C) Cleavage of cis- and trans-3-t-Butylcyclohexyl p-Toluenesulfonates. The cleavage reactions for *cis*- and *trans*-3-tosylates were carried out in the same way as above. These results are summarized in Table 1.

D) Cleavage of a Mixture of Tosylates with a Known Composition. A mixture of *cis*-4- (0.339 g), *trans*-4- (0.0723 g), *cis*-3- (0.0306 g), and *trans*-3-tosylates (0.0691 g) was cleaved in the same way as above. A mixture of four isomeric alcohols was obtained in a 90% yield; the analysis of the composition according to the analysis scheme described above gave the following results, after correction for the rearrangement of axial (*cis*-4 and *trans*-3) compounds to equatorial (*trans*-4 and *cis*-3) compounds during the cleavage reaction (see Table 1): *cis*-4, 66.3%; *trans*-4, 14.7%; *cis*-3, 5.0%; *trans*-3, 14.0%. On the other hand, the composition of the starting tosylate mixture was as follows: *cis*-4, 66.3%; *trans*-4, 14.1%; *cis*-3, 6.0%; *trans*-3, 13.5%.

Cleavage of the Tosylate Recovered from the Reaction Mixture for the Phenolysis of *cis*-4-*t*-Butylcyclohexyl *p*-Toluenesulfonate. The phenolysis of *cis*-4-*t*-butylcyclohexyl *p*-toluenesulfonate (3.11 g) in phenol-benzene (1 : 1 by wt) (100 ml) in the presence of triethylamine (0.103N) was conducted following a previously-described method[4]; the phenolysis mixture (1.002 g), containing unchanged tosylate, was recovered

after 1.0 hr (72.8% completion), by employing the procedure reported in a previous paper.[4] A part of the recovered phenolysis mixture (0.139 g) was further phenolyzed, and the composition of the tosylate present in the mixture was determined to be 72.5 wt% (23.6% based on starting tosylate) from the infinity titers. The rest of the recovered phenolysis mixture (0.863 g) was treated with sodium naphthalene in THF, prepared from 1.85 g of naphthalene, 0.325 g of metallic sodium, and 43 m*l* of THF; working-up in the usual way gave 2.2 g of a crystalline material, which was then chromatographed over silica gel (60 g, Nakarai, No. II-A. 100—200 mesh) to give *t*-butylcyclohexanone (11.1 mg, 3.6% yield) from fractions 13—17 (25-m*l* per one fraction), obtained using *n*-hexane - ether (4 : 1 by vol), and *t*-butylcyclohexanol (267 mg, 84.9% yield) from fractions 22—37, obtained using *n*-hexane - ether (3 : 2 by vol); besides these fractions, fractions containing naphthalene, *t*-butylcyclohexyl phenyl ether, and *t*-butylcyclohexylphenol were eluted. The infrared spectrum of the alcohol of fraction 22 in CCl_4 was identical with that of an authentic sample of *cis*-4-*t*-butylcyclohexanol. The crystalline alcohols from the fractions from 22 to 27 (total 190 mg) were each examined in turn by GLC to show one peak corresponding in retention time to *cis*-4-alcohol. These results show that the alcohol of the fractions from 22 to 27 is exclusively *cis*-4-*t*-butylcyclohexanol and does not contain any *trans*-3-*t*-butylcyclohexanol.[9] The oily alcohol from fractions 28—37 (total 77 mg) was submitted to GLC, which showed two peaks with retention times of 17.3 min and 20.4 min; 55.0% and 45.0% respectively. Then the fractions for both the peaks were collected as eluted in liquid-nitrogen traps by GLC (5-m column at 150°C) to give 20.0 mg of crystalline alcohol for the first peak and 22.4 mg of oily alcohol for the succeeding peak; these substance were then each oxidized with chromium trioxide in acetic acid. The GLC examination for the ketone derived from the crystalline alcohol showed one peak corresponding in retention time to 4-*t*-butylcyclohexanone; from this the first peak was confirmed to be the *cis*-4-alcohol. The ketone derived from the oily alcohol was analyzed by GLC, showing two peaks corresponding in retention time to 3- and 4-*t*-butylcyclohexanones. The calibration, carried out with a mixture of ketones derived from a mixture of *trans*-4- and *cis*-3-alcohols of known compositions, gave the following results: *trans*-4-OH, 16.6%; *cis*-3-OH, 83.4%. The composition of the *t*-butylcyclohexanol given by the cleavage reaction of the unchanged tosylate was calculated to be as follows: *cis*-4-OTs, 88.2%; *trans*-4-OTs, 1.0%; *cis*-3-OTs, 10.8%; *trans*-3-OTs, 0.0%. The results of this run are listed in Table 2, along with the results of the other runs.

Cleavage of the Tosylate Recovered from the Reaction Mixture for the Phenolysis of *trans*-4-*t*-Butylcyclohexyl *p*-Toluenesulfonate. The *trans*-4-tosylate (6.23 g) was phenolyzed in 50 wt% phenol-benzene (200 m*l*), containing triethylamine (0.107N), for two half-lives; the unchanged tosylate was then recovered following the method described in a previous paper.[4] The recovered material (2.181 g) was divided into two parts by means of the ether solution. A part of the recovered material (0.387 g) was further phenolyzed, and the measurements of the infinity titers gave the composition of the tosylate present in the recovered material. The rest of the recovered material (1.794 g) was treated with sodium naphthalene in THF much as in the working-up described above; the resulting crystalline material was chromatographed over silica gel (100 g, Nakarai, No. II-A. 100—200 mesh). Successive elution with the indicated solvents gave the following fractions (25-m*l* portions being taken): the fractions 9—57, obtained using *n*-hexane, naphthalene; the fractions 63—79, obtained using *n*-hexane - benzene (7 : 3 by vol), *t*-butylcyclohexyl phenyl ether; the fractions 84—102, obtained using benzene, *t*-butylcyclohexylphenol; the fractions 129—137, obtained using *n*-hexane - ether (4 : 1 by vol), *t*-butylcyclohexanone (29.8 mg, 4.6% yield); the fractions 138—151, obtained using *n*-hexane - ether (4 : 1 by vol), oily *t*-butylcyclohexanol (27.4 mg); the fractions 152—171, obtained using *n*-hexane - ether (1 : 1 by vol), crystalline *t*-butylcyclohexanol (554.9 mg).

The crystalline alcohol from the fractions from 152 to 171 was proved to be *trans*-4-*t*-butylcyclohexanol on the basis of its melting point (mp 80—81°C) and infrared spectrum and on the basis of the results of a GLC examination.

The oily alcohol from the fractions from 138 to 151 was submitted to GLC showing two peaks corresponding in retention times to the axial and the equatorial alcohols; the compositions were 47.2% and 52.8% respectively. Then the fractions were collected as eluted in liquid-nitrogen traps by GLC (5-m column at 150°C) to give an oily alcohol for the first peak and a crystalline alcohol for the second peak; these substances were each treated with chromium trioxide in acetic acid. The GLC examination for the ketone from the oily alcohol showed two peaks corresponding in retention times to 3- and 4-*t*-butylcyclohexanone; when the ratio was calibrated with ketones derived from a mixture of *cis*-4-OH and *trans*-3-OH of known compositions, the *cis*-4-OH/*trans*-3-OH ratio was determined to be 0.263. The GLC examination for the ketone produced from crystalline alcohol showed one peak corresponding in retention time to 4-*t*-butylcyclohexanone; from this the crystalline alcohol was confirmed to be pure *trans*-4-alcohol. From these results, the composition of the recovered tosylate was calculated to be as follows: *cis*-4-OTs, 0.7%; *trans*-4-OTs, 96.7%; *cis*-3-OTs, 0.0%, *trans*-3-OTs, 2.6%.

Cleavage of the Tosylate Recovered from the Reaction Mixture for the Phenolyses Conducted in the Presence of Triethylammonium or Diethylammonium *p*-Toluenesulfonate. The phenolysis was conducted in the presence of added triethylamine and triethyl- or diethyl-ammonium tosylate, and the composition of the recovered tosylate was analyzed in a manner similar to that described in a previous paper[4] and in the preceding sections; The results are summarized in Table 2 for the *cis*-4-tosylate and in Table 3 for the *trans*-4-tosylate.

9) When the phenolysis of the *cis*-4-tosylate was conducted in the presence of added triethylammonium tosylate, the last fraction of the crystalline alcohol, corresponding to fraction 27 in the case of this run, was converted into ketone; the ketone was then analyzed by GLC to show one peak corresponding in retention time to 4-*t*-butylcyclohexanone. On the basis of this result, the fraction 27 was considered to be pure *cis*-4-*t*-butylcyclohexanol.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 3306—3309 (1969)

Effects of the Nitrone Group in NMR Spectra of α,*N*-Diphenylnitrones

Kinko KOYANO and Hiroshi SUZUKI

Department of Chemistry, College of General Education, The University of Tokyo, Komaba, Meguro-ku, Tokyo

(Received May 17, 1969)

The NMR and UV spectra of α,*N*-diphenylnitrone and its derivatives which have a substituent at the para position of the α-phenyl group and some of which have in addition a methyl substituent at the ortho position of the α-phenyl group were measured. Examination led to the following conclusions. The NMR signal of the ortho protons of the α-phenyl group appears at a very low field. This is mainly attributed to the direct effect of the negatively charged oxygen atom of the nitrone group. Increase in the electron-donating power of the para substituent enhances this effect.

In a previous paper, we reported that the NMR signal of the ortho protons of the α-phenyl group of α,*N*-diphenylnitrone (see Fig. 1) appeared at a very low field. We ascribed this to the direct effect of the negatively charged oxygen atom of the nitrone group (–CH=NO–).[1)]

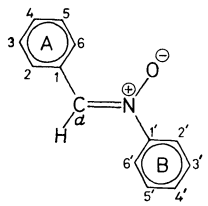


Fig. 1. α,*N*-Diphenylnitrone.

In the present paper, the NMR and UV spectra of α,*N*-diphenylnitrone and its derivatives which have a substituent at the 4-position and some of which have in addition a methyl substituent at the 2-position are examined. Special attention was paid to the effects of the nitrone group on the position of the NMR signals of the A ring protons. The conclusion of the previous paper was confirmed, and the influence of the 4-substituent on the direct effect of the oxygen atom was clarified.

Results and Discussion

The τ values of signals in the proton magnetic resonance spectra of α,*N*-diphenylnitrones in $CDCl_3$ are listed in Tables 1 and 2, and data on the longest wavelength band (referred to hereafter as the A band) in the electronic absorption spectra are shown in Table 3.

With regard to the effects of the two substituents of para-disubstituted benzenes on the chemical shift of the NMR signals of the ring protons, many

TABLE 1. THE τ VALUES OF PROTON SIGNALS OF 4-SUBSTITUTED α,*N*-DIPHENYLNITRONES IN $CDCl_3$

4-Substituted α,*N*-diphenylnitrone		Position of protons					
Entry No.	4-Substituent	α	2,6	3,5	2′,6′	3′,4′,5′	4-Methyl
1	$N(CH_3)_2$	2.26	1.77(d)	3.33(d)	2.28—2 37	2.68—2.75	
2	OCH_3	2.17	1.61(d)	3.05(d)	2.26—2.33	2.61—2.67	
3	CH_3	2.16	1.73(d)	2.77(d)	2.20—2.31	2.55—2.65	7.61
4	Unsubstituted	2.12	1.58—1.69	2.54—2.64	2.22—2.44	2.54—2.64	
5	Cl	2.13	1.69(d)	2.59(d)	2.25—2.35	2.55—2.64	
6	Br	2.12	1.74(d)	2.45(d)	2.21—2.31	2.54—2.61	
7	$COOCH_3$	2.04	1.62(d)	1.98(d)	2.24—2.35	2.58—2.65	
8	CN	2.00	1.57(d)	2.32(d)	2.23—2.36	2.50—2.60	
9	NO_2	1.99	1.45(d)	1.70(d)	2.17—2.27	2.47—2.53	

When a signal is doublet (indicated by letter d), the τ value at its center is shown. $J_{2,3}=J_{6,5}=7.5$—9.3 cps. When signals are unresolved, the range in which they appear is shown.

workers have stated that additivity holds approximately.[2] The contributions of the substituents at the ortho and meta positions to the change in the τ value of a ring proton are denoted by S_o and S_m, respectively, and they are referred to as the ortho and meta substituent constants, respectively. The values determined by Smith[3] for CCl_4 solutions are adopted here.

4-Substituted α,N-diphenylnitrones can be regarded as para-disubstituted benzenes, in which one of the two substituents is the 4-substituent (X) and the other the N-phenylnitrone group (–CH=NO–Ph). As is shown in Fig. 2, there exists an approximately linear relationship between the τ values of the 3- and 5-protons ($\tau_{3,5}$) of 4-substituted α,N-diphenylnitrones and the ortho substituent constants of the 4-substituents (S_o(X)), and the slope of the correlation line is nearly unity. From the correlation line the τ value at S_o(X)=0 is

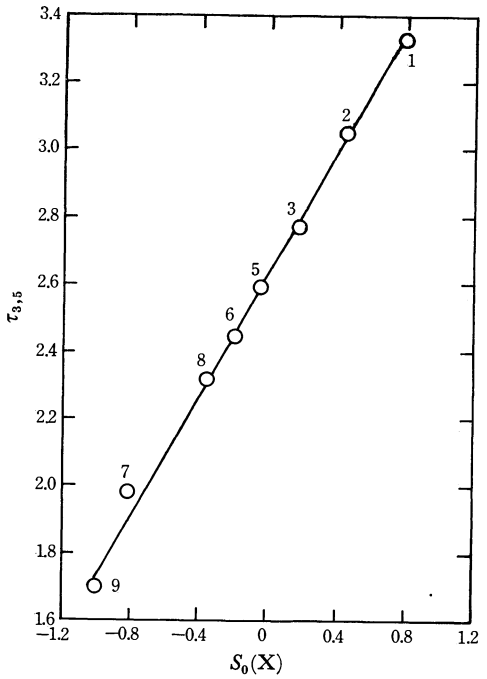

Fig. 2. The relation between the observed τ values of the 3- and 5-protons ($\tau_{3,5}$) of 4-substituted α,N-diphenylnitrones and the ortho substituent constants of the 4-substituents (S_o(X)). The numbers denote the compounds, according to the entry numbers in Table 1.

determined to be about 2.60. The difference between this value and the τ value of the protons of benzene (2.63 in $CDCl_3$), about −0.03, may be considered as the meta substituent constant of the N-phenylnitrone group, S_m(NPN). This is much smaller in absolute value than the meta substituent constant of the nitro group, $S_m(NO_2)$ (−0.21). Thus it may be said that the N-phenylnitrone group exerts only a very weak deshielding effect on the meta protons. There is also a fairly good linear relationship between the τ values of the α-protons and the Hammett σ_p values as well as Taft δ_p values[4] of the 4-substituents.

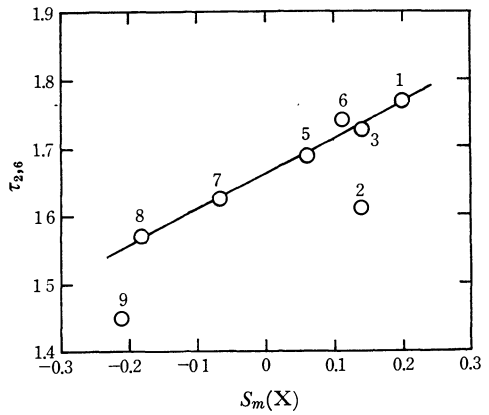

Fig. 3. The relation between the observed τ values of the 2- and 6-protons ($\tau_{2,6}$) of 4-substituted α,*N*-diphenylnitrones and the meta substituent constants of the 4-substituents (S_m (X)). The numbers denote the compounds, according to the entry numbers in Table 1.

Figure 3 shows that there is only a rough linear relationship between the τ values of the 2- and 6-protons ($\tau_{2,6}$) and the meta substituent constants of the 4-substituents (S_m(X)). The plots for the 4-methoxy and 4-nitro compounds deviate markedly from a straight correlation line. From the approximate correlation line given in Fig. 3 the τ value at S_m(X)=0 is estimated at about 1.65. If the difference between this value and the τ value of the protons of benzene, about −0.98, is tentatively considered as the ortho substituent constant of the *N*-phenylnitrone group, S_o(NPN), this substituent constant is comparable to the ortho substituent constant of the nitro group (−0.99). Thus, it might be said that the *N*-phenylnitrone group has a strong ortho substituent deshielding effect comparable to that of the nitro group.

The τ values of the 6-protons (τ_6) of the compounds having a methyl substituent at the 2-position, *viz.*, the compounds of entry numbers 1′, 2′, 3′, and 9′ in Table 2, are smaller by 0.9—1.3 than the τ values of the 2- and 6-protons ($\tau_{2,6}$) of the corresponding compounds having no methyl substituent at the 2-position, as illustrated by Fig. 4. This result is the same as that described previously for the 4-methyl compounds.[1] It is evident that the arguments are also valid in the present case. From the following facts, the most preferred conformation of the 4-substituted 2-methyl-α,*N*-diphenylnitrones seems to be a planar or nearly planar conformation in which the 6-proton is located near the oxygen atom of the nitrone group: (1) The most preferred conformation of the α,*N*-diphenylnitrones having no substituent at the ortho positions is probably a planar or nearly planar conformation;[5] (2) The values of the wavelength

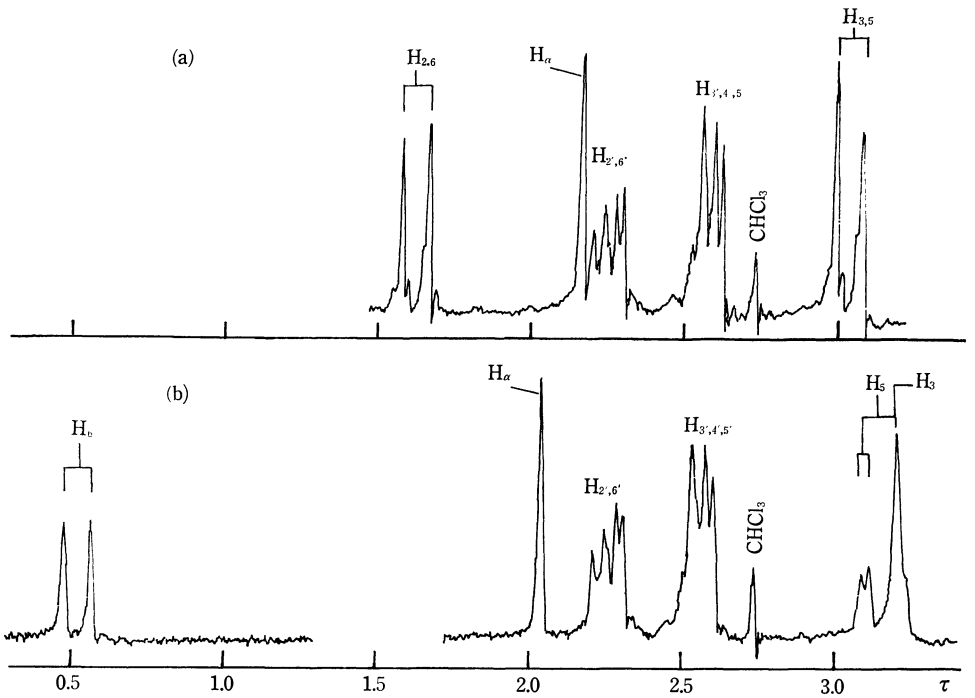

Fig. 4. The NMR spectra of (a) 4-methoxy-α,*N*-diphenylnitrone (compound 2) and (b) its 2-methyl derivative (compound 2′) in $CDCl_3$.

5) T. Kubota, M. Yamakawa and Y. Mori, This Bulletin, **36**, 1552 (1963).

and molar extinction coefficient of the A band maximum of the 4-substituted 2-methyl-α,N-diphenylnitrones are nearly equal to those of the corresponding compounds having no substituent at the 2-position (see Table 3). This seems to indicate that the most preferred conformation of the former is similar to that of the latter; (3) A scale model shows that the 2-methyl group must be sterically hindered from approaching the oxygen atom of the nitrone group. The 6-proton, being located near the negatively charged oxygen atom of the nitrone group, must be strongly affected by the oxygen atom, resulting in the marked downfield shift of its signal.

As seen in Table 2, the values of τ_6 are 0.70, 0.52, 0.51, and 0.48 for the 4-substituent (X)=CH_3, $N(CH_3)_2$, OCH_3, and NO_2, respectively. It should be noted that this order of the τ_6 values is quite different from that of the meta substituent constants of the 4-substituents.

If a 4-substituted α,N-diphenylnitrone having no substituent at the ortho positions had a fixed planar or nearly planar conformation, the 2- and 6-protons must be nonequivalent, and would show their signals at different τ values (τ_2 and τ_6). Of course, the τ value of the proton located near the oxygen atom of the nitrone group (τ_6) must be lower than that of the proton located far from the oxygen atom (τ_2). Actually, the α-phenyl group will rotate around the C_α–C_1 bond, so that the signals of the two protons coalesce. The observed values of $\tau_{2,6}$ are considered to be approximately the means of τ_2 and τ_6. Let us assume that the value of the hypothetical τ_6 of a 4-substituted compound can be calculated from the observed value of τ_6 of the corresponding 2-methyl compound by subtraction of the shift due to the substituent shielding effect of a meta methyl group, which is taken to be about 0.10. Then, from the observed $\tau_{2,6}$ values and the calculated τ_6 values, the values of the hypothetical τ_2 of 4-substituted compounds are calculated to be 3.12, 2.81, 2.86, and 2.52 for X=$N(CH_3)_2$, OCH_3, CH_3, and NO_2, respectively. These τ_2 values have a nearly linear relationship with the meta substituent constants of the 4-substituents, S_m(X).

The difference between the τ_6 value and the τ_2 value can be considered to be due to the direct effect of the oxygen atom of the nitrone group on the 6-proton. The values of this difference are −2.70, −2.40, −2.26, and −2.14 for X=$N(CH_3)_2$, OCH_3, CH_3, and NO_2, respectively. The order of these values coincides with that of the mesomeric electron-donating power of the 4-substituents. Thus, it can be said that the direct deshielding effect of the oxygen atom on the 6-proton is greater when the 4-substituent is more strongly electron-donating. This might be ascribed to the following two causes. (1) As the 4-substituent becomes more strongly electron-donating, the charge density at the oxygen atom will become larger. The inference that the π-electron density at the oxygen atom changes very sensitively by change of the 4-substituent is supported by a simple MO calculation. (2) Since the nitrone group is an electron-withdrawing group, as the 4-substituent becomes more strongly electron-donating, the conjugative interaction in the π-electron system will become stronger. As a result, the most preferred conformation will approach planarity, and its population ratio will increase. Consequently, the average distance between the 6-proton and the oxygen atom will become shorter.

Experimental

Materials. The α,N-diphenylnitrones were prepared by reaction of the adequately substituted benzaldehydes with phenylhydroxylamine in ethanol, according to the following equation:[5,6]

$$R\text{-}CHO + Ph\text{-}NHOH \longrightarrow R\text{-}CH{=}NO\text{-}Ph + H_2O$$

Their melting points (°C) were as follows (all are uncorrected): (1) 4-dimethylamino-, 140.5—141.2; (2) 4-methoxy-, 115.8—116.5; (3) 4-methyl-, 85—87; (4) unsubstituted, 113.0—113.5; (5) 4-chloro-, 153.5—154.0; (6) 4-bromo-, 161.5—162.0; (7) 4-methoxycarbonyl-, 155.5—156.0; (8) 4-cyano-, 147—149; (9) 4-nitro-, 186.0—186.5; (1′) 2-methyl-4-dimethylamino-, 142—143; (2′) 2-methyl-4-methoxy-, 97—98; (3′) 2,4-dimethyl-, 81—82; (9′) 2-methyl-4-nitro-, 153—155.

The compounds of entry numbers 1′, 2′, 3′, and 9′ are probably new compounds. The results of analysis for these compounds are as follows.

(1′) Found: C, 75.69; H, 7.22; N, 10.96%. Calcd for $C_{16}H_{18}N_2O$: C, 75.56; H, 7.13; N, 11.02%.

(2′) Found: C, 74.61; H, 6.35; N, 5.75%. Calcd for $C_{15}H_{15}NO_2$: C, 74.66; H, 6.27; N, 5.81%.

(3′) Found: C, 79.83; H, 6.82; N, 6.47%. Calcd for $C_{15}H_{15}NO$: C, 79.97; H, 6.71; N, 6.22%.

(9′) Found: C, 65.55; H, 4.44; N, 10.86%. Calcd for $C_{14}H_{12}N_2O_3$: C, 65.62; H, 4.72; N, 10.93%.

Measurement of the NMR and UV Spectra. The NMR spectra were measured on $CDCl_3$ solutions (concentration: about 120 mg in 1 ml of solvent) at room temperature with a Japan Electron Optics Laboratory spectrometer Model JNM-4H-100 (100 MC). Tetramethylsilane was used as an internal reference.

The UV spectra were measured with a Hitachi recording spectrophotometer Model EPS-2.

Synthetic Reactions by Complex Catalysts. XIV. Reaction of Isocyanide with Amine Catalyzed by Group IB and IIB Metal Compounds

Takeo SAEGUSA, Yoshihiko ITO, Shiro KOBAYASHI, Kiwami HIROTA and Hiroshi YOSHIOKA

Department of Synthetic Chemistry, Faculty of Engineering Kyoto University, Yoshida, Sakyo-ku, Kyoto

(Received May 17, 1969)

Group IB and IIB metal compounds catalyze the reaction of isocyanides (**1**) with amines (**2**) producing formamidines (**3**). In the reaction of cyclohexyl isocyanide with piperidine, the accelerating effect of catalyst was in the order AgCl>CuCl≫$ZnCl_2$, $Cd(OAc)_2$, $HAuCl_4 \cdot 4H_2O$. The AgCl catalyzed reaction proceeded almost quantitatively in 2.5 hr at 17°C. The reaction of aliphatic isocyanide with aromatic amine, *e.g.*, *N*-methylaniline, required higher reaction temperatures (160°C) even in the presence of catalyst, in which the order of catalytic activity was $HAuCl_4 \cdot 4H_2O$ >$ZnCl_2$>AgCl≫CuCl. A ternary complex of $(CuCl)_2$ (cyclohexyl isocyanide)$_2$ (piperidine) was isolated, which was unstable and decomposed gradually at room temperature to give *N*-cyclohexyl-*N'*,*N'*-pentamethylene formamidine. A mechanism through a mixed ligand complex has been proposed, in which both isocyanide and amine are coordinated with the same metal ion and the reaction takes place in the sphere of complex ligand.

The reaction of aliphatic isocyanide with amine, which does not take place without catalyst, is induced effectively by copper,[1] silver, zinc, cadmium and gold salts. Aromatic isocyanides have been known to react with amine even in the absence of the metal salt catalyst.[2] In the reaction of aromatic isocyanide with amine, however, the accelerating effect of the above metal compounds is observed.

$$\underset{(\mathbf{1})}{R\text{-}N\rightleftarrows C:} + \underset{(\mathbf{2})}{R'_2NH} \rightarrow \underset{(\mathbf{3})}{R'_2N\text{-}\overset{\overset{\|}{N}\text{-}R}{C}\text{-}H} \qquad (1)$$

A reaction mechanism through a mixed ligand complex has been proposed, in which both isocyanide and amine are coordinated with the common metal ion and the reaction takes place in the sphere of complex ligand.

Results and Discussion

Catalytic Activities of Metal Compounds. The catalytic activities of various metal compounds were examined in the reaction of cyclohexyl isocyanide with piperidine producing *N*-cyclohexyl-*N'*,*N'*-pentamethylene formamidine (Table 1).

The catalytic activities of IB and IIB metal compounds except mercuric compound are conspicuously shown. Since the formamidines are obtained in high yields, the reaction can be utilized for the synthesis of the formamidine derivatives. Lewis acids such as ferric chloride and aluminum chloride are much less active. In the isocyanide-amine reaction, zinc chloride was used in an earlier work.[3] The results of an extended screening of the metal

compounds in the present studies have indicated that the catalytic activity of zinc chloride is not ascribed to its function of the so-called Lewis acid. In the systems with typical transition metal salts such as cobalt and nickel chlorides the rapid polymerization of isocyanide took place and hence no formamidine derivative was formed.

Table 2 illustrates the catalytic activities of several copper compounds and metallic copper. Under these reaction conditions, the catalytic activity (the product yield) is not much affected by the valency of copper and the nature of anion ligand. It is to be mentioned, however, that the cupric chloride is reduced to cuprous chloride by isocyanide in a stoichiometric way according to[4]

$$2CuCl_2 + RN{\rightleftarrows}C: \rightarrow 2CuCl + R{-}N{=}CCl_2 \quad (2)$$

Consequently it may be assumed that the cupric species were reduced to the cuprous species which served as the real active catalyst.

As to the catalytic activity of metallic copper, it is of interest that metallic copper dissolves in liquid isocyanide to form a soluble complex of copper isocyanide. Metallic copper powder was put in liquid cyclohexyl isocyanide and the mixture was centrifuged. The IR spectrum in the liquid phase showed a new band at 2180 cm^{-1} in addition to the absorption band of cyclohexyl isocyanide. The new band is reasonably assigned to $\nu_{N\equiv C}$ of the isocyanide species which is coordinated with copper. Moreover, the corresponding formamidine was formed when the liquid phase was treated with piperidine at room temperature. In the metallic copper catalyzed reaction the catalytic activity is thus ascribed to the soluble complex. The actual valence state of copper in liquid isocyanide should be the subject of future research.

Table 3 shows the results of the reactions of three isocyanides with aliphatic and aromatic amines by cuprous chloride catalyst. The cuprous chloride

catalyzes the reaction of aliphatic isocyanide with aliphatic amine at considerable rates even at 25°C. The aliphatic isocyanide-aromatic amine reaction catalyzed by cuprous chloride requires higher reaction temperatures. Cuprous chloride is not a suitable catalyst for this combination of reaction. This will be discussed later.

Aromatic isocyanide reacts with amine without catalyst. As an example, the reaction of phenyl isocyanide with piperidine proceeds at 25°C to give *N*-phenyl-*N'*,*N'*-pentamethylene formamidine in a yield of 85% after 48 hr. However, the catalytic activity of cuprous chloride is clearly observed. In the presence of cuprous chloride, the reaction takes place instantaneously even at 0°C to produce the formamidine almost quantitatively (the last run of Table 3).

The catalyst activities of several salts of group IB and IIB metals are evaluated in a semiquantitative way by the time-conversion curves in the reactions of cyclohexyl isocyanide with piperidine at 17°C and with *N*-methylaniline at 160°C as shown in Figs. 1 and 2, respectively. The order of catalyst activity in the former reaction is $AgCl > CuCl \gg ZnCl_2$, $Cd(OAc)_2$, $HAuCl_4{\cdot}4H_2O$, which is quite different from that in the latter reaction of cyclohexyl isocyanide with aromatic amine, $HAuCl_4{\cdot}4H_2O > ZnCl_2 > AgCl \gg CuCl$. The specific activity of chloroautic acid in the aromatic amine-isocyanide reaction is of interest especially from the fact that it is

also quite active as the catalyst in the reaction[5] of aromatic amine with carbon monoxide which is isoelectronic to isocyanide.

Metallation of aromatic compound with $AuCl_3$, as reported by Kharasch[6] may be cited in relation to the specific catalysis of chloroautic acid for these reactions.

Mechanism. The isocyanide-amine reaction of the present studies seems to proceed in the ligand sphere of a ternary complex consisting of metal ion, isocyanide and amine. The crystalline, binary complex of cyclohexyl isocyanide and cuprous chloride, $[Cu(C{\leftleftharpoons}NC_6H_{11})]Cl$, was dissolved into liquid piperidine at 0°C. On standing the homogeneous solution at 0°C, a new crystalline solid was separated.

NMR spectrum of the crystalline solid in deuterated chloroform showed two broad signals centered at δ 3.7 (2H, $>$CH–N$\rightleftharpoons$C: of two mol of cyclohexyl isocyanide) and δ 3.3 (4H, $-N\langle^{CH_2-}_{CH_2-}$ of one mol of piperidine) and a complex signal at δ 1.0—2.1 (26H, 20H of $-(CH_2)_5-$ of two mol of cyclohexyl isocyanide plus 6H of $-(CH_2)_3-$ of one mol of piperidine). Together with the elemental analysis (Found: C, 45.92; H, 6.78; N, 8.75; Cl, 14.54%. Calcd for **4**: C, 45.51; H, 6.63; N, 8.38; Cl, 14.14%), the composition of the complex was determined as indicated by the formula

(4)

The spectrum of the ternary complex showed two key bands at 2176 and 3192, which were assigned to $\nu_{N\equiv C}$ of the isocyanide ligand and ν_{N-H} of the piperidine ligand. The band of $\nu_{N\equiv C}$ of the ternary complex is different from the corresponding $\nu_{N\equiv C}$ of the binary complex at 2192 cm^{-1} and from that of free isocyanide at 2140 cm^{-1}. Variation of $\nu_{N\equiv C}$ indicates that the coordination of isocyanide in the ternary complex is influenced by the piperidine ligand, whose ν_{N-H} band is also being shifted from that of free piperidine at 3280 cm^{-1}. These observations suggest the formation of a mixed ligand complex in which the isocyanide and amine ligands are coordinated with the common cuprous ion.

The ternary, mixed ligand complex formed here was not stable and decomposed gradually even at room temperature to produce the formamidine product, *N*-cyclohexyl-*N'*,*N'*-pentamethylene formamidine. Therefore, it is quite reasonable to assume that the cuprous chloride catalyzed reaction of isocyanide with amine proceeds in the ligand sphere of the mixed ligand complex.

Experimental

Meterials. Metal salts were of commercial, analytical reagent grade.

Metallic copper was prepared by reduction of cupric sulfate with zinc powder. In 600 m*l* of water, 100 g of cupric sulfate pentahydrate was dissolved, to which 15 g of zinc powder was added slowly with stirring below 70°C. The precipitate was washed several times with water and then with acetone. It was stored in acetone under nitrogen, and dried under nitrogen immediately prior to use.

Isocyanide was prepared by dehydration of *N*-substituted formamide with phosphorus oxytrichloride according to Ugi's procedure.[7]

General Procedure. A mixture of isocyanide (30 mmol), amine (100 mmol) and metal compound catalyst (0.2 mmol) was heated at the indicated temperature monitoring the reaction by the decrease of an infrared band $\nu_{N\equiv C}$ of isocyanide. The product of *N*,*N'*-disubstituted formamidine was isolated by distillation or by crystallization. Their structures were established by by elementary analysis, IR and NMR spectra.

Identifications of the Formamidine Products. *N*-Cyclohexyl-*N'*,*N'*-pentamethylene formamidine, bp 155—156°C/28 mmHg.

Found: C, 74.40; H, 11.71; N, 14.53%. Calcd for $C_{10}H_{20}N_2$: C, 74.17; H, 11.41; N, 14.42%. IR (neat): 1660 cm^{-1} ($\nu_{N=C}$), NMR ($CDCl_3$): δ 7.10 ppm (singlet, –N=CH–N<).

N,*N'*-Dicyclohexyl formamidine, mp 100—101°C (recrystallization from *n*-hexane).

Found: C, 74.61; H, 11.35; N, 13.64%. Calcd for $C_{13}H_{24}N_2$: C, 74.94; H, 11.61; N, 13.45%. IR (Nujol): 3280 cm^{-1} (ν_{N-H}), 1650 cm^{-1} ($\nu_{N=C}$).

N-Cyclohexyl-*N'*-methyl-*N'*-phenyl formamidine, bp 94—96°C/0.7 mmHg.

Found: C, 77.61; H, 9.58; N, 13.11%. Calcd for $C_{14}H_{20}N_2$: C, 77.73; H, 9.32; N, 12.95%. IR (neat): 1640 cm^{-1} ($\nu_{N=C}$).

Bis-*N*,*N'*-(cyclohexylformimidoyl) piperazine, mp 99—101°C (recrystallization from *n*-hexane).

Found: C, 71.16; H, 10.71; N, 18.68%. Calcd for $C_{18}H_{32}N_4$: C, 71.00; H, 10.59; N, 18.40%. Molecular weight (cryoscopic in benzene) Found: 294. Calcd for $C_{18}H_{32}N_4$: 304. IR (Nujol): 1630 cm^{-1} ($\nu_{N=C}$).

N-*n*-Butyl-*N'*,*N'*-pentamethylene formamidine, bp 118—120°C/27 mmHg.

Found: C, 71.39; H, 12.08; N, 16.79%. Calcd for $C_{10}H_{20}N_2$: C, 71.37; H, 11.98; N, 16.65%. IR (neat); 1640 cm^{-1} ($\nu_{N=C}$). NMR (CCl_4): δ 7.10 ppm (singlet, –N=CH–N<).

Preparation of Cyclohexyl Isocyanide-Cuprous Chloride (1 : 1) Complex. Cuprous chloride was added slowly to excess cyclohexyl isocyanide at room temperature, and the precipitation was collected by filtration. The white crystalline product was recrystallized from chloroform-ether, mp 95—96°C. Elementary analysis revealed that crystalline product consisted of 1 mol cyclohexyl isocyanide and 1 mol cuprous chloride.

Found: C, 40.40; H, 5.29; N, 6.73; Cl, 17.07%. Calcd for $C_7H_{11}NClCu$: C, 40.40; H, 5.22; N, 6.60; Cl, 17.01%.

Preparation of Ternary Complex. A mixture of piperidine (0.04 mol) and cyclohexyl isocyanide-cuprous chloride (1 : 1) complex (1 g) was stirred below 0°C. After several minutes a green homogeneous solution was obtained. On standing for several minutes more, a white crystalline solid was precipitated. The crystalline solid was washed with dry cold petroleum ether by decantation and dried *in vacuo*. This ternary mixed ligand complex is unstable at room temperature, and is readily decomposed to give *N*-cyclohexyl-*N'*,*N'*-pentamethylene formamidine.

α-Diketone Rearrangement. The Reaction of 1,2-Cyclohexanedione with Arginine and with Guanidine

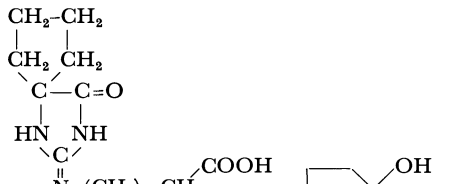
Kentaro ANZAI

The Institute of Physical and Chemical Research, Yamato-machi, Saitama

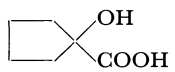
(Received May 19, 1969)

A novel rearrangement reaction of cyclohexanedione, involving the loss of hydrogen in the product, is described. Cyclohexanedione and guanidine react in an alkaline solution to produce 2-amino-4-oxo-1,3-diazaspiro[4.4]non-1-ene (VIII) and 1-hydroxy-3-amino-5-oxo-2,4-diazabicyclo-[4.3.0]non-2-ene (IX), the latter being an oxidized product. Similarly, cyclohexanedione reacts with arginine, producing, among other products, N^5-(1-hydroxy-5-oxo-2,4-diazabicyclo[4.3.0]non-2-ylidene)-ornithine (III).

Toi *et al.*[1] have reported that arginine reacts with cyclohexanedione (CHD) in basic solutions to produce N^5-(4-oxo-1,3-diazaspiro[4.4]non-2-ylidene)-L-ornithine (I). Though in strongly basic solutions the yield of I is almost quantitative, the presence of three minor products has also been shown by paper electrophoresis.[1] This reaction is unique in the sense that such rearrangements of aliphatic α-diketones similar to the benzilic-acid rearrangement have scarcely been known except that CHD is transformed to 1-hydroxycyclopentanecarboxylic acid[2] (II) in a concentrated solution of sodium hydroxide on heating.



I



II

A paper chromatogram of the reaction mixtures of CHD and arginine is schematically shown in Fig. 1. The products are all isolated by cellulose column chromatography, and the ratios of the products are found to be markedly dependent on the concentrations of sodium hydroxide, as was suggested, by Toi *et al.*[1] If the reactions are carried out at pHs of less than 11, one unidentified product (corresponding to the spot 3 in Fig. 1) is found to be predominant. Though we at first incorrectly anticipated that it might be the first intermediate, through which I is produced, the structural elucidation of this compound has unexpectedly resulted in showing a novel reaction of CHD involving an intermolecular hydride shift. This report will be concerned with the structure of the product obtained from arginine and CHD at low concentrations of sodium hydroxide.

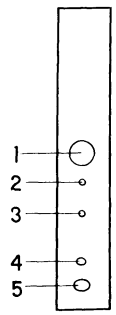


Fig. 1. The product distribution of a reaction mixture of arginine and cyclohexanedione in 0.2N NaOH: paper chromatogram developed with butanol, acetic acid, and water (4:1:2).

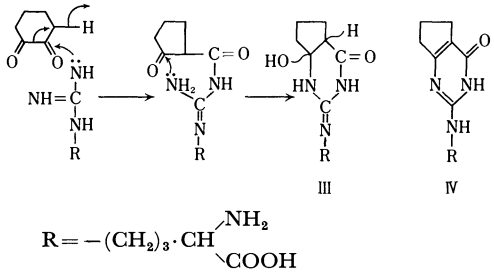
CHD and arginine were allowed to react in a 0.05N sodium hydroxide solution or at pH 11 at room temperature, and the products were isolated by cellulose column chromatography. The analytical data of the major product are consistent with the molecular formula of $C_{12}H_{20}N_4O_4$ after it has been heated at 140°C for 5 hr,[3] showing that CHD and arginine react with the loss of one mole of water and two atoms of hydrogen. A mechanistic consideration leads to two possible structures, III and IV (Scheme 1).

Though molecular-weight determination by the

1) K. Toi, F. Bynum, E. Norris and H. A. Itano, *J. Biol. Chem.*, **242**, 1036 (1967).

2) O. Wallach, *Ann.*, **437**, 174 (1924).

3) When the sample was dried over phosphorus pentoxide at room temperature, the analytical data were consistent with $C_{12}H_{20}N_4O_4 \cdot H_2O$. The water of crystallization was hardly expelled on heating at 100°C for a prolonged time over phosphorus pentoxide. When it was heated over 140°C, it gradually decomposed.

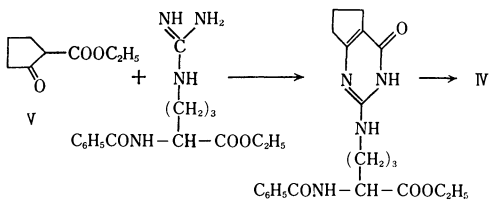


Scheme 1

parent peak seems rather to support the structure IV (Calcd for the trifluoroacetylated methyl ester of $C_{12}H_{18}N_4O_3$, 376.1358; measured, 376.1327), other physical and chemical data, to be discussed below, can more be reasonably explained by the structure III. IV is formally a dehydrated product of III, and the molecular ion of III may be rapidly dehydrated in a mass spectrometer, resulting in the loss of the parent peak.

Though the NMR spectrum is not very useful in elucidating the structure because of unanalyzable broad methylene signals, one methine proton signal at δ 4.10, a broad triplet, is inconsistent with a possible structure IV. The UV spectrum of the compound, $\lambda_{max}^{H_2O}$ mμ (ε) 217 (17100), is almost the same as that of I, $\lambda_{max}^{H_2O}$ mμ(ε) 214 (18500), supporting the idea that both have the same chromophore, –NH-C(=N–)–NHCO. The compound IV has an aromaticity and is expected to have an absorption maximum at a longer wavelength.

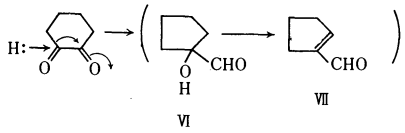
N^5-(5,6-Trimethylene-4-oxopyrimid-2-yl)ornithine (IV) was synthesized by the condensation of 2-ethoxycarbonylcyclopentanone (V) with benzoyl arginine ethyl ester, followed by acid hydrolysis (Scheme 2); as expected, IV is found to have a UV spectrum, $\lambda_{max}^{H_2O}$ mμ (ε) 230 (8800), 292 (6100), similar to that of isocytosine, $\lambda_{max}^{H_2O}$ mμ (ε) 222 (10000), 285 (5000). The mass spectra of III and IV (measured as the trifluoroacetylated methyl esters) are quite similar, strongly suggesting that the molecular ion of III is dehydrated with no observable parent peak to show a mass spectrum indistinguishable from that of IV.



Scheme 2

Though III shows a single spot on TLC, the possibility that it is a mixture of configurational isomers cannot be excluded.

After it has been established that an equimolar amount of CHD and arginine react, with the loss of two hydrogen atoms, to produce N^5-(1-hydroxy-5-oxo-2,4-diazabicyclo[4.3.0]non-2-ylidene)ornithine (III), the next problem is to determine the place where the hydrogen is accepted. As no evolution of gas is observed during the reaction, it seems reasonable to assume that CHD is reduced to 1-hydroxycyclopentanecarboxyaldehyde (VI) or 1-cyclopentene-1-carboxyaldehyde (VII), which might then suffer from further reactions (Scheme 3).



Scheme 3

Though the effort to isolate an aldehyde failed, possibly because of the susceptibility of aldehydes under these reaction conditions and because of the difficulty of separating an aldehyde from an excess of CHD, the positive reactions with Angeli's[4] and Tollens' reagent, after CHD and arginine have reacted in basic solutions, strongly suggest that two moles of CHD are needed for the formation of III; one reacts with arginine, and the other accepts the hydride anion. The following experimental findings seem to support this presumption: the spectrophotometric determination of the products on TLC shows that, when the reaction is carried out in a weakly basic solution, III is the only product, accompanied by an equimolar amount of unreacted arginine, and the use of an excess of CHD, an elevated temperature, and a prolonged reaction time have no influence on the ratio of the III to the arginine. We have still to answer the question of why half the arginine must remain unreacted. This peculiarity can be explained by presuming the following reaction path, which involves the formation of an aldehyde from CHD (Scheme 4):

2CHD + arginine → an aldehyde + III (1)

an aldehyde + arginine → a Schiff base of arginine (2)

Scheme 4

Generally, aldehydes are known to form Schiff bases more easily than ketones, and it is expected that an aldehyde, if it is involved in the reaction path on the formation of III (Eq. (1)), will at once combine with arginine to form a Schiff base (Eq. (2)), which is a species unable to react with CHD. Thus, the fact that only half the arginine is transformed to III in weakly basic solutions can be reasonably explained.

When the reaction is carried out in the presence of silver nitrate without altering the other reaction

4) A. Angeli, *Gazz. Chim. Ital.*, **34**, I, 50 (1904).

conditions, arginine is found to be almost completely consumed, being transformed to III.

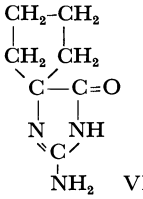
Two mechanism of the action of the silver cation are possible (Scheme 5): it might accept an electron from the hydride anion (Eq. (3)), or it might oxidize an aldehyde to prevent arginine from forming a Schiff base (Eq. (4)):

$$H^- + 2Ag^+ \rightarrow 2Ag + H^+ \quad (3)$$

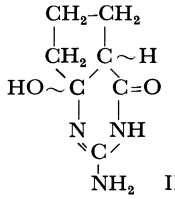
$$RCHO \xrightarrow{Ag^+} RCOOH \quad (4)$$

Scheme 5

In a similar manner, guanidine reacts with CHD in basic solutions to produce, though in low yields, 2-amino-4-oxo-1,3-diazaspiro[4.4]non-1-ene (VIII) and 1-hydroxy-3-amino-5-oxo-2,4-diazabicyclo-[4.3.0]non-2-ene (IX).



VIII



IX

Here also both the compounds have almost the same UV spectra, VIII, $\lambda_{max}^{H_2O}$ mμ (ε) 226 (7300): IX, $\lambda_{max}^{H_2O}$ mμ (ε) 227 (9900), showing that one, formed with the loss of two atoms of hydrogen, does not have an isocytosine chromophore.

Though the mass spectrum of IX exhibits the expected parent peak (*m/e* 169), the strength is found to vary markedly depending upon the measurement conditions; however, the peak corresponding to $M^+ - H_2O$ (*m/e* 151) is always predominant.

Thus, the reaction of CHD with arginine and guanidine reported here will, we believe, offer a way of approaching the novel reaction of α-diketones.

Experimental

Reaction of Arginine with Cyclohexanedione (CHD) in 0.2N NaOH. The reaction was carried out in almost the same way as that described by Toi *et al.*[1] To a solution of 900 mg of arginine in 100 m*l* of a 0.2N sodium hydroxide solution, there was added a 670-mg portion of CHD. After the solution had been left at room temperature for 4 hr, it was charged on a column of IR 120 (3×60 cm) and developed with 1N aqueous ammonia. The ninhydrin positive fractions were collected, and, after the water and ammonia had been evaporated under reduced pressure, the residue was chromatographed on cellulose (2×90 cm) and developed with a mixture of butanol, acetic acid, and water (4: 1: 2) or with a mixture of propanol, pyridine, acetic acid and water (15: 10: 3: 10). After repeated chromatography, five compounds, each showing a single spot on TLC, were obtained. The yields of Compounds **1** to **5**, corresponding to the spots from **1** to **5** in Fig. 1, were 600 mg, 2 mg, 7 mg, 2 mg, and 30 mg respectively. Compound **1** had already been established to be N^5-(4-oxo-1,3-diazaspiro-[4.4]non-2-ylidene)-L-ornithine (I), and Compound **4** was found to be arginine.

Though, under these experimental conditions, the yield of Compound **3** was too low to collect enough of a sample to study the structure, the same compound was also obtained as a major product under other conditions where the concentrations of sodium hydroxide were lower (see below).

The structure of Compound **2**, mp 172—177°C (dec), and Compound **5**, mp 205—210°C (dec), are now under investigation.

Reaction of Arginine with CHD in 0.05N NaOH: N^5-(1-Hydroxy-5-oxo-2,4-diazabicyclo[4.3.0]non-2-ylidene)ornithine (III). The reaction was carried out according to the same procedure as has been described above except that the concentration of sodium hydroxide was decreased to 0.05N. The yield of Compounds **1**, **2**, and **3**, after repeated chromatography, were 50, 100, and 130 mg respectively. Compound **3**, which was identified as N^5-(1-hydroxy-5-oxo-2,4-diazabicyclo-[4.3.0]-non-2-ylidene)ornithine (III) on the basis of the data to be presented below, was obtained as a colorless precipitate from water and ethanol. It showed no definite mp and gradually decomposed at 230—270°C; $\lambda_{max}^{H_2O}$ mμ (ε) 217 (17100); NMR (D_2O) 1.87 (broad 10H) 3.35 (t 2H J=6 cps) 3.74 (t 1H J=5.5 cps) 4.10 (broad t 1H J=6 cps).

Found: C, 47.71; H, 7.05; N, 18.60%. Calcd for $C_{12}H_{20}N_4O_4 \cdot H_2O$: C, 47.67; H, 7.33; N, 18.53%.

On heating at 140°C for 3 hr, 5.54% of the total weight was lost, corresponding to a theoretical value of 5.97% based on one mole of the water of crystallization.

Found: C, 50.30; H, 6.93; N, 19.17%. Calcd for $C_{12}H_{20}N_4O_4$: C, 50.69; H, 7.09; N, 19.71%.

The trifluoroacetylated methyl ester of IV did not show M^+; $(M-H_2O)^+$ 376.1327 (Calcd for $C_{15}H_{19}N_4O_4F_3$, 376.1358).

Reaction of Arginine with CHD at pH 11. To 10 m*l* of an aqueous solution containing 1.2 g of arginine, there were added, drop by drop, 760 mg of CHD dissolved in 10 m*l* of methanol. The consumption of arginine was followed by a decrease in the pH; the pH (10.5; initial) was kept almost constant (pH 10.5—11.0) throughout the addition by adding sodium hydroxide. After the solution had then been left at room temperature for 4 hr, the methanol was removed by evaporation and the residual aqueous solution was submitted to the procedure described in the first section.

The spectrophotometric determination of the ninhydrin-positive spots on TLC showed that, in this experimental run, the yields of Compounds **1**, **2**, and **5** were scanty and that Compound **3** was the major product, accompanied by an almost equimolar amount of the unreacting arginine. TLC also showed the presence of another, as-yet-unidentified ninhydrin-positive compound, which, on TLC, moved slightly slower than Compound **3**.

Reaction of Arginine with CHD at pH 11 in the Presence of Silver Nitrate. To a mixture of 130 mg of arginine and 115 mg of silver nitrate dissolved in 10 m*l* of water, a solution of 300 mg of CHD in 10 m*l* of methanol was added drop by drop, with the pH kept at 10.5—11.0 with sodium hydroxide. TLC on cellulose showed that Compound **3** was predominant, accompanied by small amounts of Compounds **1** and **2**. Hardly any arginine was detected.

A control experiment was carried out in the absence of silver nitrate. TLC showed that the amount of Compound **3** and arginine, after the reaction was completed, was almost the same. The isolation of Compound **3** was not attempted in this experimental run.

N^1-Benzoyl-N^5-(5,6-Trimethylene-4-oxopyrimid-2-yl)ornithine Ethyl Ester and N^5-(5,6-Trimethylene-4-oxopyrimid-2-yl)ornithine (IV). To a solution of 343 mg (10^{-3}M) of benzoyl-L-arginine ethyl ester hydrochloride dissolved in 10 m*l* of alcohol, an equimolar amount of sodium alcoholate (23 mg of sodium in 1 m*l* of alcohol) was added; the solution was then left in a refrigerator for 5 hr. The precipitate of sodium chloride was removed by filtration, and 150 mg of 2-ethoxycarbonyl-cyclopentanone were added. After the solution had been refluxed for 5 hr, water was added and the product, N^1-benzoyl-N^5-(5,6-trimethylene-4-oxopyrimid-2-yl)ornithine ethyl ester (the benzoylated ethyl ester of IV), was extracted with ethyl acetate. After the solvent had been evaporated, the residue was crystallized from benzene and ligroin; yield, 15 mg; mp 138—140°C; M^+ 398.1980 (Calcd for $C_{21}H_{26}N_4O_1$, 398.1954); $\lambda_{max}^{H_2O}$ mμ (ε) 229 (18300) 293 (8700).

N^5-(5,6-Trimethylene-4-oxopyrimid-2-yl)ornithine (IV) was obtained by the hydrolysis of the benzoylated ethyl ester of IV in a 2N hydrochloric acid solution, it being heated at 105°C for 20 hr. The hydrolysate from 10 mg of the benzoylated ethyl ester of IV was chromatographed on cellulose (2×90 cm) and the UV positive fractions were collected. Chromatography was repeated until a single spot, detected by both the ninhydrin reaction and UV absorption, was observed on TLC. After the solvent had been evaporated, the residue was precipitated from water and acetone; yield, 3 mg; it gradually decomposed over 190°C; $\lambda_{max}^{H_2O}$ mμ (ε) 230 (8800) 292 (6100). The trifluoroacetylated methyl ester of IV showed M^+, 376.1340 (Calcd for $C_{15}H_{19}N_4O_4F_3$, 376.1358).

Reaction of Guanidine with CHD: 2-Amino-4-oxo-1,3-diazaspiro[4.4]non-1-ene (VIII) and 1-Hydroxy-3-amino-5-oxo-2,4-diazabicyclo[4.3.0]non-2-ene (IX). A mixture of guanidine hydrochloride (191 mg, 2×10^{-3}M) and CHD (224 mg, 2×10^{-3}M) dissolved in a 1N sodium hydroxide solution (10 m*l*) was left to stand at room temperature overnight, and then the sodium hydroxide was removed with IR 120, as has been described in the first section. The products were eluted from the column with 1N aqueous ammonia, and, after the ammonia and water had been evaporated under reduced pressure, the residue was submitted to partition chromatography on silicic acid (2×60 cm), being developed with butanol saturated with water. Two products, which were detected by means of a Greig-Leaback reaction (*t*-butylhypochlorite-tolidine) on TLC, were isolated.

2-Amino-4-oxo-1,3-diazaspiro[4.4]non-1-ene (VIII), eluted first from the column, was crystallized from ethanol and benzene; yield, 27 mg; mp 260—265°C; $\lambda_{max}^{H_2O}$ mμ (ε) 226 (7300); M^+ 153.0911 (Calcd for $C_7H_{11}N_3O$, 153.0902).

The NMR spectrum showed a broad methylene signal at δ 1.2. The IR spectrum showed the following intense bands (cm^{-1}): 1632, 1585, 1487, 1335, 1320.

Found: C, 51.94; H, 7.32; N, 25.49%. Calcd for $C_7H_{11}N_3O\cdot\frac{1}{2}H_2O$; C, 51.83; H, 7.46; N, 25.91%.

1-Hydroxy-3-amino-5-oxo-2,4-diazabicyclo[4.3.0]non-2-ene (IX), which was eluted later, was crystallized from water; yield, 11 mg. It did not show a definite melting point; rather it gradually decomposed at 220—240°C; $\lambda_{max}^{H_2O}$ mμ (ε) 227 (9900); M^+ 169.0876 (Calcd for $C_7H_{11}N_3O_2$, 169.0851), $(M-H_2O)^+$ 151.0706 (Calcd for $C_7H_9N_3O$, 151.0746). The IR spectrum showed the following intense bands (cm^{-1}): 1675, 1662, 1612, 1490.

Found: C, 49.67; H, 6.34; N, 24.75%. Calcd for $C_7H_{11}N_3O_2$: C, 49.63; H, 6.55; N, 24.84%.

Mass-spectrum Measurements. A mass spectrometer of the JMS-01SG model of the Japan Electron Optics Laboratory, Ltd., was used. To obtain volatile samples, milligram amounts of I, III, and IV were methylated and successively trifluoroacetylated following the method described by McLafferty.[5] The products were, without further purification, dissolved in a small amount of acetone and charged into capillary tubes. The acetone was removed in the spectrometer under reduced pressure, and the spectra were taken under a direct-inlet system.

The author wishes to thank Dr. Saburo Suzuki, the chief of the Laboratory of Antibiotics, of this Institute, for his encouragement.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 3318—3323 (1969)

Total Syntheses of Tanshinone-I, Tanshinone-II and Cryptotanshinone*1,2

Yoshinobu INOUYE and Hiroshi KAKISAWA

Department of Chemistry, Tokyo Kyoiku University, Otsuka, Bunkyo-ku, Tokyo

(Received May 30, 1969)

Total syntheses of tanshinone-II (II) and cryptotanshinone (III) from 3-methylbenzofuran-4, 7-quinone (X) and 6,6-dimethyl-1-vinylcyclohexene (IX), and of tanshinone-I (I) from quinone X and *o*-methylstyrene (XVIII) are described. Preliminary accounts for the Diels-Alder reaction of methoxybenzoquinone revealed that the effect of substituents for orientation phenomena can be considered to be of electronic nature.

Tanshinone-I (I),[1] tanshinone-II (II)[2] and cryptotanshinone (III)[3]–pigments isolated from the root of *Salvia miltiorrhiza* Bunge[4]–were found to posess the unique chromophore consisting of an orthoquinone and a furan ring. Recent investigations on minor components established the structures of tanshinone-IIB (IV),[5] hydroxytanshinone-II (V)[6] and methyl tanshinonate (VI)[6] having the same framework.

Synthetic approaches to these unique pigments have been reported by three groups,[5, 7–9] of which

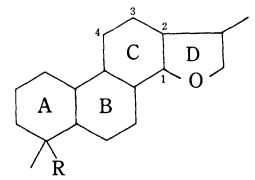

Fig. 1

two[5,9] succeeded in syntheses of tanshinones. In the early approaches,[7,8] A/B/C rings were built up by the Diels-Alder reaction of benzoquinone with suitable dienes, followed by attempted introduction of an alkyl side chain to make a furan ring. However, the alkylations resulted in an unsuitable position[7] or in an unseparable mixture.[8]

Recently these weakness were overcome by using the 1,3-dimethoxyphenanthrene derivative[9] or the 3-hydroxy-1,4-phenanthrenequinone derivatives[5] as an intermediate, where the introduction of an alkyl side chain could be controlled to occur at a suitable position (C_2).

Utilization of the Diels-Alder reaction to build the framework would be preferable for two reasons; firstly, this method will establish the general route to all tanshinones by using an appropriate quinone or diene, and secondly, some information can be obtained for the orientation in the Diels-Alder reaction, on which little is known especially in the case of substituted benzoquinones (*vide infra*).

In the purification of cryptotanshinone (III),

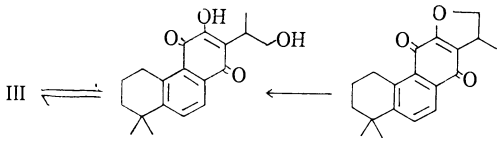
Takiura[10] found that it readily dissolved in alcoholic potassium hydroxide to give a yellow enolic compound, and that the latter was reconverted into cryptotanshinone on heating with an equal amount of ethanol and concentrated sulfuric acid. From the structure of cryptotanshinone, and the ready hydrolysis of alkoxyquinone with alkali to hydroxyquinone, these phenomena can be explained as III ⇌VII. Possibility of conversion of isomer VIII



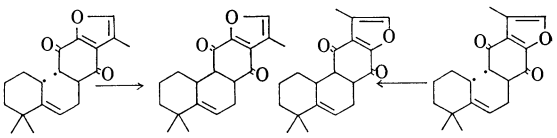
VII VIII

of cryptotanshinone (III) into cryptotanshinone through the same enolic intermediate VII prompted us to prepare isomer VIII by the Diels-Alder reaction between 6,6-dimethyl-1-vinylcyclohexene(IX)[8] and 3-methylbenzofuran-4,7-quinone (X) followed by catalytic hydrogenation of adduct XI. The unknown quinone X can be derived from 3-methyl-4-benzofuranol (XII)[11] by mild oxidation.

Before proceeding to the actual synthesis, we must briefly refer to the orientation in the Diels-Alder adduct. Although no reliable theory[12-15] has yet been given for the orientation in the adducts, the most conventional interpretation is to assume the biradical intermediates*3 of which the main product may be anticipated by considering the radical stability.

The Diels-Alder reactions of substituted benzoquinones were mostly investigated by Ansell and co-workers.[16] They found that the dienophilic activity of the ethene linkage of benzoquinones depends on whether its electron-density is greater or less than that of the other: *i. e.*, the lower the electrondensity the greater the reactivity of the ethene linkage. For example, the reaction occurs at unsubstituted ethene linkage of methoxybenzoquinone and at a substituted one of methoxycarbonylbenzoquinone. Although Ansell's works did not concern the orientation and only few examples were found for the Diels-Alder reaction between unsymmetrical benzoquinones and dienes, the effect of substituents may be considered*4 from two points of view: the radical stability in assumed biradical intermediates and the steric factor in the transition state.

Two possible structures XIIIa and XIIIb can be derived for the radical stability. XIIIa is stabilized more by the C_4-ketone which may have a large +M effect in comparison with the C_1-ketone.[17] Thus, the "radical stability" requires the reaction to proceed as XIIIa→XIVa. For the steric factor in the transition state,*5 XVa would be energetically



XIIIa XIVa XIVb XIIIb

more stable than XVb because in VXb the steric repulsion between the geminal dimethyl group of the diene and the methyl group on the furan ring would become significant. Thus, the reaction was anticipated to proceed in the favorable direction.

XVa XVb

Fig. 2. Possible transition states.

Syntheses of Tanshinone-II and Cryptotanshinone. The oxidation of 3-methyl-4-benzofuranol (XII)[11] with Fremy's salt[18] gave 3-methylbenzofuran-4,7-quinone (X) in almost quantitative yield. The *p*-quinone structure is based on physical properties: IR spectrum shows carbonyl absorptions at 1663 and 1655 cm^{-1}; UV maxima appear at 217, 248, 292 and 394 mμ;[19] and NMR spectrum

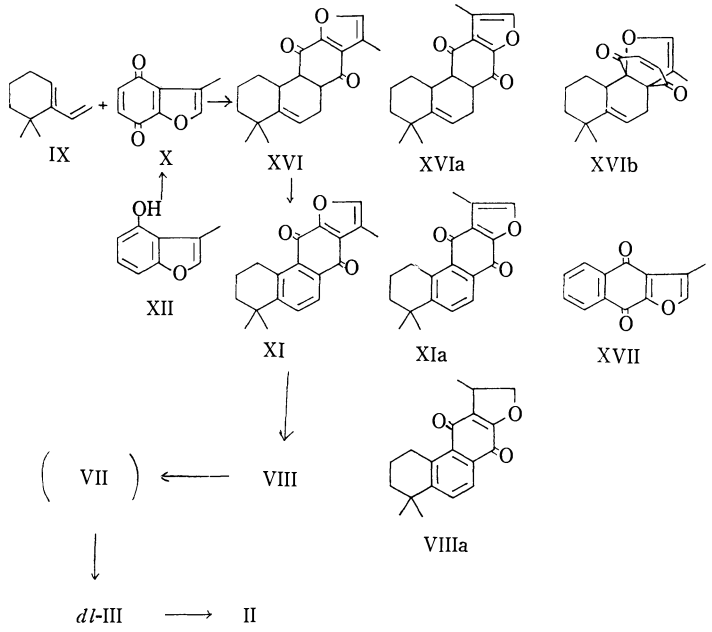
19) C. J. P. Spruit, *Rec. Trav. Chim.*, **81**, 810 (1962), reported the longest wavelength absorption of benzofuran-4,7-quinone to be at 380 mμ.



exhibits a doublet due to C_3–CH_3 at 2.30 ppm and a quartet due to C_2–H at 7.40 ppm with a coupling constant of 0.8 cps, and a two proton singlet at 6.62 ppm arising from the two hydrogen atoms on the quinone ring.

The Diels-Alder reaction between 3-methylbenzofuran-4,7-quinone (X) and 6,6-dimethyl-1-vinylcyclohexene (IX)[8] was conducted in ethanol at room temperature.[8] Only one adduct separated in crystalline form in high yield based on the quinone reacted and no other products were characterized. The adduct, mp 160—161°C, shows IR absorptions at 1695 and 1680 cm^{-1}. The molecular ion peak at *m/e* 298 in the mass spectrum and elementary analysis fitted the formula of 1 : 1 adduct, which was further confirmed by NMR spectrum; a singlet due to the geminal methyl group at 1.04 ppm and a slightly splitted signal due to the methyl group on the furan ring at 2.26 ppm. Moreover, the fact that only two vinyl protons appear at 5.40 and 7.45 ppm, and that the UV maxima at 214, 244 and 303 mμ differ makedly from the O=C–CH=C–O chromophore[16] enable us to reject the structure XVIb. The choice between the remaining two possibilities, XVI and XVIa, was not achieved at this stage.

The adduct XVI (or XVIa) was converted by air oxidation[20] into a naphtho[2,3-*b*]furan-4,9-quinone derivative XI (or XIa), mp 214—215°C, the IR absorption (1660 cm^{-1}) and UV maxima (252 sh, 255, 305 and 360 mμ) of which were very similar to those of 3-methylnaphtho[2,3-*b*]furan-4,9-quinone (XVII).[21] An AB type quartet due to C_6 and C_7 protons appears in NMR spectrum at 7.68 and 8.00 ppm with a coupling constant of 10 cps.

The furan ring in XI (or XIa) was subjected to catalytic reduction with palladium on carbon in ethanol[28a] to afford a naphthoquinone derivative VIII (or VIIIa). The selective hydrogenation of the furan ring was confirmed by NMR spectrum of the product. Thus, a secondary methyl signal is present as a doublet at 1.40 ppm.

The naphthoquinone derivative VIII (or VIIIa) was hydrolyzed with alcoholic potassium hydroxide to give an enolic compound VII (or corresponding isomer), which was treated without purification with concentrated sulfuric acid in ethanol.[10] A red crystalline oil obtained was purified by column chromatography on silicic acid. The orange crystals(64%), mp 174—175°C, showed an identical IR spectrum with that of cryptotanshinone (III).

When cryptotanshinone (III) was treated with dichlorodicyanobenzoquinone (DDQ), tanshinone-II (II) was obtained exclusively in 70% yield. The synthetic II melted at 210—211°C alone or mixed with natural tanshinone-II (II), and showed identical IR spectrum with that of the latter.

Synthesis of Tanshinone-I. 3-Methylbenzofuran-4,7-quinone(X) and *o*-methylstyrene(XVIII)[22] were heated without solvent at 100°C[23,24] for 10 hr. The resulting dark red mass was chromatographed on a column of alumina. At least five colored materials were recognized on thin layer chromatography, but only one orange pigment could be isolated in crystalline form in 25% yield.

Although this product gave only a single spot chromatographically, recrystallization from benzene gave a pure adduct of mp 219—220°C and unpurified mixtures. The former shows a molecular peak at *m/e* 276 in the mass spectrum, which together with elementary analyses leads to a formula $C_{18}H_{12}O_3$. The NMR spectrum (Fig. 3a) of the adduct shows an aromatic methyl signal at 2.66 ppm, a methyl signal on the furan ring at 2.34 ppm, and six aromatic protons at 7.0 to 9.6 ppm, which indicates that the 1 : 1 adduct had undergone facile dehydrogenation[24] to give the phenanthrene quinone XIX (or XIXa).

The NMR spectrum (Fig. 3b) of the original mixture is quite similar to that of the product of mp 219—220°C except broadening of all the signals and a new doublet at 9.43 ppm. This suggests the formation of both isomers XIX and XIXa. The ratio of XIX to XIXa was found to be *ca.* 1.4 calculated from the intensity of the signals 9.55 ppm (corresponds to XIX, *vide infra*) and 9.43 ppm (XIXa).

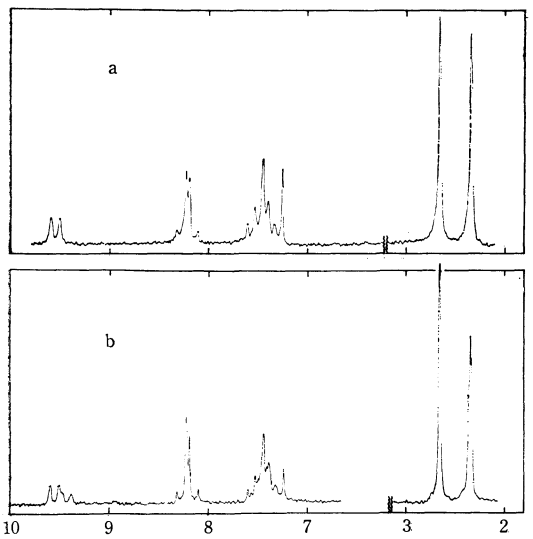

Fig. 3. NMR spectra (100 Mc*[6]) of adducts in $CDCl_3$.
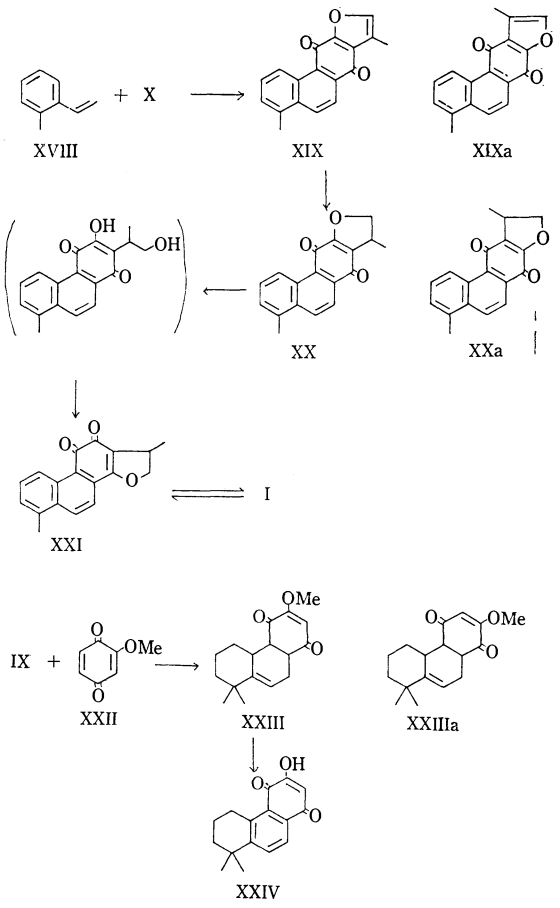
a XIX b the original mixture

The furan ring of the adduct XIX (or XIXa) resisted catalytic flydrogenation under the conditions used for the naphthoquinone XI. However, it was reduced with platinum oxide in acetic acid to afford a dihydro compound XX (or XXa).

The dihydro compound XX (or XXa), without purification, was hydrolyzed with alcoholic potassium hydroxide to give an orange enol, which was



heated with concentrated sulfuric acid in ethanol to afford known[5] dihydrotanshinone-I (XXI), mp 200—201°C in 35% yield from the adduct XIX. In the present work, the authentic dihydrotanshinone-I was prepared from tanshinone-I (I) by catalytic hydrogenation over platinum oxide in acetic acid and melted at 202°C. The UV and IR spectra of both dihydrotanshinone-I were identical and no depression of mixed melting point took place.

As in the case of cryptotanshinone (III), dihydrotanshinone-I(XXI) was dehydrogenated with DDQ to give tanshinone-I (I) in 50% yield. Synthetic tanshinone-I melted at 229—230°C alone or mixed with the natural specimen. They were identical.

Preliminary Account for Diels-Alder Reaction. The successful conversion of the Diels-Alder adduct to the natural tanshinones established the direction of the furan ring to be as in XVI, but not as in XVIa. Conversely, use of a natural product as a synthetic object clarifies the reaction mechanism to some extent, especially with respect to the stereochemical problem. The result prompted us to undertake a preliminary experiment to decide which factor, electronic or steric, would be predominant in the Diels-Alder reaction of benzoquinones.

The diene IX and methoxybenzoquinone (XXII)

*6 We are deeply indebted to Dr. Y. Nakadaira for measurement of the 100 Mc NMR spectra (performed at Tohoku University).

were allowed to react under the same conditions as used for the preparation of XVI. The structure of the adduct was confirmed to be XXIII, but not XXIIIa. Firstly, UV spectrum of the adduct fitted the chromophore O=C–C(OMe)=CH–C=O and only vinyl protons appeared at 5.4 and 6.03 ppm. Secondly, the dehydrodemethylation of the adduct with alkaline ethanol afforded a 2-hydroxynaphthoquinone derivative, which was found to be identical with XXIV.[25]

This is consistent with the electronic effect, but it shows that the steric factor is not, at least, the main factor for the orientation phenomena in the Diels-Alder reaction.

After accomplishment of the syntheses, compound XI (named isotanshinone-II), VIII (isocryptotanshinone) and XIX (isotanshinone-I) were isolated[26] as minor components from the same plant. Total syntheses of these minor pigments were achieved in the present work.

Experimental

All melting points were determined in a sealed tube and are uncorrected. IR spectra were recorded on a Hitachi EPI-2 spectrophotometer, UV spectra were measured on a Hitachi EPS-3T spectrophotometer, and NMR spectra were obtained on a Hitachi H-60 spectrometer. Mass spectra were performed at Meijo University on a Hitachi RMU-7 high resolution spectrometer operating at 70 eV (inlet: 200°C). Microanalyses were carried out at Tohoku University.

3-Methylbenzofuran-4,7-quinone (X). To an ice-cooled solution of 300 mg of 3-methyl-4-benzofuranol (XII)[11] in 20 m*l* of ethanol, was added 1.35 g of Fremy's salt[18] in 70 m*l* of water and 20 m*l* of M/6 KH_2PO_4. After stirring for 15 min, the mixture was left in an ice-box for one hour. The precipitates were collected and the filtrate was extracted with ether. The precipitates and the ether extract were combined and chromatographed on silicic acid (20 g). From benzene elute, 327 mg (100%) of quinone X was obtained.

Pure X (sublimination at *ca.* 140°C/55 mmHg), mp 129—131°C. IR (KBr): 1663, 1655, 860 cm^{-1}. UV (EtOH): 217 (log ε: 4.14), 248 (4.20), 292 (4.19), 394 mμ (3.31). NMR ($CDCl_3$): 2.30 (d, 3H, J=0.8 cps), 6.62 (s, 2H), 7.40 ppm (q, 1H, J=0.8).

Diels-Alder Reaction[8] between 3-Methylbenzofuran-4,7-quinone (X) and 6,6-Dimethyl-1-vinylcyclohexene (IX). To a solution of 255 mg of quinone X in 2 m*l* of hot ethanol, 216 mg of diene IX[8] was added and the mixture was left for 15 hr at room temperature in the dark. The light yellow solution solidified immediately when the flask wall was scratched. The solids were collected on filter-paper to give slightly yellow needles XVI (198 mg), and the filtrate was chromatographed on silicic acid (10 g). The chloroform elute (No. 1) gave 86 mg of crude adduct XVI, while the chloroform elute (No. 3) gave 75 mg of starting quinone X.

Pure XVI, mp 160—161°C (from methanol). IR (KBr): 1695, 1680 cm^{-1}. UV (EtOH): 214 (4.05), 244 (3.71), 303 mμ (3.90). NMR ($CDCl_3$): 1.04 (s, 6H), 2.26 (d, 3H, J=1), 5.40 (m, 1H), 7.45 ppm (q, 1H, J=1). Mass: *m/e* 298 (M^+).

Found: C, 76.70; H, 7.65%. Calcd for $C_{19}H_{22}O_3$: C, 76.48; H, 7.43%.

Dehydrogenation[20] of Adduct XVI to Naphtho-[2,3-*b*]furan-4,9-quinone Derivative XI. Air was bubbled through the suspension of 72 mg of adduct XVI in 12 m*l* of ethanol containing 200 mg of potassium hydroxide for 20 hr (after 20 min, the initial green color turned yellow). The solids were collected, washed with water and then with ethanol, and dried over phosphorus pentoxide to give 59 mg of naphtho[2,3-*b*]furan-4,9-quinone XI. The filtrate and washing were extracted with ether, and the extract was chromatographed on silicic acid (5 g). From the benzene elute, 4 mg of XI was obtained. Purification was conducted by initial filtration through alumina column, followed by recrystallization from benzene/*n*-hexane

Pure XI, mp 214—215°C. IR (KBr): 1660 cm^{-1}. UV (EtOH): 252 sh (4.80), 255.5 (4.81), 270 sh (4.22), 305 (4.02), 360 mμ (4.08). NMR ($CDCl_3$): 1.33 (s, 6H), *ca.* 1.7 (m, 4H), 2.35 (d, 3H), 3.38 (t, 2H), 7.40 (m, 1H), 7.68 (d, 1H, J=8), 8.00 ppm (d, 1H, J=8). Mass: *m/e* 294 (M^+).

Found: C, 77.15; H, 6.14%. Calcd for $C_{19}H_{18}O_3$: C, 77.53; H, 6.16%.

***dl*-Cryptotanshinone (III).** The naphtho[2,3-*b*]-furan-4,9-quinone XI (50 mg) was hydrogenated in 25 m*l* of methanol over 50 mg of 10% palladium on carbon. The filtrate was evaporated and the residue was dissolved in 8 m*l* of ethanol. When 115 mg of potassium hydroxide was added, the solution turned dark red immediately. After standing overnight, 25 m*l* of water was added and the solution was made acidic with dilute sulfuric adid. The ether extract (yellow) was evaporated to dryness to give a light orange oil (45 mg), which was dissolved in 2 m*l* of ethanol. Concentrated sulfuric acid (2 m*l*) was added, when the solution turned red; the solution was heated in a boiling water-bath for a few minutes. Pouring into ice-water and extracting with ether afforded a red crystalline oil, which was purified by passing through a silicic acid column (5 g). *dl*-Cryptotanshinone (32 mg, 64%) was obtained in crystalline form.

dl-Cryptotanshinone (III), mp 174—175°C (from ether). IR (KBr): 1680, 1650, 1625 cm^{-1}. UV (EtOH): 219 (4.19), 264 (4.37), 272 (4.30), 290 sh (3.78), 358 (3.36), 450 mμ (3.37).

Tanshinone-II (II). Cryptotanshinone (III, 30 mg) and 35 mg of DDQ were refluxed in benzene for 1.5 hr under nitrogen atmosphere. The mixture (containing some precipitates) was purified through alumina (5 g), upon which 21 mg (70%) of tanshinone-II and 5 mg of starting crytotanshinone were obtained.

Pure tanshinone-II (from ethanol) melted at 210—211°C alone, or mixed with the natural specimen. IR (KBr): 1690, 1670, 1640 cm^{-1}.

Diels-Alder Reaction between 3-Methylbenzofuran-4,7-quinone (X) and *o*-Methylstyrene (XVIII). The mixture of 80 mg of 3-methylbenzofuran-4,7-

25) This compound was first prepared by Baillie and Thomson.[5] We prepared it by a different method. H. Kakisawa, M. Tateishi, to be published.

26) H. Kakisawa, T. Hayashi and T. Yamazaki, *Tetrahedron Letters*, **1969**, 301.

quinone (X) and an excess amount of *o*-methylstyrene (XVIII) in a test tube containing a pinch of hydroquinone was heated at 100—110°C[23,24] for 10 hr. The resulting dark red solid (at least five colored materials were recognized by thin layer chromatography) was dissolved in hot benzene and was chromatographed on alumina (10 g). From benzene elute, 36 mg of orange substances were isolated in a crystalline from. Recrystallization from benzene afforded a pure adduct XIX.

Pure XIX, mp 219—220°C. IR (KBr): 1665 sh, 1660 cm^{-1}. UV (EtOH): 212 (4.39), 234 (4.55), 283 sh (4.29), 292.5 (4.40), 347 (3.70), 455 br mμ (3.35). NMR ($CDCl_3$): 2.34 (s, 3H), 2.66 (s, 3H), 7.2—7.7 (m, 3H), 8.21 (AB quartet center, 2H, J=9), 9.55 ppm (d, 1H, J=9). Mass: *m/e* 276 (M^+).

Found: C, 78.55; H, 4.75%. Calcd for $C_{18}H_{12}O_3$: C, 78.25; H, 4.38%.

The filtrate could not be purified, but the NMR spectrum of the original crystal (from ethanol) shows that it was composed of XIX and a very similar compound, probably XIXa (see Fig. 3).

Catalytic Reduction of the Adduct XIX. The adduct XIX (25 mg) was hydrogenated over platinum oxide (25 mg) in 20 m*l* of acetic acid. After absorption of 23 m*l* of hydrogen, the solvent was evaporated to give solids, which were stirred with DDQ (40 mg) in 2 m*l* of benzene for 1.5 hr. The mixture was filtered through alumina (10 g) with chloroform to afford 14 mg (56%) of XX, mp 175—177°C (from ethanol). IR (KBr): 1670 w, 1640 cm^{-1}.

Catalytic Reduction of Tanshinone-I (I). A) Tanshinone-I (I) was hardly reduced under the following conditions: 10% palladium on carbon in methanol, 10% palladium on carbon in ethyl acetate, and platinum oxide in ethyl acetate.

B) Tanshinone-I (I, 205 mg) was dissolved in 50 m*l* of acetic acid and was hydrogenated over 200 mg of platinum oxide (110 m*l* of hydrogen absorbed during two hours). Removal of the solvent by evaporation gave a red oil, which was purified through chromatography on silicic acid (10 g). From the chloroform elute, 160 mg of dihydrotanshinone-I (XXI) was obtained.

Pure XXI, mp 202°C (from methanol). IR (KBr): 1680, 1650, 1622 cm^{-1}. UV (EtOH): 216 (4.30), 242 (4.40), 292 br (4.20), 335 (3.48), 414 mμ (3.61). NMR ($CDCl_3$): 1.40 (d, 3H, J=7), 2.64 (s, 3H), *ca.* 3.6 (m, 1H), 4.37 (dd, 1H, J=9 and 6), 4.94 (t, 1H, J=9). 7.30—7.80 (m, 3H), 8.18 (d, 1H, J=8), 9.20 ppm (d, 1H, J=8). Mass: *m/e* 278 (M^+).

Found: C, 78.15; H, 5.34%. Calcd for $C_{18}H_{14}O_3$: C, 77.68; H, 5.07%.

Dihydrotanshinone-I (XXI) from Adduct XIX. The adduct (XIX, 40 mg) was hydrogenated over 40 mg of platinum oxide in 120 m*l* of acetic acid. After removal of the solvent, the residue was dissolved in 4 m*l* of ethanol, to which *ca.* 100 mg of potassium hydroxide was added and the mixture was left for several hours. The solution was diluted with water, acidified with 6N hydrochloric acid and was extracted with ether to give a yellow enol. The enol, without purification, was dissolved in a mixture of 2 m*l* of ethanol and 2 m*l* of concentrated sulfuric acid, heated in boiling water-bath for a few minutes, and was poured into ice-water. The ether extract was chromatographed on silicic acid (5 g). From the chloroform elute, 14 mg (35%) of dihydrotanshinone-I (XXI) was isolated.

Pure XXI, mp 200—201°C, alone or mixed with an authentic sample (from methanol).

Tanshinone-I (I). A mixture of dihydrotanshinone-I (XXI, 28 mg) and DDQ (35 mg) in benzene was refluxed for two hours under a nitrogen atmosphere. After removing the solvent by evaporation, the residue was dissolved in small amount of chloroform and filtered through alumina (5 g). The filtrate evaporated to give solids. Tanshinone-I (I) was isolated in 50% yield (14 mg) by chromatography on silicic acid (10 g) with benzene.

Pure tanshinone-I (I), mp 229—230°C, alone or mixed with the natural specimen (from ethanol). IR (KBr): 1665 br cm^{-1}.

Diels-Alder Reaction between Methoxybenzoquinone (XXII) and 6,6-Dimethyl-1-vinylcyclohexene (IX). To a solution of 338 mg of quinone XXII in 5 m*l* of hot ethanol, was added 0.5 g of diene IX and the mixture was allowed to stand overnight at room temperature. The crystals were collected and were recrystallized from methanol to give adduct XXIII (265 mg). From the filtrate, a further 44 mg of adduct XXIII was obtained by chromatography on silicic acid.

Pure XXIII, mp 151—154°C (from methanol). IR (KBr): 1690, 1670, 1603 cm^{-1}. UV (EtOH): 273 mμ (3.93). NMR ($CDCl_3$): 1.04 (s, 6H), 1.2—1.6 (6H), 3.80 (s, 3H), 5.4 (m, 1H), 6.03 (s, 1H). Mass: *m/e* 274 (M^+).

Found: C, 74.42; H, 8.08%. Calcd for $C_{17}H_{22}O_3$: C, 74.10; H, 8.04%.

Conversion of Adduct XXIII to 2-Hydroxynaphthoquinone Derivative XXIV. Air was bubbled through the solution of 106 mg of the adduct XXIII and 90 mg of potassium hydroxide in 5 m*l* of ethanol for 2.5 hr. After acidification with dilute hydrochloric acid, the product was purified by chromatography on silicic acid. From chloroform elute, 27 mg of yellow crystals were obtained.

Pure XXIV (from *n*-hexane) melted at 161.5—163.5°C alone, or at 162.5—163.5°C when mixed with the authentic sample.[25] IR (KBr): 1645, 1570 cm^{-1}.

(Received May 16, 1969)

Polypropylene was modified by the blending of the fine powdery copolymer of glycidyl methacrylate and divinyl benzene, and this modified polypropylene fiber was treated with diethyl amine, diethanol amine, monoethanol amine, and ammonia. The reactivity order was as follows: monoethanol amine>diethyl amine> diethanol amine=ammonia. Consequently, the resultant fiber showed water-wettability and could be dyed with an acidic dye.

Polypropylene shows poor dyeability, no water-wettability, and a waxy touch, as a result of its high crystallinity and nonpolarity. These properties are drawbacks in practical uses. In order to make polypropylene fiber dyeable with an acidic dye, the following procedures have been proposed: (1) the blending of polyvinyl pyridine,[1] (2) the blending of the styrene-glycidyl methacrylate copolymer and after-treatment with amines,[2] and (3) the grafting of glycidyl methacrylate and after-treatment with amines.[3]

One of the present authors has already reported the modification of polypropylene with a polymeric fine powder (PFPC), prepared from glycidyl methacrylate (GMA) and divinylbenzene (DVB). This powder is more thermally stable than such a linear polymer as a styrene-GMA copolymer, and it has been established that this modification is very effective in improving the dyeability of polypropylene fiber[4,5] and that the dyes having an amino group can be fixed in the substrate by the reaction between the epoxy group in the substrate and the amino group.[4,5] Therefore, it was presumed that an amine can easily react with the epoxy group. The introduction of the amino group into polypropylene is very interesting, because polypropylene may be modified to make it water-wettable, antistatic, and dyeable by an acidic dye; such dyes were inavailable in the previous studies.[4,5] Accordingly, the reactions of the polypropylene fiber modified by the blending of PFPC with some amines and ammonia were investigated by the use of the undrawn fiber as a model case. Furthermore, the dyeability of the modified fiber with an acidic dye was investigated by the use of the drawn fiber.

Experimental

Material. A commercial polypropylene pellet was blended with PFPC at 170—185°C by the use of a calender roller. The fabricating conditions and the properties of the fiber are shown in Table 1. The properties of the polypropylene were as follows:

Melt index (at 230°C, load: 2.16 kg/cm²): 4.4 g/10 min
Specific gravity (at 23°C): 0.914

TABLE 1. THE FABRICATING CONDITIONS AND THE PROPERTIES OF THE FIBER

5) Y. Mizutani, *ibid.*, **40**, 1519 (1967).

PFPC was prepared by the method reported in the previous papers.[4,5] Diethanol amine (DEA), monoethanol amine (MEA), and diethyl amine (DA) were used after distillation under a reduced nitrogen atmosphere.

Procedures. The fiber (0.80 g) and an aqueous solution of an amine or ammonia were placed into a pressure bottle. A piece of glass rod was placed on the fiber in order to immerse the fiber in the solution. In order to gain analytical accuracy, the concentration of the amine or ammonia was controlled so as to be 0.4—1.6 mmol/20 m*l*. The pressure bottle was immersed in an oil bath at a definite temperature without any stirring. After a definite reaction time, the pressure bottle was rapidly cooled by water. Then the fiber was taken out and rinsed with 100 m*l* of water. A washing solution was added to the reactant solution; the quantity of amine or ammonia after the treatment was determined by pH titration with a 0.01N aqueous solution of hydrochloric acid. The neutralization points are shown in Table 2. The preliminary experiment

Table 2. The neutralization point

Reagent	DA	DEA	MEA	Ammonia
pH	6.1	4.9	5.3	5.8

confirmed that Monogen-w (an emulsifier from the Daiichi Kogyo Seiyaku Co., Ltd.) did not disturb the titration. The quantity of the reacted amine or ammonia ($[A]_F$) and the reaction degree of the epoxy group in the fiber were defined as follows:

$$[A]_F = [A]_0 - [A]_t \quad (1)$$

$$R_A = [A]_F/\text{Epoxy value of the fiber} \quad (2)$$

$[A]_0$: Initial quantity of an amine or ammonia

$[A]_t$: The quantity of an amine or ammonia after treatment for t hr.

Dyeing. The fiber (50 g) was treated at 120°C for 4 hr with the following solution-mixture:

A-solution $\begin{bmatrix} Na_2SO_4\text{: 5 g/}l \\ \text{Monogen-w: 1 g/}l \end{bmatrix}$: 150 m*l*

DEA : 150 m*l*

The fiber (2 g) thus treated was dyed under the conditions shown in Table 3.

Results and Discussion

PP-F-1 (undrawn fiber; see Table 1) was used to investigate the reaction. Figure 1 shows the results of the reaction. The reactivity order was as follows: MEA>DA>DEA=ammonia. Figures 2 and 3 show the effect of the molar ratio of the amine or ammonia to the epoxy group. It was established that the increase in the reactant concentration increases the $[A]_F$ and R_A values, and that when bath

ratio increased with the constant reaction concentration, the $[A]_F$ and R_A values did not change. Figure 4 shows the effect of the reaction temperature. The reaction proceeded linearly until the reaction time had lasted 6 hr and, then, it increased. This may be attributed to the fact that the fiber became water-wettable as the reaction proceeded and to the self-catalytic effect[6] of the hydroxyl group which resulted from the reaction. It is reasonable that the reaction became more rapid with an increase in the reaction temperature. The upper limit is about 130°C because of the thermal stability of the fiber. By means of the slope of the straight line in Figure 4, the rate constant (k) was found to be as is shown in Table 4, assuming that the reaction was zero order. Figure 5 shows the Arrhenius plot; the apparent activation energy

was calculated to be 14.6 kcal/mol. It was very interesting that the fiber thus treated was water-wettable and that it did not feel waxy.

PP-F-2 (drawn fiber; see Table 1) was used to investigate the dyeability with acidic dyes. Table 5 shows the dyeing results. It was confirmed that the fiber can be well dyed by the acidic dyes. However, the dyeing fastness was insufficient and must be improved much more.

Conclusion

The polypropylene fiber, modified by the blending of a fine powdery copolymer of glycidyl methacrylate and divinylbenzene, was treated with diethyl amine, diethanol amine, monoethanol amine, and ammonia. The resultant fiber could be wettable with water and dyed with acidic dye.

NOTES

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 3327—3329 (1969)

Vinyl Polymerization. 239.*1 Polymerization of Methyl Methacrylate with Cellulose Triacetate in Presence of Various Solvents

Kanemitsu KUBUSHIRO, Kiichi TAKEMOTO*2 and Minoru IMOTO

Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sumiyoshi-ku, Osaka

(Received December 29, 1968)

Recently, fibrous cellulose triacetate (CTA) was found to initiate the polymerization of methyl methacrylate (MMA) in the presence and absence of water.[1] The present paper concerns a further study on the polymerization of MMA initiated with CTA in the presence of various solvents. The initiation of polymerization seems to be referred to an interaction of some active sites on CTA with MMA, but the essential feature of the polymerization remains uncertain.

Experimental

All of the procedures were the same as in the previous paper.[1] The degree of swelling of CTA was measured in the following way: CTA was dissolved at first in dichloromethane and ethanol mixture (9 : 1 in vol.), and the solution was spread onto a glass plate. The cast film obtained after drying was transparent and colorless, and of 0.208 mm in thickness. 0.1 g of the CTA film was placed in a test tube, with a mixture of methyl isobutyrate with other solvents. The tube was sealed off and kept at 30°C for 24 hr, and thereafter, the weight increase of the CTA films was measured.

Results and Discussion

Effect of Solvents on the Rate of Polymerization. Figure 1 shows examples of time-conversion curves, where polymerization was carried out in the presence of various solvents. As shown in Fig. 1, a small amount of ethyl acetate acted to decrease the rate of polymerization, while *n*-hexane to accelerate it considerably.

Figure 2 shows the initial rates of polymerization calculated from the initial slopes of time-conversion curves. This figure shows that the value of the rate

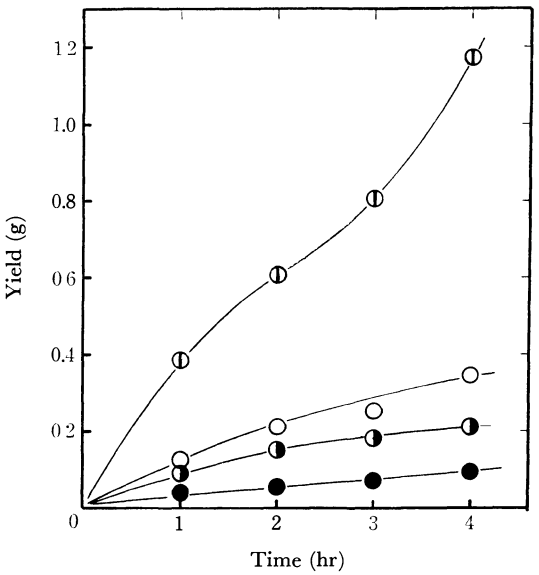

Fig. 1. Polymerization of MMA in the presence of various solvents. Total volume 5 m*l*, CTA 0.5 g, at 85°C.

◑ carbon tetrachloride ● ethyl acetate

of polymerization (percent per hour) divided by the monomer concentration is constant, regardless of the monomer concentration, except the cases where *n*-hexane, dichloromethane and ethyl acetate were used. This result means that benzene, ethanol, dimethylformamide and carbon tetrachloride acted only as diluents.

The relation between the degree of swelling and the solvent composition is shown in Fig. 3. The solvents consisted of methyl isobutyrate and other organic solvents which were used for polymerization. Methyl isobutyrate was chosen instead

seems to show no parallelism with the swelling ability of these solvents for CTA.

From Figs. 2 and 3, in which different solvents are given, we see that polymerization preceeds not only inside CTA, but also outside it. This consideration agrees with that reported in a previous paper,[1] *viz.*, the rate of polymerization is proportional to the square root of CTA and to the monomer concentration.

As can be seen from Fig. 2, in the case of *n*-hexane, the rate of polymerization increases with the decrease in the concentration of monomer. When the concentration is 3.74 mol/*l*, the rate is about six times larger than that obtained in the other normal solvents. This result seems to be in line with the following consideration: *n*-hexane dose not swell CTA but dissolves MMA, while a part of MMA swells CTA and the rest of MMA remains in *n*-hexane. Thus, MMA is divided between CTA and *n*-hexane, and CTA swells with MMA. Accordingly, the interior of the fiber becomes a viscous polymerizing system for MMA, that is, an effect similar to the gel effect arises even in the initial stage of polymerization. As MMA is consumed by polymerization in the interior of the fiber, MMA is supplied successively from the *n*-hexane solution.

Next, we may consider the retardation effect of ethyl acetate. The structure of ethyl acetate is like that of MMA and ethyl acetate also can swell CTA. If ethyl acetate has some interaction with active sites on CTA, the interaction of MMA with these sites may be hindered and then the formation

of radical is retarded.

On the other hand, a thermal polymerization of MMA in ethyl acetate was carried out in the absence of CTA. The time-conversion curve obtained was similar to that in the Fig. 1. Accordingly, the corresponding curve in the figure seems to be the one caused by thermal polymerization.

The mechanism of initiation remains still to be clarified, which will be dealt with more exactly in the near future.

Molecular Weight of Poly-MMA obtained in the Presence of Solvents. The molecular weight of homopolymer of MMA obtained in the presence of various solvents, with the exception of *n*-hexane, was found to decrease gradually with an increase in the amount of the solvent. The results are shown in Fig. 4. The decrease may be due to the chain transfer effect on the solvents. The reason why the molecular weight is not affected

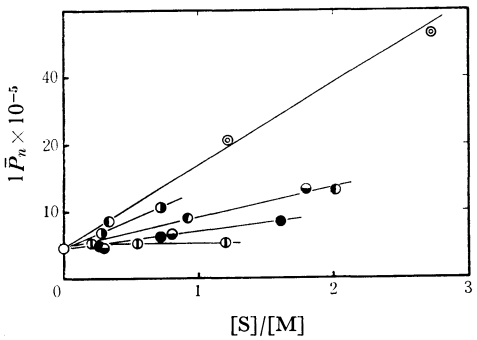

Fig. 5. Relationship between $1/\bar{P}_n$ and [S]/[M].
◎ ethyl ◑ carbon tetrachloride
◒ benzene ◐ dimethylformamide
● ethyl acetate ◑ *n*-hexane

by the presence of *n*-hexane, would come from the following view: CTA has only little affinity for *n*-hexane, so that only a very minor amount of *n*-hexane would be present in the interior of CTA, even when a larger amount of *n*-hexane was added in the reaction system.

In the presence of solvent, number average molecular weight of the polymers can be expressed by the following equation:

$$1/\bar{P}_n = C_m + C_s[\mathrm{S}]/[\mathrm{M}] + k_t/k_p \cdot \frac{[\mathrm{M}\cdot]}{[\mathrm{M}]} \qquad (1)$$

In this equation, the value of $k_t/k_p \cdot [\mathrm{M}\cdot]/[\mathrm{M}]$ would be very much smaller as compared with C_m, as was reported in the previous paper,[1] so it can be simplified to

$$1/\bar{P}_n = C_m + C_s\frac{[\mathrm{M}]}{[\mathrm{S}]} \qquad (2)$$

From the data in Fig. 4, a linear relationship between $1/P_n$ and [S]/[M] is obtained as shown in Fig. 5. The C_s value calculated is of the same order as that reported in literature,[2] where number average molecular weight of the polymers was estimated according to the following relationship, assuming that the molecular weight distribution of each polymer is identical and obeys Schulz's equation.[3]

$$M_n = 1/2 \cdot \bar{M}_w \qquad (3)$$

C_s values obtained in the experiment are shown in Table 1.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 3330—3333 (1969)

Kinetics of Multidentate Ligand Substitution Reactions. VII. Substitution Reactions of the Nickel(II)-Iminodiacetate Chelate with Ethylenediaminetetraacetic Acid and 1,2-Diaminocyclohexanetetraacetic Acid and of the Cobalt(II)-Nitrilotriacetate with 1,2-Diaminocyclohexanetetraacetic Acid

Mutsuo KODAMA

Department of Chemistry, Ibaraki University, Bunkyo-cho, Mito

(Received March 10, 1969)

In the previous paper,[1] the kinetics of the substitution reaction between the nickel(II)-nitrilotriacetate chelate and diethylenetriaminepentaacetic acid (DTPA) were investigated systematically by the polarographic method. The reaction proceeded mainly through tervalent, quadrivalent, and quinquivalent DTPA anions. In an acid medium, the contribution of the quinquivalent DTPA anion reaction was negligible. The activation parameters, $\Delta H^{\neq}$ and $\Delta S^{\neq}$, for the three elementary reactions were also determined. In the two elementary reactions which proceed through tervalent and quinquivalent DTPA anions, the $\Delta S^{\neq}$ values were negative. The reaction which involves the quadrivalent DTPA anion, however, had a positive entropy of activation. This was ascribed to the fact that in the quadrivalent DTPA anion, intramolecular hydrogen bonding among hydrogen-ion and nitrogen groups places the DTPA anion in a favorable position to from a mixed ligand reaction intermediate; thus, less freedom was lost in the formation of the intermediate. In the nucleophilic substitution reaction involving 1,2-diaminocyclohexanetetraacetic acid (CyDTA), the CyDTA anion would be placed in a favorable position to react with metal. Therefore, even the reaction involving the completely-deprotonated CyDTA anion will give a positive entropy of activation. In this paper, the substitution reactions of CyDTA with nickel(II)-iminodiacetate and cobalt(II)-nitrilotriacetate chelates were studied by observing the change in the anodic wave-height of uncomplexed CyDTA. The exchange reaction between ethylenediaminetetraacetic acid (EDTA) and the nickel(II)-iminodiacetate chelate was compared with the reaction of CyDTA with the nickel(II)-iminodiacetate chelate.

Experimental

Reagents. The ways of preparing and standardizing the nickel(II) nitrate and cobalt(II) perchlorate solutions were given in previous papers.[1,2] Iminodiacetic acid (IDA) was recrystallized three times from an aqueous solution by adding pure ethanol, and a known amount was dissolved in doubly-distilled water. The recrystallization of nitrilotriacetic acid (NTA), EDTA, and CyDTA and the preparation of their solutions have also been described previously.[3,4] Other reagents were of an analytical reagent grade and were used without further purification.

Apparatus and Experimental Procedure. All the apparatus (Pen-recording polarograph and the dropping mercury electrode) and experimental procedures were the same as have been described previoulsy.[1] All the measurements were conducted in solutions with the ionic strength of 0.20 ($NaClO_4$) in the pH range from 8.50 to 10.00. Since the sample solutions contained a large excess of uncomplexed NTA or IDA, no buffer reagent was used. The reaction rate was followed by recording automatically the change in the anodic wave-height of uncomplexed CyDTA or EDTA with the time.

Results and Discussion

The reaction of the nickel(II)-IDA chelate with EDTA and that with CyDTA were studied at 25 and 33°C respectively. The reaction beween the cobalt(II)-NTA chelate and CyDTA was studied at 18°C. All the substitution reactions investigated in solutions containing a large excess of complexed and uncomplexed IDA or NTA in the pH range from 8.50 to 10.00. Therefore, the reaction could be treated as pseude first-order reaction. In this study, the concentration of the metal(II)-IDA or -NTA chelate, $[MX]_t$, ranged from 8.50 to 20.00 mM and that of uncomplexed IDA or NTA, $[X]_f$, from 7.0 to 25.0 mM. As had been observed in the reaction of DTPA with the nickel(II)-NTA chelate,[1] the plot of $\log(i_0/i_t)$ aginst t invariably gave a straight line passing through the point of origin (Fig. 1). When the

other experimental conditions were kept constant, its slope was independent of the initial concentration of CyDTA or EDTA. The presence of the metal-(II)-CyDTA or -EDTA chelate had no effect on the slope of the linear relation. Therefore, as was discussed in the substitution reaction of DTPA with the nickel(II)-NTA chelate,[1] it can be concluded that, practically, the rate of the backward reaction of the present substitution reaction is negligible compared with that of the forward reaction, and that all the three substitution reactions studied here proceed through simultaneous reaction pathways which involve only direct second-order nucleophilic substitution reactions of the metal(II)-IDA or -NTA chelate with the CyDTA or EDTA anion. The slope of the linear relation between $-\log i_t$ and t was also proportional to the concentration of the metal(II)-IDA or -NTA chelate and inversely proportional to the value of $1+K^{X}_{MX_2}\cdot[X]_f/(\alpha_H)_X$, provided that the other experimental conditions were kept constant (Tables 1 and 2). All the symbols used here have the same meanings as previously.[1] These two facts clearly indicate that the slope is exactly proportional to the concentration of the metal(II)-IDA or -NTA chelate with a 1-to-1 composition. In the solutions with given concentrations of the complexed and uncomplexed IDA, or NTA, and with a given initial con-

centration of CyDTA or EDTA, the plot of slope $\times(\alpha_H)_Z$ *vs.* $[H^+]$ gave a linear relation (Fig. 2). Here, $(\alpha_H)_Z$ is the (α_H) value of CyDTA or EDTA.

From the above experimental facts and discussion, it can be safely concluded that all the three exchange reactions proceed mainly through the following two simultaneous reaction pathways:

$$\text{i)}\quad MX^{2-m} + Z^{4-} \underset{}{\overset{k_1^+}{\rightleftharpoons}} MZ^{2-} + X^{m-}$$
$$\updownarrow \text{rapid}$$
$$MX_2^{2-2m}$$

$$\text{ii)}\quad MX^{2-m} + HZ^{3-} \overset{k_2^+}{\rightleftharpoons} MZ^{2-} + HX^{1-m}$$
$$\updownarrow \text{rapid}$$
$$MX_2^{2-2m}$$

where MX^{2-m} and MX_2^{2-2m} mean the metal (II)-IDA or -NTA chelates with 1-to-1 and 1-to-2 compositions respectively; X^{m-}, the completley-deprotonated IDA or NTA anion, and Z^{4-}, the completely-deprotonated CyDTA or EDTA anion. On the basis of the above reaction mechanism, the slope of the linear relation between $-\log i_t$ and t can be expressed as:

$$\text{slope} = \frac{1}{2.303}\left(k_1^+ + \frac{k_2^+ \cdot [H]^+}{k_4}\right) \times \frac{[MX]_t}{(\alpha_H)_Z\left[1+\dfrac{K^X_{MX_2}\cdot[X]_f}{(\alpha_H)_X}\right]} \qquad (1)$$

where k_4 is the fourth dissociation constant of CyDTA or EDTA.

The k_1^+ and k_2^+ values determined from the slope and the intercept of the linear relation between slope $\times$ 2.303 $\times$ $(\alpha_H)_Z[1+K^X_{MX_2}[X]_f/(\alpha_H)_X]/[MX]_t$ and $[H^+]$ are given in Table 3. Similar results were also obtained in the experiments carried out at the other two temperatures. The rate constants for the two elementary reactions determined at the other two temperatures are also listed in Table 3. In all cases, linear relations were found between $\log k_i^+$ and $1/T$ for both elementary reactions; these made it possible to calculate the heats and entropies of activation. The heats and the entropies of activation determined from the linear

Co(II)-NTA chelate	3.63

* These values are calculated from the related constants in solutions of ionic strength 0.10 and the activity coefficients of the ions calculated by means of Davies equation.[12]

relation between log k_i^+ and $1/T$ are also given in Table 3. The numerical values used in the calculation of (α_H)'s, $[X]_f$, and k_2^+ are listed in Table 4. The way of calculating $[X]_f$ was given in previous paper.[3]

As is shown in Table 3, both elementary reactions gave positive entropies of activation in the substitution reactions involving CyDTA. In the NMR study of the conformation of the CyDTA anion, Reilley *et al.*[5,6] concluded that, in tervalent and quadrivalent CyDTA anions, two iminodiacetate groups occupy nearly diequatorial positions on the cyclohexane ring because of the steric effect of the cyclohexane ring. The preorientation of the CyDTA anion by the cyclohexane ring probably places the CyDTA anion in a favorable position to react with metal ion. Thus, less conformational and rotational freedom will be lost in the chelate formation reaction of CyDTA. This prediction has been confirmed by several authors[7-9] in their thermodynamic study of the chelate formation reaction. The entropies of the reaction of CyDTA chelates are always greater than those of the corresponding EDTA chelates. The experimental evidence that, in the substitution reactions involving CyDTA, both elementary reactions gave positive entropies of activation may also be ascribed to the preorientated diequatorial conformation of the CyDTA anion. Thus, these facts support the present author's explanation of the effect of the protonation of the CyDTA anion on the heat of activation given in a previous paper.[1] The positive entropy of activation for the elementary reaction (ii) in the reaction of EDTA with the nickel(II)-IDA chelate can also be attributed to the conformation of the tervalent EDTA anion, which is similar to that of the chelated EDTA anion.[6]

Finally, it can also be mentioned that the k_2^+ value for the reaction of EDTA with the nickel(II)-IDA chelate is about 1000 times greater than that with the nickel(II)-NTA chelate.[10] The k_2^+ ratio between the nickel(II)-IDA and nickel(II)-NTA systems agrees well with the ratio of the stability constants of the chelates with the 1-to-1 composition.[11] This agreement probably means that the reaction of EDTA with nickel(II)-IDA proceeds through the same reaction intermediate as that for the reaction with the nickel(II)-NTA chelate.

The present author wishes to express his hearty thanks to Mr. Tomohiko Noda and Miss Yayoe Tominaga for their help during this research.

Magnetic Properties of Organic Stable Radicals. II. Porphyrexide

Teruaki FUJITO, Hiroaki NISHIGUCHI, Yasuo DEGUCHI and Jun YAMAUCHI*

Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto
**The Institute for Chemical Research, Kyoto University, Uji, Kyoto*

(Received April 16, 1969)

The magnetic properties of triacetonamine-oxyl and its derivatives have been studied by many investigators.[1] In these radicals having penta-, hexa- or haptacyclic structures, the N–O group is masked by four methyl groups. Recently it has been found that one of these radicals, 2,2,6,6-tetramethyl-4-hydroxypiperidine-1-oxyl (TANOL), exhibits a temperature depedence of its magnetic susceptibility which can be understood by the one-dimensional Heisenberg model.[2–4] The molecular structure of porphyrexide is different from that of the TANOL radical, that is, porphyrexide is pentacyclic with a somewhat planar molecular structure, and it has a π-orbital in its cyclic ring. It has only two methyl groups, so the N–O group is not completely shielded. Therefore, it is presumed to show different magnetic properties from the TANOL radical. Müller and Müller-Rodloff have reported[5] that the paramagnetic susceptibility of porphyrexide obeys the Curie-Weiss law in the temperature range from 300°K to 90°K, with the Weiss constant $\theta=-6\pm5$°K and $\chi_{mol}=40.1\times10^{-4}$ emu at 90°K. We have measured the magnetic susceptibility of this radical at lower temperatures, the results are shown in Fig. 1.

The sample was obtained commercially and was used with no further purification. Its radical concentration was determined to be 91% by comparing the measured susceptibility with that calculated at 77°K. Magnetic susceptibility measurements were carried out using a magnetic torsion balance developed in our laboratory.[6] Diamagnetic correction was made employing the experimental value reported by Müller and Müller-Rodloff:[5] $\chi_{dia}=0.85\times10^{-4}$ emu/mol. The magnetic susceptibility of this radical follows the Curie-Weiss law (Weiss constant $\theta=-8$°K) in the temperature range from 300°K to 20K°, as Müller and Müller-Rodoff. At lower temperatures, however, it deviates from this law and reaches a broad maximum at 7.2°K, where $\chi_{max}=207.2\times10^{-4}$ emu/mol, and they gradually decrease below 7.2°K. In order to make clear the magnetism of the radical, it would be appropriate to compare this result with several typical theoretical models: the pair model, the linear Ising model, and the one-dimensional Heisenberg model (Fig. 1). χ_p is given as follows:

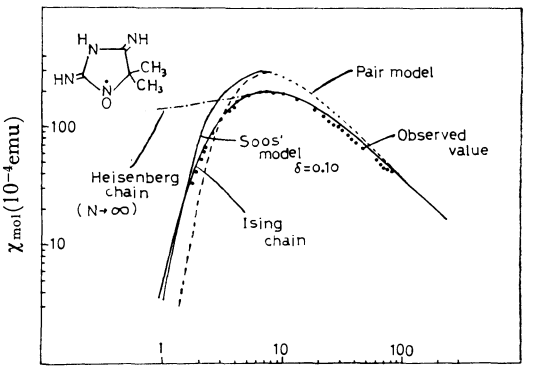

Fig. 1. Magnetic susceptibility of porpflyrexide.
Solid Curve : theoretcical susceptibility of the linear Ising model with $J/k=-7.2$°K and Soos's model with $\delta=0.10$
Dashed Curve: that of pair model with $\Delta/k=11.6$°K
Chain Curve : that of one-dimensional Heisenberg model $J/k=5.76$°K
● : observed values

$$\text{pair model: } \chi_p=\frac{Ng^2\beta^2S(S+1)}{kT}\cdot\frac{1}{3+e^{\Delta/kT}}$$

$$\text{linear Ising model: } \chi_p=\frac{Ng^2\beta^2}{4kT}e^{J/kT}$$

where Δ is the energy splitting between the ground singlet and the excited triplet states, where J is the spin-spin exchange interaction energy, and where the other letters have the usual meanings. The parameters, Δ/k and J/k, are determined to be 11.6°K and −7.2°K respectively from the temperature of the susceptibility maximum, Tm.

The theoretical calculation of the one-dimensional Heisenberg model has been performed by Bonner and Fisher for the case of $\gamma=1$ and $N\rightarrow\infty$.[2,7] In our case $J/k=5.76°K$ is obtained by fitting Tm to the theoretical value. It can be seen from Fig. 1 that the observed value fits the linear Ising model better than the others. Thus, porphyrexide has different magnetic properties from TANOL, which has a character like that of the one-dimensional Heisenberg model, as has already been reported.[2-4] The difference in the magnetic behavior of these two radicals may be attributed to the difference in their molecular frameworks. The TANOL radical has a non-planar molecular framework and forms intermolecular hydrogen bonds parallel to the a-axis,[8] and it makes one-dimensional antiferromagnetic chains by means of isotropic exchange interaction. On the other hand, porphyrexide has a somewhat planar molecular structure, like BDPA,[9] and it makes one-dimensional antiferromagnetic chains of anisotropic exchange interaction through π-orbital, probably arranged in such a way that one molecular plane is stacked upon another. Another fit is obtained when the alternating linear Heisenberg antiferromagnet model proposed by Soos[10] is used with the alternating parameter, δ, being 0.1. We can not conclude which is the better model, the Ising or Soos's model, in this case. We are now, however, performing a study of the single crystals of this radical by using the magnetic torsion balance, an ESR spectrometer and an X-ray diffractometer in order to reach definite conclusions.

Studies of Heteroaromaticity. XXXII.[1] New Synthesis of 1,2,4-Oxadiazoles, Benzoxazoles, Benzothiazoles and Benzimidazole from Aromatic Hydroxamoyl Chlorides

Tadashi SASAKI, Toshiyuki YOSHIOKA and Yasuyuki SUZUKI

Institute of Applied Organic Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya

(Received April 17, 1969)

There are many papers concerning the synthesis of five-membered heterocycles by the 1,3-dipolar cycloaddition reactions of nitrile oxides, which afforded, with double bonded dipolarophiles, dihydro-heteroaromatic compounds in general.[2] It is also known that similar reactions with dipolarophiles having hetero-multiple bond generally proceed with some difficulty, except for their activated types.[3] This note deals with a new synthesis of 1,2,4-oxadiazoles, benzoxazoles, benzothiazoles and a benzimidazole from aromatic hydroxamoyl chlorides, the precursors of nitrile oxides. It is reported that aromatic nitrile oxides do not undergo the 1,3-dipolar cycloaddition reactions with an imino heteromultiple bond, when it is a part of a simple azomethine linkage. This note is based on our finding that aromatic hydroxamoyl chlorides can react with the imino group, if it is incorporated in amidines IIa, iminoethers IIb and *S*-methylthiourea IIc, leading to the formation of 1,2,4-oxadiazoles after hetero-aromatization of the intermediated oxadiazolines III by elimination of R″H.

3) For a recent review, see T. Sasaki, *Kagaku no Ryoiki*, **23**, 220, 320 (1969).

The general preparative method for 1,2,4-oxadiazales by the 1,3-dipolar cycloaddition of aromatic nitrile oxides with nitriles has been reported originally by Huisgen.[4] It is also reported, however, that the reactions with aliphatic nitriles hardly take place.[5,6] Musante[7] and Elory[8] reported independently the preparation of 1,2,4-oxadiazoles from nitrile oxide and benzamidine and benziminoether respectively. In order to investigate the applicability of these methods to aliphatic amidines and iminoethers, we investigated similar reactions using several aromatic nitrile oxides such as *p*- (Ia), *m*-nitrobenzonitrile oxide (Ib), 2-(5-nitrofuro)nitrile oxide (Ic), benzonitrile oxide (Id) and furonitrile oxide (Ie), all derived readily from the corresponding hydroxamoyl chlorides I'a—e in the presence of base. The results are summarized in Table 1. As indicated in this table, the method using amidines is found to be superior to that using iminoethers for the preparation of 5-aryl- and 5-alkyl-3-aryl-1,2,4-oxadiazoles (IV).

Elory[9] reported the preparation of 3-phenyl-5-amino-1,2,4-oxadiazole from benzonitrile oxide and guanidine. This method could not be applied to Ia—c, so we investigated similar reactions using thiourea instead of guanidine, but no reaction occurred. However, we found that *S*-methylthiourea reacted with Ia—c, affording the corresponding 5-amino-1,2,4-oxadiazoles (Va—c) after elimination of methylmercaptane even in such basic media as given in the reaction conditions, indicating that the presence of a suitable leaving group under the basic reaction conditions is an essential factor for the hetero-aromatization of the intermediated III. The results are summarized in Table 2.

In a previous paper,[10] we reported the reaction of 2-(5-nitrofuro)hydroxamoyl chloride (I'd) with two equivalents of ethanolamine to afford *N*-(*β*-hydroxyethyl)-2-(5-nitrofuryl)amidoxime. When I'c was treated with *o*-aminophenol instead of ethanolamine under similar reaction conditions, the product was proved to be benzoxazole (VIc) which might be produced by the hetero-aromatization of the intermediated VIIa or VIIb after elimination of hydroxylamine moiety. From our previous report[11] concerning the similar hydroxylamine-elimination in the reactions of aromatic hydroxamoyl chlorides with methyl dithiocarbazinate, VIIa seems to be more plausible than VIIb. Table 3 shows the results obtained by use of several hydroxamoyl chlorides.

Similar treatment of hydroxamoyl chlorides with two equivalents of *o*-aminothiophenol afforded the corresponding benzothiazoles (VIII) as given in

Experimental

The melting points were measured on a micro hot stage and are not corrected. The microanalyses were carried out with a Yanagimoto C. H. N. Corder, Model MT-1 type. The ultraviolet spectra were obtained on a Nippon-Bunko optical rotary dispersion recorder, Model ORD/UV-5. The NMR spectra were determined on a Varian A-60 spectrometer, with tetramethylsilane as an internal standard and the peak positions are expressed by τ-values.

Aromatic Hydroxamoyl Chlorides.

They were prepared according to the methods described in previous papers.[6,10,11]

Preparation of 1,2,4-Oxadiazoles. *Method a (Table 1).* From Amidines. To a solution of *p*-nitrobenzhydroxamoyl chloride (I'a) (1.0 g, 5 mmol) in 50 m*l* of ether was added a solution of acetamidine hydrochloride (1 g, 10 mmol) in 20 m*l* of water. A 5% aqueous sodium carbonate (1.3 g, 12 mmol) was added dropwise to the above reaction mixture under ice-cooling. After stirring for 1 hr at this temperature (*ca.* 5°C), the reaction mixture was further stirred at room temperature for 3 hr. The water layer was washed with ether (20 m*l*×3). The ether washing were combined with the original ether layer and dried over sodium sulfate. The residue obtained after removal of ether was recrystallized from ethanol to afford 3-(*p*-nitrophenyl)-5-methyl-1,2,4-oxadiazole (IVa-2) as white needles. The physical constants, yield and microanalysis are given in Table 1.

Method b (Table 1). From iminoethers. A similar procedure as above, except that acetiminoethyl ether hydrochloride (1.85 g, 15 mmol) was used instead of acetamidine hydrochloride, afforded the same product. This result is given in Table 1.

Reactions with S-Methylthiourea. A similar procedure as above except that *S*-methylthiourea sulfate (1.4 g, 5 mmol) was used instead of imioether hydrochloride afforded the corresponding 5-amino-1,2,4-oxadiazole (Va), which precipitated in the reaction mixture. The yield and analysis are given in Table 2.

Preparation of Benzoxazoles. To a stirred solution of I'a (1 g, 5 mmol) in 50 m*l* of ether was added dropwise a solution of *o*-aminophenol (1.1 g, 10 mmol) in 50 m*l* of benzene-ether (1 : 1) at room temperauter. Stirring was continued for 1 week. The resulting precipitates were filtered and recrystallized from ethanol-benzene to afford 2-(*p*-nitrophenyl)benzoxazole (VIa-1), which was identical with a specimen prepared from *p*-nitrobenzaldehyde and *o*-aminophenol in the presence of lead tetraacetate in acetic acid.[12] This result is given in Table 3. When I'a (1 g, 5 mmol) and *o*-aminophenol (1.1 g, 10 mmol) were refluxed in 50 m*l* of ethanol for 5 hr, VIa-1 precipitated in the cooling reaction mixture; the yield was almost the same as that described above.

Preparation of Benzothiazoles. Similar treatment as in the preparation of benzoxazoles was applied to *o*-aminothiophenol instead of *o*-aminophenol and the results are summarized in Table 4.

Preparation of Benzimidazole. A solution of I'a (1 g, 5 mmol) and *o*-phenylenediamine (1.1 g, 10 mmol) in 100 m*l* of ether was stirred at room temperature for 2 days and the resulting precipitates were filtered. The filtrate was condensed to give a crystalline residue, which was recrystallized from acetone to give an 80% yield of dark colored crystals, mp >300°C. ν_{max}^{KBr} 3000—2600, 1608, 1520, 1450, 1400, 1340, 1230 and 1100 cm^{-1}. Found: C, 65.42; H, 3.82; N, 17.83%. Calcd for $C_{13}H_9O_2N_3$: C, 65.26; H, 3.79; N, 17.57%.

Infrared Absorption Spectra and Oxidation of Iron(II) Hydroxide and Green Rust I

Toshihei MISAWA, Wataru SUËTAKA and Saburo SHIMODAIRA

The Research Institute for Iron, Steel and Other Metals, Tohoku University, Katahira-cho, Sendai

(Received April 18, 1969)

Transformations on oxidation of hydroxide and basic salts of iron (II) have been investigated by means of X-ray and electron diffraction.[1-4] Infrared spectroscopy was applied for the observation of hydroxide and basic chloride of iron (II) in aqueous solutions. The infrared spectra of iron (II) hydroxide and Green Rust I, an oxidation intermediate, were obtained for the first time. No absorption band attributable to other intermediate compounds appeared in the course of oxidation.

Iron (II) hydroxide and basic chloride were prepared by adding adequate quantities of potassium hydroxide to the oxygen free aqueous solutions of iron (II) chloride (0.39 mol/*l*). The precipitates formed were separated from solutions by centrifugation. The infrared absorptions due to the water remaining in the precipitates were compensated by means of a reference cell containing a thin film of water. The oxidation of the precipitates in solutions was carried out at room temperature by introducing air at a constant rate of 1 *l*/min.

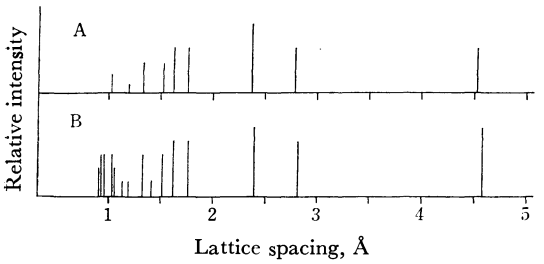

Fig. 1. X-Ray diffraction diagram of iron (II) hydroxide
A: present work B: Bernal *et al.*[1]

The precipitate obtained from basic solution (pH; 12.5—13.5), which was identified as iron (II) hydroxide by X-ray diffraction (Fig. 1), has two sharp absorption bands at 3630 and 480 cm^{-1}. The intensities of these two bands decreased with the progress of oxidation, and the absorption bands characteristic of α-FeOOH appeared. After oxidation for 30 hr, the absorption bands of iron (II) hydroxide disappeared completely, and only the bands due to α-FeOOH could be observed. Bernal *et al.* suggested an oxidation intermediate of Fe(O,OH).[1] However, no band attributable to such an intermediate compound could be detected.

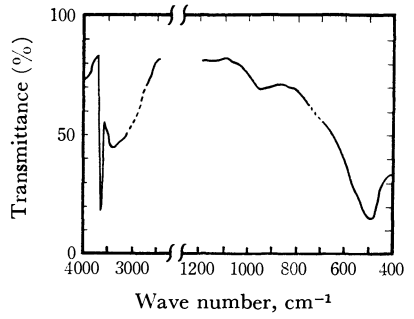

Fig. 2. Infrared absorption spectrum of iron (II) hydroxide obtained with Nujol mulling technique

Iron (II) hydroxide separated from solution was repeatedly washed with oxygen free ethanol and with petroleum ether so as to minimize the absorptions of water. The infrared spectrum of iron (II) hydroxide thus obtained is shown in Fig. 2. The high wavenumber and sharpness of the absorption band arising from O–H stretching vibration indicate that the OH group in iron (II) hydroxide is almost free from hydrogen bonding. The band at 480 cm^{-1} may be assigned to the translational mode of OH group by analogy with the spectrum of metal hydroxide having the same CdI_2 type structure as iron (II) hydroxide.[5]

The X-ray diffraction pattern showed that the precipitate formed in a slightly acidic solution (pH; 6.0—6.5) consisted of β-$Fe_2(OH)_3Cl$ and Green Rust I. The infrared absorption bands of the precipitate were located at 3540, 800, 670 and 470 cm^{-1}. While the relative intensity of the absorption band at 470 cm^{-1} decreased monotoni-

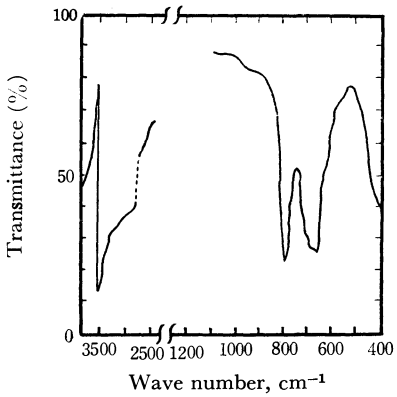

Fig. 3. Infrared absorption spectrum of Green Rust I (Nujol mull)

cally on oxidation, the bands at 3540, 800 and 670 cm^{-1} increased at first and then decreased in intensity. Since the increase of relative quantity of Green Rust I in the precipitate with oxidation was found at an early stage of oxidation by the X-ray diffraction measurement, it is likely that the latter three bands arise from the vibration of Green Rust I. The precipitate formed in neutral or slightly basic solution (pH; 7.0—8.0), was a mixture of iron (II) hydroxide and Green Rust I and was transformed to Fe_3O_4 by oxidation. It had absorption bands at 800 and 670 cm^{-1} besides the bands of $Fe(OH)_2$. This fact agrees with the assignment of the above mentioned bands to Green Rust I.

The infrared absorption spectrum of the precipitate formed in the slightly acidic solution and washed with ethanol and petroleum ether is shown in Fig. 3. The broad band at 470 cm^{-1} belonging probably to β-$Fe_2(OH)_3Cl$ disappears in the spectrum. It seems that β-$Fe_2(OH)_3Cl$ is not stable and decomposed during the course of washing with organic solvents, and thus Fig. 3 shows the spectrum of Green Rust I.

Bernal *et al.* claimed that Green Rust I might be transformed first to Green Rust II and then to γ-FeOOH.[1] Since all the absorption bands appearing on the oxidation of Green Rust I belonged to γ-FeOOH, it can be deduced that Green Rust I was not transformed as a whole to Green Rust II in the present investigation.

Gamma-Ray-Induced Addition of Formamide and Aniline to Crotonic Acid and Its Ester

Mitsuomi Itoh, Masao Tokuda, Yuji Yokoyama and Akira Suzuki*[1]

Department of Chemical Process Engineering, Hokkaido University, Sapporo, Hokkaido

(Received April 24, 1969)

Numerous reports on free radical addition reactions by various methods[1] are available, including peroxide induced reaction, photochemical reaction, and radiation-induced reaction. These varying methods tend to give different products. We reported previously on the photochemical addition of formamide and aniline to crotonic acid and its esters.[2] The present work was carried out using a γ-radiation technique on the same reactants in an attempt to compare the results with that obtained by photochemical method.

Light-induced amidation of olefins[3] and α,β-unsaturated esters,[4] and γ-radiation and electron induced amidation of olefins[5,6] and dienes[7] have been reported. According to the results, it was indicated that the light-induced addition of formamide to α,β-unsaturated esters such as methyl 2-octenoate, methyl 2-nonenoate and methyl 2-decenoate give only the β-adducts. On the other hand, we have pointed out that when crotonic acid and the esters are subjected to a photochemical addition of formamide, the α,- β- and γ-products were obtained and the product distribution between the acid and esters was different.

It was found that γ-ray-induced amidation of crotonic acid and its ethyl ester gives only the corresponding β-adduct, as summarized in Table 1.

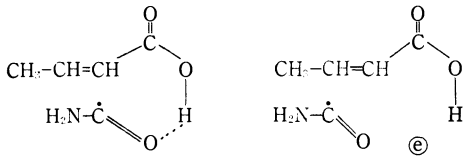
b) Irradiation time: 144 hr

$$CH_3CH=CH-CO_2R + HCONH_2 \xrightarrow{\sim\sim} CH_3-\underset{\displaystyle CONH_2}{\underset{|}{CH}}-CH_2CO_2R$$

R=H, C_2H_5

Although detailed mechanistic studies were not undertaken, the reaction probably occurred by the attack of the carbamoyl radical which was produced by direct or indirect process.[5] The preference of β-adduct is in line with the generalization that the β-carbon is more easily attacked than the α-carbon in usual free radical addition to α,β-unsaturated carbonyl compounds having no phenyl linkage.[8]

The difference of the products obtained by photochemical procedure[2] and γ-ray-induced technique might be explained as follows: the orientation effect proposed in photochemical addition reactions need not be taken into account. A six-membered transition state such as A is not expected in γ-ray-induced reaction, because of the presence of the solvated electrons which interrupt the hydrogen bond with the carbonyl oxygen of the carbamoyl radical as described in B. Consequently, the addition of carbamoyl radical seems to occur readily at the β-carbon. On the other hand, the isomerization of the α,β-unsaturated ester to the corresponding β,γ-isomer observed in photochemical



reaction[2,9] was not observed in γ-ray-induced reaction. This is apparently the reason why the γ-adduct is not obtained in the latter reaction.

A γ-ray-induced addition of aniline to crotonic acid and ethyl crotonate was found to give a small amount of 1 : 1-adduct. The distribution of the product isomers is listed in Table 2. In the case of crotonic acid, only the β-adduct was obtained with a large amount of side reaction products which are probably a mixture of polymeric and fragmentated products. It is of interest that crotonic acid is readily converted, with a 66% conversion, as compared with the ethyl ester with a mere 2% conversion. When the sealed tube was opened after irradiation, an increase of the inside pressure was observed, suggesting a generation of carbon dioxide. The photochemical alkylation of nitrogen hetero-aromatics with alkyl radical resulting from carboxylic acid by decarboxylation has been reported.[10] Thus we attempted to examine decarboxylation during the γ-ray irradiation applied to a mixture of crotonic acid and aniline. When a mixture of crotonic acid (0.2 mol), aniline (0.4 mol) and benzene (25 m*l*) was irradiated for 72 hr, one hundred and fourteen milliliters of CO_2 gas (0.006 mol) was evolved. This indicates that 3% of crotonic acid was subjected to decarboxylation. Several carboxylic acids (acetic, propionic, butyric and benzoic acids) were also treated under the same condition, but generation of CO_2 was not observed.

TABLE 2. γ-RAY-INDUCED ADDITION OF ANILINE TO CROTONIC ACID AND ETHYL CROTONATE

Substrate	Yield of 1:1-adduct, %	G-value	Distribution of products	
			α-Adduct	β-Adduct
$CH_3CH=CHCO_2H$	5 (66[a])	4.3	0	100
$CH_3CH=CHCO_2Et$	2	1.6	42	58

a) Total converstion of crotonic acid, calculated from crotonic acid unreacted.

In the γ-ray-induced addition of aniline to ethyl crotonate, a yield of a small amount of α- and β-adducts without side reaction products was detected.

Experimental

Reagents and a General Procedure. All reagents were distilled or recrystallized before use. Benzene and *t*-butanol were dried over metal sodium and calcium oxide respectively.

A mixture of reactants was charged into a 30 × 100 mm tube and the inside atmosphere was replaced with nitrogen gas several times. The sealed sample was irradiated in a cobalt-60 cavity source at room temperature. The dose rate was approximately 4×10^5

rad. hr^{-1}.

The irradiated sample was treated as described earlier.[2] Glpc analysis was made with a Yanagimoto Model GCG-220 and an Ohkura Type GT-360 (Apiezon Grease L 20% coated on Diasolid L).

γ-Ray-Induced Amidation of Crotonic Acid with Formamide. A mixture of crotonic acid (0.08 mol), formamide (1.20 mol) and *t*-butanol (20 m*l*) was irradiated for 72 hr. The total dose was 2.88×10^7 rads. Treatment of the reaction mixture gave 3.2 g of 1 : 1-adduct (yield, 30% based on crotonic acid employed). Glpc analysis (column temp., 170°C) of the esterified product indicated the presence of a large peak and two other small peaks, the former corresponding to β-adduct. Neither of the latter small peaks corresponded to α-adduct, β-adduct or oxamide.

Further irradiation (144 hr, total dose, 5.76×10^7 rads) to the same mixture gave 4.70 g of 1 : 1-adduct (45%) and the product was confirmed as the β-adduct by glpc analysis.

γ-Ray-Induced Amidation of Ethyl Crotonate with Formamide. A mixture of ethyl crotonate (0.08 mol), formamide (1.20 mol) and *t*-butanol (20 m*l*) was irradiated for 72 hr (total dose, 2.88×10^7 rads). The same treatment of the irradiated mixture gave 4.60 g of 1 : 1-adduct (36%) and glpc analysis (170°C) of the esterified product indicated the presence of only β-adduct.

γ-Ray-Induced Addition of Aniline to Crotnic Acid. A mixture of crotonic acid (0.2 mol), aniline (0.4 mol) and benzene (25 m*l*) was irradiated for 72 hr (total dose, 2.88×10^7 rads). The reaction mixture was treated by the procedure reported by Stoermer,[11] which gave 2.0 g of β-anilinobutyranilide (yield, 4% based on crotonic acid) and 0.2 g of ethyl β-anilinobutyrate (1%). Distribution of 1 : 1-adducts was determined by glpc (Apiezon Grease L, 250°C). The total conversion of this reaction was calculated as 66% from the recovered crotonic acid (5.8 g).

Decarboxylation during the irradiation was estimated by gas analysis of CO_2 evolved. When the sealed tube was destroyed in an autoclave, 116 m*l* of CO_2 (0.006 mol) was generated at 22°C, which indicated that 3% of crotonic acid used was decarboxylated during the irradiation.

γ-Ray-Induced Addition of Aniline to Ethyl Crotonate. The irradiation of a mixture of ethyl crotonate (0.07 mol), aniline (0.14 mol) and benzene (10 m*l*) for 72 hr (total dose, 2.88×10^7 rads) gave 0.08 g of ethyl anilinobutyrate (1%) and 0.12 g of anilinobutyranilide (1%). The distribution of 1 : 1-adducts was determined by glpc analysis (250°C).

The authors wish to thank the Nippon Gosei Kagaku Co. for the supply of pure crotonic acid.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 3342—3344 (1969)

The Acid-catalyzed Rearrangement of Laurinterol Derivatives[1]

Minoru SUZUKI, Yoshiki HAYAKAWA and Toshi IRIE

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo, Hokkaido

(Received May 6, 1969)

In our studies of the chemistry of laurinterol (I) and debromolaurinterol (II),[2] we observed an interesting behavior upon the acid-catalyzed reaction of these compounds. The treatment of I and II (or their acetates, III and IV) with *p*-toluenesulfonic acid (TSA) in acetic acid at 50°C afforded aplysin (V) and debromoaplysin (VI) respectively.[2,3] In contrast, debromolaurinterol acetate (IV) gave cyclopentene VII in a good yield upon treatment with TSA in acetic anhydride under comparable conditions.[4] In this paper we will describe the acid-catalyzed rearrangement of laurinterol methyl ether (VIII) and debromolaurinterol methyl ether (IX).

The treatment of VIII with TSA in acetic acid at 50°C led to only the recovery of the starting material. However, when treated with 10% sulfuric acid in acetic acid at 50°C for 3 hr, VIII afforded two isomeric cyclopentenes, X and XI, with a concomitant *racemization*, in a ratio of about 3.5 : 1. In accordance with the assigned structure, X, $C_{16}H_{21}OBr$ (M^+ 308, 310), mp 123—124°C, $[\alpha]_D \pm 0°$, showed in its NMR spectrum the presence of two olefinic methyl groups (δ 1.46 and 1.69) instead of the one tertiary methyl and cyclopropane ring in VIII. On the other hand, the isomer XI (M^+ 308, 310), mp 93°C, $[\alpha]_D \pm 0°$, λ_{max} 290 and 284 mμ (ε 4100 and 4000), exhibited in its NMR spectrum signals due to two tertiary methyl (δ 0.82 and 0.93) and a secondary methyl group (δ 0.98; d, $J=6$ Hz) as well as to an olefinic proton (δ 5.41). On osmium tetroxide oxidation, XI gave the

XII

corresponding glycol (XII), whose structure was supported by the presence of only one proton on a carbon bearing the hydroxyl group (δ 4.91; dd, J=8 and 6Hz) and the absence of a methyl group adjacent to the hydroxyl.

Similarly, debromolaurinterol methyl ether (IX) gave the corresponding isomeric cyclopentenes, XIII and XIV, in a ratio of about 3 : 1 on treatment under the conditions described above.

The prolonged treatment (15 hr) of VIII with the same catalyst produced X and XI in a ratio of about 5 : 1, but no other product could be obtained. The reaction of VIII with 0.5% sulfuric acid in acetic acid proceeded slowly and afforded X and XI in a ratio of about 1.5 : 1 after 72 hr. An examination of the latter reaction process by TLC indicates that, while X increases gradually the quantity of XI reaches its maximum after a few hours and then decreases, an equilibrium being finally attained between only X and XI. In fact, X and XI, on treatment with 10% sulfuric acid in acetic acid at 50°C for 15 hr, have formed a *ca.* 7 : 1 equilibrium mixture.

This observation can be explained by assuming that VIII undergoes protonation leading to the cleavage of the cyclopropane ring to yield a carbonium cation, XV, which, by a reversible reaction involving the migration of the methyl group, forms a cation, XVI.[5] These cations, XV and XVI, will then produce the cyclopentenes, X and XI respectively.

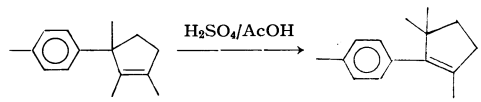
Experimental[8]

Laurinterol Methyl Ether (VIII). To a solution of I (180 mg) and dimethyl sulfate (400 mg) in dry acetone (20 m*l*), potassium carbonate (800 mg) was added, and then the mixture was refluxed for 3 hr. After the removal of the unchanged potassium carbonate by filtration, the solution was made alkaline by the addition of a dilute sodium hydroxide solution. The solvent was then removed by distillation under diminished pressure, and the residue was extracted with ether. The ether solution was washed successively with water, the dilute sodium hydroxide solution, and a saturated sodium chloride solution, and dried over sodium sulfate. A crude crystalline substance obtained after the removal of the ether was purified by recrystallization from methanol to give VIII (160 mg); mp 96—97°C; M^+ 308, 310; $[\alpha]_D$ +18.0° (*c*, 1.25; Chf); ν_{max}^{Chf} 1602, 1490, 1240, 1165, 1065, 1043, 960, 890, 845 cm^{-1}; NMR, δ 0.43 (1H, s), 0.53 (1H, s), *ca.* 1.0 (1H, m) 1.30 (6H, s), 2.35 (3H, s), 3.77 (3H, s), 6.61 (1H, s), 7.53 (1H, s). (Found: C, 62.27; H, 6.69%. Calcd for $C_{16}H_{21}OBr$: C, 62.14; H, 6.85%).

Debromolaurinterol Methyl Ether (IX). Debromolaurinterol (II, 65 mg) was methylated with dimethyl sulfate and potassium carbonate in dry acetone as has been described above. The crude product was

5) This type of methyl migration has recently been reported [Y. Hirata *et al.*, Preprints for the 22nd Annual Meeting of the Chemical Society of Japan (Tokyo, 1969)]. However, when isolaurene (XVII)[6] is treated with 10% sulfuric acid in acetic acid, both the methyl and the *p*-tolyl group migrate to give XVIII. It is



XVII XVIII

well known that the migratory aptitude of the *o*-anisyl group is small;[7] the above observation is in accord with this view.

purified by column chromatography on silica gel to give IX (50 mg); oil; M^+ 230 ($C_{16}H_{22}O$); $[\alpha]_D$ −17.6° (*c*, 1.42; Chf); ν_{max}^{Chf} 1613, 1575, 1503, 1250, 1165, 1140, 1060, 1040, 820 cm^{-1}; NMR, δ *ca.* 0.5 (2H, m), *ca.* 1.0 (1H, m), 1.31 (3H, s), 1.35 (3H, s), 2.32 (3H, s), 3.79 (3H, s), 6.58 (1H, br. s), 6.60 (1H, br. d, J=7.5 Hz), 7.32 (1H, d, J=7.5 Hz).

Rearrangement of Laurinterol Methyl Ether (VIII). *a*) A solution of VIII (301 mg) in 10% sulfuric acid in acetic acid (10 m*l*) was stirred at 50°C for 3 hr. To the ice-cold reaction mixture water (*ca.* 20 m*l*) was added, and then the whole was extracted with ether. The ether solution was washed successively with water, a 5% sodium hydrogen carbonate solution, and a saturated sodium chloride solution, and dried over sodium sulfate. After the removal of the solvent, the residual oil (297 mg) was chromatographed over silica gel - Celite (10 : 1) to yield X (205 mg) and XI (68 mg).

X: mp 123—124°C, M^+ 308, 310 ($C_{16}H_{21}OBr$); $[\alpha]_D$ ±0°; λ_{max}^{EtOH} 288 and 282 mμ (ε 3200 and 3400); NMR, δ 1.37 (3H, s), 1.46 (3H, s), 1.69 (3H, s), 2.31 (3H, s), 3.72 (3H, s), 6.56 (1H, s), 6.95 (1H, s). (Found: C, 62.25; H, 6.86%).

XI: mp 93°C, M^+ 308, 310 ($C_{16}H_{21}OBr$); $[\alpha]_D$ ±0°; λ_{max}^{EtOH} 290 and 284 mμ (ε 4100 and 4000); NMR ,δ 0.82 (3H, s), 0.93 (3H, s), 0.98 (3H, d, J=6 Hz), 2.34 (3H, s), 3.69 (3H, s), 5.41 (1H, m), 6.60 (1H, s), 7.03 (1H, s). (Found: C, 62.32; H, 6.85%).

b) When 0.5% sulfuric acid in an acetic acid solution was used, the reaction was slow; after stirring at 50°C for 72 hr, the starting material disappeared (TLC), and X (50%) and XI (35%) were obtained after the usual work-up.

Rearrangement of Debromolaurinterol Methyl Ether (IX). A solution of IX (251 mg) in 10% sulfuric acid in acetic acid (10 m*l*) was stirred at 50°C for 3 hr. After treatment as above, there was obtained an oily product (217 mg) which was subsequently purified by silica gel chromatography to yield XIII (105 mg) and XIV (45 mg).

XIII: oil, M^+ 230 ($C_{16}H_{22}O$); $[\alpha]_D$ ±0°; NMR, δ 1.39 (3H, s), 1.47 (3H, s), 1.68 (3H, s), 2.27 (3H, s), 3.73 (3H, s), 6.48 (1H, d, J=8 Hz), 6.53 (1H, s), 6.73 (1H, d, J=8 Hz).

XIV: oil, M^+ 230 ($C_{16}H_{22}O$); $[\alpha]_D$ ±0°; NMR, δ 0.81 (3H, s), 0.92 (3H, s), 1.01 (3H, d, J=6 Hz), 2.30 (3H, s), 3.67 (3H, s), 5.35 (1H, m), 6.50 (1H, s), 6.51 (1H, d, J=8 Hz), 6.73 (1H, d, J=8 Hz).

Glycol XII. To a solution of XI (128 mg) in benzene (4 m*l*), osmium tetroxide (102 mg) and pyridine (0.1 m*l*) were added. After the mixture had stood for 3 days at room temperature, pale brown precipitates (180 mg) were separated and collected by filtration. This crude product was dissolved in dichloromethane (3 m*l*) and was added to a solution of mannitol (800 mg) and potassium hydroxide (100 mg) in water (10 m*l*). The whole was stirred at room temperature for 45 hr, the reaction mixture was then extracted with dichloromethane, and the organic layer was washed with water and dried. After the removal of the solvent, the residual oil (101 mg) was purified by chromatography over silica gel to give pure XII (64 mg): ν_{max} 3500, 1105, 1045 cm^{-1}; NMR, δ 0.49 (3H, s), 0.82 (3H, s), 0.82 (3H, d, J=7 Hz), 2.34 (3H, s), 3.77 (3H, s), *ca.* 3.4 (1H, br. m), *ca.* 4.3 (1H, br. m), 4.91 (1H, dd, J=8 and 6 Hz), 6.65 (1H, br. s), 7.45 (1H, s).

Acid-catalyzed Equilibration of X and XI. Pure X and pure XI (50 mg) were each dissolved in 10% sulfuric acid in acetic acid (10 m*l*), and the mixture was stirred at 50°C for 15 hr. The reaction mixture was then worked-up as has been described above, and the composition of the products was determined by column and/or thin-layer chromatography. From each of the cyclopentenes, X and XI were obtained in a ratio of *ca.* 7 : 1.

The authors wish to express their thanks to Professor Tadashi Masamune and Dr. Etsuro Kurosawa for their valuable discussions. The authors' thanks are also due to Mr. Shigezo Shimokawa and Miss Yoshiko Kishio for their NMR measurements, to Miss Yuko Imai for her measurements of the mass spectra, and to Mrs. Toyoko Toma, Faculty of Pharmaceutical Sciences, for her microanalyses.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 3345—3348 (1969)

The Intramolecular Hemiacetal Structure of Benzoyl(2-hydroxybenzoyl)carbinol and Its Monobenzoate*1

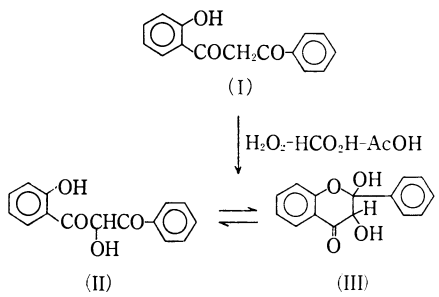
Heitaro OBARA and Jun-ichi ONODERA

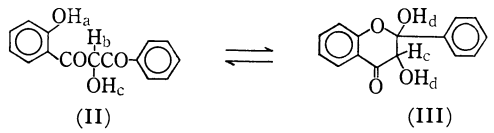
Department of Applied Chemistry, Faculty of Engineering, Yamagata University, Yonezawa

(Received May 6, 1969)

In previous studies, the present authors have reported that a ring-chain tautomerism exists between benzoyl(2-hydroxybenzoyl)methyl bromide and its cyclic intramolecular hemiacetal structure, *i. e.*, 2-hydroxy-3-bromoflavanone.[1] In the present investigation, we have found that a similar tautomerism exists between benzoyl(2-hydroxybenzoyl)-carbinol (II) and its monobenzoate (IV).

The carbinol (II) was prepared by Winicki *et al.*[2] from benzoyl(2-hydroxybenzoyl)methane (I) by oxidation with hydrogen peroxide in a mixed solution of formic and acetic acid; however, no investigation has been made concerning its hemiacetal structure (III). In order to ascertain the tautomerism between II and III, the NMR, IR, and UV spectra of this carbinol and the behavior of its monobenzoate (IV) will be discussed in the present paper.





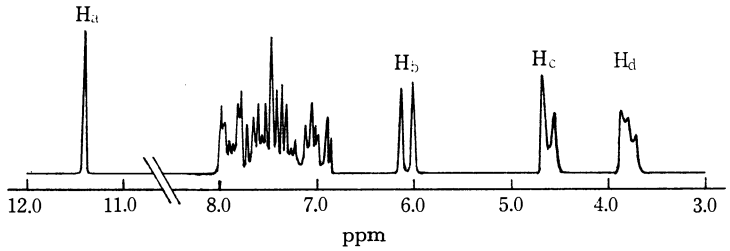


Fig. 1. NMR spectrum of II ⇋ III in $CDCl_3$.

Results and Discussion

The NMR spectrum of the carbinol (II) in $CDCl_3$ exhibits four groups of bands (a, b, c, and d) in addition to the aromatic protons (6.67 ppm—8.02 ppm), as Fig. 1 shows. These four bands were assigned as follows: 1) the a band on the low-field side of these bands is due to the hydrogen-bonding phenolic OH proton in II; 2) the b band (doublet), which changes to a singlet after deuterium exchange, is due to the methine proton of –COCH(OH)CO– in II, and the c band may be attributed to a mixture of the OH proton of –COCH(OH)CO– in II and the methine proton in III, which leaves after deuterium exchange. (They were determined by comparison with those of dibenzoylcarbinol.)*2

*2 This carbinol was prepared by the oxidation of dibenzoylmethane with hydrogen peroxide in a mixture of formic and acetic acid; mp 110°C (lit mp 110°C[3]).

3) P. Karrer, J. Kebrle and R. M. Thakkar, *Helv. Chim. Acta*, **33**, 1711 (1950).

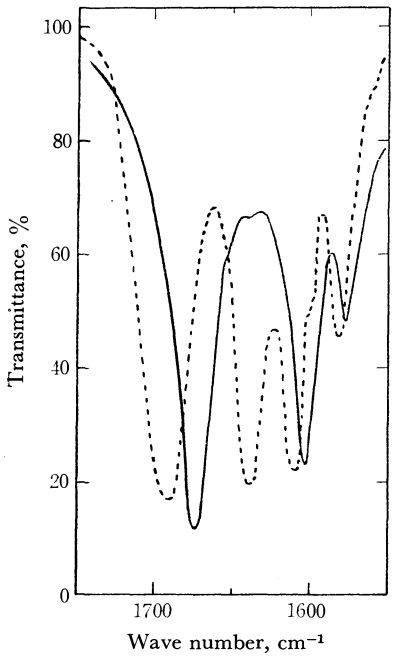

Fig. 2. IR spectra of benzoyl(2-hydroxybenzoyl)-carbinol.
——: in KBr disk, ------: in $CHCl_3$.

3) The remaining d band is due to the two OH protons in III, which disappears after the deuterium exchange. From the relative areas of the a, b, c, and d bands, the molar ratio of the tautomers II and III in this case was found to be approximately 2 : 1.

The IR spectrum of this carbinol showed a strong carbonyl absorption band at 1674 cm^{-1} in the KBr disk, while two carbonyl absorption bands at 1690 cm^{-1} and 1638 cm^{-1}, corresponding to free and bonded carbonyl groups,[4] were observed in the chloroform solution, as is shown in Fig. 2.

From the results of these NMR and IR spectral analyses, the cyclic hemiacetal structure, *i. e.*, 2,3-dihydroxyflavanone (III), rather than II must be given for this carbinol in the crystalline state; in the chloroform solution, this carbinol exists as an equilibrium state between II and III, analogous to benzoyl(2-hydroxybenzoyl)methyl bromide and its hemiacetal structure.[1] However, when this carbinol was dissolved in chloroform, no variation in the absorption band with the lapse of time has been observed in the IR spectrum. It is considered that this carbinol immediately reaches equilibrium between II and III in a solution.

The UV spectrum of this carbinol exhibits its absorption maxima at 253 mμ and 321 mμ in ethanol; the absorption curve is very similar to those of flavanone and 3-hydroxyflavanone.

Finally, the existence of a ring-chain tautomerism between II and III was ascertained by the chemical method.

Two benzoates were obtained from this carbinol by benzoylation with benzoyl chloride in pyridine. One was dibenzoate (mp 159—160°C), which had previously been reported in the literature,[2] and the other was a new monobenzoate (mp 102—104°C). The structure of this monobenzoate was identified as benzoyl(2-hydroxybenzoyl)benzoyloxymethane (IV) because it is converted into 3-benzoyloxyflavone[5] (VI) with acid or heat.

The IR spectrum of this monobenzoate in a chloroform solution gave an interesting result, as much as in the case of benzoyl(2-hydroxybenzoyl)-methyl bromide[1] in the 1600—1750 cm^{-1} region. It showed two strong carbonyl absorption bands at 1713 cm^{-1} and 1728 cm^{-1} immediately after it had been dissolved in chloroform, but the former band slowly decreased with the lapse of time; a new absorption band appeared at 1643 cm^{-1}, and then it remained unchanged for at least 1 hr (Fig. 3).

This new band is considered to be a characteristic absorption band due to the intramolecular chelated carbonyl group in the structure IV which is observed in aromatic *o*-hydroxyketones.[4] On the other hand, the IR spectrum of this monobenzoate in a KBr disk showed no chelated carbonyl absorption band near 1630—1640 cm^{-1}; such a band would appear if the structure were IV (Fig. 4).

5) J. E. Gowan, P. M. Hayden and T. S. Wheeler, *J. Chem. Soc.*, **1955**, 862.

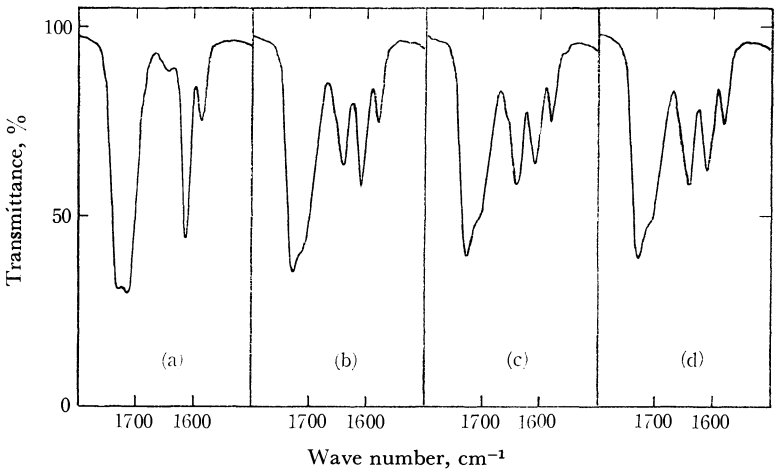

Fig. 3. The variation of IR spectra of benzoyl(2-hydroxybenzoyl)-benzoyloxymethane (IV) with the time in $CHCl_3$ solution. (a): Immediately after dissolving. (b): After 10 min. (c): After 25 min. (d): After 1 hr.

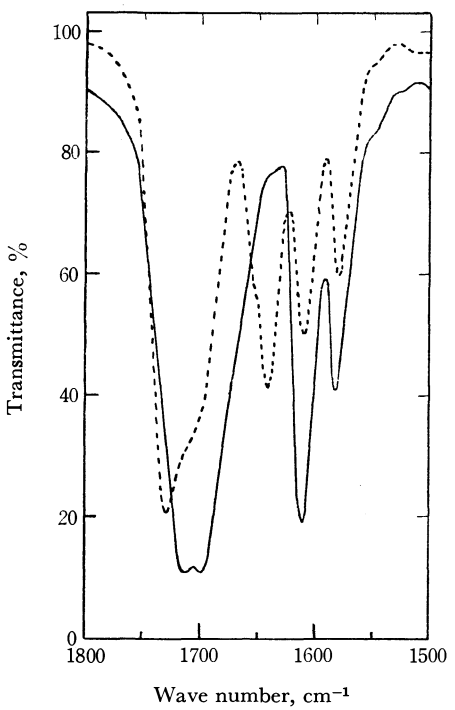

Fig. 4. IR spectra of benzoyl(2-hydroxybenzoyl)-benzoyloxymethane (IV).
——: in KBr disk, ------: in $CHCl_3$.

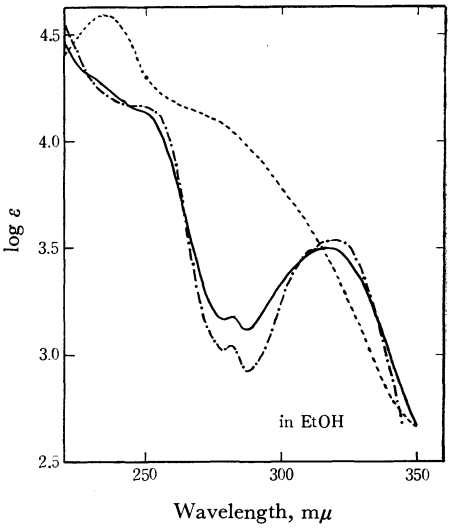

Fig. 5. UV spectra of benzoyl(2-hydroxybenzoyl)-benzoyloxymethane (IV) (——), 3-benzoyloxyflavanone (IX) (·—·—·) and benzoyl(2-benzoyloxybenzoyl)benzoyloxymethane (VII) (------).

From these results, it is expected that this monobenzoate has the structure V before dissolving and that it reaches equilibrium between IV and V in a solution; the cyclic hemiacetal structure V rather than IV must be given for this monobenzoate in the crystalline state. The isomeric monobenzoate, *i.e.*, benzoyl(2-benzoyloxybenzoyl)carbinol, was not isolated in this benzoylation.

The UV spectrum of the monobenzoate in ethanol, which exhibits absorption maxima at 248 mμ (inflect.), 283 mμ, and 316 mμ, is very similar to that of 3-benzoyloxyflavanone (IX) (Fig. 5).

On the other hand, two isomeric structures, *i. e.*, VII or VIII, must be considered for the dibenzoate. Structure VII was, however, supported by its UV spectrum, because the absorption curve does not resemble that of flavanones (Fig. 5). Another dibenzoate (VIII) has not been isolated in this benzoylation of this carbinol.

Experimental

Benzoyl(2-hydroxybenzoyl)carbinol (II). This carbinol was prepared from benzoyl(2-hydroxybenzoyl)-methane (I) in a 53% yield as has been described by Winicki *et al.*[2] Mp 101.5—103.5°C, (lit[2] mp 104°C) UV λ_{max}^{EtOH} mμ (log ε) 253 (4.00) 321 (3.50).

Found: C, 70.24; H, 4.68%. Calcd for $C_{15}H_{12}O_4$: C, 70.30; H, 4.72%.

Benzoylation of Benzoyl(2-hydroxybenzoyl)-carbinol (II). Into a solution of II (520 mg) in 2 m*l* of pyridine, there was added a 600 mg portion of benzoyl chloride. After it had been heated on a water bath for 10 min, the reaction mixture was poured into cold 3 N hydrochloric acid; the resulting pale yellow oil was extracted with ether. The ether layer was washed with water and dried over anhydrous sodium sulfate. The filtrate was concentrated to about 8 m*l*, and 4 m*l* of petroleum ether were added. After the solution had then been allowed to stand overnight in an ice-box, the resulting crystal (A) was filtered out and the filtrate was chromatographed on a column of silica gel. Elution with benzene-ethyl acetate (20 : 1) gave benzoyl-(2-hydroxybenzoyl)benzoyloxymethane (IV), which was recryltallized from carbon tetrachloride. Yield, 35 mg; mp 102—104°C. UV λ_{max}^{EtOH} mμ (log ε) 248 (inflect.) (4.14), 283 (3.18), 316 (3.50).

Found: C, 73.22; H, 4.80%. Calcd for $C_{22}H_{16}O_5$: C, 73.33; H, 4.48%.

The recrystallization of (A) from ethanol gave 235 mg of benzoyl(2-hydroxybenzoyl)carbinol dibenzoate (VII) as colorless prisms; mp 159—160°C (lit[2] mp 159°C), UV λ_{max}^{EtOH} mμ (log ε) 235 (4.59).

The authors wish to express their thanks to Professor Koji Nakanishi of Tohoku University and the members of his laboratory for their measurement of the NMR spectra.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 3348—3349 (1969)

The Oxidation of Limonene with Selenium Dioxide

Yoshitsugu SAKUDA

Chemistry Laboratory, Kochi Women's University, Kochi

(Received May 13, 1969)

The oxidations of limonene with selenium dioxide have been reported;[1-4] in them it was found that the two methyl groups of C-7[3] and C-10[2] and the methylene group of C-6[1,2] were oxidized. In a previous paper[5] dealing with the selenium dioxide oxidation of *cis*-carvyl acetate, which contained both a methine and methyl group allylic to the double bond, it was found that the methine group is oxidized mainly.[6] Because limonene has the same carbon skeleton as *cis*-carveol, it was expected that the methine group of C-4, in addition to the methyl and methylene groups, is oxidized with selenium dioxide. Therefore, in this paper *d*-limonene was taken as the sample and was oxidized with selenium dioxide. The oxidation was carried out in an alcoholic solution at reflux with a half-molar amount of selenium dioxide. The reaction products were analysed by gas chromatography using a polyethylene glycol 6000 column at 160°C. All the identities were confirmed by a comparison of the IR and NMR spectra. The *dl*-limonen-4-ol(1,8-*p*-menthadien-4-ol) was obtained as a major product (11% based on the sample taken), while *d-trans*-carveol, *cis*-carveol, perillyl alcohol, limonen-10-ol(1,8-*p*-menthadien-10-ol), and carvone were obtained as minor products (total, 6.5%).

In a study of the mechanism by which olefins are oxidized with selenium dioxide, Schaefer and

Wiberg[7] have shown that selenium dioxide or its conjugate acid acts as an electrophile and attacks a double bond, thus forming an allylic selenium ester that then decomposes to products through solvolysis reaction. When Schaefer's mechanism is applied when the methine group allylic to the double bond at C-8 of limonene is oxidized, the reaction process is as is shown in Fig. 1. This view of the mechanism of the oxidation appears to accord well with that by which *dl*-limonen-4-ol is produced. Furthermore, considering the fact that the isolated carveol consists mainly of *d-trans*-carveol, which possesses an axial hydroxyl group and which retains its optical activity, it was assumed that the displacement of the allylic selenium ester by a solvent molecule occurs through the S_N2' process.[7]

Experimental

Oxidation. To 136 g (1 mol) of *d*-limonene (bp 61°C/13 mmHg, d_4^{25} 0.8422, n_D^{25} 1.4720, $[\alpha]_D$ +122.6) in 150 cc of ethanol, which was being stirred at room temperature, there was added, drop by drop over a period of 30 min, 55 g (1/2 mol) of selenium dioxide dissolved in a mixture of 10 cc of water and 250 cc of ethanol. The mixture was heated to reflux for 1 hr and then left to stand at room temperature overnight. The reaction mixture was filtered, giving 4.7 g of selenium. The filtrate was concentrated using a rotary evaporator, and the residue was steam-distilled. The distillate was extracted twice with ether. The combined ether solution was washed with water, dried over anhydrous sodium sulfate, and distilled to remove the solvent. The residue was distilled at reduced pressure, giving three fractions: (1) bp 62—94°C/13 mmHg, 29.2 g; (2) bp 94—96°C/12 mmHg, 13.5 g; (3) 96—108°C/12 mmHg, 16.0 g. Fraction 1 consisted mainly of unchanged *d*-limonene.

The Identification of Reaction Products. *dl-Limonen-4-ol.* Fraction 2 was analysed by gas chromatography and was found to consist 90% of limonen-4-ol and 10% of unknown hydrocarbons; it was purified by redistillation. Bp 104—106°C/27 mmHg, d_4^{25} 0.9475, n_D^{25} 1.4877, $[\alpha]_D$ +1.40; phenylurethane, mp 130—131°C.[8] Gas chromatography of this oil indicated the presence of small amounts of unknown hydrocarbons in addition to limonen-4-ol. Accordingly, the small optical rotation value is due to unknown contaminating hydrocarbons. IR spectrum: 3400 cm^{-1} (OH); 3100, 1645, 900 cm^{-1} (CH_2=C–). NMR spectrum: 1.75 ppm, 3H s, 4.71, 1H, q, 4.90, 1H, s (CH_3–C=CH_2); 1.65, 3H s, 5.21, 1H unresolved (CH_3–C=CH–). The IR and NMR spectra of this alcohol coincided with those of limonen-4-ol, which was isolated from Japanese pepper by Sakai.[9] This alcohol was hydrogenated with Raney Ni in ethanol to give two known *p*-menthan-4-ols.[8]

Carvone. A gas chromatogram of Fraction 3 showed eleven peaks, which corresponded to limonen-4-ol (17%), carvone (3%), *trans*-carveol (33%), *cis*-carveol (10%), limonen-10-ol (16%), perillyl alcohol (16%), and five unknown minor components (5%). Chromatography of Fraction 3 on silica gel, with elution with ethyl acetate-petroleum ether (1 : 3), gave four fractions. The first fraction consisted a mixture of unknown hydrocarbons. The second fraction was rechromatographed on a silica-gel column and eluted with ethyl acetate-petroleum ether (1 : 20) giving carvone; 2,4-dinitrophenylhydrazone, mp 188—189°C.

d-trans-Carveol. The third fraction consisted mainly of *trans*-carveol. The 3,5-dinitrobenzoate was prepared from this fraction and was recrystallized three times from ethanol-ethyl acetate (2 : 1), giving pale yellow needles; mp 108—110°C, $[\alpha]_D$ +174.1 (*c* 1.6, $CHCl_3$); reported[10] mp 111.5°C, $[\alpha]_D$ +232.0 (*c* 2.0, $CHCl_3$) for *d-trans*-carvyl 3,5-dinitrobenzoate. The liquid alcohol obtained by the saponification of this 3,5-dinitrobenzoate gave a single peak upon gas chromatography; it was identified as *trans*-carveol by a direct comparison of the IR spectrum. Calculating from the specific rotation value of the 3,5-dinitrobenzoate, *trans*-carveol retained 75% of its optical activity.

cis-Carveol. The fourth fraction consisted of a mixture of *trans*- and *cis*-carveol, limonen-10-ol, and perillyl alcohol. Chromatography of the fourth fraction on silica gel, with elution with ethyl acetate-petroleum ether (1 : 3), gave fractions which were analysed by gas chromatography. The fractions rich in *cis*-carveol, limonen-10-ol, and perillyl alcohol were combined. The crude *cis*-carveol thus obtained was purified by rechromatography on alumina; it was identified as *cis*-carveol by a direct comparison of the IR spectrum. The crude limonen-10-ol and perillyl alcohol obtained were purified too by rechromatography on silica gel.

Limonen-10-ol. IR spectrum: 3300 cm^{-1} (OH); 3100, 1645, 900 cm^{-1} (CH_2=C–). NMR spectrum: 1.65 ppm 3H s, 5.37, 1H unresolved (CH_3–C=CH–); 4.02, 2H s (–CH_2OH); 4.84 1H s, 5.00 1H d (CH_2=C–). The oxidation product of this alcohol with chromic acid gave a semicarbazone, mp 209°C.[2]

Perillyl Alcohol. IR spectrum: 3300 cm^{-1} (OH); 3080, 1643, 890 cm^{-1} (CH_2=C–). NMR spectrum: 1.73 ppm 3H t, 4.77, 2H d (CH_3–C=CH_2); 3.93, 2H s (–CH_2OH); 5.72, 1H unresolved (–C=CH–).

Reaction of 6-Methylpicolinic Acid *N*-Oxide with Acetic Anhydride[1]

Yukito MURAKAMI and Junzo SUNAMOTO

Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Hakozaki, Fukuoka

(Received May 21, 1969)

The reactions of picoline *N*-oxides with acetic anhydride have been studied by many workers for theoretical and practical interest.[2-9] Recently, Ford and Swan[10] have found that the reaction of 2-picoline *N*-oxide with acetic anhydride gave a mixture of three isomers, 3-acetoxy-2-picoline, 5-acetoxy-2-picoline, and 2-acetoxymethylpyridine in a relative proportion of 15 : 18 : 67. Meanwhile, the reaction of pyridine *N*-oxide with acetic anhydride gave 2-acetoxypyridine.[11]

The reactions of carboxypyridine *N*-oxides with acetic anhydride also have been studied. Bain and Saxton[12] have reported that picolinic acid *N*-oxide was converted to 2-pyridone and pyridine *N*-oxide by acetic anhydride in acetonitrile along with the quantitative evolution of carbon dioxide, where pyridine *N*-oxide was the main product. On the other hand, 2-carbomethoxypyridine *N*-oxide did not undergo decarboxylation with acetic anhydride, but normally afforded 6-acetoxy-2-carbomethoxypyridine.[13]

It is of interest to investigate what reaction may occur in the case of 6-methylpicolinic acid *N*-oxide with acetic anhydride, where the *N*-oxide carries both electron withdrawing and donating groups at the α-positions of the pyridine ring. Baker *et al.*[14] have reported that the reaction product of 6-methylpicolinic acid *N*-oxide with acetic anhydride was 2-acetoxymethylpyridine, only by determining its boiling point and the melting point of the corresponding picrate. However, they did not try to hydrolyze the acylated compound. From our present results we see that they mistook 6-acetoxy-2-picoline for 2-acetoxymethylpyridine because there is no considerable difference between both compounds in their physical properties. We found that the acylated compound produced during the course of the reaction of 6-methylpicolinic acid *N*-oxide with acetic anhydride was not 2-acetoxymethylpyridine, but 6-acetoxy-2-picoline. This was confirmed by the hydrolysis of the acylated intermediate which afforded 6-methyl-2-pyridone.

The results will present an interesting question as to whether decarboxylation proceeds prior to *N*-acetoxylation as indicated in the case of picolinic *N*-oxide.[12] If decarboxylation occurred predominantly prior to acetoxylation, the principal intermediate would be 2-picoline *N*-oxide and/or 2-acetoxymethylpyridine. On the other hand, if *N*-acetoxylation and the subsequent N–O fission were predominant prior to decarboxylation, 6-acetoxymethylpicolinic acid and/or 2-acetoxymethylpyridine would be produced. When 6-methylpicolinic acid *N*-oxide was warmed to 90—98°C with acetic anhydride, a smooth evolution of carbon dioxide occurred. The main product was 6-acetoxy-2-picoline, and 6-methyl-2-pyridone was present in a very small yield. The reaction of 2-picoline *N*-oxide, which is the decarboxylation product, with acetic anhydride under the same reaction condition did not give 6-acetoxy-2-picoline and/or 6-methyl-2-pyridone, but gave 2-acetoxymethylpyridine along with a trace amount of 5-acetoxy-2-picoline, similar to the result of Ford and Swan.[10] Therefore, decarboxylation, N–O fission, and acetoxylation at the C-2 position must take place in concert to give 6-acetoxy-2-picoline. The following reaction mechanism is put forward to

explain the present result.

Picolinic acid *N*-oxide undergoes rapid decarboxylation to pyridine *N*-oxide at room temperature upon addition of benzoyl chloride.[13] Therefore, it is evident that the formation of the *N*-acetoxypyridinium ion **1** is necessary for the ease of decarboxylation. 6-Acetoxy-2-picoline may further react with acetic acid during the reaction and/or distillation to give 6-methyl-2-pyridone, because the pyridone was usually obtained from the distillation residue. When the hydrolysis was carried out without isolating the acetoxylated intermediate, 6-methyl-2-pyridone was obtained in a yield of 84%. Thus, it seems that the present reaction is an improved synthetic method of 6-methyl-2-pyridone from 2,6-lutidine, differing from the conventional method *via* diazotization and the subsequent hydrolysis of 6-methyl-2-aminopyridine.[15]

Experimental

All infrared spectra were measured on a Koken Model DS-301 spectrophotometer equipped with sodium chloride optics. Nuclear magnetic resonance spectra were taken on a Varian A-60 using TMS as an internal standard. Mass spectra were measured on a JEOL JMS-01SG mass spectrometer. The ultraviolet spectra were recorded on a Hitachi Model EPS-2 recording spectrometer.

2,6-Lutidine *N*-Oxide. 2,6-Lutidine *N*-oxide was obtained by the reaction of 2,6-lutidine (53 g) with 30% hydrogen peroxide (50 m*l*) in glacial acetic acid, according to the method described in literature:[3] yield 36 g; bp 125—128°C/18 mmHg; lit., 131°C/22 mmHg,[16] 115—119°C/18 mmHg.[3] IR (neat): 1566 cm^{-1} (ring C=C, C=N str.); 1249 cm^{-1} (N-O str.); 766, 841 cm^{-1} (C-H def.).

6-Methylpicolinic Acid *N*-Oxide. 6-Methylpicolinic acid *N*-oxide was prepared by the oxidation of 2,6-lutidine *N*-oxide (22 g) with aqueous potassium permanganate solution, according to the method of Suszko and Szafran:[17] yield 9.0 g after recrystallization from methanol, mp 197—197.5°C (decomp.); lit,[18] mp 177°C. The melting point determined in the present work was not identical with that given in literature,[14,18] but infrared spectra of the sample prepared in this work was completely consistent with that reported by Szafran;[19,20] IR (KBr): 1680, 1615 cm^{-1} (C=O str.); 768, 818, 831 cm^{-1} (C-H def.). In mass spectroscopy, a molecular radical ion M^+ (*m/e* 157) was present, corresponding to the molecular formula $C_7H_7O_3N$.

Found: C, 55.12; H, 4.58; N, 9.16%. Calcd for $C_7H_7O_3N$: C, 54.90; H, 4.61; N, 9.15%.

A sample prepared through the *N*-oxidation of 6-methylpicolinic acid was also identical with the above product.

Reaction of 6-Methylpicolinic Acid *N*-Oxide with Acetic Anhydride. A mixture of 5 m*l* of acetic anhydride and 3.2 g of 6-methylpicolinic acid *N*-oxide was placed in a 50 m*l* conical flask equipped with a reflux condenser and a calcium tube, and warmed on a steam bath at 96—98°C. After about 1 hr, the color of the reaction mixture began to turn to a transparent brownish orange along with continuous evolution of carbon dioxide. The evolution of carbon dioxide lasted about one hour and half. The reaction mixture was distilled under reduced pressure after a period of 6 hr on a steam bath; 1.88 g of colorless oil (sample I), bp 107°C/18 mmHg, mp of the picrate, 165—167°C. Prism-like crystals (sample II) were isolated from the distillation residue; yield 280 mg, mp 163.5—164°C.

Hydrolysis of Sample I. A mixture of 1.0 g of sample I and 10 m*l* of concentrated hydrochloric acid was heated under reflux for 7 hr. The resulting solution was evaporated quickly by the introduction of dried air at room temperature, poured into chloroform, and then neutralized by an aqueous carbonate. The chloroform layer was dried over sodium sulfate overnight, and con-

centrated to isolate crystals. The crystals were washed with ether; yield 230 mg, mp 163.5—164.0°C. An admixture with sample II indicated no mp depression. The product was identified as 6-methyl-2-pyridone.

IR (KBr): 2400—3200 cm^{-1} (H-bonded N–H str.); 1660 cm^{-1} (C=O str.); 1608, 1552 cm^{-1} (ring C=C, C=N str.); 733, 795, 810 cm^{-1} (C–H def.). NMR (0.5M in $CDCl_3$): 2.34 ppm (3 protons singlet, CH_3); 6.00—6.11 ppm (1 proton broad doublet, H-5), 6.33—6.48 ppm (1 proton broad doublet, H-3); 7.25—7.52 ppm (1 proton multiplets of an X-part in an ABX system, H-4 with $J_{3,4}=9.3$ cps, $J_{4,5}=6.7$ cps). UV (10^{-4}M in EtOH); λ_{max} 229.5 mμ ($\varepsilon=8700$), 288.1 mμ ($\varepsilon=8100$).

Found: C, 65.65; H, 6.51; N, 12.63%. Calcd for C_6H_7ON: C, 66.04; H, 6.46; N, 12.83%.

In another experiment, a mixture of 15 g of the *N*-oxide and 26 g of acetic anhydride was warmed at 60—65°C for 18 hr with stirring. The mixture was then directly hydrolyzed with 230 m*l* of 6N hydrochloric acid at 90—100°C for 5 hr. The resulting solution was concentrated to 100 m*l* and extracted with benzene. The benzene solution was concentrated to give crystalline mass; 9.0 g (84%) of 6-methyl-2-pyridone was obtained.

Thanks are due to Mr. Akira Iwamitsu for his assistance in part of the experimental work, also to the Research Institute of Yoshitomi Seiyaku Co., Ltd., for the measurements of mass spectra.

Disproportionation of Dimethyl *p*-Phthalate Anion Radical Paired with Alkali Metal Cation

Takeo KOWATA and Masao KOIZUMI

Department of Chemistry, Faculty of Science, Tohoku University, Katahira-cho, Sendai

(Received May 22, 1969)

This note is concerned with a new example of the disproportionation reaction of the type,[1] $2A^-Na^+ \rightarrow Na^+A^=Na^+ + A$ where A^- is a radical anion of an organic substance. According to Hirayama,[2] dialkyl *p*-phthalates when treated with alkali metals, gave the ESR signals characteristic of the radical ion pair A^-Na^+; the intensities however, often decline gradually at room temperature, as a result of some unknown reaction. We have studied the reaction in question spectrophotometrically and have arrived at the conclusion that it is the disproportionation of the above type. The dependence of the reaction upon the alkali metal cation has also been investigated and the result will be discussed in relation to Hirayama's result on the ESR hyperfine structure.

Results and Discussion

When the dimethyl *p*-phthalate (DMT) solution in THF was treated with a metallic mirror of sodium at room temperature, the solution turned purple and gave the ESR signal which was essentially similar to the one reported by Hirayama.[2] Curve 1 in Fig. 1 gives an example of the absorption spectrum of this purple solution. This spectrum was taken as quickly as possible after the appearance of the purple color. When the original concentration of DMT was *ca.* 1×10^{-3}M, the spectrum could be taken with a 1 mm cell. The exact concentration of the purple species (P), however, could not be determined. The spectrum of P-species gradually changed as shown in Fig. 1, with the isosbestic

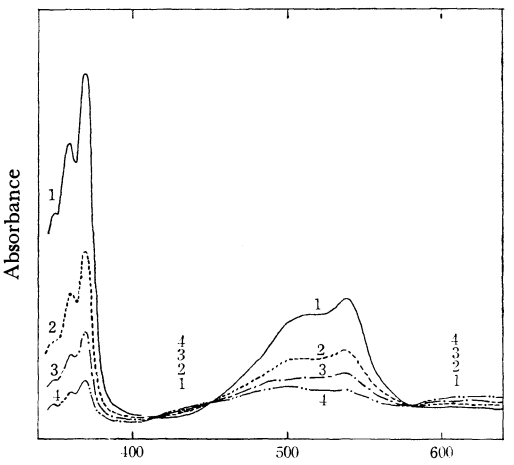

Fig. 1. Change of absorption spectrum in the course of reaction of P-species produced by the treatment with Na.

3, —·— 19 min 24 sec 4, ·····~40 min

1) Somewhat different type of disproportionation has been reported by Evans *et al.*: A. G. Evans, P. B. Roberts and B. J. Tabner, *J. Chem. Soc., B*, **1966**, 269.

2) M. Hirayama, This Bulletin, **40**, 2234 (1967).

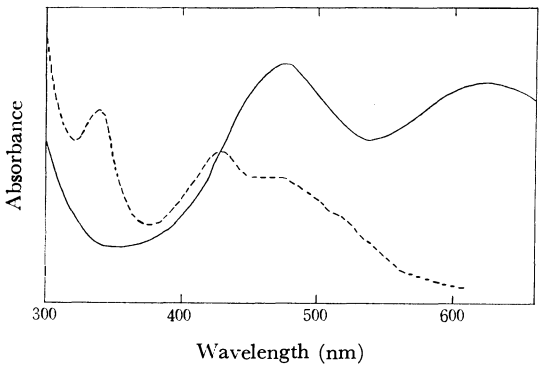

Fig. 2. Absorption spectrum of G-species (——) and that of trinitrobenzene⁻-Na⁺ (------) obtained by adding an excess quantity of trinitrobenzene to the G-species solution. The scale of ordinate is different for two curves.

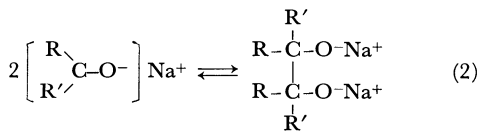
points at 410, 460 and 580 nm. It was established that the reaction is second order in P-species. The resulting solution had a tint of green and gave no ESR signal. This green species (G) is quite stable, living as long as several months, but the exact shape of the spectrum could not be reproduced. The spectrum at the last stage (curve 4), gives the general feature for the G-species. At −80°C the P-species was found to be stable. It was also stable when it was freed from solvent and kept *in vacuo*. Upon introduction of air, the solution of P-species as well as of G-species became light yellow with a white precipitate. The resulting solution from the latter gave the absorption spectrum characterestic for DMT, but the former did not.

In order to examine the radical nature of the G-species, twice as much quantity of trinitrobenzene (TNB) as DMT was added to the green solution. The color at once changed into brown and gave the spectrum of TNB radical anion as shown in Fig. 2. This solution gave the ESR signal similar to the one already reported by Ward.[3] All the above findings strongly support the view that the G-species is either a divalent anion which may be produced by the disproportionation reaction,

$$2\mathrm{DMT^-Na^+} \longrightarrow \mathrm{Na^+DMT^{2-}Na^+} + \mathrm{DMT}, \quad (1)$$

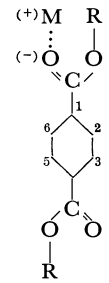
or a dimer of monoanion resulting from dimerization of the following type.[4]



(2)

Discrimination between (1) and (2) was thought to be possible by a careful measurement of the absorption spectrum, since reaction (1) should recover half as much DMT as DMT⁻. Although the experiment for this purpose could not be made very accurately, the results were favourable for mechanism (1). As an example, one measurement showed that the increase of the optical density at 242 nm (after a long time) was about one half the decrease at the same wavelength immediately after the treatment with sodium. This is very much larger than the optical density of G species at 242 nm which is 1/5—1/11 of the original DMT.

The Nature of the Radical Ion Paired with Other Alkali Metal Cations. According to Hirayama,[2] the hyperfine structures of ESR for Li and Na are such that the values of $a_H^{(2)}$ are larger than $a_H^{(3)}$, whereas for K and Cs the values are $a_H^{(2)} \approx a_H^{(3)}$. He interpreted this as resulting from



the fact that in the former group, metallic ions are located on one of the two carbonyl groups while in the latter group, they are situated in the symmetrical position between the two carbonyl groups. In view of this interpretation, we have examined the absorption spectra and the behaviour of P-species paired with different alkali cations.

The P-species from Li and K gave essentially the same spectra as from Na both in the UV and visible region while the one from Cs showed a clear difference, as shown in Fig. 3 where the free radical anion produced by electrolysis (using tetrabutyl-

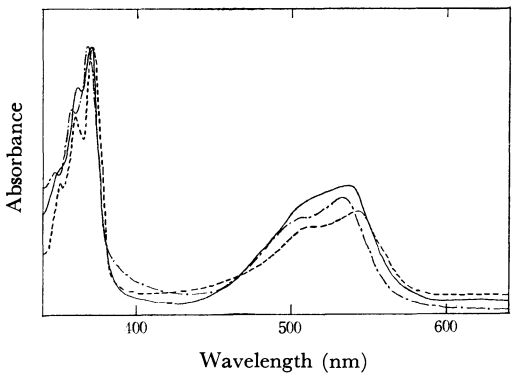


Fig. 3. Absorption spectra of three kinds of P-species, produced by the treatment with Na (------), Cs (——) and by electrolytic reduction (———): P(Li) and P(K) give essentially the same spectrum as that of P(Na).

3) R. L. Ward, *J. Am. Chem. Soc.*, **83**, 1296 (1961).
4) C. B. Wooster, *ibid.*, **57**, 377 (1957); E. de Bore, *Recueil*, **84**, 609 (1965).

ammonium perchlorate (T-BAPC) as a supporting electrolyte, [DMT] $\sim 1 \times 10^{-3}$M, [T-BAPC] $\sim 1 \times 10^{-1}$M) is also shown.

The free radical anion was found to be quite stable at room temperature. The reaction P→G occurred with Li just as with Na, while in the case of K and Cs, the spectrum of P only decayed slowly without the appearance of the G-species.

The present results can, as a whole, be interpreted as the ion pair model presented for the analogous systems. McClelland[5] discussed the ion pair of fluorenon and benzophenone in terms of a point charge model and concluded that the potential minimum lies in the neighbourhood of C=O group. Atherton and Goggins[6] studied the ion pair of pyrazine and reached the conclusion that the potential minimum lies on the two nitrogen atoms for Li and Na, while for K and Cs the potential minimum is above the aromatic ring.

Our result that the reaction P→G occurs for Li and Na but not for K and Cs, is phenomenologically consistent with Hirayama's result, if one assumes that the disproportionation reaction occurs only when the alkali cation is fixed on one of the two carbonyl groups. There is however, one discrepancy in the spectrum of P-species when compared with the ESR structure. Thus the spectrum for K-ion pair is quite the same as for Li- and Na-ion pair, while from ESR, the K-ion pair should behave like Cs. This may be interpreted as follows. The similarity of the electronic spectrum suggests that the above three alkali metal cations are located at a C=O position. On the other hand, Cs^+ ion which is situated above the aromatic ring affects the electronic state in a different way. For K, however, the following situation may exist. The K-ion being larger than Li and Na, its potential minima may be more shallow than those of Li and Na. Then the K^+ ion may be able to move from one carbonyl group to the other. If the transfer frequency is $\lesssim 10^7$ sec^{-1}, the two states cannot be separately observed by ESR technique, the resulting hyperfine structure resembling that of Cs^+ ion pair. The absorption spectrum under such circumstances, however, is expected to correspond to one of the two equivalent configurations. If such is the case, the different feature of K^+ in ESR and in UV is very reasonable.

To sum up, the monoradical anion of DMT has tendency to undergo more or less the disproportionation reaction, and the reaction occurs more easily when the alkali cation is located and fixed on one of the two carbonyls.

Homolytic Chlorination of Aliphatic Compounds. III.[1] Photochlorination of 1-Substituted Propanes; Steric Effects

Masanori KOSUGI, Kohji TAKEUCHI and Toshihiko MIGITA

Department of Chemistry, Gunma University, Kiryu, Gunma

(Received May 26, 1969)

We have recently discussed the relative reactivities of aliphatic compounds in liquid-phase photochlorination and found that in CH_3–X type compounds inductive effect of the substituents X was the principal factor controlling the reactivities.[1-3] A linear free energy relationship was found between the reactivities of methyl hydrogens and Taft's σ^* constants[4] of the substituents X (X: CH_2Cl, CCl_3, CH_2CHCl_2, CH_2CMe_2Cl, CH_2CN).

In this note we wish to describe remarkable deviations from the relationship that were observed in photochlorination of 1-substituted propanes bearing ethyl groups on 1-position. The deviations are considered to be due to steric hindrance by the substituents. Table 1 lists the results obtained in the competitive photochlorination of the series of 1-substituted propanes.

$CH_3-CH_2-CEt_3$[c] 27 39	$CH_3-CH_2-CEt_2Cl$[c] 9.3 19	$CH_3-CH_2-CEtCl_2$[c] 4.4 7.2

a) The values are relative to the reactivity of a C–H bond of 2,2-dichloropropane and average of several runs.
b) See Ref. 2.
c) Carbon tetrachloride was used as solvent.

Table 1 shows that the successive introduction of chlorine substituent in 1-position of propane derivatives deactivates, and introduction of methyl groups in the 1-positions enhances the reactivities of C–H bonds on the 2- and 3-positions. This tendency is explainable in terms of inductive effects of chlorine and methyl substituents. However, when ethyl groups were introduced in 1-position, the reactivities of 2- and 3-position were found to be definitely lowered. For example, in substituted 1-chloropropane series, the reactivities of C–H bonds of 2- and 3-position decreases in the order:

$$CH_3CH_2CMe_2Cl > CH_3CH_2CH_2Cl > CH_3CH_2CEt_2Cl$$

Similar trends were observed in the other series of compounds. This is not expected from inductive effect of an ethyl group. Figure 1 shows the Hammett plot of the data in Table 1.

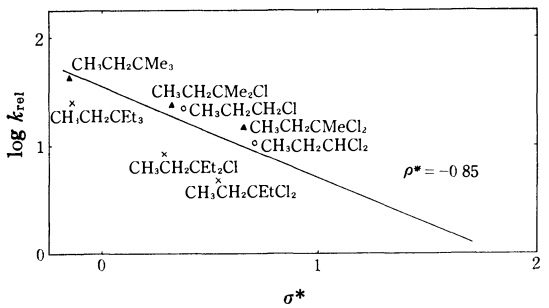

Fig. 1. Hammett plot for CH_3–X.
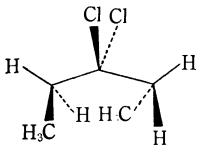
(σ^* values for X were estimated as described in the previous paper.)

The straight line in Fig. 1 represents the Hammett relationship obtained in our previous study,[2] ρ^* value being −0.85. As shown in Fig. 1, methyl groups in 1,1,1-triethylpropane (3,3-diethylpentane), 1-chloro-1,1-diethylpropane (3-chloro-3-ethylpentane) and 1,1-dichloro-1-ethylpropane (3,3-dichloropentane) are less reactive than expected from the relationship, while those of the other compounds have expected reactivities. This indicates that ethyl substituent on 1-position of propane derivatives causes the deactivation of the molecule, but methyl substituent does not.

Russell[5] reported that the methine hydrogens of 2,4-dimethylpentane and 2,2,4-trimethylpentane possessed unusually low reactivities toward the free or complexed chlorine atom, and explained that result in terms of the preferred conformation in which methine hydrogen atoms were protected from attack of the chlorine atom along the axis of C–H bond. A similar situation may be considered to be the deactivating factor in our cases. For example, for 3,3-dichloropentane, the presence of two chlorine atoms on 3-position will make the following conformation preferable.



In this conformation, one of methylene hydrogens and methyl hydrogens will protect each other from attack of the chlorine atom. In 2,2-dichlorobutane having normal reactivities, however, such crowding at the back of molecule would be reduced.

Experimental

Materials. *3,3-Dichloropentane.* A charge of 917.4 g of phosphorus pentachloride was dissolved in 344 g of diethylketone prepared from propionic acid.[6] After stirring overnight, the solution was refluxed for one hour. The reaction mixture was subjected to steam distillation followed by fractional distillation. 71 g of 3,3-dichloropropane was obtained, bp 132°C (lit[7] 127—135°C), n_D^{20} 1.442 (lit[7] 1.442).

3-Chloro-3-ethylpentane. Ethylmagnesium bromide solution prepared from 164 g of ethyl bromide and 36 g of magnesium in ether was added to 186 g of diethyl ketone. The usual work-up yielded 153 g of triethylcarbinol boiling at 69—72°C/50 mmHg (lit[8]

3. Et_3CCl

Since 3-chloro-3-ethylpentane inevitably contains a small quantity of olefin, chlorinations of the compounds were carried out in carbon tetrachloride in the presence of a small amount of bromine, in order to exclude the possibility of addition of chlorine to the olefin. Intramolecular reactivity pattern was found to be:

$$\underset{0.482}{CH_3}—\underset{1}{CH_2}—CEt_2Cl$$

Competitive chlorination with 1,2-dichloroethane was carried out to find the relative reactivity of a methyl group of 3-chloro-3-ethylpentane.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 3357—3359 (1969)

Relative Rate of Hydrogen Abstraction by the Triplet State of Phenanthraquinone

Kazuhiro MARUYAMA, Keiichi ONO and Jiro OSUGI

Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto

(Received May 30, 1969)

The ability of the triplet state of some carbonyl compounds such as benzophenone to abstract hydrogen from a suitable substrate is well known and recognized as a critical step in the photoreduction of the carbonyl compound.[1] The triplet state of the carbonyl compound is, therefore, radicalic in nature, and it is interesting to compare the relative ability of hydrogen abstraction by the triplet state with the case of other radicals.

By a preliminary experiment we found the great ability of photo-activated phenanthraquinone to abstract hydrogen from the hydrogen donor. The great ability to hydrogen abstraction of the photo-activated species is reflected in the fact that phenanthraquinone can be reduced easily when it is irradiated in benzene. Phenanthraquinone has a maximum absorption at 410—420 mμ, it may be correspond to the $n\rightarrow\pi^*$ absorption band because it can be reduced even if it is irradiated with visible light (any light in the UV region was excluded by ordinary glass and a thick water layer, 150 mm).

Since the rate of hydrogen abstraction is strongly inhibited in the presence of oxygen, it seems resonable to deduce that the triplet state of phenanthraquinone is responsible for the hydrogen abstraction.

The rate of the disappearance of phenanthraquinone dissolved in a large excess of a suitable substrate when it is irradiated follow the first-order kinetics for the concentration of phenanthraquinone.

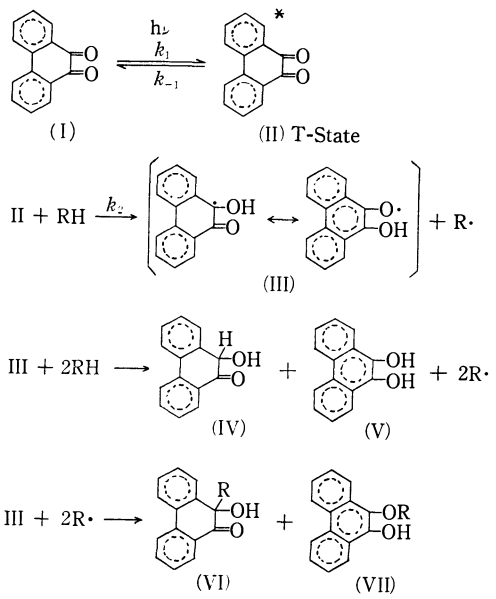
TABLE 1. RELATIVE RATE OF HYDROGEN ABSTRACTION BY THE TRIPLET STATE OF PHENANTHRAQUINONE

Substrate	20°C	40°C	60°C
Benzene	0.33	0.41	0.44
Toluene	1.00	1.42	1.85
Ethylbenzene	1.27	1.48	2.25
Cumene	2.33	2.65	2.36
t-Butylbenzene	0.42	0.48	0.53
Diethyl ether	3.44	3.59	—
Dioxane	2.47	2.48	2.58
Tetrahydrofuran	1.78	2.96	3.06
Methanol	0.92	1.14	1.32
Ethanol	2.16	2.42	2.75
2-Propanol	5.03	2.20	5.00

1) C. Walling and M. J. Gibian, *J. Am. Chem. Soc.*, **86**, 3902 (1964); G. S. Hammond and N. Turro, *Science*, **142**, 1541 (1963).

Therefore, the relative rate of hydrogen abstraction was determined from the plot of log(phenanthraquinone) against the time. Representative examples are shown in Fig. 1, while the relative rates obtained are tabulated in Table 1.

If we assume the steady-state concentration for the triplet state of phenanthraquinone, the pseudo-first-order kinetics can be formulated as follows:



$$\frac{d[I]}{dt} = -\frac{k_1 k_2[RH][I]}{k_{-1}+k_2[RH]} = -K[I] \qquad (5)$$

As to the relation between the rate of hydrogen abstraction and the structure of a substrate, we usually found the following order; *t*-C–H>*s*-C–H>*p*-C–H, as it was expected. However, the differences among them are rather small in this reaction. For example, the relative rates of hydrogen abstraction from different types of alkylbenzenes are,

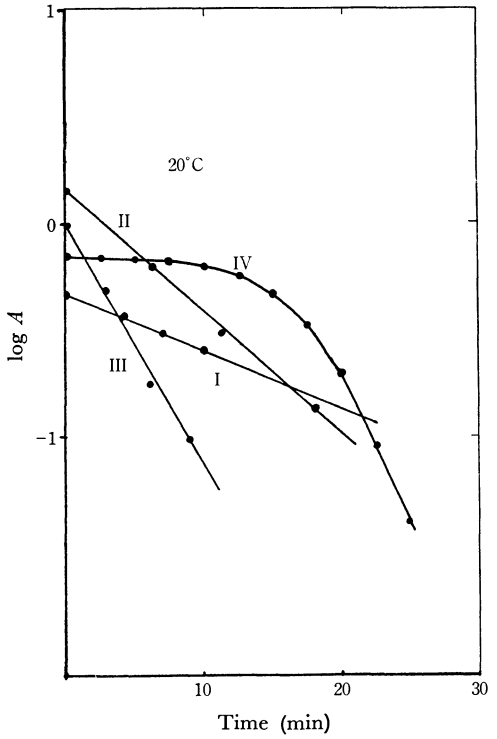


Fig. 1. I. methanol
II. ethanol
III. 2-propanol
IV. methanol in the presence of oxygen
(in this case sample was irradiated from the position of a half distance to light source through water layer for the sake of too slow decay to observe.)
A: Absorbance of phenanthraquinone

respectively: toluene (1.00 standard), ethylbenzene (1.27), and cumene (2.33) at 20°C. The relative rate of hydrogen abstraction of the triplet state of benzophenone has been investigated by Walling and Gibian,[2] who also determined the relative

Table 2. Relative reactivity of hydrogens of hydrocarbons toward various radicals[a] (per hydrogen)

Type of C–H	CH_3· 182°C	C_6H_5· 60°C	*t*-BuO· 40°C	Cl· 23°C	$(C_6H_5)_2CO$ (T)[b] 22°C	PQ (T)[c] 20°C	PQ (T)[c] 60°C	F.[d] 23°C
Primary	1	1	1	1	1	1	1	1
Secondary	7	8—9.4	8—15	3.6	4.6	1.9	1.8	1.2
Tertiary	50	44	44	4.2	9.9	6.3	3.8	1.4

b) C. Walling and M. J. Gibian, *J. Am. Chem. Soc.*, **86**, 3902 (1964).
c) This work. The values described in this table are not corrected for the abstraction of hydrogens on benzene ring and on β-carbon of side-chain, however, if corrected under the consideration of the values for benzene and *t*-butylbenzene, then the relative reactivity becomes; 1°:2°:3°=1:2.0:8.1 (20°C), 1:1.9:3.9 (60°C).
d) J. M. Tedder, *Quart. Rev.*, **14**, 339 (1960).

2) C. Walling and M. J. Gibian, *J. Am. Chem. Soc.*, **87**, 3361 (1965).

reactivity of C–H bonds to hydrogen abstraction. Such results are compared with others determined for several radicals in Table 2.

Since the relative selectivity to the different type of C–H bonds is a reflection of the reactivities of the radicals, we can conclude the high reactivity to hydrogen abstraction of the triplet state of phenanthraquinone (see Table 2). The reactivity is rather higher than that of benzophenone, and is roughly between that of the chlorine atom and that of the fluorine atom. Such a high reactivity is also indicated by the small temperature dependence of the relative rate and by the fact that benzene serves as a hydrogen donor.

Irregularities in the temperature dependence of the relative rate are observed in some substrates, especially 2-propanol and cumene.*1 The causes of these irregularity are not yet clear, but both the solvation and steric factors seem to be responsible. Concerning the photoreduced products of phenanthraquinone, a 1,2-addition compound of the VI type and a 1,4-addition compound of the VII type have been described in the literature.[3] However, we can always find phenanthrahydroquinone and its quinhydrone as the main products, while the addition compounds form only a small portion.

*1 These irregularities are not experimental errors, for they are reproducible.

Experimental

Materials and Irradiation. The phenanthraquinone was prepared by the oxidation of guaranteed-grade phenanthrene and was recrystallized from acetic acid three times (mp 207°C). With the exception of the alcohols, all the substrates used as solvents were dried over K-Na alloy and vacuum-sealed with a known amount of phenanthraquinone in an ordinary glass tube (8 mm in diameter, 50 mm long) by using the vacuum line. The alcohols were dried over calcium oxide. A sample was irradiated through water layer 400 mm thick and two ordinary glass layers 2 mm thick with 400-W high-pressure mercury arc lamp, while the decay of phenanthraquinone was followed spectrophotometrically at 420 mμ. The products were analysed by the TLC technique and were separated by means of a Florisil column.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 3359—3362 (1969)

Effects of Metal Chlorides on the Reaction of Acetylacetone with *n*-Butyryl Chloride*1

Tetsuro NOJIRI, Iwao HASHIMOTO,*2 Masatoshi MOTOI and Kiyotada MATSUI

Department of Industrial Chemistry, Faculty of Technology, Kanazawa University, Kodatsuno, Kanazawa

(Received June 13, 1969)

Aluminum chloride-catalyzed acylation reactions of active methylene compounds such as diethyl malonate[1] and ethyl acetoacetate[2] with acid chlorides have been reported. These reactions are reversible and accompanied by deacetylation and/or decarbethoxylation reaction to give di- and triacylated methane derivatives. This prompted us to extend our studies to the acylation of acetylacetone (Ia) and also to search for any effective condensing agents other than aluminum chloride.

The reaction conditions for acylation of Ia with *n*-butyryl chloride and the yields of main products, *n*-butyrylacetone (IIa) and di-*n*-butyrylmethane (IIb), are summarized in Table 1.

The treatment of Ia in the presence of 0.5 equivalent of aluminum chloride in nitrobenzene at 45°C produced only IIa in about the same yield irrespective of the amount of acyl chloride used, while a similar treatment carried out with 1 equivalent of aluminum chloride gave IIa in a higher yield, together with IIb. Therefore, failure in the formation of IIb is ascribed to the insufficiency of the condensing agent. The formation of IIa will be explained by the mechanism proposed by Doolan and Gore[3] for the Friedel-Crafts acetylation of

aluminum trisacetylacetonate (III) of aromaticity or Ia (which is regarded as converting into III during the reaction) with aluminum chloride followed by decomposition of butyrylated III during separation process. However, the formation of IIb may be explained if IIa (or Ib) derived either by the butyrylation of Ia without ring-closure or by the ring-opening before or after butyrylation of III is further acylated during the course of the reaction.

$$RCOCH_2COCH_3 \rightleftarrows RCOCHCOCH_3 \quad (\mathrm{COPr})$$
(I)
$$\rightleftarrows RCOCH_2COPr + CH_3COCl$$
(II)

a: R=$-CH_3$; b: R=$-C_3H_7$=$-Pr$

In the presence of 1 equivalent of aluminum chloride the yields of IIa and IIb obtained by using 2 equivalents of *n*-butyryl chloride were hardly changed by the reaction periods, 0.5 and 1 hr, but the extended reaction period of 24 hr led to an increased yield of IIb at the expense of IIa. This means that the acylation reaction of Ia proceeds rapidly to reach an equilibrium in 0.5 hr, after which IIa is converted slowly into IIb. The fact that the yields afforded at 45°C are the same as those at 30°C is due to the insufficiency of eth condensing agent for the reaction at 45°C. This is also proved by the fact that the higher yields are provided by increasing only the condensing agent to 2 equivalents. The good yields, however, were lowered more or less both by the fall of reaction temperature and by the increase of the condensing agent to 3 equivalents, but increased by using 3 equivalents of *n*-butyryl chloride. These findings suggest that there is a suitable amount of aluminum

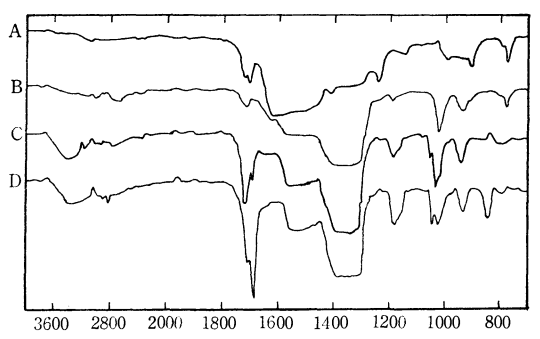

Fig. 1. Infrared spectrum of acetylacetone in nitrobenzene (A); with 0.3 (B); with 0.8 (C); and with 2 equivalents of $AlCl_3$ (D).

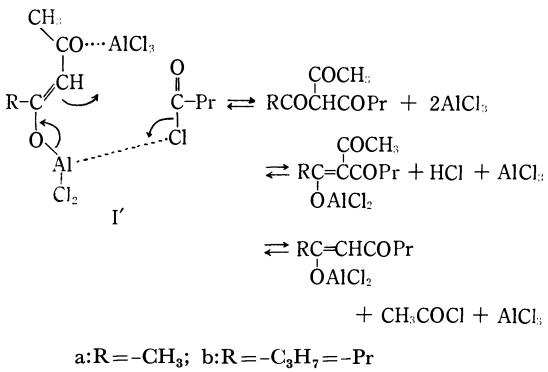
chloride for the acylation. Therefore, it can be expected that one half of the aluminum chloride enolizes one carbonyl group to form its enolate and the other half tends to coordinate with the other carbonyl group of the β-diketone. The infrared spectrum of Ia in the nitrobenzene solution of 2 equivalents of aluminum chloride shows strong carbonyl absorption peaks at 1710 and 1693 cm^{-1}, while such peaks are greatly reduced in intensity in the presence or absence of 0.3 equivalent of aluminum chloride in nitrobenzene (see Fig. 1). This is in substantial accord with expectations for the above experimental results. It follows then that it becomes difficult for the resulting species to close its chelate ring and it becomes susceptible to acylation with easy coordination of acyl chloride to the metal atom of enolate.

The above-mentioned fall of the yield caused by 3 equivalents of aluminum chloride suggests that the aluminum chloride competes with dichloroaluminum enolate for acyl chloride in order to coordinate, and that the reaction proceeds with liberation of aluminum chloride. The most predominant species, I'a and I'b, seem to react as follows:



a:R=$-CH_3$; b:R=$-C_3H_7$=-Pr

In order to compare the relative efficiencies of different metal chlorides several experiments were carried out using 1 equivalent of metal chloride, and the results in Table 1 were obtained. In nitrobenzene solution the order of decreasing efficiencies of metal chlorides on the basis of the yields is as follows:

$AlCl_3$, $TiCl_4$>$SnCl_4$>$ZnCl_2$, $FeCl_3$>$SbCl_5$>$CuCl_2$

Since this order differs from the one observed both for the Friedel-Crafts acetylation reaction of toluene[4] and for the addition of acid chloride to alkenes,[5] these reactions seem to be almost independent of the present acylation reaction.

Experimental

Materials. Acetylacetone[6] bp 136.5°C (lit bp 134—136°C), di-*n*-butyrylmethane[7] bp 82—84°C/11mmHg (lit[8] bp 101—102°C/20 mmHg), *n*-butyryl chloride,[9] bp 102°C, were prepared according to literature. *n*-Butyrylacetone was prepared from acetone and ethyl *n*-butyrate in yield of 20%, bp 55—56°C/11 mmHg (lit[6] bp 87—90°C/38 mmHg); copper chelate, mp 173—174°C (lit[10] mp 160—161°C), (Found: C, 52.80; H, 6.93%). Anhydrous aluminum chloride,[1] ferric chloride,[11] and cupric chloride[12] were prepared as described in a literature. Commercial anhydrous zinc chloride was used after fusion. The following commercial chemicals were distilled with exclusion of moisture: stannic chloride bp 113.5—113.8°C; titanium tetrachloride bp 135.5—136.5°C; antimony pentachloride bp 70.8—71.5°C/17 mmHg.

Acylation. As a typical example, to 10 m*l* of freshly distilled nitrobenzene in a 50-m*l* flask equipped with a calcium chloride tube was added the weighed amount of appropriate catalyst, and the mixture was cooled with ice water, then acetylacetone was added. After evolution of hydrogen chloride subsided the acid chloride was added to the resulting mixture with cooling, and then stirred vigorously with a magnetic stirrer.

Separation of the Product. The reaction mixture was put into crushed ice acidified with hydrochloric acid. After repeated extractions with ether, the aqueous layer was extracted again with ether next day, refluxed with ether for ten minutes, cooled, extracted with ether. The combined ether extract was washed with a saturated sodium bicarbonate solution, then extracted with 5% sodium hydroxide solution (four 15-m*l* portions) and with water. The combined sodium hydroxide and water extract, after acidification with hydrochloric acid, was extracted with ether repeatedly. The combined ether extract was dried over anhydrous sodium sulfate, then the solvent was removed by distillation through a column. The residue obtained was analyzed by gas-liquid chromatography. The organic layer containing nitrobenzene was steam distilled *in vacuo* to give neutral oily substance.

Gas-liquid Chromatographic Analysis. The analyses were carried out with gas-liquid chromatography on a Shimadzu GC-3AH, stainless steel column (0.3×200 cm; high vacuum silicone grease (30%) on Celite; He carrier (50 m*l*/min)). The thermostat temperature was 130°C for analyses of methyl propyl ketone, acetyl-

acetone, and *n*-butyrylacetone, 155°C for di-*n*-butyrylmethane. The amounts of products were determined from the apparent peak area by using acetophenone as an internal standard.

Infrared Spectra. The infrared spectra were obtained with a Model DS-301 Spectrophotometer of Japan Spectroscopic Mfg. Co., Ltd. The spectra were obtained by compensation method with nitrobenzene. For preparation of specimen, 0.2 g of acetylacetone was dissolved in 10 m*l* of anhydrous nitrobenzene containing a given quantity of aluminum chloride (0.08, 0.21, 0.54 g), then allowed to stand for 0.5 hr at 45°C. The spectrum characteristic of nitrobenzene containing aluminum chloride (0.54 g in 10 m*l*) exhibits the broad band in the 1367—1315 cm^{-1} region and the sharp band at 852 cm^{-1}.

The authors wish to thank Mr. Yoshitaka Itatani of the Faculty of Pharmacy, Kanazawa University, for elemental analyses.

Acid Anhydride as an Electron Scavenger in the Radiolysis of Tetrahydrofuran

Masao MATSUI and Masashi IMAMURA

The Institute of Physical and Chemical Research, Yamato-machi, Saitama

(Received June 16, 1969)

Nitrous oxide has been used as a specific electron scavenger in radiation chemistry. In the cases of aqueous and neutral alcoholic solutions of nitrous oxide, the yield of nitrogen produced seems to reflect the yield of the solvated electron. On the other hand, more nitrogen is produced than is to be expected from the decrease in $G(H_2)$ in the radiolysis of hydrocarbon solutions[1-6] with lower dielectric constants.

This excess nitrogen formation may be interpreted by assuming, for example, the reaction of nitrous oxide with the O^- formed by the reaction between nitrous oxide and the solvated electron. An example of the electron-scavenging process including no such side reaction will be presented in this paper.

Experimental

Tetrahydrofuran (THF) (G.R., Junsei Chem. Co.) and methyltetrahydrofuran (MTHF) (R.G., K & K Lab., Inc.) were carefully dried on metallic potassium and distilled. Maleic anhydride (G.R., Kanto Chem. Co., Inc.) was recrystallized from ether or benzene solutions. Succinic, glutaric (G.R., Tokyo Kasei Ind. Co.) and phthalic anhydrides (G.R., Wako Pure Chem. Ind. Co.) were used as received. The gas fraction at −196°C was determined on a conventional, calibrated gas burette and a Toepler pump. The hydrogen was determined by means of a heated palladium thimble, while the carbon monoxide and methane were analyzed gas-chromatographically by using a molecular sieve, 5A. Irradiation was carried out with a 10 kCi ^{60}Co source. The G-values were calculated on the basis of $G(Fe^{3+})=15.5$ and were corrected for the electron densities of THF and MTHF.

Results and Discussion

In the γ-radiolysis of liquid THF containing nitrous oxide, the amount of $G(N_2)$ always exceeds the decrease in $G(H_2)$.[7] The $G(H_2)$ decreases with an increase in the concentration of nitrous oxide, and $\Delta G(H_2)$ is seen to be 0.6 at the concentration of $(5-18)\times10^{-2}$M, where $G(H_2)$ is almost constant.

When the solutions of some aliphatic acid anhydrides in THF or MTHF were subjected to ^{60}Co-γ-irradiation at 20 ± 1°C and at a dose rate of $(0.81-0.89)\times10^{17}$ eV·ml^{-1}·min^{-1}, it was found that $G(H_2)$ decreases with an increase in the concentration of acid anhydride, eventually reaching an approximately constant value which is practically the same as that observed for the THF-N_2O system. A typical example is illustrated in Fig. 1, where maleic anhydride is the solute.

Carbon monoxide is one of the gaseous products from THF, its yield is relatively low and is not affected by the addition of nitrous oxide and other solutes.[8] The $G(CO)$ in the THF-maleic anhydride

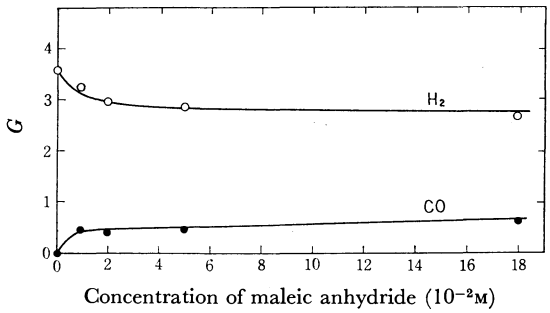

Fig. 1. Variation of $G(H_2)$ and $G(CO)$ with concentration of maleic anhydride.

system increases with an increase in the concentration of acid anhydrides. In Fig. 1, the difference between the total $G(CO)$ from the solution and that for pure THF, $G'(CO)$, is also plotted as a function of the concentration of maleic anhydride. It is interesting to note that the stationary value of $G'(CO)$ is approximately the same as that of $\Delta G(H_2)$. This fact presumably indicates that the precursor giving the additional carbon monoxide is that of hydrogen. It may be reasonable to assume that the solvated electron gives rise to the hydrogen formation in THF, as in MTHF[9] and alcoholic solutions,[10] *i. e.*, one solvated electron produces one hydrogen molecule. Therefore, it may be assumed that electrons react with the anhydrides to split off carbon monoxide, presumably by dissociative electron attachment.

Similar experiments have been carried out with a few other acid anhydrides. Succinic and glutaric anhydrides have been shown to behave much like maleic anhydride. Phthalic anhydride decreases the $G(H_2)$, but gives no additional carbon monoxide. The difference in reactivity is not clear at this moment.

The reactivities of these acid anhydrides towards electrons have been ascertained in experiments using the rigid matrix technique at 77°K. The optical absorption attributed to the matrix-trapped electron was found to diminish upon the addition of these additives.

An examination of the adaptability to other systems and of the mechanism of the carbon monoxide formation in the radiolysis of systems including acid anhydride is now in progress.

The authors wish to thank Dr. T. Shida for his rigid matrix work and Miss R. Maki for carrying out the gas-chromatographic analysis.

Reactions of Titanium Tetrahalides with Benzoylhydrazine

R. C. AGGARWAL and S. K. SINGH

Chemistry Department, Lucknow University, Lucknow, India

(Received January 14, 1969)

As there has been no previous work on the reactions of titanium tetrahalides with hydrazine-derivatives containing carbonyl group such as benzoylhydrazine, it was considered of interest to study the reactions of these Lewis acids with benzoylhydrazine and the results obtained are described in this communication.

Experimental

Titanium tetrahalides and organic solvents used in the present work were purified and made anhydrous employing the standard literature methods. Benzoylhydrazine was prepared from the reaction of ethyl benzoate and hydrazine hydrate and purified by crystallization from benzene, mp 111°C.[1)]

Preparation of Complexes. *i) Tetrafluorobis(benzoylhydrazine)titanium(IV).* Solution of benzolyhydrazine (1—5%) in tetrahydrofuran was added gradually with vigorous shaking to the clear solution of titanium tetrafluoride in the same solvent. The homogeneous solution was refluxed for 30 min and the solvent removed till a saturated solution was obtained. Addition of carbon tetrachloride to the above solution yielded a yellow-orange precipitate, which was filtered, washed with a mixture of tetrahydrofuran and carbon tetrachloride and dried under reduced pressure. The complex was recyrstallized from tetrahydrofuran-carbon tetrachloride mixture.

The compound is readily hydrolyzed on exposure

1) T. Curtius, *J. Prakt. Chem.*, **50**, (2), 278 (1894).

to atmosphere.

ii) Dichlorobis(benzoylhydrazino)titanium (IV). 40 mmol of titanium tetrachloride, 20 mmol of benzoylhydrazine and 50 ml of chloroform were taken in a flask and the suspension refluxed for several hours in an inert atmosphere. The brown solid product formed was filtered, washed with chloroform till free from excess amount of Lewis acid and dried under vacuum. The complex was recrystallized from the tetrahydrofuran-chloroform mixture. The complex is hygroscopic and soluble in tetrahydrofuran.

Dibromobis(benzoylhydrazino)titanium(IV) and diiodobis(benzoylhydrazino)titanium(IV) complexes were prepared in the same way as the chloro complex; iodo complex took a comparatively longer time for drying under reduced pressure. These complexes were also recrystallized form the tetrahydrofuran-chloroform mixture. These complexes are hygroscopic and soluble in tetrahydrofuran too.

The complexes thus prepared were all diamagnetic and the analytical results and general behaviour of the complexes are given in Table 1.

Discussion

An examination of Table 1 shows that titanium tetrafluoride forms adduct of the composition, $TiF_4 \cdot 2BZH$, while other tetrahalides undergo condensation reaction, yielding products of the general formula, $TiX_2(BZ)_2$. When a mixture of benzoylhydrazine and titanium tetrachloride (excess) was kept at 25°C for several days, an unstable 1 : 2 adduct was obtained which lost hydrogen chloride slowly at room temperature but rapidly on heating around 80°C yielding eventually the same condensation product as described above.

The insolubility of titanium tetrahalide complexes of benzoylhydrazine in common organic solvents seriously limits the number of physical measurements that could be carried out for establishing their structures.

The assignment of important absorption bands

Table 1. Analytical data and general behaviour of the complexes

Composition of the solid reaction product	% Found		% Calcd		Colour	Temperature of decomposition (°C)
	Ti	Halogen	Ti	Halogen

in the infrared spectra of benzoylhydrazine and its complexes with titanium tetrahalides has been made on the basis of the reported infrared spectral studies of the titanium tetrahalide complexes of similar bases.

Infrared Spectral Discussion. The spectrum of $TiF_4 \cdot 2BZH$ gives a very broad band in the ν(C=O) region. If 1642 cm^{-1} is taken as the centre of the broad band, a negative shift is obtained in this band indicating coordination through oxygen. A positive shift in one of the N–H stretching bands also supports coordination through oxygen.

A doublet in the spectrum of $TiCl_2(BZ)_2$ with maxima at 1632 and 1629 cm^{-1} and broad bands in the spectra of $TiBr_2(BZ)_2$ and $TiI_2(BZ)_2$ with maxima at 1655, 1650 cm^{-1} and 1658, 1642 cm^{-1} respectively are assigned to amide I. The negative shift in C=O stretching frequency in the complexes indicates coordination through oxygen.

An examination of Table 2 shows that there occurs a decrease in the number of N–H stretching bands in the spectra of above complexes as compared with the parent base. This is probably due to the change of $-NH_2$ group into $>$N–H group as a result of Ti–N bond formation. The appearance of two ν(N–H)[2] bands in acetylbenzoylhydrazine and dibenzoylhydrazine supports the above view point. This is further supported by the disappearance of the $\delta(NH)_2$[2,3] band in the spectra of the complexes.

Since M–O[4,5] and M–N[6] stretching vibrations for a number of transition metal complexes occur in 400—500 cm^{-1} region, it is difficult to assign ν(Ti–N) and ν(Ti–O) unambiguously in the complexes.

Rivest and Jain[7] have assigned ν(Ti–O) mode in the complexes, $TiCl_4 \cdot CH_3CONH_2$ and $TiCl_4 \cdot CH_3CONEt_2$ at 505 and 507 cm^{-1} respectively. The bands occurring in 510—520 cm^{-1} region in the benzoylhydrazine complexes may probably be due to ν(Ti–O) and the bands appearing at 552, 545, and 535—628 cm^{-1} in $TiCl_2(BZ)_2$, $TiBr_2(BZ)_2$ and $TiI_2(BZ)_2$ respectively are tentatively assigned to ν(Ti–N).

The occurrence of ν(Ti–X) in the complexes in the octahedral region[8,9] indicates an octahedral geometry of the complexes.

The infrared spectral studies thus show that BZH acts as a monodentate ligand in $TiF_4 \cdot 2BZH$ coordinating through oxygen and as a bidentate ligand in $TiX_2(BZ)_2$ (X=Cl, Br and I) involving nitrogen, in addition to oxygen, in bond formation with titanium. Two five-membered rings are thus formed around the titanium atom in these complexes.

IR spectral studies also show all the complexes to be octahedral in geometry.

The authors are grateful to the Council of Scientific and Industrial Research, New Delhi, for the award of Junior Research Fellowship to one of them (S.K.S.) and to Dr. M. Onyszchuk, McGill University, Montreal, for his kind help in the form of chemicals and equipments.

SHORT COMMUNICATIONS

Total Synthesis of (−)-Artemisin

Masao NAKAZAKI and Koichiro NAEMURA

Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka

(Received September 5, 1969)

The key compound chosen in our total synthesis of (±)-artemisin (**1**)[1] was racemic 3-oxo-8β(H), 11α(H)-eudesm-4-en-8,13-olide (**2**); and its dextrorotatory modification mp 142°, $[\alpha]_D^{18}$ +19.4° was derived from (+)-isoalantolactone or (+)-alantolactone as described in our preceding communication.[2] Since this (+)-**2** from the natural sources was converted into (−)-artemisin,[2] any optically active intermediate compound between (+)-**2** and isoalantolactone or alantolactone could be the relay substance in the total synthesis of natural (−)-artemisin.

Our choice was unsaturated ketoester (**3**), preparation of which is dealt in the present communication.

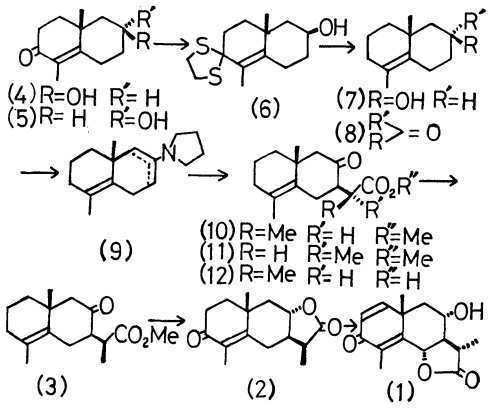
To make unsaturated ketoester (**3**) by enamine alkylation required the preparation of unsaturated ketone (**8**), which was accomplished following the general synthesis route employed previously.[1]

From the reaction mixture of Robinson's annelation of *cis*-2-methyl-4-acetoxycyclohexanone with diethylaminopentan-3-one methiodide in the presence of sodium methoxide, *cis*-bicyclic ketoalcohol (**4**), mp 101°C and its *trans* form (**5**), mp 82—83°C in ratio of 7 : 3, were isolated.

To remove the keto group without affecting the double bond, *cis*-ketoalcohol (**4**) was first converted into thioketal (**6**) with ethanedithiol and BF_3-etherate.

Desulfurization of thioketal (**6**) with sodium in liquid ammonia[3] gave unsaturated alcohol (**7**), mp 72°C which was then oxidized with chromic acid anhydride in acetone[4] to the requisite unsaturated ketone (**8**), bp 130—132°C/15 mmHg.

The oily enamine (**9**) obtained by refluxing unsaturated ketone (**8**) with piperidine in benzene solution, was dissolved in methanol and treated with ethyl α-bromopropionate. After being decomposed with water, the reaction mixture was



saponified to furnish a mixture of esters, bp 120—125°C/0.1 mmHg. Inspection of thin layer and vapor chromatograms revealed the presence (1 : 1) of the two epimers (**10**) and (**11**) differing at C_{11}-center, whose chromatography on silica gel led to isolation of the unsaturated ketoester (**10**) as a fast moving elute.

Infrared and NMR spectra data together with vapor phase chromatogram established the identity of this unsaturated ketoester (**10**) with the intermediate (**3**) from the natural sources.

In order to complete the total synthesis, there only remained the optical resolution which was accomplished by working with brucine as the resolving agent.

Crystallization from methanol-water of brucine salt of acid (**12**) obtained by alkaline hydrolysis of **10** furnished the salt, $[\alpha]_D^{22}$ −15.7° (*c* 0.5, ethanol). The acid regenerated from the salt was esterified with diazomethane to ester (**3**), bp 118—121°C/0.1 mmHg, $[\alpha]_D^{22}$ +42.9° (*c* 0.3, in ethanol) (**3** from the natural sources: bp 116—122°C/0.1 mmHg, $[\alpha]_D^{18}$ +41.4°).[2] Comparison of their infrared and NMR spectra established their identity which was further supported by a mixed melting point determination of their semicarbazone, mp 165—166°C.

(−)-Artemisin has been obtained therefore by total synthesis.

The Crystal Structures of Pentaglycerol and Neopentylglycol

Etsuko NAKANO, Ken HIROTSU and Akira SHIMADA

Department of Chemistry, Faculty of Science, Osaka City University, Sumiyoshi-ku, Osaka

(Received August 9, 1969)

We have made a structural investigation of neopentylglycol $(CH_3)_2C(CH_2OH)_2$ and pentaglycerol $CH_3C(CH_2OH)_3$ in order to elucidate the molecular structure and hydrogen bonds in the crystal and to make a comparison with pentaerythritol $C(CH_2OH)_4$.[1-4]

For pentaglycerol, three-dimensional intensity data were collected by the photographic method. In these photographs, diffuse scatterings are observed in addition to Bragg reflections. If we disregard the diffuse scatterings, the photographs show the same space group and almost the same cell size and intensity distribution as pentaerythritol. This indicates that the crystal structure is similar to that of pentaerythritol. In the crystal of pentaerythritol, each molecule is required by space-group symmetry to be located at the special position of a unit cell with the molecular symmetry of $\bar{4}$. In the case of pentaglycerol, on the other hand, the molecule can not have such a high symmetry, since only three CH_2OH groups exist in a molecule. Thus, it would be necessary to assume some disordered arrangement of molecules in the crystal of pentaglycerol. A more detailed analysis of the structure is now in progress.

The crystal structure of neopentylglycol was established; it will be mentioned below. Specimens suitable for X-ray work were obtained from the benzene solution in the form of colorless needles elongated along the *a* axis. The crystals are monoclinic, with four molecules in a unit cell with the dimensions of $a=6.01$, $b=10.91$, $c=10.18$ Å, and $\beta=100.0°$. The space group was found to be $P2_1/n$. The density calculated was 1.05 g·cm^{-3}. Since the crystal was fairly volatile, samples were sealed into glass capillaries. Weissenberg intensity data were collected by means of Cu$K\alpha$ radiation on the *a* axis for from zero to the fourth layer, and on the *c* axis for from zero to the fifth layer. 808 reflections were observed; 105 were too weak to be measured.

From the three-dimensional sharpened Patterson function, molecular orientation and intermolecular O- - -O (the hydrogen bond) vectors were established by interpreting vectors from 2.4 to 3.0 Å around the point of origin. Using the 0kl data, an approximate structure was obtained by the trial method, the molecular orientation being taken into consideration. Refinements were carried out by means of a block-diagonal least-squares method, and the discrepancy index, R was reduced to 18.5%, excluding unobserved reflections.

The partial structure–$C(CH_2OH)_2$ group in neopentylglycol is the same as that in pentaerythritol. The average bond distance is 1.56 Å for C–C and 1.45 Å for C–O. The average bond angle is 109.5° for C–C–C and 110.9° for C–C–O. The mode of packing of the molecules in the crystal and the electron density can be seen in Fig. 1. Two intermolecular separations, O(1)- - -O(2) of 2.65 Å and O(1)- - -O(2) of 2.72 Å, correspond to hydrogen bonds which link the molecules in infinite ribbons along the *a* axis. It is also interesting that the arrangement of four hydrogen bonds around the center of symmetry is similar to that of pentaerythritol. A detailed account of this work will be published in the near future.

The Crystal Structure of Pyromellitic Acid Dihydrate (Benzene-1,2,4,5-tetracarboxylic Acid Dihydrate)

Fusao TAKUSAGAWA, Ken HIROTSU and Akira SHIMADA

Department of Chemistry, Faculty of Science, Osaka City University, Sumiyoshi-ku, Osaka

(Received August 11, 1969)

Since the pyromellitic acid dihydrate, $C_6H_2(COOH)_4 \cdot 2H_2O$ has four –COOH and two H_2O, it is of interest to elucidate the steric hindrance of adjacent carboxyl groups and the hydrogen bond formation in this crystal and to compare the structure of this compound with those of other similar carboxylic acids.

The crystal of this compound is triclinic, with cell dimensions of $a=10.05$, $b=6.46$, $c=5.44$ Å, $\alpha=74.5°$, $\beta=112.2°$, and $\gamma=77.3°$. The space group is $P\bar{1}$, and the unit cell contains one molecule. The calculated density is 1.64 g/cm³, while the observed value obtained by the flotation method is 1.63 g/cm³. The intensities were estimated visually from Weissenberg photographs around b and c axes taken with Cu$K\alpha$ radiation; 1070 were recorded, but of these 148 were too weak to be measured.

The crystal structure was derived by a consideration of Patterson maps and was confirmed by three-dimensional Fourier syntheses. The positional and thermal parameters of each atom thus obtained were refined by the block-diagonal least-squares method. The R factor is 0.09 at the present stage.

The projection of the crystal structure along the c axis and the molecular configuration of the pyromellitic acid are shown in Figs. 1 and 2 respectively. The average C(ring)–C(ring) distance is 1.39 Å, and the average C(ring)–C(carboxyl) distance is 1.49 Å. One carboxyl group is twisted by 21.4°, and the other is twisted by 74.5°, out of the plane of the benzene ring. The C–O(H) and C=O distance differ significantly from each other, the average values being 1.31 and 1.21 Å respectively. Four types of hydrogen bonds, with the average O–H···O distance of 2.72 Å, form a three-dimensional network, as shown in Fig. 1. Each molecule is joined to two other molecules through hydrogen bonds around the center of symmetry, forming an endless chain in the [1 $\bar{1}$ 1] direction. Water molecules are arranged on the plane parallel to [1 1 0], which hold the chains together by means of hydrogen bonds. A detailed account of this work will be presented in the near future.

An ESR Study of Photochemical Intermediates from Rigid Organic Solvents Containing Benzene*1

Tadayoshi TANEI*2 and Hiroyuki HATANO

Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto

(Received March 10, 1969)

The present work was undertaken in order to examine a photochemical intermediate from benzene using rigid organic matrices: EPA (a mixture of E: diethyl ether, P: isopentane, and A: ethyl alcohol, 5 : 5 : 2, v/v), diethyl ether, and isopentane. The UV irradiation of EPA, diethyl ether, and ethyl alcohol at 77°K, in wavelength regions from approximately 2200Å to 2600Å, gave ESR spectra which can be ascribed to the ethyl and/or the ethanol radical, even when a solute was not added. On the contrary, the UV irradiation of isopentane under similar conditions did not show any ESR spectrum. However, the UV irradiation of isopentane containing benzene in concentration regions from 10^{-1} to 10^{-2} M gave two kinds of ESR spectra, ascribed to phenyl and *tert*-pentyl radicals. This reaction may be interpreted as a sensitized photodecomposition brought about by an excitation and/or a photolytic degradation of benzene.

In previous papers,[1,2] we reported a study of photochemical intermediates from benzene in the solid state and in an adsorption state on silica gel using the electron spin resonance technique. Migirdicyan[3] reported the sensitized photodecomposition of a methylcyclohexane rigid matrix by the addition of benzene, but they did not observe a spectrum arising from benzene.

In the present work, we attempted to examine a photochemical intermediate from benzene using rigid organic matrices of EPA, diethyl ether, ethyl alcohol, and isopentane, which have been used for the study of photochemical intermediates by electronic spectroscopy since the pioneering work by Lewis and Lipkin.[4] From the present experiments, it was found that the rigid matrices of EPA, diethyl ether, and ethyl alcohol not containing benzene were decomposed by UV irradiation in the wavelength regions longer than approximately 2200Å, and that one could not observe a photochemical intermediate from benzene because of the superposition of spectra arising from the solvents. On the other hand, it was confirmed that the UV-irradiated isopentane matrix gave no ESR signal, and that, when benzene was added to isopentane, the photodecomposition of its "isopentane-benzene mixture" was induced to exhibit ESR spectra attributable to phenyl and *tert*-pentyl radicals. This phenomenon can be interpreted as being an example of the sensitized photodecomposition of isopentane, accompanied by the photodegradation of benzene.

Experimental

Materials. An EPA (E: diethyl ether, P: isopentane, A: ethyl alcohol) solvent was prepared in the mixing ratio of 5 : 5 : 2 v/v. The diethyl ether was Nakarai Chemicals' pure grade; it was dried over calcium chloride in a nitrogen atmosphere and then passed through an activated alumina column. Isopentane from Nakarai Chemical Co., Ltd., Kyoto, was distilled in the presence of metallic sodium; no further purification was made. Ethyl alcohol (Special Grade) from the Nakarai Chemical Co., Ltd., was purified by the following procedure; it was distilled in the presence of sulfuric acid, and then its distillate was boiled for several hours in the presence of silver nitrate before further distillation. The distillate was distilled over calcium oxide and passed through a newly-activated silica gel column. The final purification was performed using a Widmer refining column. These solvents were purified immediately before use and were kept in the dark. The benzene was Merck's spectro-grade, which had been purified according to the method described in a previous paper.[2] The EPA, ethyl alcohol, and isopentane solutions containing benzene were prepared in the concentration regions from 10^{-1} to 10^{-4} M.

The solution was added to a 4-mm-i.d. quartz ampoule by the use of a syringe, and was degassed through repeated freezing and thawing on a vacuum line at the temperature of liquid nitrogen.

Irradiation. The UV irradiation was performed at the temperature of liquid nitrogen using either a Toshiba 400 W high-pressure mercury lamp or a low-pressure mercury lamp (germicidal lamp). In some

experiments, mainly in the case of a high-pressure mercury lamp, we used a UV filter, either Toshiba UV-25 or UV-D25. γ-Irradiation was carried out with Co-60 (750 Ci) at the temperature of liquid nitrogen.

ESR Measurements. The ESR spectra were recorded using a Varian V-4560 EPR spectrometer operating at X-band frequency and with a 100 kc/sec field modulation, over the temperature region from the temperature of liquid nitrogen to about 130° K. Temperature control was done by means of a Varian variable-temperature accessory.

Results and Discussion

The UV irradiation of the matrices of EPA, diethyl ether, and ethyl alcohol containing no benzene gave ESR signals which can be ascribed to ethyl and to ethanol radicals. This phenomenon made it impossible to observe the ESR spectra from benzene in these rigid solvents. Namely, the UV irradiation of both EPA, and diethyl ether rigid matrices containing no benzene showed a prominent four-line spectrum, with a splitting value of about 27 gauss and an intensity ratio of approximately 1 : 3 : 3 : 1 at 77°K, as is shown in Fig. 1(a) and Fig. 2(a). This spectrum was easily observed just after UV irradiation, but it completely disappeared within about 20 hr when the sample was kept at the temperature of liquid nitrogen.

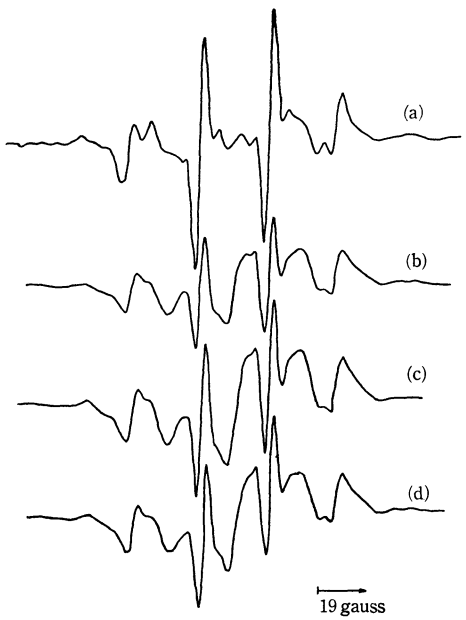

Fig. 1. ESR spectra from UV-irradiated EPA, and "EPA-Benzene" mixtures at 77°K. UV-Irradiation was performed for 15 min at liquid nitrogen temperature. Alphabetical marks correspond to the following samples: (a) EPA, (b) EPA containing benzene in the concentration of 1×10^{-4} M, (c) EPA containing benzene in 1×10^{-3} M, and (d) EPA containing benzene in 1×10^{-2} M.

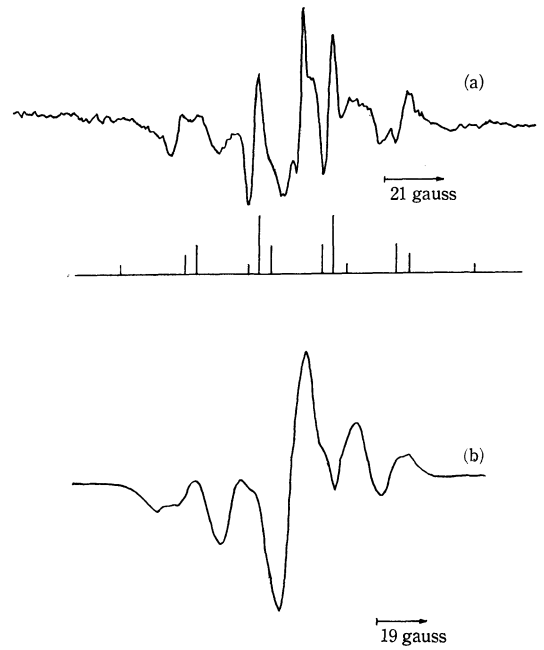

Fig. 2. (a) ESR spectrum from UV-irradiated diethyl ether at 77°K. UV-Irradiation was carried out at liquid nitrogen temperature for 15 min. The lines in the drawing below the spectrum represent the position and the intensity of the resonance lines expected for the radical ($CH_3\dot{C}H_2$). (b) ESR spectrum from UV-irradiated ethyl alcohol at 77°K. UV-Irradiation was performed at liquid nitrogen temperature for 15 min.

The present four-line spectrum can be ascribed to the ethyl radical,[5,6] which is theoretically expected to show four isotropic resonance lines in a reconstruction based on the two α-H with the coupling constant of 22 gauss, and the three β-H with the coupling constant of 27 gauss. The UV irradiation of ethyl alcohol gave a five-line spectrum with a splitting value of about 20 gauss. The five-line spectrum can be ascribed to the ethanol radical($CH_3\dot{C}HOH$) with the α-H coupling constant of 22 gauss and the β-H coupling constant of 27 gauss. The UV irradiation of an "EPA-benzene mixture," which contains benzene in the concentration regions from 10^{-1} to 10^{-4} M, produced ethyl radicals overlapping with ethanol radicals, as is shown in Fig. 1(b)—(d), but no photochemical intermediates from benzene could be observed.

Isopentane-Benzene Mixture. A prolonged irradiation (120 min) of the isopentane rigid matrix did not show any ESR signal, in contrast with the

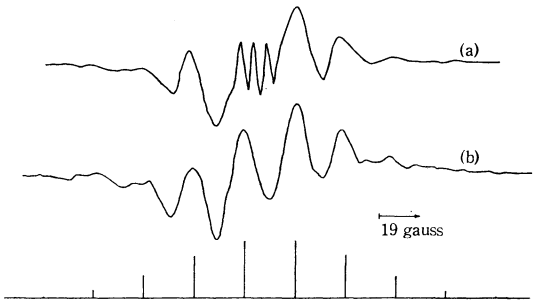

Fig. 3. ESR spectrum from UV-irradiated "isopentane-benzene mixtures," (a), and γ-irradiated "Isopentane," (b), at 77°K. The lines in the drawing below the spectrum represent the position and the intensity of the resonance lines expected for the radical ($(CH_3)_2\dot{C}CH_2CH_3$). UV-Irradiation was performed for 30 min at 77°K. γ-Irradiation was carried out at 77°K using Co-60 (750 Ci) under the following condition: dose rate of 6×10^5 r/hr, and total dose of 3×10^5 R.

cases of EPA, diethyl ether, and ethyl alcohol.

The UV irradiation of the "isopentane-benzene mixture," which contained benzene in the concentration region from 10^{-1} to 10^{-2} M, gave an apparent eight-line spectrum, with a splitting value of about 23 gauss, in addition to three other central lines with approximately a 6-gauss separation, as is shown in Fig. 3(a). On gradually raising the temperature of the above "isopentane-benzene mixture" from the temperature of liquid nitrogen up to about 113°K, the eight-line spectrum showed a rapid decay, and then the three central lines changed to a six-line spectrum with approximately a 6-gauss separation, as is shown in Fig. 4.

The apparent eight-line spectrum showed a very good accordance with the eight-line spectrum observed from γ-irradiated isopentane at 77°K, as is shown in Fig. 3(b). This eight-line spectrum seems to be coincident with that from γ-irradiated *t*-pentyl iodide which was previously reported by

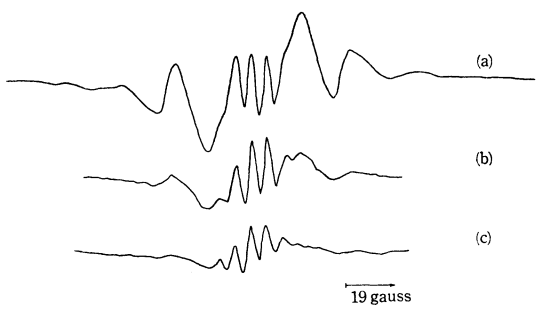

Fig. 4. Change with increasing temperature in ESR spectrum shown. Spectra were recorded at the temperature of 77°K (a), 103°K (b), and 113°K (c).

Ayscough and Thomson.[7] Accordingly, the apparent eight-line spectrum in the present "isopentane-benzene mixture" can be ascribed to the *t*-pentyl radical($(CH_3)_2\dot{C}CH_2CH_3$), in which one estimates the hyperfine coupling constant of both six protons of two methyl groups and the one proton of the CH_2 group, and that of another proton of the CH_2 group, at 23 and 46 gauss respectively.

The six-line spectrum observed after the disappearance of *tert*-pentyl radicals is in complete accordance with that of the tentatively-assigned phenyl radical which was previously observed in UV-irradiated polycrystalline benzene at 77°K.[1] Furthermore, it was observed that phenyl radicals did not induce any abstraction reaction of hydrogen atoms from a surrounding isopentane mloecule. This fact seems to suggest that phenyl radicals remaining after the disappearance of *tert*-pentyl radicals may be trapped on the surface of the quartz ampoule. The present experiment failed to observe the formation of benzene cation radicals such as have already been observed upon the UV irradiation of both benzene adsorbed on silica gel[2] and that dispersed in an acidic matrix.[8] This is probably because the isopentane matrix could not provide a site suitable for trapping both benzene-ion radicals and electron ejected from benzene.

An Aspect of the Mechanism of the Photodecomposition of Isopentane. From the above-described experiments, it is evident that the presence of benzene is responsible for the photodecomposition of isopentane. The photolysis of isopentane can be explained in terms of the energy transfer from an excited benzene ($^3B_{1u}$) to isopentane molecules, while one may also suppose the possibility of the photodecomposition of benzene dispersed in the isopentane matrix bringing about the abstraction reaction of hydrogen atoms from the surrounding isopentane molecules. On analogy with the behavior of benzene in the isopentane matrix, one may suppose that the photodegradation of rigid matrices of diethyl ether and ethyl alcohol is induced through an energy transfer from aromatic impurities unremoved by the present purification.

From the above experimental results, we may conclude that: (1) EPA, diethyl ether, and ethyl alcohol are not inert to UV light in the wavelength regions longer than approximately 2200Å, probably because of the presence of unremoved aromatic impurity, and this leads to the failure to observe intermediates from benzene, and (2) isopentane is inert to UV light in the wavelength regions

longer than approximately 2200Å. The UV irradiation of the "isopentane-benzene mixture" induced the sensitized photodecomposition of isopentane and produced phenyl radicals, and *tert*-pentyl radicals from benzene and isopentane respectively.

Infrared Absorption Spectra of Urea-formaldehyde Initial Condensation Products. II. Dimethylurea

Yoshiyuki MIDO*1 and Hiromu MURATA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda, Hiroshima

(Received April 10, 1969)

The infrared absorption spectra of symmetric and asymmetric dimethylurea have been observed in the 4000—400 cm^{-1} region. In order to investigate the amide characteristic bands, the spectra of $CH_3NHCONHCH_3$ and $CH_3NDCONDCH_3$ have also been measured in the solid and liquid states, and in solutions. The in-plane normal vibrations of these molecules have been calculated. As a result of our measurements and calculations, it has been found that: (1) The contribution of the polar resonance structure of asymmetric dimethylurea is small compared with that of symmetric dimethylurea, and molecular geometry contributes to the formation of hydrogen bonding. (2) From the position of the amide bands, the molecular configuration of symmetric dimethylurea is the "*trans*" form as well as that of methylurea. (3) The results of normal coordinate analysis show a good agreement with that observed within an average deviation of 2.6%

In a previous paper,[1] we reported the vibrational spectra of methylurea (MMU) as one of urea-formaldehyde initial condensation products; we also undertook a normal coordinate analysis of this molecule in order to determine the vibrational assignmments. The polar resonance structure of the H-N-C=O system has also been discussed on the basis of the assignments specified for the amide characteristic bands.[2]

As a continuation of that research, we have now extended our study to the vibrational spectra of symmetric and asymmetric dimethylurea (referred to as *s*-DMU and *a*-DMU). The observed bands of DMU have been assigned by comparing the spectra of MMU and by observing the changes in spectra according to the state of the aggregation in which the substance has been measured. The normal coordinate treatments of *s*-DMU have been made in order to give a basis for the assignments.

Becher and Griffel have observed the infrared spectra of *s*-DMU[3] and methylenediurea[4] in the NaCl region, and some of the spectral bands have been assigned empirically.

Experimental

Materials. The *s*-DMU was obtained from Wako Pure Chemical Industries, Ltd., and was purified by recrystallization from a chloroform or an acetone solution. It had a mp of 106°C (lit,[5] 107°C). The *a*-DMU was synthesized by adding dimethylamine to nitrourea,[6] and it was purified from a chloroform solution. It had a mp of 181.5—182.2°C (lit,[5] 182°C).

The *N*-deuterated compounds of these samples were obtained from simple exchange with D_2O at room temperature; the excess of D_2O was evaporated in vacuum after the exchange reaction had been completed.

Infrared Spectra. The infrared spectra were measured in the 4000—400 cm^{-1} region with a Hitachi EPI-2G Infrared Grating Spectrophotometer. The spectrometer was calibrated with standard polystyrene film H_2O vapor. The spectra of *s*-DMU and *s*-DMU-d*2 were measured in the solid and liquid states and in so-

lutions. The solid-state spectra were taken in a KBr disk and in Nujol mull;[*3] they are shown in Fig. 1. The liquid-state spectra in a capillary heated at 107—110° C and the spectra of the sample cooled from the molten liquid in a capillary (the *quenched* sample) are shown in Figs. 3 and 4, in which the *quenched* sample spectra differ from the solid-state ones. The spectra of *a*-DMU and *a*-DMU-d were also measured in the solid state and in solutions; they are shown in Fig. 2. The spectra of *s*- and *a*-DMU dissolved in H_2O and D_2O are shown in Figs. 6 and 7 respectively. The observed frequencies are summarized in Tables 5 and 6.

[*3] The preparations of KBr disk exchanged the deuterium of d-compounds for normal hydrogen and weakened the strength of ν(ND), but in Nujol mull such a phenomenon was observed little.

Normal Coordinate Treatment

The frequency calculations for *s*-DMU were made by means of Wilson's *GF* matrix method.[7] The *trans* symmetric plane model (C_{2v}) was adopted except for two hydrogen atoms attached to each of the two methyl carbon atoms (C')*4 (see Fig. 5). The normal vibrations are classified into the 23 in-plane modes (A_1 : 12, B_2 : 11) and the 13 out-of-plane modes (A_2 : 6, B_1 : 7), the A_2 species of which is infrared-inactive. The normal coordinate treatment was made for the in-plane vibrations using the internal coordinates shown in Fig. 5 and the symmetry coordinates given in Table 1. The potential function used is that of the Urey-Bradley type,[8] and the structural parameters (Table 2)*5 and the force constants (Table 3) are the same as those of the MMU transferred directly from urea,[9] *N*-methylacetamide,[10] and *N*-methylformamide.[11] The observed and calculated frequencies are listed in Table 4, together with the main potential energy distributions (P.E.D.).[12] The frequencies show a good agreement with the observed values (an average deviation of 2.6%),*6 indicating that the transferabilities of the force constants and the potential function are sufficient for this molecule. However, some of the calculated values deviate considerably from the observed values. The deviations of $\delta_s(CH_3)$, $\delta_a(CH_3)$, $\delta_r(CH_3)$, and $\nu(C'N)$ for *s*-DMU are similar to those for MMU;[1] this probably

means that the corresponding force constants are not sufficiently good. On the other hand, the difference between the deviation for *s*-DMU and that for MMU (−0.4%) of the amide III bands may be attributed to the steric or electronic effect of methyl groups.[1] The deviation of δ(NCN) for *s*-DMU is more than that for MMU (0.2%), but the deviation of δ(NCO) for *s*-DMU is less than that for MMU (8.1%). The same tendency was found in methylenediurea.[13] Accordingly, the geometry of the molecule may strongly affect these vibrations.

The numerical calculations in the present treatment of normal vibrations were carried out with a HITAC 103 computer (Hitachi Ltd.) at Hiroshima University.

Results and Discussion

There are many points of similarity between the spectra of *s*-DMU and MMU,[1] but those of *a*-DMU differ from those of *s*-DMU and MMU in the numbers of the spectral bands (see Figs. 1 and 2). If the bonding of *s*-DMU as a whole is analogous to that of urea,[9,14–16] the *s*-DMU molecule can be expected to possess the considerable double-bond character of the C–N bonds and to have an approximately plane structure. Then, *s*-DMU will have three possible configurations with respect to the relative positions of two imides and a carbonyl group, the *cis-cis*, *cis-trans*, and *trans-trans* configurations of which the *cis-trans* one (C_s symmetry) is less expected than the other ones (C_{2v} symmetry).

Miyazawa and his co-workers investigated the infrared spectra of various monosubstituted amides[2,10] and of diketopiperazine,[17] and concluded that the characteristic amide bands of the *trans*-CONH group are different from those of the *cis*-CONH group. Lane and his colleagues[18] showed in their study of the methylthiourea metal complexes that the molecular form of this ligand exists in the *trans* form in comparison with the *trans*- and *cis*-thioamide. Generally the amide frequencies are markedly affected by hydrogen-bonding effects, so considerable shifts can occur on passing from the solid to a solution; moreover, the shifts are often very useful for assigning the observed bands.[2,19] A similar consideration of the amide bands of *s*-DMU will provide information regarding the configuration of *s*-DMU.

Amide I, II, and III Bands. In *s*-DMU, the amide I, II, and III bands usually observed in 1700—1250 cm^{-1} region can be related to ν(CO), ν(CN), and δ(NH), as is shown in the P.E.D. of Table 4, but they are not pure vibrations. The amide I band observed at 1625 cm^{-1} has the greatest contribution of ν(CO) and a smaller one of δ(NH), since the band shows a small frequency shift on deuteration. On the other hand, the amide II

* Unpublished data.

contribution of δ(NH), together with the additional ones of ν(CN) and ν(C'N). Contrary to the expectation of a strong peak from *trans* amides,[2,10] the amide III' band is observed at 941 cm^{-1} as a weak one. The reason for this may be that there is a considerable mixed-contribution of ν(C'N) to the band.

In the spectra in the liquid and solutions, two noticeable bands appear newly near 1330 and 560 cm^{-1}. The former is assigned to the amide III band because: (1) Figs. 6 and 7 illustrate the spectra of both DMU dissolved in water, but in *s*-DMU the marked band disappears in a D_2O solution, and in *a*-DMU, even in a H_2O solution. (2) In the solid-state spectra for *s*-DMU, the strong amide III band is likely to have a shoulder band towards a higher frequency. (3) The investigation of the N-H stretching region in *s*-DEU[20] can not show the possibility of the rotational isomer.[21] (4) The spectra in MMU do not show the corresponding bands (see Table 7).

From Table 5, it can be found that the amide I band decreases and the II band increases in frequency on passing along the series solution, liquid, solid, and *quenched* sample (in the *quenched* sample, the two bands overlap). This can be explained by the fact that the contribution of the polar resonance structure increases on passing along this series. The changes in the frequencies of the amide bands with the change in state are shown in Table 7 and compared with those of analogues, where similar tendencies are found in all. Accordingly, from the positions of the amide bands, the configuration of *s*-DMU as well as that of MMU is concluded to be the "*trans-trans*" form.

On the other hand, as the *a*-DMU molecule does not include the -CO-NH- group, the polar resonance structure may contribute less than that for *s*-DMU. In *a*-DMU, the isotopic shift from the amide II band to the II' band is very little, but in *s*-DMU, it is quite large (86 cm^{-1}) and the amide II' bands in *s*- and *a*-DMU are observed at the same positions. There is a similar relation between *s*- and *a*-DEU[20]; these questions were discussed in a previous paper.[1]

It can be concluded that the contribution of the polar resonance structure of the asymmetric form is smaller than that of the symmetric form, since the molecular geometry affects the formation of hydrogen-bondings and since the contribution of ν(CN) to the amide II band in the asymmetric form is larger than that in the symmetric form.

NH_2 Deformation Vibrations. In *a*-DMU, the ratios of the NH_2 band to the ND_2 band are 1.37 and 1.21 for $\delta(NH_2)$ and $\delta_r(NH_2)$ respectively. When we multiply a ratio of $\delta(ND_2)$ to $\delta(NH_2)$ by a ratio of $\delta_r(ND_2)$ to $\delta_r(NH_2)$ such as the product rule, the product values are regularly within 1.67 ± 0.02; urea: 1.69,[9],*[8] MMU: 1.66,[1] *a*-DMU; 1.66 and *a*-DEU: 1.68.[20]

Amide IV, V, and VI Bands and δ(NCN). The amide IV, V, and VI bands are related to δ(NCO), out-of-plane; π(NH), and π(CO) respectively.[2,10,19] In *s*-DMU, three amide bands and δ(NCN) can be predicted in the region from 800 to 400 cm^{-1}, in which the band at 672 cm^{-1} can easily be assigned to the amide V band because of its breadth and susceptibility to a change of state, while the band at 772 cm^{-1} can be assigned to the

20) Y. Mido and H. Murata, to be published.

*[8] In urea, there are two ratios for A_1 and B_2 species concerned with these vibrations and this value is the average of these ratios.

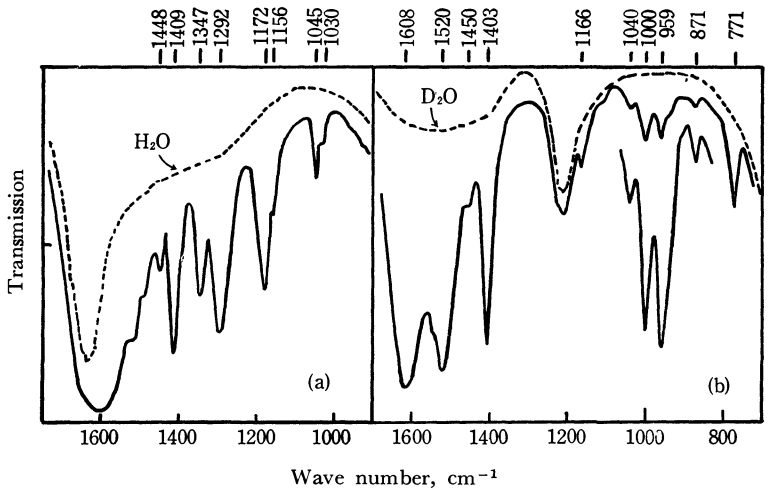

Fig. 6. Infrared spectra of *s*-DMU dissolved in (a) H_2O and (b) D_2O.

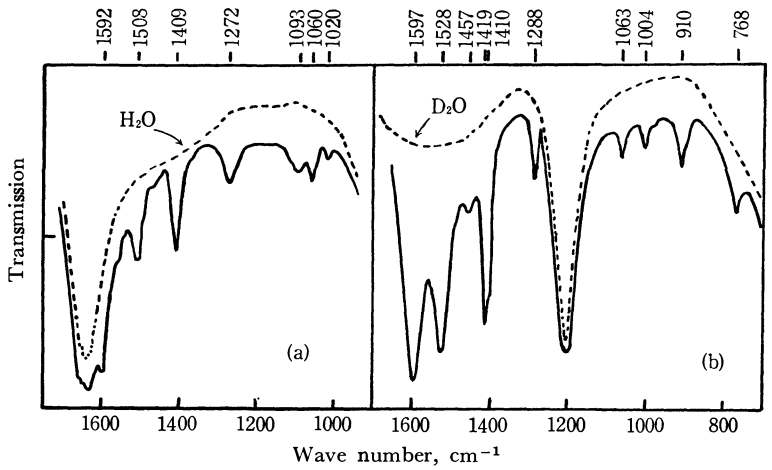

Fig. 7. Infrared spectra of *a*-DMU dissolved in (a) H_2O and (b) D_2O.

VI band because this band appears at a fixed position in the spectra of urea derivatives and because the band is hardly affected at all by deuteration. There are three bands observed in this region; the position of the V band is higher than that in MMU by 72 cm^{-1}, while the IV band in MMU has been assigned to 653 cm^{-1}; in *s*-DMU, however, the IV band is not observed in this position. Therefore, it may be considered that the IV band in *s*-DMU is covered with the V band and, on deuteration, appears at 622 cm^{-1} because the V band shifts toward a lower frequency side. The band at 504 cm^{-1} can be assigned to the undecided vibration, δ(NCN). In *a*-DMU, the bands at 773, 720, 604, and 552 cm^{-1} are associated with the amide VI band, $\pi(NH_2)$, the amide IV band and δ(NCN) respectively.

The Other Bands. In *s*-DMU, the bands at 1455, 1410, 1170, and 925 cm^{-1} (in *a*-DMU, the bands at 1450, 1412 and 1400, and 1067 cm^{-1}) are assigned to $\delta_a(CH_3)$, $\delta_s(CH_3)$, $\delta_r(CH_3)_i$, and $\delta_r(CH_3)_o$ respectively by comparing the vibrational frequencies of the related compounds of the CH_3 group attached to the nitrogen.[2] In *s*-DMU-d, the band at 1231 cm^{-1} corresponds to the band at 1212 cm^{-1} in *s*-DEU-d^{20} and can be assigned to ν(C'N) of A_1, but in *s*-DMU and *s*-DEU there are no corresponding bands in this region. The weak bands at 1037 and 980 cm^{-1} in *s*-DMU and at 1018 and 977 cm^{-1} in *s*-DMU-d are assigned to the ν(C'N) of B_2 and the ν(CN) of A_1 respectively.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 3380—3384 (1969)

Effects of Solvent on the Copolymerization of Ethylene with Tetrafluoroethylene by Cobalt-60 Gamma Radiation

Miyuki HAGIWARA, Takeshi MIURA and Tsutomu KAGIYA

Japan Atomic Energy Research Institute, Takasaki Radiation Chemistry Research Establishment, Takasaki, Gunma

(Received April 10, 1969)

The cobalt-60, γ-radiation induced copolymerization of ethylene with tetrafluoroethylene was carried out in the gas phase and in the liquid phase by using five solvents (liquefied carbon dioxide, carbon tetrachloride, ethylchloride, chloropentafluoroethane, and 1,2-dichloro-tetrafluoroethane) at a dose rate of 25000 rad/hr under a pressure of 300 kg/cm^2 at 30°C. A lower rate of the copolymerization and a copolymer of a lower molecular weight were obtained in liquid carbon dioxide and carbon tetrachloride than in the gas phase without a solvent. In ethyl chloride, the rate increased slightly, but the molecular weight decreased. On the other hand, both the rate and the molecular weight increased markedly in the fluorocarbon solvents. As a result of a detailed investigation of the copolymerization in 1,2-dichloro-tetrafluoroethane, a linear increase in the copolymerization rate and the copolymer molecular weight with the amount of solvent was noted, and there was no noticiable influence of the solvent on the copolymer composition. A kinetical discussion indicated that the addition reaction of tetrafluoroethylene to radicals produced by the influence of primary radiation on the reaction mixture is an important step in initiating the copolymerization. Also, the propagation reaction seemes to be strongly promoted by the fluorocarbon solvents.

The copolymer of ethylene with tetraflouroethylene made by γ-radiation at −78°C has been found to be a highly crystalline, random copolymer.[1] It has also been suggested that the copolymer is formed by a free radical-chain process.

In this work, the copolymerization of ethylene with tetraflouroethylene was carried out in the gas phase and in various solvents under a total pressure of 300 kg/cm^2 at 30°C by using cobalt-60 radiation, and the effects of solvents on the copolymerization were investigated. The variation in the structure of the copolymer formed with its composition was also reported.

Experimental

Materials. Tetrafluoroethylene synthesized by the debromination of 1,2-dibromo-tetrafluoroethane in the presence of a large excess of zinc dust and acetic acid was purified by freeze-thaw cycles using liquid nitrogen and pumping with a rotary vacuum pump, and was then stored in a stainless steel cylinder at −60°C. The ethylene was a polymerization-grade material from the Nisseki Kagaku Company; it was listed as 99.9% pure and showed typical analytical results of 5 ppm of oxygen and 10 ppm of acetylene. All the other materials were reagent grade and were used without further purification.

Copolymerization and Analysis. The copolymerization runs were carried out in a 100-m*l* stainless steel cylindrical vessel which had been evacuated before being filled with the reaction mixture. The transfer of tetrafluoroethylene and solvents (carbon dioxide, ethylchloride, chloro-pentafluoroethane, and 1,2-dichloro-tetrafluoroethane) from their steel storage cylinders was accomplished by cooling the reaction vessel with a dry ice-methanol bath. Ethylene was then fed in until the pressure reached 300 kg/cm^2 by means of an oilless-type compressor at a reaction temperature of 30°C. When carbon tetrachloride was used as the solvent, the reaction vessel was charged with a definite amount of carbon tetrachloride, and then the vessel was closed. Ethylene was then introduced until a pressure of 50 kg/cm^2 was reached and carefully bled out into the atmosphere to remove the dissolved air. This was repeated five times. During the reaction, the temperature was maintained constant within ±1°C by using an automatic controller. The γ-radiation was from a cobalt-60 source, and the dose rate was 25000 rad/hr.

The copolymer yield was determined by direct weighing, while the number-average molecular weight of the copolymer was obtained from osmotic pressure measurements of solutions of the copolymer in tetralin at 130°C with the use of a Hewlett-Packard osmometer, Model 502. The molar ratio of ethylene-tetrafluoroethylene in the copolymer was evaluated by checking the carbon-hydrogen contents of the copolymer. X-Ray diffraction diagrams were obtained with a powder camera in a Rigaku Denki diffractometer, Model D-6C. Ni-filtered Cu$K\alpha$ radiation was used. The infrared absorption spectra were recorded for film samples by means of a Perkin Elmer spectrophotometer, Model-521, in the range of 400—2000 cm^{-1}. Differential thermal analyses were carried out by means of a Rigaku Denki thermal spectrometer, Model 4.

Reaction conditions: pressure, 300 kg/cm²; temperature, 30°C; dose rate, 2.5×10^4 rad/hr; reaction time, 1.0 hr; molar ratio of monomers, $C_2F_4/C_2H_4=1.0/99.0$; reactor volume, 100 ml.

* This was obtained by checking the fluorine content of the copolymer together with the contents of carbon and hydrogen.

Results and Discussion

Copolymerization in the Gas Phase and in Various Solvents. Table 1 summarizes the results of the copolymerization in the gas phase and in various solvents under a total pressure of 300 kg/cm² at 30°C. The solvents used in this work have been selected because of their different stabilities in reaction to ionizing radiation and because of the fact that they can be separated from the copolymer thus formed without difficulty. The addition of liquid carbon dioxide or carbon tetrachloride as a solvent was found to depress the polymerization rate and the molecular weight of the copolymer. In radiation polymerization in the presence of an added substance, it must be considered that the radiolysis products of the substance play an important role in the initiation and termination reactions. As has been reported in previous papers[2,3] pertaining to the γ-radiation-induced polymerization of ethylene in liquid carbon dioxide, growing chain radicals have been found to be terminated by oxygen produced by the radiolysis of carbon dioxide. Therefore, it is reasonable to conclude that the lower rates of copolymerization in these systems result from this type of contribution of solvents to termination reaction. The lowest molecular weight, obtained in a carbon tetrachloride solution, may be ascribed to a rapid transfer to the solvent.

In contrast to the above-mentioned results, the rate increases in ethylchloride, chloro-pentafluoroethane, and 1,2-dichloro-tetrafluoroethane. It should be noted especially that both the rate and the copolymer molecular weight increase markedly in the latter two fluorinated solvents. The results listed in the last column of Table 1 show that the molar ratio of tetrafluoroethylene to ehylene in the copolymer is little affected by the solvents used. The significance of these results will be discussed below from the viewpoint of kinetics.

Infrared Spectra of the Copolymers. The infrared spectra of the copolymers, together with the assignments of the absorption bands,[1] are shown in Fig. 1. The spectra of polyethylene and polytetrafluoroethylene are also given for ready comparison. It is obvious that the spectra of the copolymers are quite different from those of the two homopolymers. The bands at 1175, 1045, and 950 cm^{-1} which are characteristic of the copolymer become stronger with increase in the molar fraction of tetrafluoroethylene in the copolymer. This tendency is commonly observed in the spectra of the copolymers formed in other solvents.

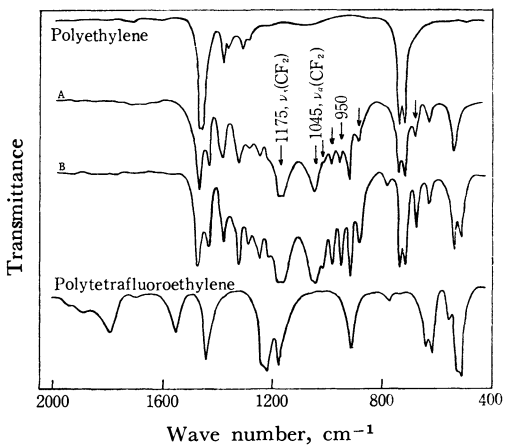

Fig. 1. Infrared spectra of copolymers. Molar fractions of tetrafluoroethylene in copolymers are (A) 3.9 and (B) 12.6 mol%.

X-Ray Diffraction Diagrams of the Copolymers. The X-ray diffraction diagrams of the copolymers, polyethylene, and polytetrafluoroethylene are given in Fig. 2. The diffraction peaks at $2\theta=20.9°$ and $2\theta=20.4°$ are observed, the strongest peaks for the copolymers of the molar fractions of tetrafluoroethylene in copolymers being 3.9 and 12.6% respectively. These peaks exist between

3) M. Hagiwara, H. Mitsui, S. Machi and T. Kagiya, *ibid., A-1*, **6**, 721 (1968).

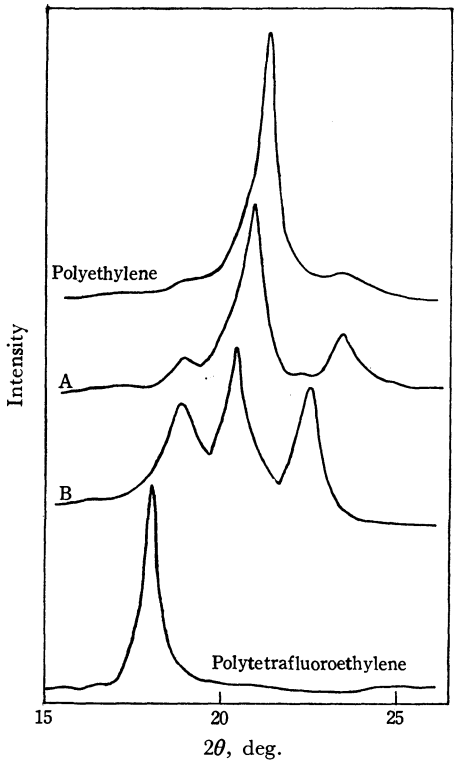

Fig. 2. X-ray diffraction diagrams of copolymers. The signs of each spectra are the same as shown in Fig. 1.

those of the two homopolymers, and their position varies continuously depending upon the molar ratio of the two monomers in the copolymer.

Thermograms of the Copolymers. Figure 3 shows the thermograms of the copolymers, together with those of polyethylene and polytetrafluoroethylene. It is obvious that the thermograms of the coplymers show no peaks obtained by the superposition of the thermograms of the two homopolymers, and that the crystalline melting temperature of the copolymer (134°C in Curve A and 187°C in Curve B) rises with the molar fraction of tetrafluoroethylene in the copolymer. In addition, a small endothermic peak at *ca.* 100°C was observed in the copolymer of which 12.6% was tetrafluoroethylene.

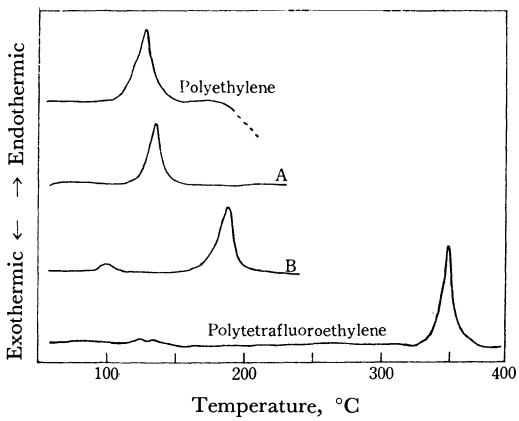

Fig. 3. Thermograms of copolymers for α-alumina in ambient air at heating rate of 5°C per minute. The signs of each curves are the same as shown in Fig. 1.

Polytetrafuoroethylene has been found to show several kinds of transitions at various temperatures. In the range studied in this work, two first-order transitions occurring in the crystalline region at relatively closely-spaced teaperatures around 90°C, and two second-order transitions in the amorphous region around 130°C, have been reported.[4-6] In our thermograms of polytetrafluoroethylene, we observed, no peak at 90°C, but we did find small endothermic peaks near 130°C. Thus, although it has not been clearly shown, the small peak near 100°C in the copolymer is considered to correspond to the transitions around 130°C in polytetrafluoroethylene.

From these results of the infrared, X-ray diffraction, and from the differential thermal analyses, the alternative possibilities of the formation of a mixture of homopolymers and a block copolymer can be excluded.

Copolymerization in 1,2-Dichloro-tetrafluoroethane. The results given in Table 2 show the characteristic effects of 1,2-dichloro-tetrafluoroethane as a solvent on the copolymerization. We were able to observe the appearance of the reaction mixture throughout the copolymerization reaction by using a specially-designed stainless steel autoclave with a quartz window.[7] When a sufficient amount of solvent was used (thirty grams of 1,2-dichloro-tetrafluoroethane were found to be quite enough for a vessel with a capacity of 100 ml), it was observed that the mixture of the two monomers and the solvent exists in a homogeneous liquid phase, with no phase separation in the reaction vessel, and that copolymers formed separate continuously from the mixture as fine particles during the course of the reaction. Thus, in all the copolymerization runs carried out by the use of the solvent, the reaction takes place in the homogeneous-liquid-phase mixture of two monomers and the solvent used. On the other hand, the copolymerizationis a gas-phase reaction when no solvent is used.

In Fig. 4 the rate of copolymerization is plotted against the amount of solvent for three different concentrations of tetrafluoroethylene in the reaction mixture. In all cases, the rate is shown to increase linearly with the amount of solvent. Another

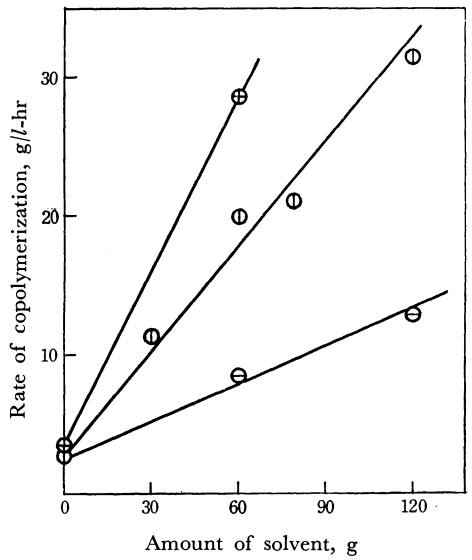

Fig. 4. Rate of copolymerization *vs.* amount of 1,2-dichloro-tetrafluoroethane. Reaction conditions: total pressure, 300 kg/cm²; temperature, 30°C; dose rate, 2.5×10^4 rad/hr; reactor volume, 100 ml; concentrations of tetrafluoroethylene in monomers are about (⊖) 0.5, (⦶) 1.0 and (⊕) 1.5 mol%.

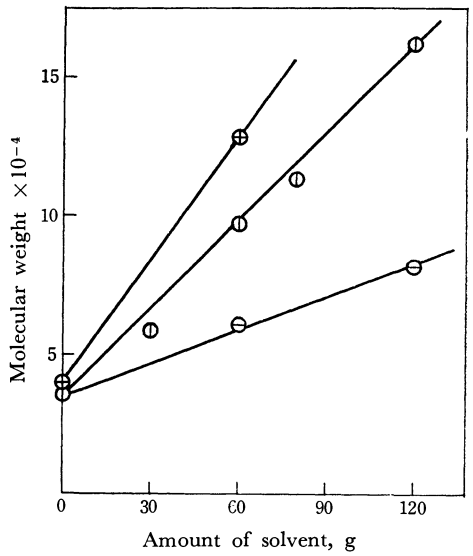

Fig. 5. Molecular weight of copolymers *vs.* amount of 1,2-dichlorotetrafluoroethane. Reaction conditions are the same as shown in Fig. 4.

characteristic phenomenon is the effect of the solvent on the molecular weight of the copolymer formed. As is shown in Fig. 5, our observation clearly demonstrates that the molecular weight increases linearly with the amount of solvent used. On the other hand, as can be seen in the last column of Table 2, the copolymer composition is not affected by the amount of solvent, but is determined exclusively by the molar ratio of the two monomers in the reaction mixture. The fraction of tetrafluoroethylene in the copolymer is much larger than that in the monomers.

By using Eq. (1) (given below), the rate of copolymer chain formation can be calculated; the results are plotted in Fig. 6 against the molar fraction of tetrafluoroethylene in monomers.

Rate of copolymer chain formation

$$=(M_p/t)(1/\bar{P}_n) \quad \text{(mol/l-hr)} \qquad (1)$$

M_p: copolymer yield (mol/l)

$\bar{P}_n$: total number of monomer units in one copolymer chain (–)
t: reaction time (hr)

A small amount of tetrafluoroethylene is shown to be quite effective in producing copolymer chains. In all cases when different amounts of a solvent are used, the rate increases with an increase in the fraction of tetrafluoroethylene. In the range where the molar fraction of tetrafluoroethylene is less than 1%, a higher rate is obtained when a larger amount of solvent is used. Three point on the ordinate show a significant contribution of the solvent to the polymer chain formation. In contrast to this, though a higer rate is obtained than in the case of no solvent at all, the rate comes not to be affected by the amount of solvent in the range above 1% of tetrafluoroethylene. From these observations, it can be concluded that 1,2-dichloro-tetrafluoroethane used as a solvent does not act as a transfer agent in the copolymerization, and that the addition reaction of tetrafluoroethylene to the radicals produced by the influence of radiation on the reaction mixture is important in initiating the copolymerization. Thus, the addition of tetrafluoroethylene to the primary radicals is considered to produce more reactive radicals, which can then effectively initiate the copolymerization with less activation energy. Further, the data in Fig. 6 show that, when a sufficient amount of a solvent is used, the rate of initiation is virtually independent of the amount of solvent at tetrafluoroethylene concentrations above 1%.

In connection with the discussions above, it is interesting to note that the copolymerization rate and the copolymer molecular weight increase linearly with the amount of solvent, as is reported in Figs. 4 and 5. These facts may indicate that the propagation reaction of the copolymerization is strongly promoted by the solvent. Further, the information on the copolymer composition given in Table 2, which shows no noticiable influence of the amount of solvent on the copolymer composition, leads to the conclusion that the enhancement in reactivity might occur at an active site of the propagating copolymer chain. The strongly electro-negative flourine atoms of the solvent might have some effect on the reactivity of the active site in a solvated state. A careful study of this aspect is being carried out and will be reported on later.

Energy Transfer from the Triplet Excited States of Aromatic Molecules to Chromium(III) Complexes

Takeshi OHNO and Shunji KATO

Institute of Chemistry, College of General Education, Osaka University, Toyonaka, Osaka

(Received April 11, 1969)

The quenching efficiencies of five tervalent chromium complexes on the phosphorescence of erythrosin and benzil have been compared at the temperatures of dry ice and liquid nitrogen. The results were well explained in terms of the collisional energy transfer. It was observed that aromatic ligands enhanced the rate of the energy transfer even if the triplet energy of the donor was lower than that of the ligands.

It is well known that the triplet excited states of the aromatic compounds are quenched by some paramagnetic transition metal complexes. Porter and Wright, however, observed no relation between the magnetic susceptibilities of quenchers and the rate constants of the quenching processes of the triplet states, they classified the paramagnetic substances into the following three groups on the basis of the quenching rate constants[1]:

1) simple molecules (NO,O_2) having unpaired electrons in the 2p orbital,
$$k \sim 10^{10}\ \text{M}^{-1}\,\text{sec}^{-1},$$
2) transition metal complexes having unpaired electrons in the 3d orbitals,
$$k \sim 10^{7}\ \text{M}^{-1}\,\text{sec}^{-1},$$
3) rare earth metal complexes having unpaired electrons in the 4f orbitals,
$$k \sim 10^{5}\ \text{M}^{-1}\,\text{sec}^{-1}.$$

These results, which were partly confirmed by Linschitz and Pekkarinen,[2] showed that the quenching of the triplet excited states could not be attributed to the enhancement in the intersystem crossing of the triplet state caused by the inhomogeneous field of the paramagnetic molecule, but only to the overlapping beween the orbitals of the triplet state and the quencher.

Linschitz and Steel found that the aromatic ligands in transition metal chelates accelerated the rate of the quenching as well as the rate of the redox reaction between metal complexes, and supposed that the quencher transiently formed a charge-transfer complex with the triplet state, in which the intersystem crossing was increased.[3]

An alternative mechanism—electronic energy transfer—in the quenching of the triplet states was proposed by Hammond and his co-worker.[4] Their proposal seems to be supported by the fact that overlapping of the orbitals of the two reactants allows an energy transfer from the triplet state to quencher if the energy level of the acceptor is lower than that of the donor.[5] Hammond and his co-worker hesitated to insist on the importance of the energy transfer on the quenching process, however, because the triplet state of anthracene, whose energy is very low (42.6 kcal/mol), is still very efficiently quenched by all the complexes investigated, $Fe^{III}(acac)_3$,*2 $Cu^{II}(acac)_2$, $Cr^{III}(acac)_3$, $Ni^{II}(dpm)_2$,*3 *etc.*[6]

The purpose of this work is to make clear the quenching mechanism of the triplet states in the presence of a transition metal complex, the tervalent chromium complex. The effect and the role of the aromatic ligands of chromium complexes in the quenching were investigated, too. Independent work along these lines has also been done by Forster and his co-workers.[7]

Experimental

Procedure. Figure 1 schematically illustrates the simple apparatus for measuring the emission spectra. A quartz cell 10 mm in diameter was cooled with dry ice or liquid nitrogen. Solutions of 6×10^{-4} M erythrosin in 90% ethanol were illuminated at 534 mμ, while those of 2×10^{-2} M benzil were illuminated at 365 mμ. In order to avoid the scattering of the excitation light,

a glass filter, Toshiba UV-D2, was set in front of the cell for the benzil solution, and a Toshiba VY-42 filter for the erythrosin solution. The emission spectra were recorded with a LER-10A recorder (Yokogawa Co.).

To measure the emission life-time, a flash lamp was used with 4-71 Corning filter for the erythrosin solution and a UV-D2 filter for the benzil solution. The solutions were thoroughly degassed by six bulb-to-bulb distillations *in vacuo*.

Materials. Benzil was recrystallised three times from ethanol, erythrosin, from water. Three chromium(III) complexes——$NH_4[Cr^{III}(NCS)_4(NH_3)_2]\cdot 3/2H_2O$, $K_3[Cr^{III}(NCS)_6]\cdot 4H_2O$, and $NH_4[Cr^{III}(NCS)_4\cdot(aniline)_2]\cdot 3/2H_2O$——were prepared by the usual method.[8] $Cr^{III}(acac)_3$ was prepared by the method of Cooperstein.[9] $Cr^{III}(8\text{-oxyquinolinate})_3$ was obtained by warming chromium(III) chloride and 8-hydroxyquinoline in 2N acetic acid.

Ethanol was dried over calcium oxide; then it was refluxed with silver nitrate and distilled.

Results and Discussion

I) The emission and the absorption spectrum of 6×10^{-4} M erythrosin solution are shown in Fig. 2. The emission peaks at 17.9 and 14.3 kK can easily be assigned to the fluorescence and the phosphorescence respectively, the life-times of the latter being 0.63 msec at −72°C and 0.91 msec at −196°C.

Figure 3 shows the emission spectrum of the 2×10^{-2} M benzil solution at −72°C. The fluorescence at 20 kK is weak and the phosphorescence, with peaks at 14.5, 16.0, and 17.6 kK, is much stronger, with the life-time of 0.67 msec. Elevating the temperature made the phosphorescence as weak as the fluorescence.

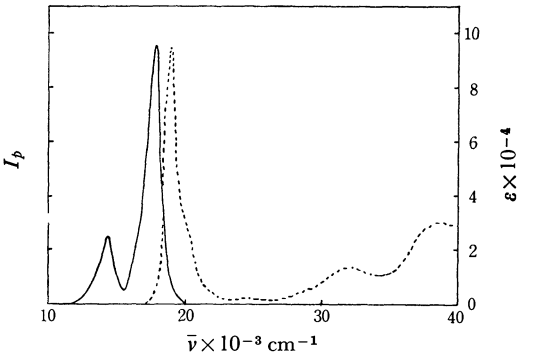

Fig. 2. Absorption spectrum and emission spectrum of erythrosin.

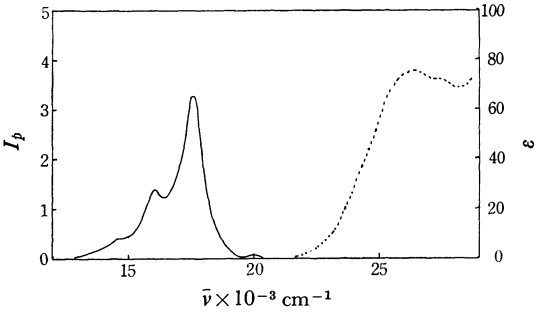

Fig. 3. Absorption and emission spectra of benzil.

The phosphorescences of some chromium(III) complexes which had no fluorescence were observed at −196°C. For $NH_4[Cr^{III}(NCS)_4(NH_3)_2]$, $NH_4[Cr^{III}(NCS)_4(aniline)_2]$, and $K_3[Cr^{III}(NCS)_6]$, the phosphorescences were found at −72°C. Table 1 shows the levels of the phosphorescent states of the aromatic compounds and the chromium(III) complexes.

II) The intensity of the phosphorescence of erythrosin decreased in the presence of 2×10^{-4} M $NH_4[Cr^{III}(NCS)_4(NH_3)_2]$, and a sharp emission with its maximum at 13.3 kK was observed; this was the same value as that of the phosphorescence of the chromium(III) complex observed under direct excitation. As is shown in Fig. 4, the phosphorescence of the donor at 14.3 kK decreases, and that of the acceptor at 13.3 kK increases, with the concentration of the complex. Because the light absorbed by the complex was less than two hundredths that by erythrosin, even at the highest concentration of the complex, the phosphorescence at 13.3 kK must be the sensitized one.

Oxygen did not quench the phosphorescence of a pure solution of the complex, but it did quench the phosphorescence of both the complex and

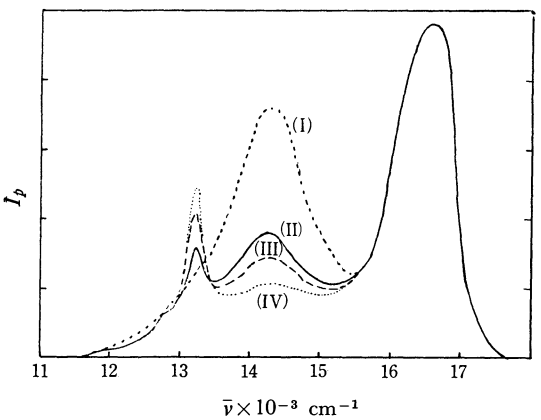

Fig. 4. Change of emission spectrum of erythrosin with $NH_4[Cr^{III}(NCS)_4(NH_3)_2]$, (I) erythrosin 6×10^{-4} M, (II) erythrosin 6×10^{-4} M, the complex 2×10^{-4} M, (III) erythrosin 6×10^{-4} M, the complex 4×10^{-4} M, (IV) erythrosin 6×10^{-4} M, the complex 7×10^{-4} M.

erythrosin in the binary system. At −196°C, where the solution was frozen, the sensitized phosphorescence vanished and the donor phosphorescence emerged very strongly. These facts support the theory that the sensitized phosphorescence is due to collisional energy transfer from the triplet state of the erythrosin to the complex. Such a collisional energy transfer has been reported in the system of benzil-$[Cr^{III}(en)_3{}^{*4}]^{3+}$, $Cr^{III}(acac)_3$, and $[Cr^{III}(CN)_6]^{3-}$ by Forster and his co-workers.[7]

The most probable scheme of the energy transfer may be as follows:

$$^3D^* \rightarrow {}^1D + h\nu \qquad k_1 \qquad \text{(P-I)}$$
$$^3D^* \rightarrow {}^1D \qquad k_2 \qquad \text{(P-II)}$$
$$^3D^* + {}^4A \rightarrow {}^1D + {}^2A^* \qquad k_3 \qquad \text{(P-III)}$$
$$^3D^* + {}^4A \rightarrow {}^1D + {}^4A \qquad k_4 \qquad \text{(P-IV)}$$
$$^2A^* \rightarrow {}^4A + h\nu \qquad k_5 \qquad \text{(P-V)}$$
$$^2A^* \rightarrow {}^4A \qquad k_6 \qquad \text{(P-VI)}$$

where D and A denote a donor and an acceptor respectively; the prefixes the multiplicity of the electronic state, and the asterisk, an excited state. An energy transfer to the first excited quartet state ($^4T_2$) of the complex from the donor triplet state is allowed according to the spin conservation rule. Therefore, P-III includes both the direct-energy transfer to the first excited doublet state (^2E) and that to $^4T_2$, followed by the intersystem crossing to ^2E. According to this scheme, some of the k's values are calculated from three different measurements: (i) The observed decay rates of the donor

phosphorescence (k_{obs}) are expressed as:

$$k_{obs} = k_1 + k_2 + (k_3 + k_4)\ [A] \qquad (I)$$

The intercept and the slope of the straight line in Fig. 5 give the values of k_1+k_2 and k_3+k_4 respectively, which are listed in Table 2. (ii) The Stern-Volmer depencence on the acceptor concentration is shown in Fig. 6. I_D^0 and I_D show the intensities of the donor phosphorescence in the absence and in the presence of the acceptor respectively. The slope of the straight line in Fig. 6 is $(k_3+k_4)/(k_1+k_2)$, according to the reaction scheme. The value of k_3+k_4, which is calculated by using the value of k_1+k_2, agrees with that obtained by the first method. (iii) The reaction scheme produces Eq. (II);

$$\frac{1}{I_A} = \frac{k_5}{k_5 + k_6}\left(\frac{k_3 + k_4}{k_3} + \frac{k_1 + k_2}{k_3}\right)\frac{1}{[A]} \qquad (II)$$

where I_A denotes the intensity of the sensitized phosphorescence. Figure 7 shows that Eq. (II) holds. The ratio of the slope to the intercept is equal to $(k_3+k_4)/(k_1+k_2)$.

III) Four chromium(III) complexes—$Cr^{III}(acac)_3$, Cr^{III}(8-oxyquinolinate)$_3$, $NH_4[Cr^{III}(NCS)_4(aniline)_2]$, and $K_3[Cr^{III}(NCS)_6]$—were examined as acceptors. The rate constants (k_3+k_4) calculated in two different ways ((i) and (ii)) are shown in the last column of Table 1. Sensitized

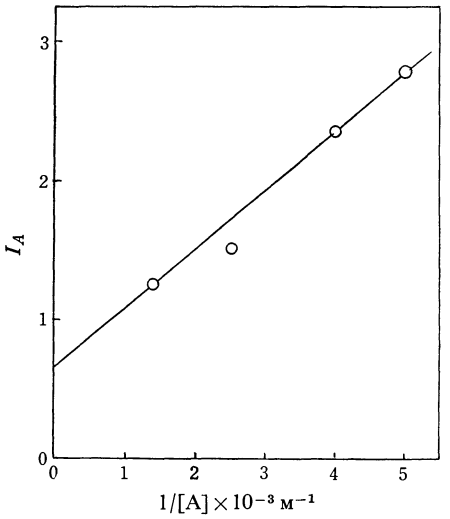

Fig. 7. Confirmation of Eq. (II).

phosphorescences were found in the cases of $K_3[Cr^{III}(NCS)_6]$ and $NH_4[Cr^{III}(NCS)_4(aniline)_2]$, which were phosphorescent at −72°C on direct excitation. For $Cr^{III}(acac)_3$ and Cr^{III}-(8-oxyquinolinate)$_3$, k_6 must be larger than k_5, because these complexes emit no direct phosphorescence nor any sensitized phosphorescence at −72°C.

When a mixture of erythrosin and one of the complexes besides $K_3[Cr^{III}(NCS)_6]$ was excited by a 534 mμ light at −196°C, only the phosphorescence of the former was observed. These facts support the idea of the occurence of a collisional energy transfer at −72°C.

For $K_3[Cr^{III}(NCS)_6]$, the phosphorescence was sensitized by erythrosin even at −196°C. Because collisional energy transfer can not occur in a rigid solution, the possible mechanisms to make a sensitized phosphorescence are: (i) a long-range energy transfer[10] (from the excited singlet state of erythrosin to the $^4T_2$ of the complex) and (ii) the complex formation of the donor with $K_3[Cr^{III}(NCS)_6]$. There is no reliable evidence on the basis of which to select one of them. However, the long-range energy transfer is unlikely to be operative because three complexes—$NH_4[Cr^{III}(NCS)_4(NH_3)_2]$, $NH_4[Cr^{III}(NCS)_4(aniline)_2]$, and $Cr^{III}(acac)_3$—all with absorption spectra similar to that of $K_3[Cr^{III}(NCS)_6]$, had no sensitized phosphorescence at −196°C. The long-range energy transfer at −72°C can be excluded because of the fact the value of k_3+k_4 obtained from the Stern-Volmer plot of the intensity of the donor phosphorescence was not larger than the value calculated from the decay constants of the donor phosphorescence. The alternative mechanism—static quenching—can be excluded at −72°C,

too, because oxygen quenches the phosphorescence of both the acceptor and the donor completely. These results are partly different from Forster's results in the system of benzil-$K_3[Cr^{III}(NCS)_6]$.

It is worth noticing that the values of k_3+k_4 are $10^7\,M^{-1}\,sec^{-1}$ for the complexes containing aromatic ligands and $10^6\,M^{-1}\,sec^{-1}$ for the complexes containing only inorganic ligands. The rate constant for $NH_4[Cr^{III}(NCS)_4(aniline)_2]$ is twice that for $NH_4[Cr^{III}(NCS)_4(NH_3)_2]$. These results show that these aromatic ligands play an important role in the quenching and in the energy-transfer reaction. The effect of some aromatic ligands upon the quenching rates is more distinct in the reaction at room temperature.[4,6] It has been reported that the quenching of the triplet states of some aromatic compounds with Cr^{III}-$(acac)_3$ was diffusion-controlled and that the quenching rate was several hundred times as great as that for the naphthalene-$Cr^{III}Cl_3$ system.*5,[1] In the case of rare earth complexes, it is well known that the aromatic ligands with triplet levelslower than that of the donor triplet accept the excitation energy from the donor very efficiently as in the case of the energy transfer between aromatic molecules.[11] The proposed mechanism is a series of successive processes as follows:

$$^3D^* + M\text{-}^1L \rightarrow {}^1D + M\text{-}^3L^* \qquad \text{(P-VII)}$$

$$M\text{-}^3L^* \rightarrow M^*\text{-}^1L \qquad \text{(P-VIII)}$$

The $M\text{-}^3L^*$ symbol indicates that the triplet-excited energy is localized in part of the ligands. The energy transfer process (P-VII) is diffusion-controlled if the energetical requirement is satisfied.[12]

In the case of the 8-oxyquinolinate complex, the energy of the triplet state of the ligand (16.2 kK for Pb^{II}(8-oxyquinolinate)$_2$[13]) may be lower than that of the benzil molecule, therefore, the following reaction must be diffusion-controlled:

$$^3Benzil^* + Cr^{III}(8\text{-oxyquinolinate})_3 \rightarrow {}^1Benzil + Cr^{III}(8\text{-oxyquinolinate})_3^* \qquad \text{(P-IX)}$$

However, for the complexes of other lignads, a different type of energy transfer is required, because the triplet levels of the ligands higher than erythrosin make it impossible for the (P-VII) process to occur (see Table 1).

It is well known that 3d electrons in chromium (III) are likely to mix with the p_π electrons of aromatic ligands more than do 4f electrons in rare earth chelates. It is plausible that this mixing makes the interaction between 3d electrons and donor triplet electrons much larger at the frontier of the complexes, then, the excitation energy of the donor in triplet state can be directly transferred to the central chromium ion. It may be through this mechanism that $Cr^{III}(acac)_3$, the ligand triplet state of which is located at 25.4 kK, very efficiently quenches the triplet state of six aromatic molecules—triphenylene (23.8 kK), benzanthrone (16.8kK), anthracene (15.2 kK), *etc.* These quenching rate constants have been measured by Hammond and his co-worker.[6]

A financial support from Fuji Photo Film Co., Ltd., is gratefully acknowledged.

*5 Present results show that the rate constants of the quenching with Werner type complexes, such as $K_3[Cr^{III}(NCS)_6]$ and $NH_4[Cr^{III}(NCS)_4(NH_3)_2]$ are not much smaller than those with complexes containig aromatic ligands at −72°C. This fact is explained as follows. Since the solvent of high viscosity at low temperature makes the contact time longer the energy is effectively transfered from the donor to the acceptor.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 3390—3393 (1969)

The Low Temperature n–π^* Absorption Spectra of the Cyclohexane-1,4-dione Crystal

Kayoko Ozeki*1 and Jiro Tanaka

Department of Chemistry, Faculty of Science, Nagoya University, Chikusa, Nagoya

(Received April 15, 1969)

Cyclohexane-1,4-dione is an aliphatic ketone with two carbonyl groups. The absorption due to the n–π^* transition of the carbonyl group extends from the 30000 cm^{-1} to the 42000 cm^{-1} region. The transition is symmetrically forbidden and is assigned to the A_1–A_2 transition in the C_{2v} system. The spectra in the crystal and in a solution of EPA at 77°K show only prominent carbonyl stretching vibrations. The polarized single crystal absorption spectra at 4.2°K are composed of many sharp lines; the vibrational structures are analyzed in detail. The 0-0 transition is observed at 31408 cm^{-1}; the distinct basic frequencies of the excited state are 1096, 790, 557, 375, 247, and 122 cm^{-1}, while the lattice vibrations are 61, 32, and 22 cm^{-1}. The transition is explained by the vibronic coupling mechanism, assuming the C_{2v} symmetry for the carbonyl group. Two different types of progressions are noticed; one is induced by the out-of-plane b_2-type vibration, while the other is allowed by the a_2-type vibration. The dichroic properties of the crystal spectra allowed the assignment of the vibrational modes. These vibrations are compared with the infrared and Raman spectral data.

There have been many experimental and theoretical studies of the n–π^* transitions of aliphatic and aromatic carbonyl compounds.[1] The first vibrational analysis of the spectra of formaldehyde was made by Herzberg,[2] who thus established the vibrational intervals for the carbonyl stretching frequency. Complete rotational analysis was made by Dieke and Kistiakowsky[3] on formaldehyde; they concluded that the n–π^* transition is polarized in plane and perpendicular to the carbonyl axis. Brand[4] and Robinson[5], by absorption and emission spectral measurements, determined that the configuration of formaldehyde in the singlet excited states is non-planar. Pople and Sidman[6] studied the mechanism of the vibronic coupling in formaldehyde and concluded that most of the intensities of the perpendicularly polarized bands arose from the mixing of the A_2 ($n\pi^*$) state with the B_1($n\sigma^*$) state by the perturbation of the b_2-type vibration. These result may be applicable to the interpretation of n–π^* transitions in more complex aliphatic aldehydes and ketones.

The asymmetric carbonyl compounds are known to show the optical rotatory dispersion in the n–π^* transition regions, and the octant rule has been found to hold for the complex carbonyl compounds.[7] Mason[8] discussed the optical activity of the carbonyl

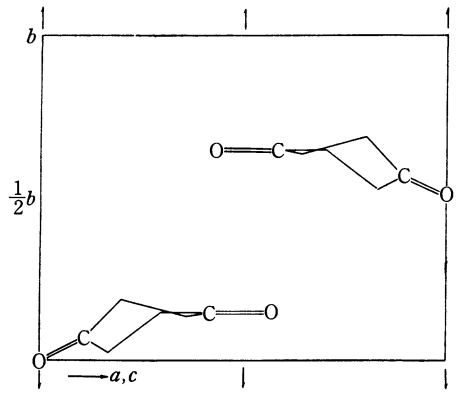

Fig. 1. The projected view of cyclohexane-1,4-dione on to the ($10\bar{1}$) plane according to the X-ray results. The absorption spectra were photographed through this plane. One carbonyl axis is nearly parallel to the [$10\bar{1}$] axis, while another is inclined to the b and [$10\bar{1}$] directions. The molecular C_2 axis is nearly perpendicular to both carbonyl groups.

compounds and suggested that the parallel component to the carbonyl axis is important in any interpretation of the optical activity. The transition moment along the carbonyl axis may be produced by *a* vibronic coupling through the a_2-type vibration or by the other kinds of perturbations[9]

In this paper the vibrational analysis of the spectra of aliphatic ketone at low temperatures will be presented with a view to elucidating the mechanism of the intensity gain. Cyclohexane-1,4-dione is a cyclic diketone, as is shown in Fig. 1. The polarized absorption spectra of this diketone at 4.2°K shows several vibrational progressions; the detailed analysis of these progressions gives unambiguous assignments for the vibrational modes and for the mechanism of the vibronic coupling. The vibrational frequencies for the excited states are compared with the infrared and Raman spectral data.

Experimental

The cyclohexane-1,4-dione was the product of Nakarai Chem., Ltd., Kyoto, Japan; it was recrystallized from an ethanol solution and was used immediately after preparation because the crystal is not stable at room temperature.

The spectrum of the solution in EPA at the temperature of liquid nitrogen was recorded on a Cary spectrophotometer model 15. Crystal absorption experiments at the temperatures of liquid nitrogen and liquid helium were carried out on a Shimadzu GE-100 spectrograph equipped with a Bausch & Lomb grating, as has been reported before.[10] A standard Zeiss hydrogen lamp was employed as the radiation source. The smaple was mounted between two black paper masks, placed between quartz disks. The crystal axes were checked by a polarizing microscope and by the X-ray photographic method. The light incident upon the sample was a plane polarized by a rotable Glan-Thompson calcite polarizer; it was focussed with the appropriate lens system on the spectrograph slit. The exposure times ranged from 4 to 12 min with a slit width of 0.1 mm using Kodak 103a-0 photographic plates. Reference ion-arc spectra were photographed adjacent to each absorption spectrum. This molecule has the symmetry of C_2 in the crystal, but the two-fold axis is nearly perpendicular to the carbonyl axes. The carbon atoms attached to the carbonyl carbon are coplanar with the oxygen atom; the projection of molecules analyzed by Mossel and Romers[11] and Groth and Hassel[12] is shown in Fig. 1. Two carbonyl groups are separated by the saturated bonds; therefore, the chromophores are considered to be nearly independent of each other, although they are related by the symmetry operation. From a rigorous point of view, there should be an exciton interaction between the chromophores, however, no detectable effect can be found on the absorption spectra. Therefore, a treatment based on the independent system will be used in the following dissussion. The spectrum of the solution at 77°K is shown in Fig. 2. It shows several maxima, but the vibrational intervals are not so clear as those in the crystal spectrum. The crystal spectrum at 77°K shows several progressions of 1100 cm^{-1}; these may be assigned to the carbonyl stretching. However, no other vibrational modes can be detected clearly.

Vibrational Analysis of the 4.2°K Crystal Spectra

The single crystal spectra at the temperature of liquid helium are shown in Fig. 3 for the light polarized parallel and perpendicular to the *b* axis. At 4.2°K each vibrational envelope is composed of many sharp lines. No detectable splitting between the *b* and the [10$\bar{1}$] axis has been found; this supports the independent-system approach. Several characteristic fundamental vibrational frequencies have been observed along the *b* and the [10$\bar{1}$] axes; some of them are peculiar to the [10$\bar{1}$] axis. The spectrum starts with a sharp line at 31408 cm^{-1}; this line we assigned to the 0–0 transition for several reasons. No trace of any absorption to the red of this origin could be found in crystals up to 0.2 mm in thickness. The appearance of the weak 0–0 band and the subsequent strong vibrational bands are consistent with the vibrational progression built on a forbidden transition. Definite proof is given by the observation of the highest

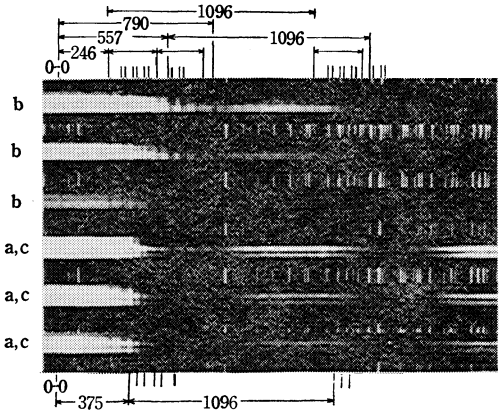

Fig. 3. The polarized absorption spectra at liquid-helium temperature showing the details of first and second band systems. Three different exposure times (12, 8 and 4 min) were used. The basic vibrations, which are common to both *b* and [10$\bar{1}$] axes spectra, are indicated on the top of the spectra. The vibration which is peculiar to the [10$\bar{1}$] axis spectrum is indicated in the bottom.

energy fluorescence band of the same origin, but no fluorescence has been observed with this compound. The frequencies, intensities, and assignments of the absorption bands are shown in Table 1. The carbonyl stretching progressions are observed up to the fourth level. Only the first member of each of the progressions is accompanied by many sharp lines, and the dichroic properties are clearly observed. The second member can be analyzed to some extent, but analysis is difficult for the higher members.

The important vibrational frequencies found along the [10$\bar{1}$] direction are 375 cm^{-1} and 1096 $^{-1}$. The progression of 1096 cm^{-1}, which is common to the *b*-axis spectrum, can safely be regarded as the stretching mode of the carbonyl group because it is already established with other carbonyl compounds.[2] The frequency is greatly reduced as compared with that of the ground state. If we suppose the local symmetry of the carbonyl group to be valid for the discusssion of the excited state of the present molecule, then the carbonyl stretching mode has a symmetry of a_1. It is reasonable

Intensity designations are: s, strong; m, medium; w, weak; vw, very weak.
When two intensity designations are written *a*, *c* axis absorptions are marked by *.

that this frequency is often coupled with other type of vibrations.

From the arrangement of the molecule in a unit cell shown in Fig. 1, the symmetry properties of the vibronic state can be discussed. The component parallel to the carbonyl axis (A_1 type) can be strongly observed, particularly along the [10$\bar{1}$] direction. In order for us to find the symmetry-forbidden n-π^* state (A_2 state) along the carbonyl axis, the vibronic coupling with the a_2-type vibration should be operative. The observed band at 0-0+375 cm^{-1} is thus shown to correspond to the vibronically-a_2-coupled state. This band is only weakly observed in the b-axis direction. For the molecule having an exact C_{2v} symmetry, the a_2-type vibration is not effective for the vibronic intensity borrowing. For molecules of a lower symmetry such as this diketone, the strict geometry of the C_{2v} system does not hold; the a_2-type torsion will induce the electronic transitions vibronically. The band progression starting at 31782 cm^{-1} should, therefore, be assigned to the component parallel to the carbonyl axis, which is itself produced by the coupling with the a_2-type torsional mode. The lattice vibration of 30 cm^{-1} is found only along the [10$\bar{1}$] direction.

It is noteworthy that no important progressions have been found which are observed only along the b axis. In a previous paper the out-of-plane component of the n-π^* transition was rejected on the grounds of the measurement of several crystals.[9]

It has been confirmed again in the present research that no particular b_1-type vibration is associated with the induction of the B_2 excited state, which is active in the out-of-plane of the carbonyl group. The transitions polarized parallel to the other directions, in the plane and perpendicular to the carbonyl axis, will be found along both the b and the [10$\bar{1}$] directions. The vibrations of 247, 557, and 790 cm^{-1} are regarded as b_2-type vibrations, which will mix the B_1 excited level with the forbidden A_2 n-π^* state. The small spacings of 60 cm^{-1} and the doublet structure of 20 cm^{-1} may be assigned to the lattice vibration. It is remarkable that the 60 cm^{-1} and 20 cm^{-1} intervals are associated with the 247, 557, and 790 cm^{-1} vibronic states.

The infrared and Raman spectra of this molecule in the crystalline state show the corresponding frequencies of 60, 122, 247, 375, 557, and 790 cm^{-1}. These frequencies are compared with the present values for the excited state in Table 2. It is noticeable that the frequencies assigned to the excited state nearly coincide with the values given for the ground state except for the carbonyl stretching mode.

The quantitative estimate of the intensity of the component of the a_2-type induced A_1-excited state is rather difficult because of the complexity of the spectra, but an approximate value would be about 20% of the total n-π^* transition intensities. The result is very closely connected with the theory of the optical activity. A theoretical discussion of the mechanism of the intensity gain will be presented in a separate paper.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 3394—3398 (1968)

Spectroscopic Investigation of Foreign Gas Effects upon CO_2 Laser Frequencies

Isao Suzuki* and Shigeko Suzuki**

* *Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo*

** *Department of Pure and Applied Sciences, College of General Education, The University of Tokyo, Komaba, Meguro-ku, Tokyo*

(Received May 7, 1969)

The change in the oscillation frequencies of a CO_2 laser was examined when foreign gases were introduced into a cell placed inside the cavity. Several gases which have absorption bands around 10 μ region were investigated: sulfur hexafluoride, ammonia, ethylene, *trans*-dichloroethylene, methyl bromide, trichloroethylene, acrolein, and isopropyl alcohol. The CW laser oscillations in the P-branch of the 9.6 μ band as well as those in the R-branch of the 10.6 μ band were observed when some foreign gases with appropriate pressures were introduced in the cavity. It was also found that the presence of ammonia or methyl bromide even in a very low pressure suppressed the usually strong P(20) line of the 10.6 μ band. This is interpreted as due to a near coincidence of the laser line with one of the vibration-rotation transitions in these molecules.

Under ordinary CW operating conditions in a CO_2 laser, the laser action occurs on a few P-branch transitions of the 10.6 μ band of CO_2. Wood and Schwartz[1] reported that introduction of sulfur hexafluoride gas to a cell placed within the cavity causes the laser frequencies to shift to a few R-branch transitions. Similar phenomena occur in a wide variety of organic and inorganic gases,[2] and the oscillation frequencies are very sensitive to the pressures of given gases. We have also observed the CW laser action in a few P-branch lines of 9.6 μ band, a Fermi resonance partner of the 10.6 μ band. In the present paper, we describe the results of our spectroscopic investigation on the effect of foreign gases, which have some absorptions around the 10 μ region on a CO_2 laser system.

Experimental

The diagram for experimental setting is shown in Fig. 1. A mixture of CO_2 (9.9%), N_2 (15.8%) and He (74.3 %) with the total pressure of 8 mmHg was sealed in a pyrex tube of 1.2 m in length and inner diameter of 30 mm. The tube was cooled with water. The tube had a concave mirror of radius 3.5 m at one end and a potassium chloride plate at the other end. A 10 cm infrared gas cell with KCl windows was placed adjacent to the pyrex tube (see Fig. 1 (a)). The laser cavity was completed with a plane mirror with a 2 mm diameter hole in the center, through which the laser beam was coupled out. Both mirrors were aluminized. The gas mixture was excited by an ac-discharge at a current of

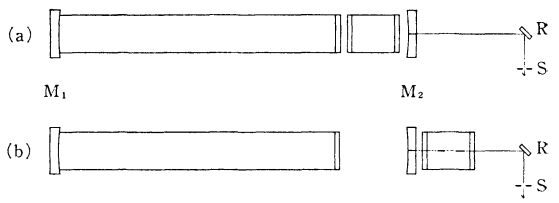

Fig. 1. Diagram for experimental setting: (a) an infrared gas cell was placed inside the cavity, and (b) the cell was placed just outside the cavity. M_1: Concave mirror (R=3.5 m), M_2: plane mirror with a 2 mm diameter hole in the center, R: reflector, and S: slit of the spectrophotometer.

8 mA. The laser beam was scattered with a diffuse reflector, and a part of the emission radiation was introduced to the entrance slit of a spectrophotometer. With the evacuated cell placed inside the cavity, four or five lines distributed around the P(20) transition were normally observed. We have also examined a flow system, but no essential change was observed. In order to minimize the thermal extension effect of the pyrex tube due to discharge, the measurements were made after a certain equilibrium had been reached in the cavity length.

We used a Perkin-Elmer 112G grating spectrophotometer with a KBr foreprism.[3] The 9—11 μ region was covered with the first order of a 75/mm grating. The gases which have absorption bands around 10 μ region were chosen. They are listed in Table 1 with the relevant absorption center and the approximate vibrational mode for each gas. We have also examined

some liquids. In this case, liquid cells with thickness 1.0 mm and 0.1 mm with NaCl windows were used in place of the 10 cm gas cell.

Results and Discussion

The results of our present investigation are summarized in Table 2, in which the observed laser transitions for each foreign gas at various pressures are listed. With foreign gas present within the cavity, the laser output is usually distributed among several vibration-rotation transitions in one branch. However, under certain conditions simultaneous transitions in two branches are observed. The laser oscillations are usually too unstable, probably due to the competition effect among various vibration-rotation transitions, to allow quantitative measurements, but they are listed in Table 2 in approximate order of their intensities.[4] As in Table 2, a primed P hereafter refers to the P-branch transitions of the 9.6 μ band, while unprimed P and R refer, respectively, to the P- and R-branch transitions of the 10.6 μ band.

In most cases, their effects can be interpreted simply from the absorbances of given foreign gases in this region. Good examples are sulfur hexafluoride and *trans*-dichloroethylene: Both absorb strongly in the P-branch region of the 10.6 μ band, much less strongly in the R-branch region, and they have practically no absorptions in the P'-branch region. This explains rather remarkable changes in their oscillation frequencies with the gas pressures. This interpretation seems to hold for the case of liquids also, when a liquid sample was placed inside the cavity instead of gas. The results for several liquid samples are summarized in Table 3.

However, ammonia and methyl bromide seem to be exceptions. In Fig. 2(a), we show the absorption spectrum of 85 mmHg ammonia in a 10 cm cell superimposed with the emission lines of the CO_2 laser when the same cell was placed within the cavity, while in Fig. 2(b) similar spectra for the P-branch region are shown when the pressures of ammonia was reduced to 20 mmHg. No R-branch transitions were observed in the latter case. We note that the usually strong P(20) line was completely missing from the emission spectrum when ammonia was introduced into the cavity, whereas no strong absorption seems to be present at the corresponding frequency. We have shown in Fig. 2(c), the emission spectrum when the same cell containing 20 mmHg NH_3 was placed just outside the cavity (see Fig. 1(b)). The emission spectrum was almost unaffected by the presence of the outside cell.

As may be seen in Fig. 3 and Table 2(e), a similar effect was found when methyl bromide gas was introduced into the cavity. In this case the usually strong P(20) and P(22) lines are missing from the emission spectrum.[5] Even when the pressure of CH_3Br was reduced to 3 mmHg, the P(20) line was the weakest among the transitions in the P-branch region, which is rather unusual.

The results with ammonia and methyl bromide may be related with a near coincidence of the laser line with one of vibration-rotation transitions of a foreign gas. Recently, Ronn and Lide have investigated an infrared-microwave double resonance of methyl bromide using a CO_2 laser.[6] They

4) When the laser oscillations occur simultaneously among the lines in two branches, the laser action seems to become very unstable. A number of other weaker lines than those listed in Table 2 appear spasmodically in such cases.

5) The absence of the P(22)line may be explained from the fact that the line is located close to the fairly strong $^PQ_2$ line of CH_3Br: the P(22) line is at 942.54 cm^{-1} and the $^PQ_2$ is reported to locate at 942.25 cm^{-1}. (v) CH_3NO_2	20 (only)		

a) CCl_4, C_6H_5, and CH_2Cl_2 have little effect upon the laser oscillation pattern.
b) 1.0 mm cell.

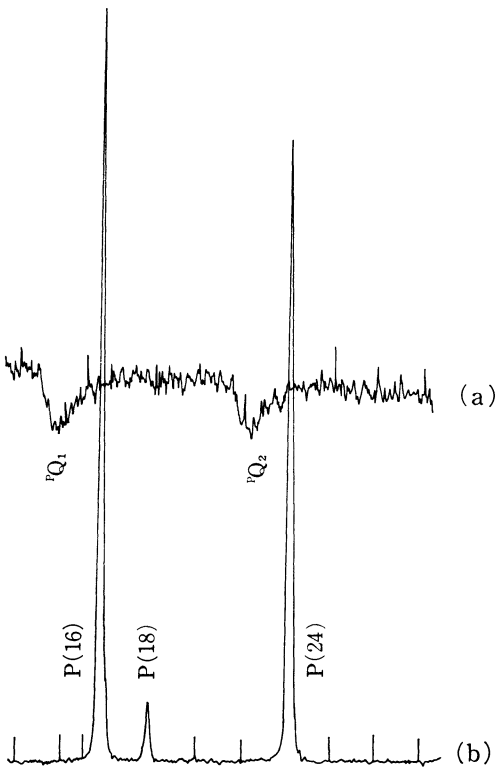

Fig. 3. (a) Absorption spectrum of 18 mmHg CH_3Br in a 10 cm gas cell superimposed with (b) the emission lines from the CO_2 laser when the same cell was inserted in the cavity. The $^PQ_1$ and $^PQ_2$ bands are at 949.14 and 942.25 cm^{-1}, respectively.

interpreted the results as due to a very near coincidence between the P(20) line and the $^PP(9)$ line of the ν_6 fundamental within 0.001 cm^{-1}. The ^PP lines of a symmetric top molecule are usually very weak in intensity,[7] however, such a close matching in frequency may suppress the laser oscillation of the particular line involved.

The spectrum of ammonia in this region was studied extensively by Garing, Nielsen, and Rao under high resolution.[8] In the spectrum of ammonia, a number of weak bands are found in the P-branch region. However, the 2sQ(4,2) line[9] which Garing *et al.* reported at 944.14 cm^{-1} is most likely to coincide with the P(20) line at 944.18 cm^{-1}.

Although the present study is rather qualitative, it opens some interesting possibilities in the study and the application of the CO_2 laser system. Mixtures of foreign gases may be used, for example, and we may be able to control the oscillation frequencies of a CO_2 laser by changing the ratios of the gases as well as their pressures.

The authors wish to express their deep gratidude to Professor Takehiko Shimanouchi and Professor Mikio Katayama for their encouragement and helpful discussions during the course of this study.

7) We see in Fig. 3 two successive Q branches, $^PQ_1$ at 949.65 cm^{-1} and $^PQ_2$ at 942.25 cm^{-1}. Jones, Popplewell and Thompson reported six weaker bands between these two Q-branches, which they assigned to the $^PP_1(10)$. (see Footnote 5). They are too weak to be seen in Fig. 3.

8) J. S. Garing, H. H. Nielsen and K. N. Rao, *J. Mol. Spectry.*, **3**, 496 (1959).

9) We have used the notation in Ref. 8. The transition is related to the hot band $\nu_2^s \rightarrow 2\nu_2^a$ with $J=4\rightarrow4$ and $K=2\rightarrow2$.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 3399—3409 (1969)

An MO-theoretical Interpretation of the Nature of Chemical Reactions. II. The Governing Principles

Kenichi FUKUI and Hiroshi FUJIMOTO

Department of Hydrocarbon Chemistry, Kyoto University, Kyoto

(Received May 19, 1969)

The importance of the overlapping between the highest occupied (HO) molecular orbital (MO) of an electron donor and the lowest unoccupied (LU) MO of an electron acceptor in determining the favorable position and spatial direction of a chemical reaction is emphasized by setting up the following auxiliary principles: the principle of a positional parallelism between the charge-transfer and the bond-interchange, the principle of a narrowing of the inter-frontier energy-level separation, and the principle of a growing frontier density along the reaction path. These sub-principles work in a cooperative manner to enable us to arrive at this general governing principle: most of the chemical interactions are liable to occur at the position and in the direction where the overlapping of the HO and the LU of the respective reactants is at its maximum; in an electron-donating reactant, HO predominates in the overlapping interaction with the MO's of the other reactant, whereas LU does so in an electron-accepting reactant; in the reactants which possess singly-occupied (SO) MO's, these play the part of HO or of LU, or of both. These particular MO's, HO, LU, and SO are "generalized frontier orbitals" in chemical reactions. This principle is applied to uni-centric reactions to give the orientation rule; if it is applied to multi-centric reactions, the stereoselection rule is obtained.

Our previous paper[1] has treated, on the assumption of no nuclear configuration change, the interac tion energy between two reactant systems; this energy is partitioned into the Coulomb interaction, exchange interaction, delocalization, and polarization terms. It has been shown that the Coulomb interaction and the delocalization terms are important. The former comes from the net atomic charges and dominates the long-range interaction, while the delocalization term is ascribed to the charge-transfer interaction and is dominant in the usual donor-acceptor interaction energy. The quantity D, which represents the delocalization term, plays a dominant role in determining the energy of charge-transfer interaction, serving as a measure of the reactivity.

The expression of D is analogous to the chemical reactivity indices, superdelocalizability[2] and delocalizability,[3] which were originally defined by the Hückel MO formulation. These indices were derived as being closely related to the frontier electron density. The interrelation of theseq uantities is worth discussing.

In the present paper, we will attempt to investigate the essential features of the charge-transfer interaction in connection with the change in nuclear configuration along the reaction path. It may be permitted to discuss such a problem in the framework of the Born-Oppenheimer approximation. The auxiliary principles which characterize the mode of change will be sought in order to derive the fundamental orientation rule and, at the same time, to disclose the relation between the orientation rule and the reactivity indices.

The Delocalization Term in Degenerate Cases

The delocalization term comes from the mixing of the charge-transfer states into the initial state in an adiabatic interaction of two ground-state reactant molecules. The delocalization term, D, is expressed[1] as:

$$D = \sum_{i}^{\text{occ}} \sum_{l}^{\text{uno}} \frac{|H_{0,i\to l} - S_{0,i\to l} H_{0,0}|^2}{H_{i\to l,i\to l} - H_{0,0}} + \sum_{k}^{\text{occ}} \sum_{j}^{\text{uno}} \frac{|H_{0,k\to j} - S_{0,k\to j} H_{0,0}|^2}{H_{k\to j,k\to j} - H_{0,0}} \qquad (1)$$

in which the suffix 0 implies the initial configuration and in which $i\to l$ signifies the monotransferred configuration in which an electron in the ith occupied MO of the reactant A is transferred to the lth unoccupied MO of the reactant B. Similarly, k and j represent an occupied MO of B and an unoccupied MO of A respectively. The corresponding wave-functions are designated as Ψ_0, $\Psi_{i\to l}$ and $\Psi_{k\to j}$ and:

1) K. Fukui and H. Fujimoto, This Bulletin, **41**, 1989 (1968).

2) K. Fukui, T. Yonezawa and C. Nagata, *ibid.*, **27**, 423 (1954).

3) K. Fukui, H. Kato and T. Yonezawa, *ibid.*, **34**, 1111 (1961).

$$H_{p,q} = \int \Psi_p^* H \Psi_q \mathrm{d}\tau \tag{2}$$

$$S_{p,q} = \int \Psi_p^* \Psi_q \mathrm{d}\tau \tag{3}$$

It is assumed, as has been done in our previous paper,[1] that the wave-function for a certain electron configuration, Ψ_p, of the total system composed of interacting reactants, A and B, is represented by an antisymmetrized product of the MO's of the two reactants, constructed so as to correspond to the electron configuration, in which each MO is made SCF (self-consistent-field) of the Roothaan type with respect to each *isolated* ground-state reactant molecule, taken as constructing an orthonormal set. The symbols $\sum^{\mathrm{occ}}$ and $\sum^{\mathrm{uno}}$ imply the summation over occupied and unoccupied MO's. The Hamiltonian operator, H is that of the combined system consisting of mutually-interacting A and B. For a more detailed explanation, see Ref. 1.

Equation (1) is obtained by the usual configuration interaction procedure as a second-order perturbation term, on the assumption that the interaction is still not very strong.[1] If one of the monotransferred configurations happens to have the same energy as the initial configuration, first-order perturbation term will appear. Such a case can arise in reference to the configuration in which one electron is shifted from the highest occupied (HO) molecular orbital (MO) of the donor molecule to the lowest unoccupied (LU) MO of the acceptor molecule in the case of donor-acceptor interaction. In that case the quantity D will be dominated by the first-order term:

$$D \sim |H_{0,\mathrm{HO}\to\mathrm{LU}} - S_{0,\mathrm{HO}\to\mathrm{LU}} H_{0,0}| \tag{4}$$

This equation is obtained from Eq. (7′) of Ref. 1.

Even in a not exactly degenerate case, the monotransferred term corresponding to the one-electron transfer from the HO of the donor to the LU of the acceptor can make an overwhelming contribution to the delocalization term when the denominator of this term in Eq. (2) is sufficiently small in comparison with the other monotransferred terms.

$$D \sim \frac{|H_{0,\mathrm{HO}\to\mathrm{LU}} - S_{0,\mathrm{HO}\to\mathrm{LU}} H_{0,0}|^2}{H_{\mathrm{HO}\to\mathrm{LU},\mathrm{HO}\to\mathrm{LU}} - H_{0,0}} \tag{5}$$

As Mulliken has already pointed out, $H_{0,\mathrm{HO}\to\mathrm{LU}}$ is approximately proportional to $S_{0,\mathrm{HO}\to\mathrm{LU}}$, so that the magnitude of D and, accordingly, the interaction (stabilization) energy can be measured in terms of the extent of orbital overlapping between HO and LU, since:

$$S_{0,\mathrm{HO}\to\mathrm{LU}} \cong \sqrt{2}\, s_{\mathrm{HO,LU}} \tag{6}$$

where:

$$s_{\mathrm{HO,LU}} = \int a_{\mathrm{HO}}(1) b_{\mathrm{LU}}(1) \mathrm{d}v(1) \tag{7}$$

and where a_{HO} and b_{LU} are the HO MO of A and the LU MO of B respectively, both being taken as having a real spatial part.

In this way, Eq. (5) leads to the "overlap and orientation" principle of Mulliken.[4] Equation (4) will lead to the same conclusion with regard to the orientation principle. The favorable orientation in such cases can be determined by the rule of the maximum overlapping of HO and LU. Namely, the interaction takes place at the position and in the direction in which the largest overlapping of these particular MO's is attained.

In addition, there are special circumstances which make these particular orbitals, HO and LU, discriminatively important. The importance of the interaction term between HO and LU prevails over a wider range of combination of two reactants; furthermore, it is enhanced in actually-occurring reactions if the nuclear-configuration change along the reaction path is taken into consideration. This point will be discussed on the basis of auxiliary principles later. In any event, the usefulness of the equations of the type of Eq. (4) or (5) is in fact, far more than could be expected simply from the conditions for the fitness of these equations.

The Principle of a Positional Parallelism between the Charge-transfer and the Bond-interchange

It has already been shown[5-7] that the nodal property of HO and LU MO's plays an essential role in determining the steric course of electrocyclic reactions. The same property is important in promoting the alteration of the molecular shape in the case of orbital interaction.

Usually, an atom is, as a whole, bonding with neighboring atoms in occupied MO's and antibonding in unoccupied MO's. This circumstance can be understood by a very simple example which employs the linear-combination-of-atomic-orbitals (LC AO) MO scheme. If we use the Hückel MO theory (overlap neglected) in the frame of π-electron approximation for a planar conjugated molecule, the following relation holds with respect to the rth π AO:

$$(\alpha_r - \varepsilon_i)(C_r^{(i)})^2 + \sum_s^{\mathrm{nei}} C_r^{(i)} C_s^{(i)} \beta_{rs} = 0 \tag{8}$$

where α_r is the Coulomb integral of the rth AO; β_{rs}, the resonance integral between the rth and the sth AO's; ε_i, the energy of the ith MO, and $C_r^{(i)}$, the coefficient of the rth AO in the ith MO. The notation $\sum^{\mathrm{nei}}$ implies summation over all the neighboring AO's of the rth AO. In the case of con-

6) K. Fukui, This Bulletin, **39**, 498 (1966).
7) K. Fukui and H. Fujimoto, *ibid.*, **39**, 2116 (1966).

jugated hydrocarbons, all the α_r's and all the β_{rs}'s can be put equal to constant values, α and β respectively. Then, it follows from Eq. (8) that:

$$\sum_{s}^{\text{nei}} C_r^{(i)} C_s^{(i)} = \frac{\alpha - \varepsilon_i}{(-\beta)} (C_r^{(i)})^2 \qquad (9)$$

As usual, the energies of the occupied orbitals are lower than α, while those of the unoccupied orbitals are higher than α. Therefore, the following relations hold for any r: $\sum_{s}^{\text{nei}} C_s^{(i)} C_t^{(i)}$ is positive and proportional to $(C_r^{(i)})^2$ for occupied MO's and is negative and proportional to $(C_r^{(i)})^2$ for unoccupied MO's.

In this way, it is established that the position of the largest HO or LU density is, at the same time, that position which is most liable to weaken the bonds with neighboring atoms in case of electron-releasing or accepting interaction respectively.[8] Namely, the charge-transfer weakens the bonds most greatly at the position of the largest frontier electron density.[5,9]

Some examples of the nodal property of the π HO's and LU's of several conjugated hydrocarbons are shown in Fig. 1, in which the shaded and unshaded areas correspond to the positive and negative regions of the MO coefficients. It can be qualitatively understood from the figure that there is a parallelism between the partial population and the partial sum of the bond-order with neighbors. Even in heteroaromatic systems similar relationships hold. We can see the circumstances in Fig. 2.

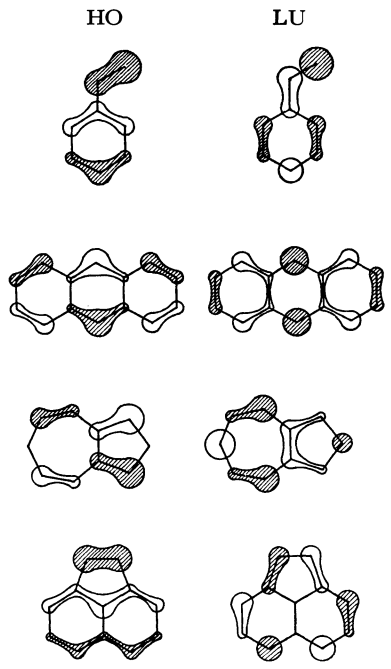

Fig. 1. The nodal property of π HO and LU of some conjugated hydrocarbons.

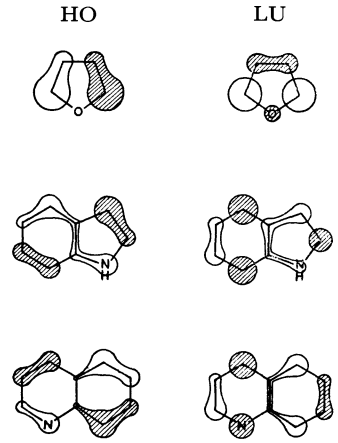

Fig. 2. The nodal property of π HO and LU of some heteroconjugated systems.

Such a character of MO's is to a certain extent perceived in more elaborate calculations, independent of the order of approximation adopted. An example is given in Table 1 using the Pariser-Parr-Pople approximation.[10] The suffix f signifies HO or LU. A distinct parallelism is recognized among the partial population and the partial sum of the bond-order with the neighbors.

Similar circumstances also exist in the extended Hückel treatment[11] of three-dimensional molecules. The orientation in the E2 reaction of halogenated hydrocarbons has previously been discussed.[12,13] If we concentrate our attention on one of the hydrogen 1s AO's, say r, the following equation is

8) When the HO energy happens to be higher than α, the electron-releasing will cause bond-strengthening. The result is the same with the electron-accepting in the LU MO when its energy is lower than α.

9) The extent of this bond-loosening will, therefore, be a measure of the ease of intramolecular electron localization at the reaction center in the case of interaction with another molecule. This may be one of the reasons why the localization energy gives a parallel prediction with the frontier electron density for the chemical reactivity of a majority of conjugated molecules (*cf.* A. Streitwieser, Jr., "Molecular Orbital Theory for Organic Chemists," John Wiley & Sons, New York (1961), p. 305).

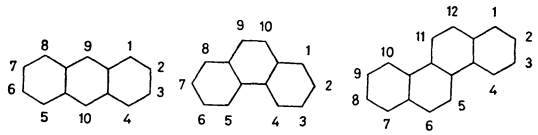
	6	0.14446	0.07687	−0.07687

Numberings are as follows:



Anthracene Phenanthrene Chrysene

All C–C distances and all C–C–C angles were assumed to be 1.4Å and 120°, respectively, for the sake of simplicity of computations.

obtained in place of Eq. (8):

$$(h_{rr}-\varepsilon_i)(C_r^{(i)})^2 + \sum_{s(\neq r)} (h_{rs}-\varepsilon_i s_{rs})C_r^{(i)}C_s^{(i)} = 0 \quad (10)$$

where:

$$h_{rs} = \frac{K}{2}(h_{rr}+h_{ss})s_{rs} \quad (11)$$

where h_{rr}, h_{rs} and s_{rs} are the Coulomb, resonance, and overlap integrals respectively, and where K is the Wolfsberg-Helmholtz constant.[11] The other symbols have the same meaning as in the Hückel scheme. Although the value of the Coulomb integral varies, of course, from one AO to another, it may be possible to employ tentatively, in place of the individual h_{ss}, a sort of mean value, h, which makes the second term of the right side of Eq. (10) equal to:

$$\sum_{s(\neq r)} \left\{\frac{K}{2}(h_{rr}+h)-\varepsilon_i\right\} C_r^{(i)}C_s^{(i)}s_{rs} \quad (12)$$

Hence, it follows that:

$$\sum_{s(\neq r)} C_r^{(i)}C_s^{(i)}s_{rs} = -\frac{h_{rr}-\varepsilon_i}{\frac{K}{2}(h_{rr}+h)-\varepsilon_i}(C_r^{(i)})^2 \quad (13)$$

Then, with respect to LU, the relations $h_{rr}-\varepsilon_{\text{LU}}<0$ and $(K/2)(h_{rr}+h)-\varepsilon_{\text{LU}}<0$ usually hold. The left side of Eq. (13) is equal to $(1/2)v_r^{(i)}$, which is the valence-active part[14] of the partial AO population of the rth AO in the ith MO defined by:

$$v_r^{(i)} = 2\sum_{(s\neq r)} C_r^{(i)}C_s^{(i)}s_{rs} \quad (14)$$

Therefore, $v_r^{(\text{LU})}$ must be negative and proportional to $(C_r^{(\text{LU})})^2$, indicating that the hydrogen atom having the largest frontier electron density is most liable to a loosening of the bond with the remaining part of the molecule.

This conclusion may be confirmed by actual numerical calculation in which the approximation using the mean h value is, of course, not applied. Examles are shown in Table 2. The table contains the frontier electron density $(C_r^{(\text{LU})})^2$ and the valence-active part of the partial population of the frontier orbital, $v_r^{(\text{LU})}$. Exemplifications by the various calculations mentioned above indicate the existence of a parallelism among actually reactive sites in a molecule; the position of the largest frontier orbital extension is at the same time the position where the bonds with neighboring atoms are, as a whole, most liable to be loosened. Since

the frontier orbital extension is a measure of the ease of charge-transfer interaction, this conclusion represents a parallel relationship between the position of charge-transfer and the position of bond-interchange in a molecule in chemical reactions; it will later be shown to act as one of the two auxiliary principles which lead to the general orientation principle.

The Principle of a Narrowing of the Inter-frontier Level Separation

As has been mentioned above, the charge-transfer interaction takes place at the position of the largest frontier electron density, the position which is simultaneously most susceptible to a weakening of the bonds with the neighboring atoms. This bond-loosening causes the nuclear configuration to change in a definite direction, which should be controlled by the nodal property of the frontier orbitals.

This direction of nuclear-configuration change may be characterized by the mode of change in the energy-level separation between the HO of the donor and the LU of the acceptor. Namely, the HO MO of the donor becomes, in general, higher, while LU of the acceptor becomes lower, in the event of charge-transfer, causing a narrowing of the inter-frontier energy level separation. Sush a conclusion can very easily be understood, since a bonding MO is made unstable by electron-releasing and since an antibonding MO is made unstable by electron-accepting, in both cases through bond-loosening.

Let us consider this problem by quoting several examples. In the first place, let us take the Diels-Alder-type addition of ethylene and butadiene as an instance. The nodal properties of the HO and LU of ethylene and butadiene are shown in Fig. 3, together with the mode of charge-transfer interaction. The HO MO of butadiene is bonding in the region of 1,2- and 3,4-π-bonds and antidonding in the 2,3-region, while the LU of butadiene has the opposite nodal property. The HO of ethylene is bonding, while LU is antibonding. This implies that both

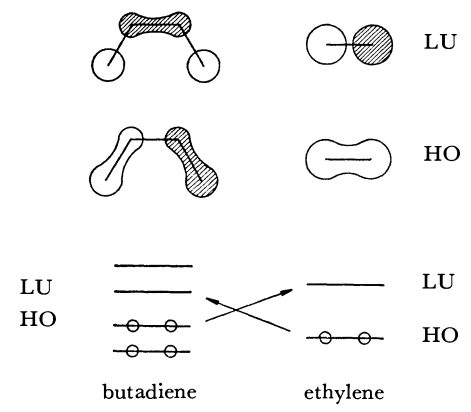

Fig. 3. The nodal property of HO and LU in ethylene and butadiene.

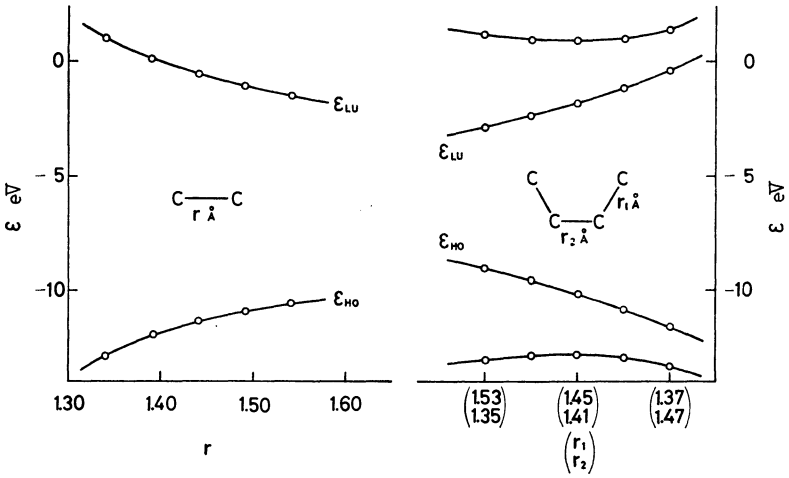

ethylene butadiene

Fig. 4. The change in energy of molecular orbitals in ethylene and butadiene along the reaction path.

the charge-transfer from the HO of ethylene to the LU of butadiene and that from the HO of butadiene to the LU of ethylene will decrease the π bond-order of ethylene and cause a double-bond shift in butadiene.

The results of calculations by the Pariser-Parr-Pople scheme[10] for several altered nuclear coordinates are shown in Fig. 4. The transient nuclear configurations along the reaction path could reasonably be assumed by considering the direction of charge-transfer and the nodal property of the HO and LU. We can see that the changes in the HO and LU can be clearly distinguished from those of the other orbitals. The separation of these MO levels is considerably contracted as the reaction proceeds. Such a property is common in dienes and dienophiles.

The mode of change in the MO energies of this sort is more conspicuous in the sigma electron systems. As a typical example, let us present the results of an extended Hückel calculation on the SN-2 reaction of methyl chloride by the chloride anion. The reaction coordinates were extracted from the calculation of Kato *et al.*[15] The solid line in Fig. 5 indicates the change in the energy of the LU of methyl chloride, while the broken line shows that of the system composed of methyl chloride and chloride anion. The other unoccupied MO's are located much higher than LU,[16] and the changes in these levels were found to be small in comparison with that in LU.

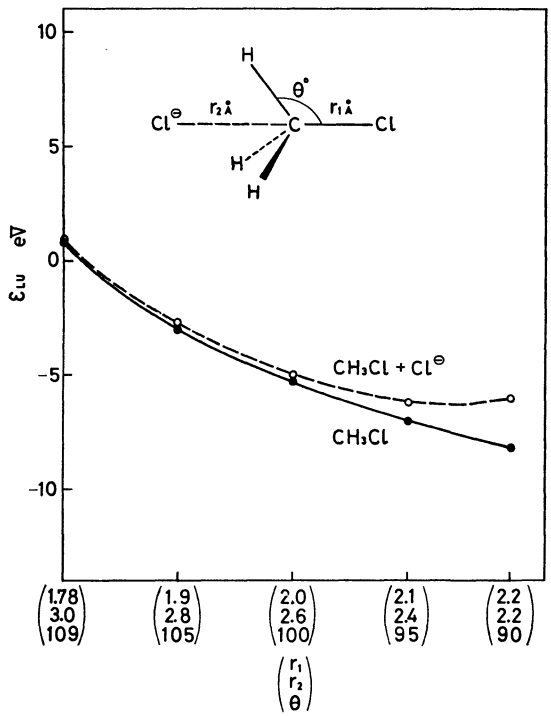

Fig. 5. The change in the energy of LU MO of methyl chloride with and without another approaching chloride anion.

It may be of interest to investigate the content of the activation energy. The stretching of the C–Cl bond in methyl chloride will require enough energy to form an important fraction of the activation energy of the reaction. The LU MO is highly localized at the C–Cl bond and exhibits an antibonding char-

15) H. Kato, K. Morokuma, T. Yonezawa and K. Fukui, This Bulletin, **38**, 1749 (1965).

16) The unoccupied MO's are expressed in terms of a set of limited-basis AO's chosen so as to be suitable in representing the occupied MO's. This is an unsatisfactory point. However, the essential features will never be changed by the employment of any extended-basis set of AO's.

acter. The charge-transfer from the attacking base to LU will, therefore, cause the C–Cl bond stretching. However, this will produce stabilization on account of the lowering of the MO level, as is shown in Fig. 5. In this way, a considerable part of the activation energy is reduced. It can be understood that the charge-transfer and the nuclear configuration change cooperate in driving the chemical reactions.

The circumstances are similar also in nucleophilic elimination reactions. For instance, the LU of ethyl chloride is highly localized at the carbon-chlorine bond, which shows an antibonding nature. Accordingly, the charge-transfer to the LU from the attacking base through *trans*-β-hydrogen may cause a weakening of the C–Cl bond as well as of the β-carbon-hydrogen bond, resulting in a lowering of the LU MO energy. Such a lowering of the MO energy may be of great importance in facilitating the bimolecular elimination of halogenated paraffins by a nucleophile. The results of the numerical calculation have been given in previous papers.[12,13]

Next, let us consider aromatic substitutions. In these reactions the bonds between the reaction center and the neighboring atoms may be lengthened to some extent by the decrease in the π bond-orders of this region. This will cause an elevation of the HO level and a lowering of the LU level. In addition, the leaving hydrogen atom at the reaction center will leave the molecular plane as the reaction proceeds. It may be of interest to examine the energy change in the frontier orbitals in this case. The results of the numerical calculation are shown in Fig. 6.

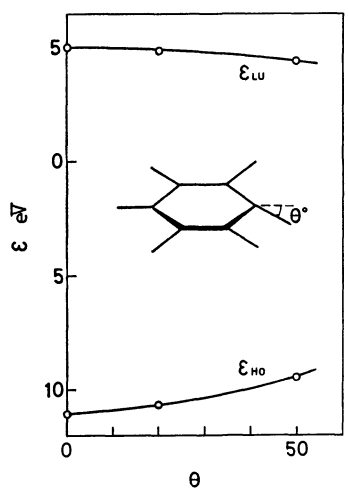

Fig. 6. The change in the energy of HO and LU in benzene due to the C–H bending.

The changes in the energies of HO and LU due to such a change in the bond angle are, in general, small in comparison with those due to the bond-stretching. However, the change is significant in the sense that the effect of valence angles can never be left out of account in discussing the problem.

The ascending HO energy and the descending LU energy of aromatic molecules couple with the descending LU of electrophilic reagents and with the ascending HO of nucleophilic reagents respectively to give rise to a narrowing of the inter-frontier level separation. In the case of liquid-phase ionic reactions, it must frequently be remarked that one should take into account the process of desolvation and solvation in the level change of the reagent orbitals. In homolytic reactions, the ascending HO and descending LU levels both approach the singly-occupied (SO) MO level of reagent radicals, bringing about a simultaneous charge-transfer to and a back-transfer from the SO MO.

In order to confirm these circumstances, the frontier MO's of attacking electrophiles are examined. The hydronium ion is taken as a simple example of solvated electrophiles. The extended Hückel calculation indicates that the LU of hydronium ion lowers as the distance between the proton, which is the bare electrophilic reagent, and the water molecule, that is the solvent, grows with the proceeding of the reaction. The results are shown in Fig. 7.

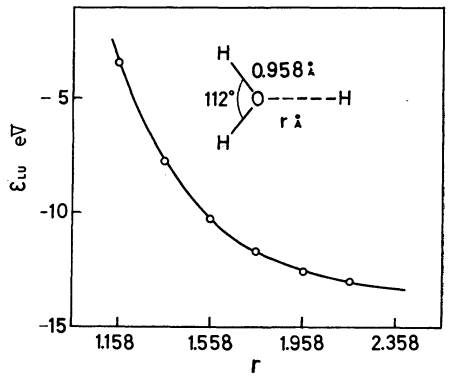

Fig. 7. The change in the energy of LU in hydronium ion due to the O–H stretching.

Lastly, the heterolytic addition to an olefinic double bond will be cited. The reagent is here typified by a chlorine molecule in order to simplify the calculation. The first stage of this reaction is assumed to be the formation of a bridged cation,[17] which may cause the stretching of the carbon-carbon bond.

An extended Hückel calculation is made to obtain a relation between the position of chlorine and the MO energy. The chlorine is shifted in the direction parallel to the carbon-carbon bond. As can be seen in Fig. 8, the total energy, E, increases as the chlorine atom separates from the center plane

17) An energy minimum arises in the event of approaching the C–C bond on the bisecting line. The stability of triangular interaction is discussed in Ref. 6.

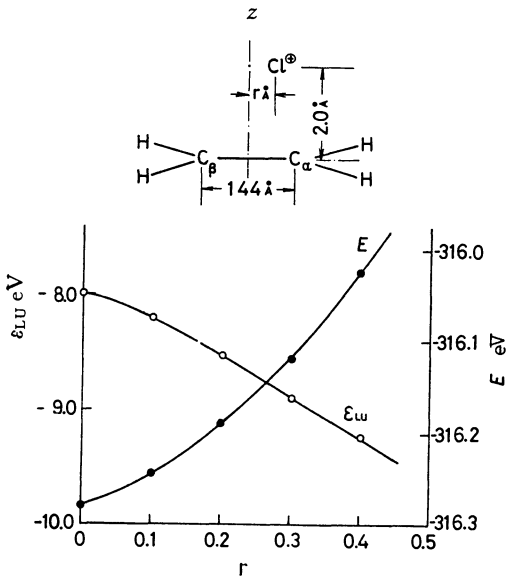

Fig. 8. The change in the energy of LU and in the total energy of ethylene-chorine cation system.

to approach the α-carbon; also, the LU level becomes lower in the event of change in this direction. The progress of the charge-transfer causes the narrowing of the inter-frontier separation, so the contribution of LU of the cation becomes enhanced as the interaction goes on.

The results of numerical calculations with respect to the several examples of chemical reactions cited above suggest the general relationship between the inter-frontier energy level separation and the nuclear configuration change along the reaction path. This implies that the importance of the frontier orbitals is more than would be expected from the case where the separation narrowing is left out of account.

The Principle of a Growing Frontier Electron Density along the Reaction Path

In order to make the third auxiliary principle concrete, it is recommended that we discuss the simplest case first. The well-discussed problem of aromatic substitution fits this purpose. As the reaction proceeds, the sum of the mobile bond-orders of the bonds between the reaction center and the neighboring atoms will decrease according to Eq. (9), causing a loosening of these bonds. The effect of this π-bond weakening may be represented, in the frame of the Hückel MO method, by the decrease in the absolute value of the resonance integrals corresponding to these bonds.

It is important to investigate the change in the frontier electron density at the actual reaction site according to the increase in the resonance integrals (that is, the decrease in the absolute value) with the neighboring atoms. In actual reactions, this change evidently never amounts to as large values as $(-\beta)$, where β is the original value of the resonance integral. However, as an extremely assumptive case, this increment may be taken as $(-\beta)$, so that the general tendency of the effect of such changes might more dinstinctly be realized. In that case the π AO at the reaction center finally becomes isolated (Stage(IV)). Stage (III), immediately before Stage (IV), indicates that a small π conjugation still remains between the reaction center and the neighboring atoms.

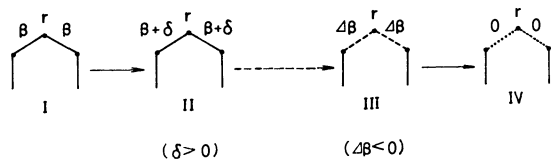
The frontier electron densities, $(C_r^{(HO)})^2$ and $(C_r^{(LU)})^2$, usually increase along the (I)→(II) path. This is valid with respect to the positions in alternant hydrocarbons, and also in a majority of positions of nonalternant hydrocarbons.

In order to understand these circumstances qualitatively, although not in a mathematically strict sense, it is convenient to consider Stage (III). In this stage it is very easy to prove that:

$$\lim_{\Delta\beta\to 0}(C_r^{(HO)})^2 \quad \text{and} \quad (C_r^{(LU)})^2 = \frac{1}{2} \qquad (15)$$

provided that the system obtained by deleting the atom r from the original hydrocarbon has a nonbonding level, $\varepsilon=\alpha$.[18] Since the original values of $(C_r^{(HO)})^2$ and $(C_r^{(LU)})^2$ are usually far less than 0.5, this result suggests that the frontier electron density increases along the path (I)—(III). The relation of Eq. (15) holds in alternant hydrocarbons and also in several, actually reactive positions of some nonalternant hydrocarbons, like the $(C_1^{(HO)})^2$ of fulvene, the $(C_1^{(HO)})^2$ of acenaphthylene, and the $(C_7^{(HO)})^2$ of fluoranthene.[19]

When the remaining system has no nonbonding MO, the following two sub-cases are possible. Let



18) If the remaining system possesses n nonbonding MO's, $(C_r^{(HO)})^2$ and $(C_r^{(LU)})^2$ become $1/(n+1)$.

19) The numbering of these nonalternants conforms to: K. Fukui, T. Yonezawa and C. Nagata, This Bulletin, **34**, 37 (1961).

the number of occupied MO's of the original system be n, and let the number of occupied MO's of the remaining system obtained by deleting the atom r from the original system be m. The first sub-case is the one where $m=n$. In this case it follows that:

$$\lim_{\Delta\beta\to 0}(C_r^{(\mathrm{LU})})^2 = 1 \qquad (16)$$

Such a relation holds in the position 6 of fulvene, the position 5 of acenaphthylene, the position 6 of azulene, and the position 3 of fluoranthene. The second sub-case is specified by $m=n-1$, so that:

$$\lim_{\Delta\beta\to 0}(C_r^{(\mathrm{HO})})^2 = 1 \qquad (17)$$

which is actually satisfied in the position 1 of azulene. All of these cases indicate that the rule of growing frontier electron density might hold in actually reactive positions.

One of the few exceptions is $(C_3^{(\mathrm{HO})})^2$ of fluoranthene. In this case we have $m=n$, so that $\lim_{\Delta\beta\to 0}(C_3^{(\mathrm{HO})})^2=0$. However, it should be noted that in this case the HO MO energy of the remaining system is very close to the nonbonding orbital energy ($\varepsilon=\alpha+0.1317\beta$) whereas the energy of the isolated AO of the position 3 will easily become lower than $\varepsilon=\alpha$ under the influence of an approaching electrophile, so that the isolated AO energy might not become higher than the HO MO of the remaining system. In this way, it is possible even in this case that:

$$\lim_{\Delta\beta\to 0}(C_3^{(\mathrm{HO})})^2 = 0.5 \text{ or } 1 \qquad (18)$$

Such a Coulombic effect of the attacking reagent should be considered in the other cases which have already been mentioned. In all of these cases, however, the circumstances are more favorable, in view of this effect, for the validity of the rule of growing frontier electron density along the reaction path.

The heterolytic addition of chlorine to a C=C bond (discussed in preceding section) is also an example. Figure 9 shows that the partial valence-inactive population of the $2p_z$ AO of β-carbon in the LU increases with the progress of the reaction.

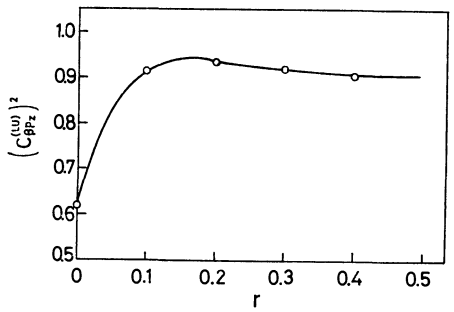


Fig. 9. The change in the partial population of p_z orbital at β-carbon of ethylene-chlorine cation system.

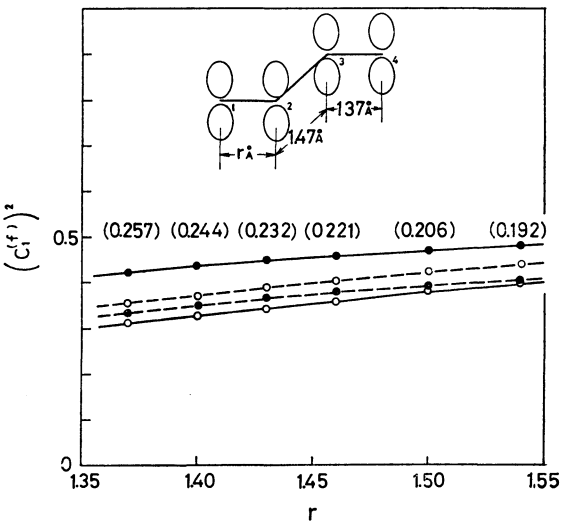

Fig. 10. The change in frontier electron density in the π electronic part of *trans*-butadiene along the departing of the end carbon atom.
—●— LU including overlap
—○— HO including overlap
--●-- LU neglecting overlap
--○-- HO neglecting overlap
(The values in parenthses indicate the overlap integral between two $p\pi$ atomic orbitals at the carbon atoms 1 and 2.)

This rule is not essentially violated by the adoption of more elaborate methods of calculation. With the change in the nuclear configuration, the overlap integrals between the AO's belonging to the departing atom and the AO's belonging to the remainder of the molecule vary. In order to discuss the change in the magnitude of the frontier electron density as a measure of the numerator of Eq. (1), the effect of the change in the overlap integrals upon the frontier electron density through the normalization condition can never be neglected. Figure 10 gives the change in the $(C_r^{(f)})^2$ in the π electronic part of butadiene due to the stretching of the C=C bond. We can see that the essential conclusion mentioned above also holds in the extended Hückel calculation, explicitly including overlap integrals.

The Co-operation of Sub-principles and the General Orientation and Stereoselection Rule

It is obvious that the three sub-principles work co-operatively in promoting the chemical reaction. The charge-transfer interaction takes place predominantly at the position and in the direction in which the overlapping of the HO and LU of the two reacting species is largest, as is to be expected from Eqs. (5) and (6). This interaction brings about a local bond-weakening, which is mainly controlled by the nodal property of the frontier orbitals. The ex-

tent of bond-weakening positionally parallels the frontier-orbital extension according to the first sub-principle. The bond-loosening leads to the nuclear configuration change in a definite direction, which causes the narrowing of the inter-frontier energy level separation according to the second sub-principle and, at the same time, the increase in the frontier electron density at the reaction center according to the third sub-principle. These make the denominator on the right side of Eq. (5) smaller and the numerator larger, so the contribution of the frontier orbital interaction term to the delocalization part (Eq. (1)) of the interaction energy becomes larger. Hence, the charge-transfer interaction increases, resulting again in a bond-interchange near the reaction center, a molecular shape deformation, a narrowing of the inter-frontier separation, and an increase in the frontier electron density, in turn. The importance of the term of Eq. (5) thus becomes greater and greater, the form of the delocalization term approaching that of Eq. (4).

It should be remarked in this connection that the MO's which can participate in such a type of cooperation are obviously restricted to the HO and LU. The energies of the other MO's undergo only the minimum change which is absolutely needed for the occurrence of the reaction and is assumed to be almost constant with respect to every possible position of the reaction. This is because a stable molecule originally takes the nuclear configuration which is energetically most favorable, and, in the event of reaction, any change in the nuclear configuration will be accompanied by an unstabilization which resembles the promotion in atoms in the case of molecule formation. Therefore, the change in the nuclear configuration will take place in such a direction that the unstabilization will be most effectively reduced, while a direction of change in which no energetical advantage can be expected will be avoided. As has already been mentioned, the charge-transfer between the HO and LU causes an alteration in the molecualr shape at the site of the greatest HO or LU MO density. In this way, the change in molecular shape is automatically limited to the proximity of the particular position in the reacting species. This self-controlling action seems to underlie the empirical rule which has been known as "the principle of least motion" or "the principle of least molecular deformation."[20]

It is evident from the above discussion that the most effective means to promote a chemical reaction smoothly by reducing the unstabilization attributable to the nuclear configuration change due to the interaction is to give rise to a change by which the charge-transfer from the HO of one species to the LU of the other is effectuated. This charge-transfe rmay be uni-directional or mutual according to the magnitude of the difference between the electron-donating power of one reactant and the electron-accepting power of the other. Other directions of nuclear configuration change are all rejected as bringing about little gain in stabilization energy.

In this way, the reaction pathway becomes dominantly controlled by the frontier-orbital interaction. The position of the reaction will be determined, through Eq. (6), by the rule of the maximum overlapping of the HO and LU (sometimes the SO in place of the HO or LU) of the two reacting species. The general orientation principle is, therefore, as follows: "*A majority of chemical reactions are liable to take place at the position and in the direction where the overlapping of the HO and LU of the respective reactants is at its maximum; in an electron-donating species, HO predominates in the overlapping interaction, while the LU does so in an electron-accepting reactant; in the reacting species which possess SO MO's, these play the part of the HO or of the LU, or of both.*"

In some intramolecular reactions, like the cyclization of a conjugated olefinic chain, the dominantly controlling factor seems to be the first-order inteaction term,[6,21] in which the HO-LU interaction is concealed; however, the same reaction can be discussed by considering the HO-LU interaction between two parts of a molecule.[22] The HO-LU interaction has also been considered between the sigma- and pi-parts of conjugated molecules in order to derive a stereoselection rule.[7]

In this view, the particular MO's which control the reaction pathway in chemical reactions in general, *i.e.*, HO, LU, and SO, are referred to as "generalized frontier orbitals."

It seems in this way that the principle presented above is a general one which will qualitatively govern almost all sorts of chemical interactions, including intermolecular and intramolecular as well as unicentric and multicentric. The principle can be applied to a unicentric reaction to derive an orientation rule; and if it is employed to discuss multicentric reactions, the result is the stereoselection rule, which has already been discussed.[7,21,22]

The reactivity indices, the frontier electron density, the delocalizability, and the superdelocalizability, are those for unicentric reactions and give predictions consistent with the general orientation principle. In this connection, it is worthwhile to mention the relation between these chemical reactivity indices and the general orientation rule. These indices are derived from Eq. (1), in which the nuclear-configration change along

20) See, for example, J. Hine, *J. Org. Chem.*, **31**, 1236 (1966), and the references cited therein.

22) K. Fukui and H. Fujimoto, "Mechanism of Molecular Migrations," Vol. 2, ed. by B. S. Thyagarajan, Wiley-Interscience (1969).

the reaction path is left out. Namely the indices, like most other reactvity indices ever proposed, are calculated with regard to an isolated, undeformed molecule. If the molecular deformation along the reaction path is taken into consideration, the values of these indices will be changed. The change in the value of delocalizability and superdelocalizability will be controlled by the sub-principles discussed above, so the contribution of the terms corresponding to the frontier orbitals will become more dominant than in the original expression.

In the superdelocalizability thus modified, the frontier terms should be weighted more. The index of the type of Eq. (5), the one-term approximation of superdelocalizability,[23] and Brown's Z-value[24] are all this line. We prefer the frontier terms and recommend that the frontier electron density be used as a reactivity index.

The calculations have been carried out partly on the HITAC 5020E computer at the Computer Center of the University of Tokyo and partly on the FACOM 230·60 computer at the Computer Center of Kyoto University.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 3409—3414 (1969)

On the Emission of Excited Complexes Formed between Condensed Aromatic Hydrocarbons and Aliphatic Amines*[1]

Akira NAKAJIMA*[2]

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received May 21, 1969)

Anomalous emission observed at long wavelengths in the systems of condensed aromatic hydrocarbons and aliphatic tertiary amines has been studied. The anthracene-tri-*n*-butylamine system has been dealt with in detail. On the basis of the absorption spectrum, the temperature dependence of the long-wavelength emission and the relation between the quenching of the hydrocarbon fluorescence and the intensity of the long-wavelength emission, it has been concluded that this emission originates from the excited complex formed between an excited hydrocarbon and an amine. The interaction involved in excited-complex formation is of a charge-transfer type. This was confirmed by the correlation of the wavelengths of the excited-complex emission with the ionization potentials of amines and the electron affinities of aromatic hydrocarbons and by the large dipole moment of the excited complex.

In general, the behavior of a molecule in the electronically excited state differs considerably from that in the ground state. Its ionization potential is smaller and its electron affinity is larger in the excited state, so that the molecular interaction may be expected to bring about new interesting phenomena. Many aromatic hydrocarbons dissolved in such solvents as *N,N*-dialkyl aromatic amines have been demonstrated to fluoresce at much longer wavelengths than in inert solvents.[1-4] As the absorption spectra of the hydrocarbons in the amines do not suffer any essential change, it is evident that no specific interaction exists between a ground-state hydrocarbon and an amine. From this observation it has been concluded that the new fluorescence can be ascribed to the excited complex formed exclusively from an excited-state hydrocarbon and an amine. Based on the relation of the energies of the new fluorescence with the electron affinities of the hydrocarbons and the ionization potentials of the amines, it has also been confirmed

that the charge-transfer(CT) interaction between an excited hydrocarbon and an amine is responsible for the formation of an excited complex. The fact that the appearance of the new fluorescence is accompanied by the quenching of the hydrocarbon fluorescence seems to suggest that the fluorescence quenching should be intimately connected with the excited-complex formation.

Since similar excited complexes have been discovered in many other systems,[5-9] it can reasonably be proposed that the excited CT complex formed diffusionally as an intermediate species plays an important role in the mechanism of fluorescence quenching.

The present author has found that anomalous emission can be observed in the systems of the condensed aromatic hydrocarbons and some of the aliphatic amines in various solvents. The absorption spectra indicated such small interactions between the ground-state hydrocarbons and the amines that the emission should be considered to originate from some kind of molecular complex existing only in the excited state.

In the case of aromatic amines the interaction involved should be classified as a π-π interaction, whereas that for aliphatic amines may be regarded as an n-π interaction. No fluorescence study of this has yet been reported. Thus, it is worth while to undertake an investigation with a view to clarifying the character of the interaction and its correlation with fluorescence quenching.

The present paper reports the results of some experiments on the systems of the condensed aromatic hydrocarbons and the aliphatic amines. The system of anthracene and tri-*n*-butylamine was studied in some detail.

Experimental

All the amines used were dried over pellets of potassium hydroxide and/or distilled. Triethylamine, tri-*n*-butylamine and diethylamine were further distilled fractionally in an atmosphere of nitrogen under reduced pressure. Naphthalene and phenanthrene were recrystallized from ethanol, zone-refined and sublimed in a vacuum. Acenaphthene and triphenylene were recrystallized from ethanol. 1,2-Benzanthracene was recrystallized from benzene. 9,10-Diphenylanthracene was recrystallized from xylene and sublimed in a vacuum. Anthracene was purified by recrystallization from xylene, zone-refining and sublimation in a vacuum. Pyrene was recrystallized from xylene, chromatographed, zone-refined and sublimed in a vacuum. Perylene was chromatographed and recrystallized. *n*-Hexane used was a Super special grade reagent of Wako Junyaku Co. G. R. grade cyclohexane and acetone, also from Wako Junyaku Co., were used without further purification. Benzene, chloroform and dichloromethane used were Dotite Spectrosol reagents of Dojin Yakukagaku Co. Spectro-grade carbon tetrachloride from Tokyo Kasei Co. was used. Chlorobenzene was a G. R. grade reagent from Koso Kagaku Co. and was fractionally distilled after being dried with phosphorus pentoxide. Fluorobenzene of British Drug Houses Ltd. was used without purification. G. R. grade ethyl ether was a product of Showa Ether Co. and was fractionally distilled after being dried with sodium. G. R. grade di-*n*-butyl ether from Tokyo Kasei Co. was dried with sodium and distilled. Ethyl acetate, cyclohexanone and benzonitrile of Wako Junyaku Co., G. R. grade, were treated with phosphorus pentoxide and distilled twice. Dibutyl phthalate of Wako Junyaku Co. was distilled twice under reduced pressure. Anisole was distilled in a nitrogen atmosphere. Tetralin and decalin were distilled. 1,2-Dichloroethane and dioxane of Wako Junyaku Co., *p*-xylene, isopropylbenzene and *t*-butylbenzene of Tokyo Kasei Co., G. R. or E. P. grade, were used. Spectro-grade *N*,*N*-dimethylformamide of Tokyo Kasei Co. was used without further purification. Methanol was a G. R. grade reagent of Wako Junyaku Co. Toluene was distilled from a G. R. grade reagent of Wako Junyaku Co.

The fluorescence and absorption spectra were measured with a Hitachi EPS-2U recording spectrophotometer.

The exciting light source was a Toshiba SHL-100UV high-pressure mercury lamp, combined with a UV filter or a Bausch & Lomb grating monochromator to select the wavelength of excitation.

The wave numbers of the emission-band maxima were determined from the emission spectra corrected for the spectral sensitivity of the instrument.

Measurements were made on the aerated samples at room temperature. For the anthracene-tri-*n*-butylamine-toluene system, however, the sample solutions were repeatedly degassed by the usual freeze-pump-thaw method.

For measuring the temperature dependence of the emission spectra, a Pyrex tube containing the sample solution was immersed in a quartz Dewar with liquid nitrogen or a mixture of dry ice and acetone for low temperatures, or with warm water above room temperature. The usual concentrations of the aromatic hydrocarbons and the amines were 10^{-4}—10^{-3} M and 0.1—1 M, respectively. It was confirmed that the amines used exhibited no emission, though they slightly absorbed the exciting light at higher concentrations.

Results and Discussion

The absorption spectra of the solutions used for the observation of emission showed no essential change, except for the slight differences due to the ordinary solvent effects, in absorbance and wavelength, as is shown in Fig. 1. This indicates that an amine makes no specific interaction with a ground-state condensed aromatic hydrocarbon; no

Wavelengths of Anomalous Emission Observed in Solutions Containing Aromatic Hydrocarbons and Aliphatic Amines. The emission spectra were measured on the systems of the condensed aromatic hydrocarbons and various aliphatic amines. While the normal fluorescence of an aromatic hydrocarbon was quenched considerably, a new anomalous emission was observed for some kinds of amines at longer wavelength regions. This long-wavelength emission should be regarded as a kind of fluorescence because it decayed instantaneously after the exciting light was shut off. Table 1 gives the results for the *n*-hexane solutions of anthracene and the amines. The same behavior was also found with 1,2-benzanthracene.

The observed emissions may be ascribed to some excited species formed diffusionally from the excited-state aromatic hydrocarbons and the amines.

As can be seen from Table 1, the appearance of a long-wavelength emission seems to depend largely upon the property of the amine employed; only the tertiary amines may be considered to satisfy the requirements for its appearance. Primary amines uniformly quenched anthracene fluorescence with the increase of their concentration without any other emission, while secondary amines showed a new emission at about 530 mμ, obviously due to the photochemical reaction products. However, the absorption and fluorescence spectra for the solutions involving the tertiary amines remained reproducible after irradiation by the exciting light. Although the explanation does not seem to be easy, the hydrogen atom attached to the nitrogen atom of an amine may have some connection with its quenching action; the hydrogen atom of a secondary amine should be considered as very reactive. It may be favorable for the appearance of the long-wavelength emission that tertiary amines have no reactive hydrogen atom and their ionization potentials are relatively low. As the importance of tertiary amines seemed to have been confirmed, a similar experiment was performed for the *n*-hexane solutions containing naphthalene and the tertiary amines, the result of which is given in Table 2.

It may be said that the increasing order of the wavelengths of the long-wavelength emission, despite their rather small differences, corresponds to the decreasing order of the ionization potentials of the amines, as is shown in Table 2.

Table 1. Long-wavelength emission observed in the anthracene - amine -*n*- hexane systems
(excitation wavelength: 365 mμ)

Amine		Wavelength
Primary	*n*-Butylamine *t*-Butylamine Dodecylamine	not observed
Secondary	Diethylamine Di-*n*-butylamine	photoproduct emission (*ca.* 530 mμ)
Tertiary	Triethylamine	489±2 mμ
	Tri-*n*-butylamine	483±2 mμ

Table 2. Naphthalene - *t*-amine - *n*-hexane systems
(excitation wavelength: 310 mμ)

Tertiary amine	Wavelength of long-wavelength emission (mμ)
Triethylamine	405±3
Tripropylamine	405±3
Tri-*n*-butylamine	411±2
N,*N*-Dimethylcyclohexylamine	416±3

The long-wavelength emission was measured for the systems of tri-*n*-butylamine (TBA) and the aromatic hydrocarbons in toluene. Table 3 lists their wavelengths. For the pyrene-TBA system, pyrene excimer fluorescence overlapped the long-wavelength emission, and discrimination between them was difficult. In the cases of 9,10-diphenylanthracene and perylene, a slight quenching of the fluorescence occurred with no long-wavelength emission, and even in pure TBA only the broadening of the fluorescence spectrum of the hydrocarbon was observed. This may be interpreted neither in terms of their short fluorescence lifetimes, which are comparable with that of anthracene, nor in terms of the formation of the non-emissive solvated ions in view of the solvent polarity.[1,10] It can be inferred

*3 No CT band could be observed at a longer wavelength. The increase in absorbance in the short-wavelength region for the curve (3) in Fig. 1 is due to the absorption of tri-*n*-butylamine.

10) H. Knibbe, K. Rollig, F. Schafer and A. Weller, *J. Chem. Phys.*, **47**, 1184 (1967).

from Table 3 that the wavelengths of the long-wavelength emission are related to the electron-affinities of the aromatic hydrocarbons.*4 Dependence of the wavelengths of the long-wavelength emissions on the ionization potentials of the amines and the electron affinities of the aromatic hydrocarbons suggests that the CT interaction is important.[1-4,6,7]

TABLE 3. TRI-*n*-BUTYLAMINE - AROMATIC HYDROCARBON - TOLUENE SYSTEMS

Aromatic hydrocarbon	Emission wavelength (mμ)	Excitation wavelength (mμ)
Naphthalene	437±5	310

Perylene	not observed	

Dependence of the Intensities of Anthracene Fluorescence and the long-wavelength Emission on TBA concentration. Variations in the relative intensities of anthracene fluorescence and the long-wavelength emission were measured for different TBA concentrations. The anthracene concentration was maintained at 4.22×10^{-4} M and the solvent was *n*-hexane. The result is shown in Fig. 2.

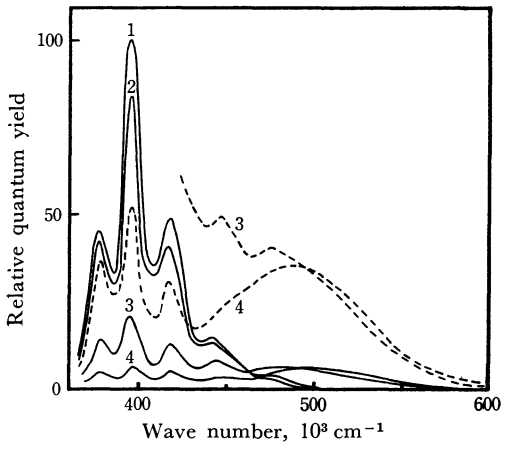

Fig. 2. Emission spectra for the anthracene-TBA - *n*-hexane system.
[TBA] M: 1) 0, 2) 2.04×10^{-2}, 3) 4.01×10^{-1}, 4) 1.34. [A]: 4.22×10^{-4} M.

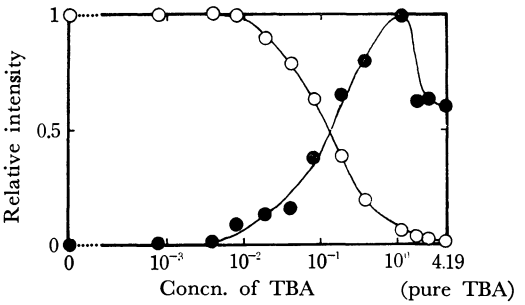

Fig. 3. Quenching curve for anthracene fluorescence and the intensity change of the long-wawelength emission with the respect to TBA concentration.
[A] = 4.22×10^{-4} M, solvent: *n*-hexane.
○: anthracene fluorescence
●: long-wavelength emission

The quenching curve for anthracene fluorescence and the intensity change of the long-wavelength emission are shown in Fig. 3. The quenching constant of TBA for anthracene fluorescence was estimated as 7.9 M^{-1}; this value is smaller than that assumed for a diffusion-controlled process,*5 suggesting the small reaction probability or the establishment of equilibrium in the excited state. That the increasing intensity of the long-wavelength emission is accompanied by the decreasing intensity of anthracene fluorescence implies the formation of an excited complex from excited anthracene and TBA. In the region of higher TBA concentrations, the long-wavelength emission diminished to a considerable extent, indicating the existence of the quenching effect of TBA on the excited complex or the formation of a triple complex[9] with no emissivity.

Effect of Temperature on the Intensities of the Long-wavelength Emission and Anthracene Fluorescence. In order to obtain information on the fluorescence quenching and the origin of the long-wavelength emission, anthracene fluorescence and the long-wavelength emission were measured on a degassed solution for the anthracene-TBA-toluene system at various temperatures from −196 to 95°C. Their temperature dependence is illustrated in Fig. 4.

At liquid nitrogen temperature, anthracene fluorescence is very intense and its spectrum is somewhat sharper than that at room temperature. At low temperatures where molecular diffusion is prevented, only anthracene fluorescence is observed. With

*5 The quenching constant for a diffusion-controlled quenching process is given by the following equation:

$$K_q = \frac{8RT\tau}{3000\eta} \sim 80$$

where η is the viscosity of *n*-hexane (3.2×10^{-3} poise) and τ, the fluorescence lifetime of anthracene (5×10^{-9} sec).

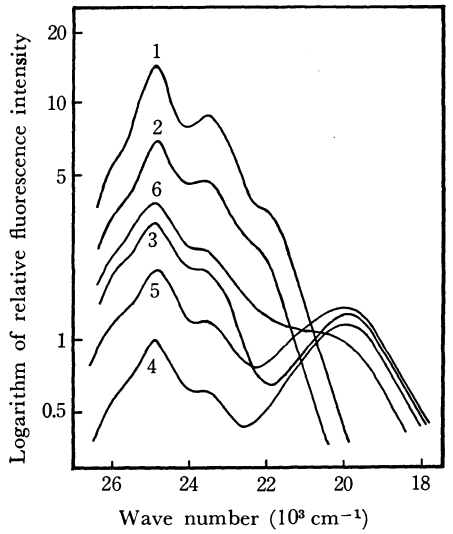

Fig. 4. Temperature dependence of anthracene flouorescence and the long-wavelength emission for the anthracene-TBA-toluene system.
[A]$=5.1\times10^{-4}$ M, [TBA]$=0.84$ M
Temperature °C: (1) −196, (2) −33, (3) 11, (4) 29, (5) 61, (6) 95
(uncorrected for the instrumental factors)

increasing temperature the long-wavelength emission appears at about 520 mμ at the expense of anthracene fluorescence and gradually grows up to a maximum intensity at about 60°C. Above this temperature the intensity of the long-wavelength emission falls off, while that of anthracene fluorescence rises to some extent, suggesting the dissociation of the excited complex backward into excited anthracene and TBA. It is not fully understood at present that both anthracene fluorescence and the long-wavelength emission increase with the rise of temperature at temperatures somewhat above room temperature. A diffusional excited-complex formation may account for their general temperature behaviors.

Solvent Effect on the Long-wavelength Emission. The effects of the solvents of different polarities on the long-wavelength emission for the anthracene-TBA system were examined and were found to be very remarkable.[4-6,11] The result is summarized in Table 4.

With the increase of solvent polarity, the emission-band maximum shifts to the longer wavelength and the intensity increases and finally decreases toward zero. This behavior may be understood on the basis of the fact that the excited CT complex can exist more stably in moderately polar solvents than in non-polar solvents, whereas its dissociation into the solvated radical ions occurs in highly polar solvents, such as methanol and *N*,*N*-dimethylformamide.[1,2,6,10,11] probably carbon tetrachloride reacts with excited anthracene.[12]

* +++: strong, ++: medium, +: weak, 0: none.

If the solvent shift of the emission band can be attributed to the dipole moment m of the excited CT complex, the wave number $\bar{\nu}$ of the emission band maximum is approximately expressed as follows:[4,5]

$$\bar{\nu} = -\frac{2m^2}{hca^3}\left(\frac{\varepsilon-1}{2\varepsilon-1}-\frac{n^2-1}{4n^2+2}\right) + \text{small terms} + \text{constant}$$

where ε and n denote the dielectric constant and the refractive index of the solvent, respectively; a is the assumed cavity radius for the complex.

Figure 5 shows the plots of $\bar{\nu}$ against

$$f = (\varepsilon-1)/(2\varepsilon+1) - (n^2-1)/(4n^2+2).$$

The straight line in the figure was obtained by the least-squares method from 20 points exclusive of those for benzene, toluene and dioxane, which are

known to be specific in the solvent effects. From the slope of this line, the value of m was evaluated as 12.8 D, assuming that a ~5.5 Å.*6 This is a very reasonable value for an excited CT complex in view of those reported by various authors.[4,5,11]

Conclusion

The anomalous emission observed at the long wavelengths in the systems of the condensed aromatic hydrocarbons and the tertiary amines seems to show every behavior of an emission due to an excited CT complex, the nature of which has already been studied by several authors.[1-7,9-11] In fact, the following conclusions can be derived:

1) According to the abosorption spectra of the solutions, the temperature dependence of the long-wavelength emission and the relation between the quenching of the hydrocarbon fluorescence and the intensity of the long-wavelength emission, the species responsible for the long-wavelength emission is considered as an excited-state complex formed dynamically from an excited-aromatic hydrocarbon and a tertiary amine.

2) The correlation of the wavelengths of the long-wavelength emission with the electron affinities of the aromatic hydrocarbons and the ionization potentials of the amines, as well as the large dipole moment estimated for the excited complex indicates the importance of the CT interaction.

The present work may have cleared to some extent the relation between the quenching phenomenon and the excited-CT-complex formation.

It is very plausible that the CT interaction occurs between the lone pair of electrons on the nitrogen atom and the π-electrons of the aromatic ring. Such an n-π interaction is of great interest because the localization of the n-electrons may restrict the region of interaction in the CT complex to part of the π-system and the n-orbital and the CT complex formed may assume such a configuration as minimizes the localization energy of the π-system. Thus, the model involved seems somewhat simpler and a theoretical consideration on this problem will be fruitful

The temperature dependence and variations with TBA concentration of the intensities of anthracene fluorescence and the long-wavelength emission may be analyzed by a kinetic approach.

The author wishes to thank Professor Hideo Akamatu for his continuous support and encouragement during the course of this work.

*6 This value was estimated from the molal volumes of anthracene and TBA.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 3415—3421 (1969)

Thermodynamic Properties of Carbon Tetrafluoride from 4°K to Its Melting Point*1

Hisae ENOKIDO,*2 Takako SHINODA and Yo-ichiro MASHIKO

Government Chemical Industrial Research Institute, Tokyo, Shibuya-ku, Tokyo

(Received May 22, 1969)

Thermodynamic properties of solid and liquid carbon tetrafluoride were measured at temperatures from 4°K to 100°K. The heat of transition was found to be 349.5±0.9 cal/mol, the transition temperature 76.221°K, the heat of fusion 168.6±0.05 cal/mol, the triple point temperature 89.515°K and the triple point pressure 0.80±0.03 Torr. The amount of impurity in the specimen of CF_4 was estimated to be 0.014_7 mol% from the measurement of the melting point range. The values of molal entropy of CF_4 as an ideal gas at 298.2°K, were calculated from the calorimetric and spectroscopic data as 62.63 e.u. and 62.45 e.u., respectively. The Debye characteristic temperature at 0°K was derived from the low temperature heat capacity data, and the $\theta_D(T)$ curve was compared with that for neopentane taking into account the octupole interaction of molecules in the crystal.

Carbon tetrafluoride CF_4 is one of a few tetrahedral molecules which undergo phase transition in solid state. The measurements of heat capacity were made by Eucken and Schröder in the region from 12°K to its boiling point,[1] and by Kostryukov *et al.* in the region from 12—13°K to its melting point.[2] The vapor pressure was measured by Menzel and Mohry in solid and liquid states.[3]

The purpose of this paper is to provide more complete and accurate data on the thermodynamic properties of CF_4 from 4°K to its melting point and give a theoretical consideration on the vibrational property of the molecule at low temperature. The data are compared with those of others. A comparison of the entropy calculated from calorimetric data with spectroscopic data is made based on the third low of thermodynamics.

The Debye characteristic temperature, $\theta_D(T)$, is derived from the low temperature heat capacity data, and a comparison of the temperature dependence of $\theta_D(T)$ below 15°K is made with these for other molecular crystals reported by the present authors on a reduced scale using the Debye characteristic temperature at 0°K, $\theta_D(0)$.

Experimental

Material. Chemically pure CF_4 obtained from the Matheson Co., was found to contain about 2.2% of air. This was purified before introduction into the calorimeter vessel. The gas was passed through a 3N KOH solution to remove impurities such as CO_2, SiF_4, SO_2, F_2, and then through a tube containing $CaCl_2$. The resulting material was distilled three times, at liquid nitrogen temperature, through pyrex glass fractionating bulb in a vacuum. The middle fraction collected was cooled to liquid nitrogen temperature and pumping was carried out for two days at a pressure less than 10^{-3} Torr in order to remove the trace of air from the sample. The mole numbers of actual specimen were measured by using a calibrated bulb attached to the calorimeter filling system, and then condensed into the calorimeter vessel. As grease of cock, 'Phynal' was employed instead of silicone grease. No impurity of the sample was found from gas chromatography using a Shimadzu Gas Chromatograph GC-1C. The amount of solid-insoluble liquid-soluble impurity found from measurement of the melting point was 0.014_7 mol%.

Apparatus. The cryostat, experimental techniques and temperature scale were the same as those used in the measurement of $C(CH_3)_4$.[4] A new calorimeter vessel made of silver-plated copper (0.2 mm thick, internal volume about 45 cm^3) was employed.

Results

Heat Capacity of CF_4. The calorimeter contained 0.21789 mol of the sample in measurement series I, 0.34522 mol in series II and 0.33264 mol in series III. Samples in series I, II and III were taken from separate fillings from the same sample. The heat capacity data are given in Table 1. Correction was necessary above 80°K for vaporization of CF_4 which occurred during the measure-

*1 Presented at the 22nd Annual Meeting of the Chemical Society of Japan, Tokyo, April, 1969.

ment. For values of heat of vaporization and of heat capacity of gaseous CF_4 those obtained by Eucken and Schröder[1] and Hwang and Martin[5] were used. The volume of the sample condensed in the calorimeter vessel was calculated using densities of solid and liquid CF_4 given by Stewart and Rock[6] and Knobler and Pings[7]. Gas imperfection correction was negligible over the termperature range of measurement. Correction was made with respect to curvature where necessary. The heat capacity data are plotted in Fig. 1 along with those given by Eucken and Schröder.[1] The results agree in the terperature range from 12 to 55°K. However, above 60°K, in particular between transition point and melting point, a difference is seen. The heat capacity of solid CF_4 between 12—13°K and the melting point was measured by Kostryukov *et al.*[2] The results were given graphically, but numerical values were not reported. A comparison of the result of Kostryukov *et al.* with ours from the heat capacity curve for CF_4 in Fig. 4 of Ref. 2 may be regarded as in good agreement.

The transition seemed to be first-order at the start, but changed into second-order type gradually after passing the middle point of the process and finished as the second-order one. This situation is different from that in $C(CH_3)_4$ crystal reported previously which seemed to be second-order over the whole transition range. We observed this heat capacity anomaly to have a very large value (*i.e.* 61.31 cal/mol deg at 76.336°K). No hysteresis was observed.

The Transition and the Triple Points. The transition temperature was determined from percentages of the specimen transformed and the measured equilibrium termperatures using the first-order law. The result is summarized in Table 2.

The triple point temperature corresponding to pure CF_4 was obtained from a plot of the equilibrium temperatures against the reciprocals of the fraction melted, and the result is given in Table 2 together with the triple point pressures. The triple point temperatures for pure CF_4 and the sample used are found to be 89.529°K and 89.515°K, and the values are compared with those given by others in Table 2.

Heat of Transition and Fusion. Data of the heat of transition and fusion are summarized in Table 3 together with those given by others. Our results are in good agreement with those of Eucken and Schröder, but not with Kostryukov *et al.*, particularly in that of the heat of transition which deviates considerably from ours. In the present measurement the average deviation of the result of the heat of transition is larger than that of the heat of fusion. This is probably due to the fact that a $\int C_p dT$ correction at temperatures slightly above the transition point was not estimated exactly, because the end of transition is a second-order type.

The Vapor Pressure Measurements. The vapor pressure of CF_4 was measured at temperatures

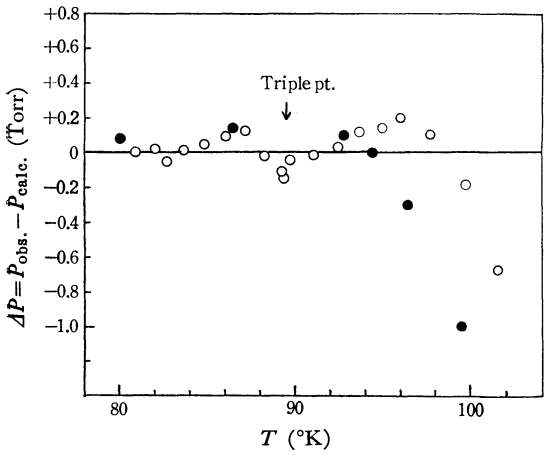

Fig. 2. Deviation of observed vapor pressure of CF_4 from the calculated one by using Eqs. (1) and (2).
●: Menzel and Mohry ○: Present research

In Fig. 2 are shown also the deviations between the pressures observed by Menzel and Mohry[3] and those calculated. Over a large part of the temperature region of measurement these differences are considerably large, since the absolute values of pressure are very small.

Entropy. The calorimetric and spectroscopic entropies of the ideal gaseous CF_4 at 298.2°K were calculated and compared with those obtained by Eucken and Schröder as shown in Table 5. The entropy below 4°K was estimated by using the value of Debye characteristic temperature obtained from the extrapolation of plots of $\theta_D(T)$ *versus* T. As the entropy of the vaporization and that above 122°K the values given by Eucken and Schröder were used.

As the entropy obtained by Eucken and Schörder is largely different from ours between 12°K and the transition point even taking into account probale errors in both measurements, we re-calculated the value using the heat capacity data observed by them. The value obtained is not 15.26 e.u. but 15.56 e.u. and agrees with ours within accuracy of their measurement. Therefore, the calorimetric entropy

*3 This is the value calculated using atomic distances obtained by Hoffman and Livingston (*J. Chem. Phys.*, **21**, 565 (1953)) from their measurements of electron diffraction.

8) D. M. Yost, E. N. Lassettre and S. T. Gross, *J. Chem. Phys.*, **4**, 325 (1936).

obtained by these authors is to be estimated as 62.73 e.u. On the other hand, the difference of the spectroscopic entropy may arise from the discrepancy of the values of the moment of inertia and the vibrational frequencies used in calculations as listed in Table 5. Agreement of the calorimetric entropy of 62.63 e.u. and the spectroscopic entropy of 62.45 e.u. is satisfactory as is seen in Table 5.

Discussion

In order to elucidate lattice vabrations at low temperature, we converted the observed heat capacity data of CF_4 and $C(CH_3)_4$ to the Debye characteristic temperature, $\theta_D(T)$, assuming $6N$ degrees of vibrational freedom (where N is Avogadro's number). Here, $C_p - C_v$ correction was neglected, since little is known about the thermal expansion and compressibility of CF_4 and $C(CH_3)_4$ crystals. We can neglect this term, since the contribution to $\theta_D(T)$ will be small at low temperature. However, the contribution of the intramolecular vibrations to the heat capacity was taken into account using the observed infrared and Raman spectral data.[8] In order to compare the temperature dependence of the $\theta_D(T)$ for CF_4 with that for $C(CH_3)_4$, the values of $\theta_D(T)$ were plotted against temperature on a reduced scale using the Debye characteristic temperature at 0°K, $\theta_D(0)$, as shown in Fig. 3. Here the intramolecular rotational frequency of the methyl group in $C(CH_3)_4$ of 286 cm^{-1} obtained by Rush[9] from his cold-neutron study was used. The values of $\theta_D(0)$ for CF_4 and $C(CH_3)_4$ were calculated from the first coefficients of the expansion of low temperature heat capacity, *i.e.*

d) R. H. Orcutt, *ibid.*, **39**, 605 (1963).
e) The octupole moment of 5.48×10^{-34} esu for CF_4 has recently been estimated by Spurling *et al.* (*J. Chem. Phys.*, **48**, 1006 (1968)) in the same way as ours. Also from their measurements of far-infrared absorption in gaseous CF_4 Rosenberg *et al.* (*J. Chem. Phys.*, **48**, 1396 (1968)) obtained the octupole moment for CF_4 of 4.5 or 4.8×10^{-34} esu.

$$\theta_D(0) = (935.14/\boldsymbol{a})^{1/3}, \quad (3)$$

where $\boldsymbol{a}$ has the unit of cal·mol^{-1}·deg^{-4}. The values of $\boldsymbol{a}$ obtained from plots of C_p/T^3 against T^2 as given in Fig. 4 correspond to $\theta_D(0)=108.7°$ for CF_4 and $\theta_D(0)=125.9°$ for $C(CH_3)_4$.

In higher temperature region above $T/\theta_D(0)=0.1$, it is difficult to obtain information on lattice vibrations in solid CF_4 and $C(CH_3)_4$ from the $\theta_D(T)/\theta_D(0)$ curves, since in this region C_p-C_v correction and anharmonicity in lattice vibrations must be taken into consideration. At low temperature region below $T/\theta_D(0)=0.1$, however, difference in the shapes of the $\theta_D(T)/\theta_D(0)$ curves for CF_4 and $C(CH_3)_4$ shown in Fig. 3 may be accounted for by the interaction between molecular octupoles which plays the most important part in lattice vibrations of tetrahedral molecules.*4 The values of octupole moment for CF_4 and $C(CH_3)_4$ was estimated using the second virial coefficient data. The analysis is given in Appendix, and the values obtained are listed in Table 6 together with the other potential parameters. The octupole moment for CF_4 is smaller than that for $C(CH_3)_4$. Treatment on the basis of lattice theory already made for CO crystal[10] will give us insight into the molecular motions at low temperature of CF_4 and $C(CH_3)_4$. For comparison, the $\theta_D(T)/\theta_D(0)$ curve and the values of the potential parameters of molecular interactions for CO are given in Fig. 3 and Table 6, where multipole is quadrupole.

Data of the thermodynamic properties for CF_4 reported in this paper provide the first observed values in the temperature range below 12°K. The values are complete and more accurate than have been available heretofore in the temperature range above 12°K.

The authors are grateful to Mr. Ichiro Takeda of the Government Chemical Industrial Research Institute, Tokyo for help in measurement of gas chromatography.

Appendix

The second virial coefficient $\boldsymbol{B}$ for a tetrahedral molecule has been given by Kielich[11] as follows:

$$\boldsymbol{B} = (2/3)\pi N r_0^3[F(y) - \kappa^2(0.050+0.095\kappa^2)H_{12}(y) - (3/5y^2)(\alpha/r_0^3)(\Omega^2/\varepsilon r_0^7)H_{10}(y) - (297/350)\Omega^2/\varepsilon r_0^7)^2 H_{14}(y)], \quad (4)$$

where the first term represents the contribution of a Lennard-Jones 6-12 potential, the second the effect of anisotropy on the dispersion forces, the third from the interaction of an induced dipole with the octupole and the fourth the inetraction between octupole moments. Here ε and r_0 are the Lennard-Jones potential parameters, α is the polarizability of the molecule, Ω is its anisotropy and Ω is defined by the octupole moment $\sum_i e_i x_i y_i z_i$ as

$$\Omega = (5/2)\sum_i e_i x_i y_i z_i \quad (5)$$

for a tetrahedral molecule.

The function $F(y)$ is tabulated by Hirschfelder *et al.*[12] with $y=2(\boldsymbol{k}T/\varepsilon)^2$, and the function $H_n(y)$ is tabulated by Buckingham and Pople.[13] By using known values of ε, r_0, α, and κ, the value of the octupole moment was

*4 Although information on the effect of the octupole interaction on lattice vibrations for tetrahedral molecules has not yet been given, the phase transitions in solid methane have been successfully explained by the octupole interaction. estimated from Eqs. (4) and (5). The values of Lennard-Jones (Table 6, a)) were obtained from the analysis of viscosity data in which the effect of octupole mement could be neglected. Average values of the octupole moment for CF_4 and $C(CH_3)_4$ estimated in this way using the observed values of second virial coefficients $\boldsymbol{B}$ are listed in Table 6, together with the other parameters used in calculations. The second virial coefficients calculated from the average octupole moment in Eq. (4) and the observed second virial coefficients are given in Table 7 for comparison.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 3422—3424 (1969)

Studies of Helical Aggregates of Molecules. I. Enantiomorphism in the Helical Aggregates of Optically Active 12-Hydroxystearic Acid and Its Lithium Salt

Taro TACHIBANA and Hideko KAMBARA

Department of Chemistry, Ochanomizu University, Bunkyo-ku, Tokyo

(Received May 22, 1969)

It was found, by electron-microscope observation, that D(or L)-12-hydroxystearic acid and its Li soap crystallize from a solution in various solvents in the form of a twisted fiber. The twist was left-handed for the D-acid and right-handed for the L-acid, while the Li soap gave results just opposite to those of the corresponding acid. The DL-acid separated out not fibers, but plate-like crystals, and its Li soap produced non-twisted fibers. Thus, an enantiomorphic relationship for the sense of twist between the D-enantiomer and the L-enantiomer was found both for the acid and for the Li soap.

Spirals or helices are often seen in various biological systems (*e.g.*, chromosome, bines, and snail shells). Curiously, some biological helices have a definite sense; they have either a right-handed or left-handed sense, depending upon the kind of biological system. Though one may imagine that this fact is related to the asymmetry of biological molecules, no evidence has yet been presented for such a speculation. Interest in this problem has lead us to notice the sense of twist in the helical aggregates of molecules.[1,2]

It has been known by electron-microscope study, that some crystalline aggregates of soap from lubricating grease consist of fibers in the form of twisted ribbon or helical rope. On examining the electron micrographs of the fibers hitherto published, we found that the fibers from hydrated calcium tallowate grease exhibit both right-handed and left-handed twists, while the fibers from lithium 12-hydroxystearate grease all twist by the same hand. This fact had also been pointed out by Hotten and Birdsall,[3] but they did not report the sense of twist of the lithium soap fibers. We found in the literature that some micrographs[4a-c] exhibit a right-handed twist and others,[3,5a,b] a left-handed twist. There is, then, confusion in the literature, but undoubtedly either sense of the twist could occur in a specimen. Since 12-hydroxystearic acid is an optically-active compound and since the naturally-occuring enantiomer is the D-form, the molecular asymmetry may be reflected in the sense of twist. In the present investigation, we have undertaken to determine the sense of twist in the specimens and to confirm whether or not there exists an enantiomorphic relationship between the helical aggregates from each enantiomer.

Experimental

Materials. D-12-Hydroxystearic acid was purified by the urea-adduct method from a commercial product containing as impurities about 15% stearic and palmitic acids. This procedure consists of dissolving the methyl ester into urea-saturated methanol with warming, letting the solution stand at room temperature, and then precipitating the adduct. Since the adduct initially precipitated was rich in methyl stearate and palmitate, they was removed by filtration. The methyl hydroxystearate-rich adduct was obtained by adding further urea to the filtrate. The adduct was decomposed with water, thus isolating the methyl hydroxystearate. The methyl hydroxystearate was repeatedly purified by the urea-adduct method. The final product was over 99% pure. The acid was obtained by saponifying the methyl ester with alcoholic KOH and by then acidifying it with dilute H_2SO_4; mp 79.3—79.8°C, $[\alpha]_D^{15}$ $-0.3 \pm 0.1°$ (pyridine); lit[6] mp 80.5—81°C, $[\alpha]_D^{19}$ $-0.41°$ (pyridine).

DL-12-Hydroxystearic acid[7] was obtained by the reduction of 12-ketostearic acid derived from D-12-hydroxystearic acid.

(c) DL-form, no twist

Fig. 1. The effect of optical isomerism on the sense of the twist in fibrous aggregates of 12-hydroxystearic acid (A) and lithium 12-hydroxystearate (B).

L-12-Hydroxystearic acid was prepared by the Walden inversion of the D-acid. The methyl ester of the D-acid was tosylated with *p*-toluenesulfonyl chloride in pyridine at a low temperature. The tosylate was then converted to the acetate by refluxing it with sodium acetate in acetic acid containing a small amount of acetic anhydride. The Walden inversion then occurred. L-12-Hydroxystearic acid was obtained by saponifying the acetate with KOH, followed by acidification with dilute H_2SO_4 and purification by recrystallization from methanol and then from acetone; mp 75.6—76.0°C, $[\alpha]_D^{15}$ $+0.40\pm0.05°$ (pyridine), lit,[6] mp 80.4—80.6°C and 78°C (dimorphous), $[\alpha]_D^{20}$ $+0.3\pm0.1°$ (pyridine). The infrared spectra of this L-acid was identical with that of the D-acid.

The analysis of the hydroxy acids was done by gas chromatography after they had been converted into the methyl ester of the acetoxy acid.

The Li soap was prepared by neutralizing the acid with LiOH in an ethanol solution, then recrystallizing the acid several times from ethanol, and finally drying it over P_2O_5 *in vacuo*.

The Formation of the Aggregate. The method consists of dissolving the soap into a hot solvent and then allowing it to stand at room temperature. The solution then solidifies into grease or gel, or separates out a gel-like precipitate, depending on the concentration and on the nature of the solvent used. The solvents were a highly refined mineral oil, Nujol, and ethanol. In a similar manner, 12-D(or L)-hydroxystearic acid itself was also found to form a helical aggregate from Nujol, benzene, carbon tetrachloride, chloroform, acetone, and ethanol.

Electron-microscope Observation. In order to make a specimen for the electron microscope, a small portion of the gel was placed on a copper grid covered with a thin film of carbon-collodion; the solvent was then evaporated *in vacuo*. When an involatile solvent, such as mineral oil or Nujol, was used, a small portion of the gel was dispersed in solvent naphtha, in which the dispersed phase is insoluble. Then a small drop of the dispersion was placed on the grid and dried. After that, the specimens were shadowed with Pt-Pd metal. The observations were done with a JEM-T6 electron microscope (direct magnification, X 30000).

In order to determine the helical sense from an electron micrograph, some care must be taken. The helical sense appearing in the electron micrograph depends on whether the specimen shadowed previously with metal was exposed to the electron beam directly or through a support film, since only the metal-shadowed side of a helix gives the electron-microscope image clearly. Accordingly, a right-handed helix appears as either a right-handed image or a left-handed image, depending on the mode of the exposure of the specimen to the electron beam. Consideration should be also given to the process of making a copy of the photograph. These factors seem to us to have escaped earlier workers' notice. The photographs in this paper are printed to show the same sense as that of the twist in the specimen.

Results and Discussion

Some typical micrographs are shown in Fig. 1, in which the twisted fibers are clearly visible. It can also be seen that the structure is actually made up of two or more individual fibers twisted about one another. The widths of the fibers varied over a considerable range.

The hydroxy acid was found to form a twisted fibril 0.01—0.1 μ in width, regardless of the kind of solvent used. Sometimes the fibers from benzene and from carbon tetrachloride were several tens of microns long.

In the case of the lithium soap, twisted fibrils about 0.03 μ in width were formed from ethanol, while helical ribbons 0.03—0.3 μ in width were formed from mineral oil and from Nujol. The thickness of the ribbon was so thin that, when a ribbon was laid upon another ribbon, the lower ribbon was visible through the upper. This was observed clearly when the specimen was lightly shadowed with metal. The thickness of the ribbons appeared to be about 0.01 μ; however, the value could not be estimated accurately from our micrographs. When very thin ribbons are separated out from a nonpolar solvent, they should develop a nonpolar surface. Therefore, it may be plausible to assume that the soap molecules are oriented along the direction of the thickness of the ribbon, exposing the methyl groups. In this case, the thickness corresponds to approximately the length of four molecules, and the width, to from several tens to several hundreds of molecules. In general, these ribbon-like fibers have a tendency to increase in width rather than in thickness by molecular association. The twisting is more clearly seen in a thinner fiber or a narrower ribbon.

One of the parameters of a helix is the sense of twist, to which we have particularly directed our interest in this study. The sense of twist is always definite for each enantiomer, regardless of the experimental conditions. The results are presented in Table 1. The sense of twist is left-handed for the D-acid and right-handed for the L-acid. On the other hand, the lithium soap gave results just opposite to the corresponding acid. The DL-acid (the racemic form) separated out not fibers, but plate-like crystals, and its lithium soap produced non-twisted fibers. Thus, an enantiomorphic relationship for the sense of twist between the D-enantiomer and the L-enantiomer was established for the acid as well as for the lithium soap.

It is a problem for further study what mechanism serves to twist the fibers. As is well known, twisted

Table 1. The sense of twist in the fibers from both enantiomers of 12-hydroxystearic acid and their lithium soaps

Enantiomer	The sense* of twist	
	Acid	Li soap
D	l	r
L	r	l

* r: right-handed twist, l: left-handed twist.

fibers are also formed from hydrated calcium tallowate grease. They consist of fibers with a right-handed twist and fibers with a left-handed twist in the same proportion. This indicates that, when optically non-active molecules aggregate to form twisted fibers, they exhibit both the sense of twist with an equal probability.

Several investigators[8a,b] have observed that the grease soap fibers have distinctly less twist without free end when prepared by a gentle deoiling manipulation, and that twisted fibers with a free end are often exhibited in cases involving the deformation of the gel structure by mechanical force during deoiling. Thus, it has been concluded that the twisted form is probably the result of mechanical breakdown. These investigations have been made with interest directed to the gel structure in lubricating grease. However, it is noticeable, from the molecular point of view, that the fibers exhibit the twisting when the fibers with a free end are produced. This fact shows also that the twisting occurs not only when the fibers grow, but also after they were formed. This indicates that the the isolated fiber has in itself a tendency to twist spontaneously. The enantiomorphism found for the sense of twist may also be considered as evidence that the twisting involves a molecular mechanism.

Here it seems appropriate to cite a paper by Weitkamp,[9] who observed that the dextro-rotatory anteiso acids ($CH_3CH_2CH(CH_3)(CH_2)_{2n}COOH$) from degras crystallize from solution in mineral oil in a tubular form which is generated by the counterclockwise spiral growth of a very thin and quite narrow ribbon. If the levo-rotatory acid is employed, the clockwise spiral growth of the ribbon will be observed.

As is well known, single crystals of optically-active antipodes exhibit the phenomenon of enantiomorphism. It is interesting to note that the enantiomorphism has been found to occur in the crystalline aggregate when the optical isomer aggregates to possess helical symmetry.

We wish to thank Professor Michio Shiota of this University for his helpful advice on the preparation of L-12-hydroxystearic acid. Thanks are also due to Miss Sanae Makino for her technical assistance. The expenses of this work have been defrayed by a Scientific Research Grant from the Ministry of Education.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 3425—3433 (1969)

A Solvent-extraction and Spectrophotometric Study of Copper(II) Complexes in Organic Solvents Containing Acetylacetone and Thenoyltrifluoroacetone

Yuko HASEGAWA

Department of Chemistry, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo

(Received May, 27, 1969)

The complex-formation equilibria of copper(II) in chloroform, benzene, or methyl isobutyl ketone (MIBK) containing both acetylacetone (AA) and thenoyltrifluoroacetone (TTA) have been determined by means of a liquid-liquid distribution method and a spectrophotometric method. The extraction constants or the extinction coefficients of the pure complexes were first determined in solutions containing only one of the liquids, and then these constants for the mixed complex and the equilibrium constants among the three complexes in these solvents were determined by the analysis of the results obtained from the experiments in mixed-ligand solutions. From these data, the following conclusions were reached. The constants experimentally obtained are almost identical with those statistically expected. The absorption spectrum of the mixed complex isolated from the absorption of the mixed-ligand system by the statistical analysis is more similar to that of the TTA complex than to that of the AA complex. The results obtained by these two methods are somewhat different from each other.

When the metal ion, the ligand ion, and the solvent molecules are denoted by M^{m+}, L^{l-}, and S respectively, the stepwise equilibria and the stability constants for the "*n*th" uninuclear complex in a solvent can generally be described as;

$$M_{n-1}^{m-(n-1)l}S_a + L^{l-}S_b \rightleftarrows ML_n^{m-nl}S_c + (a+b-c)S \quad (1)$$

$$K'_n = \frac{\{ML_n^{m-nl}S_c\}\{S\}^{a+b-c}}{\{ML_{n-1}^{m-(n-1)l}S_a\}\{L^{l-}S_b\}} \quad (2)$$

The over-all formation equilibria and the stability constants can be described as;

$$M^{m+}S_d + n(L^{l-}S_b) \rightleftarrows ML_n^{m-nl}S_c + (d+nb-c)S \quad (3)$$

$$\beta'_n = \frac{\{ML_n^{m-nl}S_c\}\{S\}^{d+nb-c}}{\{M^{m+}S_d\}\{L^{l-}S_b\}^n} \quad (4)$$

The complex formation can be represented more generally by Eqs. (1) and (2) or (3) and (4). However, as it is not easy to determine the solvation number or the activity of each chemical species, the solvent molecules are eliminated from these equations, assuming that the solvent activity is kept constant, and in many cases the concentration unit is adopted instead of the activity unit, assuming that the changes in the activity coefficients are negligible under the considerations employed. Thus, the stability constants can usually be represented by these two equations:

$$K_n = \frac{[ML_n^{m-nl}]}{[ML_{n-1}^{m-(n-1)l}][L]^{-l}} \quad (5)$$

$$\beta_n = \frac{[ML_n^{m-nl}]}{[M^{m+}][L^{l-}]^n} \quad (6)$$

The constant in Eq. (5) or (6) is a conventional expression for Eq. (2) or (4).

In aqueous solutions, the stability constants in Eqs. (5) and (6) are determined by various experimental methods. In usual organic solvents, however, the dielectric constant is much smaller, and consequently the concentration of any charged species is too small to measure by practical experimental methods; thus, the determination of the stability constants of metal complexes in Eqs. (5) and (6) is not possible. In order to correlate various complex formation equilibria of a metal ion with various ligands in organic solutions, the present author has employed the following equations instead of Eqs. (5) and (6), because the chemical species experimentally determined in usual organic solvents should be uncharged only.

$$MA_m(org) + nHB(org) \rightleftarrows MA_{m-n}B_n(org) + nHA(org) \quad (7)$$

$$K_{m,n} = \frac{[MA_{m-n}B_n]_{org}[HA]^n_{org}}{[MA_m]_{org}[HB]^n_{org}} \quad (8)$$

$$MA_m(org) + MB_m(org) \rightleftarrows MA_aB_{(m-a)}(org) + MA_{(m-a)}B_a(org) \quad (9)$$

$$K = \frac{[MA_aB_{(m-a)}]_{org}[MA_{(m-a)}B_a]_{org}}{[MA_m]_{org}[MB_m]_{org}} \quad (10)$$

The present paper will describe the complex formation of copper(II) in chloroform, benzene, and

methyl isobutyl ketone (MIBK) containing acetylacetone (AA), thenoyltrifluoroacetone (TTA), or a mixture of these two β-diketones. The equilibrium constants given by Eqs. (8) and (10) will be calculated from the solvent extraction data and the spectrophotometric data, and some discussion will be given of this type of stability constants of metal complexes in such organic solvents.

Statistical Treatment

When an organic solvent contains copper(II) and two organophilic chelating acids, HA and HB, and when no formation of polynuclear complex or of adduct complex is assumed, three sorts of copper(II) complexes, CuA_2, CuAB, and CuB_2 may be expected to exist. The equilibria among these three species may be described as follows:

$$CuA_2(org) + HB(org) \rightleftharpoons CuAB(org) + HA(org) \quad (11)$$

$$CuA_2(org) + 2HB(org) \rightleftharpoons CuB_2(org) + 2HA(org) \quad (12)$$

and the equilibrium constants may be defined as:

$$K_{1,1} = \frac{[CuAB]_{org}[HA]_{org}}{[CuA_2]_{org}[HB]_{org}} \quad (13)$$

$$K_{0,2} = \frac{[CuB_2]_{org}[HA]^2_{org}}{[CuA_2]_{org}[HB]^2_{org}} \quad (14)$$

The following equlibrium constant can also be defined:

$$CuA_2(org) + CuB_2(org) \rightleftharpoons 2CuAB(org)$$

$$K = \frac{[CuAB]^2_{org}}{[CuA_2]_{org}[CuB_2]_{org}} \quad (15)$$

Solvent Extraction Method. In an earlier paper, Sekine and Dyrssen[1] have demonstrated that the equilibrium constants in Eqs. (13), (14), and (15) can be determined by a solvent extraction method. When copper(II) ions in aqueous solutions are extracted with HA in the organic phase, the equilibrium constant can be described as;

$$Cu^{2+} + 2HA(org) \rightleftharpoons CuA_2(org) + 2H^+ \quad (16)$$

$$K_{ex_{2,0}} = \frac{[CuA_2]_{org}[H^+]^2}{[Cu^{2+}][HA]^2_{org}} \quad (17)$$

The net distribution ratio of copper(II) can be determined as;

$$D = \frac{[Cu(II)]_{org,total}}{[Cu(II)]_{total}} \quad (18)$$

When only Cu^{2+} species is assumed to exist in the aqueous phase and only the CuA_2 species in the organic phase, Eq. (17) can be described as;

$$K_{ex_{2,0}} = D[H^+]^2[HA]^{-2}_{org} \quad (19)$$

In the same manner, the following can serve to describe the extraction constant for copper(II) with HB:

$$K_{ex_{0,2}} = \frac{[CuB_2]_{org}[H^+]^2}{[Cu^{2+}][HB]^2_{org}} \quad (20)$$

or:

$$K_{ex_{0,2}} = D[H^+]^2[HB]^{-2}_{org} \quad (21)$$

When the organic phase contains both HA and HB, copper(II) may be extracted as CuA_2, CuAB, and CuB_2 species and the extraction constant to the mixed complex may be described as:

$$Cu^{2+} + HA(org) + HB(org) \rightleftharpoons CuAB(org) + 2H^+ \quad (22)$$

$$K_{ex_{1,1}} = \frac{[CuAB]_{org}[H^+]^2}{[Cu^{2+}][HA]_{org}[HB]_{org}} \quad (23)$$

The net distribution ratio in such a system can be described as:

$$D = \frac{[CuA_2]_{org} + [CuAB]_{org} + [CuB_2]_{org}}{[Cu^{2+}]} \quad (24)$$

$$\frac{[CuAB]_{org}}{[Cu^{2+}]} = D - \frac{K_{ex_{2,0}}[HA]^2_{org} + K_{ex_{2,0}}[HB]^2_{org}}{[H^+]^2} \quad (25)$$

By introducing Eq. (25) into Eq. (23), the extraction constant for the mixed complex, $K_{ex_{1,1}}$, can be determined.

From Eqs. (17), (20), and (23), the K constant, the equilibrium constant for the mixed complex in Eq. (15), is obtained as;

$$K = \frac{K^2_{ex_{1,1}}}{K_{ex_{2,0}}K_{ex_{0,2}}} \quad (26)$$

Sekine and Dyrssen[1] reported that the statistical value of K is 4.

Moreover, the constants can be introduced into Eqs. (13) and (14) as;

$$K_{1,1} = K_{ex_{1,1}}/K_{ex_{2,0}} \quad (27)$$

$$K_{0,2} = K_{ex_{0,2}}/K_{ex_{2,0}} \quad (28)$$

Spectrophotometric Method. The equilibrium constants in Eqs. (13) and (14) can also be determined by a spectrophotometric method.

When the molar extinction coefficients of the CuA_2, CuAB, and CuB_2 species at a certain wavelength are ε_{A_2}, ε_{AB}, and ε_{B_2}, the total absorbance of a sample solution may be described as;

$$E = \varepsilon_{A_2}[CuA_2]_{org} + \varepsilon_{AB}[CuAB]_{org} + \varepsilon_{B_2}[CuB_2]_{org} \quad (29)$$

By introducing Eqs. (13) and (14) into Eq. (29), the following equation is obtained:

$$E = [CuA_2]_{org}(\varepsilon_{A_2} + \varepsilon_{AB}K_{1,1}\alpha + \varepsilon_{B_2}K_{0,2}\alpha^2) \quad (30)$$

where α denotes the mixing ratio: $[HB]_{org}/[HA]_{org}$.

The total concentration of copper(II) is written as:

$$C = [CuA_2]_{org} + [CuAB]_{org} + [CuB_2]_{org} = [CuA_2]_{org}(1 + K_{1,1}\alpha + K_{0,2}\alpha^2) \quad (31)$$

1) T. Sekine and D. Dyrssen, *J. Inorg. Nucl. Chem.*, **26**, 2013 (1964).

From Eqs. (30) and (31), the following equation is obtained:

$$\frac{E}{C} - \varepsilon_{B_2} = \frac{(\varepsilon_{A_2} - \varepsilon_{B_2}) + (\varepsilon_{AB} - \varepsilon_{B_2})K_{1,1}\alpha}{1 + K_{1,1}\alpha + K_{0,2}\alpha^2} \quad (32)$$

The ε_{A_2} and ε_{B_2} values can be determined by separate experiments. The total copper(II) concentration, C, can be known from the initial concentration, and the total extinction, E, can be determined by spectrophotometry. Moreover, when the concentrations of the chelating acids are much larger than the total copper(II) concentration, we may assume no change in the chelating acid concentrations by the complex formation and may use the initial concentrations instead of those at equilibrium for the calculation of the constants.

In the above case, the unknown terms in Eq. (32) are ε_{AB}, $K_{1,1}$ and $K_{0,2}$ and we can determine these from the total absorbances determined at more than three different α values.

Graphical Treatment of the Spectrophotometric Data. From Eq. (32), the following equation is obtained:

$$\log\left(\frac{E}{C} - \varepsilon_{B_2}\right) = \log\{(\varepsilon_{A_2} - \varepsilon_{B_2}) + K_{1,1}(\varepsilon_{AB} - \varepsilon_{B_2})\} - \log(1 + K_{1,1}\alpha + K_{0,2}\alpha^2) \quad (33)$$

The values $\log(E/C - \varepsilon_{B_2})$ obtained experimentally at a certain wavelength are plotted against α, while a certain set of the assumed values of $K_{1,1}(\varepsilon_{AB} - \varepsilon_{B_2})$, $K_{1,1}$ and $K_{0,2}$ are introduced to Eq. (33) and the curve thus drawn is fitted with the plot. The trial is repeated until the best-fit curve for the data is found. The constants will be then determined from the parameters of the best-fit curve.

Experimental

Tracer. A pure copper sheet (99.98%) was irradiated with thermal neutrons in the TRIGA-3 reactor at the Atomic Research Institute of St. Paul's University, Kanagawa. The copper sheet was then dissolved in hot concentrated nitric acid. The solution was evaporated gradually on a water bath, and the residue was dissolved in 0.1 M perchloric acid. The solution thus obtained was used as the copper tracer stock solution.

Reagents. All of the reagents used were of a reagent grade. The acetylacetone and thenoyltrifluoroacetone were obtained from Dojindo & Co. When they were dissolved in an organic solvent, the solution was allowed to stand overnight before use. The methyl isobutyl ketone was washed with 0.1 M perchloric acid, water, and a 0.1 M sodium hydroxide solution, and then several times with water. The chloroform was washed three times with water. The other reagents were used without further purification.

Procedures. All of the procedures were carried out in a thermostatted room at 25±0.5°C.

Solvent Extraction Method. The distribution ratio of copper(II) was measured as follows. Stoppered glass tubes (volume, 20 m*l*) were used to equilibrate the two liquid phases. Five milliliters of chloroform, benzene, or MIBK containing 0.1 M TTA or AA or containing both of them at a different mixing ratio, and 5 m*l* of a mixture of 0.1M perchloric acid and 0.1M sodium perchlorate containing the copper(II) tracer were placed in the tubes. The initial concentration of copper(II) in the aqueous phase was in the range $1-5\times10^{-5}$M. The two phases were agitated mechanically for thirty minutes and then centrifuged. A two-milliliter portion was pipetted from each phase. These portions were transferred into small glass tubes for the measurement of the γ-radioactivity with a well-type (NaI) scintillation counter. For the experiments at hydrogen-ion concentrations smaller than 0.01 M, a small portion was also taken from the aqueous phase and transferred into a glass vessel; the hydrogen-ion concentration of this solution was measured potentiometrically by using 0.0100 M $HClO_4$ +0.09 M $NaClO_4$ as the standard of $-\log[H^+]$ 2.00.

The net distribution ratio was calculated as:

$$D = \frac{[Cu(II)]_{org,total}}{[Cu(II)]_{total}} = \frac{\gamma\text{-count-rate per m}l\text{ of the org. phase}}{\gamma\text{-count-rate per m}l\text{ of the aq. phase}}$$

Spectrophotometric Method. A certain amount of metallic copper (99.98%) was dissolved in concentrated nitric acid. An excess amount of a dilute sodium hydroxide solution was added to the copper(II) solution, and the copper(II) hydroxide precipitates were collected by decantation and gradually heated in water. The copper(II) oxide thus prepared was finally obtained as a dry powder and was dissolved in an organic solution containing a large excess of TTA or AA to make the stock solution. The sample solutions of copper(II) were prepared from one of the stock solutions or from mixtures of them and were measured by a spectrophotometer (Hitachi-Perkin Elmer type 139) using quartz cells 1 cm thick.

Results

Solvent Extraction Experiments.

Extraction with a Single Chelating Acid. The distribution of copper(II) between 0.1 M (H, Na)ClO_4 and chloroform, benzene, or MIBK containing 0.1 M TTA or AA was determined as a function of $-\log[H^+]$. The log$D$ *vs.* $-\log[H^+]$ plot in these systems almost falls on a straight line, with a slope of +2 in the region around $-\log[H^+]$ 2.00, but some deviations from the line were observed (especially in the AA system) in the higher $-\log[H^+]$ range. These deviations were assumed to be due to the aqueous chelate formation. Some other experiments showed no adduct formation of these Cu(II) chelates with the extractants in the undissociated form. Thus, it was concluded that when the organic phase contains 0.1 M chelating acid and when the aqueous phase contains the 0.1 M hydrogen ion, the net distribution ratio can be described by the relation: $D=[CuA_2]_{org}/[Cu^{2+}]$. * From these data, the values of $K_{ex_{1,1}}(=D_{mixed}[H^+]^2[HA]^{-1}{}_{org}[HB]^{-1}{}_{org})$ were calculated and the average values are given in Table 1.

these results, the extraction constants for copper(II) with TTA or AA were calculated to be as given by Eq. (19) or (21) (*cf.* Ref. 2). The extraction constants obtained are given in Table 1.

Extraction with Mixed Chelating Acids. The distribution of copper(II) between 0.1 M (H, Na)ClO_4 and chloroform, benzene, or MIBK containing both TTA(HA) and AA(HB) was also studied. For these experiments, $-\log[H^+]$ was always kept at 2.00 and the total concentration of the chelating acids in the organic phase was kept at 0.10 M. The results are given in Table 2. From these results, the extraction constant of the mixed chelate was determined by means of Eqs. (23) and (25). The constants are also given in Table 1.

Spectrophotometric Experiments.

Absorption Spectra of Copper(II)-bis-TTA and Copper-(II)-bis-AA Chelates. The absorption spectra of the copper(II)-bis-TTA chelates and of the copper-(II)-bis-AA chelates were measured in chloroform, benzene, or MIBK containing 0.1 M of the chelating acid, while the copper concentration was 2×10^{-4} to 8×10^{-4} M. Figure 1 gives the results in chloroform.

As may be seen in Fig. 1, the absorption spectrum of copper(II)-bis-TTA chelates has a pronounced peak at 407 mμ, while that of the copper(II)-bis-AA chelates has one at 332 mμ. From these results, the molar extinction coefficients were determined to be as given in Table 3.

The Absorption of Copper(II) Complexes in Mixed Chelating-acid Systems. The absorption of copper-(II) complex was also measured when the organic solvents contained both TTA and AA at various mixing ratios and when the copper concentration was 8×10^{-4} M.

Figure 2 gives the absorption curves obtained when the mixing raio α was 1, 3, 5, 9, 13, and 47, together with the curve obtained when the organic phase contained only TTA or AA.

A graphic method was used to analyze the results in Fig. 2. For example, the data obtained in

the chloroform system were analyzed as follows. The log $(E/C-\varepsilon_{B_2})$ *vs.* α plot was made from the absorption data, E, at 400, 410, and 420 mμ, as is shown in Fig. 3, and attempts were made to find the best-fit constants, $K_{1,1}$ and $K_{0,2}$, for these data. Finally, it was found that the "best-fit" was obtained when $K_{1,1}$ and $K_{0,2}$ were 1.2 and 0.20 and when the ε_{AB} values were 1150, 740, and 407 at 400, 410, and 420 mμ respectively. The values of ε_{AB} from 380 mμ to 430 mμ were calculated by introducing these $K_{1,1}$ and $K_{0,2}$ values and the values ε_{A_2} and ε_{B_2} calculated from the data in Fig. 1. The molar extinction coefficients thus calculated are given in Fig. 4 as a function of the wavelengths.

Figure 5 shows the contribution of each chelate species to the total absorption in chloroform, as calculated by Eqs. (13), (14) and (31), when the

Solvent; chloroform
The dotted line gives the observed spectrum in the sample solution where $[Cu(II)]_{total}$ is 8×10^{-4} M, $[TTA]_{org}$ is 1.67×10^{-2} M and $[AA]_{org}$ is 8.33×10^{-2} M ($\alpha=5$).
The solid lines show the calculated spectra of $Cu(TTA)_2$ and $Cu(AA)_2$ at this concentration of TTA and AA.

total copper(II) concentration is 8×10^{-4} M and when the the concentrations of TTA and AA are 1.67×10^{-2} and 8.33×10^{-2} M respectively.

The same procedures were carried out on the data obtained in benzene and MIBK. The equilibrium constants, $K_{1,1}$ and $K_{0,2}$, in these systems are also given in Table 1.

By using the $K_{1,1}$ and $K_{0,2}$ constants, in Table 1, which were obtained by both the methods, the percentage distribution of the mixed chelate complex was calculated by the following equation:

$$\%\ \text{distribution of } [CuAB]_{org} = \frac{[CuAB]_{org}\times 100}{[CuA_2]_{org}+[CuAB]_{org}+[CuB_2]_{org}} = \frac{K_{1,1}\alpha\times 100}{1+K_{1,1}\alpha+K_{0,2}\alpha^2} \quad (34)$$

Figure 6 shows the percentage distribution of the three sorts of Cu(II) chelates in chlofoform as a function of the mixing ratio, α. Figure 6-a was calculated from the constants obtained by the solvent extraction, and Fig. 6-b, by spectrophotometry. It may be seen from Fig. 6 that the area of the zone of the mixed complex obtained by the spectrophotometry is larger than that obtained by the solvent extraction. Moreover, the α value at the maximum percentage distribution of the mixed complexes is different ($\alpha=0.88$ by the solvent extraction and 0.51 by the spectrophotometry).

The results thus obtained may be summarized as follows: i) The extraction constant of the copper (II) TTA complex is always larger than that of the copper(II) AA complexes (Table 1).

ii) The extraction constants of the copper(II) TTA-AA mixed complexes experimentally determined are in all cases a little smaller than those statistically calculated, but the differences are not large (the $K_{ex_{1,1}exp.}/K_{ex_{1,1}stat.}$ values are 0.72, 0.81 and 0.69 in chloroform, benzene and MIBK respectively) (Table 1).

iii) The absorption peak of the copper(II)-bis-TTA complex exists over a longer wavelength range than that of the AA complex, and the molar extinction coefficient at the peak of the former is

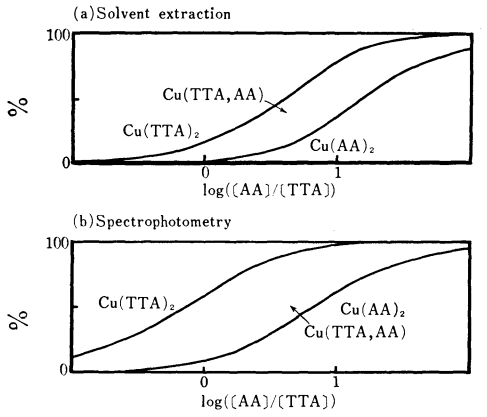

Fig. 6. Percentage distribution of the mixed complexes in chloroform as a function of the mixing-ratio is calculated from the constants in Table 1.

lower than that of the latter (Fig. 1).

iv) The absorption peak of the copper(II) mixed complex with TTA and AA exists over a little shorter wavelength range than that of the Cu(II)-bis-TTA complex, and the molar extinction coefficient of the mixed complex at the peak is a little higher than that of the bis-TTA complex, but much lower than that of the bis-TTA complex (Fig. 4).

v) The values of these constants, $K_{1,1}$, $K_{0,2}$, and K, are different in different organic solvents. The constants obtained by the solvent extraction method are larger in the order: chloroform > MIBK > benzene, while those obtained by the spectrophotometric method are larger in the order: benzene > chloroform > MIBK. Thus, there are some differences in the constants obtained by these two different methods.

Discussion

The extraction constant of copper(II) with AA in benzene has been given as $\log K_{ex}$ −3.76 (present work), −3.93 (Stary and Hladky[3]), and −4.32 (Newman and Klotz[4]), while that with TTA in benzene has been given as $\log K_{ex}$ −0.73 (present work) and −1.32 (Newman and Klotz[4]). It seems to be difficult to ascertain why these extraction constants are so different from each other. However, according to the present results, some part of the copper(II) ions in the aqueous phase are complexed with AA (aqueous chelate formation) under the experimental conditions which Newman and Klotz used in working (0.2 M TTA in benzene and $-\log[H^+]$ 2.20 in 2 M LiCl), and thus the K_{ex} value calculated by using Eq. (19) or (21) is apparently smaller because of the aqueous chelates.[5] Moreover, the presence of chloride ions at such a high concentration may form copper chloride complexes.[6]

The extraction constant of the copper mixed complex with AA and TTA in benzene in the present study is a little smaller than the statistically-calculated values ($K=[CuAB]^2_{org}/[CuA_2]_{org}[CuB_2]_{org}=$ 2.4, compared with the statistical value, 4), although Newman and Klotz reported that the experimental value is larger than the statistical value ($K=10$). The difference between the present results and the earlier results is not small. One possible explanation for this might be that the use of the underestimated $K_{ex_{0,2}}$ due to the aqueous chelate complex in the earlier work caused an overestimation of the concentration of the mixed chelate in the organic phase.

It was observed by Sekine and Dyrssen[1] that the experimental value of the copper mixed chelate complex with TTA and β-isopropyltropolone (IPT) is more stable than the statistical value and that the stabilization increases with the decrease in the polarity of the solvents (K is 54 for carbon tetrachloride, 30 for chloroform, and 8.9 for MIBK). This order is still retained in the present results, though the mixed complexes are less stable than the statistical values.

The formation of the mixed complex can be apparently observed in the spectrophotometric data in Fig. 2; for example, the absorption peak in the chloroform solution containing 0.05 M TTA and 0.05 M AA (in Fig. 2, it is denoted as the 1 : 1 curve) shifts to a shorter wavelength for the TTA complex and the maximum absorbance increases a little. This can not be explained only in terms of the synthesis of the $Cu(AA)_2$ and $Cu(TTA)_2$ absorption curves.

Figure 7 gives the curve synthesized from the data in Fig. 1 assuming no mixed complex formation. The mixed complex formation can be seen also from Fig. 7, in which the peak of the calculated curve shifts to the shorter wavelength side for the peak of $Cu(TTA)_2$, while the maximum absorbance decreases considerably. This is quite different from the formation observed in Fig. 2. The difference is probably due to the absorption of the mixed complex.

It is remarkable that the maximum extinction of the mixed complex does not appear in midway in the maxima of the extinction of the pure complexes, but appears quite close to that of the $Cu(TTA)_2$ complex. The value of the extinction at the maximum absorption of the mixed complex is also

nearer to that of the TTA complex. Further consideration seems to be necessary in order to discuss this resemblance of the extinction of the mixed complex to that of the $Cu(TTA)_2$ complex.

In order to analyze the spectrophotometric data, it was always assumed that the ligands exist in a large excess to copper(II), that, that is, the free-ligand concentration is not changed by the complex formation. This assumption seems to hold even when the mixing ratio is very large or when the initial TTA concentration is very low. For example, in Fig. 3 it may be understood that the analysis can be made even by using the data at $\alpha=40$. Here the total copper concentration is 8×10^{-4} M, while the initial TTA concentration is 2.5×10^{-3} M. However, as may be seen from Fig. 6-b, more than 85% of the copper(II) exists in the CuA_2 form, and thus only about 1.2×10^{-4} M of TTA is complexed with copper(II). The change in the free TTA concentration is only about 5%, which might not cause any significant error in the calculation.

The analysis of the spectrophotometric data is more complicated than that of the solvent extraction data, because in the solvent extraction the unknown constants to be calculated are only $K_{1,1}$ and $K_{0,2}$. As we can see from Eqs. (27) and (28), $K_{0,2}$ can be easily determined from the extraction constants for the pure complexes, $K_{ex2,0}$ and $K_{ex0,2}$, which can themselves be determined by separate experiments. The $K_{ex1,1}$ constant can be calculated from the experimental data in the mixed extractant system by using these $K_{ex2,0}$ and $K_{ex0,2}$ values and Eqs. (25) and (23). Thus, these equilibrium constants can be obtained even from a single value of the distribution data in the mixed chelate system. On the other hand, the unknown constants to be determined in the spectrophotometric study are not only $K_{0,2}$ and $K_{1,1}$, but also the molar extinction coefficients of the mixed complex, ε_{AB}. Thus, we have to determine these three constants simultaneously from a series of absorption data.

As we can see in Table 1 or in Fig. 6, the stabilities of the mixed complex as calculated by the solvent extraction data and by the spectrophotometric data are somewhat different from each other. The essential difference in the experimental conditions is that the organic phase in the spectrophotometry is not saturated with water, while that in the solvent extraction is saturated with water; probably this does not cause any significant difference, although our present information on these systems seems not to be enough for us to discuss whether these differences are due to some unknown factors which cause a systematic deviation in the results of one or both of the methods or whether they are due to an essential difference, one which might arise from the fact that these two methods determined the mixed complex formation from different sides of the phenomenon. Further study seems to be necessary before we can obtain an explanation of this observation.

As was described in the beginning of this paper, the usual stability constants of aqueous complexes defined by Eqs. (5) and (6) are a convenient expression of Eqs. (2) and (4). This means that the stability constants in Eqs. (5) and (6) show the "relative" stability of the metal aquo complex and the metal complexes with L^-, just as Eq. (8) gives the relative stability of the MA_m complex and $MA_{m-n}B_n$ complex. If we take the $Cu(TTA)_2$ complex as the standard of various uncharged complexes in a certain organic phase, we can compare the stabilities of two or more other complexes by using these constants.

When we compare the stability of an aqueous "nth" complex, MA_n^{m-n}, with another "nth" complex, MB_n^{m-n}, we usually use the β_n^A/β_n^B ratio. When we can assume that the hydration numbers of the MA_n^{m-n} and MB_n^{m-n} complexes and those of the A^- and B^- ligands are the same, we see that the ratio of the more generalized stability constants in Eq. (4), β'^A_n/β'^B_n, should be the same as β_n^A/β_n^B.

In the present paper, the relative stability constants for only a pair of ligands, TTA and AA, have been determined. However, if the relative stability constants for another pair of ligands, for example, TTA and a chelating acid HBB, we can compare the stability of the AA complex with the BB complex, as in the follwoing equations:

$$Cu(TTA)_2 + 2HAA \rightleftharpoons Cu(AA)_2 + 2HTTA \quad (35)$$

$$Cu(TTA)_2 + 2HBB \rightleftharpoons Cu(BB)_2 + 2HTTA \quad (36)$$

$$K_{0,2}^{TTA-AA} = \frac{[Cu(AA)_2]_{org}[HTTA]^2_{org}}{[Cu(TTA)_2]_{org}[HAA]^2_{org}} \quad (37)$$

$$K_{0,2}^{TTA-BB} = \frac{[Cu(BB)_2]_{org}[HTTA]^2_{org}}{[Cu(TTA)_2]_{org}[HBB]^2_{org}} \quad (38)$$

$$\frac{[Cu(BB)_2]_{org}[HAA]^2_{org}}{[Cu(AA)_2]_{org}[HBB]^2_{org}} = \frac{K_{0,2}^{TTA,\,BB}}{K_{0,2}^{TTA,\,AA}} \quad (39)$$

This could be compared with the aqueous complexes with AA and BB as follows:

$$Cu^{2+}(H_2O)_a + 2AA^-(H_2O)_b \rightleftharpoons Cu(AA)_2(H_2O)_c \quad (40)$$

$$Cu^{2+}(H_2O)_a + 2BB^-(H_2O)_b \rightarrow Cu(BB)_2(H_2O)_c \quad (41)$$

$$(\beta^{AA})'_2 = \frac{[Cu(AA)_2(H_2O)_c]}{[Cu^{2+}(H_2O)_a][AA^-(H_2O)_b]^2} \quad (42)$$

$$(\beta^{BB})'_2 = \frac{[Cu(BB)_2(H_2O)_c]}{[Cu^{2+}(H_2O)_a][BB^-(H_2O)_b]^2} \quad (43)$$

Then we can introduce:

$$\frac{[Cu(BB)_2(H_2O)_2][AA^-(H_2O)_b]^2}{[Cu(AA)_2(H_2O)_c][BB^-(H_2O)_b]^2} = \frac{(\beta^{BB})'_2}{(\beta^{AA})'_2} \quad (44)$$

Equation (44) should be essentially the same as the ratio of the usual stability constants, $\beta_2^{BB}/\beta_2^{AA}$, which is very often used in order to compare the stabilities. The difference between Eqs. (39) and (44) is that the former deals with the acid-form ligands, while the latter deals with the ionic-form ligands. When we can determine the acid-dissociation constants in the organic phase by some experimental methods, we may also calculate the relative stability of the organic complexes in Eq. (44).

As we have seen from the above equation, the "relative" stability constants in Eq. (8) seem to be useful for comparing the stability of complexes of a certain metal with various ligands. As it is not easy to measure ionic species in organic solvents with low dielectric constants, the present expression for the stabilities of various complexes seems to be the most convenient concept for this purpose.

The author wishes to express a great appreciation to Professor Tatsuya Sekine of the Science University of Tokyo for many helpful discussions during the course of this work. The author is also indebted to Mr. Toshio Fukushima for his assistance in this experimental work.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 3433—3438 (1969)

The "Circular Dichroism-sensitive Band" in the Optical Absorption of the Lanthanide(III) Complexes with Some Optically Active Ligands

Seizo MISUMI, Sigeo KIDA, Toshiyuki ISOBE, Yuzo NISHIDA and Haruko FURUTA

Inorganic Chemistry Laboratory, Faculty of Science, Kyushu University, Hakozaki, Fukuoka

(Received June 30, 1969)

The circular dichroism and absorption spectra of Pr(III), Nd(III), Sm(III), Dy(III), Ho(III), Er(III) and Tm(III) complexes with some natural amino acids and L-EDDS have been measured at room temperature. The "circular dichroism-sensitive bands" have been observed on the J-bands where magnetic dipole transitions are allowed to some extent. The experimental results are in accordance with the theory proposed previously. The theory can be applied at least for lanthanide(III) complexes.

In previous papers,[1,2] we reported the circular dichroism (CD) and absorption spectra of f-f transitions of 1-PDTA(propylenediaminetetraacetic acid) complexes of Pr(III), Nd(III), Sm(III), Ho(III), Dy(III) and Er(III) in aqueous solutions, and compared the relative intensities of CD and absorption bands. In most of the J-bands, CD intensities were found to be parallel to the corresponding absorption intensities. However, some CD bands were observed to be exceptionally strong in comparison to the corresponding absorption bands. Those J-bands were named "CD-sensitive bands". The CD intensity of the "CD-sensitive

bands" was well elucidated on the basis of Condon's theory[3] *i.e.*, the CD intensity is proportional to the imaginary part of the scalar product of the magnetic and the electric dipole moments associated with the electronic transitions.

CD and absorption spectra of Pr(III), Nd(III), Sm(III), Dy(III), Ho(III), Er(III) and Tm(III) complexes of six natural amino acids and L-EDDS (ethylenediaminedisuccinic acid) have been measured. The relative intensities of CD and absorption bands with regard to the calculated oscillator strengths of magnetic dipole transitions of the J-bands have been discussed in order to verify the general validity of the theory which was previously proposed for the elucidation of the "CD-sensitive bands".

Experimental

Materials. The natural amino acids, L-alanine, L-serine, L-threonine, L-aspartic acid, L-arginine and L-lysine were commercial products and were of GR grade. L-Ethylenediaminedisuccinic acid (EDDS) was prepared by Neal's method[4] from 1,2-dibromoethane and L-aspartic acid.

Found: C, 32.95; H, 6.80; N, 7.42%. Calcd for $C_{10}H_{24}N_2O_{12}$: C, 32.97; H, 6.59; N, 7.69%.

Lanthanide perchlorate was obtained by dissolving commercial lanthanide oxide of 99.9% purity. The concentration of lanthanide(III) ions were determined by means of volumemetric EDTA titration.

Measurements. Absorption and CD spectra were measured by a JASCO-ORD/UV-5 optical rotatory dispersion recorder with a CD attachment.

The solutions used for the measurements were prepared by dissolving lanthanide(III) perchlorate and the ligand in water in about 1 : 5 mole-ratio (except for EDDS complexes where metal to ligand ratio is 1 : 1), and were made alkaline with aqueous ammonia.

Results and Discussion

CD and absorption spectra of 51 complexes were measured. A few examples of these results are shown in Fig. 1. As was observed in PDTA

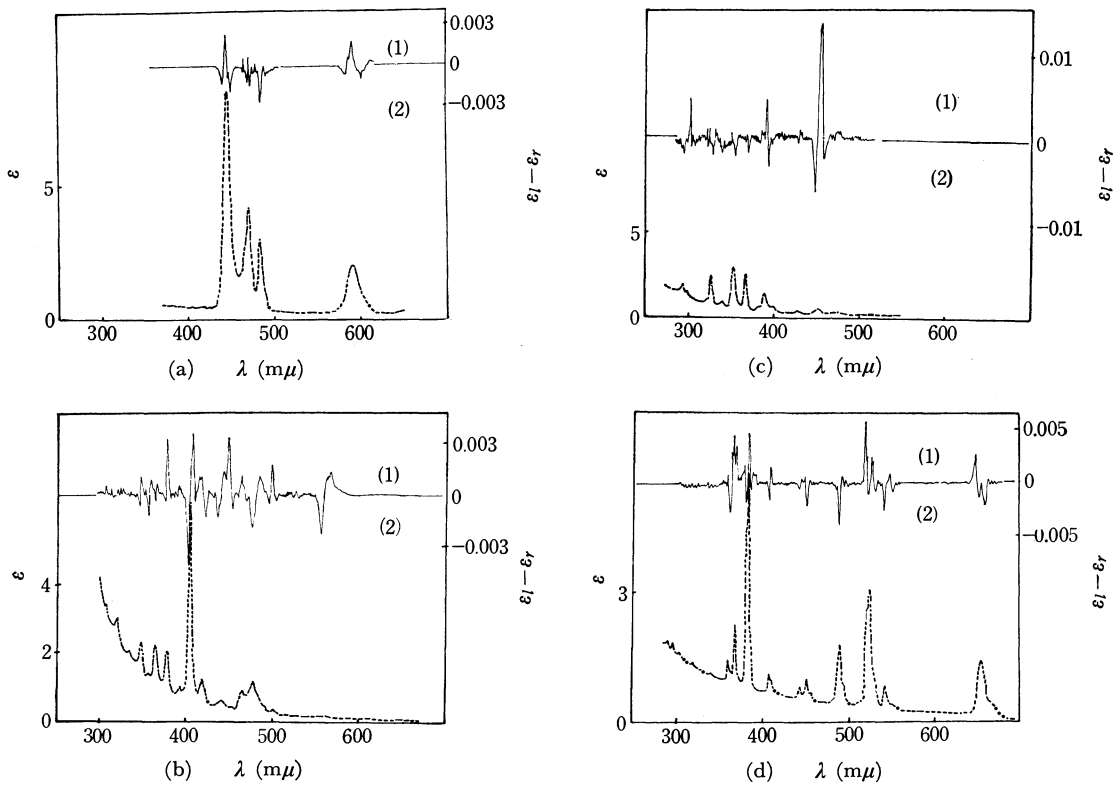

Fig. 1. Examples of CD and absorption spectra of lanthanide(III) complexes in aqueous solutions. (1 cm cell)

complexes,[2] a group of sharp CD bands was observed in the region of each absorption region.

The intensities of CD bands are parallel to those of corresponding absorption bands in most of the J-bands. However, as expected, unusually strong CD bands in comparison to the absorption bands were observed in the regions where the "CD-sensitive bands" were observed in the PDTA complexes.

In order to make clear the relation between the CD intensity and the magnetic dipole transition, we have calculated the oscillator strength, P, of magnetic dipole transition of J-bands by means of Pasternack's method[5] using eigen vectors of the secular equations for the intermediate coupling scheme.[6-9]

The results are summarized in Table 1, where $\alpha(=(\varepsilon_l-\varepsilon_r)/\varepsilon)$ was used as a parameter for representing relative intensities of CD and absorption bands. As seen in Table 1, when $P=0$, α remains only in the order of 10^{-5}—10^{-4}. However, when P exceeds the value $\sim 10^{-7}$, α becomes the order of 10^{-4}—10^{-3}, and the "CD-sensitive bands" were observed distinctly. Agreement between theory and experiment is satisfactory as is seen from Table 1. Thus we may conclude that our theory for the "CD-sensitive bands" is on the whole valid. However, one exception was the band at 660 mμ in the spectra of some Tm(III) complexes, where α shows a large value (100—200×10^{-4}) for $P=0$. This can not be explained at present.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 3437—3447 (1969)

Group Theoretical Treatment of Crystal Vibrations; Application to Orthorhombic Polyethylene

Teizo KITAGAWA and Tatsuo MIYAZAWA

Institute for Protein Research, Osaka University, Joan-cho, Kita-ku, Osaka

(Received June 30, 1969)

Irreducible representations of k groups of the space group *Pnam* were derived with Slater's method. Degeneracies of crystal vibrations due to space symmetry and time reversal symmetry were treated on the basis of Maradudin's theory. With irreducible representations of k groups, symmetry coordinates of the carbon atoms of orthorhombic polyethylene were constructed from translational-symmetry coordinates with nonintegral index vectors. A general matrix method was worked out for treating crystal vibrations of any phase-difference vector. Useful methods were derived for treating molecular crystals and chain polymer crystals and for approximate treatment of low frequency lattice vibrations.

For orthorhombic polyethylene crystal, various experimental data have become available, including infrared bands due to CH_2 bending and rocking vibrations,[1] for infrared bands due to lattice vibrations,[2,3] elastic and inelastic scattering cross sections of thermal neutrons[4-6] and low temperature specific heat.[7] All these data are related with the force field and normal vibrations of the crystal. For a molecular crystal, far infrared bands due to lattice vibrations arise from the intermolecular force field. Splitting of infrared bands due to intramolecular vibrations depends primarily on intermolecular force field but also on normal modes (atomic displacements) of the unperturbed vibrations concerned. Specific heat in the lowest temperature region is due to low frequency vibrations of three acoustic branches. On the other

hand, elastic and inelastic scattering cross sections of thermal neutrons depend on the vibrational frequencies and also on vibrational displacements (of scattering nuclei) for all the acoustic and optical branches of crystal vibrations.

For an analysis of any one of these data, a highly simplified model may be useful, but often such a model is not necessarily applicable for analyses of other data. In our present series of studies on orthorhombic polyethylene crystal, available experimental data were all systematically treated on the basis of the intrachain and interchain force field and the acoustic and optical branches of crystal vibrations.

Chain-polymer crystals such as polyethylene are highly anisotropic and the restoring force along the chain axis is intramolecular in contrast with the intermolecular forces along two other directions. Accordingly these crystals form a special group of molecular crystals which practically behave as polymer molecules along the chain direction. A general method for treating molecular vibrations of helical polymer chains have been worked out previously,[8-10] and frequency-dispersion curves of the polyethylene chain[11] were obtained for analyzing band progression of intramolecular vibrations. However, for treating specific heat and neutron-scattering cross sections, normal coordinate treatments of the acoustic and optical vibrations of the three-dimensional crystal in the first Brillouin zone are required.

A dynamical theory of crystal lattices was established by Born and Huang[12] and a general method was worked out for treating crystal vibrations with Cartesian symmetry coordinates of any given wave vector ($\boldsymbol{k}$) [constructed in accordance with the translational symmetry of crystal lattices]. However, for crystal lattices of high space-group symmetry, crystal vibrations of special wave vectors may be grouped into symmetry classes and corresponding dynamical matrices may be factored into small matrices after unitary transformations. Accordingly computer time for numerical calculation is much reduced. Symmetry considerations are also required in drawing dispersion curves of the same symmetry class which should not intersect one another.

In the present study, therefore, group theoretical treatments were made of crystal vibrations of the space group *Pnam*. Furthermore, general matrix methods were worked out for treating molecular crystals and chain-polymer crystals and were applied to orthorhombic polyethylene crystal.

Space Group Operations and k Groups

For a crystal lattice, constituent atoms of a unit cell are classified into sets, each set consisting of equivalent atoms. In the case of orthorhombic polyethylene[13] (Fig. 1), two molecular chains pass through a unit cell along the c axis and there are four methylene groups per unit cell. There are two sets of hydrogen atoms and one set of carbon atoms. In the present paper, symmetry coordinates for carbon atoms will be described, but same considerations apply also for the other two sets of hydrogen atoms.

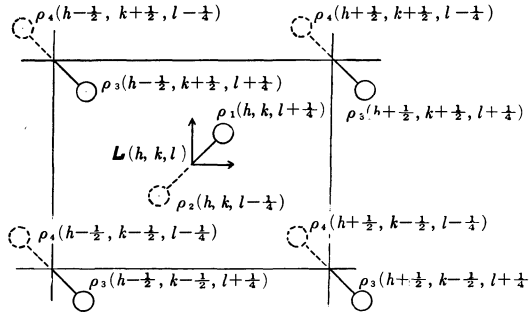

Fig. 1. Crystal structure and nonintegral index vectors ($\boldsymbol{\rho}$) of the carbon atoms of orthorhombic polyethylene (*Pnam*).

A unit cell of a crystal lattice is denoted with an index vector $\boldsymbol{L}$ with integral components (h,k,l). Then the ith atom of the $\boldsymbol{L}$th cell may be denoted with a nonintegral index

$$\boldsymbol{\rho}_i(\boldsymbol{L}) = \boldsymbol{L} + \boldsymbol{\rho}_i^0 , \tag{1}$$

where components of the position vector $\boldsymbol{\rho}_i^0$ from the cell origin are given in units of lattice constants (a_0,b_0,c_0). For the crystal lattice of orthorhombic polyethylene (Fig. 1), the position vectors are given as

$$\boldsymbol{\rho}_1^0=\begin{bmatrix} 0 \\ 0 \\ 1/4 \end{bmatrix} \quad \boldsymbol{\rho}_2^0=\begin{bmatrix} 0 \\ 0 \\ -1/4 \end{bmatrix} \quad \boldsymbol{\rho}_3^0=\begin{bmatrix} -1/2 \\ 1/2 \\ 1/4 \end{bmatrix} \quad \boldsymbol{\rho}_4^0=\begin{bmatrix} 1/2 \\ -1/2 \\ -1/4 \end{bmatrix} \tag{2}$$

and space group operations are listed in Table 1. Then, with respect to the translational-symmetry of the crystal lattice, the Cartesian symmetry coordinate vector $\boldsymbol{\sigma}$ for the ith atom is constructed as

$$\boldsymbol{\sigma}_i(\boldsymbol{\delta}) = N^{-1/2}\sum_{\boldsymbol{L}} \boldsymbol{X}(\boldsymbol{\rho}_i)\exp(-i\boldsymbol{\rho}_i\cdot\boldsymbol{\delta}) , \tag{3}$$

where $\boldsymbol{\delta}$ is a phase difference vector (corresponding to a wave vector $\boldsymbol{k}$; $\delta_a=a_0k_a$, $\delta_b=b_0k_b$, $\delta_c=c_0k_c$), N is the total number of unit cells and $\boldsymbol{X}(\boldsymbol{\rho}_i)$ is the Cartesian coordinate vector (x,y,z) of the $\boldsymbol{\rho}_i$th

R_8	$\sigma_g(ab)$	$\begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & -1 \end{bmatrix}$	(0, 0, 1/2)

* Components of a nonprimitive translation vector $\boldsymbol{\tau}_u$ are given in units of lattice constants a_0, b_0 and c_0.

atom.

A symmetry operation of a crystal lattice consists of a rotation ($\boldsymbol{\alpha}_u$) and a nonprimitive translation($\boldsymbol{\tau}_u$).[14] For the crystal lattice of orthorhombic polyethylene, symmetry operations are listed in Table 1. A symmetry operation R_u (at the lattice origin $\boldsymbol{L}=0$) will transform the Cartesian coordinate vector $\boldsymbol{X}$ of the $\boldsymbol{\rho}_i$th atom as

$$R_u\boldsymbol{X}(\boldsymbol{\rho}_i) = \boldsymbol{\alpha}_u\boldsymbol{X}(\boldsymbol{\alpha}_u\boldsymbol{\rho}_i+\boldsymbol{\tau}_u) = \boldsymbol{\alpha}_u\boldsymbol{X}(\boldsymbol{\rho}_j) \tag{4}$$

and accordingly will transform the translational-symmetry coordinate $\boldsymbol{\sigma}_i(\boldsymbol{\delta})$ as

$$R_u\boldsymbol{\sigma}_i(\boldsymbol{\delta}) = N^{-1/2}\sum_{\boldsymbol{L}}\boldsymbol{\alpha}_u\boldsymbol{X}(\boldsymbol{\alpha}_u\boldsymbol{\rho}_i+\boldsymbol{\tau}_u)\exp(-i\boldsymbol{\rho}_i\cdot\boldsymbol{\delta}). \tag{5}$$

However, since

$$\boldsymbol{\rho}_i\cdot\boldsymbol{\delta} = (\boldsymbol{\alpha}_u\boldsymbol{\rho}_i)\cdot(\boldsymbol{\alpha}_u\boldsymbol{\delta}) \tag{6}$$

the exponential factor in Eq. (5) may be rewritten as

$$\begin{aligned}\exp(-i\boldsymbol{\rho}_i\cdot\boldsymbol{\delta}) &= \exp[-i(\boldsymbol{\alpha}_u\boldsymbol{\rho}_i)\cdot(\boldsymbol{\alpha}_u\boldsymbol{\delta})] \\ &= \exp[-i(\boldsymbol{\alpha}_u\boldsymbol{\rho}_i+\boldsymbol{\tau}_u)\cdot(\boldsymbol{\alpha}_u\boldsymbol{\delta})] \times \exp[i\boldsymbol{\tau}_u\cdot(\boldsymbol{\alpha}_u\boldsymbol{\delta})].\end{aligned} \tag{7}$$

From Eqs. (3)—(5) and (7), the effect of R_u may finally be given as

$$R_u\boldsymbol{\sigma}_i(\boldsymbol{\delta}) = \boldsymbol{\alpha}_u\boldsymbol{\sigma}_j(\boldsymbol{\alpha}_u\boldsymbol{\delta}) \times \exp[i\boldsymbol{\tau}_u\cdot(\boldsymbol{\alpha}_u\boldsymbol{\delta})]. \tag{8}$$

Accordingly, the phase-difference vector is now transformed into a vector $\boldsymbol{\alpha}_u\boldsymbol{\delta}$ and the translational-symmetry coordinate $\boldsymbol{\sigma}_i(\boldsymbol{\delta})$ of the ith atom is transformed into the translational-symmetry coordinate $\boldsymbol{\alpha}_u\boldsymbol{\sigma}_j(\boldsymbol{\alpha}_u\boldsymbol{\delta})$ of the jth atom as multiplied with the phase-factor of $\exp[i\boldsymbol{\tau}_u\cdot(\boldsymbol{\alpha}_u\boldsymbol{\delta})]$. For the carbon atoms of orthorhombic polyethylene, atom-index transformations $i\rightarrow j$ and exponents of phase factors are listed in Table 2.

A $\boldsymbol{k}$ group[14] is defined as the ensemble of space-group operations (R_u) which satisfy the condition.

$$\boldsymbol{\alpha}_u\boldsymbol{\delta} = \boldsymbol{\delta} + 2\pi\boldsymbol{m}, \tag{9}$$

where $\boldsymbol{m}$ is a vector with integral components. Naturally $\boldsymbol{k}$ groups are subgroups of the factor group. Accordingly, the dynamical matrix of the phase-difference vector $\boldsymbol{\delta}$ may be factorized into submatrices, each belonging to an irreducible representation of the $\boldsymbol{k}$ group. For a general phase-difference vector $\boldsymbol{\delta}(\delta_a,\delta_b,\delta_c)$, however, only the identity operation constitutes the $\boldsymbol{k}$ group and the dynamical matrix is not factorized any further.

With the space group *Pnam*, all the eight operations of Table 1 satisfy the condition of Eq. (9) $[\boldsymbol{m}=0]$ for $\boldsymbol{\delta}=0$ and accordingly the $\boldsymbol{k}$ group is the factor group D_{2h} itself. However, for $\boldsymbol{\delta}(\delta_a,0,0)$, only four operations, R_1 (identity), R_2 (twofold

Table 2. Transformations of atom indices ($i\rightarrow j$) and phase-difference vectors ($\boldsymbol{\delta}\rightarrow\boldsymbol{\alpha}_u\boldsymbol{\delta}$) and exponents $\boldsymbol{\tau}_u\cdot(\boldsymbol{\alpha}_u\boldsymbol{\delta})$ of phase-factors involved in the effects of factor-group operations (R_u) upon translational-symmetry coordinates $\boldsymbol{\sigma}_i(\boldsymbol{\delta})$

screw axis along the a axis), R_7 (glide plane normal to the b axis) and R_8 (glide plane normal to the c axis) satisfy Eq. (9) [$\boldsymbol{m}=0$] and therefore the $\boldsymbol{k}$ group is C_{2v}. Finally, for $\boldsymbol{\delta}(\pi,0,0)$, remaining four operations of R_3 (twofold screw axis along the b axis), R_4 (twofold screw axis along the c axis), R_5 (inversion) and R_6 (glide plane normal to the a axis) satisfy Eq. (9) [$\boldsymbol{m}=(-1,0,0)$] and the $\boldsymbol{k}$ group again becomes D_{2h}. All the $\boldsymbol{k}$ groups of the space group *Pnam* are given in Table 3, where BSW notation[15] was followed for special phase-difference vectors.

Irreducible Representations

Irreducible representations of $\boldsymbol{k}$ groups were given by Slater[14] for 20 space groups including D_{2h}^{16}-*Pnam*. On the other hand, Kovalev[16] treated all the 230 space groups with the use of multiplier representation method. However, for polymer-chain crystals, it is a common practice to take the c axis parallel to the chain-direction and accordingly the space group of orthorhombic polyethylene is preferably taken as *Pnam* rather than *Pnam*. Furthermore, in the field of molecular dynamics, the effect of symmetry operations given in Eq. (8) is more intelligible than the reverse one (Slater[14]). In the present study, therefore, basis functions and irreducible representations for all the $\boldsymbol{k}$ groups of *Pnam* were derived on the basis of multiplication tables.

Successive applications of point-group operations is equivalent to one of point-group operations, whereas for a space group, effects of nonprimitive translations ($\boldsymbol{\tau}_u$) are involved. Suppose a symmetry operation R_u operates on a translational-symmetry coordinate vector and then R_v operates on the resulting coordinate vector, then from Eq. (8), we have

$$\begin{aligned} R_vR_u\boldsymbol{\sigma}_i(\boldsymbol{\delta}) &= R_v[\boldsymbol{\alpha}_u\boldsymbol{\sigma}_j(\boldsymbol{\alpha}_u\boldsymbol{\delta})]\exp[i\boldsymbol{\tau}_u\cdot(\boldsymbol{\alpha}_u\boldsymbol{\delta})] \\ &= \boldsymbol{\alpha}_v\boldsymbol{\alpha}_u\boldsymbol{\sigma}_k(\boldsymbol{\alpha}_v\boldsymbol{\alpha}_u\boldsymbol{\delta})\exp[i\boldsymbol{\tau}_v\cdot(\boldsymbol{\alpha}_v\boldsymbol{\alpha}_u\boldsymbol{\delta})]\exp[i\boldsymbol{\tau}_u\cdot\boldsymbol{\alpha}_u\boldsymbol{\delta})] \\ &= \boldsymbol{\alpha}_v\boldsymbol{\alpha}_u\boldsymbol{\sigma}_k(\boldsymbol{\alpha}_v\boldsymbol{\alpha}_u\boldsymbol{\delta})\exp[i(\boldsymbol{\alpha}_v\boldsymbol{\tau}_u+\boldsymbol{\tau}_v)\cdot(\boldsymbol{\alpha}_v\boldsymbol{\alpha}_u\boldsymbol{\delta})], \end{aligned} \tag{10}$$

where the symmetry operation R_v transfers $\boldsymbol{\rho}_j$th atom to the site of a $\boldsymbol{\rho}_k$th atom. The multiplication rule for the rotational parts is identical with the case of point-group operations

$$\boldsymbol{\alpha}_v\boldsymbol{\alpha}_u = \boldsymbol{\alpha}_w. \tag{11}$$

However with a space group, $\boldsymbol{\tau}_v+\boldsymbol{\alpha}_v\boldsymbol{\tau}_u$ is not necessarily equal to $\boldsymbol{\tau}_w$. Accordingly, the effect of two successive space-group operations on a translational-symmetry coordinate may be written as

$$R_vR_u\boldsymbol{\sigma}_i(\boldsymbol{\delta}) = \exp[i(\Delta\boldsymbol{\tau})\cdot(\boldsymbol{\alpha}_w\boldsymbol{\delta})]R_w\boldsymbol{\sigma}_i(\boldsymbol{\delta}), \tag{12}$$

where

$$\Delta\boldsymbol{\tau} = \boldsymbol{\alpha}_v\boldsymbol{\tau}_u + \boldsymbol{\tau}_v - \boldsymbol{\tau}_w. \tag{13}$$

For the space-group *Pnam*, $\Delta\boldsymbol{\tau}$ vectors were derived for all possible combinations of symmetry operations (R_1—R_8) and the multiplication table is shown in Table 4. From this table, basis functions for irreducible representations may be constructed. Irreducible representations for all the $\boldsymbol{k}$ groups of *Pnam* were described by Kitagawa.[17] In the present paper, however, representations of a few $\boldsymbol{k}$ groups will now be discussed.

For the phase-difference vector of $\boldsymbol{\delta}(\delta_a,0,0)$, the $\boldsymbol{k}$ group includes four operations, R_1, R_2, R_7 and R_8 (Table 3). The operations R_2 and R_7 are associated with nonzero components of $\boldsymbol{\tau}_u$ along the a axis but the operations R_1 and R_8 are not (Table 1). Accordingly, basis functions were constructed as

$$\left.\begin{aligned} \phi_1 &= [R_1+R_8+\omega_a{}^*(R_2+R_7)]\phi_0 \\ \phi_2 &= [R_1+R_8-\omega_a{}^*(R_2+R_7)]\phi_0 \\ \phi_3 &= [R_1-R_8+\omega_a{}^*(R_2-R_7)]\phi_0 \\ \phi_4 &= [R_1-R_8-\omega_a{}^*(R_2-R_7)]\phi_0 \end{aligned}\right\}, \tag{14}$$

where

$$\omega_a = \exp(i\delta_a/2). \tag{15}$$

According to the multiplication table (Table 4), these basis functions are transformed with symmetry operations as

$$

For the $\boldsymbol{k}$ group of $\Sigma(\delta_a,0,0)$, the irreducible representations are all one-dimensional (see Table 5) where ϕ_1, ϕ_2, ϕ_3 and ϕ_4 are basis functions of Σ_1, Σ_2, Σ_3, and Σ_4, respectively (these correspond to the species A_1, B_2, A_2, and B_1 of the point group C_{2v}). The multiplication tables for $A(\delta_a,\pi,0)$, $C(\delta_a,0,\pi)$ and $E(\delta_a,\pi,\pi)$ are common with the table for $\Sigma(\delta_a,0,0)$ and accordingly the matrix elements of irreducible representations are shown commonly in Table 5.

For $\Lambda(0,\delta_b,0)$, $H(0,\delta_b,\pi)$, $G(\pi,\delta_b,0)$ and $Q(\pi,\delta_b,\pi)$, the $\boldsymbol{k}$ group (C_{2v}) includes four operations (R_1, R_3, R_6, and R_8). However, the multiplication table of Λ and G is different from that of H and Q.

The irreducible representations of Λ and G (Table 5) are one-dimensional whereas those of H and Q are two-dimensional.[17]

For special points of $(0,\delta_b,\delta_c)$, (π,δ_b,δ_c), $(\delta_a,0,\delta_c)$, (δ_a,π,δ_c), $(\delta_a,\delta_b,0)$ and (δ_a,δ_b,π), the $\boldsymbol{k}$ group is C_s (Table 3) and the dynamical matrix is factorized into two matrices after suitable symmetry transformations (there are no BSW symbols for these special points in the first Brillouin zone).

For $\Gamma(0,0,0)$, the factor group D_{2h} is $\boldsymbol{k}$ group itself and the irreducible representations are shown in Table 6. For each of $X(\pi,0,0)$, $Z(0,\pi,0)$, $Y(0,0,\pi)$, and $T(0,\pi,\pi)$, the $\boldsymbol{k}$ group again becomes D_{2h}. However, in contrast with the one-dimensional representations of Γ (Table 6), irreducible representations of X (Table 7), Z, Y, and T are two-dimensional.

For $U(\pi,\pi,0)$, the $\boldsymbol{k}$ group is also D_{2h}. With the following basis functions,

$$\left.\begin{aligned}
\varphi_1(U_1') &= (R_1+R_4+R_5+R_8)\phi_0\\
\varphi_2(U_1') &= (R_2+R_3+R_6+R_7)\phi_0\\
\varphi_1(U_2') &= (R_1+R_4-R_5-R_8)\phi_0\\
\varphi_2(U_2') &= (R_2+R_3-R_6-R_7)\phi_0\\
\varphi_1(U_3') &= (R_1-R_4+R_5-R_8)\phi_0\\
\varphi_2(U_3') &= (R_2-R_3+R_6-R_7)\phi_0\\
\varphi_1(U_4') &= (R_1-R_4-R_5+R_8)\phi_0\\
\varphi_2(U_4') &= (R_2-R_3-R_6+R_7)\phi_0
\end{aligned}\right\} \quad (17)$$

four two-dimensional representations (real) are obtained. However, from group theory, the sum of squared dimensionalities of irreducible representations should be equal to the number of symmetry operations. In fact, four two-dimensional representations are reduced to eight one-dimensional representations (Table 8). Finally for $S(\pi,0,\pi)$ and $R(\pi,\pi,\pi)$, a four-dimensional representation (real) is obtained with the following basis functions,

$$\left.\begin{aligned}
\varphi_1 &= (R_1+R_8+R_2+R_7)\phi_0\\
\varphi_2 &= (R_1+R_8-R_2-R_7)\phi_0\\
\varphi_3 &= (R_5+R_4+R_6+R_3)\phi_0\\
\varphi_4 &= (R_5+R_4-R_6-R_3)\phi_0.
\end{aligned}\right\} \quad (18)$$

However, the four-dimensional representation is reduced to two two-dimensional representations (Table 9). Dimensionalities (f_s) of irreducible representations are summarized in Table 11.

Degeneracy of Crystal Vibrations

The relation between the dimensionality of irreducible representations and degeneracy of crystal vibrations was generally treated by Maradudin and Vosko[18] with the use of the irreducible multiplier co-representation method. The pth frequency parameter $[\lambda_p(\boldsymbol{\delta})]$ and characteristic vector $[\boldsymbol{L}_p(\boldsymbol{\delta})]$ of the dynamical matrix $\boldsymbol{D}_S(\boldsymbol{\delta})$ are given by

$$\lambda_p(\boldsymbol{\delta})\boldsymbol{L}_p(\boldsymbol{\delta}) = \boldsymbol{D}_S(\boldsymbol{\delta})\boldsymbol{L}_p(\boldsymbol{\delta}). \quad (19)$$

The unitary matrix, $\boldsymbol{T}(\boldsymbol{a}_u,\boldsymbol{\tau}_u)$, associated with the

18) A. A. Maradudin and S. H. Vosko, *Rev. Modern Phys.*, **40**, 1 (1968)

uth operation of the space group was derived and a similarity transformation of the dynamical matrix may be carried out, yielding[18]

$$\boldsymbol{T}(\boldsymbol{a}_u, \boldsymbol{\tau}_u)\boldsymbol{D}_S(\boldsymbol{\delta})\boldsymbol{T}(\boldsymbol{a}_u, \boldsymbol{\tau}_u)^{-1} = \boldsymbol{D}_S(\boldsymbol{a}_u\boldsymbol{\delta}) \tag{20}$$

and accordingly

$$\boldsymbol{\Delta}(\boldsymbol{\delta}) = \boldsymbol{\Delta}(\boldsymbol{a}_u\boldsymbol{\delta}). \tag{21}$$

Therefore the irreducible volume of the first Brillouin zone depends upon the factor-group symmetry. For D_{2h} systems, the irreducible volume is one-eighth of the first Brillouin zone and treatments of crystal vibrations for $0 \leq \delta_a, \delta_b, \delta_c \leq \pi$ are sufficient.

For a unitary-type operation R_u of the $\boldsymbol{k}$ group ($\boldsymbol{a}_u\boldsymbol{\delta} = \boldsymbol{\delta}$), $\boldsymbol{T}(\boldsymbol{a}_u, \boldsymbol{\tau}_u)$ commutes with $\boldsymbol{D}_S(\boldsymbol{\delta})$ so that Eq. (19) is transformed,

$$\lambda_p(\boldsymbol{\delta})\{\boldsymbol{T}(\boldsymbol{a}_u, \boldsymbol{\tau}_u)\boldsymbol{L}_p(\boldsymbol{\delta})\} = \boldsymbol{D}_S(\boldsymbol{\delta})\{\boldsymbol{T}(\boldsymbol{a}_u, \boldsymbol{\tau}_u)\boldsymbol{L}_p(\boldsymbol{\delta})\}. \tag{22}$$

On the other hand, for an antiunitary-type operation (R_w) of the space group which inverts the phase-difference vector ($\boldsymbol{a}_w\boldsymbol{\delta} = -\boldsymbol{\delta}$), Eq. (19) is transformed into

$$\begin{aligned}\lambda_p(\boldsymbol{\delta})\{\boldsymbol{T}(\boldsymbol{a}_w, \boldsymbol{\tau}_w)\boldsymbol{L}_p(\boldsymbol{\delta})\} &= \boldsymbol{D}_S(-\boldsymbol{\delta})\{\boldsymbol{T}(\boldsymbol{a}_w, \boldsymbol{\tau}_w)\boldsymbol{L}_p(\boldsymbol{\delta})\} \\ &= \boldsymbol{D}_S(\boldsymbol{\delta})^*\{\boldsymbol{T}(\boldsymbol{a}_w, \boldsymbol{\tau}_w)\boldsymbol{L}_p(\boldsymbol{\delta})\}.\end{aligned} \tag{23}$$

Accordingly, if $\boldsymbol{T}(\boldsymbol{a}_w, \boldsymbol{\tau}_w)\boldsymbol{L}_p(\boldsymbol{\delta})$ and $\boldsymbol{T}(\boldsymbol{a}_u, \boldsymbol{\tau}_u)\boldsymbol{L}_p(\boldsymbol{\delta})$ are linearly independent of each other, so-called time-reversal degeneracy arises over space degeneracy [dimensionality (f_s) of irreducible representation]. According to Maradudin,[18] time-reversal degeneracy may be studied after treating

$$\Phi = \sum_u \phi(\boldsymbol{\delta}, R_aR_u)\chi^\mu(\boldsymbol{\delta}, R_aR_uR_aR_u), \tag{24}$$

where R_a is any antiunitary operation and $\phi(\boldsymbol{\delta}, R_w)$ is the multiplier representation of an antiunitary operation ($R_w \leftarrow R_aR_u$).

$$\phi(\boldsymbol{\delta}, R_w) = \exp[-i(\boldsymbol{\delta} + \boldsymbol{a}_w{}^{-1}\boldsymbol{\delta})\cdot\boldsymbol{\tau}_w]. \tag{25}$$

As an example of $\sum(\delta_a, 0, 0)$ of the space group *Pnam*, R_1, R_2, R_7, and R_8 are unitary-type operations whereas R_3, R_4, R_5, and R_6, are antiunitary-type operations. The inversion operation (R_5) always serves as an antiunitary operation for any phase-difference vector and is preferably used as R_a. In Eq. (24), $\chi^\mu(\boldsymbol{\delta}, R_aR_uR_aR_u)$ is the character of the μth irreducible representation for the operation $R_aR_uR_aR_u$. Summation runs over all the operations of a $\boldsymbol{k}$ group, and if Φ is equal to the order (g) of the $\boldsymbol{k}$ group, time-reversal degeneracy does not arise but, if Φ is equal to $-g$ or equal to 0, time-reversal degeneracy arises.[18] Accordingly with an f_s-dimensional representation of a $\boldsymbol{k}$ group, crystal vibrations are f_s-fold degenerate for $\Phi/g = 1$ but are $2f_s$-fold degenerate for $\Phi/g = -1$ or 0. Formulas of $\phi(\boldsymbol{\delta}, R_w)$ were obtained, as shown in Table 11, for symmetry operations of the space group *Pnam*, and the values of Φ/g were calculated as listed in Table 10. The time-reversal degeneracy ($t_s = 2$) is now expected for U, S, R, A, C, E, G, F, and Q. It may be remarked that crystal vibrations

are doulby-degenerate ($t_s f_s=2$) if a component of the phase-difference vector is equal to π. If more than two components are equal to π, crystal vibrations are doubly-degenerate ($t_s f_s=2$ for T, U, E, and F) or fourfold-degenerate ($t_s f_s=4$ for S, R, and Q).

Symmetry Coordinates of Polyethylene

Symmetry coordinates of a crystal lattice for the μth symmetry species may be constructed from the sum of $\sum_u K_\mu(R_u)^* R_u \boldsymbol{\sigma}_i(\boldsymbol{\delta})$ over symmetry operations of the $\boldsymbol{k}$ group, where $K_\mu(R_u)^*$ is the complex conjugate of a matrix element (for R_u) of the μth irreducible representation of the $\boldsymbol{k}$ group.

The symmetry coordinates of orthorhombic polyethylene for $\Gamma(0,0,0)$ may be constructed from Tables 2 and 6, as follows.

$$
\left.\begin{array}{ll}
\Gamma_1(A_g) & S_1=(\sigma_1{}^x-\sigma_2{}^x+\sigma_3{}^x-\sigma_4{}^x)/2 \\
 & S_2=(\sigma_1{}^y-\sigma_2{}^y-\sigma_3{}^y+\sigma_4{}^y)/2 \\
\Gamma_2(A_u) & S_3=(\sigma_1{}^z+\sigma_2{}^z-\sigma_3{}^z-\sigma_4{}^z)/2i \\
\Gamma_3(B_{3g}) & S_4=(\sigma_1{}^x-\sigma_2{}^x-\sigma_3{}^x+\sigma_4{}^x)/2 \\
 & S_5=(\sigma_1{}^y-\sigma_2{}^y+\sigma_3{}^y-\sigma_4{}^y)/2 \\
\Gamma_4(B_{3u}) & S_6=(\sigma_1{}^z+\sigma_2{}^z+\sigma_3{}^z+\sigma_4{}^z)/2i \\
\Gamma_5(B_{1g}) & S_7=(\sigma_1{}^z-\sigma_2{}^z-\sigma_3{}^z+\sigma_4{}^z)/2 \\
\Gamma_6(B_{1u}) & S_8=(\sigma_1{}^x+\sigma_2{}^x+\sigma_3{}^x+\sigma_4{}^x)/2i \\
 & S_9=(\sigma_1{}^y+\sigma_2{}^y-\sigma_3{}^y-\sigma_4{}^y)/2i \\
\Gamma_7(B_{2g}) & S_{10}=(\sigma_1{}^z-\sigma_2{}^z+\sigma_3{}^z-\sigma_4{}^z)/2 \\
\Gamma_8(B_{2u}) & S_{11}=(\sigma_1{}^x+\sigma_2{}^x-\sigma_3{}^x-\sigma_4{}^x)/2i \\
 & S_{12}=(\sigma_1{}^y+\sigma_2{}^y+\sigma_3{}^y+\sigma_4{}^y)/2i
\end{array}\right\} \quad (26)
$$

	0	0	0	δ_c

* For examples, numerals of 1, 2, 3,⋯ in the column headed with Γ denote $\Gamma_1, \Gamma_2, \Gamma_3, \cdots$.
** $0<\delta_a, \delta_b, \delta_c<\pi$.

It may be recalled here that translational-symmetry coordinates ($\sigma_i{}^x, \sigma_i{}^y$, and $\sigma_i{}^z$) are functions of phase-difference vector $\boldsymbol{\delta}$ as shown in Eq. (3), so are $S_1(\boldsymbol{\delta})$—$S_{12}(\boldsymbol{\delta})$. From analyses of the effects of symmetry operations, these symmetry coordinates (S_1—S_{12}) are found useful, as themselves, for $\sum(\delta_a,0,0)$, $\Lambda(0,\delta_b,0)$, and $\Delta(0,0,\delta_c)$. As examples, symmetry coordinates of S_1, S_2, S_8, and S_9 may be used for the $\sum_1$ species, S_4, S_5, S_{11}, and S_{12} for the $\sum_2$ species, S_3 and S_7 for the $\sum_3$ species, and S_6 and S_{10} for the $\sum_4$ species. Furthermore the symmetry coordinates of Eq. (26) may be used for $(0,\delta_b,\delta_c)$, $(\delta_a,0,\delta_c)$, $(\delta_a,\delta_b,0)$, and $(\delta_a,\delta_b,\delta_c)$ and also for phase-difference vectors $\boldsymbol{\delta}$ on boundaries of the first Brillouin zone. It may be remarked that, for any phase difference vector, the real parts of the symmetry coordinates of Eq. (26) are symmetric with respect to the inversion operation whereas the imaginary parts are antisymmetric. Accordingly, the dynamical matrix $\boldsymbol{D}_S(\boldsymbol{\delta})$ associated with $S_1(\boldsymbol{\delta})$—$S_{12}(\boldsymbol{\delta})$ are real. Elements of the dynamical matrix are functions of $\boldsymbol{\delta}(\delta_a,\delta_b,\delta_c)$ and the vibrational frequencies for a $\boldsymbol{\delta}$ vector may be calculated after diagonalization of the dynamical matrix.

As a few examples of $X(\pi,0,0)$, $U(\pi,\pi,0)$, and $R(\pi,\pi,\pi)$, degeneracy of crystal vibrations will now be discussed from analyses of symmetry coordinates. For $X(\pi,0,0)$, symmetry coordinates may be constructed from $\sum_u X_\mu(R_u)^* R_u \boldsymbol{\sigma}_i$ (Tables 2 and 7) as follows.

$$
\left.\begin{array}{ll}
S(X_1)_{1a}=(\sigma_1{}^x-i\sigma_4{}^x)/2^{1/2} & \\
 & S(X_1)_{1b}=(-\sigma_2{}^x-i\sigma_3{}^x)/2^{1/2} \\
S(X_1)_{2a}=(-\sigma_2{}^x+i\sigma_3{}^x)/2^{1/2} & \\
 & S(X_1)_{2b}=(\sigma_1{}^x+i\sigma_4{}^x)/2^{1/2} \\
S(X_1)_{3a}=(\sigma_1{}^y+i\sigma_4{}^y)/2^{1/2} & \\
 & S(X_1)_{3b}=(-\sigma_2{}^y+i\sigma_3{}^y)/2^{1/2} \\
S(X_1)_{4a}=(-\sigma_2{}^y-i\sigma_3{}^y)/2^{1/2} & \\
 & S(X_1)_{4b}=(\sigma_1{}^y-i\sigma_4{}^y)/2^{1/2} \\
S(X_2)_{5a}=(\sigma_1{}^z-i\sigma_4{}^z)/2^{1/2} & \\
 & S(X_2)_{5b}=(\sigma_2{}^z+i\sigma_3{}^z)/2^{1/2} \\
S(X_2)_{6a}=(\sigma_2{}^z-i\sigma_3{}^z)/2^{1/2} & \\
 & S(X_2)_{6b}=(\sigma_1{}^z+i\sigma_4{}^z)/2^{1/2}
\end{array}\right\} \quad (27)
$$

Now, from Table 2 and Eqs. (2) and (3), effects of inversion (R_5) are

$$
\left.\begin{array}{l}
R_5\boldsymbol{\sigma}_1(\pi,0,0)=-\boldsymbol{\sigma}_2(-\pi,0,0)=-\boldsymbol{\sigma}_2(\pi,0,0) \\
R_5\boldsymbol{\sigma}_3(\pi,0,0)=-\boldsymbol{\sigma}_4(-\pi,0,0)=\boldsymbol{\sigma}_4(\pi,0,0)
\end{array}\right\} \quad (28)
$$

Accordingly, pairs (a and b) of symmetry coordinate vectors of $X(\pi,0,0)$ are transformed upon inversion as follows,

$$
\left.\begin{array}{l}
S(X_1)_a \leftrightarrow S(X_1)_b \\
S(X_2)_a \leftrightarrow -S(X_2)_b
\end{array}\right\} \quad (29)
$$

and crystal vibrations are doubly degenerate for X_1 and X_2.

Next, for $U(\pi,\pi,0)$, symmetry coordinates may

be constructed from Tables 2 and 8 as follows.

$$\left.\begin{aligned}
S(U_1)_1 &= [(\sigma_1{}^x-\sigma_2{}^x)-i(\sigma_3{}^x-\sigma_4{}^x)]/2\\
S(U_1)_2 &= [(\sigma_1{}^y-\sigma_2{}^y)+i(\sigma_3{}^y-\sigma_4{}^y)]/2\\
S(U_2)_1 &= [(\sigma_1{}^x-\sigma_2{}^x)+i(\sigma_3{}^x-\sigma_4{}^x)]/2\\
S(U_2)_2 &= [(\sigma_1{}^y-\sigma_2{}^y)-i(\sigma_3{}^y-\sigma_4{}^y)]/2\\
S(U_3)_3 &= [(\sigma_1{}^z+\sigma_2{}^z)+i(\sigma_3{}^z+\sigma_4{}^z)]/2\\
S(U_4)_3 &= [(\sigma_1{}^z+\sigma_2{}^z)-i(\sigma_3{}^z+\sigma_4{}^z)]/2\\
S(U_5)_4 &= [(\sigma_1{}^z-\sigma_2{}^z)+i(\sigma_3{}^z-\sigma_4{}^z)]/2\\
S(U_6)_4 &= [(\sigma_1{}^z-\sigma_2{}^z)-i(\sigma_3{}^z-\sigma_4{}^z)]/2\\
S(U_7)_5 &= [(\sigma_1{}^x+\sigma_2{}^x)-i(\sigma_3{}^x+\sigma_4{}^x)]/2\\
S(U_7)_6 &= [(\sigma_1{}^y+\sigma_2{}^y)+i(\sigma_3{}^y+\sigma_4{}^y)]/2\\
S(U_8)_5 &= [(\sigma_1{}^x+\sigma_2{}^x)+i(\sigma_3{}^x+\sigma_4{}^x)]/2\\
S(U_8)_6 &= [(\sigma_1{}^y+\sigma_2{}^y)-i(\sigma_3{}^y+\sigma_4{}^y)]/2
\end{aligned}\right\} \quad (30)$$

However, since translational-symmetry coordinate vectors $\boldsymbol{\sigma}_1$—$\boldsymbol{\sigma}_4$ are all real for $U(\pi,\pi,0)$, symmetry coordinates of (U_1 and U_2), (U_3 and U_4), (U_5 and U_6) and (U_7 and U_8) are mutually conjugate and accordingly crystal vibrations of these pairs are doubly degenerate due to time-reversal symmetry ($t_s=2$, see Table 10).

Finally, for $R(\pi,\pi,\pi)$, symmetry coordinates may be obtained from Tables 2 and 9 as follows.

$$\left.\begin{aligned}
S(R_1)_{1a} &= (\sigma_1{}^x+i\sigma_3{}^x)/2^{1/2}\\
S(R_1)_{2a} &= (\sigma_1{}^y-i\sigma_3{}^y)/2^{1/2}\\
S(R_1)_{3a} &= (-\sigma_2{}^z-i\sigma_4{}^z)/2^{1/2}\\
S(R_1)_{1b} &= (-i\sigma_2{}^x+\sigma_4{}^x)/2^{1/2}\\
S(R_1)_{2b} &= (-i\sigma_2{}^y-\sigma_4{}^y)/2^{1/2}\\
S(R_1)_{3b} &= (-i\sigma_1{}^z+\sigma_3{}^z)/2^{1/2}\\
S(R_2)_{1c} &= (\sigma_1{}^x-i\sigma_3{}^x)/2^{1/2}\\
S(R_2)_{2c} &= (\sigma_1{}^y+i\sigma_3{}^y)/2^{1/2}\\
S(R_2)_{3c} &= (\sigma_2{}^z-i\sigma_4{}^z)/2^{1/2}\\
S(R_2)_{1d} &= (-i\sigma_2{}^x-\sigma_4{}^x)/2^{1/2}\\
S(R_2)_{2d} &= (-i\sigma_2{}^y+\sigma_4{}^y)/2^{1/2}\\
S(R_2)_{3d} &= (i\sigma_1{}^z+\sigma_3{}^z)2^{1/2}
\end{aligned}\right\} \quad (31)$$

However, from Table 2 and Eqs. (2) and (3), effects of inversion (R_5) are

$$\left.\begin{aligned}
R_5\boldsymbol{\sigma}_1(\pi,\pi,\pi) &= -\boldsymbol{\sigma}_2(-\pi,-\pi,-\pi) = i\boldsymbol{\sigma}_2(\pi,\pi,\pi)\\
R_5\boldsymbol{\sigma}_3(\pi,\pi,\pi) &= -\boldsymbol{\sigma}_4(-\pi,-\pi,-\pi) = i\boldsymbol{\sigma}_4(\pi,\pi,\pi)
\end{aligned}\right\} \quad (32)$$

and therefore symmetry coordinate vectors are transformed upon inversion, as follows,

$$\boldsymbol{S}(R_1)_a \leftrightarrow -\boldsymbol{S}(R_1)_b \qquad \boldsymbol{S}(R_2)_c \leftrightarrow -\boldsymbol{S}(R_2)_d. \quad (33)$$

Furthermore, for the phase-difference vector of (π,π,π),

$$\boldsymbol{S}(R_1)_a = -i\boldsymbol{S}(R_2)_c{}^* \qquad \boldsymbol{S}(R_1)_b = -i\boldsymbol{S}(R_2)_d{}^* \quad (34)$$

and accordingly, the symmetry coordinate vectors of R_1 and R_2 form doubly-degenerate pairs (a-c and b-d) due to time-reversal symmetry. However, since the symmetry coordinate vectors of R_1 and R_2 form doubly degenerate pairs (a-b and c-d) due to space symmetry, crystal vibrations of $R(\pi,\pi,\pi)$ are four-fold degenerate (see Table 10, $f_s=2$, $t_s=2$).

Normal Vibration Treatment

Symmetry Coordinates. For a crystal containing an atoms per unit cell, there are $3n$ normal modes of crystal vibrations for a given phase-difference vector $\boldsymbol{\delta}=(\delta_a,\delta_b,\delta_c)$. Accordingly, the Cartesian symmetry coordinate vector $\boldsymbol{S}(\boldsymbol{\delta})$ with $3n$ components may be constructed as

$$\boldsymbol{S}(\boldsymbol{\delta}) = \sum_{\rho}\boldsymbol{U}(\boldsymbol{\delta},\boldsymbol{\rho})\boldsymbol{X}(\boldsymbol{\rho}), \quad (35)$$

where $\boldsymbol{U}(\boldsymbol{\delta},\boldsymbol{\rho})$ is a unitary transformation matrix and $\boldsymbol{X}(\boldsymbol{\rho})$ is the Cartesian coordinate vector (three components) of the $\boldsymbol{\rho}$th atom. For the case of orthorhombic polyethylene, real parts of the Cartesian symmetry coordinates of Eq. (26) may be used, *viz.*,

$$\boldsymbol{S}(\boldsymbol{\delta})\dagger = (S_1\ S_2\ S_3\ S_4\ S_5\ S_6\ S_8\ S_9\ S_7\ S_{11}\ S_{12}\ S_{10}) \quad (36)$$

so that

$$\boldsymbol{S}(\boldsymbol{\delta}) = (2N)^{-1/2}\sum_{\boldsymbol{L}}\begin{bmatrix} \boldsymbol{u}_1{}^c & \boldsymbol{u}_2{}^c & \boldsymbol{u}_3{}^c & \boldsymbol{u}_4{}^c\\ \boldsymbol{u}_1{}^c & \boldsymbol{u}_2{}^c & -\boldsymbol{u}_3{}^c & -\boldsymbol{u}_4{}^c\\ \boldsymbol{u}_1{}^s & -\boldsymbol{u}_2{}^s & \boldsymbol{u}_3{}^s & -\boldsymbol{u}_4{}^s\\ \boldsymbol{u}_1{}^s & -\boldsymbol{u}_2{}^s & -\boldsymbol{u}_3{}^s & \boldsymbol{u}_4{}^s \end{bmatrix}\begin{bmatrix} \boldsymbol{X}(\boldsymbol{\rho}_1)\\ \boldsymbol{X}(\boldsymbol{\rho}_2)\\ \boldsymbol{X}(\boldsymbol{\rho}_3)\\ \boldsymbol{X}(\boldsymbol{\rho}_4) \end{bmatrix} \quad (37)$$

$$\left.\begin{aligned}
\boldsymbol{u}_1{}^c &= \begin{bmatrix} c_1 & 0 & 0\\ 0 & c_1 & 0\\ 0 & 0 & s_1 \end{bmatrix} & \boldsymbol{u}_1{}^s &= \begin{bmatrix} s_1 & 0 & 0\\ 0 & s_1 & 0\\ 0 & 0 & c_1 \end{bmatrix}\\
\boldsymbol{u}_2{}^c &= \begin{bmatrix} -c_2 & 0 & 0\\ 0 & -c_2 & 0\\ 0 & 0 & s_2 \end{bmatrix} & \boldsymbol{u}_2{}^s &= \begin{bmatrix} -s_2 & 0 & 0\\ 0 & -s_2 & 0\\ 0 & 0 & c_2 \end{bmatrix}\\
\boldsymbol{u}_3{}^c &= \begin{bmatrix} c_3 & 0 & 0\\ 0 & -c_3 & 0\\ 0 & 0 & -s_3 \end{bmatrix} & \boldsymbol{u}_3{}^s &= \begin{bmatrix} s_3 & 0 & 0\\ 0 & -s_3 & 0\\ 0 & 0 & -c_3 \end{bmatrix}\\
\boldsymbol{u}_4{}^c &= \begin{bmatrix} -c_4 & 0 & 0\\ 0 & c_4 & 0\\ 0 & 0 & -s_4 \end{bmatrix} & \boldsymbol{u}_4{}^s &= \begin{bmatrix} -s_4 & 0 & 0\\ 0 & s_4 & 0\\ 0 & 0 & -c_4 \end{bmatrix}
\end{aligned}\right\} \quad (38)$$

where

$$\left.\begin{aligned}
c_i &= \cos(\boldsymbol{\rho}_i\cdot\boldsymbol{\delta})\\
s_i &= \sin(\boldsymbol{\rho}_i\cdot\boldsymbol{\delta})
\end{aligned}\right\} \quad (39)$$

Dynamical Matrix. The potential energy (V) of crystal vibrations may be expressed with internal coordinates $\boldsymbol{R}$ (bond lengths, bond angles, internal-rotation angles, and others) as

$$2V = \tilde{\boldsymbol{R}}\boldsymbol{F}_R\boldsymbol{R}, \quad (40)$$

where $\boldsymbol{F}_R$ is the potential energy matrix. With the use of the $\boldsymbol{B}(\boldsymbol{\rho})$ matrix,[19] the $\boldsymbol{R}$ vector is derived from Eq. (35) as

$$\boldsymbol{R} = \sum_{\rho}\boldsymbol{B}(\boldsymbol{\rho})\boldsymbol{X}(\boldsymbol{\rho}) = \sum_{\rho}\boldsymbol{B}(\boldsymbol{\rho})\sum_{\delta}\tilde{\boldsymbol{U}}(\boldsymbol{\delta},\boldsymbol{\rho})\boldsymbol{S}(\boldsymbol{\delta}). \quad (41)$$

Then, the potential energy for the phase-difference

19) E. B. Wilson, *J. Chem. Phys.*, **7**, 1047 (1939); *ibid.*, **9**, 76 (1942).

$\boldsymbol{\delta}$ is derived as

$$2V(\boldsymbol{\delta}) = \tilde{\boldsymbol{S}}(\boldsymbol{\delta})\boldsymbol{F}_S(\boldsymbol{\delta})\boldsymbol{S}(\boldsymbol{\delta}) \tag{42}$$

$$\boldsymbol{F}_S = \sum_{\rho'}\sum_{\rho} \boldsymbol{U}(\boldsymbol{\delta}, \boldsymbol{\rho}')\tilde{\boldsymbol{B}}(\boldsymbol{\rho}')\boldsymbol{F}_R\boldsymbol{B}(\boldsymbol{\rho})\tilde{\boldsymbol{U}}(\boldsymbol{\delta},\boldsymbol{\rho}), \tag{43}$$

where a transposed conjugate vector (or matrix) is denoted with a tilde. On the other hand, the kinetic energy (T) for $\boldsymbol{\delta}$ is given as

$$2T(\boldsymbol{\delta}) = \tilde{\dot{\boldsymbol{S}}}(\boldsymbol{\delta})\boldsymbol{M}_S\dot{\boldsymbol{S}}(\boldsymbol{\delta}), \tag{44}$$

where $\dot{\boldsymbol{S}}$ is the time derivative of $\boldsymbol{S}$ and $\boldsymbol{M}_S$ is the diagonal mass matrix whose elements are masses of constituent atoms of a unit cell.

The dynamical matrix $\boldsymbol{D}_S(\boldsymbol{\delta})$ for $\boldsymbol{\delta}$ is then derived as

$$\boldsymbol{D}_S(\boldsymbol{\delta}) = \boldsymbol{M}_S{}^{-1/2}\boldsymbol{F}_S(\boldsymbol{\delta})\boldsymbol{M}_S{}^{-1/2}, \tag{45}$$

where $\boldsymbol{M}_S{}^{-1/2}$ is a diagonal matrix whose elements are square root of reciprocal masses of atoms.

Diagonalization. A general method for diagonalizing hermitian matrices $\boldsymbol{D}_S(\boldsymbol{\delta})$ has been described,[20] although dynamical matrices of polyethylene are real if the symmetry-coordinates of Eq. (36) are used. After diagonalizing $\boldsymbol{D}_S(\boldsymbol{\delta})$,

$$\tilde{\boldsymbol{L}}_S(\boldsymbol{\delta})\boldsymbol{D}_S(\boldsymbol{\delta})\boldsymbol{L}_S(\boldsymbol{\delta}) = \boldsymbol{\Lambda}(\boldsymbol{\delta}) \tag{46}$$

the diagonal frequency-parameter matrix $\boldsymbol{\Lambda}(\boldsymbol{\delta})$ is obtained whose elements are squared angular frequencies. With the unitary eigenvector matrix $\boldsymbol{L}_S(\boldsymbol{\delta})$, the transformation from the $\boldsymbol{S}(\boldsymbol{\delta})$ vector to the normal coordinate vector $\boldsymbol{Q}(\boldsymbol{\delta})$ is given as

$$\boldsymbol{S}(\boldsymbol{\delta}) = \boldsymbol{M}_S{}^{-1/2}\boldsymbol{L}_S(\boldsymbol{\delta})\boldsymbol{Q}(\boldsymbol{\delta}) \tag{47}$$

and, from Eq. (35), the Cartesian coordinate vector $\boldsymbol{X}(\boldsymbol{\rho})$ of the $\boldsymbol{\rho}$th atom is finally given as

$$\boldsymbol{X}(\boldsymbol{\rho}) = \sum_{\delta}\tilde{\boldsymbol{U}}(\boldsymbol{\delta}, \boldsymbol{\rho})\boldsymbol{M}_S{}^{-1/2}\boldsymbol{L}_S(\boldsymbol{\delta})\boldsymbol{Q}(\boldsymbol{\delta}). \tag{48}$$

In actual numerical treatments for a number of phase-difference vectors in the first Brillouin zone, computation time is consumed primarily in diagonalization of dynamical matrices and careful procedure is desirable for reducing computation time.

Molecular Crystals. In three-dimensional molecular crystals, high-frequency intramolecular vibrations are primarily due to intramolecualr force field and weak intermolecular interactions give rise to small band-splitting. Usually the force field of a free molecule is brought over to the crystalline state and the potential energy matrix ($\boldsymbol{F}_R$) of a molecular crystal is expressed as a sum of the intramolecular part ($\boldsymbol{F}_R{}^M$) and the intermolecular part ($\boldsymbol{F}_R{}^C$),

$$\boldsymbol{F}_R = \boldsymbol{F}_R{}^M + \boldsymbol{F}_R{}^C. \tag{49}$$

From Eqs. (43), (45), and (49), it is readily seen that the dynamical matrix $\boldsymbol{D}_S(\boldsymbol{\delta})$ is now expressed as a sum of the intramolecular part $\boldsymbol{D}_S{}^M(\boldsymbol{\delta})$ and intermolecular part $\boldsymbol{D}_S{}^C(\boldsymbol{\delta})$. If, however, each molecule of the crystal is brought inside a unit cell, the intramolecular force field of a molecule can be expressed with Cartesian coordinates of a common index vector and accordingly $\boldsymbol{D}_S{}^M$ becomes independent of $\boldsymbol{\delta}$,

$$\boldsymbol{D}_S(\boldsymbol{\delta}) = \boldsymbol{D}_S{}^M + \boldsymbol{D}_S{}^C(\boldsymbol{\delta}). \tag{50}$$

Then it is advisable to diagonalize $\boldsymbol{D}_S(\boldsymbol{\delta})$ in two steps, since large off-diagonal elements of $\boldsymbol{D}_S(\boldsymbol{\delta})$ are primarily from the intramolecular part. The first step is to diagonalize $\boldsymbol{D}_S{}^M$ that is independent of $\boldsymbol{\delta}$,

$$\tilde{\boldsymbol{L}}_S{}^M\boldsymbol{D}_S{}^M\boldsymbol{L}_S{}^M = \boldsymbol{\Lambda}^M \text{ (diagonal)}. \tag{51}$$

Accordingly, the dynamical matrix $\boldsymbol{D}_S(\boldsymbol{\delta})$ is now transformed into

$$\tilde{\boldsymbol{L}}_S{}^M\boldsymbol{D}_S(\boldsymbol{\delta})\boldsymbol{L}_S{}^M = \boldsymbol{\Lambda}^M + \tilde{\boldsymbol{L}}_S{}^M\boldsymbol{D}_S{}^C(\boldsymbol{\delta})\boldsymbol{L}_S{}^M \tag{52}$$

and the diagonalization of the second step is carried out to yield the frequency parameter matrix and eigenvector matrix,

$$\boldsymbol{\Lambda}(\boldsymbol{\delta}) = \tilde{\boldsymbol{L}}_S{}^C(\boldsymbol{\delta})[\boldsymbol{\Lambda}^M + \tilde{\boldsymbol{L}}_S{}^M\boldsymbol{D}_S{}^C(\boldsymbol{\delta})\boldsymbol{L}_S{}^M]\boldsymbol{L}_S{}^C(\boldsymbol{\delta}) \tag{53}$$

$$\boldsymbol{L}_S(\boldsymbol{\delta}) = \boldsymbol{L}_S{}^M\boldsymbol{L}_S{}^C(\boldsymbol{\delta}). \tag{54}$$

The off-diagonal elements meeting in the second step are due to the intermolecualr force field and are relatively small so that total computation involved in numerical treatments for many $\boldsymbol{\delta}$ vectors is thus greatly reduced.

Polymer-chain Crystals. For the dynamical matrix $\boldsymbol{D}_S(\boldsymbol{\delta})$ of polymer-chain crystals, the intrachain part $\boldsymbol{D}_S{}^M$ depends upon the phase-difference along the chain axis,

$$\boldsymbol{D}_S(\boldsymbol{\delta}) = \boldsymbol{D}_S{}^M(\delta_c) + \boldsymbol{D}_S{}^C(\delta_a,\delta_b,\delta_c). \tag{55}$$

Accordingly for each chosen value of δ_c, the first step is carried out to diagonalize $\boldsymbol{D}_S{}^M(\delta_c)$ and then the second step is carried out, for many values of δ_a and δ_b, to yield $\boldsymbol{\Lambda}(\boldsymbol{\delta})$ and $\boldsymbol{L}_S(\boldsymbol{\delta})$,

$$\boldsymbol{\Lambda}(\boldsymbol{\delta}) = \tilde{\boldsymbol{L}}_S{}^C(\boldsymbol{\delta})[\boldsymbol{\Lambda}^M(\delta_c) + \tilde{\boldsymbol{L}}_S{}^M(\delta_c)\boldsymbol{D}_S{}^C(\boldsymbol{\delta})\boldsymbol{L}_S{}^M(\delta_c)]\boldsymbol{L}_S{}^C(\boldsymbol{\delta}) \tag{56}$$

$$\boldsymbol{L}_S(\boldsymbol{\delta}) = \boldsymbol{L}_S{}^M(\delta_c)\boldsymbol{L}_S{}^C(\boldsymbol{\delta}). \tag{57}$$

Low Frequency Vibrations. Low frequency crystal vibrations are concerned with low temperature specific heat, neutron-scattering cross sections or mean squared amplitudes of atoms. In treating these properties theoretically, it is required to calculate vibrational frequencies and eigenvectors for a large number of phase-difference vectors. Accordingly, it is highly desirable to develop a useful approximation procedure for treating low frequency vibrations.

For orthorhombic polyethylene, however, a gap of frequency distribution[11] lies at 550—700 cm^{-1} and low-frequency vibrations may approximately

20) T. Miyazawa, K. Fukushima and Y. Ideguchi, *J. Chem. Phys.*, **38**, 2709 (1963).

be treated separately from high-frequency vibrations. Thus, from the eigenvector matrix $\boldsymbol{L}_S{}^M(\delta_c)$ of Eq. (51), columns associated with low-frequency modes are extracted to form a rectangular matrix $\boldsymbol{L}_l{}^M(\delta_c)$ and the corresponding minor matrix $\boldsymbol{\Lambda}_l(\delta_c)$ is extracted from the frequency-parameter matrix $\boldsymbol{\Lambda}^M(\delta_c)$. Then, the dynamical matrix $\boldsymbol{D}_l(\boldsymbol{\delta})$ for low-frequency modes is approximately obtained by a congruent transformation with $\boldsymbol{L}_l{}^M(\delta_c)$,

$$\boldsymbol{D}_l(\boldsymbol{\delta}) = \boldsymbol{\Lambda}_l(\delta_c) + \tilde{\boldsymbol{L}}_l{}^M(\delta_c)\boldsymbol{D}_S{}^C(\boldsymbol{\delta})\boldsymbol{L}_l{}^M(\delta_c) \tag{58}$$

and the frequency-parameter matrix and eigenvector matrix for low-frequency vibrations are given as

$$\boldsymbol{\Lambda}_l(\boldsymbol{\delta}) = \tilde{\boldsymbol{L}}_l{}^C(\boldsymbol{\delta})\boldsymbol{D}_l(\boldsymbol{\delta})\boldsymbol{L}_l{}^C(\boldsymbol{\delta}) \tag{59}$$

$$\boldsymbol{L}_l(\boldsymbol{\delta}) = \boldsymbol{L}_l{}^M(\delta_c)\boldsymbol{L}_l{}^C(\boldsymbol{\delta}). \tag{60}$$

For orthorhombic polyethylene, the order of dynamical matrices is reduced from 36 [$\boldsymbol{D}_S$] to 8 [$\boldsymbol{D}_l$] and therefore the approximate procedure stated above saves a lot of computation time, allowing vibration treatments over a greater number of phase-difference vectors in the first Brillouin zone.

Conclusion

Irreducible representations of $\boldsymbol{k}$ groups of the space group *Pnam* and degeneracies of crystal vibrations due to space symmetry and time-reversal symmetry were treated in the present study. Symmetry coordinates of carbon atoms of orthorhombic polyethylene were constructed from translational-symmetry coordinates with nonintegral index vectors. Similar coordinates may readily be constructed for sets of hydrogen atoms. Furthermore, general matrix methods were worked out for treating molecular crystals and chain-polymer crystals and for approximately treating low frequency lattice vibrations.

These methods are applicable for treating frequency distributions and specific heat, mean squared thermal amplitudes of scattering atoms (temperature factor for X ray scattering), and scattering cross sections (elastic and inelastic) of thermal neutrons. Symmetry considerations are indispensable for treating dispersion curves of optical and acoustic branches of crystal vibrations. These studies on orthorhombic polyethylene will be presented in forthcoming papers.

Effect of γ-Preirradiation on Catalytic Activity of Nickel Oxide for the Oxidation of Carbon Monoxide

Yoshisato TEZUKA and Toyosaburo TAKEUCHI

Faculty of Literature and Science, Toyama Universiy, Gofuku, Toyama

(Received July 1, 1969)

The change in NiO catalytic activity upon the variation in the irradiation of γ-rays in the presence of O_2 gas was studied. Activities were determined for the reaction of CO with NiO and for the oxidation reaction of CO on NiO. The results showed a decrease in the CO-NiO reaction rate with an increase in the irradiation of NiO, particularly in the absence of oxygen; if the irradiation was more than 7×10^7R, the reaction rate increased as both the irradiation in the presence of oxygen and the oxygen partial pressure increased. The activity change in NiO was explained by assuming the migration of the specially-active oxygen into the oxide bulk by means of the irradiation of γ-rays.

Various types of adsorbed oxygen have been proposed as the reaction intermedia of the catalytic oxidation caused by the metallic oxide. The correlation between the type of oxygen and its reactivity does not, however, bear this out clearly since the metal oxide catalytic activity is greatly affected by: (1) the treatment of the metal oxide, (2) the impurity present in the oxide, and (3) the reactant employed.

Several studies[1,2] published recently on the catalytic effects of the irradiation of γ-rays on nickel oxide have concluded that the activity of the oxide is greatly influenced by the irradiation of γ-rays; it sometimes increases and sometimes decreases. This fact indicates that the behavior of the oxygen of the metal oxide upon the irradiation is very complicated. Many areas remain unexplored concerning the behavior of the oxygen of the metal oxide

1) T. Yamashina and T. Nagamatsuya, This Bulletin, **38**, 507 (1965).

2) T. Yamashina and M. Sano, *ibid.*, **38**, 1801 (1965).

which had been subjected to the irradiation of γ-rays and the role of oxygen in catalytic reactions.

This study concerns the reactivity of the oxygen of the nickel oxide, which was irradiated with various doses of γ-rays. The reactivity was observed through the reaction between carbon monoxide and the oxygen of the oxide, and the catalytic reaction between carbon monoxide and oxygen gas.

Experimental

For each test run, 0.5g of nickel oxide was used. The nickel oxide used was obtained by igniting extra-pure nickel nitrate furnished by the Wako Chemicals Co. in an atmosphere of air at 550°C for 24 hr. The irradiation of the oxide was made in a vessel with a breaker joint, as is shown in Fig. 1. Two kinds of samples were prepared. One was the oxide which was evacuated under 10^{-6} mmHg at 300°C for 4 hr and then sealed. The other was prepared in the same manner, but after evacuation a certain amount of oxygen was admitted. The tube was pressured to 7 or 18 cmHg with oxygen. Both tubes were sealed and irradiated by ^{60}Co γ-rays. The dose rate was 5.84×10^5 R/hr. After irradiation, the samples were drawn out and kept at room temperature for about one week. The tube was then connected to the apparatus.

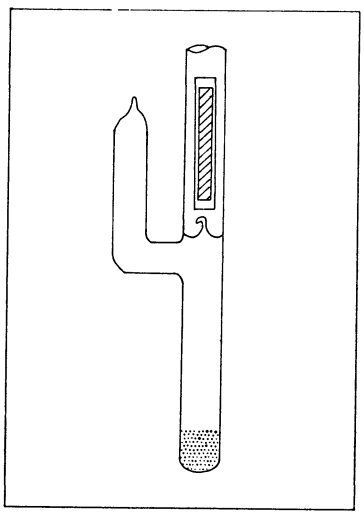

Fig. 1. The reaction vessel.

The reaction was carried out by the statistical method. The volume of the reaction vessel, including the manometer, was about 150 m*l*. In order to freeze the carbon dioxide produced by the reaction, a U-tube cooled by liquid oxygen was used to connect the reaction vessel and the manometer. Apiezon oil was used to measure the pressure decreases resulting from the reaction. Prior to use, the samples were evacuated again for about 2 hr at a temperature of 300°C to a pressure of 10^{-5} mmHg; then the temperature was lowered to the reaction temperature of 131° or 251°C. For the reaction between carbon monoxide and nickel oxide, carbon monoxide (12 cm oil) was introduced into the vessel. For the reaction between carbon monoxide and oxygen on nickel oxide, the 12 cm oil of a mixture of cardon monoxide and oxygen (mol ratio 2 : 1) was introduced into the vessel.

The oxygen used was of a commercial grade. It was purified by passing it through a trap cooled by liquid nitrogen. The carbon monoxide (purity: 99.9%) was supplied by the Takachiho Chemicals Co.

The surface areas were measured by the B.E.T. method, using ethylene at −183°C, as had been by Wooten and Brown,[3] after the test of the activity was finished.

The structure of nickel oxide was examined by a X-ray diffractometer (Rigaku Denki, Model D-3F) operated at 30 kv and 40 mA and adopting the Debye-Scherrer method.

Results

No change due to the γ-irradiation was observed in the oxide structure by means of X-ray diffraction.

The relation between the radiation dose and the B.E.T. surface area is shown in Table 1.

TABLE 1

Radiation Dose (R)	0	1.04×10^8	4.6×10^8
Surface area (m^2/g)	8.9	8.9	8.8

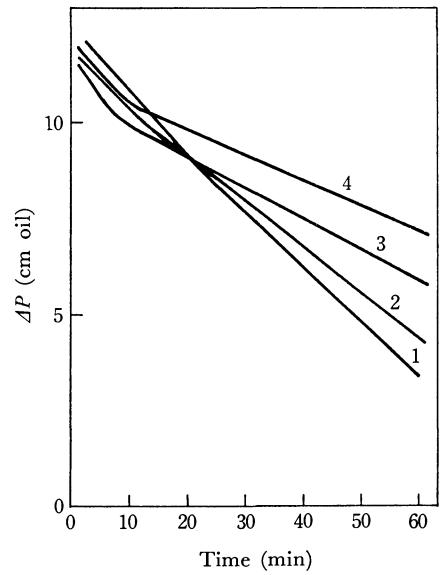

Fig. 2. The decrease of pressure of carbon monoxide on nickel oxide irradiated with γ-rays in the absence of oxygen gas.
1, no irradiation
2, 5×10^6 R
3, 7.1×10^7 R
4, 4.6×10^8 R

3) L. A. Wooten and C. Brown, *J. Am. Chem. Soc.*, **65**, 113 (1943).

The results show that irradiation did not affect the B.E.T. surface area.

In the reaction of nickel oxide with carbon monoxide, the time-pressure relationship was approximately linear when the radiation dose was small. However, a curved line was given when the radiation dose was greater than 5×10^7 R and when the radiation was carried out in a vacuum. Several results are shown in Fig. 2. The rate of reaction in the latter case was determined from the slope of the linear part of the curve at the initiation of the reaction. Figure 3 shows the dependency of the radiation dose on the reaction rate. The figure shows that the irradiated oxide reaction rate is greater in the presence of oxygen than in the absence of oxygen. Also, in both cases the rate decreases with an increase in the radiation dose.

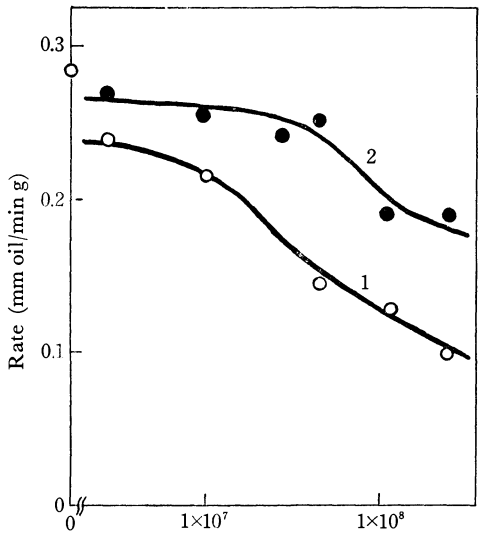

Fig. 3. The dependency of the reaction rate of carbon monoxide and nickel oxide on dose of γ-rays.
1, in the absence of oxygen gas
2, in the presence of oxygen gas (7 cmHg)

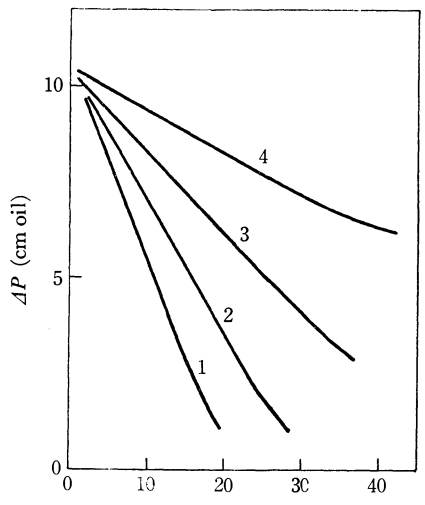

Fig. 4. The decrease of carbon monoxide and oxygen gas on nickel oxide irradiated with γ-rays in the absence of oxygen gas.
1, no irradiation
2, 5×10^6 R
3, 1.04×10^8 R
4, 4.6×10^8 R

In the oxidation of carbon monoxide on nickel oxide, the time-pressure relationship was given approximately as a straight line. Figure 4 shows the correlation. The rate of reaction in Fig. 5 was determined from the slope of the line. Figure 5 indicates that the reaction rate on nickel oxide irradiated in the absence of oxygen gas decreases with an increase in the radiation dose, but the rate on nickel oxide irradiated in the presence of oxygen increases upon a radiation of more than 7×10^7 R and with increases in the pressure of the oxygen environment.

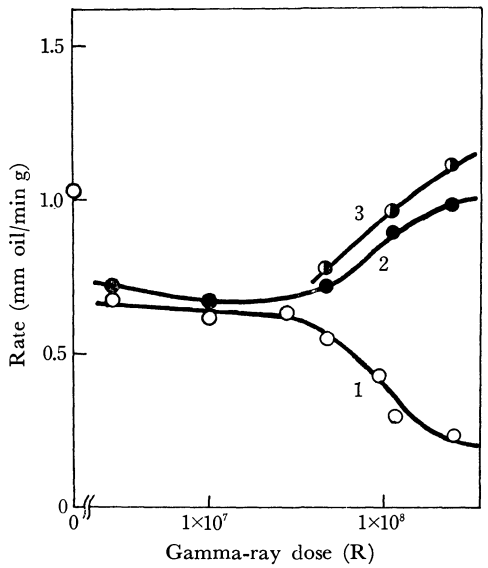

Fig. 5. The dependency of the reaction rate of carbon monoxide and oxygen on dose of γ-rays.
1, in the absence of oxygen gas
2, in the presence of oxygen gas (7 cmHg)
3, in the presence of oxygen gas (18 cmHg)

Discussion

A remarkable change was found in the catalytic reaction rate of carbon monoxide with oxygen gas on nickel oxide irradiated with γ-rays of more than 7×10^7 R in the presence (A-1) and in the absence (A-2) of oxygen. The dose which changed the rate is very similar to that reported by Yamashina[2] who studied the decomposition of hydrogen peroxide on nickel oxide irradiated in an atmosphere

of air.

The rates of the reaction of nickel oxide with carbon monoxide irradiated both in the presence (B-1) and in the absence (B-2) of oxygen gas decrease as the radiation dose increases. The decrease is smaller, however, when the oxide is irradiated in the presence of the oxygen. This fact would suggest that the active oxygen on the surface becomes inactive or migrates into the interior upon irradiation. It was found that the irradiation of γ-rays promotes the migration of oxygen into the bulk of nickel oxide.[4]

Several types of oxygen have been proposed as the intermedium of the reaction on catalytic oxidation.[5-9] The oxygen which is active in the catalytic oxidation and in the migration into the bulk of the metal oxide has been considered to be charged as O^-.[10] The vacancy of the site caused by the migration of the adsorbed oxygen into the bulk during the irradiation would be replaced by another oxygen. The amount of oxygen on the surface would then be kept constant if the oxygen exists in the gaseous phase because the replacement of the adsorbed oxygen is enchanced. The almost constant reaction rate on the oxide irradiated with doses up to 7×10^7 R in the presence of oxygen (A-1 and B-1) can be explained in terms of the replacement of the adsorbed oxygen. The great rate decrease in B-1 in the area of doses of more than 7×10^7 R can be explained by assuming that the bond energy of the adsorbed oxygen changes due to the variation in the electronic property[11] of the surface, which is itself affected by the concentration of the migrated oxygen. In this study, the oxide was evacuated under 10^{-5} mmHg before the admission of carbon monoxide. The evacuation leads to a loss of the adsorbed oxygen. The amount of loss is affected by the radiation dose because the change in the radiation dose alters the concentration of oxygen in the bulk. We may expect a remarkable decrease in the bond energy of the adsorbed oxygen when the concentration of the oxygen in the bulk approaches to saturation. In consequence, the adsorbed oxygen in such a condition would desorb more readily by evacuation. Thus, the amount of oxygen remaining on the surface would be smaller. The decrease in adsorbed oxygen results in a decrease in the reaction rate, as was found when A-2 was irradiated with a dose of more than 7×10^7 R.

The small decrease found in the rates of the A-1 and B-1 reaction on the oxide irradiated with less than 7×10^7 R in the presence of oxygen can be explained similarly in terms of a decrease in the amount of adsorbed oxygen with an increase in the inner oxygen. The marked in the rate in the A-1 catalytic reaction on the oxide irradiated with more than 7×10^7 R in the presence of oxygen can not, however, be explained on only the simple assumption of the marked decrease in the amount of the adsorbed oxygen, as was done with the B-1 reaction. We assume that the irradiation of of γ-rays of more than 7×10^7 R increases the fraction of the site of active oxygen which can be desorbed readily by the evacuation; such sites would be occupied by the oxygen admitted together with the carbon monoxide.

We appreciate the help of the Japan Atomic Energy Institute in performing the irradiation tests.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 3451—3454 (1969)

Studies of the Mixed Chromium(III) Complexes Containing Ethylenediamine-*N,N'*-diacetic Acid*[1]

Yuki FUJII and Katsumi YAMAMOTO

Department of Chemistry, Faculty of Science, Ibaraki University, Mito, Ibaraki

(Received February, 5, 1969)

Three new mixed chromium(III) complexes containing ethylenediamine-*N,'N*-diacetic acid (EDDA) and amino acid, [Cr(edda)(L)] (L=anion of glycine, α-alanine and β-alanine), were prepared from $[Cr_2(OH)_2(edda)_2]\cdot 6H_2O$. On the basis of their chemical analyses and the visible and infrared absorption spectra, the geometrical structure of the three mixed ligand complexes was estimated to be the facial form with respect to the coordinated three nitrogen atoms, where the configuration of the coordinated edda was inferred to take the β-form (*cis* with respect to the coordinated oxygen atoms of edda). The new mixed ligand complex containing the glycine anion, $[Cr(ox)(gly)(en)]\cdot H_2O$, was also prepared from *cis*-$[Cr(ox)(H_2O)_2(en)]Br$, and its geometry was discussed in the connection with its visible absorption spectrum.

In a previous paper[1] the preparation of the chromium(III) complexes containing ethylenediamine-*N,N'*-diacetic acid (EDDA) was reported. The configuration of the coordinated edda was, however, not established on the basis of their visible absorption spectra, because it was very difficult to distinguish whether the configuration of edda takes the α-form or the β-form on the basis of only their visible absorption spectra in general.

However, if it is possible to prepare the mixed ligand chromium(III) complexes containing edda and the anion of amino acid, their visible absorption spectra will be very useful in identifying the configuration of edda. Thus, if the spectra of the mixed ligand complexes show the pattern of the spectra of a facial-form (N_3O_3)-type complex, the configuration of edda can be determined to be the β-form. Therefore, we tried to prepare the mixed ligand complexes of the [Cr(edda)(L)]*[2] type (L= glycine, α-alanine, and β-alanine), investigating the geometry of these complexes on the basis of their visible absorption spectra.

Since the spectral data of (N_3O_3)-type chromium-(III) complexes are scanty, we also tried to prepare a mixed-ligand complex, $[Cr(ox)(gly)(en)]\cdot H_2O$, to provide additional spectral information.

Experimental

Preparation. *1) Ethylenediamine-N,N'-diacetatoglycinatochromium(III) Dihydrate,* [Cr(edda)(gly)]·$2H_2O$ (I). All three mixed-ligand complexes containing edda were derived from bis-(ethylenediamine-*N,N'*-diacetato)-μ-dihydroxodichromium(III) hexahydrate, $[Cr_2(OH)_2(edda)_2]\cdot 6H_2O$ (i).[1] A 2.8 g portion (0.005 mol) of the (i) complex as a starting material was suspended in 15 m*l* of water and warmed on the water bath. Then, 4.5 g (0.06 mol) of glycine were added and the mixture was maintained at 90°C for half an hour. When the complex (i) was then gradually dissolved in water, the color of the solution turned from purple to a reddish purple. About 50 m*l* of ethanol were then added, and the glycine thus precipitated was removed by filtration. When the solution was cooled to 0°C, reddish crystals were separated out. They were washed with hot 80% ethanol. Yield, about 2.7 g (81.8%). Found: C, 28.55; H, 5.51; N, 12.18%. Calcd for [Cr(edda)(gly)]·$2H_2O$: C, 28.57; H, 5.41; N, 12.51%.

2) Ethylenediamine-N,N'-diacetato-α-alaninatochromium(III) Dihydrate, [Cr(edda)(α-ala)]·$2H_2O$ (II). A 2.8 g portion (0.005 mol) of the complex i was suspended in 15 m*l* of water, and the resulting mixture was warmed on the water bath. 5.3 g (0.06 mol) of α-alanine were then added, and the mixture was heated to about 90°C. When the color of the solution turned from purple to a reddish purple, about 50 m*l* of ethanol were added. On cooling to 0°C, reddish crystals were separated out. The crystals were washed with hot 80% ethanol. Yield, about 2.9 g (82.2%). Found: C, 31.09; H, 5.74; N, 12.29%. Calcd for [Cr(edda)(α-ala)]·$2H_2O$: C, 30.85; H, 5.77; N, 12.00%.

3) Ethylenediamine-N,N'-diacetato-β-alaninatochromium(III) Monohydrate, [Cr(edda)(β-ala)]·H_2O (III). This

* Abbreviations: str.=stretching; asym.=antisymmetric; sym.=symmetric; wag.=wagging; bend.=bending.

substance was prepared from the complex i and β-alanine in the manner described above in 2). Reddish crystals were obtained in an 80.0% yield. Found: C, 32.53; H, 5.47; N, 12.65%. Calcd for [Cr(edda)(β-ala)]·H_2O: C, 32.52; H, 5.42; N, 13.21%.

4) Oxalatoglycinatoethylenediaminechromium(III) Monohydrate, [Cr(ox)(gly)(en)]·H_2O (IV). To an aqueous solution of 4.0 g (0.013 mol) of *cis*-oxalatodiaquoethylenediaminechromium(III) bromide,[2] *cis*-[Cr(ox)$(H_2O)_2$(en)]Br, 2.0 g (0.073 mol) of glycine were added, the solution was kept at about 60°C for five minutes. The solution was then cooled to 0°C, whereby a small amount of impurity was deposited out. After the impurity had been filtrated off, 1 g of glycine was added to the filtrate heated to 80°C. The pH of the solution was adjusted to 5.5 by dilute aqueous ammonia, and the resulting solution was allowed to stand for 3 days at room temperature. A pink powder was thus separated out and washed with hot water. Yield, about 2.2 g (60.0%). Found: C, 25.10; H, 4.74; N, 14.56%. Calcd for [Cr(ox)(gly)(en)]·H_2O: C, 25.49; H, 4.84; N, 14.39%.

Measurements. The visible absorption spectra of the complexes obtained were recorded on a EPS-3 Hitachi recording spectrometer at room temperature. Since the complex I, II and III all decompose to yield the complex i in an aqueous solution at room temperature, the spectra were measured by using dimethylsulfoxide (the complex I and II) or 50% dimethylsulfoxide (the complex III). Water was used as the solvent in the spectral measurement of the complex IV. The IR spectra were taken on potassium bromide disks using a Hitachi EPI-S2 spectrometer.

Results and Discussion

IR Spectra. The infrared absorption spectra were measured to confirm whether the carboxylate groups were coordinated or not. Since all the spectra of the complexes studied showed asym. νCOO-Cr bands in the range from 1630 to 1670 cm^{-1}, as is shown in Table 1, and since there was no band due to the free carboxylate or free carboxylic acid group, it is clear that all the carboxylate groups are coordinated to the chromium(III) ion.[3-5]

In the case of the complex III, two bands assigned to the asym. νCOO-Cr band were observed, these bands can be explained as follows. Since β-alanine may form a six-membered ring with the chromium(III) ion in the complex III and since the steric strain is thought to be larger in the six-membered ring than in the five-membered ring, the band assigned to the νCOO-Cr of β-alanine will shift to lower evergy sites compared with the band assigned to the νCOO-Cr of acetate groups.

Electronic Absorption Spectra. The visible absorption spectra of the complexes are shown in Figs. 1 and 2. The numerical values of the absorption maxima are summarized in Table 2, together with those of related compounds.[5-10]

It is found that the first bands of the complex I, II, and III have the only one peak located at sites of higher energy than that of the fac-(N_3O_3) type chromium(III) complexes, $[Cr(L)_3]$(L=anions of glycine, α-alanine, α-amynobutylic acid and *l*-leucine).

On the other hand, the four cobalt(III) complexes with amino acids, fac-[Co$(gly)_3$]·H_2O, fac-[Co$(\alpha\text{-ala})_3$], mer-[Co(edda)(gly)]·$2H_2O$ and mer-[Co(edda)(α-ala)]·$2H_2O$, have been reported to show the first bands at 57.7×10^{13}/sec, 58.0×10^{13}/sec, 55.3×10^{13}/sec, and 55.3×10^{13}/sec respectively. Since the interpretations of the absorption peaks of cobalt(III) complexes are thought to hold also for the discussions of those of chromium(III)

complexes under these circumstances,[11] values of 53.0×10^{13}/sec and 53.5×10^{13}/sec may be anticipated as the peaks of the mer-form complexes of [Cr(edda)(L)] (L=glysine and α-alanine) on the basis of the values of the absorption peaks on fac-[Cr(gly)$_3$]·3H$_2$O and fac-[Cr(α-ala)$_3$]·2H$_2$O.

11) H. Yamatera, this Bulletin, **31**, 95 (1956).

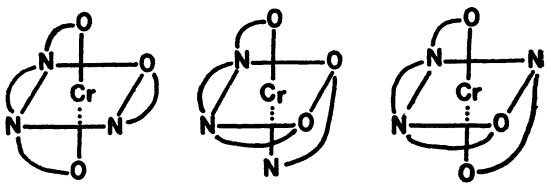

Fig. 3. Possible structures of [Cr(edda)(amino acid)].

Since the peaks of the I, II, and III complexes appeared at about 59.5×10^{13}/sec and since these values are too high to assign the configuration of the complexes to the mer-form one, it may be suggested that the configuration of the complexes [Cr(edda)(L)](L=anion of glycine, α-alanine and β-alanine) may be fac-form with respect to the coordinated three nitrogen atoms. Though there are three possible geometrical structures for [Cr(edda)(L)], only one structure is possible as a fac-form one. Therefore the structure (b) in Fig. 3 is the most probable as the structure of the complexes I, II, and III. From these observations, it can be concluded that the configuration of edda may take the β-form (*cis* with respect to the coordinated carboxylate oxygen atoms of edda).

Since the complex IV shows the first band at 57.8×10^{13}/sec, and since this band seems to be constructed from only one peak, the configuration of the complex IV probably takes the fac-form with respect to the coordinated three nitrogen atoms.

When plotting the locations of the first band (in sec^{-1}) of the chromium(III) complexes containing oxalic acid and/or ethylenediamine[2,12] against the number of the nitrogen atoms participating in the coordination bond formation, we can obtain

the linear relation shown in Fig. 4.[13] From this linear relation, a value of *ca.* 59.0×10^{13}/sec is obtained as the maximum of the first band of the (N_3O_3)-type chromium(III) complex. On the other hand, it has been reported that the amino acid complexes with the chromium(III) ion, which have been identified as (N_3O_3)-type complexes,[6-8] show the first band between 55.0 and 58.0×10^{13}/sec. Therefore, it may be reasonable to conclude that the mixed chromium(III) complex containing oxalic acid, glycine, and ethylenediamine, [Cr(ox)(gly)(en)], shows the first band at about 58.0×10^{13}/sec, which is intermediate between the 55.0×10^{13}/sec of the tris-glycine complex and the 59.0×10^{13}/sec of the oxalato-ethylenediamine complex.

The authors wish to express their deep thanks to Professor S. Ito and his coworkers of Tohoku University for their kind help in the elemental analyses. One of the authors (Y.F.) also gratefully acknowledges the encouragement of Professor R. Tsuchiya and Professor E. Kyuno, Kanazawa University.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 3454—3458 (1969)

Adsorption of *N'*-(2-Hydroxyethyl)-ethylenediamine-*N,N,N'*-triacetic Acid on the Hydrogen Form of Resin

Zenzi HAGIWARA and Hideo ŌKI

Faculty of Engineering, Tohoku University, Sendai

(Received February 24, 1969)

The adsorption of HEDTA (H_3Ch) on the hydrogen form of Dowex 50W, X-8, 100—200 mesh, has been studied as a function of the concentration of H_3Ch in the aqueous phase. The experiments were performed by means of either the column or a combination of the column and batch methods, with the latter being employed for the adsorption of HEDTA on the resin in equilibrium with dilute solutions. In solutions up to approximately 0.07 mol/*l*, such as H_3Ch, the experimental data are consistent with the Langmuir equation expressed by: $[H_3Ch]/(\overline{Ch}_T/E)=1/Bk+[H_3Ch]/B$. The adsorbed amount is represented in the term $\overline{Ch}_T/E$, where $\overline{Ch}_T$ is the total amount of cationic species of HEDTA on the resin, and E, the exchange capacity of resin. A good straight line is obtained with $B=0.571$ and $k=0.420$. The results show that, because of a high concentration of hydrogen ion inside the resin, the adsorbed HEDTA is present mainly in the H_5Ch^{2+} species and partly in the H_4Ch^{+} species.

Due to the stable chelate formation of polyamino acids with metal ions, such buffered solutions as ethylenediaminetetraacetic acid (EDTA) and *N'*-(2-hydroxyethyl)ethlenediamine-*N,N,N'*-triacetic acid (hereafter abbreviated as HEDTA and H_3Ch)[1,2] were used as the eluants for the ion-exchange separation of the rare-earth series. For example, various compositions of HEDTA were employed for isolating the above series by ion exchange. When the rare earth is eluted with the HEDTA eluant with a closed composition to $(NH_4)_2HCh$ and with a hydrogen-retaining bed, a chelate

band[3] corresponding to H_5Ch^{2+} in the resin phase is steadily formed between the rare earth and hydrogen bands; this band grows with the progress of the elution distance of the rare-earth band. The formation of the chelate band[4] during elution was investigated under several variables, such as the concentration and composition of the eluant, the crosslinkage of the cation exchanger and the temperature. The results show that the previously-proposed mechanism for the chelate band formation was only applicable within a narrow range of elution conditions and that it is difficult to explain all the phenomena observed in the resin in terms of this mechanism alone. Thus, the present authors have arrived at the opinion that the research into the adsorption of HEDTA on the hydrogen form of resin should be extended to high concentrations of H_3Ch.

Generally, polyamino acid molecules have some additional sites available for protonation. For example, the existence[5] of the protonated species, H_5Y^+ and H_6Y^{2+}, in strong acid solutions of EDTA (H_4Y) was confirmed by Olson and Margerum. The HEDTA molecule with a structure analogous to EDTA would also have the protonate forms, H_4Ch^+ and H_5Ch^{2+}, in strongly acidic solutions. The presence of the above protonated species can easily be predicted in the hydrogen form of resin, because of the extremely high concentration of hydrogen ions inside the resin matrix (approximately $[H^+]=6$—7 mol/l adsorbed solvent). Matorina[6-8] investigated the ion-exchange equilibrium of DTPA (diethylenetriaminepentaacetic acid; H_5A) in combination with a polystyrene type of resin (KU-2) and confirmed the presence of protonated species in the resin due to the reaction: $H_5A+\overline{2H}^+ \rightleftarrows \overline{H_7A}^{2+}$. (Here the superscript barred quantities refer to the resin phase of the indicated species.)

The main object of this study is to investigate the adsorption of HEDTA species on the resin as a function of the concentration of H_3Ch in the aqueous phase, and to clarify the adsorption character.

Experimental

Using Dowex 50W, X-8, 100—200 mesh, as the cation exchanger and an analytical grade of HEDTA, the adsorption experiments of HEDTA on the resin were performed at 25°C by the following three methods.

Column Method-I. This procedure was applied for the experimental series corresponding to Exp. No. AE-1 to AE-9. With a flow of 0.26 cm/min, the HEDTA eluant buffered with ammonium hydroxide was passed through the top of a Pyrex column involving a hydrogen form of resin. The tail of the exchange column was connected in series with small appendages (exchange capacity=20—30 meq. per column) for the analysis of HEDTA species in the resin phase. With the progress in elution, the formation of a chelate band due to the adsorption of HEDTA on the hydrogen form of resin was seen between the eluant and hydrogen bands. After the elution system had arrived at a steady state, the HEDTA eluate from the chelate band was collected into small fractions and analyzed. The experimental conditions used are listed in detail in Table 1, in which the $\widetilde{Ch}_T$ and $\widetilde{NH}_{4T}$ symbols indicate the total concentrations of the anionic species of HEDTA and ammonium respectively in the eluant; the column dimensions are also given.

Column Method-II. This method was used for Exp. No. AE-1′ to AE-5′. Different concentrations of HEDTA solutions were passed through small exchange columns (exchange capacity=34 meq. per column) at a flow rate of 0.1 cm/min. After passing 4 to 5 l of a HEDTA solution for the attainment of equilibrium, the resin phase was separated from the aqueous phase and analyzed (Table 2).

Combination of Column and Batch Methods. This method was used for Exp. No. AE-10 to AE-15. When a dilute solution of HEDTA is used as the load solution for the column method, it takes a long time to reach equilibration. Therefore, the experiment was divided into two steps to save time. According to Column Method-II, a dilute solution of HEDTA corresponding to 15—20 l was passed through the hydrogen form of a resin column with a capacity of 10 meq. After that, the resin in the column was removed and mixed with one liter of the same load solution of HEDTA. The mixture was maintained at 25°C for 3 days in a constant-temperature-bath; then, after equilibration, the two phases were separated for analysis.

Analysis. The ammonium content in the HEDTA load solutions was determined by the usual Kjeldahl method; further, the total HEDTA was determined by chelometry with the standard $ZnCl_2$ and with E.B.T. (Eriochrome Black T) as the indicator. An ammonium chloride-ammonium hydroxide buffer solution with a pH of 10 was used in the titration.

The small appendages attached to the tail of the main exchange column for the analysis of the chelate band were analyzed as follows: after the aqueous solution had been removed by suction, the resin phase was eluted with 2 M NH_4Cl; the total of anionic species of HEDTA in the collected eluate was then determined by chelometry, using the zinc standard solution, according to the previously-described method.

Experimental Results and Discussion

The results obtained by the experimental methods described in the foregoing section are summarized in Table 2, in which the equilibrium compositions of the aqueous phase under different conditions are

Resin used: Dowex 50W, X-8, 100—200 mesh
Temp: 25°C

also given. The mean values of Ch_T in the HEDTA fractions obtained in elution under the steady-state conditions are also listed in Table 2; the deviation of Ch_T is about ±2% from Exp. No. AE-1 to AE-9.

The concentration of H_3Ch in the aqueous phase can be calculated by the following relations:

$$[H_3Ch] = \frac{[H^+]^3}{k_1\cdot k_2\cdot k_3}\,\frac{Ch_T}{\overline{Y}}, \qquad (1)$$

where:

$$\overline{Y} = \frac{[H^+]^3}{k_1\cdot k_2\cdot k_3} + \frac{[H^+]^2}{k_2\cdot k_3} + \frac{[H]^+}{k_3} + 1.$$

The Ch_T symbol represents the concentration of the total anionic species of HDETA, while the $\overline{Y}$ represents the functions of the pH and of the three dissociation constants of HEDTA. Using Eq. (1) and the values of the dissociation con-

stants of HEDTA ($pk_1=2.39$, $pk_2=5.37$, $pk_3=9.93$)[9] the values of H_3Ch are calculated as given in Table 2, in which the adsorbed HEDTA on the resin is expressed in the term $\overline{Ch}_T/E$, where $\overline{Ch}_T$ refers to the amount of the adsorbed HEDTA species in the resin, and E, the exchange capacity of the hydrogen form of resin employed for the equilibrium experiments (one gram of the dried hydrogen form of Dowex 50W, X-8, 100—200 mesh=4.84 meq).

The adsorption of HEDTA species is assumed to take place in the form:

$$H_3Ch + n\overline{H}^+ \rightleftarrows \overline{H_{3+n}Ch^{n+}},$$

where the superscript barred quantities refer to the resin phase of the indicated species. The apparent exchange constant can then be written:

$$K_n' = \frac{[\overline{H_{3+n}Ch^{n+}}]}{[H_3Ch][\overline{H}^+]^n} = \frac{A\frac{\overline{Ch}_T}{E}}{[H_3Ch]\left\{A\left(1-\frac{n\overline{Ch}_T}{E}\right)\right\}^n} \quad (2)$$

where the two symbols $\overline{H_{3+n}Ch^{n+}}$ and $\overline{H}^+$ related to the resin phase are expressed in the concentration unit of moles per unit gram of the hydrogen form of resin, and where the H_3Ch in the aqueous phase is expressed in m moles per liter. Further, the A is the exchange capacity of resin in meq per unit gram of resin on the basis of the hydrogen form.

Taking the logarithm of Eq. (2), one obtains:

$$\log\frac{A\frac{\overline{Ch}_T}{E}}{[H_3Ch]} = \log K_n' + n\log\left\{A\left(1-\frac{n\overline{Ch}_T}{E}\right)\right\}. \quad (3)$$

The plots of $\log(A\overline{Ch}_T/E)/[H_3Ch]$ with respect to

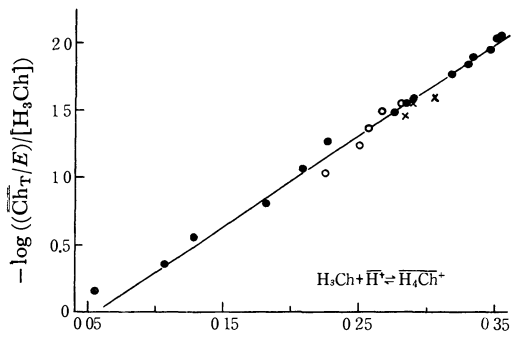

Fig. 1. $\log((\overline{Ch}_T/E)/[H_3Ch])$ *vs.* $\log(1-(\overline{Ch}_T/E))$.

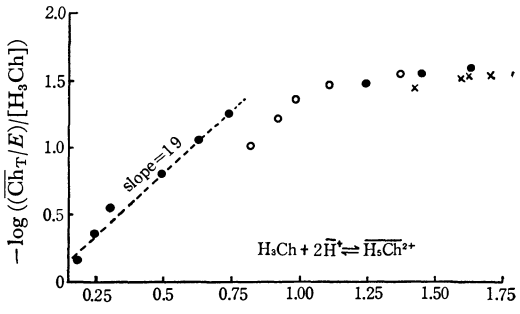

Fig. 2. $\log((\overline{Ch}_T/E)/[H_3Ch])$ *vs.* $\log(1-(2\overline{Ch}_T/E))$. Notations of experimental data are the same as those used in Fig. 1.

$\log A\{1-(n\overline{Ch}_T/E)\}$ should give a straight line whose slope is n and whose intercept is $\log K_n'$. As is shown in Fig. 1, the former values are plotted against the latter on the assumption of $n=1$; a value of 6.8 is thus obtained as the slope of the straight line. This result indicates that the adsorption of HEDTA does not conform to the reaction expressed by $H_3Ch+\overline{H}^+ \rightleftarrows \overline{H_4Ch}^+$. Similar plots appear in Fig. 2, in which n is assumed to be equal to 2. However, the linearity is not maintained over the whole experimental range, and a linear relation with a slope of 1.9 is only obtained in a small range corresponding to Exp. No. AE-10 to AE-15. Therefore, it is obvious that the adsorbed form of H_5Ch^{2+} on the resin exists only in the region of 0.15 to 0.75 as the value of $-\log\{1-(2\overline{Ch}_T/E)\}$ in Fig. 2. Further, the linear relationship is not held at $n=3$. It may be concluded that the experimental data are not explained by Eq. (3).

The adsorption of HEDTA on the resin is considered to take place according to an equation similar to that of Langmuir:

$$\frac{\overline{Ch}_T}{E} = \frac{Bk[H_3Ch]}{1+k[H_3Ch]}, \quad (4)$$

where B is the maximum amount of sorbed HEDTA per unit equivalent of resin at the maximum solubility of H_3Ch, and where k is a constant relating to the adsorption energy. It may be more convenient to utilize a plot which gives a straight line. Thus, Eq. (4) may be rearranged in the form:

$$\frac{[H_3Ch]}{\frac{\overline{Ch}_T}{E}} = \frac{1}{Bk} + \frac{1}{B}[H_3Ch]. \quad (5)$$

A plot of $[H_3Ch]/(\overline{Ch}_T/E)$ against H_3Ch is linear and yields the slope $1/B$ and the intercept $1/Bk$. Since H_3Ch, $\overline{Ch}_T$, and E are known experimentally, a plot of the term of the left side in Eq. (5) *versus* $[H_3Ch]$ leads to a straight line with the value of 1.75 as the slope and that of 4.17 as the intercept ($B=0.571$, $k=0.420$), as may be seen in Fig. 3.

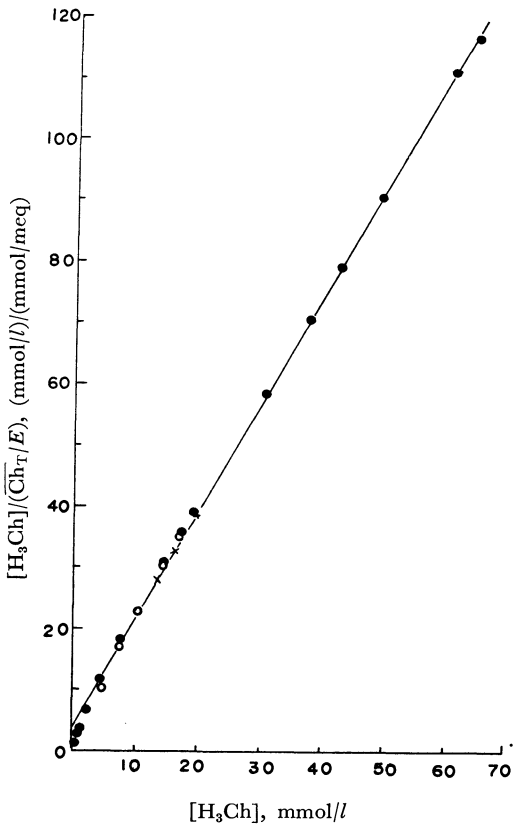

Fig. 3. Langmuir plots for the adsorption of HEDTA on the hydrogen form of resin at 25°C. Notations of experimental data are the same as those used in Fig. 1.

In dilute concentrations less than 20 mmol/*l*, such as H_3Ch, a reciprocal number of B is equal to 2.0. It is obvious from the above fact that the adsorbed state of H_3Ch on the hydrogen form of resin may be attributed to the H_5Ch^{2+} species. In a higher concentration range, the decrease in $1/B$ is principally due to the formation of the H_4Ch^+ species as a minor constituent, in addition to H_5Ch^{2+}: $\overline{H_5Ch^{2+}}+H_3Ch \rightleftarrows 2\overline{H_4Ch^+}$.

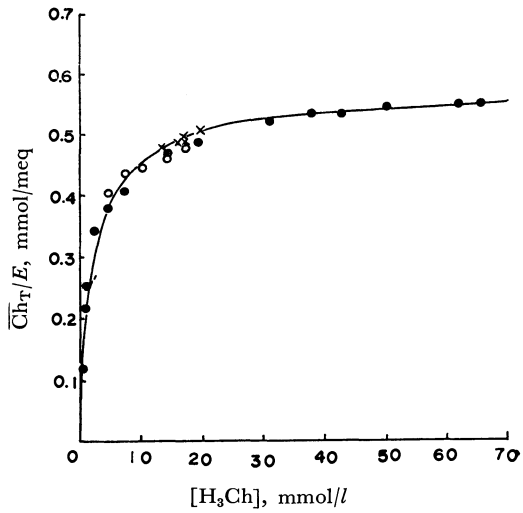

Fig. 4. Adsorption isotherm of HEDTA at 25°C. Notations of experimental data are the same as those used in Fig. 1.

Further, the adsorption isotherm of HEDTA on Dowex 50W, X-8, 100—200 mesh, is shown in Fig. 4, in which the calculated isotherm is represented by a solid line, using Eq. (4), where $B=0.571$ and $k=0.420$. For purposes of comparison, some experimental data concerning the chelate band formed in elutions of the erbium band with a 0.015 M HEDTA buffered solution are plotted in the same figure.

It may be concluded that the sorption of HEDTA on the hydrogen form of resin can be explained well by the Langmuir equation, and that the adsorbed HEDTA species is present mainly in H_5Ch^{2+} and partly in H_4Ch^+ due to a high concentration of hydrogen inside the resin.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 3459—3461 (1969)

Reactions of Tungsten Oxy-dichlorodialkoxides with Cyclopentadiene and Sodium Cyclopentadienide

S. P. ANAND, R. K. MULTANI and B. D. JAIN

Department of Chemistry, University of Delhi, Delhi-7, India

(Received April 8, 1969)

The formation of π-cyclopentadienyl tungsten oxychlorodialkoxides as a result of the interaction between cyclopentadiene or its sodium derivative with tungsten oxy-dichlorodialkoxides, having the general formula $C_5H_5WOCl(OR)_2$, where R is CH_3, C_2H_5, $\begin{matrix}CH_3\\CH_3\end{matrix}\!\!>\!CH$, $CH_3CH_2CH_2$ and $CH_3CH_2CH_2CH_2$ along with the thermal stabilities and infrared spectra of the above products, has been studied and reported.

Though a large number of cyclopentadienyl compounds having alkyl,[1] aryl,[2] acetyl,[3] carbonyl,[4] nitrosyl,[1] and hydride[5] groups linked to the transition metal atoms have been reported, only a few cyclopentadienyl complexes having one or more alkoxy groups attached to the metal atoms in the π-cyclopentadienyl complexes are known, and these include the alkoxy derivatives of cyclopentadienyl compounds of titanium,[6a,b] zirconium,[7] uranium and thorium.[8] Recently we have prepared mono- and di-alkoxy derivatives of π-biscyclopentadienyl tungsten oxydichloride by its interaction with various alcohols with and without the use of triethylamine.[9,10] The present communication deals with the preparation of π-cyclopentadienyl compounds of tungsten oxydichlorodi-alkoxides[11] (by the interaction of cyclopentadiene and its sodium derivative with tungsten oxydichloro dialkoxides in presence of tetrahydrofuran as solvent) and their characterisation.

$$WOCl_4 + 2ROH \xrightarrow{C_6H_6} WOCl_2(OR)_2 + 2HCl$$

$$WOCl_2(OR)_2 + C_5H_6 \xrightarrow{THF} C_5H_5WOCl(OR)_2 + HCl$$

$$WOCl_2(OR)_2 + NaC_5H_5 \xrightarrow{THF} C_5H_5WOCl(OR)_2 + NaCl$$

Where R is CH_3, C_2H_5, i-C_3H_7, n-C_3H_7 and n-C_4H_9. During these studies the removal of both chlorine atoms from $WOCl_2(OR)_2$ by treatment with cyclopentadiene as well as sodium cyclopentadienide has been attempted and even on refluxing the reactants for 24 hr it has been found that only one chlorine atom is replaced by cyclopentadienyl group.

Results and Discussion

Infrared spectra of the compounds taken in KBr, Nujol mull and $CHCl_3$ on Perkin Elmer Cord Model-137 between 4000—650 cm^{-1} is given in Table 1. The absorption at 3050—3100 cm^{-1} and 2910—2950 cm^{-1} in IR spectra of the compounds indicate the presence of C-H stretching frequencies,[12] the absorption bands at 1650—1740 cm^{-1} show the (π-C_5H_5) ring stretching while the C-C bands (asymmetric ring breathing) is evident at 1400—1450 cm^{-1}, which resemble those located in cyclopentadiene itself.[13] In the above IR spectra the vibrational bands observed at 1190 cm^{-1} indicate methoxy, at 1140, 1160 cm^{-1} indicate ethoxy, at 1110, 1170 cm^{-1} indicate isopropoxy while n-butoxy group are evident at 1090, 1120—

1160 cm^{-1} frequencies[14,15] and these are given in Table 1.

The above details of the IR spectra show the presence of alkoxy groups attached to the tungsten atom as is the case with other π-cyclopentadienyl transition metal compounds.[6-9]

The above products which are green in colour, are very sensitive to moisture though stable in inert atmosphere and in vacuum. They are soluble in THF, acetone, dioxane, dimethoxyethane, and miscible in hot dilute acids and alkalies and form a resinous mass when in contact with hot water. These compounds do not sublime under reduced pressure (5 mmHg) and decompose at high temperatures. They change the orange chromic acid (12% H_2SO_4, N-$K_2Cr_2O_7$) to green colouration. The compounds containing lower alkoxide groups have been found to be thermally less stable than those containing higher alkoxide groups. The temperatures at which various compounds undergo decomposition as shown by (i) the change in their colour from green to dirty yellow, and (ii) the decrease in their weights, have been recorded with a Koffler heating block apparatus as given in Table 2.

From infrared spectra and elemental analysis, the following formula is proposed for the compounds, $C_5H_5WOCl(OR)_2$, where R is CH_3 to C_4H_9 groups. The interaction of cyclopentadiene and sodium cyclopentadienide with $WOCl_2(OR)_2$ involves the replacement of electronegative radical (Cl^-) by another electronegative radical ($C_5H_5^-$). It has been further observed that the interaction between $WOCl_2(OR)_2$ and excess of sodium cyclopentadienide does not result in the replacement of more than one chlorine atom by cyclopentadienyl group and this observation is at variance with the results reported by earlier workers.[6-9]

Experimental

All operations were carried out under anhydrous conditions with guard tubes containing silica gel. In some cases, a P_2O_5 and $CaCl_2$ (fused) guard tube had to be used in series with the silica gel tube under reduced pressure, using an oil vacuum pump. Tetrahydrofuran before use was first dried by refluxing with potassium hydroxide and then distilling from lithium aluminium hydride. Aromatic hydrocarbons were first dried with sodium wire and then distilled, whereas the alcohols were dried by usual methods including azeotropic distillation. Tungsten oxytetrachloride obtained as reddish crystals on refluxing WO_3 with thionyl chloride for 16—18 hr and after drying under reduced pressure, was finally sublimed under reduced pressure (5—10 mmHg) at 135—140°C to give scarlet red crystals. Sodium cyclopentadienide was always freshly prepared before use.

Preparation of Tungsten Oxy-dichlorodimethoxide. 70 m*l* methyl alcohol, 40 m*l* dry benzene and 3.42 g (0.1 mol) of tungsten oxytetrachloride were placed in a 500 m*l* round bottom flask fitted with a reflux condenser and a $CaCl_2$ guard tube, and refluxed at 65—70°C over an oil bath for 4—5 hr. From the colourless product so obtained, benzene was removed by distillation under reduced pressure (20—25 mmHg) and the compound finally dried under reduced pressure (15 mmHg).

Higher alkoxy derivatives ranging from ethoxy to *n*-butoxy of tungsten oxytetrachloride were similarly prepared by refluxing with suitable alcohols at requisite temperatures.

Preparation of Cyclopentadienyl Tungsten Oxy-chlorodiethoxide. *1) By Using Cyclopentadiene.* 2 m*l* (0.025 mol) of freshly depolymerized cyclopentadiene was added to a mixture of 3.6 g (0.01 mol) of tungsten oxydiethoxide and 50 m*l* THF, and the contents were refluxed at 100—110°C for 10—12 hr. After cooling, excess of THF was removed by distillation under reduced pressure. The dark greenish product on crystallization from petroleum ether (40—60°C) gave greenish crystals. The compound is soluble in chloroform, THF, carbon disulphide, but insoluble in ether and aromatic hydrocarbons. The compound is extremely sensitive to moisture and readily gets hydrolysed in dilute acids and alkalies. It melts with decomposition at 96—97°C to a dirty yellow mass.

Found: W, 47.1; Cl, 9.0; OC_2H_5, 23.1%. Calcd for $C_5H_5WOCl(OC_2H_5)_2$: W, 47.07; Cl, 9.07; OC_2H_5, 23.05%.

2) By Using Sodium Cyclopentadienide.[16] To freshly prepared sodium cyclopentadienide (0.04 mol; approx. 1 g Na; 3.4 m*l* C_5H_6) in 50 m*l* tetrahydrofuran, was added 7.22 g (0.02 mol) tungsten oxydichlorodiethoxide in 30 m*l* THF in a three necked round bottom flask. The mixture was vigorously stirred while being refluxed for 6—8 hr till the contents turned to greenish products. After filtering the products through a porous plug and a G-4 sinitered glass filter disc, the filtrate was distilled under reduced pressure. The analysis of the product corresponded to the composition of $C_5H_5WOCl(OC_2H_5)_2$. The compound on crystallization from petroleum ether (60—80°C) yielded green crystals and was found to be identical to the product obtained by the reaction of cyclopentadiene with $WOCl_2(OC_2H_5)_2$.

The cyclopentadienyl derivatives of the methoxy and higher alkoxy compounds of tungsten were prepared by a similar procedure and under similar conditions, but at suitable temperatures. Their analytical data is given in Table 3.

Infrared spectra for all the above compounds are recorded in Table 1.

After decomposing the compounds with perchloric acid, tungsten was estimated as 8-hydroxyquinolate, chloride was estimated as silver chloride, and the alkoxy group was determined by chromic acid method.[17,18]

Kinetics of Isotopic Exchange between Acetylacetone-^{14}C and Bisacetylacetonatopalladium(II) in Organic Solvents

Kazuo SAITO and Michihiko TAKAHASHI*1

Department of Chemistry, Faculty of Science, Tohoku University, Katahira-cho, Sendai

(Received May 14, 1969)

Bisacetylacetonatopalladium(II) [Pd acac$_2$] was precipitated crystalline free from excessive acetylacetone (Hacac) by adding the reaction mixture in anisole, benzene or 1,2-dichloroethane to chilled petroleum ether. Its specific counting rate was measured by liquid scintillation technique. The isotopic exchange rate is measurable at 40 to 80°C and the kinetics is expressed by the ordinary two term formula, Rate$=$[Pd acac$_2$](k_1+k_2[Hacac]). The second term corresponds to the reagent path, in which acetylacetone molecule rather than acetylacetonate anion acts as nucleophilic reagent. The first term seems to express a dissociation mechanism rather than the solvent path; the break of Pd–O bond without the aid of nucleophilic attack by the solvent molecule is responsible for determining the exchange rate. The exchange reaction is accelerated by acids, and the acid-catalyzed reaction path operates independent of the reagent path to give the following kinetic formula:

$$\text{Rate} = [\text{complex}](k_1 + k_2[\text{Hacac}] + k_3[\text{acid}])$$

Mechanism of substitution reactions involving square planar complexes of platinum(II) and palladium(II) has been discussed mainly in polar solvents such as water and alcohols.[1] These reactions generally give two term formulae [complex](k_1+k_2[Y]), where Y stands for the nucleophilic reagent which substitutes for one of the coordinated ligands. The rate constants k_1 and k_2 are considered to interpret the "solvent path" and the "reagent path", in which the solvent molecule and the reagent Y operate as nucleophilic reagent to give S_N2 reaction mechanism, respectively.

It seems interesting to examine the isotopic exchange kinetics of square planar complexes in non-polar solvents, since little information is available concerning reaction mechanism in such solvents, and isotopic exchange directly reflects the reactivity of complexes without being bothered by chemical equilibrium. We have examined the solubility of bisacetylacetonatopalladium(II) (henceforth written as [Pd acac$_2$]) and free acetylacetone (Hacac) in a variety of organic solvents and found that the complex is precipitated free from an excess of the ligand by pouring the reaction mixture in anisole, benzene or 1,2-dichloroethane into petroleum ether chilled at −20°C. Hence the experimental technique which was useful for studies with octahedral complexes such as trisacetylacetonatoaluminum(III)[2] and tris-8-quinolinolatogallium(III)[3] is also useful for the present study.

Bisacetylacetonatopalladium(II) is very inert in organic solvents, and the isotopic exchange kinetics is measurable only at elevated temperatures from 40 to 80°C in such solvents with high boiling points as mentioned above.

Experimental

Materials. Acetylacetone-^{14}C was synthesized by the same method as in a previous paper.[2] The specific activity was 0.02 mCi per mg. Bisacetylacetonatopalladium(II) was synthesized and purified by the method given in literature.[4] Extra pure grade anisole was shaken with sodium hydroxide solution, dried with calcium chloride, refluxed with sodium and distilled. The same product was used both for the solvent and the scintillator. The water content of dehydrated product was 1.7×10^{-2} M. Extra pure grade benzene was shaken with concentrated sulfuric acid until the acid layer became almost colorless, then with water, 5% sodium hydroxide solution, and water, dried with calcium chloride, refluxed with sodium and distilled. Extra pure grade 1,2-dichloroethane was shaken with 5% sodium hydroxide solution and water, dried with calcium chloride and phosphorus pentoxide, and distilled immediately before use.

Extra pure grade *m*-toluic acid and *o*-bromobenzoic

acid were sublimed at 90°C at 5 mmHg. Extra pure grade *p*-terphenyl was recrystallized from xylene. Scintillation grade *p*-di-(5-phenyl-2-oxazolyl)-benzene (POPOP) was used without further purification. Petroleum ether was of guaranteed grade and used without further purification.

Experimental Procedure. Weighed amount of the complex (60 to 250 mg) was dissolved in 10 m*l* of the solvent, and the ligand (10 to 150 mg) (both of the order of 10^{-2} M) added at room temperature. The amount of added reagents was known from the difference in weight of the reaction mixture before and after the addition. Other reagents such as acid and water were added to the solvent in advance, whenever necessary. The reaction mixture was then placed in a thermostat at 40 to 80°C, and aliquots (of the order of 1 m*l*) were withdrawn at appropriate intervals (several hours) and poured into chilled petroleum ether (−20°C) (20 m*l*) in order to stop the reaction. Pure [Pd acac$_2$] was separated crystalline instantaneously free from an excess of the ligand. The precipitate was swiftly filtered off with filter paper, washed with petroleum ether, dried at 60 to 70°C, and submitted to liquid scintillation counting.

The time taken for separation was about 5 min. The purity of precipitate was confirmed by chemical analysis of carbon and hydrogen, and ultraviolet absorption spectrometry. Absorption spectra of the reaction mixture also made it clear that no reaction other than isotopic exchange took place.

Measurements. The precipitate (2 to 3 mg) was dissolved in anisole (30.0 m*l*) containing 0.01% POPOP and 0.4% *p*-terphenyl as wavelength shifter, and the specific counting rate determined with a coincidence liquid scintillation counter. The complex is pale yellow and provides significant quenching effect on the scintillation. The effect was examined with standard benzoic acid-^{14}C and non-radioactive complex to obtain a calibration curve, with which the counting rate was duly corrected. The scintillation efficiency was 15% less in the presence of 2 mg per 30 m*l* of the complex as compared with that in its absence. The counting at the end of isotopic exchange reaction (infinite time) was calculated from that of the acetylacetone-^{14}C and the used amounts of the respective compounds.

Water content in the solvent and the reaction mixture was determined by Karl-Fischer titration in a mixture of pyridine and ethyleneglycol (5+1, v/v) as solvent. The ultraviolet absorption spectra were measured with a Hitachi EPU-3-spectrophotometer.

Results

The experimental data were treated with McKay's formula,

$$R = -2.303 \frac{2ab}{2a+b} \cdot \frac{\log(1-F)}{t} \qquad (1)$$

where a and b denote the concentrations of the complex (containing two moles of exchangable ligands per mole) and acetylacetone, respectively. F is the fraction of reaction and t the lapse of time in minutes. The plots of $\log(1-F)$ *vs.* t were all linear to permit the treatment with Eq. (1). Zero time exchange was not observed in this isotopic exchange reaction. The relative error in R values is less than 8 %.

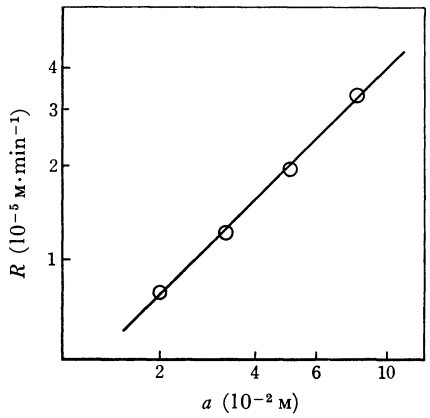

Fig. 1. Relationship between the exchange rate and the concentration of the complex. [acacH], 0.050 M, 80°C in anisole

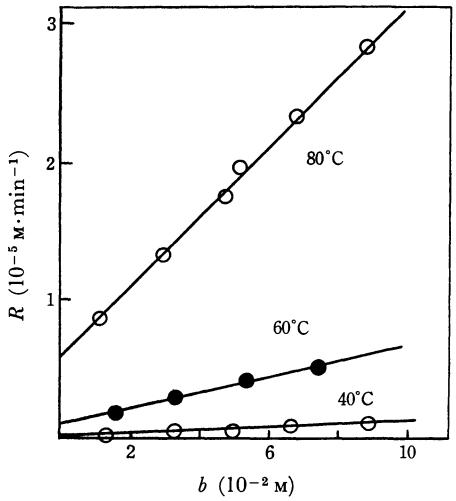

Fig. 2. Relationship between the exchange rate and the concentration of the free ligand. [Pd acac$_2$], 0.050 M, in anisole

Good first order dependence was observed between the exchange rate R and the concentration of the complex (Fig. 1). R is linearly dependent on the concentration of the free ligand (Fig. 2), but the straight line does not pass the zero point and gives a small positive intercept. Therefore R is expressed by

$$R = a(k_1 + k_2 b) \qquad (2)$$

where k_1 and k_2 are rate constants.

The exchange reaction is accelerated by acids. The influence of the concentration of acids (*m*-toluic and *o*-bromobenzoic acid) was examined as shown in Fig. 3. Good first order relationship is observed over the acid concentration range. Figure 4 shows the relationship between R and b in

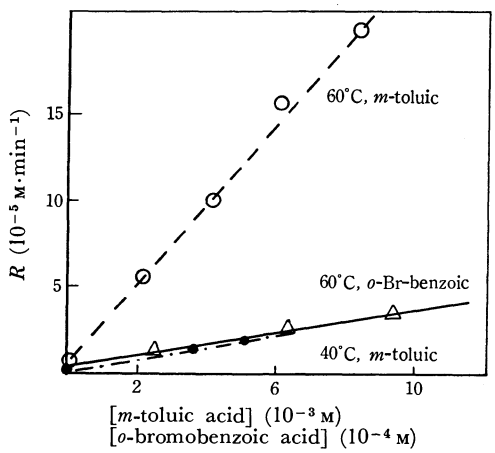

Fig. 3. Relationship between the exchange rate and the concentration of acid in anisole.
[Pd acac$_2$], 0.050 M, [acacH], 4.96×10^{-2} M for *m*-toluic acid at 40°C, 4.90×10^{-2} M for *m*-toluic acid at 60°C, 5.23×10^{-2} M for *o*-bromobenzoic acid at 60°C

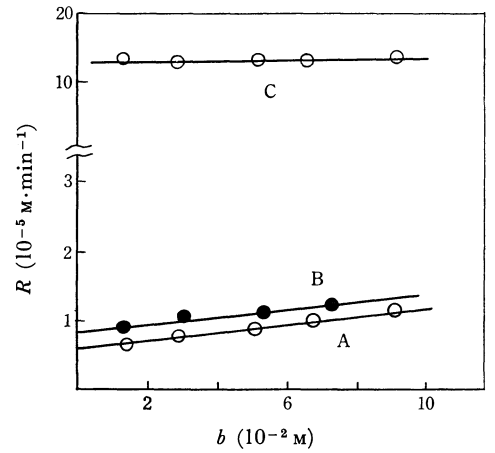

Fig. 4. Relationship between the exchange rate and the concentration of free ligand in the presence of given amounts of acids in anisole.
[Pd acac$_2$], 0.050 M at 60°C. A, 0,00024 M *m*-toluic acid, B, 0.00025 M *o*-bromobenzoic acid, C, 0.0050 M *m*-toluic acid.

the presence of given amounts of the complex and the acid at 60°C. The slopes of lines are equal to the k_2 values obtained from the experiments in the absence of acids. This fact indicates that the acid-catalyzed reaction path operates independent of *b*.

$$R = a(k_1 + k_2 b + k_3[\text{acid}]) \qquad (3)$$

So far as this formula is correct, the values of intercept in Fig. 4 should be equal to the value $a(k_1+k_2[\text{acid}])$. Experimental values obtained from the figure are in fact equal to those obtained from Figs. 2 and 3. When the acid concentration was increased to 0.005 M, the first and the second term of

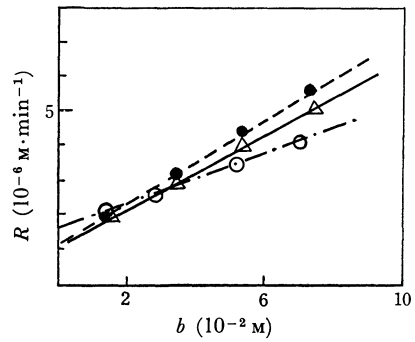

Fig. 5. Relationship between the exchange rate and the concentration of free ligand in various solvents.
[Pd acac$_2$], 0.050 M at 60°C. -△- in anisole, -●- in benzene, -○- in 1,2-dichloroethane

TABLE 1. RATE CONSTANTS IN VARIOUS ORGANIC SOLVENTS

Temp. °C	Solvent	k_1 (min^{-1})	k_2 (M^{-1}·mol^{-1})
40.0	anisole	2.0×10^{-6}	1.8×10^{-4}
60.0	anisole	2.0×10^{-5}	1.1×10^{-3}
80.0	anisole	1.2×10^{-4}	5.1×10^{-3}
E_a (kcal/mol)	anisole	23	18
60.0	benzene	2.4×10^{-5}	1.2×10^{-3}
60.0	1,2-dichloroethane	3.4×10^{-5}	7.4×10^{-4}

Eq. (3) were overwhelmed by the third, and an apparently horizontal diagram was obtained as seen in Fig. 4 C.

Figure 5 shows the relationship between *R* and *b* in various solvents. Equation (1) holds in all these solvents. The rate constants and the Arrhenius activation energy E_a are summarized in Table 1. There was no influence of water concentration upon *R* in the concentration range from 0.017 to 0.12 M in anisole. Because of the solubility of water in these solvents and the dehydration technique employed in this experiment, water concentration changed only within such a range.

Discussion

The k_2 Path. This reaction path is considered to be the so-called "reagent path," which proceeds with nucleophilic displacement mechanism S_N2, through direct attack by the free ligands.[1] There is still a question whether acetylacetone itself or acetylacetonate anion is the nucleophilic reagent. If the anion were the effective reagent, k_2 values should be influenced by the presence of other acids, because acetylacetone is a very weak acid and only a small fraction can be dissociated in the solvents. However, they remain unchanged on addition of stronger acids, and acetylacetone molecule seems

to be the nucleophilic reagent.

The k_1 Path. Generally the k_1 path is explained as the so-called "solvent path," in which the reaction proceeds with nucleophilic attack by the solvent molecule. Many experimental evidences have been postulated for reactions in polar solvents including water and methanol.[5] It seems rather doubtful, however, to apply the same reaction mechanism to the k_1 path in those solvents with poor coordination ability. In the present case it appears as if the k_1 path involves a kind of dissociation mechanism. The reason is as follows.

The k_1 values do not change significantly in varying solvents (Table 1). Anisole is a relatively polar solvent ($\mu=1.35$ Debye) whereas benzene is nonpolar; the k_1 values are nearly equal in these two solvents. Since palladium(II) is a soft acid,[6] it could interact with π-electrons of the aromatic solvent molecules. 1,2-Dichloroethane does not contain benzene ring, but the k_1 value in this solvent is nearly equal to those in the other two solvents. This fact indicates that the π-electron interaction between the phenyl ring and the palladium(II) complex does not affect the reaction rate appreciably.*2

Larger E_a values for k_1 than for k_2 and the negligible influence of water concentration upon the exchange rate seem to provide further support for the dissociative nature of the k_1 path.*3

The fact that k_1 in 1,2-dichloroethane is somewhat larger than that in other solvents could be interpreted by the larger dielectric constant of this solvent ($\varepsilon=10.36$, 25°C) than the other two (4.33 at 25°C for anisole and 2.28 at 20°C for benzene). Larger dielectric constant would facilitate the bond break between palladium(II) and oxygen of the ligand.

Thus the solvent molecule near the coordination sphere would have only a negligible affect on the elimination rate of the coordinated ligand, and the ease of break of the bond between the metal ion and the ligand would be responsible for determining the rate through k_1 path.

The k_3 Path. Three kinds of mechanism of acid catalysis can be considered: (i) displacement of coordinated ligand through the nucleophilic attack by acid molecule or its anion. (ii-a) dissociation of one end of chelate ligand is the rate determining step, and the other end of unidentate ligand dissociates fast. Protons attack the coordinated oxygen and accelerate the first step of bond break between palladium(II) and oxygen. (ii-b) The ligand can be present as unidentate rather stable, and the break of the remaining bond is the rate determining step. Protons trap the free end of unidentate ligand and retard its recombination to increase the reaction rate.

If the acid anion acted as nucleophilic reagent, salts of the acids should give the same catalytic effect. Unfortunately no salts of the acids, including those of lithium and tetramethylammonium have sufficient solubility in the organic solvents to permit such a comparison.

If the reaction mechanism were ii-a or ii-b, *o*-bromobenzoic acid ($pK=2.85$) would be the better catalyst than *m*-toluic acid ($pK=4.27$). If mechanism i were valid, *o*-bromobenzoic acid would be the weaker catalyst owing to its steric hindrance coming from bromine on the *o*-position. As shown in Table 2, *o*-bromobenzoic acid has greater catalytic ability. Hence mechanism ii-a or ii-b would be more appropriate.

Table 2. Influence of acid in anisole

Temp. °C	k_3 ($M^{-1}\cdot min^{-1}$)	
	m-Toluic	*o*-Bromobenzoic
40.0	7.5×10^{-2}	—
60.0	4.7×10^{-1}	6.7×10^{-1}
E_a (kcal/mol)	19	

Pearson and Johnson studied the substitution reaction of [Pd $acac_2$] in water containing methanol and accounted for the acid catalysis by mechanism ii-b.[7] Saito and Masuda investigated the isotopic exchange kinetics between acetylacetone-^{14}C and trisacetylacetonatoaluminum in organic solvents and interpreted the acid-catalyzed reaction path by mechanism ii-b, too, on the basis that the E_a values are identical in varying solvents and in the presence or absence of acid.[8]

In the present case, however, reaction mechanism ii-a cannot be easily eliminated, because the E_a value for k_3 (19 kcal per mole in anisole) is significantly smaller than that for k_1 (23 kcal per mole in anisole). Further, bond energy between palladium-

B. Gray and F. Basolo, *ibid.*, **82**, 787 (1960); U. Belluco, L. Cattalini, F. Basolo, R. G. Pearson and A. Turco, *ibid.*, **87**, 241 (1965).

6) R. G. Pearson, *ibid.*, **85**, 3533 (1963).

*2 If the k_1 path were the "solvent path," the apparent k_1 values should be divided by the molar concentration of the solvent species. They are 9.2, 11.2 and 12.7 M for benzene, anisole and 1,2-dichloroethane, respectively, and the divided values are 6.17×10^{-6}, 2.14×10^{-6} and 2.64×10^{-6} *l*/mol/min, respectively.

*3 Dissociative nature of the k_1 path has been exemplified by use of a palladium(II) complex with a large ligand, which brings about significant steric hindrance against nucleophilic attack by the solvent molecule in water. (W. H. Braddley and F. Basolo, *J. Am. Chem. Soc.*, **86**, 2075 (1964); **88**, 2944 (1966).) The present complex [Pd $acac_2$] does not seem to provide such an effect.

7) R. G. Pearson and D. A. Johnson, *ibid.*, **86**, 3983 (1964).

8) K. Saito and K. Masuda, This Bulletin, **42**, 3184 (1969).

(II) and oxygen is apparently smaller than that between aluminum(III) and oxygen as seen from their formation enthalpies, and non-polar solvents would hold the unidentate acetylacetonate less firmly than polar solvents. We would thus consider that the k_3 term is regarded as a catalytic process by protons, although neither the proton carrier nor the species subject to proton catalysis is evidently known.

The authors wish to express sincere thank to Nishina Memorial Foundation for Grant in Aid, and to Miss Mizue Tachikawa for her help in experiments.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 3466—3470 (1969)

The Indirect Determination of Mercury in an Aqueous Solution using the Ligand Exchange Reaction

Itsuro KAWAI and Tadashi HARA

Department of Chemical Engineering, Faculty of Engineering, Doshisha University, Kamikyo-ku, Kyoto

(Received May 15, 1969)

A new method for the indirect determination of mercury in an aqueous solution has been established on the basis of the fact that the absorption and evolution of propylene in the reaction between mercuric ion and propylene take place reversibly and quantitatively under proper conditions. In the method proposed, the propylene in the 1 : 1 π-complex is displaced with such complexing agents as chloride, bromide, iodide and EDTA, and the quantity of the propylene evolved is measured manometrically. By the present method, up to 70 mg Hg can be estimated within $\pm$0.08 mg in about 15 min. Common cations and anions do not interfere. Though silver(I) and palladium ions interfere, their interferences are removed by suitable procedures. By improving the apparatus, it should be possible to estimate much smaller amounts of mercury than the above value.

It has been well established that a mercuric ion in an aqueous solution reacts with olefins to form π-complxes.[1-10] However, the present authors have found that the absorption and evolution of propylene in the reaction between the mercuric ion and propylene take place reversibly and quantitatively under proper conditions. On the basis of this phenomenon, a new method for the indirect determination of mercury in an aqueous solution has been established; in this method the propylene in the π-complex is displaced with complexing agents, such as chloride, bromide, iodide, and EDTA, and the quantity of the propylene evolved is measured manometrically.

Experimental

Apparatus. The quantity of propylene absorbed or evolved was measured at a constant temperature and pressure using the apparatus shown in Fig. 1. The apparatus was made of glass except the parts connecting the sample bottle (B) and the leveler (G) with the cock,6, and the gas-burette, F. Water saturated with propylene was placed in the manometer, E, and the gas-burette, F. An aqueous solution of perchloric acid is placed in (D) and (G), and its acidity is the same as in the sample solution. To the sample solution containing mercury (10—70 mg), 3 m*l* of a 2 M sodium sulfate solution is added; the acidity was adjusted to 0.7M for the use of chloride, bromide, and iodide, or to pH 5 for the use of EDTA, as the complexing agent.

Reagents. *Standard Mercury(II) Solution.* The stock solution of mercury(II) was prepared by dissolving 21.66 g of mercuric oxide (JIS special grade) in 100 m*l* of 1 M perchloric acid. The concentration of mercury was determined by chelometric titration.

Complexing Agent Solutions. Solutions containing sodium sulfate in 2 M, and sodium chloride, sodium bromide or sodium iodide in 0.2 M or EDTA in 0.12 M were prepared. The acidities were 0.7 M in perchloric acid

except at pH 5 in a solution containing EDTA.

Acetate Buffer. The solution was prepared from sodium acetate and acetic acid.

All the reagents used were of a guaranteed grade.

Procedure. Cocks (1)—(19) are set to the positions shown in Fig. 1, and about 7 m*l* of a sample solution is taken into the sample bottle (B), the capacity of which is about 7 m*l*. Cock (9) is opened, and the inside of the apparatus is evacuated, and the cock closed. To adjust the inside to a constant vopor pressure, Cock (3) is opened and closed. To introduce propylene into the apparatus, Cock (8) is gradually opened after opening Cocks (1) and (10), and Cocks (8) and (10) are closed. Here the meniscus in the gas-burette is brought to the lower part by moving the leveler (G). Then the inside is equilibrated with the atmospheric pressure by regulating Cock (5), and the sample solution is dropped into the reaction vessel (A) (about 30 m*l*) through Cock (7) by operating Cock (6). The solution is stirred by a magnetic stirrer, and propylene is absorbed. After an equilibrium has been established, the stirrer is stopped and Cocks (6) and (7) are set to the positions shown in Fig. 1. The meniscus in the gas-burette is read after the internal pressure has been equilibrated with the atmospheric pressure through a manometer. Seven milliliters of a complexing agent are placed in the (B) and then added to the (A) in the way previously described. The solution is stirred and the meniscus read similarly. The quantity of propylene evolved is calculated by the difference between two readings. All the experiments were carried out at 25°C under an atmospheric pressure.

Results and Discussion

The Absorption of Propylene. Since the reaction between mercuric ions in an aqueous solution and propylene was controlled by the diffusion of propylene into the liquid, the time necessary for 40 mg of mercury ions to reach an equilibrium was measured by the apparatus shown in Fig. 1. The equilibrium was established in about 5 min; the time required was independent of the acidity in the range of pH 0—6. The quantity of propylene absorbed was 4.89 m*l*; this agreed approximately with the theoretical value, showing the composition to be that of a 1 : 1 π-complex. It may be supposed that the formation of the π-complex goes to completion in a short period.

The Evolution of Propylene. To the π-complex obtained in the above experiment there was added a complexing agent containing three times as many moles as mercury, and the quantity of propylene evolved was read against the time. The equilibrium was established within 10 min by adding either a halide solution (0.7 M perchloric acid) or EDTA solution (pH 5) to it. The time required increased in the order of; iodide (2 min)

<bromide (6 min)<chloride (8 min) and decreased with an increase in the stability constant of tetrahalogeno-mercuriates.

The Effect of Acidity. The relationship between the pH and the quantity of propylene evolved in a solution containing EDTA and Hg (3 : 1) was shown in Fig. 2. The evolution of propylene was quantitative at pH≧5. The experiment at pH> 7.0 was not feasible since some mercuric compound began to precipitate. The relationship between pH and the quantity of propylene evolved in a solution containing halide and Hg (3 : 1) is also shown in Fig. 3. As can be seen from Fig. 3, propylene is evolved quantitatively in the ranges of the following acidity: molarity of perchloric acid ≧0.7 for chloride, pH≦2.1 for bromide, and pH ≦4.0 for iodide. It can be concluded from these results that the propylene molecule is easily displaced with a halide ion at a lower pH, while it is replaced with EDTA at a higher pH.

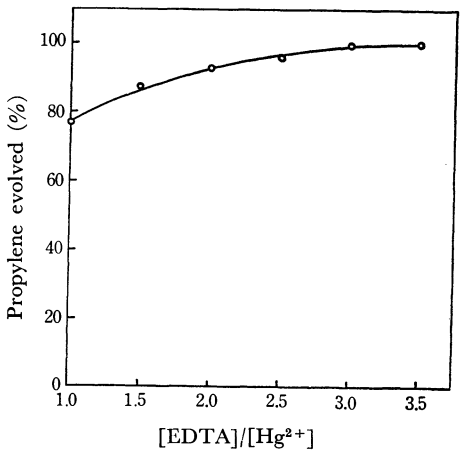

Fig. 4. Evolution of propylene with EDTA. t=25°C, P_{tot}=1 atm, μ=0.8, pH=5

The effect of the Mole Ratio. The relationship between the mole ratio of [EDTA]/[Hg] or [halide]/[Hg] and the quantity of propylene evolved was shown in Figs. 4 and 5. Propylene was evolved quantitatively under the following conditions: [EDTA]/[Hg^{2+}]≧3.0, [Cl^-]/[Hg^{2+}]≧3.0, [Br^-]/[Hg^{2+}]≧2.5 and [I^-]/[Hg^{2+}]≧2.0.

The Calibration Curves. The sample solutions containing 10, 20, 30, 40, 50, 60 and 70 mg of Hg were prepared, and the π-complexes were allowed to form in the apparatus shown in Fig. 1. Then the quantities of propylene evolved on the addition of halides of EDTA were measured. The

results shown in Fig. 6 were obtained by plotting the quantities of propylene evolved as the ordinate, and the concentration of mercury, as the abscissa. It was confirmed that all the experimental values fall on the same line regardless of the kind of complexing agent. Up to 70 mg Hg gave a straight line.

The Effect of Diverse Ions. The effects of such cations as Na^+, K^+, Mg^{2+}, Cu^{2+}, Co^{2+}, Mn^{2+}, Zn^{2+}, Pb^{2+}, Cd^{2+}, Ni^{2+}, Al^{3+}, Fe^{3+} and Cr^{3+} in mole ratios of $[cation]/[Hg^{2+}]\leqq 10$ on the determination of 40.26 mg of Hg were examined, but their interferences were negligible (Table 1). However, Ag^+ and Pd^{2+} interfered seriously. It is generally[10] said that the metals with eight or ten electrons in the *d*-orbital show a tendency to combine with olefins. The fact that no influence was observed on Ni^{2+} (d^8), Zn^{2+} (d^{10}) and Cd^{2+} (d^{10}) shows that the interaction between one of these ions and propylene is negligible. As can be seen from Table 1, the silver(I) ion gave a positive error, while the palladium(II) ion gave a negative error. The former is reasonable since it was confirmed experimentally that the reaction between the silver ion and propylene is quite similar to that between the mercuric ion and propylene, but the silver complex is less stable than the mercuric complex. The latter can also be understood by the following reactions, which were previously proposed by one of the present authors[11]:

$$\text{Propylene} + Pd^{2+} \longrightarrow \text{Acetone} + Pd^* \quad (1)$$

$$Hg^{2+} + \text{Propylene} \longrightarrow Hg^{2+}\cdot\text{Propylene} \quad (2)$$

$$Hg^{2+}\cdot\text{Propylene} + Pd^* \longrightarrow Pd^0 + Hg^0 + \text{Product} \quad (3)$$

Under the present experimental conditions, Reaction (1) goes to completion very fast, while the π-complex produced in Reaction (2) remains stable in the absence of the palladium ion. However, the mercuric complex in the presence of the palladium ion goes to completion in accordance with Reaction (3). These phenomena satisfactorily explain the results shown in Table 1. The interference of the silver ion was eliminated by adding a siutable amount of sodium chloride and by driving off an excess of chloride as hydrogen chloride; that of the palladium ion was also eliminated by adding an alcoholic dimethylglyoxime solution and by precipitating the palladium ion (Table 2). The suspensions were treated much as before.

The effects of such anions as SO_4^{2-}, NO_3^-, ClO_4^-, CH_3COO^-, and $H_2PO_4^-$ in mole ratios of $[anion]/[Hg^{2+}]\leqq 35$ on the determination of 40.12 mg Hg were also examined, but no interference was observed (Table 3). Since the blank value was reduced to zero with an increase in the amount of sodium sulfate, the determination of mercury was always carried out in the presence of a definite amount of sodium sulfate. According to the present procedure, the errors based the temperature change, impurities, *etc.* can be minimized.

In the above experiment, the blank value was

equal to 0.02 ml and was reproducible. The ionic strength in the reaction mixture was approximately 5 throughout the experiment. Up to 70 mg of mercury was determined in the present study, but it should be possible to determine smaller amounts of mercury by improving the apparatus, especially the gas-burette.

The authors wish to thank the Maruzen Sekiyu Co. for its donation of propylene.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 3470—3477 (1969)

The Oxygenation-deoxygenation of Cobalt(II) Complexes on Polymers

Akira MISONO, Seiichiro KODA and Yasuzo UCHIDA

Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received May 19, 1969)

Three cobalt(II) complexes, bis-(salicylaldehyde)-ethylenediimine-cobalt(II), bis-(salicylaldimino)cobalt(II), and di-(salicylal)-3,3′-diimino-di-*n*-propylamine-cobalt(II), were mixed with poly-4-vinylpyridine. These mixtures showed ESR signals which reversively appeared under oxygen. We tried to identify these signals on the basis of the electonic structure, cobalt(III)-O_2^{-1}. The oxygenation-deoxygenation rates were also observed and found to obey the Elovich rate equation.

Many oxygen-carrier cobalt(II) chelates have been investigated,[1] of these, bis-(salicylaldehyde)-imine-cobalt(II) complexes have long been investigated, especially by Calvin *et al.*[2,3] These complexes, however, do not seem to have been studied from the viewpoint of technological designs for producing solid-state oxidizing catalysts from them.

It is known that the paramagnetic bis-(salicylaldehyde)-ethylenediimine-cobalt(II) yields a diamagnetic-oxygenated complex ($Co/O_2=2/1$).[3] The present authors found that an ESR signal appeared when a mixture of this chelate and poly-4-vinylpyridine (PVP) was exposed to oxygen; on the other hand, the signal disappeared when the mixture was placed in a vacuum. Several cycles were successfully tried; they have already been reported briefly.[4]

The paramagnetic species in mixtures of a cobalt(II) chelate with a polymer have been identified, and also the properties of oxygenation-deoxygenation rates have been investigated in this study. The chelates which have been tried successfully are: bis-(salicylaldimino)cobalt(II) (Complex B-1 and Complex B-2; the abbreviations are explained in the Experimental part), and di-(salicylal)-3,3-diimino-di-*n*-propylamine-cobalt(II) (Complex C), as well as the above bis-(salicylaldehyde)-ethylenediimine-cobalt(II) (Complex A).

Results

The four mixtures, Complex A-PVP, Complex B-1-PVP, Complex B-2-PVP, and Complex C-PVP, each showed an ESR signal which appeared (or

increased) under oxygen (or air) and disappeared (or decreased) *in vacuo*. The ESR signals are shown with their approximate g and A values in Figs. 1—3. (These g values were roughly estimated so as to explain the signal shapes (and are, therefore, not very accurate) according to the method for randomly-oriented particles in a fixed position.[5]) The A values were approximate intervals (in gauss) between two appropriate hfs signal peaks). The PVP itself and the mixture of cobalt(II) acetylacetone with PVP showed no corresponding ESR signal, even under oxygen.

Polyacrylonitrile was also tried as a chelate-carrier instead of PVP, but the chelates could not be successfully carried on the polymer by any means tried.

The ESR signal shapes (investigated in the case of A-PVP) were almost independent of the temperature over the range from about 40 to −140°C. The signal in the case of the Complex C became a little sharper at a lower temperature.

The shape was almost independent of the oxygen pressure over the range from 1 atom to several mmHg (investigated in the case of A-PVP) and also of the relative mole ratio of cobalt(II) *vs.* the pyridine ring in the polymer over the range from 1/20 to 1/400 (investigated in the case of B-2-PVP).

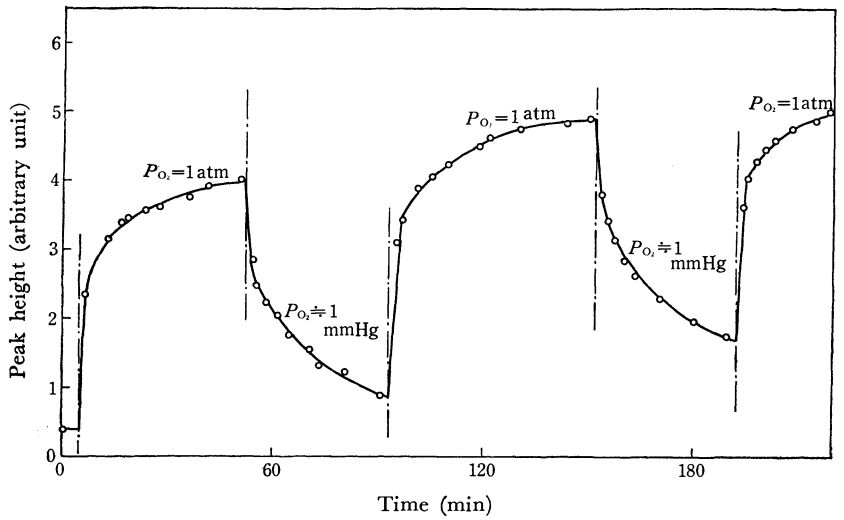

Fig. 5. Oxygenation-deoxygenation cycle (for B-1-PVP). Co/pyridine ring = 1/50 at room temp.

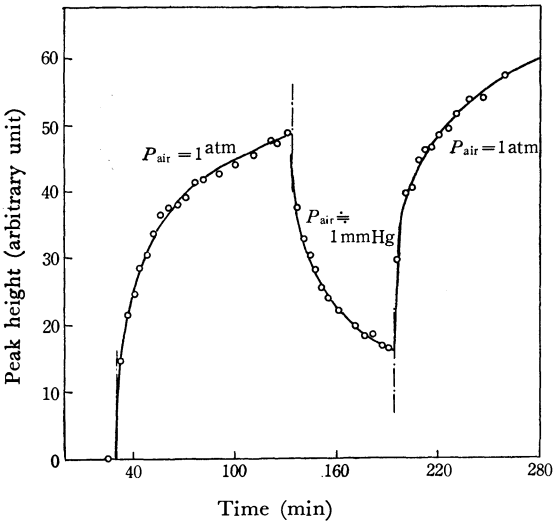

Fig. 6. Oxygenation-deoxygenation cycle (for C-PVP). Co-pyridine ring = 1/160, at room temp.

The changes in the relative strength of the ESR signal (which was considered to be proportional to the amounts of the corresponding paramagnetic species, as will be explained in the Experimental part) upon the introduction and exhaustion of oxygen (or air) are illustrated in Fig. 4 (for A-PVP), in Fig. 5 (for B-1-PVP), and in Fig. 6 (for C-PVP).

The rate of the increase and decrease of the signal strength seems to obey the Elovich rate equation (Figs. 7—9); that is,

increasing:

$$\log (t + t_0) = av - b$$

decreasing:

$$\log (t + t_0) = cv + d$$

t_0, a, b, c, d: constants independent of the contact time

v: signal strength

t: contact time

The signal strength is not proportional to $t^{1/2}$. Here, the strength proportionate to $t^{1/2}$ can be expected at an earlier stage if the rate is determined by gas diffusion through a polymer film.[6] Moreover, the first derivative of the signal strength against the contact time (Fig. 10) sufficiently obeyed the equation derived from the above Elovich equation:

$$dv/dt = Ae^{-Bv}$$

$$A = e^{2.303b}/2.303a$$

$$B = 2.303a$$

Moreover, it did not follow the equation:

$$dv/dt = k(v_e - v) \qquad k,\ v_e : \text{constants}$$

This equation can be expected to hold in the case of Langmuir adsorption,[7] and also at a later stage when the adsorption is determined by gas diffusion through a polymer film.[6]

The constants, a, b, c, and d, seemed, however, not to be independent of the previous history of the mixture (*cf.* Table 1). Above all, the enlargement of the b values agrees with the observation that the oxygenation rate increases with the repetition of the oxygenation-deoxygenation.

The relative signal strength changed easily with the temperature (Fig. 11). The signal strength seemed to decrease more rapidly with the rise in

This example is the first oxygenation stage of B-1-PVP; the full line is calculated by the equation $\log(t + t_0) = av - b$, where, $t_0 = 0$, $a = 0.085$, $b = -0.055$; the particles are observed values.

the temperature than can be expected when the signal strength fits the Curie law (the ESR strength of a paramagnetic ion $\propto 1/T$). This perhaps indicates that the equilibrium is more declined to the dissociated state at higher temperatures.

Discussion

The ESR signals, shown in Figs. 1—3, can be considered for the following reasons to be caused by a 1 : 1 adduct of molecular oxygen with the cobalt complex. The signals are observed only when the cobalt complexes on PVP are exposed to oxygen. Even if a 1 : 2 adduct ($Co/O_2=2/1$) of molecular oxygen with the chelate is made, the adduct may be diamagnetic. In fact, bis-(salicylaldehyde)-ethylenediimine-cobalt(II) (which is paramagnetic) forms a 1 : 2 oxygen adduct which is diamagnetic, and di-(salicylal)-3,3′-diimino-di-*n*-propylamine-cobalt(II) (which is paramagnetic) forms a 1 : 1 oxygen adduct which is paramagnetic, in the solid state.[2] Apparently a 1 : 2 adduct can be identified as Co(III)-O_2^{-2}-Co(III) which has no free spin, while a 1 : 1 adduct can be schematically considered to be Co (III)-O_2^{-1} or Co(II)-O_2, and therefore paramagnetic (one unpaired electron).

All three ESR signals can be explained as apparently caused by a paramagnetic species which has three different g values (one g value is larger than the other two g values, which are almost equal to each other). The hyperfine structures were found only on the high-magnetic-field side in the cases of A-PVP and B-PVP. In the signal for C-PVP, the hf structures were a little clearer. The hf structures can be considered to be caused by the mononucleus cobalt atom ($I=7/2$). Only a few lines appeared, although eight lines were expected.

There could be two ways of analysing these ESR signals; one way is based on the electronic structure, Co(II)-O_2 (in this structure, the valence d electrons of cobalt are considered to localize in metal orbitals), while the other is based on the electronic structure, Co(III)-O_2^{-1} (in this structure, one of the valence d electrons of cobalt is considered to migrate in a molecular orbital of oxygen).

There are several low-spin cobalt(II) complexes, for example, cobalt(II) phthalocyanine,[8] $Co(CH_3NC)_5^{2+}$,[9] and $Co(CN)_5^{3-}$.[9] These low-spin cobalt(II) complexes have g values which are relatively close to 2 (for example, $g_{\parallel}=2.000$, and $g_{\perp}=2.117$ for $Co(CH_3NC)_5^{2+}$, and $g_{\parallel}=1.992$, and $g_{\perp}=2.157$ for $Co(CN)_5^{3-}$). In general, however, the A values caused by the cobalt atom of these complexes are relatively large (for example, $A_{\parallel}=87$ gauss, and $A_{\perp}=57$ gauss for $Co(CH_3NC)_5^{2+}$, and $A_{\parallel}=87$ gauss, and $A_{\perp}=28$ gauss for $Co(CN)_5^{3-}$). From a con-

9) J. J. Alexander and H. B. Gray, *ibid.*, **89**, 3356 (1967); M. E. Kimball, D. W. Pratt and W. C. Kaska, *Inorg. Chem.*, **7**, 2006 (1968).

sideration of these reports, the Δ values of the adducts of oxygen with the chelates on PVP may be much larger than the approximately-estimated values if the electronic structure of the adduct is considered to be mainly Co(II)-O_2.

On the contrary, the method based on the Co(III)-O_2^{-1} electronic structure is more fruitful. The radical anion of molecular oxygen is analysed as having the following three different g values[10] (here, the Δ and E are illustrated in Fig. 12. g_e, λ and l have the ordinary meaning):

$$g_1 = g_e + 2(\lambda^2/\lambda^2 + \Delta^2)^{1/2}l$$

$$g_2 = g_e\left(\frac{\Delta^2}{\Delta^2+\lambda^2}\right)^{1/2} - (\lambda/E)\cdot\left[-\left(\frac{\lambda^2}{\lambda^2+\Delta^2}\right)^{1/2} - \frac{\Delta}{(\lambda^2+\Delta^2)^{1/2}} + 1\right]$$

$$g_3 = g_e\left(\frac{\Delta^2+\lambda^2}{\Delta^2}\right)^{1/2} - (\lambda/E)\cdot\left[\left(\frac{\lambda^2}{\lambda^2+\Delta^2}\right)^{1/2} - \frac{\Delta}{(\lambda^2+\Delta^2)^{1/2}} - 1\right]$$

When the oxygen molecule (as a radical anion) coordinates to the cobalt chelate (the structure is not clear now; for example, a structure in which the oxygen molecule coordinates to the cobalt chelate with its molecular axis oblique against the cobalt hf tensor is a common one for binuclear cobalt complexes bridged by molecular oxygen[11]), there may be some interaction between the antibonding $2p\pi$ orbital of oxygen and one of the d orbitals (perhaps d_{z^2}, though this identification is tentative) of the chelate. The larger interaction makes Δ larger. When the following values are assumed: $l=1$, $\lambda=226\ cm^{-1}$ (taken from atomic oxygen[10]) E is considered to be enough large to neglect λ/E, because the energy interval between $2p\pi_g$ and $2p\sigma_g$ (as one-electron orbitals) are calculated to be 2.25 Rydberg.[12]

The g values are to be calculated as follows:

$g_1 = 2.09$, $g_2 = g_3 = 2.00$, when $\Delta = 5000\ cm^{-1}$

$g_1 = 2.05$, $g_2 = g_3 = 2.00$, when $\Delta = 10000\ cm^{-1}$

These estimated values seem to agree roughly with the observed values. Moreover, only a small migration of the free spin into the metal orbitals may be sufficient to result in the observed hf structures, in which the Δ values are quite small, according to Kon and Sharpless.[13]

The rates of oxygenation and deoxygenation seem to obey the Elovich equation, at least in the earlier stages. Theoretically speaking, the Elovich equation can be derived when the rate of adsorption is determined by the reaction of gases and the adsorption sites, with, in general, one of the following conditions (1) or 2)) being satisfied:[14]

1) $N_s(E)/N_s$ = constant (heterogeneous surface)
   $N_s(E)$: the number of sites having E as the adsorption heat
   N_s: the total number of sites existing
2) $\varepsilon(\theta) = \varepsilon_0 - c\theta$ (homogeneous surface)
   θ: percentage covered
   $\varepsilon(\theta)$: adsortpion heat
   ε_0: constant
   $c\theta$: interaction energy between the adsorbed molecules

The chelates are perhaps coordinated on PVP in miscellaneous states. Also, small molecules such as methanol (which is used as the solvent in preparing the complex-polymer mixtures) may be left behind in the neighborhood of the chelates; then the adsorption heat on the chelate (the chelate with its neighborhood is considered to constitute the adsorption site) could be distributed over a wide range.

The constants of the Elovich equation seem not to be independent of the repeating number of the oxygenation-deoxygenation cycle. This may be the result of small changes in the structure of the adsorption site (for example, such molecules as methanol, which have been left behind in the neighborhood of the metal ion, though perhaps small in amount, may evaporate in the deoxygenation cycle), of the resulted changes in the adsorption heat distribution, and/or of some irreversible oxygenation. The stage of gas diffusion itself through the polymer film may have little effect on the changes of the constants.

It has been reported[13] that the ESR signal of the oxygen adducted to di-(salicylal)-3,3′-diimino-di-*n*-propylamine-cobalt(II) disappeared at lower temperatures in solution; this was attributed to the assumed dimerization of the cobalt(II)-oxygen adduct (paramag.) to yield cobalt(II)-oxygen-cobalt(II) (diamag.). However, the ESR signals on the mixtures investigated in the present paper did not disappear at lower temperatures. This may mean that the cobalt-oxygen adduct on the polymer does not dimerize to give cobalt-O_2-cobalt even at lower temperatures, because the chelates are fixed on hardly-moving polymer chains; this is perhaps the most important reason why the paramagnetic mononuclear cobalt-oxygen adduct is formed on the polymer.

Experimental

Reagents. *Poly-4-vinylpyridine (PVP).* Commercially-obtained 4-vinylpyridine was polymerized by copper acetate (the molecular weight was considered to be about 4000).[15] Found: C, 71.81; H, 7.32; N, 11.88%. Calcd for $(C_7H_7NO \cdot 0.67H_2O)_n$: C, 71.74; H, 7.18; N, 11.95%.

It was also polymerized by $K_2S_2O_8$ in water (the molecular weight was abut 50000).[16] Found: C, 76.88; H, 7.23; N, 12.43%. Calcd for $(C_7H_7NO \cdot 0.30H_2O)_n$: C, 76.05; H, 6.93; N, 12.67%.

These two polymers were found to have no detectable differences when used as chelate carriers.

Bis-(salicylaldehyde)-ethylenediimine-cobalt(II). This chelate was synthesized according to the litetrature[17] and was recrystallized from methanol. Found: C, 58.85; H, 4.08; N, 8.62%. Calcd for $C_{16}H_{14}N_2O_2Co$: C, 59.10; H, 4.30; N, 8.63% (Complex A).

Bis-(salicylaldimino)cobalt(II). This chelate was synthesized according to Endo.[18] At first as a dihydrate (Found: C, 50.94; H, 4.86; N, 7.91%. Calcd for $C_{14}H_{12}N_2O_2Co \cdot 2H_2O$: C, 50.16; H, 4.81; N, 8.36%); then it was dehydrated at 130°C for 2.5 hr *in vacuo*. Found: C, 56.18; H, 3.93%. Calcd for $C_{14}H_{12}N_2O_2Co$: C, 56.20; H, 4.04% (Complex B-1).

Also according to Yamada:[19] Found: C, 56.20; H, 4.13; N, 9.12, 9.43%. Calcd for $C_{14}H_{12}N_2O_2Co$: C, 56.20; H, 4.04; N, 9.36% (Complex B-2).

The infrared spectra of B-1 agreed with those of B-2. The B-1 and B-2 complexes showed no differences in the present experiments.

Di-(salicylal)-3,3'-diimino-di-n-propylamine-cobalt(II). This chelate was synthesized according to the literature[17] and was purified by reprecipitating it by water from an ethanol solution as a monohydrate. Found: C, 57.81; H, 6.21; N, 10.21%. Calcd for $C_{20}H_{23}N_3O_2Co \cdot H_2O$: C, 58.00; H, 6.09; N, 10.14% (Complex C).

Cobalt(II)-acetylacetone. This complex was obtained commercially and was used without further purification.

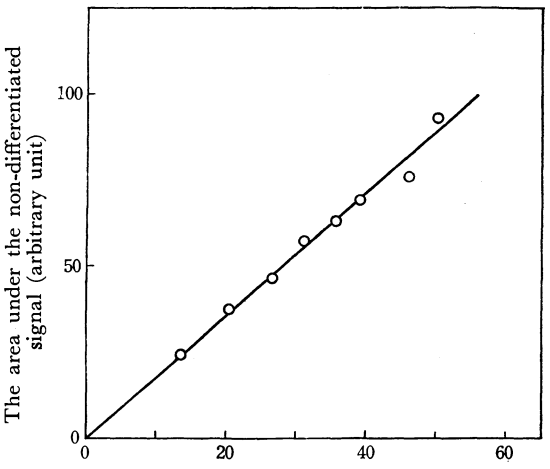

Fig. 13. The relation between the peak height of a first derivative signal and the area under the corresponding non-differentiated signal (in the case of B-1-PVP). Co/pyridine ring = 1/50, $P_{O_2} = 1$ atm.

Methanol. Commercial methanol was dehydrated by anhydrous calcium sulfate and was distilled under nitrogen.

Preparation of the Chelate-polymer Mixtures. These mixtures were made as thin, transparent films by mixing one of the complexes with PVP in methanol under nitrogen, and by then evaporating the solvent methanol.

ESR Measurements. The ESR spectra were observed with a Japan Electron Optics Laboratory Co., EPR spectrometer, Model JES-3BS-X (X-band). The value of the field strength was calculated from the observed signal of the manganese marker. The estimation of the *g* values were based on accurate measurements of the changes in field strength from the point of view of approximate calibration.

The relative amounts (arbitrary unit) of paramagnetic species of a given sample were measured as the peak heights of the first derivative signals, because the peak heights were found to be proportionate to the areas under the non-differentiated signal (Fig. 13), which are themselves considered to be proportionate to the amounts of paramagnetic species at a given temperature.

Solvolysis of Organic Phosphates. II. Pyridylmethyl Phosphates as Effected by the Presence of Polyvalent Metal Ions*[1]

Yukito MURAKAMI and Makoto TAKAGI

Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Hakozaki, Fukuoka

(Received May 23, 1969)

Influence of polyvalent metal ions on the hydrolysis of 2-, 3- and 4-pyridylmethyl phosphate was investigated at $\mu=0.10$ in a lower pH range. The thorium ion accelerated the hydrolysis rate of all the phosphates to a remarkable extent as investigated at 40, 70 and 90°C. The primary participation of the phosphate moiety of each pyridylmethyl phosphate in the interaction with thorium(IV) was considered to be the main cause of this catalysis. Thus, the thorium catalysis was mechanistically distinguished from the copper catalysis which has been clarified previously. In addition, the vanadyl ion also demonstrated positive catalytic effect. On the other hand, iron(III) and aluminum(III) retarded the hydrolysis rate. This was ascribed to the reduced fraction of the active monoionic species as a result of metal-complex formation with the phosphates in the course of hydrolysis.

The effect of metal ions on the hydrolytic reactions of phosphate monoesters is an interesting aspect of metal-ion catalysis, and has been the subject of a number of research groups.[1] However, previous investigations have not provided any satisfactory explanation for the reaction mechanism involved in the catalysis.

In continuation of our previous work[2] on the hydrolysis of the three isomeric pyridylmethyl phosphates, *i.e.*, 2-pyridylmethyl phosphate, 3-pyridylmethyl phosphate and 4-pyridylmethyl phosphate, the catalytic effects of polyvalent metal ions on these hydrolytic reactions were investigated in the present work. The hydrolysis of phenyl phosphate was also studied in the presence of some metal ions in an attempt to obtain an additional information on the catalytic reaction mechanism.

Experimental

Source of the organic phosphates and apparatus used in the present work have been described previously.[2] The stock solutions of metal ions were prepared from their nitrate salts, with the exception of vanadyl ion which was obtained as sulfate. These solutions were standardized by means of chelatometric titration.

Kinetic Measurements. The initial concentration of a substrate in solution was adjusted to 2×10^{-3} M and the ionic strength was maintained at 0.10 with an inorganic salt such as potassium nitrate, potassium chloride or sodium perchlorate. The rate of hydrolysis was determined by measuring the amount of inorganic phosphate liberated in the course of reaction. The pH-value of a solution was adjusted to a desired value by adding standard acid or base (0.1 N perchloric acid or 0.1 N sodium hydroxide). The experimental solution was made up to 100 m*l* in total volume and placed in a thermostated cell. After a desired temperature was attained, an aliquot sample (usually 2.5 m*l*) was taken out at an appropriate time interval and placed in a test tube. The tube was quickly cooled in cold water, and a specified volume (usually 2 m*l*) of the sample was pipetted into a 25-m*l* volumetric flask which contained a cold mixture of 60 % perchloric acid (2 m*l*) and water (15 m*l*). The whole solution was then kept in a refrigerator for some time before the subsequent colorimetric analysis of inorganic phosphate.

Analysis of Inorganic Phosphate. The analytical method employed for the analysis of phosphoric acid was essentially that of Allen.[3] To a mixture which contained a 2.0-m*l* sample of the experimental solution, 2 m*l* of 60 % perchloric acid and 15 m*l* of water in a 25-m*l* volumetric flask, 2.0 m*l* of amidol reagent (a 100 m*l* aqueous solution contained 1.0 g of amidol and 20 g of sodium bisulfite) and 1.0 m*l* of 8.3% aqueous ammonium molybdate were added in succession. The mixture was diluted to 25 m*l* with water, and then placed in a constant temperature bath at 25°C for 15—25 min to develop the blue color. The absorbance was measured at 720 mμ with a Shimadzu-Bausch & Lomb Spectronic 20 colorimeter immediately after development of the molybdenum blue color. The amount of inorganic phosphate was

determined by referring to a calibration curve established by the use of a standard KH_2PO_4 solution. Some of the metal ions were found to interfere with the phosphate analysis to some extent. The vanadyl ion has absorption in the 720 mμ range, and the observed absorbance had to be corrected for the presence of this metal ion. On the other hand, the ferric ion was found to decrease the absorbance of the molybdenum blue slightly through interaction with the molybdenum complex, while the thorium ion to increase it appreciably. Nevertheless, the interference of the ferric ion was of a negligible order under the present experimental conditions. The absorbance increase due to the presence of the thorium ion was corrected by establishing a relevant calibration curve. The presence of chelating agents employed in this work did not show any interference with the colorimetric determination of inorganic phosphate.

pH Measurements. Since the reaction temperature was so high (usually 90°C), the glass electrode could not demonstrate a sufficiently linear response to the pH values established by standard buffers[4] over the pH range studied. Thus, calibration of the electrode system was performed by dividing the whole pH range into three parts: pH 1.0—4.2, oxalate and phthalate buffers; pH 4.2—6.9, phthalate and phosphate buffers; pH above 6.9, phosphate and borate buffers. Since the glass electrode was not durable for prolonged use at elevated temperatures in a relatively high pH range (above 6), particularly in the presence of metal ions, the electrode membrane had to be reactivated rather often by treating with aqueous ammonium fluoride. However, careful operation made it possible to achieve the pH reproducibility within ±0.01. The pH meter was calibrated before and after each kinetic run, and the pH variation was usually controlled within ±0.03.

pH-Values obtained from the procedure described above need to be converted into hydrogen ion concentrations. Thermodynamic data for weak electrolytes, which make the conversion of pH into hydrogen ion concentration possible, are not available at present. Thus, a conventional method was employed in this work: the pH values of aqueous perchloric acid of known concentrations were measured at an ionic strength of 0.10 to determine the apparent activity coefficient. The apparent activity coefficient thus obtained was used over the whole pH range. The following relation holds at 80°C and $\mu=0.10$.

$$-\log [H^+] = pH - 0.09$$

Results

Polyvalent Metal Catalysis. With a 1 : 1 molar ratio of substrate to metal ion, the hydrolysis reactions of pyridylmethyl phosphates were studied at 90°C and the ionic strength of 0.10. In general, metal ions of tervalence or higher are far more susceptible to hydrolysis than bivalent metal ions. Thus, the choice of conditions for the homogeneous catalytic reaction is often restricted. The reaction followed first-order kinetics with respect to unreacted substrate species in most cases. When deviation from the first-order rate law was extreme, the apparent rate constants were evaluated from the initial stage of hydrolysis. The results for aluminum-ion and the vanadyl-ion catalysis are listed in Table 1. The equimolar existence of the aluminum ion reduces the hydrolysis rates of pyridylmethyl phosphates into about half of the corresponding spontaneous rates at $-\log[H^+]\approx 2.5$, regardless of the type of the phosphate isomers. This retardation effect is pH-dependent and is not noticeable in a lower pH region as shown in Table 1. The presence of a ligand capable of coordinating to metal ion, nitrilotriacetic acid in this case, tends to restore the rate to the spontaneous one.

The ferric ion yielded a similar catalytic effect

Table 1. Effects of aluminum and vanadyl ions on the hydrolysis of pyridylmethyl phosphates at 90.0±0.1°C and $\mu=0.10$ ($HClO_4$-$NaClO_4$)[a]

Phosphate	Metal ion	$-\log[H^+]$[b]	k, hr^{-1}	$(k/k_0)\times 100$[e]

a) $T_E=2.00\times 10^{-3}$ M, $T_M/T_E=1$ where T_E and T_M stand for the total molar concentration of the substrate species and of the metal ion, respectively.
b) Variation within±0.01.
c) NTA present, $T_M/T_L=1$ where T_L stands for the total molar concentration of the ligand.
d) Deviation from the first-order rate law is large.
e) k_0, spontaneous hydrolysis rate.

4) Four standard buffers, oxalate, phthalate, phosphate and borate buffers, were prepared in accordance with JIS (Z8802-1964).

as observed for the aluminum-ion catalysis under the same experimental condition. As an example, the presence of equimolar amounts of the ferric ion and 2-pyridylmethyl phosphate at 90°C and $\mu=0.10$ resulted in the reduction of hydrolysis rate to 65 % and 53 % of the corresponding spontaneous rates at $-\log[H^+]=1.04$ and 1.89, respectively.

A survey on the catalytic effects of other tervalent metal ions, *i.e.*, indium, lanthanum and cerium, revealed that the tendency of precipitate-formation was remarkable. Thus, the metal-ion catalysis was investigated in an acidic region ($-\log[H^+]=1-2$). The results indicate these metal ions were inactive in this low pH region. For example, in the presence of equimolar amounts of lanthanum(III) and 2-pyridylmethyl phosphate the hydrolysis rates of the phosphate at 90°C were 100 % and 99 % of the corresponding spontaneous ones at 1.06 and 1.91 in $-\log[H^+]$, respectively. The first-order rate law holds in both cases. However, in the latter, the first-order kinetics was disturbed after some precipitates were produced during the course of hydrolysis.

Among other polyvalent metal ions, the uranyl ion revealed the distinct tendency to form precipitates with the substrates. Thus, no reasonable experiment was carried out. On the other hand, the vanadyl ion showed an appreciable catalytic effect in promoting the hydrolysis of 2-pyridylmethyl phosphate even in a relatively low pH range as shown in Table 1. It should be noted that the hydrolysis at $-\log[H^+]=2.67$ did not follow first-order kinetics, and was accelerated with the progress of the reaction. Such an acceleration effect was observed only with the vanadyl ion, although the cause of this phenomenon is not obvious at present. Meanwhile, whenever a deviation from the first-order plots was observed in other metal-ion-effected hydrolysis of pyridylmethyl phosphates, the reaction rate was invariably decelerated and the rate plot appeared below the initial first-order rate curve.

Thorium(IV) Catalysis. The hydrolytic behavior of pyridylmethyl phosphates in the presence of the thorium ion at 90°C and $\mu=0.10$ is shown in Fig. 1. The reaction rates were so rapid that the hydrolysis proceeded to a considerable extent before thermal equilibrium was attained. It seems that the excessive enhancement of the catalytic reaction rate is reduced by the decrease of the concentration of catalyst species. However, the relative deficiency of the thorium ion ($T_M/T_E<1$) resulted in precipitate-formation even in a strongly acidic region (pH$\approx$1) at the beginning or during the course of reaction. This is most likely due to the complex formation between thorium(IV) and the substrate species.

In order to study the catalytic effects in more detail, the hydrolysis of 2- and 3-pyridylmethyl phosphate was also investigated at lower temperatures, and the results are shown in Figs. 2, 3 and

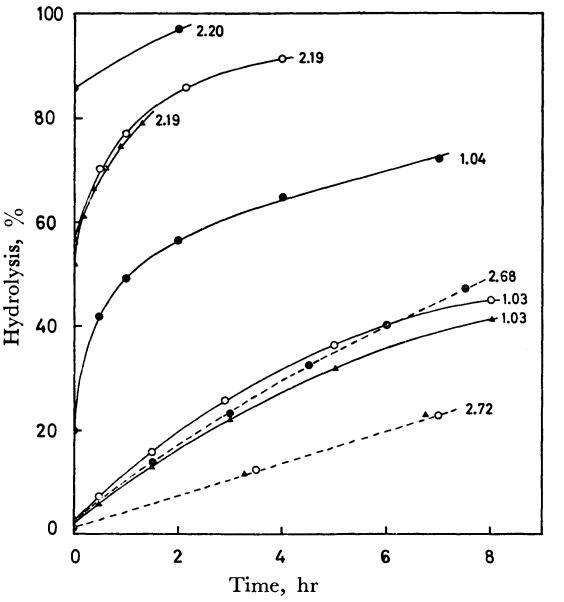

Fig. 1. Hydrolysis of pyridylmethyl phosphates in the presence of thorium(IV) ion: 90.0±0.1°C, $\mu=0.10$ ($HClO_4$-$NaClO_4$), $T_E=2.00\times10^{-3}$ M, $T_M/T_E=1$; ●, 2-isomer; ○, 3-isomer; ▲, 4-isomer; the broken lines indicates the spontaneous hydrolysis at their maximum rate; number refers to $-\log[H^+]$ value. First sampling was made 15—19 min after the solution was introduced into the reaction vessel (time=0).

4. As the pH value of the system was raised, an increasing tendency of precipitate-formation was observed. However, when the amount of precipitates was small, they disappeared gradually as hydrolysis proceeded to a certain extent. Thus, precipitates formed at the initial stage seem to be a thorium complex of the substrate. As the rate plots in Figs. 2 and 4 indicate, the hydrolysis curve tends to level off after a certain period of time. As shown in Figs. 2 and 3, the thorium-ion catalyzed hydrolyses of 2- and 3-pyridylmethyl phosphate reach their maximum rate at around pH 2.7 and slow down as the pH of the system departs from this optimum value. This fact suggests that essentially the same catalytic process is operative for these substrates, although the rate-promoting effect of the thorium ion for the hydrolysis of the 2-isomer was found to be considerably greater than that for the hydrolysis of the 3-isomer. The catalytic reaction rates at 40°C ($T_M/T_L=1$, Fig. 4) are now compared with the corresponding spontaneous rates, which were calculated by the aid of activation energies evaluated previously, in terms of the required reaction time to carry out 30 % hydrolysis. The $-\log[H^+]$ value of 2.7 was selected for this comparison, since the maximum rates were observed both in the presence and in the absence of thorium: 2-isomer, 2300 hr (spontaneous), 0.8 hr (catalytic); 3-isomer, 7000 hr (spontaneous), 8.5 hr (catalytic).

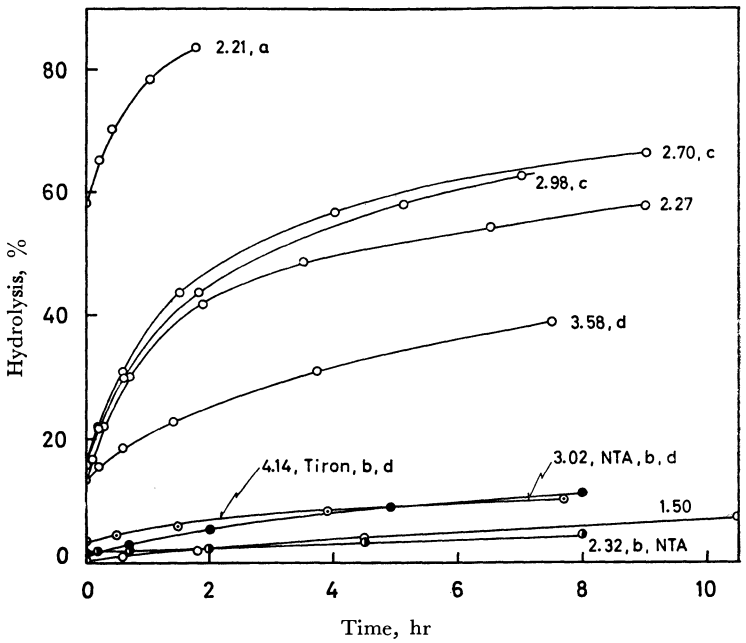

Fig. 2. Hydrolysis of 2-pyridylmethyl phosphate in the presence of thorium(IV) ion and its chelates: 40.0±0.1°C, μ=0.10 ($HClO_4$-$NaClO_4$), $T_E=2.00\times10^{-3}$ M, $T_M/T_E=1$; *a*, 70°C; *b*, $T_M/T_L=1$; number refers to $-\log[H^+]$ value. In some cases, precipitation was observed at the initial stage (*c*) or throughout the reaction (*d*). First sampling was made 15 min after the solution was introduced into the reaction vessel (time=0).

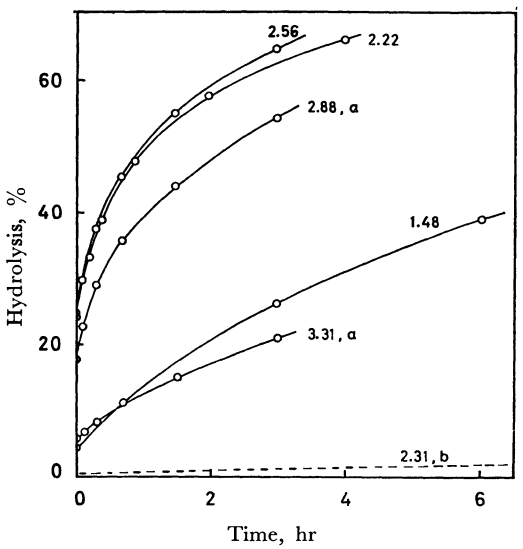

Fig. 3. Hydrolysis of 3-pyridylmethyl phosphate in the presence of thorium(IV) ion: 70.0± 0.1°C, μ=0.10 ($HClO_4$-$NaClO_4$), $T_E=2.00\times10^{-3}$ M, $T_M/T_E=1$; a, precipitates exist; b, spontaneous hydrolysis ; number refers to $-\log[H^+]$ value. First sampling was made 15 min after the solution was introduced into the reaction vessel except the run at 1.48 and the spontaneous one at 2.31 in $-\log[H^+]$ value, where 23 min was taken instead (time = 0).

Thus, the catalytic effect of the thorium ion is striking, and the observableh ydrolysis is entirelydue to the catalytic process in the low temperature range.

The catalytic effect of the thorium ion in these hydrolysis reactions diminished when a certain kind of chelating agent was present (Fig. 2). This is probably due to the so-called masking effect of these ligands on the thorium ion, so that the affinity of the metal ion toward the substrate species was considerably reduced. The thorium-ion catalysis did not follow simple kinetic laws after all.

Hydrolysis of Phenyl Phosphate. The hydrolysis of phenyl phosphate was studied at 80°C and the ionic strength of 0.10 in aqueous media in the presence of metal ions as listed in Table 2. It should be noted that all the bivalent metal ions listed in this table tend to retard the hydrolysis rate. This is even more marked with the vanadyl and the aluminum ion, and particularly with the ferric ion. In the ferric-ion catalysis, the reaction followed first-order kinetics fairly well up to 20 % hydrolysis of the substrate initially present, but deviated from this significantly thereafter.

The thorium ion produced some insoluble precipitates of unknown character with phenyl phosphate over the wide pH range even in the presence of some chelating agents, *e.g.*, NTA or Tiron. Thus, the hydrolysis reaction in the presence of the thorium ion was inadequate for study in a homo-

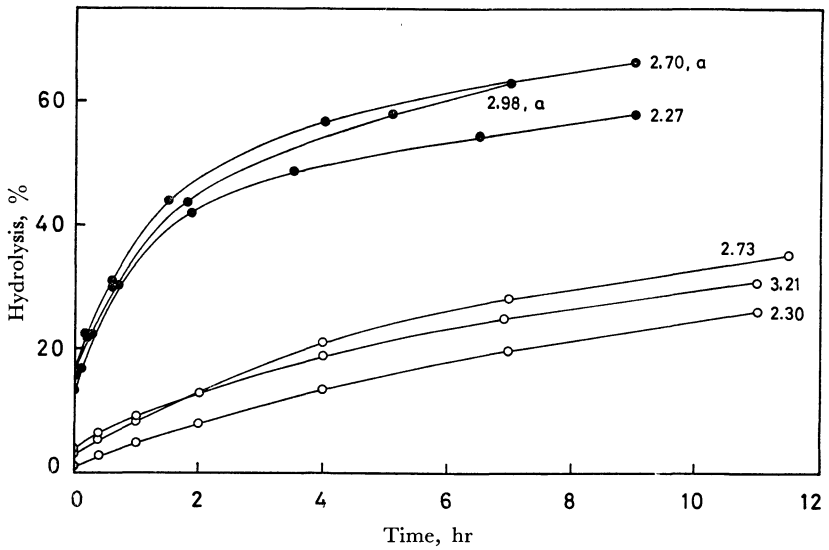

Fig. 4. Hydrolysis of pyridylmethyl phosphates in the presence of thorium(IV) ion: 40.0± 0.1°C, μ=0.10 ($HClO_4$-$NaClO_4$), $T_E=2.00\times10^{-3}$ M, $T_M/T_E=1$; ●, 2-isomer; ○, 3-isomer; *a*, precipitates were noticed at the initial stage; number refers to $-\log[H^+]$ value. First sampling was made 15 min after the solution was introduced into the reaction vessel. (time=0).

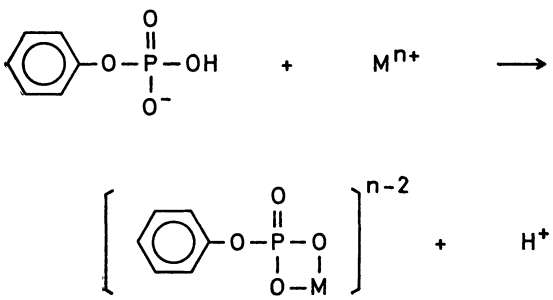
geneous system.

Discussion

The ferric and the aluminum ion gave retardation effect to the hydrolysis of phenyl phosphate. These metal ions may form the corresponding phenyl



phosphate complexes due to the following reaction. Judging from the stability constants of metal complexes formed with inorganic phosphate (PO_4^{3-}),[5] tervalent metal ions would give much more stable metal complexes of simple organic phosphate, such as phenyl phosphate, than bivalent metal ions. Thus, the complex-formation may proceed to a certain extent even in an acidic region (pH≈1), where the metal complex is supposed to be inert, and the concentration of the active monoionic species is reduced as a result. Since iron(III) and aluminum(III) do not show significant affinity toward *N*-donor atom in general,[5] these metal ions would interact with pyridylmethyl phosphates at the phosphate group even in the case

5) L. G. Sillén and A. E. Martell, "Stability Constants of Metal-Ion Complexes," Special Publication No. 17, the Chemical Society, London (1964).

of the 2-isomer. Thus, the same explanation can be given for the retarded hydrolysis rate of pyridylmethyl phosphates, regardless of metal species.

Of all other metal ions, the thorium ion promoted the hydrolysis of the present phosphates to the greatest extent. Nevertheless, no simple kinetic law can be applied to this system. Since the catalytic effect does not show large isomer-dependency, the primary catalytic process must involve interaction between thorium(IV) and the phosphate moiety of the substrates. Large stability constants obtained for the thorium-phosphate complexes may provide a sound basis for this discussion.[6] In addition, the hydrolysis rate reached its maximum at $-\log[H^+]\approx 2.7$, where the corresponding spontaneous hydrolysis also attained the maximum rate. This suggests that the substrate undergoes interaction with thorium(IV) in its zwitterion form. In spite of the primary participation of the phosphate moiety in the thorium-ion catalysis, the ring-nitrogen may be involved in the interaction with the metal ion in the hydrolysis of 2-pyridylmethyl phosphate since the highest acceleration effect on the rate was obtained with the 2-phosphate.

Bamann, Trapmann and their coworkers have studied in recent years the hydrolytic behavior of some phosphate monoesters in the presence of quadrivalent metal ions.[7-13] Quadrivalent titanium, zirconium, hafnium and thorium were found to show catalytic activity in an acidic region and the effect of thorium was the greatest. According to their work, solvolysis was accelerated several hundred times in most cases due to the presence of thorium ion, and the reaction rate was observed to be very rapid at the initial stage followed by leveling-off after a while. In spite of the fact that their experimental conditions are not directly comparable with ours, the catalytic pathway, which would elucidate the present thorium-ion catalysis, may also be applied to their system.

Meanwhile, in the hydrolysis of α-D-glucose-1-phosphate[14] the thorium ion retarded the hydrolysis rate in an acidic region below $-\log[H^+]\approx 2$ and the positive catalytic effect was observed above $-\log[H^+]=2.7$. Thus. the thorium-ion catalysis depends upon the structure of an alcoholic residue of a selected phosphate and also on the corresponding spontaneous reaction mechanism.

In our previous work,[2] the copper ion was found to promote the reaction rate of 2-pyridylmethyl phosphate to a significant extent in a $-\log[H^+]$ range above 3.3, while the same metal ion did not show any meaningful catalysis for other pyridylmethyl phosphates. The particular copper complex formed with the 2-isomer in the transition state, where the chelate ring involves both pyridyl nitrogen and ester oxygen as donor atoms, was postulated in order to elucidate the enhanced catalytic effect. On the other hand, the thorium complexes of the present substrates were not well characterized under present experimental conditions. Thus, presentation of an acceptable catalytic mechanism is not possible at present. The thorium-ion promoted hydrolysis seems to be much different from the corresponding copper-ion-effected reaction in respest of their catalytic mechanisms.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 3484—3487 (1969)

Reactions of Metal Chelates. IV.[1] The Reactions of Bis(salicylaldehydato)-copper(II) with Diethylenetriamine and Triethylenetetramine

Yasuo NAKAO and Akitsugu NAKAHARA

Institute of Chemistry, College of General Education, Osaka University, Toyonaka, Osaka

(Received May 30, 1969)

The reactions of bis(salicylaldehydato)copper(II) with diethylenetriamine and triethylenetetramine were investigated under several different conditions. In water, in the absence of other reagents, the reactions gave uncharged bis(salicylaldehyde)-diethylenetriamine- and -triethylenetetramine-copper(II), respectively. In the presence of an acid the resulting complexes were the respective cation complexes, in which only one of the two terminal nitrogen atoms was in the form of Schiff base with salicylaldehyde. In the presence of a salt, the resulting complex from diethylenetriamine was a cation complex, and that from triethylenetetramine an uncharged complex. Three new copper(II) chelates were obtained.

It was reported by Sarma and Bailar[2] that bis(salicylaldehydato)copper(II) reacts with triethylenetetramine to give bis(salicylaldehyde)triethylenetetraminecopper(II), (IV), in which the two terminal nitrogen atoms of the original triethylenetetramine molecule link to copper(II) in the form of Schiff base, whereas the other two imine-nitrogen atoms are free from coordination. However, we have recently found that the same reaction, under somewhat modified conditions, produces an entirely different chelate, (V), as indicated in Fig. 1. The reaction of complex (I) with diethylenetriamine (instead of triethylenetetramine) was found to proceed differently according to the conditions. The present paper deals with the results of reactions between bis(salicylaldehydato)copper-(II), I, and diethylenetriamine or triethylenetetramine under three different conditions: (1) the reaction in water in the absence of other reagents; (2) the reaction in the presence of various salts such as sodium perchlorate, nitrate, bromide or chloride; (3) the reaction in the presence of some acids such as perchloric, nitric, hydrobromic or hydrochloric acid. In most cases, resulting chelates were isolated. The structures of these complexes have been confirmed from elemental analyses and spectrophotometric measurements. For the systems where isolation of the reaction products was very difficult, the electronic spectra of reaction solutions were measured. The structure of complexes produced in solutions has been concluded also from the spectral data. All the results are schematically presented in Fig. 1.

2) B. D. Sarma and J. C. Bailar, Jr., *J. Am. Chem. Soc.*, **77**, 5476, (1955).

The Reaction of Bis(salicylaldehydato)copper(II), I, with Diethylenetriamine. The reaction of complex I in water with diethylenetriamine in the absence of other reagents gave an olive-green crystalline powder, whereas the same reaction in the presence of sodium perchlorate, bromide or nitrate gave violet crystals. The olive-green complex was found to have the structure (II) in Fig. 1, by taking into account the results of elemental analyses and the quadri-coordinating character of copper(II) complexes. As is clear from the structural formula, II, the two terminal amino groups of diethylenetriamine link to copper(II) in the form of Schiff base with salicylaldehyde, while the central imine-nitrogen is free from coordination. The complex is, therefore, an uncharged neutral molecule. The absorption maximum for the d–d band of the complex II was observed at 570 mμ.

Inspection of the infrared spectra of the violet crystals obtained from the system containing perchlorate or nitrate reveals the band characteristic of perchlorate or nitrate in the region between 1100 and 1380 cm^{-1} (Fig. 2). An aqueous solution of the violet crystal obtained from the system containing bromide ion gives the white precipitate by the addition of a solution of silver nitrate, which indicates the existence of bromide ion as the external ion of the complex. Thus the structure of these violet chelates has been concluded as III in Fig. 1. The results of elemental analyses of these perchlorate, nitrate and bromide complexes also supported the above conclusion. In the case of the chloride of the same complex, it was necessary to concentrate the reaction solution because of its comparatively high solubility in order to isolate the crystals. The absorption maximum in the visible region of the four violet complexes (chloride, bromide, nitrate and perchlorate) always appears at 570 mμ. In

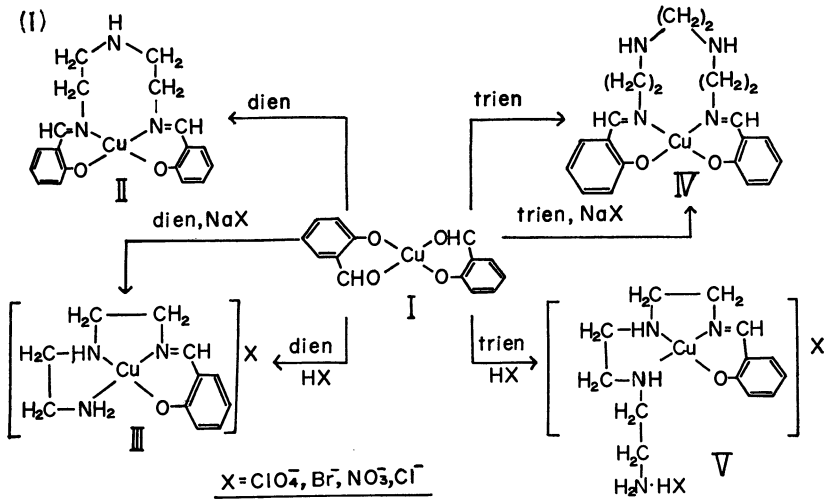

Fig. 1. The Reactions of bis(salicylaldehydato)copper(II) with diethylenetriamine and triethylenetetramine.

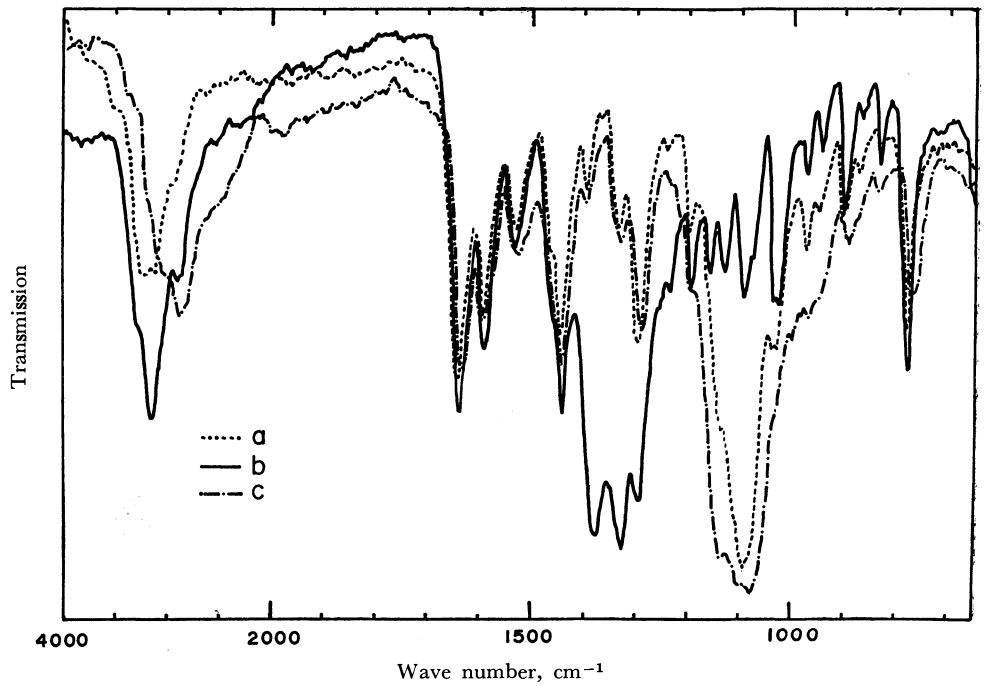

Fig. 2. Infrared spectra of a, [Cu salal=dien]$ClO_4 \cdot H_2O$; b, [Cu salal=dien]$NO_3 \cdot H_2O$; c, [Cu salal=trienH]$(ClO_4)_2$.

spite of their widely different color in the crystalline state, complexes II and III reveal no great difference as far as the d-d band is concerned. However, a considerable difference was observed in the absorption bands in the near ultraviolet region. It is to be noted that chelate III obeys Beer's law even in the concentration of 5×10^{-3} to 5×10^{-5} M, whereas chelate II does not in such a dilute solution. It has been confirmed by infrared study that the resulting chelate from the reaction of complex I with diethylenetriamine in acidic solution is identical with chelate III. These results suggest that the 6-5-5*1 fused-chelate-ring is so stable that only the presence of some anions favors its formation, instead of the complex of the less stable 6-8-6 fused-chelate-ring structure, II.

*1 The abbreviation 6-5-5 indicates the fused-chelate-ring structure containing six-, five-, and five-membered ring in counter-clockwise direction.

The Reaction of Bis(salicylaldehydato)copper(II), I, with Triethylenetetramine. In this reaction the product was a bluish green complex, regardless of the absence or presence of salts. As is clear from the structural formula IV, triethylenetetramine is coordinated around copper(II) only through the two terminal nitrogen atoms which are in the form of Schiff base with salicylaldehyde. The complex is, therefore, identical with that reported by Sarma and Bailar[2]. On the other hand, the resulting compound from the reaction in an acidic solution was a cation complex as indicated in (V), in which one terminal amino group was in the form of Schiff base and the other terminal amino nitrogen was in the form of quaternary ammonium salt. Hence the complex has a 6-5-5 fused-chelate-ring structure. The infrared spectrum of the perchlorate of chelate V is shown in Fig. 2. Though the chelate of type V was successfully isolated as perchlorate, its nitrate, bromide or chloride could not be isolated. However, the spectrophotometric investigation of the latter solutions enabled us to conclude the formation of the same type complex cations in each case. In other words, the visible and ultraviolet absorption spectra of these reaction solutions have been disclosed to be more similar to that of V than that of complex IV. Thus in the case of triethylenetetramine, the tendency for producing the 6-5-5 fused-chelate-ring structure seems to be characteristic of the presence of acid, and is in marked contrast with the case of diethylenetriamine. In the latter case, the 6-5-5 fused-chelate-ring structure was produced even by the presence of a neutral salt instead of acids. It is interesting to note that there is a delicate difference between diethylenetriamine and triethylenetetramine in the way of chelate-formation.

Experimental

Bis(salicylaldehydato)copper(II) was prepared according to the direction described in the first paper of this series.[3]

The Preparation of Copper(II) Chelate, II. To a 3.1 g (0.01 mol) of bis(salicylaldehydato)copper(II) in 20 m*l* of water was added 0.9 g (0.01 mol) of diethylenetriamine in 10 m*l* of water. The mixture was stirred at 25°C for about half an hour. After it had been filtered, the solution was evaporated to dryness *in vacuo* to give an olive-green powder. The powder was recrystallized from ethanol containing a small volume of water. Found: C, 55.19; H, 5.05; N, 10.97%. Calcd for $[Cu(C_{13}H_{19}N_3O_2)]\cdot H_2O$: C, 55.31; H, 5.38; N, 10.76%.

The Preparation of the Perchlorate, Nitrate or Bromide of Chelate, III. To a mixture of 0.01 mol each of bis(salicylaldehydato)-copper(II) and diethylenetriamine in 30 m*l* of water was added 0.01 mol of sodium perchlorate, nitrate or bromide. The reaction mixture was stirred at 25°C for about half an hour. After it had been cooled, a small violet crystal was deposited from the solution. This was filtered by suction, and was recrystallized from water. Analytical data of the complexes are given in Table 1.

The Preparation of Chloride of Chelate, III. An almost same procedure as that described above was applied. Since the corresponding violet crystal could not be separated only by allowing the solution to stand, the reaction mixture had to be evaporated to dryness *in vacuo*. The crystalline powder thus obtained was recrystallized from aqueous ethanol. This compound can be prepared by the following method. The mixture of 0.01 mol each of bis-(salicylaldehydato)copper(II), diethylenetriamine and sodium chloride in 30 m*l* of water was adjusted to pH 3—5 by hydrochloric acid. The mixture was stirred at 25°C for half an hour, and a dark blue solution was obtained. After it had been filtered, the filtrate was evaporated to dryness *in vacuo* to give a dark blue powder. Recrystallization of this powder was performed by using aqueous ethanol. The result of elemental analysis is shown in Table 1.

The Reaction between Bis(salicylaldehydato) copper(II) and Diethylenetriamine in Acidic Media. The mixture of 0.01 mol each of bis(salicylaldehydato)copper(II) and diethylenetriamine in 30 m*l* of water was adjusted to pH 3—5 by perchloric, nitric, hydrobromic, or hydrochloric acid. The reaction mixture was stirred at 25°C for half an hour. A violet crystalline product was deposited from the solution except for the case in which hydrochloric acid was used. The crystals were respectively identified as perchlorate, nitrate or bromide of cation complex, III, from their infrared spectra. In the case of chloride of III, visible and ultraviolet absorption spectrum of the reaction solution was measured.

The Preparation of Copper(II) Chelate, IV. Though this compound has already been reported by Sarma and Bailar,[2] a similar procedure as for complex II, was adopted.

The Preparation of the Perchlorate of Chelate, V. The mixture of 0.01 mol each of bis(salicylaldehydato)-copper(II) and triethylenetetramine in 30 m*l* of water

TABLE 1. ANALYTICAL DATA OF [Cu salal=dien]X

Compound	C, %		H, %		N, %	
	Calcd	Found	Calcd	Found	Calcd	Found
$[Cu\ salal{=}dien]ClO_4\cdot H_2O$	34.11	34.07	4.65	4.55	10.85	10.37
$[Cu\ salal{=}dien]NO_3\cdot H_2O$	37.77	37.94	5.15	5.08	16.02	15.90
$[Cu\ salal{=}dien]Br\cdot H_2O$	35.92	36.04	4.90	4.93	11.43	11.38

was adjusted to pH 3—5 by dilute perchloric acid. After it had been stirred at 25°C for about half an hour, the reaction mixture was filtered by suction. A red-violet crystal was deposited, and this was recrystallized from water.

Found: C. 30.65; H, 4.19; N, 10.44 %. Calcd for $[Cu(C_{13}H_{21}N_4OHClO_4)]ClO_4$: C, 30.47; H, 4.30; N, 10.94%.

The Reaction between Bis(salicylaldehydato)-copper(II) and Triethylenetetramine in the Presence of Sodium Perchlorate, Nitrate, Bromide or Chloride. The reactions were carried out in the same way as for chelate III. Each product was identified as the chelate IV from infrared spectrum.

The Reaction between Bis(salicylaldehydato)-copper(II) and Triethylenetetramine in Acidic Media. A similar procedure as for bis(salicylaldehydato)copper(II) with diethylenetriamine in acidic media was adopted. A red-purple crystal was separated only from the system using perchloric acid, but not in the other cases. However, the structure of the complex in each reaction was verified as IV from their absorption spectra.

Measurements

The measurements of visible and ultraviolet absorption spectra were made with a Shimadzu Spectrophotometer QR-50. The infrared spectra were recorded with a Hitachi EPI-2 infrared spectrophotometer. The measurements were carried out at room temperature using the pressed potassium bromide disk technique in the wave number range from 700 to 4000 cm^{-1} with a rock-salt prism.

The authors wish to thank Miss Yoshiko Komuro for the elemental analysis and the Ministry of Eduction for a grant-in-aid.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 3487—3490 (1969)

Hydrodynamic Voltammetry with the Convection Electrode. III. The Measurements of the Kinetic Parameters of the Electrode Reaction. Part I

Junsuke SUZUKI

Faculty of Education, Shizuoka University, Oiwa, Shizuoka

(Received June 11, 1969)

We have proposed the determination of the kinetic parameters of the electrode reaction by means of convective voltammetry. At the pushed-out mercury-drop convection electrode (PM-DCE), the ratio of the current on a totally-irreversible wave to the limiting current was derived as follows:

$$\frac{i}{i_l} = \frac{1.64\, k_R D_O^{-2/3} v^{-1/2} \nu^{1/6} d^{1/2}}{1+1.64\, k_R D_O^{-2/3} v^{-1/2} \nu^{1/6} d^{1/2}}$$

This equation was applied to the determination of the kinetic parameters for the electro-reduction of cupric ions in a 0.1 M perchloric acid solution containing 0.05% Triton X-100. It was found that the values of αn and k° the kinetic parameters are 0.59 and 4.2×10^{-9} cm/sec respectively.

In our previous papers,[1,2] the convection electrode system developed by the present authors was applied to the microdetermination of electroactive substances. The results showed that it had a high sensitivity and a good reproducibility. At the convection electrode in the laminar flow, the limiting current, i_l, was found to be given by:[3,4]

$$i_l = 0.61 n\boldsymbol{F}ACD^{2/3} v^{1/2} \nu^{-1/6} d^{-1/2}$$

where n is the number of electrons involved in the electrode reaction; $\boldsymbol{F}$, the Faraday constant; A, the area of the electrode surface; C, the bulk concentration of electroactive substances; D, the diffusion coefficient of an electroactive substance; v, the tangential velocity of the rotating disk; ν, the kinematic viscosity of the solution, and d, the diameter of the convection electrode (the working part plus the non-working shield). The rate of mass transfer at the convection electrode can be controlled by changing the tangential velocity of the rotating disk.

In the present paper, the use of the convection electrode for the study of the kinetics of the electrode reactions will be investigated and the rate constant

4) J. Suzuki, *ibid.*, **16**, 69 (1969).

for the electro-reduction of cupric ions in 0.1 M perchloric acid containing 0.05% Triton X-100 will be determined by analyzing the current-voltage curve.

Theoretical

In the quantitative treatment of the electrode reaction, it is necessary to consider the rates of both the mass and the electron transfer. For the reduction of an oxidized species, *Ox*, to a reduced species, *Red*, when both of the species are soluble, the simplest electrode reaction can be presented in the form of:

$$Ox + n\,e = Red \tag{1}$$

where n is the number of the electron.

The net electron transfer may be given by the difference between the rates of a forward (reduction) process and a backward(oxidation) one. The corresponding rates are expressed as follows, in accordance with the treatment of Kimball:[5]

$$\text{forward process:} \quad R_R = k_R \cdot a_O^\circ \tag{2}$$

$$\text{backward process:} \quad R_O = k_O \cdot a_R^\circ \tag{3}$$

where k_R and k_O denote the rate constants of the first order. Therefore, the net electron transfer is given as follows:

$$R = R_R - R_O = k_R a_O^\circ - k_R a_R^\circ = k_R f_O C_O^\circ - k_O f_R C_R^\circ \tag{4}$$

where a° and C° denote the activities and concentrations at the electrode surface respectively; f, the activity coefficient, and the subscripts, O and R, the oxidized and reduced forms of the electroactive species.

The rate constants of k_R and k_O can be defined as:

$$k_R = k^\circ \exp\left[-\alpha(E-E^\circ)n\boldsymbol{F}/\boldsymbol{R}T\right] \tag{5}$$

$$k_O = k^\circ \exp\left[(1-\alpha)(E-E^\circ)n\boldsymbol{F}/\boldsymbol{R}T\right] \tag{6}$$

Here, k° is the specific rate constant at the standard potential, E°, where k_R, k_O, and k° equal each other; α, the transfer coefficient, and $\boldsymbol{F}$, $\boldsymbol{R}$, and T, the usual thermodynamic signature.

By combining Eqs. (4), (5), and (6), the net current at the potential, E, is given as follows:

$$\frac{i}{n\boldsymbol{F}A} = k^\circ \exp\left[\alpha(E^\circ-E)n\boldsymbol{F}/\boldsymbol{R}T\right] f_O \cdot C_O^\circ - k^\circ \exp\left[(1-\alpha)(E-E^\circ)n\boldsymbol{F}/\boldsymbol{R}T\right] f_R \cdot C_R^\circ \tag{7}$$

where i is the net current at the electrode surface of A cm^2.

On the other hand, the rate of mass transfer, that is, the flux at the electrode surface, depends upon the mechanism of mass transfer, diffusion, forced convection, *etc.*

The rate of mass transfer is in proportion to the difference between the bulk concentration of electroactive substances and their concentration at the electrode surface. Therefore, the rate of mass transfer is given by:

$$\text{for oxidized species:} \quad j_O = m_O(C_O - C_O^\circ) \tag{8}$$

$$\text{for reduced species:} \quad -j_R = m_R(C_R^\circ - C_R) \tag{9}$$

Here, m denotes the mass transfer coefficient, which was in a previous work[3] determined at the convection electrode as follows:

$$m = 0.61\, D^{2/3}\nu^{1/2}\nu^{-1/6}d^{-1/2} \tag{10}$$

Assuming a steady state, one has:

$$\frac{i}{n\boldsymbol{F}A} = j_O = -j_R = m_O(C_O - C_O^\circ) = m_R(C_R^\circ - C_R) \tag{11}$$

From Eqs. (7) and (11), the following equation is obtained:

$$\frac{i}{n\boldsymbol{F}A} = \frac{\left(\begin{array}{l} m_O(f_O C_O \exp\left[\alpha(E^\circ-E)n\boldsymbol{F}/\boldsymbol{R}T\right] \\ -f_R C_R \exp\left[(1-\alpha)(E-E^\circ)n\boldsymbol{F}/\boldsymbol{R}T\right]) \end{array}\right)}{\left(\begin{array}{l} (m_O/k^\circ)+f_O \exp\left[\alpha(E^\circ-E)n\boldsymbol{F}/\boldsymbol{R}T\right] \\ +(m_O/m_R)f_R \exp\left[(1-\alpha)(E-E^\circ)n\boldsymbol{F}/\boldsymbol{R}T\right]) \end{array}\right)} \tag{12}$$

Under the initial condition of $C_R=0$, Eq. (12) becomes:

$$\frac{i_l - i}{i} = \frac{m_O}{k^\circ f_O}\exp\left[\alpha(E-E^\circ)n\boldsymbol{F}/\boldsymbol{R}T\right] + \frac{m_O f_R}{m_R f_O}\exp\left[(E-E^\circ)n\boldsymbol{F}/\boldsymbol{R}T\right] \tag{13}$$

where i_l is the limiting current, which is equal to $n\boldsymbol{F}AC_O m_O$.

Equation (13) represents a current-voltage curve-equation for a stationary electrode-moving solution system.

In Eqs. (12) and (13) m_O/k° was defined as the "irreversibility index" (IRI) by Jordan and Javick.[6] The character of the current-voltage curve depends upon the IRI value; that is, the current-voltage curve varies from reversible to irreversible with an increase in the IRI value, as is shown below.

a) $\boldsymbol{m_O/k^\circ \ll 1}$. In Eq. (13), the first term on the right hand side can be neglected; it is clear that the current-voltage curve has a reversible character, that is,

$$E = E^\circ - \frac{\boldsymbol{R}T}{n\boldsymbol{F}}\ln\left(\frac{D_O}{D_R}\right)^{2/3}\cdot\frac{f_R}{f_O} - \frac{\boldsymbol{R}T}{n\boldsymbol{F}}\ln\frac{i}{i_l - i} \tag{14}$$

$$E_{1/2}{}^r = E^\circ - \frac{\boldsymbol{R}T}{n\boldsymbol{F}}\ln\left(\frac{D_O}{D_R}\right)^{2/3}\cdot\frac{f_R}{f_O} \tag{15}$$

where $E_{1/2}{}^r$ is the reversible half-wave potential.

b) $\boldsymbol{m_O/k^\circ \approx 1}$. In this case, the current-voltage curve obeys Eq. (13).

c) $\boldsymbol{m_O/k^\circ \gg 1}$. In Eq. (13), the last term on the right hand side can be neglected; that is, the current-voltage curve has an irreversible character.

5) G. E. Kimball, *J. Chem. Phys.*, **8**, 199 (1940).

6) J. Jordan and R. A. Javick, *Electrochimica Acta*, **6**, 23 (1962).

$$E = E^\circ + \frac{RT}{\alpha nF} \ln \frac{1.64k^\circ \nu^{1/6}}{D_O{}^{2/3}} + \frac{RT}{\alpha nF} \ln \left(\frac{d}{v}\right)^{1/2} - \frac{RT}{\alpha nF} \ln \frac{i}{i_l - i} \quad (16)$$

Equation (16) is rearranged in the following manner:

$$\frac{i}{i_l} = \frac{1.64k_R D_O{}^{-2/3} v^{-1/2} \nu^{1/6} d^{1/2}}{1 + 1.64k_R D_O{}^{-2/3} v^{-1/2} \nu^{1/6} d^{1/2}} \quad (17)$$

This is analogous to the equations for an irreversible wave derived by Koutecky[7] and by Okinaka and Kolthoff.[8] Equation (17), also, allows us to calculate the values of k_R from the measurement of the i/i_l ratio at various potentials on the current-voltage curve obtained with the convection electrode, and a plot of the calculated log k_R *vs.* the potential may yield a straight line. The values of α and k° can be determined from the slope of this line and from its intercept at the potential of E° respectively.

Experimental

Materials. All the chemicals were of a chemical pure grade and were used without further purification. A solution of cupric ions was prepared by dissolving copper perchlorate in redistilled water, and the copper content was determined by titrating with a standard EDTA solution. A stock solution of Triton X-100 was prepared by dissolution in redistilled water.

Electrodes. The electrode system, a pushed-out mercury-drop convection electrode (PMDCE), used in the present investigation was almost the same as has been described in previous papers[9,10] with the exception of the orientation of the working surface against the liquid flow (Fig. 1). A saturated calomel electrode was used as the reference electrode.

Measurements. A current-voltage curve was recorded by using a Yanagimoto Polarograph, Model PA 102. All the solutions were kept at 25±0.1°C.

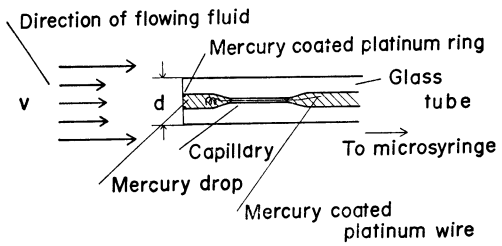

Fig. 1. Pushed-out mercury-drop convection electrode assembly.

Results and Discussion

Reduction of the Copper(II) Ion in Perchloric Acid Containing Triton X-100. The logarithmic plot of an irreversible wave yields either a straight line or a curve. When the rate of the electrode reaction was not slow enough to increase the over-voltage more than about $0.12/n$ V[11] (n, the number of electrons involved in the rate-determining step), the logarithmic plot shows a curve because the backward reaction can not be neglected. Such a wave is "quasi-reversible" and it is to be distinguished from a "totally irreversible wave," which has an over-voltage greater than $0.12/n$ V. In this case, the logarithmic plot yields a straight line. In a recent investigation,[12] the reduction wave of copper(II) ion in 0.1M perchloric acid was found to be quasi-reversible, because the logarithmic plot showed a curve.

The reduction of the cupric ion in a perchloric acid solution gives a one-step wave, but in a solution containing Triton X-100, a non-ionic surface-active substance, it shows two step-waves. The first step-wave has a kinetic character and is very small in comparison with the second step-wave. Kolthoff *et al.*[12] have shown that the kinetic current of this case is caused by the penetration of the copper(II) ion through the adsorbed film of Triton X-100. However, in a perchloric acid solution containing 0.05% Triton X-100 the penetration is negligibly small. This can be attributed to the extremely slow penetration of the cupric ion through the adsorbed film, because the film exhibits a very compact nature. Consequently, the reduction wave of the cupric ion in perchloric acid is slightly irreversible, *i.e.*, quasi-reversible, in the absence of Triton X-100, but in the presence of 0.05% Triton X-100 it becomes completely irreversible. That is, the second step-wave is "totally irreversible," and its half-wave potential at the ordinary DME is shifted about 0.5 V in the negative direction compared with the case of the absence of Triton X-100.[11]

The Determination of the Kinetic Parameters for the Second Step-wave. The observed waves were analyzed by applying Eq. (17); the results are shown in Fig. 2. It can be seen from the figure that the plot of log k_R *vs.* E yields a perfectly straight line. From the intercept of this line and its slope, the values of the rate constant, k°, at the standard potential of the copper(II)-copper amalgam and of αn were determined at four different tangential velocities of the rotating disk; the results are summarized in Table 1. As is shown in the table, the values of k° and αn are almost constant. They agree with the results obtained at the ordinary DME[12] by applying Koutecky's

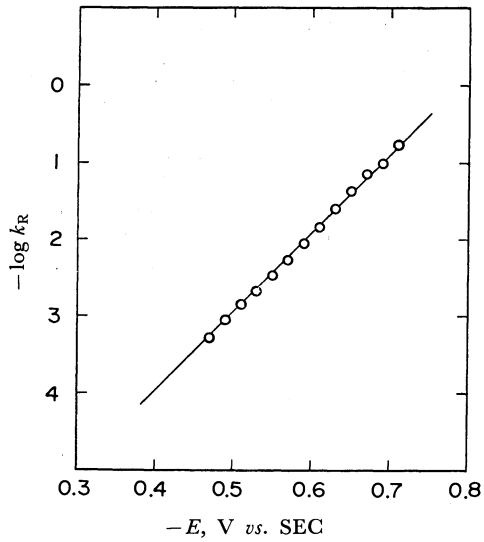

Fig. 2. The plots of $\log k_R$ *vs.* applied potential for the reduction of cupric ion in 0.1 M perchloric acid containing 0.05% Triton X-100; the tangential velocity of the rotating disk, 157.0 cm/sec.

Table 1. The values of the kinetic parameters for the electro-reduction of cupric ions in 0.1 M perchloric acid containing 0.05% Triton X-100 (at 25°C)

v, cm/sec	αn	$k°$, 10^{-9} cm/sec
94.2	0.59	4.0
125.6	0.59	3.8
157.0	0.59	4.7
188.4	0.59	4.2
Average	0.59	4.2
Standard deviation (%)	—	6.6

equation[7] and at the other electrode.[8]

The Difference in the Half-wave Potential at the DME and at the PMDCE. From Eq. (16), the half-wave potential, $(E_{1/2})_p$, at the PMDCE is given by:

$$(E_{1/2})_p = E° + \frac{RT}{\alpha nF} \ln \frac{1.64k°v^{1/6}}{D_O^{1/2}} + \frac{RT}{\alpha nF} \ln \left(\frac{d}{v}\right)^{1/2} \quad (18)$$

Equation (18) shows that the half-wave potential shifts gradually in the negative direction with an increase in the tangential velocity of the rotating disk. That is, the plots of the half-wave potential *vs.* the logarithmic value of the tangential velocity yield a straight line; the slope of this line is given as:

$$-\frac{\Delta(E_{1/2})_p}{\Delta \log v} = \frac{29.5}{\alpha n} \text{(mV)} \quad (19)$$

On the other hand, the half-wave potential at the DME is given as follows:[7,11,13]

$$(E_{1/2})_D = E° + \frac{RT}{\alpha nF} \ln \frac{0.87k°}{D_O^{1/2}} + \frac{RT}{\alpha nF} \ln t^{1/2} \quad (20)$$

The half-wave potential at the DME varies with the drop time, t.

From Eqs. (18) and (20), the difference between the half-wave potentials at the DME and at the PMDCE is given by:

$$\Delta E_{1/2} = (E_{1/2})_D - (E_{1/2})_p$$

$$= \frac{RT}{\alpha nF} \ln 0.53 \left(\frac{D_O}{\nu}\right)^{1/6} \cdot \left(\frac{v \cdot t}{d}\right)^{1/2} \quad (21)$$

Table 2 shows the slope of the plots of the half-wave potential *vs.* the logarithmic value of the tangential velocity in the range from 94.2 to 188.4 cm/sec, and also the difference between the half-wave potential at the DME and at the PMDCE.

Table 2. Difference in the half-wave potential at DME and at PMDCE, and the slope of the plots of the half-wave potential *vs.* the tangential velocity of the rotating disk

v, cm/sec	Difference $\Delta E_{1/2}$, mV		Slope $-\frac{\Delta(E_{1/2})_p}{\Delta \log v}$, mV	
	Obsd	Calcd	Obsd	Calcd
94.2	61	69	>57	>57
188.4	86	84		

Drop time of DME: 3.0 sec at −0.80 V *vs.* SCE in 0.1 M $HClO_4$+0.05% Triton X-100.

It can be seen from the table that the experimental values of the slope and of the difference in the half-wave potential are in good agreement with the values calculated from Eqs. (19) and (21) respectively.

The author wishes to express his thanks to Professors Nobuyuki Tanaka of Tohoku University and Tokuro Ozaki of Shizuoka University for their helpful discussion, and to Miss Yoko Komiya for her earnest assistance.

Oxytocin Analogues Containing No Disulfide Bond. I. Synthesis of the Lactam of L-Tyrosyl-L-isoleucyl-L-glutaminyl-L-asparaginyl-L-α-aminosuberyl-L-prolyl-L-leucylglycine Amide*[1]

Akiko KOBAYASHI, Satoe HASE, Reiko KIYOI and Shumpei SAKAKIBARA

(Received December 10, 1968)

The synthesis of an analogue of deamino-oxytocin, which has an ethylene linkage in place of the disulfide bond, was studied in order to establish a general route for the synthesis of such cyclic peptides. L-α-Aminosuberic acid (Asu) was converted to the *N*-benzyloxycarbonyl-ω-*t*-butyl ester and was used as the starting substance for the synthesis. A protected octapeptide was prepared by the step-by-step elongation method with the respective benzyloxycarbonylamino acid active esters, and finally the cyclization of the ω-carboxyl group of the Asu-residue to the amino group of the tyrosyl-residue was achieved by the trifluoroacetate method. The final product showed obviously higher oxytocin-like activities than those reported previously. The conditions for the syntheses of *p*-nitrophenyl and 2,4,5-trichlorophenyl trifluoroacetates were improved during the investigation.

The twenty-membered ring in oxytocin is known to be essential for biological activities. This was demonstrated by comparing the biological activities of [mercaptoacetyl[1]]-oxytocin,[1] which has a 19-membered ring, and of [γ-mercaptobutyl[1]]-oxytocin,[1,2] (21-membered ring), with the activity of [β-mercaptopropionyl[1]]-oxytocin[3] (20-membered ring). Although [β-mercaptopropionyl[1]]-oxytocin, which is called deamino-oxytocin, is well known to show rather higher biological activities than the natural oxytocin, both the 19- and 21-membered derivatives have almost no biological activity. Furthermore, the hydrogenation of oxytocin to linear dihydro-oxytocin results in the disappearance of hormonal activities.[4]

Recently, two analogues of deamino-oxytocin (deamino-carba[1]-oxytocin and deamino-dicarba-oxytocin), in which the disulfide bonds are replaced by a methylene-thio and an ethylene linkage respectively, were synthesized by Rudinger and Jošt.[5,6] These compounds were found to exhibit weaker but definite oxytocin-like activities. These facts can be interpreted by supposing that the disulfide linkage in the 20-membered ring of oxytocin is important as a structural element, but is not essential for biological activities.

Studies along the same lines have been carried out independently in our laboratory to elucidate the relationship between the steric structure of the hormone molecule and its biological activities.[7] In the present paper, a new method for the synthesis of deamino-dicarba-oxytocin will be described. This synthesis was investigated in order to establish a widely-applicable procedure for the syntheses of such series of cyclic peptides.[8] Although Jošt and Rudinger had already succeeded in synthesizing this compound,[6] their method is not considered to be generally applicable.

Before starting the synthesis of this peptide, the *N*-benzyloxycarbonyl-L-α-aminosuberic acid ω-*t*-butyl ester (III) was synthesized from *N*-benzyloxycarbonyl-L-α-aminosuberic acid (I)[9] as is shown in Scheme 1. The first step from I to II represents an application of the Nefkens method.[10] The compound, III, thus obtained was coupled with L-prolyl-L-leucylglycine amide[11] by the tri-

fluoroacetate method[12] because the *p*-nitrophenyl ester of compound III was not crystallizable and the application of the dicyclohexylcarbodiimide method seemed undesirable. The benzyloxycarbonyl group in the tetrapeptide amide (IV) was removed by catalytic hydrogenolysis, and the peptide chain was elongated by the step-by-step addition of the respective benzyloxycarbonylamino acids using the active-ester method, as is shown in Scheme 2. The *t*-butyl ester group in the side chain of α-aminosuberic acid was removed by trifluoroacetic acid before the removal of the benzyloxycarbonyl group of isoleucyl heptapeptide amide (VIII). The protected octapeptide amide (IX) was converted to its 2,4,5-trichlorophenyl ester (X) in a good yield using the trifluoroacetate method.[12] The cyclized compound, XI, was then obtained smoothly by the catalytic hydrogenolysis of a dilute solution of X in dimethylformamide. The unchanged compound was removed by passing the aqueous solution successively through Dowex 50 and Amberlite IR-45 columns; the neutral fraction obtained was then purified by passing it through a column of Sephadex G-25, giving a homogeneous product. No dimer or polymer was detectable in the eluate after gel-filtration, as is shown in Fig. 1. The homogeneity of the final product was confirmed by paper chromatography, paper electrophoresis, amino acid analysis, and elemental analysis of the lyophilizate. The molecular weight of this compound was estimated by sedimentation equilibrium methods to be about 850, which indicates that this is a monomeric cyclic peptide.

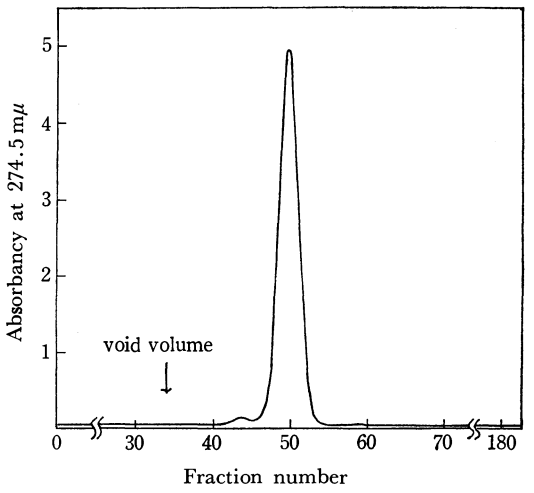

Fig. 1. Gel-filtration of the final product on Sephadex G-25. See Experimental part for details of conditions.

The biological activities of the product, XI, were determined as shown in Table 1; these values were compared with those reported by Rudinger and Jošt for the same compound[6] and with those of oxytocin and of deamino-oxytocin. This compound was found, contrary to the reported values, to

show about one-tenth of the biological activities of deamino-oxytocin and to show a faint rat-pressor activity, as has been reported previously.

The syntheses of *p*-nitrophenyl and the 2,4,5-trichlorophenyl trifluoroacetates used as reagents in the trifluoroacetate method were improved during the investigation. Formerly these compounds were synthesized by refluxing the respective hydroxy compounds with trifluoroacetic anhydride for a long time,[12] but there was a danger that the reaction was incomplete. In the present study the reaction was carried out under pressure in a sealed bottle and at a higher temperature. This improved procedure should be useful in routine work in the preparation of all other trifluoroacetate reagents.

Experimental[13]

Removal of the Benzyloxycarbonyl Group by Catalytic Hydrogenolysis. Hydrogen was gently bubbled through a solution of the benzyloxycarbonyl compound at room temperature, using palladium black as the catalyst. The completion of the reaction was checked by thin-layer chromatography using Merck's silica-gel G. The solvent systems used for the chromatography were chloroform: methanol: acetic acid (95: 5 : 3 v/v) for IV and V, and *n*-butanol : acetic acid: water (4 : 1 : 1 v/v) for VI, VIII, and X. After the reaction, the catalyst was removed by filtration, the filtrate was concentrated under reduced pressure, and the residue was subjected to the next reaction.

***p*-Nitrophenyl Trifluoroacetate.** A mixture of *p*-nitrophenol (75 g, 0.538 mol), benzene (130 m*l*), and trifluoroacetic anhydride (190 g, 0.904 mol) was placed in a glass pressure-vessel which had been sealed by a screw cap equipped with a Teflone stopper. The mixture was heated to 80—90°C in an oil bath for about 8 hr. Then the yellow solution was concentrated to a residue under reduced pressure, taking care to exclude moist air from the mixture. The trace of trifluoroacetic acid present was removed in a desiccator over phosphorus pentoxide *in vacuo*, and the residue was used without further purification. The yield of the reagent was quantitative.

2,4,5-Trichlorophenyl Trifluoroacetate. A mixture of 2,4,5-trichlorophenol (1.98 g, 0.01 mol), benzene (2 m*l*), and trifluoroacetic anhydride (4.20 g, 0.02 mol) was heated for 8 hr in a sealed bottle as has been described above. The reaction mixture was then concentrated under reduced pressure, and the residue was used without further purification.

Benzyloxycarbonyl-L-α-aminosuberic Acid α-Benzyl Ester (II). A solution of benzyloxycarbonyl-L-α-aminosuberic acid (I)[9] (32.3 g, 0.1 mol) and triethylamine (14 m*l*, 0.1 mol) in dimethylformamide (20 m*l*) was treated with benzyl bromide (18.8 g, 0.11 mol) at room temperature. After 20 hr, water (200 m*l*) was added to the reaction mixture, and the oil which separated was extracted twice with ethyl acetate. The combined extract was washed with water and then with a 5 % sodium bicarbonate solution. (The unchanged I was extractable from the ethyl acetate solution with a sodium bicarbonate solution, but the main product, II, remained in the ethyl acetate under the present conditions. The unchanged I was recovered from the sodium bicarbonate solution after acidification with hydrochloric acid; wt, 8.5 g). The ethyl acetate solution, which should contain the sodium salt of II, was converted to the ether solution, and the main product was extracted three times with a sodium carbonate solution. The acidification of the carbonate solution with 6 N hydrochloric acid afforded an oily material which was extracted with ethyl acetate. After washing with water and drying over sodium sulfate, the solution was concentrated under reduced pressure; the oily residue was crystallized by the addition of petroleum ether; yield of crude material, 24.8 g, mp 66.5—69°C. Recrystallization from ethyl acetate and petroleum ether (1 : 2 v/v) gave 19.5 g of needles (yield, 47 %). When a correction is made for the unchanged I, the yield is 64 %; mp 71—72°C, $[\alpha]_D^{25}$ −19.1° (*c* 3, dimethylformamide).

Found: C, 66.64; H, 6.82; N, 3.40 %. Calcd for $C_{23}H_{27}O_6N$: C, 66.81; H, 6.66; N, 3.39 %.

Bis(benzyloxycarbonyl-L-α-aminosuberic Acid ω-*t*-Butyl Ester) Piprazine Salt (III). A solution of compound II (20.7 g, 0.05 mol) in methylene chloride (100 m*l*) was allowed to react with isobutylene (50 m*l*) in the presence of sulfuric acid (0.5 m*l*) as the catalyst. After 2 days at room temperature, the reaction mixture was poured into 5 % sodium carbonate, and then the methylene chloride and the excess isobutylene were removed by distillation under reduced pressure. The oily material which appeared was extracted into ether,

13) All the melting points were determined by the capillary method, and all are given as uncorrected values. All products were dried over phosphorus pentoxide *in vacuo* at room temperature unless otherwise noted.

and the ether solution was washed successively with 5 % sodium carbonate, water, 0.2N hydrochloric acid, and water. The concentration of the solution under reduced pressure yielded an oily material (α-benzyl ω-*t*-butyl esters of L-α-aminosuberic acid), which was then dissolved in acetone (200 m*l*) and saponified with 1 N sodium hydroxide (50 m*l*) for 3 hr at 0—5°C. The reaction mixture was neutralized with 1 N hydrochloric acid, the acetone was removed under reduced pressure, ether was added to the residual solution, and the main product was transferred to the aqueous layer by the addition of 5 % sodium carbonate. The neutral material was removed with ether, and the aqueous layer was acidified with 1 N hydrochloric acid; then the oil which separated was extracted with ethyl acetate. The concentration of the extract gave an oily material, which was then neutralized with piperazine hexahydrate (4.4 g, 0.0225 mol) in acetone. The solution was concentrated under reduced pressure, and the residue was flushed twice with toluene to remove the water. The trituration of the dried residue with ethyl acetate yielded crude crystals which were recrystallized from ethyl acetate; yield, 16.0 g (76 %); mp 130—131°C, $[\alpha]_D^{28}$ −2.7° (*c* 2, acetic acid). This material was dried over phosphorus pentoxide *in vacuo* at 80°C for 10 hr for analysis.

Found: C, 62.28; H, 8.17; N, 6.57 %. Calcd for $C_{41}H_{68}O_{12}N_4$: C, 62.54; H, 8.11; N, 6.63 %.

Benzyloxycarbonyl-ω-*t*-butyl-L-α-aminosuberyl-L-prolyl-L-leucylglycine Amide (IV). The benzyloxycarbonyl-L-α-aminosuberic acid ω-*t*-butyl ester (7 mmol) was extracted from III (2.96 g) with ethyl acetate by shaking with 1N hydrochloric acid; the ethyl acetate layer was then dried over sodium sulfate. The dried solution was concentrated to a syrup, which was dissolved in pyridine (4 m*l*). The solution was then treated with *p*-nitrophenyl trifluoroacetate (1.97 g, 8.4 mmol) at room terperature for 3 hr. A large amount of water was added to the reaction mixture, and the oily material thus precipitated was extracted with ethyl acetate; the ethyl acetate extract was washed with 0.5N hydrochloric acid and water successively, and dried over anhydrous sodium sulfate. The concentration of the dried solution left an oily residue which corresponded to the *p*-nitrophenyl ester of the starting material; the oily residue was allowed to react with L-prolyl-L-leucylglycine amide[11] (2.39 g, 8.2 mmol as the hemihydrate) in dimethylformamide (7 m*l*) for 2 days at room temperature. The addition of water gave a precipitate which was taken into ethyl acetate. The organic layer was washed successively with 1N aqueous ammonia, water, 1N hydrochloric acid, and water. Finally the solution was dried over sodium sulfate and concentrated to a residue which was crystallized by the addition of ether; yield, 4.08 g (90 %), mp 108—110°C, $[\alpha]_D^{13}$ −66.8° (*c* 2, ethanol). This material was dried for analysis at 80°C for 2 hr over phosphorus pentoxide *in vacuo*.

Found: C, 61.19; H, 8.37; N, 10.82%. Calcd for $C_{33}H_{51}O_8N_5$: C, 61.37; H, 7.96; N, 10.85 %.

Benzyloxycarbonyl-L-asparaginyl-ω-*t*-butyl-L-α-aminosuberyl-L-prolyl-L-luecylglycine Amide (V). The benzyloxycarbonyl group in compound IV (5.83 g, 9 mmol) was removed in ethanol by catalytic hydrogenolysis. The catalyst was then removed by filtration, and the filtrate was concentrated under reduced pressure. The residue was allowed to react with the benzyloxycarbonyl-L-asparagine *p*-nitrophenyl ester[14] (3.48 g, 9 mmol) for 2 days in dimethylformamide at room temperature. The product was then precipitated by the addition of a large amount of ethyl acetate, and the precipitate was collected by filtration. Recrystallization from 90 % ethanol yielded an analytically-pure product; yield, 6.10 g (89 %), mp 212°C (decomp.), $[\alpha]_D^{27}$ −47.7° (*c* 1, dimethylformamide). This material was dried for analysis at 80°C for 2 hr over phosphorus pentoxide *in vacuo*.

Found: C, 58.70; H, 7.70; N, 12.92%. Calcd for $C_{37}H_{57}O_{10}N_7$: C, 58.55; H, 7.56; N, 12.90%.

Benzyloxycarbonyl-L-glutaminyl-L-asparaginyl-ω-*t*-butyl-L-α-aminosuberyl-L-prolyl-L-leucylglycine Amide Monohydrate (VI). The benzyloxycarbonyl group of compound V (6.20 g, 8.2 mmol) was removed by catalytic hydrogenation in a mixture of dioxane (70 m*l*) and water (35 m*l*). After the reaction, the catalyst was removed by filtration, and the filtrate was concentrated under reduced pressure. The residue was flushed several times with toluene, and then dissolved in dimethylformamide (18 m*l*). The benzyloxycarbonyl-L-glutamine *p*-nitrophenyl ester[14] (3.93 g, 9.8 mmol) was added to the solution, and the mixture was allowed to react overnight at room temperature. The reaction product was precipitated by the addition of excess ethyl acetate, and the precipitate was collected by filtration and recrystallized from 90% ethanol; yield, 5.85 g (81 %), mp 207—208°C (decomp.), $[\alpha]_D^{26}$ −45.7° (*c* 1, dimethylformamide). This material was dried for analysis at 80°C *in vacuo* for 3 hr over phosphorus pentoxide.

Found: C, 55.71; H, 7.51; N, 13.88 %. Calcd for $C_{42}H_{65}O_{12}N_9 \cdot H_2O$: C, 55.68; H, 7.45; N, 13.90%.

Benzyloxycarbonyl-L-isoleucyl-L-glutaminyl-L-asparaginyl-ω-*t*-butyl-L-α-aminosuberyl-L-prolyl-L-leucylglycine Amide Monohydrate (VII). The benzyloxycarbonyl group was removed from compound VI (5.70 g, 6.3 mmol) by catalytic hydrogenolysis in a mixture of dioxane and water (50 m*l*+50 m*l*). The catalyst was then removed by filtration, and the filtrate was concentrated under reduced pressure. The residue was flushed several times with toluene, and the oil which remained was allowed to react with the benzyloxycarbonyl-L-isoleucine *N*-hydroxysuccinimide ester[15] (3.44 g, 9.5 mmol) for one day at room temperature in dimethylformamide (25 m*l*). The product was precipitated by the addition of ethyl acetate; the precipitate was recrystallized from hot 90 % ethanol. The yield was 5.66 g (88 %); mp 225°C (decomp.), $[\alpha]_D^{27}$ −41° (*c* 1, dimethylformamide). This material was dried for analysis at 80°C *in vacuo* for 10 hr over phosphorus pentoxide.

Found: C, 56.93; H, 7.63; N, 13.71 %. Calcd for $C_{48}H_{76}O_{17}N_{10} \cdot H_2O$: C, 56.56; H, 7.71; N, 13.74 %.

Benzyloxycarbonyl-L-isoleucyl-L-glutaminyl-L-asparaginyl-L-α-aminosuberyl-L-prolyl-L-leucylglycine Amide Monohydrate (VIII). Compound VII (1.00 g, 0.98 mmol) was dissolved in trifluoroacetic acid (20 m*l*), and the solution was allowed to stand for 3 hr at room temperature. Then the solvent was removed by evaporation under reduced pressure, and the

residue was triturated with ether and reprecipitated from hot 90 % ethanol; yield, 0.75 g (80 %), mp 212—214° (decomp.), $[\alpha]_D^{17}$ −44.2° (*c* 1, dimethylformamide). This material was dried for analysis at 80°C *in vacuo* for 10 hr over phosphorus pentoxide.

Found: C, 54.99; H, 7.36; N, 14.64 %. Calcd for $C_{44}H_{68}O_{13}N_{10}\cdot H_2O$: C, 54.87; H, 7.33; N, 14.55%.

Benzyloxycarbonyl-*O*-benzyl-L-tyrosyl-L-isoleucyl-L-glutaminyl-L-asparaginyl-L-α-aminosuberyl-L-prolyl-L-leucylglycine Amide Monohydrate (IX) The benzyloxycarbonyl group was removed from VIII (710 mg, 0.74 mmol) by catalytic hydrogenation in a mixture of dioxane (30 m*l*) and water (10 m*l*). The catalyst was removed by filtration; the filtrate was concentrated under reduced pressure, and the residue was dried by flushing with toluene. This residue was dissolved in dimethylformamide (40 m*l*), and the *N*-benzyloxycarbonyl-*O*-benzyl-L-tyrosine *N*-hydroxysuccinimide ester[16] (557 mg, 1.1 mmol) was added together with *N*-ethylmorphorine (0.1 m*l*, 0.98 mmol). The mixture was allowed to react for 2 days at room temperature, and then the product was precipitated by the addition of excess ethyl acetate and collected by filtration. Reprecipitation from 90 % ethanol afforded an amorphous powder; yield, 660 mg (73 %), mp 231—232°C (decomp.), $[\alpha]_D^{28}$ −36.4° (*c* 0.74, dimethylformamide). This material was dried over phosphorus pentoxide *in vacuo* at 80°C for 10 hr before analysis.

Found: C, 59.42; H, 7.28; N, 12.78%. Calcd for $C_{60}H_{83}O_{15}N_{11}\cdot H_2O$: C, 59.24; H, 7.04; N, 12.66%.

Benzyloxycarbonyl-*O*-benzyl-L-tyrosyl-L-isoleucyl-L-glutaminyl-L-asparaginyl-ω-2, 4, 5-trichlorophenyl-L-α-aminosuberyl-L-prolyl-L-leucylglycine Amide Monohydrate (X). 2,4,5-Trichlorophenyl trifluoroacetate (733 mg, 2.5 mmol) was added to a suspension of IX (304 mg, 0.25 mmol) in a mixture of dimethylformamide (4 m*l*) and pyridine (2 m*l*), and the mixture was allowed to react for 3 hr at 50°C; gradually the suspension changed to a clear solution during the reaction. A large amount of ether was added to the solution to precipitate the product, which was then collected by filtration. Reprecipitation from dimethylformamide and ether yielded 327 mg of the product; yield 95 %, mp 231—232°C (decomp.), $[\alpha]_D^{23}$ −27.8° (*c* 0.75, dimethylformamide). This material was dried over phosphorus pentoxide at 60°C *in vacuo* for 10 hr before analysis.

Found: C, 56.70; H, 6.27; N, 11.12; Cl, 7.79 %. Calcd for $C_{66}H_{84}O_{15}N_{11}Cl_3\cdot H_2O$: C, 56.79; H, 6.21; N, 11.04; Cl, 7.62 %.

Lactam of L-Tyrosyl-L-isoleucyl-L-glutaminyl-L-asparaginyl-L-α-aminosuberyl-L-prolyl-L-leucylglycine Amide Monohydrate (XI). The benzyloxycarbonyl and benzyl ether groups were simultaneously revomed from X (419 mg, 0.3 mmol) by catalytic hydrogenolysis in dimethylformamide (300 m*l*). The catalyst was removed by filtration, the filtrate was concentrated under reduced pressure, and the residue was dissolved in water (27 m*l*). The trichlorophenol formed was removed by extraction with ether. The aqueous solution was passed successively through columns (1.0 × 10 cm) of Dowex-50 X2 (100—200 mesh, H^+ form) and of Amberlite IR-45 (100—200 mesh, OH^- form). These columns were washed with water, and the effluent and washing were combined and lyophilized to obtain 97.4 mg (33 %) of the cyclized product. A portion (75 mg) of this product was dissolved in 1N acetic acid (1.5 m*l*), and the solution was applied to a column of Sephadex G-25 (fine, 1.8 × 170 cm). The flow rate of the solvent, 1N acetic acid, was 25 m*l* per hr. Fractions of 5 g each were collected, and peptide was detected by the UV-absorption at 274.5 mμ, as is shown in Fig. 1. The effluents in tubes No. 48 to 52 were pooled and lyophilized; wt, 62 mg (recovery 83 %). This material was found to be homogeneous, as judged by paper electrophoresis and by paper chromatography. Rf: 0.66 (*n*-butanol : acetic acid : water, 4 : 1 : 1 v/v) and 0.74 (*n*-butanol : acetic acid : pyridine : water, 15 : 3 : 10 : 6 v/v). These spots were located with Pauli's reagent. Reported Rf's: 0.50 and 0.70 respectively with the above solvent systems.[6] $[\alpha]_D^{18}$ −98.4° (*c* 0.46, water).

Found for sample dried at 60°C for 10 hr *in vacuo*: C, 54.39; H, 7.13; N, 15.26 %. Calcd for $C_{45}H_{69}O_{12}N_{11}\cdot 2H_2O$: C, 54.45; H, 7.42; N, 15.53 %.

Found for sample dried at 90°C for 18 hr *in vacuo*: C, 55.01; H, 7.12; N, 15.95 %. Calcd for $C_{45}H_{69}O_{12}N_{11}\cdot H_2O$: C, 55.48; H, 7.35; N, 15.82 %. Ratio of amino acids after acid hydrolysis: $Tyr_{1.00}$, $Ile_{1.01}$, $Glu_{0.97}$, $Asp_{1.00}$, $Asu_{1.01}$, $Pro_{1.02}$, $Leu_{1.00}$, $Gly_{0.97}$. A mol wt of about 850 was estimated by the sedimentation equilibrium method: 0.1 M NaCl solution was used as the solvent, and a partial specific volume of 0.73 was assumed for the calculation. Calcd mol wt: 956.

The authors wish to express their gratitude to Dr. Sho Yoshida of the University of Tokyo and to Dr. Tadao Okada of Yoshitomi Pharmaceutical Ind. for determining the biological activities of the synthetic peptides, and to Dr. Kinji Kakiuchi of Osaka University for his determination of the molecular weight by the sedimentation equilibrium method.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 3496—3498 (1969)

Constitution of Mucilage from *Ulva Conglobata*. I. Separation of Rhamnobiose Derivative by Partial Methanolysis

Kiyo MITA

Home Economics, Hiroshima Women's University, Hiroshima

(Received February 19, 1969)

Partial methanolysis of the mucilage from *Ulva conglobata* gave methyl α-L-rhamnoside (29.07%), methyl α-D-xyloside (7.04%) and methyl α-D-glucoside (5.13%). Separation of a new disaccharide (methyl α-L-rhamnobioside, 3.4%) from methanolysate was achieved chromatographically. The biose was attacked by maltase but not by emulsin. The results and infrared spectrum show that the rhamnobiose derivative consists of rhamnose units linked by α-link.

It was shown[1] that an acid hydrolysis of the mucilage from *Ulva conglobata* collected in Saga prefecture gave L-rhamnose, D-xylose and D-glucose as neutral constituents and D-glucuronic acid and sulfuric acid as acidic constituents.

The present investigation was to determine the manner of the linkages of these constituents in the polysaccharide molecule.

Percival *et al.*[2-7] have studied water-soluble sulfated polysaccharides which contain glucose, galactose, mannose, arabinose, xylose, rhamnose and uronic acid residues, from *Caulerpa filiformis*, *Acrosiphonia centralis*, *Cladophora rupestvis*, *Ulva lactuca*, *Enteromorpha compressa*, *Codium fragile*, *Chaetomorpha capillaris*. Furthermore, partial hydrolysis of the above mucilages led to the isolation of 3-*O*-β-D-xylopyranosyl-D-xylose, 4-*O*-α-D-glucopyranosyl-D-glucose, 4-*O*-D-xylopyranosyl-L-rhamnose, 4-*O*-D-glucopyranosyl-L-rhamnose and 4-*O*-glucuronosyl-L-rhamnose-2-sulfate.

Partial methanolysis was conducted by refluxing the suspension of the mucilage in a methanolic hydrogen chloride (1%) for 2 hr. The methanolysate was treated with a barium hydroxide solution (0.3 N) to effect saponification. The neutral methanolysate passed through a cation- and anion exchange resins was subjected to charcoal chromatography, which led to the isolation of methyl α-L-rhamnoside (29.07%), methyl α-D-xyloside (7.04%), methyl α-D-glucoside (5.13%), a mixture of methyl glycosides of disaccharides (5.5%) and methyl glycosides of oligosaccharides (32.5%).

The mixture of methyl glycosides of disaccharides was further resolved into its components by chromatography on a powdered filter paper column (Table 2). Fraction III-a in Table 2 gave only L-rhamnose by acidic hydrolysis. The fraction was not attacked at all by emulsin but by maltase. The results are very interesting because methyl α-L-rhamnobioside has not yet been isolated from natural substance and its synthesis has not been reported.[8]

Barker *et al.*[9,10] have studied structures of carbohydrates by means of IR spectra and reported that α-anomers give absorption at 844±8 cm^{-1} and β-anomers at 891±7 cm^{-1}. This seems to be one of the C–H deformation modes. The absorption bands are observed in all saccharides. Judging from the absorption band at 850 cm^{-1}, the isolated rhamnobioside appears to be α-anomer.

The IR spectrum of xyloside fraction indicated the presence of hydroxy groups from the absorption bands at 3400 and 1100—1000 cm^{-1} and α-anomer from the absorption band at 740 cm^{-1} (type 3 of pyranose ring). The IR spectrum of glucoside fraction also identified as α-anomer from the absorption bands: 3400, 1100—1000 (OH), 840 (type 2a of pyranose ring) and 745 cm^{-1} (type 3 of pyranose ring). Furthermore, these α-anomers were identified by direct comparison of the melting

point, the specific rotation and the IR spectrum with authentic samples.

Experimental

Materials. The mucilage was obtained from *Ulva conglobata* (collected in Saga prefecture) as described in the previous paper.[11] All reagents were of analytical or practical grade. Reagents of practical grade were purified by recrystallization and distillation. All melting points are uncorrected.

Apparatus. The IR spectra were obtained with KBr disk on a Hitachi EPI-S2 infrared spectrophotometer.

Partial Methanolysis of the Mucilage. Powdered mucilage (20 g, moisture 12.2 %, ash 17.6 %) was swelled in a 1 % methanolic hydrogen chloride solution (300 m*l*) at room temperature for 12 hr and then refluxed for 2 hr. After filtration, the insoluble substance (7.0 g) was dried *in vacuo* at 40°C and refluxed again with a 1 % methanolic hydrogen chloride solution (200 m*l*) for 2 hr and then filtered. Finally, the insoluble substance (1.85 g) was washed with methanol and dried *in vacuo*.

All filtrates and washings were combined and neutralized with silver carbonate. After filtration, the filtrate was evaporated to a syrup (22.3 g) *in vacuo* at 40°C. This was saponified at 60°C for 2 hr with a 0.3 N barium hydroxide solution (350 m*l*), and excess barium hydroxide was neutralized with carbon dioxide. After filtration, the filtrate was evaporated to a syrup (18.05 g).

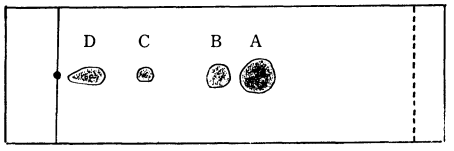

Fig. 1. Paper chromatogram of the neutral fraction of methanolysates.
Solvent system is *n*-butanol : ethanol : water : ammonia = 40 : 10 : 49 : 1 (v/v).[13]
A: methyl α-L-rhamnoside
B: methyl α-D-xyloside
C: methyl α-D-glucoside
D: unknown

Separation of the Neutral Methanolysate. The saponified syrup was dissolved in water (10 %) and the aqueous solution was allowed to pass through columns (3×40 cm) of Amberlite IR 120 (H form; 210 m*l*) and then Amberlite IR 45 (OH form; 210 m*l*). Both columns were washed with water (5 *l*) at a flow rate of 200 m*l*/hr. The combined eluates and washings were evaporated in order to obtain the neutral syrup (8.45 g); $[\alpha]_D^{30}$ −21.4° (*c* 1.5, water), OCH_3 15.31 %. The neutral fraction from the methanolysates gave four distinct colored spots with R_f values 0.10 (D: orange brown), 0.43 (C: orange brown), 0.55 (B: violet blue) and 0.64 (A: orange, main) on a paper chromatogram with *o*-aminophenol reagent,[12] as shown in Fig. 1.

Adsorption Chromatography for the Neutral Methanolysate. The neutral methanolysate (8.0 g) was dissolved in water (72 m*l*), placed on a charcoal-Celite 545 (1 : 1 w/w) column (5×34 cm) and eluted successively with water and then aqueous ethanol (2, 5, 7.5, 15 and 30 %) at room temperature according to the method of Whistler.[14]

The eluates were measured for specific rotation and chromatographed on papers. The chromatograms were sprayed with *o*-aminophenol[12] and potassium periodate-potassium permanganate reagents.[15] The results are summarized in Table 1.

Separation and Identification of Methyl α-D-Xyloside, Methyl α-L-Rhamnoside and Methyl α-D-Glucoside. Fraction I in Table 1 gave three distinct spots on a paper chromatogram: R_f 0.64 (orange; corresponding to methyl α-L-rhamnoside), 0.55 (violet-blue; corresponding to methyl α-D-xyloside) and 0.43 (brown-orange; corresponding to methyl α-D-glucoside).

Fraction I (2.7 g) was further separated through a charcoal-Celite 545 column (2×35 cm), water being used as a mobile phase. Each eluate was examined by specific rotation and then chromatographed on paper. The eluates gave the same specific rotation and R_f values were combined and then evaporated to dryness. They were identified as follows.

Methyl α-D-Xyloside: The xyloside fraction (white solid, 1.05 g) was dissolved in methanol-acetone (1 : 3

v/v) on heating and then filtered. The filtrate gave white crystals (1.0 g), $[\alpha]_D^{22.8}$ +143.96° (*c* 2.7, water), mp 103.5°C and identified as methyl α-D-xyloside by means of mixed melting point and comparison of the IR spectrum (KBr): 3400, 1100—1000 (OH), 740 cm^{-1} (type 3 of pyranose ring) with that of the authentic sample.

Found: OCH_3, 18.55 %. Calcd for $C_5H_9O_4(OCH_3)$: OCH_3, 18.9 %.

Methyl 2,3,4-Tri-O-acetyl-α-L-rhamnopyranoside: After dissolving the methyl α-L-rhamnoside fraction (1.1 g) in pyridine (10 m*l*), acetic anhydride (20 m*l*) was added. After 24 hr the solution was dropped into ice water and the white solid (0.88 g) separated was filtered. Recrystallization from aqueous-methanol (1 : 2 v/v) gave white crystals, $[\alpha]_D^{14.4}$ −8.10° (*c* 0.29, methanol), mp 84—85°C (lit 86—87°C),[16] identified as methyl 2,3,4-tri-*O*-acetyl-α-L-rhamnopyranoside by means of mixed melting point and comparison of the IR spectrum (KBr): 1745, 1375 and 1225 cm^{-1} (OAc), 850 cm^{-1} (type 2a of pyranose ring) with the authentic sample.

Found: OCH_3, 18.00%. Calcd for $C_6H_{11}O_4(OCH_3)$: OCH_3, 17.4%.

Methyl α-D-Glucoside: The glucoside fraction (white solid: 0.58 g) was dissolved in methanol-acetone (1 : 2 v/v) on heating and then filtered. The filtrate gave white crystals (0.55 g) mp 163—164°C, $[\alpha]_D^{28.0}$ +150.30° (*c* 0.24, water) which recrystallized from the same mixed solvent. The crystals were identified as methyl α-D-glucoside by means of mixed melting point and comparison of the IR spectrum (KBr): 840 cm^{-1} (type 2a of pyranose ring), 745 cm^{-1} (type 3 of pyranose ring) with that of the authentic sample.

Found: OCH_3, 15.40%. Calcd for $C_6H_{11}O_5(OCH_3)$: OCH_3, 15.97%.

Separation and Identification of Methyl α-L-Rhamnobioside. A solution (3 m*l*) of *n*-butanol-water (6 : 1 v/v) containing fraction III (0.5 g) was chromatographed on a column (2×50 cm) of cellulose powder with *n*-butanol saturated with water according to the method of Hough[17] and the eluates (5 m*l* each) were collected automatically and analyzed by means of specific rotation and paper chromatography. The eluates containing the same components were combined, and then *n*-butanol was distilled off *in vacuo*. The residues dried on pottassium hydroxide in a dessiccator gave white crystals.

TABLE 2. CHROMATOGRAPHIC SEPARATION OF FRACTION III ON CELLULOSE POWDER

Fraction	Eluate No.	Yield (g)	R_f value
III-a	51— 58	0.11	0.31
III-b	59—100	0.33	0.31, 0.24
III-c	101—110	0.04	0.24

Fraction III-a in Table 2 recrystallized from methanol-water (4 : 1 v/v) gave needles, mp 123—125°C, $[\alpha]_D^{22.5}$ −16.0° (*c* 2.0, water), R_f 0.31 (orange brown by *o*-aminophenol reagent).

Found: C, 48.11; H, 7.39 %. Calcd for $C_{13}H_{24}O_9$: C, 48.14; H, 7.40 %.

Found: OCH_3, 8.89%. Calcd for $C_{12}H_{21}O_8(OCH_3)$: OCH_3, 9.56%.

Fraction III-a was hydrolyzed with 0.1 N sulfuric acid solution (5 m*l*) in a boiling water bath for 1 hr, neutralized with barium carbonate and then filtered. The filtrate was vacuum evaporated and chromatographed. It gave only rhamnose spot (R_f 0.37).

Enzymic Hydrolysis of Fraction III-a. Fraction III-a (20 mg) was hydrolyzed with β-glucosidase (emulsin, 0.1 g) in an acetic acid-sodium acetate buffer solution (pH 4.1) at 30°C in a water bath for 1 hr. After filtration, the filtrate was chromatographed on paper. The R_f value did not change at all before treatment with β-glucosidase. However, Fraction III-a gave rhamnose by hydrolysis with maltase in a phosphoric buffer solution (pH 6.4) at 37°C for 1.5 hr.

Fractions III-b and III-c in Table 2 were hydrolyzed with 0.1 N sulfuric acid solution as Fraction III-a and then chromatographed. The hydrolysates from both fractions gave two spots corresponding to xylose and rhamnose by paper chromatography.

The author is indebted to Professor T. Matsuura of Hiroshima University for his continued advice and encouragement, to Professor C. Araki and Dr. K. Arai of Kyoto Tech. University for their helpful discussion and generous gift of the authentic samples.

The Diels-Alder Reactions of Polychloro-2,4-cyclohexadienones

Kenichi SOMEKAWA,* Taku MATSUO** and Sanetada KUMAMOTO*

* *Department of Applied Chemistry, Faculty of Engineering, Kagoshima University, Kamoike, Kagoshima*
** *Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Hakozaki, Fukuoka*

(Received March 10, 1969)

2,3,4,5,6,6-Hexachloro-, 2,3,4,6,6-pentachloro-, and 2,4,6,6-tetrachloro-2,4-cyclohexadienones were found to undergo Diels-Alder reactions when the compounds were heated with such dienophiles as acrylic acid, methyl acrylate, methyl vinyl ketone, acrylonitrile, and ethyl vinyl ether. It was concluded, chiefly through analysis of these NMR spectra, that the reactions proceed stereospecifically to give a series of 7-substituted and polychlorinated bicyclo-[2.2.2]oct-5-en-2-ones, which is in agreement with the endo rule. The stereospecificity of these adducts does not, however, agree with the results of calculations by means of the perturbation method.

The Diels-Alder reaction is one of the most popular and useful reactions for organic chemists.[1] Accordingly, a number of theoretical studies have been made on the various problems concerning the reaction mechanism.[2] The arguments, however, have not been settled in many respects.[3] One of the most important questions is the nature of the factor that determines the final orientation between the diene and dienophile.[4,5] Most recently, Herndon and Hall have made a quantitative prediction, on the basis of the second-order perturbation calculations, on the relative reactivities and adduct structures in several competitive Diels-Alder reactions.[6] In that case, both the dienes and the dienophiles have been assumed to be axially symmetric and planar molecules. The predictions are in fairly good agreement with the experimental results. It may be worthwhile, then, to test the applicability of Herndon and Hall's method to the Diels-Alder reaction, where neither component is a symmetrical molecule. In the present experiment, unsymmetrical molecules were chosen both as the dienophiles and as the dienes. In relation to the choice of the compound, it should be mentioned here that the Diels-Alder reactions easily proceed, in spite of Woodward's prediction,[5] if a dienophile with an electron-donating substituent is added either to a polyhalogenated diene like haxachlorocyclopentadiene[7] or to an α,β-unsaturated, exocyclic carbon compound like dehydroindigo.[8] The diene components investigated here (Fig. 1) are polyhalogenated compounds, and all have an exocyclic carbonyl group in conjugation with the double bond. Thereupon, one would expect that the experimental results would not be in accordance with the theoretical predictions. Therefore, the structures of the adducts obtained were carefully investigated by means of their NMR spectra. Since the reactions were found to be stereospecific, the mechanisms were speculated about from various standpoints, such as the second-order perturbation energies and the steric hindrances in the course of the reactions.

ing method. 2,3,4,6-Tetrachlorophenol (16 g) was mixed with *t*-butyl hypochlorite[10] (11 g) at 0°C. The mixture was then kept at 40°C for 30 min, and the *t*-butanol thus produced, together with the excessive *t*-butyl hypochlorite, was removed under reduced pressure.[11] The remaining yellow liquid (18 g) was B (Found: C, 28.16; H, 0.60; Cl, 65.64%. Calcd for C_6HOCl_5: C, 27.56; H, 0.38; Cl, 66.02%. IR: $\nu_{C=O}=1718\ cm^{-1}$, NMR: $\delta_H=6.9$ ppm from TMS in the carbon tetrachloride solution). It is suspected, from the small NMR peak downfield from B, that B contains as impurities small amounts of 2,4,5,6,6-pentachloro-2,4-cyclohexadienone (B′) or 2,3,4,4,6-pentachloro-2,5-cyclohexadienone. Since, however, no Diels-Alder products of B′ were obtained, no further description of the properties will be made in this paper. 2,4,6,6-Tetrachloro-2,4-cyclohexadienone (C) was analogously prepared from 2,4,6-trichlorophenol (10 g) and *t*-butyl hypochlorite (10 g).[11] 11.5 g of the product were obtained; the properties were as follows:

Found: C, 31.70; H, 1.08; Cl, 60.43%. Calcd for $C_6H_2OCl_4$: C, 31.58; H, 0.88; Cl, 61.00%. $\nu_{C=O}=1715\ cm^{-1}$, $\delta_H=6.58$, 7.08 ppm, $J_{H-H}=2.0$ cps. The compounds used as the dienophiles were extra-pure-grade chemicals supplied by the Tokyo Kasei Ind. Co., Ltd., and were further purified before the experiments. The purities of the samples were proved by gas chromatography to be above 95%.

Procedure. In general, the reaction was carried out by refluxing a nearly equimolar mixture of a diene and a dienophile on a water bath. The precipitated product was separated from the remaining solution and was recrystallized from one of the following solvents: toluene, benzene, petroleum benzine, or petroleum ether. When the product was an oily substance, column-chromatography on activated alumina was used to purify the material. The reaction conditions, yields, mp, analytical data, and characteristic IR absorption bands of the pure products are summarized in Tables 1, 2, and 3. Chromatographic separations of the filtrates were also carried out on columns of alumina or on TLC of silica gel (Wakogel B-5) in order to detect possible isomeric by-products. No products other than those in Table 1 were, however, detected. Moreover, the products which were given by slow reactions at room temperature were identical with those in Table 1, indicating that no isomerizations had occurred under the present experimental conditions (Table 1).

Measurement and Analysis of NMR Spectra. The spectra were obtained by the use of a Varian A-60 analytical NMR spectrometer. The concentrations of the samples were kept at 0.5—5 mol %, and a small amount of TMS was dissolved in the solution as an internal reference. The obtained spectra were analyzed by the use of an electronic computer.*1 The computer programs for calculating the energies and the intensities for ABC[12] and ABCD[13] spin systems were made by the present authors.*2 The calculations were repeated until the calculated energy and intensity came within ±0.3 cps and ±10 % respectively of the observed values.

Results and Discussion

The results of elementary analyses for the reaction products are summarized in Table 2. The results are in good agreement with the values calculated for the rational formula which correspond to 1 : 1 adducts of the reactants. The characteristic IR absorption bands of the products are shown in

Table 3. The presence of a double bond is suggested (third column). However, there are no signs of the absorption bands due to the mono-substituted ethylenes. The sharacteristic absorption bands of the substituents (Z), on the other hand, are clearly observed, as are given in the table from the fourth column to sixth. As may be seen from the frequencies, the substituents are not likely to be conjugated with any unsaturated groups. The frequencies of the carbonyl absorption bands (1762—1771 cm^{-1}) in the second column are close to that of octachloro-3-cyclohexenone (1779 cm^{-1}).[14] Therefore, the presence of a polychloro-3-cyclohexenone ring is indicated.*[3] The above facts suggest strongly that the product is a 4+2 adduct which could be obtained by a Diels-Alder reaction between the polyhalogenated dienone and the monosubstituted ethylene.

In order to decide on the most probable structures for the adducts, the NMR spectra were carefully examined. Examples of the analyzed spectra are shown in Figs. 2—4. The chemical shifts (δ) and the coupling constants (J) thus obtained are summarized in Tables 4 and 5. As a consequence, the

*3 Carbonyl absorption bands are known to shift to frequencies higher by 10—25 cm^{-1} if a chlorine atom is attached to the carbon atom alpha to the carbonyl group.[15] Hence, the difference between the carbonyl absorptions of octachloro-3-cyclohexenone and those of the adducts in Table 3 may be reasonably explained as due to the difference in the number of alpha chlorine atoms.

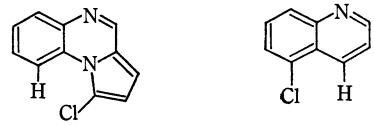
Fig. 5. The steric structures of adducts.

mutual orientation between the diene and the dienophile components in the adduct molecules were deduced to be as are shown in Fig. 5. The reasons will be described in detail below.

In the case of methyl acrylate adducts, one can clearly notice that the signals b and c of the adducts become increasingly complex upon the variation of the diene component from A to B (Figs. 2 and 3). The analysis shows that the proton H_D is almost equally coupled to H_B and H_C, but not to H_A (Table 5). The newly-appearing signals, d, in Fig. 3 should correspond to the proton at the 5-position of B, which should be found at the bridge head in the adduct molecule. Therefore, it may be suggested that the α-methine and β-methylene groups of the dienophile component are bonded to the 2- and 5-positions respectively of the diene component, B.

Similar arguments with the adduct obtained from C and methyl acrylate also indicate that the mutual orientation of the two components is the same as that in the case of B and methyl acrylate. In the case of the adduct obtained from A, one should notice at first that the coupling constants among the protons H_A, H_B, and H_C are almost the same as those in the adducts from B or C (Table 5). Therefore, the steric arrangements of these three protons may be expected to be the same among the three adducts. In addition, the replacement of the bridge head proton, H_D, with a chlorine atom, *i.e.*, the variation of the diene from B to A, is seen to have much greater effects on the chemical shifts of the protons H_B (+18.5 cps) and H_C (+23.5 cps) than on H_A (+2.2 cps), as is shown in Run 4 and Run 6 of Table 4. One may think, then, that the methylene group of the dienophile component is bonded to the 5-position of A. In other words, the orientation of the diene with respect to the dienophile component is the same between the adducts obtained from A, B, and C.

The signals for H_B invariably appear in a field lower by 34.2—55.6 cps than those for H_C in chloroform (Table 4). There may be two explanations for this nonequivalence of the geminal protons. Granting the configuration in Fig. 5 to be correct, one would expect that H_B would be considerably deshielded because it is very close (*ca.* 2.5 Å) to the chlorine atom alpha to the carbonyl group of the polychloro-3-cyclohexenone ring. There are a number of examples of such van der Waals shifts



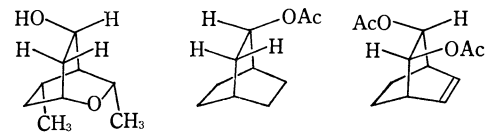
−60 cps[a] −29 cps[b]

Fig. 6. Van der Waals shifts induced by chlorines.
a) C. F. Raymond *et al.*, *J. Org. Chem.*, **29**, 2440 (1964).
b) F. A. L. Anet, *J. Chem. Phys.*, **32**, 1274 (1960).

(Fig. 6). The H_C proton, on the other hand, is shielded because of the anisotropy of the carbon-carbon double bond. The joint effect of these two factors seems to give a reasonable explanation of the observed difference between H_B and H_C.

The vicinal coupling constants for bicyclic systems similar to the compounds under investigation have been studied by several investigators. Some relevant examples are shown in Fig. 7. It is generally found in these examples that J_{cis} is larger than J_{trans}. Both of these coupling constants decrease with the electron-withdrawing property of the substituent (Z) attached to the ethylene group. The same could be said of the cases of bicyclo-[2.2.1]-heptane derivatives.[16] It is reasonable to expect that the vicinal coupling constants of the adducts under investigation will follow the same trend as those described above.

On this basis, it may be suggested that H_B and H_C are, respectively, at the *cis*- and *trans*-positions



J_{trans}=3.6[a] J_{trans}=2.6[b] J_{trans}=6.0[b]
J_{cis}=9.8 J_{cis}=8.2

Fig. 7. Vicinal coupling constants in bicyclo-[2.2.2]ring system.

J_{AB}=9.1—9.8, 8 (when Z=OC_2H_5)
J_{AC}=5.4—6.7, 3 (when Z=OC_2H_5)

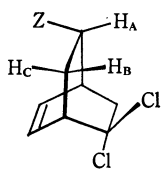

Fig. 8. Configuration.

16) K. L. Williamson, *J. Am. Chem. Soc.*, **85**, 516 (1963).

with respect to H_A (Fig. 8). This suggestion is further confirmed by observing the large vicinal coupling constant (9.1 cps) of the maleic anhydride adduct,[9a] where only *cis*-coupling might be expected to be present. The values for the geminal coupling constant (J_{BC}) and the long-range coupling constant (J_{AE}) are also resonable for this type of bicyclic compound.[17-19] The configuration which is in best agreement with the above discussion is thus concluded to be the one shown in Fig. 5.

Since the reaction products were found to be stereospecific, as has been described above, an attempt has been made to elucidate the reaction mechanism by the use of a simple molecular orbital method.*4 The charge densities in the electron systems of a diene, A, and a dienophile, methyl vinyl ketone (F), are shown in Fig. 9. On the basis of the charge densities of the two components (Fig. 9), the β carbon of the dienophile may be expected to be attracted to the cardon atom at the 2-position of the cyclohexadienone system. Since the experimental result is just the opposite of this prediction, however, the electrostatic attraction in the ground state is not considered to play an important role in the reaction mechanism. If the reaction proceeds *via* a one-step, cyclic, concerted mechanism,[6] the relative preferences among several different geometries in the activated states may be compared by evaluating the stabilization energy for the interacting electron systems in each case. The stabilization energies were estimated by the second-order perturbation method for the three orientations shown in Table 6. The molecular planes of the diene and dienophile (below) were assumed to be parallel to each other.

Fig. 9. The charge density of 2,3,4,5,6,6-hexachloro-2,4-cyclohexadienone (A) and methyl vinyl ketone (F).

TABLE 6. STABILIZATION ENERGIES CALCULATED BY SECOND ORDER PERTURBATION METHOD (in β unit)

Inter-planar distance (Å)	Mutual orientations (*ortho-endo*)	(*ortho-exo*)	(*meta-endo*)
2.5	0.429	0.514	0.492
3.4	0.013	0.017	0.016

Geometries of A and F used for calculation.

A: O–C_1, 1.24Å; C_1–C_2, 1.43Å; C_2–C_3, 1.37Å; C_3–C_4, 1.45Å; C_4–C_5, 1.34Å; C–Cl, 1.76Å; $\angle OC_1C_2$, $\angle C_1C_2C_3$, $\angle C_2C_3C_4$, $\angle C_3C_4C_5$, 121°; $\angle CCCl$, 119.5°.

F: O–C_1, 1.24Å; C_1–C_α, 1.45Å; C_α–C_β, 1.34Å; $\angle OC_1C_\alpha$, $\angle C_1C_\alpha C_\beta$, 121°.

The calculations were made for the cases of two different interplanar distances, 3.4 and 2.5Å, and all π orbitals of the two components were taken into consideration.*5 The results are summarized in Table 6. The stabilization energies indicate that an *ortho-exo* addition is most favored. In actuality, however, *ortho-endo* adducts are produced exclusively. Thus, it is clear that Herndon and Hall's method is not powerful enough to cover all of the Diels-Alder reactions. For that matter, Woodward and Katz's simple method[20] can not be expected to give the answer, either.*6 The true cause of the formation of stereospecific products may be found either in steric factors or in electronic factors which can not be taken into consideration by simple molecular orbital calculation. Further investigation is being undertaken to solve this complex problem the results will be reported in later paper.

The authors are indebted to the members of the computing center at Kyushu University. Thanks are also due to Mr. Y. Kodera and Mr. M. Fukumitsu, who made careful measurements of the NMR spectra reported in this paper.

*6 Polychloro-2, 4-cyclohexadienones (A, B, and C) are characterized by their high electron affinities and ionization potentials. Therefore, the situation is just the opposite of the case which Woodward and Katz have presumed in their discussion. It may be worth mentioning, in this connection, that the diene reacts with cyclopentadiene, but not with maleic anhydride.

BULLETIN OF THE CHEMICAL SOCEITY OF JAPAN VOL. 42 3505—3508 (1969)

Studies of Phosphorylation. III. Selective Phosphorylation of Unprotected Nucleosides[1)]

Masaharu YOSHIKAWA, Tetsuya KATO and Tadao TAKENISHI

Central Research Laboratories, Ajinomoto Co., Inc., Kawasaki

(Received April 15, 1969)

During an investigation of the factors affecting the reaction of 2′,3′-*O*-isopropylidene nucleosides with phosphoryl chloride, trialkyl phosphates were found to be powerful accelerators and useful solvents for the phosphorylation. The addition of a trialkyl phosphate to a large excess of phosphoryl chloride was markedly effective in promoting the phosphorylation; further, the lower alkyl phosphates, such as trimethyl and triethyl phosphates, were able to replace the excessive amount of phosphoryl chloride as solvents. When unprotected nucleosides were treated with phosphoryl chloride in trimethyl phosphate, the corresponding 5′-phosphates were mainly produced, together with a small amount of highly-phosphorylated products, in good yields. On the contrary, the treatment of 5′-*O*-acetyl nucleosides in a similar manner gave the corresponding 2′(or 3′)-nucleotides in low yields. The formation of the 2′(or 3′)-phosphate was strongly inhibited by the addition of a small amount of water to the reaction mixture. Thus, the selective phosphorylation of unprotected nucleosides to the 5′-nucleotides in a one-step procedure was accomplished.

It has been reported, in a previous paper,[2)] that 5′-nucleotides can be conveniently prepared in high yields by the treatment of 2′,3′-*O*-isopropylidene nucleosides with a large amount of phosphoryl chloride in the absence of any organic solvent. When a small amount of water was added to posphoryl chloride prior to the reaction, the yield of nucleotides was very much increased.

A similar effect was also observed upon the addition of alcohols. The reaction of *t*-butyl alcohol with an excessive amount of phosphoryl chloride gives hydrogen phosphorodichloridate according to Eq. (1):[2)]

$$t\text{-}C_4H_9OH + POCl_3 \rightarrow t\text{-}C_4H_9Cl + HOP(O)Cl_2 \quad (1)$$

On the other hand, it has been reported that the reaction of a primary alcohol with phosphoryl chloride proceeds satisfactorily at a low temperature according to Eq. (2):[3)]

$$ROH + POCl_3 \rightarrow ROP(O)Cl_2 + HCl \quad (2)$$

Therefore, an alkyl phosphorodichloridate may be considered to function as a potential accelerator for the phosphorylation as well as hydrogen phosphorodichloridate.

In the presence of an excessive amount of an alcohol, this reaction is known to proceed further to form the dialkyl phosphorochloridate and the trialkyl phosphate. The accelerating effect of these compounds, particularly the latter, on the reaction rate has been studied and found to be positive, as will be discussed later. It has also been found that an excessive amount of phosphoryl chloride may be replaced by a trialkyl phosphate as a solvent.

The treatment of an unprotected nucleoside with phosphoryl chloride in a trialkyl phosphate gives the phosphorylated products in a high yield. Analysis of the products showed that the phosphorylation always occurred preferentially on the hydroxyl group at the 5′-position in nucleosides. The selective phosphorylation of an unprotected nucleoside with phosphoryl chloride in a trialkyl phosphate has already been briefly communicated.[1)] This paper will deal with an extensive study of the factors affecting the reaction of nucleosides with phosphoryl chloride and the phosphorylation of nucleosides in the presence of a trialkyl phosphate.

Results and Discussion

The effect of the addition of alcohols on the phosphorylation of 2′,3′-*O*-isopropylideneinosine with phosphoryl chloride is shown in Fig. 1. Although the yield of inosine 5′-phosphate was not affected by the addition of *t*-butyl alcohol, the yield was significantly decreased with an increase in the amount of methyl or of isopropyl alcohol. The disadvantage of the latter cases may be due to the production of a high concentration of hydrogen chloride according to Eq. (2). In order to eliminate the influence of hydrogen chloride, methyl phosphorodichloridate,

dimethyl phosphorochloridate and trimethyl phosphate were synthesized and added similarly to the phosphorylation mixture. Table 1 shows the results of the phosphorylation of 2',3'-*O*-isopropylidene nucleosides in the $POCl_3$-$(RO)_nPOCl_{3-n}$ systems. Although the reaction of a nucleoside with methyl phosphorodichloridate scarcely proceeds at all under these conditions, the phosphorylation of a nucleoside with phosphoryl chloride was markedly promoted in the presence of the phosphorodichloridate. The increasing effect of those additives on the reaction rate is arranged in the order: $ROP(O)Cl_2 < (RO)_2P(O)Cl < (RO)_3PO$. An especially interesting result observed here was a sharp increase in the rate of phosphorylation with an increase in the amount of trimethyl phosphate. 2',3'-*O*-Isopropylidene nucleosides were moderately soluble in anhydrous trimethyl phosphate. Thus, an excessive amount of phosphoryl chloride was advantageously replaced by trimethyl phosphate as the solvent.

In a first stage, the reaction mixture of a 2',3'-*O*-isopropylidene nucleoside and phosphoryl chloride was a suspension in trimethyl phosphate. After the reaction had been completed, the suspension containing the corresponding 5'-phosphorodichloridate became clear. Thus, the phosphorylation reactions were successfully achieved; the results are summarized in Table 2. In the case of the xanthosine derivative, the phosphorylation was insufficiently, as in the previous method.

For the reaction, triethyl phosphate and trimethyl phosphate are both suitable as solvents, but the former is less effective than the latter. The reaction rate is affected by the size of the alkyl groups in trialkyl phosphates, as is shown in Fig. 2, particularly in the phosphorylation of 2',3'-*O*-isopropylideneguanosine with phosphoryl chloride. That is, the yield of guanosine 5'-phosphate decreases as the alkyl group becomes larger. This phenomenon is supposed to be concerned primarily with the solubility and the reactivity of the nucleoside derivative. The more reactive 2',3'-*O*-isopropylideneinosine was well phosphorylated also in tri-*n*-butyl phosphate, but a prolonged reaction time was required for its completion in comparison with the phosphorylation in trimethyl phosphate.

In contrast with this excellent ability of trialkyl phosphates, the analogous trialkyl phosphorothioates and triaryl phosphates do not fulfil these conditions. The utilization of other polar organic

solvents possessing S→O, N→O, or C=O groups, such as dialkyl sulfates, dialkyl sulfites, dialkyl sulfones, dialkyl sulfoxides, alkyl nitrates, alkyl nitrites, dialkyl carbonates, and alkyl ketones, gave generally unsatisfactory results.

Trialkyl phosphates were also attractive solvents in the phosphorylation of nucleosides with pyrophosphoryl tetrachloride. The yields of 5'-nucleotides were slightly better than those with phosphoryl chloride, particularly in the case of 2',3'-*O*-isopropylideneguanosine.

An attempt at the selective phosphorylation of unprotected nucleosides was made for the purpose of establishing the manufacturing method of 5'-nucleotides. In the previous experiments, nucleoside 5'-phosphates have been produced together with the 2'(or 3')-phosphate[4] or the 2'(or 3'), 5'-diphosphate,[5] and the yields have been reported to be low.[6] The method reported by Ikehara involving the use of 2,6-lupetidyl phosphorodichloridate is better, but it is still not satisfactory in either yield or selectivity.[7]

When treated with phosphoryl chloride in trialkyl phosphates, naturally-occurring nucleosides gave the corresponding nucleotides in nearly quantitative yields without any prior protection of the 2'- and 3'-hydroxyl groups; the products consisted mainly of the 5'-phosphates, accompanied by a small amount of such highly-phosphorylated products as the 2'(or 3'),5'-diphosphate and 2',3',5'-triphosphate (Table 3). Thus, this reaction proceeds selectively at the 5'-position. The competitive phosphorylation of the 2'(or 3')-hydroxyl group was strongly inhibited in the acidic medium; this was easily achieved by the addition of an adequate amount of water to the mixture, as is shown in Table 3. This result is of interest in comparison with the result reported by Barker and Foll[4] that the addition of a small amount of water tends to decrease the mole ratio of the 5'-phosphate in the products of the phosphorylation of adenosine with phosphoryl chloride in pyridine. As another example, 5'-*O*-acetylinosine was phosphorylated to give the corresponding 2'(or 3')-nucleotide in only a 22% yield without any prior treatment with water; moreover, it did not react under the acidic conditions, as has been described above.

Thus, the synthesis of 5'-nucleotides was emancipated from such complicated treatments as the prior protection of the nucleoside sugar, the extreme dehydration of the solvent required in the case of pyridine, or the dissolution of a nucleoside in a solvent before the phosphorylation.

It should be noted that xanthosine, which is generally unaffected by any chemical phosphorylation, was easily converted to the corresponding 5'-phosphate. Thus, this method can be applied generally to the synthesis of naturally-occurring ribonucleotides and offers a convenient procedure for industrial purposes.

In comparison with phosphoryl chloride, pyrophosphoryl tetrachloride yielded large amounts of the 2'(or 3'),5'-di- and 2',3',5'-triphosphates together with the 5'-phosphate because of its stronger reactivity. In this case, the highly-phosphorylated products were proved to be *O*-phosphate in the sugar moiety by comparison with the ultraviolet absorption spectra of the corresponding 5'-phosphate. The improvement of this technique may make an effective synthesis of a nucleoside diphosphate possible.

For the synthesis of deoxynucleoside 5'-phosphates, the phosphorylation of 3'-*O*-acetyl 2'-deoxynucleosides has been adopted, usually *via* 3'-*O*-acetyl 5'-*O*-trityl 2'-deoxynucleosides.[8] The direct treatment of thymidine with dibenzyl phosphorochloridate, followed by hydrogenolysis, has been reported to produce mainly thymidine 3',5'-diphosphate, together with some 5'-phosphate.[9] However, the phosphorylation of deoxynucleosides at a lower temperature, carried out by the use of the method described above, gave mainly the cor-

responding 5′-phosphates (Table 3).

Most nucleosides are fairly soluble in trimethyl and triethyl phosphates, while those nucleosides are insoluble or only slightly soluble in pyridine, which has been used hitherto. The effect of trialkyl phosphates may be, at least partly, due to the higher solubility of nucleosides in these phosphates. This idea is supported by the difficulty of the phosphorylation in tri-*n*-butyl phosphate, in which the solubility of nucleosides is fairly low. Interaction between a trialkyl phosphate and the phosphorylating reagent may also play a role. It is considered that the interaction between a trialkyl phosphate and phosphoryl chloride is possible; an ionized structure may be formed according to the following equation:

$$(RO)_3PO + POCl_3 \rightarrow [(RO)_3P\text{-}O\text{-}\overset{\overset{O}{\|}}{P}Cl_2]^+ \; Cl^-$$

The ionized structure may be postulated as an active phosphorylating agent.

Experimental

Identification of the Products on the Paper Chromatograms. The location of the nucleoside phosphate on the chromatograms was detected by means of ultraviolet light, and it was identified by a comparison of the R_f value with that of an authentic sample. Ribonucleoside diphosphate was confirmed further by a negative periodate-benzidine test, and deoxyribonucleoside phosphate by a Hanes and Isherwood spray.[10]

Phosphorylation of 2′,3′-O-Isopropylidene Nucleoside. *Method A.* Into a cold mixture of freshly-distilled phosphoryl chloride and an alcohol or some other additive, such as methyl phosphorodichloridate, dimethyl phosphorochloridate, or trimethyl phosphate, a 2′,3′-*O*-isopropylidene nucleoside was added with stirring. After a predetermined period the reaction mixture was poured into ether, and then the precipitate was separated by centrifuge. The product was dissolved carefully in ice water, and the aqueous solution was adjusted to pH 1.5 with a sodium hydroxide solution and warmed at 70°C for 30—45 min. The resulting solution was analyzed by the paper chromatographical method described in a previous report.[2]

Method B. After a few moles of phosphoryl chloride (or pyrophosphoryl tetrachloride) per mole of a nucleoside had been mixed with a trialkyl phosphate, a 2′,3′-*O*-isopropylidene nucleoside was added to the cold mixture and the mixture was stirred. The reaction mixture was then treated in the same way as in Method A.

Selective Phosphorylation of an Unprotected Nucleoside. An unprotected nucleoside was phosphorylated according to Method B. An adequate amount of water was added to a mixture of phosphoryl chloride and a trialkyl phosphate before the addition of a nucleoside. The phosphorylation mixture was hydrolyzed in ice water after ether treatment and was then immediately analyzed by the paper chromatographical method.

The authors wish to thank Mr. Koji Kusashio and Mr. Mitsuru Sakuraba for their kind assistance in the experiment.

Photochromic Color Change of the Dimer of Triphenylimidazolyl at Low Temperatures

Koko MAEDA and Taro HAYASHI*1

Department of Chemistry, Faculty of Science, Ochanomizu University, Bunkyo-ku, Tokyo

(Received April 23, 1969)

The photochromic dimer of triphenylimidazolyl which is one of two dimers obtained by oxidation of triphenylimidazole shows photochromism at temperatures between room temperature and −196°C in solutions and in a solid state. At temperatures higher than about −20°C the photochromic color in solutions is reddish-purple, at temperatures lower than about −150°C the color is bluish-purple and at intermediate low temperatures the photochromic color does not appear. Absorption spectrum and ESR measured with the change of temperature showed variations corresponding to the change of color. The photochromic color in a solid state was light reddish-purple above about −70°C and bluish-purple at −196°C. The mechanism of the color change was discussed in connection with that of the photochromism at room temperature and the results obtained from spectroscopic and ESR studies.

We obtained a photochromic compound[1] and a piezochromic compound[2] by oxydation of 2,4,5-triphenylimidazole. The photochromic compound exhibited photochromism and thermochromism in solid state[3] as well as in solutions at temperatures near room temperature. It was confirmed by kinetic studies with absorption spectrum and ESR, that the compounds are dimers of triphenylimidazolyl[4,5] and that photochromism, thermochromism and piezochromism are due to the dissociation of the dimers into triphenylimidazolyl radical caused by irradiation, heating and grinding. White and Sonnenberg[6] reported that the photochromic and piezochromic dimers are isomers and the piezochromic dimer shows thermochromism at temperatures lower than room temperature, and discussed the interconversion between two dimers and radical.

We found that a solution of the photochromic dimer in benzene exhibited photochromism within a wide range of temperatures from room temperature down to −196°C, except for temperatures between about −20°C and −150°C.[7] At temperatures higher than about −20°C, the photochromic color is reddish-purple and at temperatures lower than about −150°C bluish-purple. In the present paper, the results of studies on a reversible color change of the photochromic dimer in solutions and in a solid state at temperatures between room temperature and −196°C under irradiation or in the dark are presented.

Experimental

Materials. The piezochromic dimer of 2,4,5-triphenylimidazolyl (piezo-dimer) $C_{42}H_{30}N_4$ and its isomer, the photochromic dimer (photo-dimer), were prepared according to the method given in a previous report.[1] Piezo-dimer prepared by the oxidation of 2,4,5-triphenylimidazole was almost colorless fine powder, mp 191—192°C and photo-dimer obtained by recrystallization of piezo-dimer from benzene was light yellow fine crystals, mp 199—201°C.

The photochromic dimer of 2-*p*-chlorophenyl-4,5-diphenylimidazolyl (photo-dimer(Cl)), $C_{42}H_{28}N_4Cl_2$, almost colorless fine crystals, mp 219—220°C and its isomeric piezo-dimer (piezo-dimer (Cl)), almost colorless powder, mp 205—207°C, were prepared according to previous reports.[1,5]

Measurements. Absorption spectra were measured with a Hitachi recording spectrophotometer, EPS 2 type.

The electron spin resonance absorption was measured with an ESR instrument of the Japan Electron Optics Laboratory, JES 3B type (100 kc modulation), with a variable temperature controller, JES VT 2 type.

As an exciting source the 365 mμ light obtained from a Toshiba 100 watt super high-pressure mercury lamp combined with a Toshiba glass filter UV D1B was used.

Results and Discussion

Reversible Changes of Color and ESR of Photo-dimer in Solutions with Temperature. Change of the color of photo-dimer in solutions with the temperatures from room temperature to −196°C was observed under irradiation and without irradiation. ESR signal intensity of the solution showed variation corresponding to the change of color.

When a reddish-purple benzene solution of photo-dimer obtained by irradiation of a light yellow solution at room temperature was cooled under irradiation, the color gradually faded and disappeared at about −20°C. When the resulting frozen solution was further cooled to about −150°C, it remained colorless. However, with further cooling to −196°C the solution showed a bluish-purple color which became more intense with the fall of temperature. When the bluish-purple solution was warmed from −196°C to room temperature under irradiation, a color change reverse to that on cooling was observed.

Figure 1 shows variation of the ESR signal intensity, which corresponds to the change of the color with temperature under irradiation.

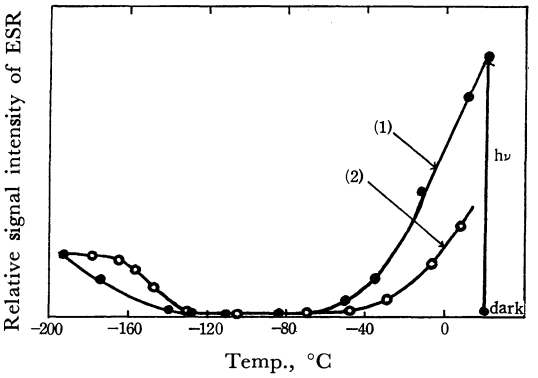

Fig. 1. Variation of the ESR signal intensity of photo-dimer in deaerated benzene under irradiation.

When the reddish-purple benzene solution of photo-dimer was cooled from room temperature without irradiation, the color gradually faded and disappeared at about −20°C. The resulting frozen solution remained colorless on further cooling to −196°C. When the colorless frozen solution was warmed from −196°C without irradiation, a color change reverse to that on cooling was observed. On irradiation at −196°C, the colorless frozen solution

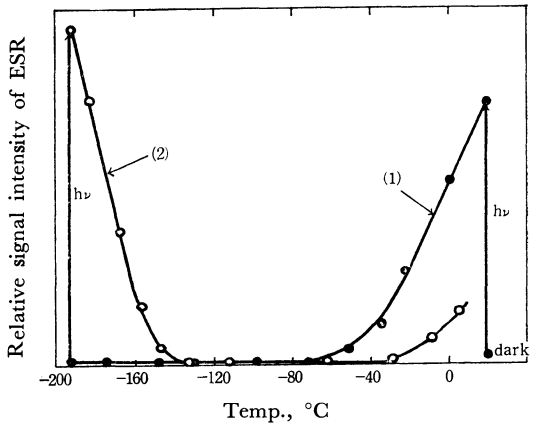

Fig. 2. Variation of the ESR signal intensity of photo-dimer in deaerated benzene.
(1) with cooling to −196°C in the dark after irradiation at room temperature
(2) with warming to room temperature in the dark after irradiation at −196°C
Concn.: 6.8×10^{-5} mol/l

turned deep bluish-purple. By warming the solution to room temperature without irradiation, the color showed a change similar to that observed with warming under irradiation. Figure 2 shows variation of the ESR signal intensity which corresponds to the change of color with temperature in the dark.

When the light yellow solution of photo-dimer in benzene prepared in dim light at room temperature was cooled to −196°C without irradiation, color and ESR did not appear during cooling. On irradiation at −196°C, the frozen solution showed an intense bluish-purple color and a strong ESR signal.

In solutions of photo-dimer in other solvents, changes of color and ESR signal intensity similar to those in benzene were observed with the change of temperature between room temperature and −196°C. On cooling from room temperature, the temperature at which the reddish-purple color disappears differs to some extent with solvents, and the temperature at which a bluish-purple color appears seems to be about −150°C, irrespective of solvents. In a solvent of a relatively high melting point, such as benzene and dioxane, the temperature at which the reddish-purple color disappears is about −20°C and the solutions are frozen. However, in a solvent of a relatively low melting point, such as ethanol and toluene, the temperature at which the color disappears is about −70—−100°C, and the solutions mostly remain unfrozen. The fact suggests that freezing favors the disappearance of the reddish-purple color at a relatively high temperature.

Figure 3 shows the variation of the ESR signal measured in EPA with the change of temperature.

The ERS signal measured at −196°C in the intense bluish-purple solutions of benzene and EPA showed three pairs of signals at 3120—3375 gauss

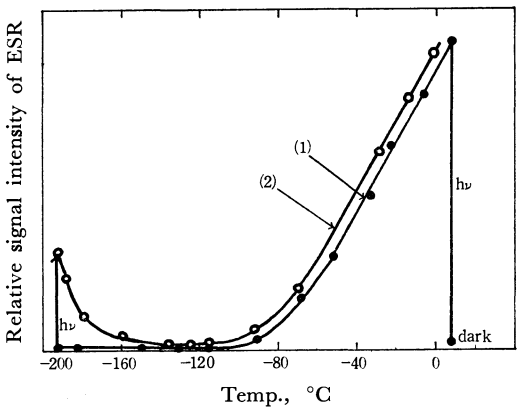

Fig. 3. Variation of the ESR signal intensity in deaerated EPA.

(1) with cooling to −196°C in the dark after irradiation at room temperature
(2) with warming to room temperature in the dark after irradiation at −196°C

Concn.: 4.5×10^{-5} mol/*l*

and a single peak signal at 1750 gauss as well as a strong signal at 3250 gauss.

The intensity of the bluish-purple color and the ESR siganls observed at −196°C did not diminish at −196°C after irradiation was cut off. With irradiation of an infrared light at −196°C the intensity of the ESR signal decreased.

The rate of formation of triphenylimidazolyl radical under irradiation with different intensities of light in benzene at −196°C was measured by means of ESR. As a signal intensity of the radical was assumed to be directly proportional to the concentration of the radical, the rate of formation of the radical was measured from the rate of the increase of the signal intensity under irradiation with different intensities. The signal intensity was proportional to irradiation time. In Fig. 4, the rate of the radical formation measured in benzene is plotted against the intensity of the irradiation.

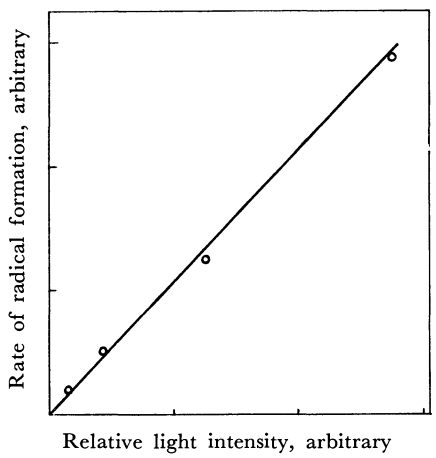

Fig. 4. Dependence of rate of the radical formation in benzene at −196°C, on light intensity.

From the dependence of the rate of the radical formation on the light intensity in Fig. 4, we see that the formation of the bluish-purple radical is a one-photon process.

When a benzene solution of photo-dimer (Cl) which showed a violet color with irradiation at room temperature was cooled under irradiation, the color gradually faded and disappeared at about −20°C. A light bluish-violet color appeared at about −150°C and became deeper with further cooling to −196°C. When the deep bluish-violet solution was warmed from −196°C to room temperature under irradiation, a change of color reverse to that with cooling was observed. Similar to the case of photo-dimer, the violet benzene solution of photo-dimer (Cl) obtained by irradiation at room temperature and the bluish-violet solution obtained by irradiation at −196°C showed ESR ($g=2.003$).

Change of Absorption Spectrum of Photo-dimer in EPA. Disappearance of the photochromic color at the intermediate low temperature range and appearance of the bluish-purple color by irradiation at temperatures below about −150°C were also studied by means of absorption spectrum.

An almost colorless solution of photo-dimer in

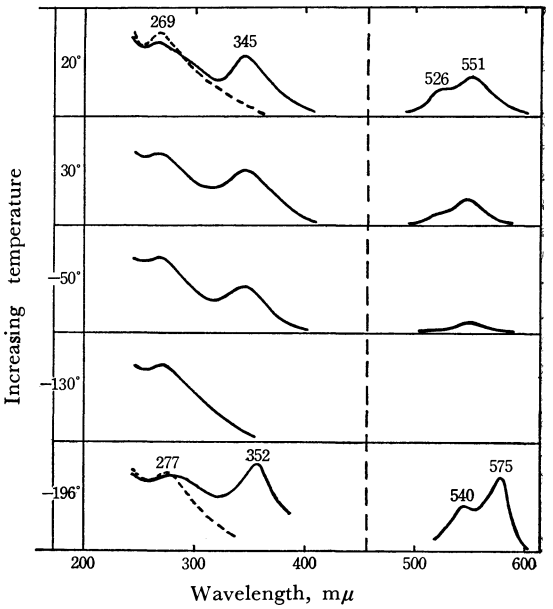

Fig. 5. Absorption spectra of photo-dimer in EPA at temperatures from −196°C to room temperature.

--- Before irradiation
—— After irradiation by a mercury lamp without a filter for 2 min at −196°C

Concn.: 2.54×10^{-5} mol/*l* for shorter than 400 mμ; 4.48×10^{-4} mol/*l* for longer than 400 mμ

EPA (4.48×10^{-4} mol/l) which was prepared in dim light at room temperature was frozen into a glassy state in a quartz cell (1 cm thick) by immersing it in liquid nitrogen in a Dewar provided with quartz windows. On irradiation of the glassy solution with a mercury lamp for 2 min from outside the Dewar, a bluish-purple color appeared. Absorption spectra were measured at several temperatures between −196°C and room temperature obtained by evaporation of liquid nitrogen. In Fig. 5, absorbance at a wavelength region shorter than 400 mμ is shown on a reduced scale.

A red shift of the absorption maxima at 345 and 551 mμ at room temperature to 352 and 575 mμ at −196°C corresponded to the change of color from reddish-purple to bluish-purple. With the fading of the bluish-purple color, the absorption band with λ_{max} 352 and 575 mμ gradually decreased to vanish at about −150°C, and the absorption band with λ_{max} 345 and 551mμ appeared at about −50°C. The band increased with further rise of temperature to room temperature. The maxima at 345 and 551 mμ agreed with those of a reddish-purple solution obtained by irradiation of photo-dimer in EPA at room temperature.

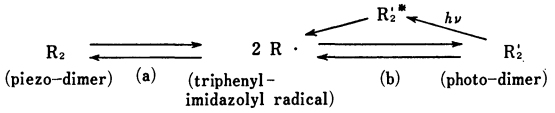
The violet solution of photo-dimer (Cl) in EPA obtained with irradiation showed absorption maxima at 356 and 568 mμ at room temperature. The bluish-violet solution obtained with irradiation at −196°C showed absorption maxima at 361 and 580 mμ. At temperatures between about −60 and −150°C, the absorption band in the visible region disappeared as in the case of photo-dimer.

Reversible Color Change of Piezo-dimer in Solutions with Temperature. A benzene solution of piezo-dimer which was prepared under dim light at room temperature showed an intense reddish-purple color due to triphenylimidazolyl radical formed by the dissociation of dimer.[6] When the reddish-purple solution was allowed to stand at room temperature without irradiation, the reddish-purple color gradually turned light yellow[1] by dimerization of triphenylimidazolyl radical to photo-dimer. The resulting solution is an equilibrium mixture of photo-dimer and a small amount of piezo-dimer.[6] When the temperature of the solution changed between room temperature and −196°C under irradiation, the solution showed a color change similar to that of the solution of photo-dimer.

When the reddish-purple solution of piezo-dimer in benzene was cooled without irradiation immediately after preparation, the reddish-purple color faded with the fall of temperature and disappeared at temperatures lower than about −20°C. The colorless solution showed no change of color even with irradiation at −196°C. When the colorless solution was warmed with or without irradiation from −196°C, a light reddish-purple color due to thermochromism of piezo-dimer appeared above about −20°C and became more intense at room temperature.

In other solvents piezo-dimer showed a color change similar to that in benzene observed with the change of temperature between room temperature and −196°C, with or without irradiation. The temperature at which the reddish-purple color disappeared was to some extent different with solvents, as the case of photo-dimer which was cooled under irradiation.

Mechanism of Riversible Color Change of Photo-dimer in Solutions. Disappearance of the photochromic reddish-purple color and ESR signal in benzene at temperatures between about −20 and −150°C is interpreted as follows. In solutions the following equilibria (a) and (b) take place between piezo-dimer, triphenylimidazolyl radical and photo-dimer.[6] Equilibrium (a) lies far on the side of the radical at room temperature and shifts toward piezo-dimer at temperatures lower than about −20°C,[6] while the position of equilibrium (b) lies far on the side of photo-dimer at room temperature and shifts further toward photo-dimer at low temperatures.



Under irradiation, the reddish-purple triphenylimidazolyl radical produced by photo-dissociation of photo-dimer dimerizes quickly to piezo-dimer at temperatures lower than about −20°C owing to a low activation energy for the dimerization of the radical to piezo-dimer.[6] As a result, the reddish-purple color and ESR signal do not appear within the temperatures between about −20 and −150°C.

Appearance of the photochromic bluish-purple color and ESR signal at temperature slower than about −150°C with irradiation is interpreted by means of the following mechanism.[8] At temperatures lower than −150°C, a part of the radicals produced by photo-dissociation remains unchanged in the solution, because it becomes difficult for the radical to surmount the barrier of the activation energy of dimerization at such low temperatures, although equilibria (a) and (b) lie very far on the sides of the two dimers. The concentration of the radical increases with the fall of temperature to −196°C, because the difficulty in surmounting the energy barrier increases at low temperatures. The intensity of ESR signal appearing at −196°C when the solution was cooled under irradiation, was weaker than that in the solution which was

8) T. Hayashi and K. Maeda, *Nippon Kagaku Zasshi (J. Chem. Soc. Japan, Pure Chem. Sect.)*, **90**, 325 (1969).

irradiated after cooling from room temperature in the dark, because photo-dimer isomerizes to piezo-dimer through the radical during cooling under irradiation.

The bluish-purple color appearing at temperatures lower than about −150°C is attributed to triphenylimidazolyl radical S·[9] which has a conformation different from that of the reddish-purple triphenylimidazolyl radical, R·. The red shift of the absorption maxima shows an increase in resonance stability due to the increase in coplanarity of a conjugated system in the radical S·. ESR signals at 3120—3375 gauss and 1750 gauss ($\Delta m = \pm 1$ and ± 2) in frozen solutions of photo-dimer irradiated at −196°C is likely to be a radical pair[9] of triphenylimidazolyl radical. On warming the deep bluish-purple benzene solution of photo-dimer from −196°C, the bluish-purple radical S· gradually surmounts the barrier of the activation energy for dimerization to a colorless dimer S_2 and the solution turns colorless above about −150°C. From the thermochromic behavior of the solution warmed near room temperature without irradiation, the structure of the dimer S_2 is likely to be the same as that of piezo-dimer. With the rise of temperature to about −20°C the dimer S_2 seems to be transformed into piezo-dimer.

The reddish-purple color which appeared as the solution was warmed above about −20°C under irradiation is attributed to triphenylimidazolyl radical, produced by the thermal dissociation of piezo-dimer isomerized from photo-dimer and also by the photo-dissociation of photo-dimer remaining unchanged in the solution.

The mechanism of the changes of color and ESR shown by the solutions of photo-dimer (Cl) with temperatures from room temperature to −196°C is similar to that of photo-dimer.

Changes of Photochromic Color and ESR of Photo-dimer in Solid State. When a light yellow solid of photo-dimer was irradiated at low temperatures such as −20°C or −70°C, it showed a light reddish-purple color similar to that of the photochromism[3] at room temperature. On irradiation, after cooling to −196°C without irradiation, the solid showed an intense bluish-purple color which scarcely faded after irradiation was cut off.

The color change of the solid with the change of temperature was studied with ESR. With cooling from room temperature to −196°C in the dark, no ESR signal appeared. On irradiation at room teaperature a weak ESR signal corresponding to the light reddish-purple color was observed. When the solid was cooled after irradiation was cut off, a small increase in signal intensity was observed at temperatures near −196°C as shown in Fig. 6. On irradiation of the solid at −196°C a very strong ESR signal (Fig. 6) appeared. It corresponds to the intense bluish-purple color. The signal intensity increased with the time of irradiation and scarcely decreased after irradiation was cut off. However, it decreased on warming a little in the dark or under irradiation, as shown in Fig. 6. With cooling of the solid from room temperature under irradiation, the small ESR signal increased slightly at temperatures below about −80°C, and with further cooling the signal increased considerably near −196°C.

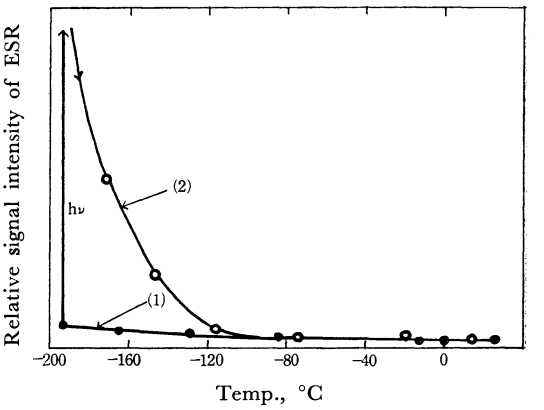


Fig. 6. Variation of ESR of the solid of photo-dimer.
(1) with cooling in the dark after irradiation at room temperature
(2) with warming in the dark after irradiation at −196°C

The light reddish-purple color appearing at temperatures above about −70°C is attributed to triphenylimidazolyl radical produced by photo-dissociation of photo-dimer.[3] The light color which corresponds to a small concentration of the radical seems to result from the recombination of the radical owing to difficulty of diffusion in the solid. Differing from the change in solutions, the color does not disappear at the intermediate low temperatures, because photo-dimer is not transformed into piezo-dimer owing to the retarded thermal motion of the radical. The bluish-purple color appearing at temperatures near −196°C is considered to be due to the triphenylimidazolyl radical S·, as in the solutions. Three pairs of ESR signals at 3160—3400 gauss and a single peak signal at 1750 gauss observed at −196°C are considered to be due to a radical pair similar to that formed in solutions. The large concentration of the radical corresponding to the strong ESR signal and deep bluish-purple color near −196°C might be attributed to a very small rate of dimerization at the low temperatures.

9) Presented at the Symposium on Photochemistry of the Chemical Society of Japan (Oct., 1968, Sendai) by T. Shida, K. Maeda and T. Hayashi; T. Shida, K. Maeda and T. Hayashi, This Bulletin, **42**, 3044 (1969).

The authors wish to express their hearty thanks to Dr. Hiroshi Midorikawa of the Institute of Physical and Chemical Research, Professor Saburo Nagakura of The University of Tokyo, Professor Hiroshi Tsubomura of Osaka University and Professor Katsumi Kimura of Hokkaido University for their kind help and to the Ministry of Education for the financial support granted this research.

Mechanism of the Solvent Effect in a Binary Solvent System on the Cationic Polymerization of *N*-Phenylethylenimine

Tsutomu KAGIYA and Tomizo KONDO

Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received May 10, 1969)

The effect of the binary solvent systems on the polymerization of *N*-phenylethylenimine with a formic acid catalyst was studied quantitatively. In an acetonitrile - acetone system composed of components with similar nucleophilicities but with very different dielectric constants, the polymerization rate increases with an increase in the dielectric constant of the binary solvent system. In an acetonitrile - *N*,*N*-dimethylacetamide system composed of components with very different nucleophilicities but with similar dielectric constants, on the other hand, the rate was markedly depressed by the addition of a small amount of *N*,*N*-dimethylacetamide with a large nucleophilicity. On the basis of these results, a mechanism of the solvent effect in a binary solvent system was proposed; the rate equation of the polymerization was expressed empirically as a function of both the dielectric constant of the binary solvent mixture and the nucleophilic equilibrium constant, and the concentration of the component.

It has been well known that the reaction rate is dependent on the nature of the solvent in an ionic polymerization. Little attention has, however, been paid to the quantitative study of the solvent effect on the ionic polymerization. It has been previously reported by the present authors[1] that, in the polymerization of *N*-phenylethylenimine with a formic acid catalyst in various solvents, the polymerization rate depended upon the nucleophilicity and the dielectric constant of the solvent, and that the initiation rate was not very much influenced by the nature of the solvent, whereas that of the propagation was remarkably affected.

As a continuation of our quantitative study of the solvent effect in the cationic polymerization of *N*-phenylethylenimine, we focused on the binary solvent system in the polymerization. The purpose of this report is to determine quantitatively the solvent effect in a binary mixture of the solvent on the polymerization of *N*-phenylethylenimine.

Experimental

The method of preparing and purifying *N*-phenylethylenimine has been described in our previous paper.[1] Guaranteed-reagent-grade formic acid was used without further purification. The acetonitrile, acetone, and *N*,*N*-dimethylacetamide were purified by the usual method.[2] The method of polymerization was also described in the previous paper.[1] The polymerization was carried out under the following conditions: monomer, 0.005 mol; catalyst, formic acid (4 mol% for monomer); total volume of solvent, 3 m*l*; temperature, 0°C. The measurement of the dielectric constant of the solvent was carried out at 25°C by the use of a Kikusui Electronic Industry 231 A-type LC meter.

Results and Discussion

Polymerization in Binary Solvent Systems. Both acetonitrile and acetone have similar nucleophilic equilibrium constants to methanol-d (K_D),[3,4] and a very different dielectric constant, (acetonitrile, K_D; 0.4,*1 ε; 37.5 and acetone, K_D; 0.6,*1 ε;

4) T. Kagiya, Y. Sumida and T. Inoue, *ibid.*, **41**, 773 (1968).

*1 The nucleophilic equilibrium constants of acetonitrile, acetone, and *N*,*N*-dimethylacetamide were obtained by the method of literature[4] on the basis of the $\Delta\nu_D$ values shown in Ref. 3.

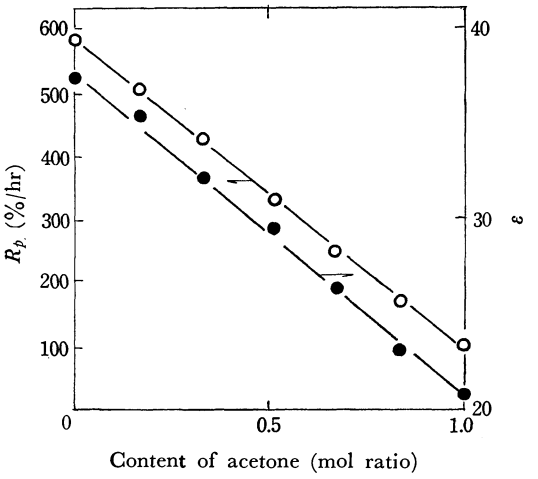

Fig. 1. Plots of polymerization rate (R_p) and the dielectric constant (ε) of the mixed solvent against the composition of the solvent in the acetonitrile - acetone binary solvent system.

20.7). As is shown in Fig. 1, the polymerization rate, defined as the ratio of the polymer yield (<20%) to the reaction time, and the dielectric constant of the binary solvent both decrease with an increase in the amount of acetone in the acetonitrile - acetone system. The rate increases with an increase in the dielectric constant of the binary solvent (Fig. 2). This fact suggests that, in the binary solvent system with a similar ability for nucleophilic solvation, the polymerization is mainly dependent upon the degree of ionic dissociation of the propagating species.

On the other hand, in the acetonitrile - *N*,*N*-dimethylacetamide (K_D*[1], 1.6; ε, 36.7) binary system,

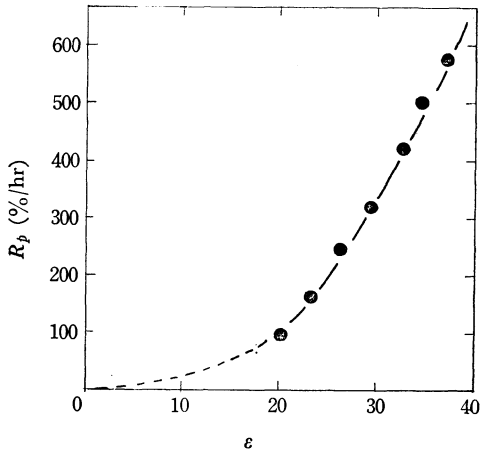

Fig. 2. Relation between the polymerization rate (R_p) and the dielectric constant (ε) of the mixed solvent in the acetonitrile-acetone binary solvent system.

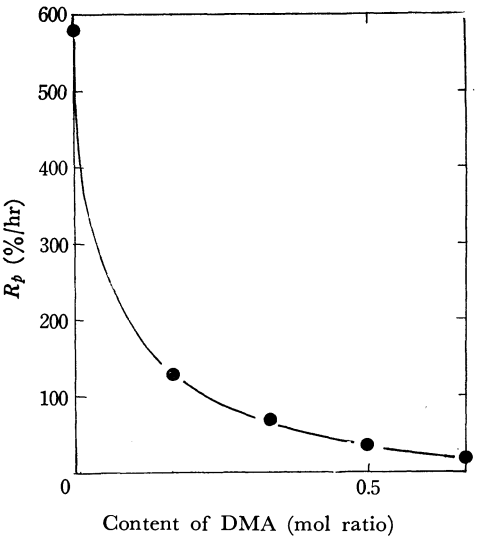

Fig. 3. Relation between polymerization rate (R_p) and the composition of the solvent in the acetonitrile - *N*,*N*-dimethylacetamide (DMA) binary solvent system.

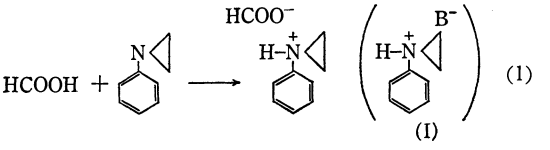
the dielectric constant of the mixed solvent remains constant on varying the ratio of the two components, while the rate of polymerization is markedly depressed by the addition of a small amount of *N*,*N*-dimethylacetamide (Fig. 3). This fact suggests that the solvent and monomer coordinate competitively to the cationic growing end, and that coordination of the solvents increases with the amounts of *N*,*N*-dimethylacetamide with a larger nucleophilicity than that of acetonitrile and so depresses the monomer addition to the growing end. This is in accord with the finding that the rate decreased with an increase in the nucleophilicity of the solvent.[1)]

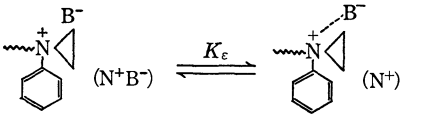
Mechanism of the Solvent Effect of the Polymerization. On the basis of these experimental facts and the results obtained previously,[1)] the mechanism of the polymerization and the role of the solvent were postulated as follows:

Initiation:



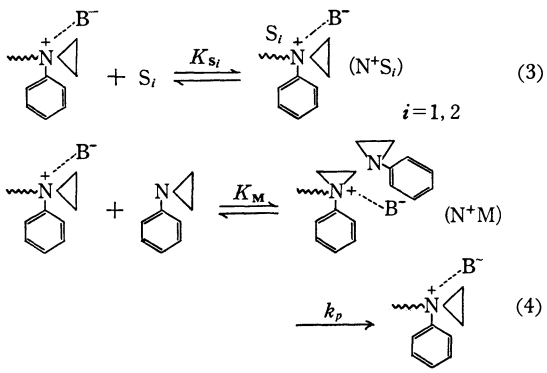
(1)

Propagation:



(2)

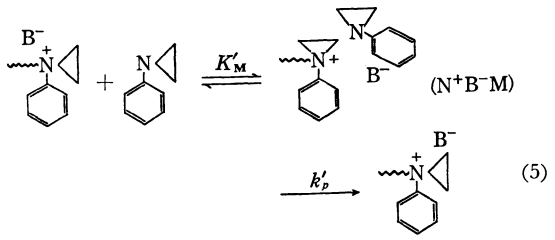
Propagation by the dissociated immonium ion:



(3)

(4)

Propagation by the undissociated immonium ion:



(5)

where K_ε, K_{S_i}, K_M, and K_M' are equilibrium constants and where k_p and k_p' are rate constants.

The initiation reaction is the reaction of formic acid with *N*-phenylethylenimine to produce Compound I. This compound dissociates partially to the immonium ion, and the reaction is in equilibrium. The equilibrium constant (K_ε) is considered to increase with an increase in the dielectric constant of the solvent. Equation (3) shows the nucleophilic solvation of the solvent to the dissociated immonium ion. Since the coordination of the solvent to both the propagating species and methanol-d are nucleophilic reactions, the equilibrium constant (K_{S_i}) is considered to increase with an increase in the K_D value. From the fact that, in the solvent with a high dielectric constant, the polymerization rate decreased with an increase in the nucleophilicity of the solvent, the propagation is considered to occur by means of the reaction of the monomer and nonsolvated immonium ion, as is shown in Eq. (4). On the other hand, the propagation can also proceed in the solvents with a low dielectric constant. Therefore, the reaction of the undissociated immonium ions with the monomer (Eq. (5)) is also probable.

Kinetics. On the basis of the mechanism postulated, the effect of the solvent on the polymerization rate was quantitatively investigated. As was established in the previous paper,[1] the concentration of the propagating species was constant regardless of both the reaction time and the nature of the solvent. Therefore, the concentration of Compound I, $\alpha[C]_0$, may be expressed by Eq. (6), where $[C]_0$ is the initial concentration of the catalyst and where α is the constant $(0<\alpha<1)$:

$$\alpha[C]_0 = [N^+] + [N^+B^-] + \sum_{i=1}^{2}[N^+S_i] + [N^+M] + [N^+B^-M] \quad (6)$$

On the other hand, according to Eqs. (2), (3), (4), and (5), the equilibrium equations will be:

$$[N^+]/[N^+B^-] = K_\varepsilon \quad (7)$$

$$[N^+S_i]/([N^+][S_i]) = K_{S_i} \quad (8)$$

$$[N^+M]/([N^+][M]) = K_M \quad (9)$$

$$[N^+B^-M]/([N^+B^-][M]) = K_M' \quad (10)$$

where [M] is the concentration of *N*-phenylethylenimine. By combining Eqs. (6), (7), (8), (9), and (10), the concentrations of N^+B^-M and N^+M may be represented by Eqs. (11) and (12) respectively:

$$[N^+B^-M] = \frac{\alpha[C]_0K_M'[M]}{1+K_M'[M]+K_\varepsilon\{1+K_M[M]+\sum_{i=1}^{2}(K_S[S])_i\}} \quad (11)$$

$$[N^+M] = \frac{K_\varepsilon K_M\alpha[C]_0[M]}{1+K_M'[M]+K_\varepsilon\{1+K_M[M]+\sum_{i=1}^{2}(K_S[S])_i\}} \quad (12)$$

The polymerization rate is represented by Eq. (13):

$$R_p = -d[M]/dt = k_p[N^+M] + k_p'[N^+B^-M] \quad (13)$$

Then, by substituting Eqs. (11) and (12) into Eq. (13), Eq. (14) is derived:

$$R_p = \frac{(K_\varepsilon K_M k_p + K_M'k_p')\alpha[C]_0[M]}{1+K_M'[M]+K_\varepsilon\{1+K_M[M]+\sum_{i=1}^{2}(K_S[S])_i\}} \quad (14)$$

Since, in the solvents with high dielectric constants, propagation may occur mainly with the dissociated immonium ions, Eq. (14) may be approximately expressed by Eq. (15):

$$R_p \fallingdotseq \frac{K_\varepsilon K_M k_p\alpha[C]_0[M]}{1+K_\varepsilon\{1+K_M[M]+\sum_{i=1}^{2}(K_S[S])_i\}} \quad (15)$$

The reciprocal of Eq. (15) is:

$$1/R_p \fallingdotseq \frac{1}{K_M k_p\alpha[C]_0[M]}\{(1+K_M[M]) + \sum_{i=1}^{2}(K_S[S])_i + 1/K_\varepsilon\} \quad (16)$$

By considering that, in an acetonitrile-acetone binary solvent system (K_D is almost constant, while ε varies from 20.7 to 37.5), the value of $\sum_{i=1}^{2}(K_S[S])_i$ is constant regardless of the composition of the solvent, it can be interpreted by means of Eq. (16) that the polymerization rate increases with an increase in the K_ε value (that is, the dielectric constant of the solvent). On the other hand, in

the case of the acetonitrile - *N,N*-dimethylacetamide system having a similar dielectric constant ($\varepsilon \fallingdotseq 37$), the term of K_ε is constant. Therefore, Eq. (16) explains the fact that the rate decreases with the $\sum_{i=1}^{2}(K_S[S])_i$ value or with the amont of *N,N*-dimethylacetamide.

The empirical equations of the polymerization rate were obtained as follows. On the assumptions that $K_{S_i}=aK_{D_i}{}^m$ and $K_\varepsilon=(1/b)\varepsilon^n$, where m, n, a, and b are constants, Eq. (16) may be written in this form:

$$1/R_p \fallingdotseq \frac{1}{K_M k_p \alpha [C]_0[M]} \{(1+K_M[M]) + a\sum_{i=1}^{2}(K_D{}^m[S])_i + b(1/\varepsilon)^n\} \quad (17)$$

Taking the logarithm of Eq. (17) gives Eq. (18):

$$\log(1/R_p) \fallingdotseq \log\{1/(K_M k_p \alpha [C]_0[M])\} + \log\{(1 + K_M[M] + a\sum_{i=1}^{2}(K_D{}^m[S])_i + b(1/\varepsilon)^n\} \quad (18)$$

In the acetonitrile - acetone binary solvent system, it is found that the plot of $\log(1/R_p)$ against $\log(1/\varepsilon)$ gives a straight line whose slope is 2.5. This fact indicates that the value of $(1+K_M[M] + a\sum_{i=1}^{2}(K_D{}^m[S])_i)$ is much smaller than that of the $b(1/\varepsilon)^n$ in Eq. (17).

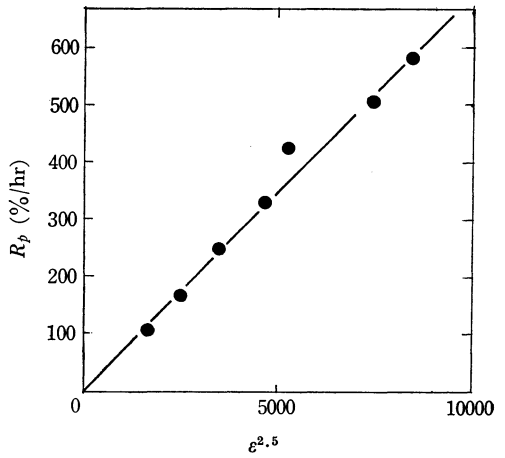


Fig. 4. Plots of R_p against $\varepsilon^{2.5}$ (ε : the dielectric constant of the mixed solvent) in the acetonitrile - acetone binary solvent system.

From the slope in the linear relation between R_p and $\varepsilon^{2.5}$ (Fig. 4), the value of $(K_M k_p \alpha [C]_0[M])/b$ is obtained as 0.07:

$$(K_M k_p \alpha [C]_0[M])/b = 0.07 \quad (19)$$

Therefore, the polymerization rate in the acetonitrile - acetone system can be approximately expressed by:

$$R_p \fallingdotseq \frac{K_M k_p \alpha [C]_0[M]}{b}\varepsilon^{2.5} = 0.07\varepsilon^{2.5} \quad (20)$$

On the other hand, in the acetonitrile - *N,N*-dimethylacetamide binary solvent system (K_D varies from 0.3 to 1.6, while ε is almost constant, 37), the empirical equation of the rate was obtained as follows. If it takes $m=2$, Eq. (17) is written:

$$1/R_p = \frac{1+K_M[M]}{K_M k_p \alpha [C]_0[M]} + \frac{a\sum_{i=1}^{2}(K_D{}^2[S])_i}{K_M k_p \alpha [C]_0[M]} + \frac{b(1/\varepsilon)^{2.5}}{K_M k_p \alpha [C]_0[M]} \quad (21)$$

By substituting the values of $b/(K_M k_p \alpha [C]_0[M]) = 14$ and $\varepsilon=37$ into Eq. (21), one obtaines:

$$1/R_p = \frac{1+K_M[M]}{K_M k_p \alpha [C]_0[M]} + \frac{\sum_{i=1}^{2}(K_D{}^2[S])_i}{(1/a)K_M k_p \alpha [C]_0[M]} + 5.4\times 10^{-4} \quad (22)$$

A plot of the $1/R_p$ against $\sum_{i=1}^{2}(K_D{}^2[S])_i$ gives a straight line (Fig. 5), this straight line is written in form:

$$1/R_p = 0.33\sum_{i=1}^{2}(K_D{}^2[S])_i \quad (23)$$

By comparing Eq. (23) with Eq. (22), we discover that the value of 5.4×10^{-4} is much smaller than the term of K_D in Eq. (22), and that:

$$(1+K_M[M])/(K_M k_p \alpha [C]_0[M]) \fallingdotseq 0 \quad (24)$$

$$1/\{(1/a)K_M k_p \alpha [C]_0[M])\} \fallingdotseq 0.33 \quad (25)$$

By combining Eqs. (21) and (24), the rate equation in the solvent with a high dielectric constant can be expressed generally as:

$$R_p \fallingdotseq \frac{K_M k_p \alpha [C]_0[M]}{a\sum_{i=1}^{2}(K_D{}^2[S])_i + b(1/\varepsilon)^{2.5}} \quad (26)$$

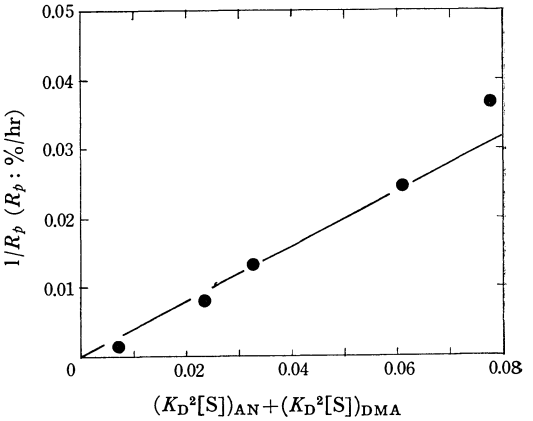

Fig. 5. Plot of $1/R_p$ against $(K_D{}^2[S])_{AN} + (K_D{}^2[S])_{DMA}$ in the acetonitrile (AN) - *N,N*-dimethylacetamide (DMA) binary solvent system.

Then:

$$R_p \fallingdotseq \frac{K_M k_p(\alpha/a)[C]_0[M]}{\sum_{i=1}^{2}(K_D^2[S])_i + (b/a)(1/\varepsilon)^{2.5}} \quad (27)$$

By substituting the value of $b/a \fallingdotseq 40$ obtained from Eqs. (19) and (25) into Eq. (27), Eq. (27) may be written in the form:

$$R_p \fallingdotseq \frac{K_M k_p(\alpha/a)[C]_0[M]}{\sum_{i=1}^{n}(K_D^2[S])_i + 40(1/\varepsilon)^{2.5}} \quad (28)$$

Eq. (28) can then be applied to the results obtained in the single solvent system ($10<\varepsilon<37.5$). As is shown in Fig. 6, although the polymerization rate, R_p, increases with an increase in the dielectric constant of the solvent, the order can not necessarily be explained by the dielectric constant of the solvent. The plot of R_p against $\{(K_D^2[S])+40(1/\varepsilon)^{2.5}\}^{-1}$ gives a straight line through the point of origin (Fig. 7). This fact indicates that Eq. (29) can be applied as an empirical equation of the polymerization rate to both the single and the binary solvent system.

Structural Study of the Catalytic Activity of Alkyl Chloride in the Polymerization of *N*-Phenylethylenimine

Tsutomu KAGIYA, Tomizo KONDO and Keigo OBATA

Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received May 10, 1969)

The catalytic activity of various alkyl chlorides in the polymerization of *N*-phenylethylenimine was studied from the structural point of view. Both the polymerization rate and the molecular weight of the polymer obtained varied with the kind of alkyl chloride. The rate of monomer consumption is expressed by a first-order rate equation with respect to the monomer concentration in the early stage of the polymerization. The efficiency factors of the catalysts differ with the kind of alkyl chloride and increase with an increase in the reaction time. When the chloride of a conjugated alkyl group is used, the polymerization rate decreases with an increase in the ionization potential of the alkyl radical, while it increases when chlorides of a non-conjugated alkyl are used. The structural study of the catalytic activity of the alkyl chloride was made quantitatively from the energetic point of view.

It has already been reported by the present authors[1] that, in the polymerization of *N*-phenylethylenimine withv arious carboxylic acid catalysts (pK_a=0.23—4.87), there was no chain transfer reaction, and that the rates of the initiation, propagation, and termination reactions increased with a decrease in the pK_a values of the acids. These results indicate that the rates of the elementary reactions are dependent on the structural nature of the catalyst.

The purpose of this paper is to investigate the relation between the polymerization rate and the structure of the alkyl chloride catalyst in the polymerization of *N*-phenylethylenimine.

Experimental

The methods of preparing and purifying *N*-phenylethylenimine were described in the previous paper.[1] Acetonitrile and alkyl chlorides of a guaranteed reagent were purified by the usual method.[2]

The methods of the polymerization of the polymer and the determination of its molecular weight were also described in the previous paper.[1] The polymerization was carried out under the following conditions: monomer, 0.01 mol; acetonitrile as the solvent, 5 m*l*; catalyst, 0.00067 mol; temperature, 0°C.

The infrared spectrum of the polymer was measured by the use of the potassium bromide pellet technique on a Shimadzu infrared spectrophotometer, Model IR-27.

2) A. Weissberger, E. S. Proskauer, J. A. Riddick and E. E. Toops, "Technique of Organic Chemistry, Vol VII, Organic Solvents," Interscience Publishers, Inc., New York (1955).

Results and Discussion

The Infrared Spectrum of the Polymer. The infrared spectrum of the polymer initiated with allyl chloride shows the characteristic peaks at 910 cm^{-1} and 930 cm^{-1} assigned to the vinyl group and the piperazine ring respectively. This may indicate that the polymer contains the allyl group and the piperazine ring at both ends of the polymer. Therefore, it may be considered that this polymerization is initiated with alkyl chloride and is terminated by forming the piperazine ring at the end of the polymer, as has been described in the previous paper.[1]

Polymerization with Various Alkyl Chlorides. The plots of the polymer yield ($[M_p]$; polymerized monomer mol/*l*) against the reaction time are shown in Figs. 1 and 2. The curves of these figures show that the polymerization rate varies markedly with the kind of alkyl chloride. As is shown in Fig. 3, the rate of the monomer consumption is expressed by a first-order rate equation with respect to the monomer concentration in the early stage of the polymerization (polymer yield $<20\%$). In view of this fact, it is considered that the steady-state assumption that the initiation rate is equal to the termination one is applicable in the early stage of this polymerization.

The relations between the number-average molecular weight ($\bar{M}_n$) and the reaction time are shown in Fig. 4. The molecular weight is almost constant regardless of the reaction time. This may be ascribed, not to the chain transfer, but to the fact that the steady-state assumption is applicable, for, as has been described in the previous paper,[1]

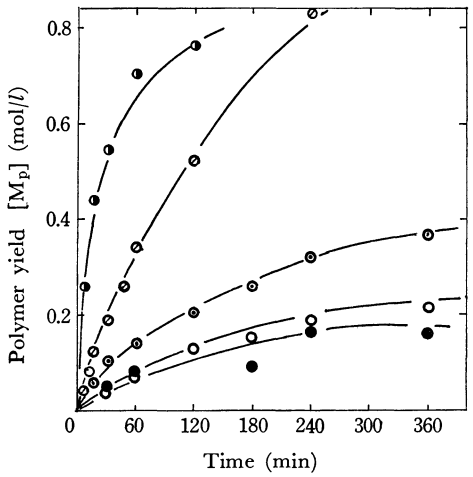

Fig. 1. Polymer yield ([M_p]) *vs.* polymerization time.

there is essentially no chain transfer in the polymerization of *N*-phenylethylenimine. On the other hand, since the structure of the initiating and propagating species depend on only the chlorine atom of the chlorides, the rate constant of the propagation and termination reactions may be considered to be constant regardless of the kind of chloride. Therefore, the difference in the molecular weight with the kind of chloride may be due to the difference in the initiation rate constant. These fact will be discussed below.

In the polymerization without chain transfer and bimolecular termination, the value of $[M_p]/([C]_0\overline{M}_n)$ is called the efficiency factor of the catalyst (α), where, $[C]_0$ is the initial catalyst concentration. The increase in α with an increase in the reaction

The notes are the same as Fig. 1 and Fig. 2.

time (Fig. 5) indicates that the initiation reaction occurs continuously during the course of the polymerization. Moreover, since α differs greatly from alkyl chloride to alkyl chloride (about from 1×10^{-4} to 0.8), there is perhaps a very large difference in the initiation rate as well. From these facts, it is assumed that the difference in the polymerization rate with the kind of alkyl chlorides is due to the difference in the rate constant of the initiation reaction.

Since the initiation reaction may be the addition reaction of alkyl chloride with *N*-phenylethylenimine, the initiation reaction is expected to proceed by the same mechanism as the Menschutkin reaction, as will be described later in connection with Eq. (1). Therefore, the polymerization rates (k), defined as the slopes of the straight lines in Fig. 3,

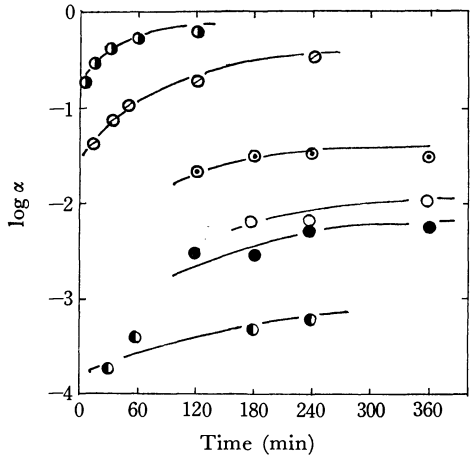

Fig. 5. Plots of log α against reaction time.
The notes are the same as Fig. 1 and Fig. 2.

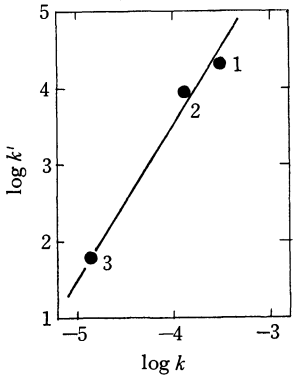

Fig. 6. Relation between the rate constant (k') of Menschutkin reaction (RI+Di-Me-Aniline) and polymerization rate (k) with the use of RCl.
R: 1, Benzyl; 2; Allyl; 3, Ethyl

were studied in comparison with the rate constant of the Menschutkin reaction. The plots of the k values against the rate constants in the reaction of alkyl iodides with dimethylaniline,[3] which had a structure similar to that of *N*-phenylethylenimine, are shown in Fig. 6. The fact that the rate of the Menschutkin reaction is almost proportional to the polymerization rate is in good accordance with the above assumption.

Since the peculiar nature of alkyl chloride (RCl) is considered to be caused by the difference in the electronic nature of the alkyl radical, the k value was plotted against the ionization potential of the alkyl radical (I_p(R·)) (Fig. 7). There is a good relation between the catalytic activity and the ionization potential of the alkyl radical; the curves may be

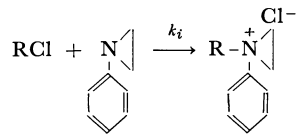
classified into two groups, that is, alkyl chloride with the conjugated alkyl group and that with the non-conjugated alkyl one. With the catalysts of the chloride of the conjugated alkyl group, the polymerization rate decreases with an increase in the I_p(R·) value, while it increases in the non-conjugated alkyl group.

On the other hand, it is found that the relation between the rate constant of the Menschutkin reaction and the I_p(R·) value of the alkyl chloride is similar to the relation in this polymerization, as Fig. 8 shows. The structural study of these reactions will be discussed below.

Kinetics. From these experimental facts and the results obtained in the previous paper,[1] the

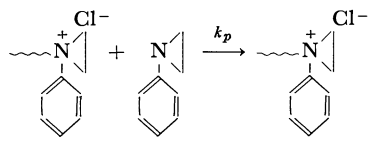
following mechanism of the polymerization may be postulated:

Initiation:



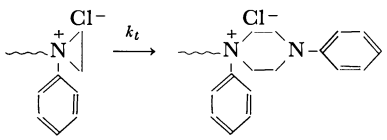
(1)

Propagation:



(2)

Termination:



(3)

The initiating step may be the reaction of the alkyl chloride with *N*-phenylethylenimine to produce the initiating species, compound (I). As has been mentioned in the previous paper,[1] the polymer chain is considered to terminate with the formation of the piperazine derivative ring.

According to the mechanism of the polymerization postulated, the rate equations of the elementary reactions may be written as follows:

$$R_i = k_i[\mathrm{RCl}][\mathrm{M}] \quad (4)$$

$$R_p = k_p[\mathrm{P^*}][\mathrm{M}] \quad (5)$$

$$R_t = k_t[\mathrm{P^*}][\mathrm{M}] \quad (6)$$

where,

[RCl], [M], [P*]; the concentrations of the catalyst, the monomer, and the propagating species;

R_i, R_p, R_t: the rates of the initiation, propagation, and termination reactions, and

k_i, k_p, k_t: the rate constants of the initiation, propagation, and termination reactions.

Considering that the concentration of the monomer is much larger than that of the catalyst, Eq. (4) may be expressed by Eq. (7):

$$R_i = k_i[\mathrm{RCl}] \quad (7)$$

Since, in the early stage of the polymerization, the steady-state is realized ($R_i = R_t$), Eq. (8) is obtained:

$$k_i[\mathrm{RCl}] = k_t[\mathrm{P^*}] \quad (8)$$

On the other hand, from Eq. (7) the concentration of the catalyst can be expressed by Eq. (9):

$$[\mathrm{RCl}] = [\mathrm{RCl}]_0 e^{-k_i t} \quad (9)$$

Then, from Eqs. (8) and (9), the concentration of the propagating species can be represented by Eq. (10):

$$[\mathrm{P^*}] = (k_i/k_t)[\mathrm{RCl}]_0 e^{-k_i t} \quad (10)$$

By substituting [P*] into Eq. (5) and by then integrating it, Eq. (11) is derived:

$$\ln([\mathrm{M}]_0/[\mathrm{M}]) = (k_p/k_t)[\mathrm{C}]_0\,(1-e^{-k_i t}) \quad (11)$$

In the early stage of the polymerization, Eq. (11) may be represented approximately by Eq. (12):

$$\ln([\mathrm{M}]_0/[\mathrm{M}]) = (k_i k_p/k_t)[\mathrm{RCl}]_0 t \quad (12)$$

The fact that the molecular weight is almost constant, regardless of the reaction time, and the fact that it differs with the kind of alkyl chloride may be explained as follows. If there is no chain-transfer reaction, the number average of the degree of the polymerization, $\overline{P_n}$, is represented by Eq. (13):

$$\overline{P_n} = \int R_p dt / \int R_i dt \quad (13)$$

The polymer yield, $[\mathrm{M}_p]$, is expressed by Eq. (14):

$$[\mathrm{M_p}] = [\mathrm{M}]_0 - [\mathrm{M}] \quad (14)$$

Therefore, from Eqs. (11) and (14), Eq. (15) is derived:

$$[\mathrm{M_p}] = [\mathrm{M}]_0 \left\{1 - \exp \frac{k_p}{k_t}[\mathrm{C}]_0(1-e^{-k_i t})\right\} \quad (15)$$

On the other hand, $\int R_i dt$ is expressed by Eq. (16):

$$\int R_i d_t = [\mathrm{C}]_0 - [\mathrm{C}] = [\mathrm{C}]_0(1-e^{-k_i t}) \quad (16)$$

Therefore, by combining Eqs. (13), (15), and (16), $\overline{P_n}$ may be written by Eq. (17):

$$\overline{P_n} = \frac{[\mathrm{M}]_0\left\{1 - \exp \frac{k_p}{k_t}[\mathrm{C}]_0(1-e^{-k_i t})\right\}}{[\mathrm{C}]_0(1-e^{-k_i t})} \quad (17)$$

Figure 9 shows the plots of $\overline{P_n}$ against the reaction time assuming that $(k_p/k_t)[\mathrm{C}]_0 = 10$ in Eq. (17). From Fig. 9 it may be seen that the variation in $\overline{P_n}$ is small within the definite period of the reaction time, and that the value of $\overline{P_n}$ differs with the value of k_i. These facts are considered to agree with the results shown in Fig. 4.*1

Energetic Study of the Initiation Reaction. The relation between the kind of alkyl chloride and the initiation rate was studied quantitatively from the energetic point of view. The initiation reaction may be written by Eq. (18) in view of the

*1 In the case of the polymerization of *N*-phenylethylenimine with various carboxylic acids (pK_a=2.85—4.87), the molecular weight of the polymer was almost constant in the early stage of the polymerization, whereas in the later stage of the polymerization it increased. This may indicate that, in the early stage of the polymerization, the steady-state method is applicable, but not in the later stage. Although the steady-state method is thus not applicable in all periods of the reaction time, in order to estimate the rate constant of the initiation reaction the steady-state method was used.

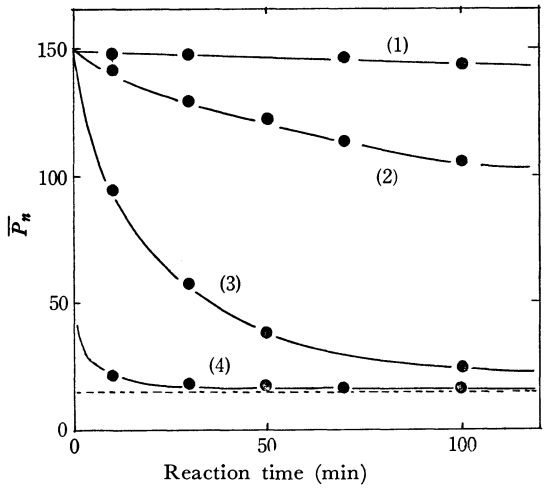


Fig. 9. The plots of $\overline{P}_n$ against the reaction time assuming (k_p/k_t) $[C]_0=10$ in Eq. (17).
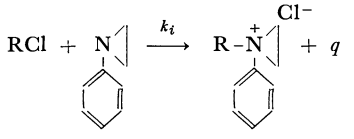
The value of k_i: (1) 0.0001, (2) 0.001, (3) 0.01, (4) 0.1

heat of reaction (q);



(18)

If it can be assumed that the relation between the activation energy and the heat of reaction is:

$$\Delta E = C_1 - C_2 q \tag{19}$$

the initiation rate can be evaluated by the heat of reaction as follows:

The heat of the reaction of the initiation reaction is considered to depend on the energy needed for dissociation of alkyl chloride to give the alkyl cation and the chlorine anion and for the addition of the alkyl cation to *N*-phenylethylenimine. The ionic dissociation energy of the alkyl chloride is considered to be proportional to the value of $-D(\mathrm{RCl})-I_p(\mathrm{R}\cdot)+E_a(\mathrm{Cl}\cdot)+T\Delta S$, with the same solvent system, where $D(\mathrm{RCl})$, $I_p(\mathrm{R}\cdot)$, $E_a(\mathrm{Cl}\cdot)$, and $T\Delta S$ are the bond dissociation energy of the alkyl chloride, the ionization potential of the alkyl radical, the electron affinity of the chlorine, and the entropy term respectively. Since the addition of the alkyl cation to *N*-phenylethylenimine may be the electrophilic reaction of the alkyl cation to *N*-phenylethylenimine and the nucleophilic reaction of *N*-phenylethylenimine to the alkyl cation, it may be considered that the larger the electron affinity of the alkyl cation ($E_a(\mathrm{R}^+)=I_p(\mathrm{R}\cdot)$) and the ionization potential of *N*-phenylethylenimine ($I_p(\mathrm{Imine})$), the smaller the energy of the addition of the alkyl cation to *N*-phenylethylenimine. On the basis of these considerations, the following empirical expression can be proposed for the evaluation of the heat of reaction of the initiation reaction in Eq. (18):

$$q = -D(\mathrm{RCl}) - I_p(R\cdot) + E_a(\mathrm{Cl}\cdot) + T\Delta S + C_3 I_p(\mathrm{R}\cdot) - C_4 I_p(\mathrm{Imine}) + C_5 \tag{20}$$

Considering that $E_a(\mathrm{Cl}\cdot)$ and $I_p(\mathrm{Imine})$ are constant and that, in the experiment with the same solvent, the value of $T\Delta S$ is almost constant, Eq. (20) may be written in the form:

$$q = -D(\mathrm{RCl}) - I_p(\mathrm{R}\cdot)(1 - C_3) + C_6 \tag{21}$$

By a combination of Eqs. (19) and (21), the activation energy may be expressed by Eq. (22):

$$\Delta E = C_1 - C_2\{-D(\mathrm{RCl}) - I_p(\mathrm{R}\cdot)(1 - C_3) + C_6\} \tag{22}$$

Subsequently, we tried to express the bond-dissociation energies of alkyl halides as a function of $I_p(\mathrm{R}\cdot)$ and $E_a(\mathrm{R}\cdot)$. As is shown in Fig. 10, the dissociation energy of alkyl halide increases almost in proportion to the value of $I_p(\mathrm{R}\cdot)-E_a(\mathrm{R}\cdot)$.

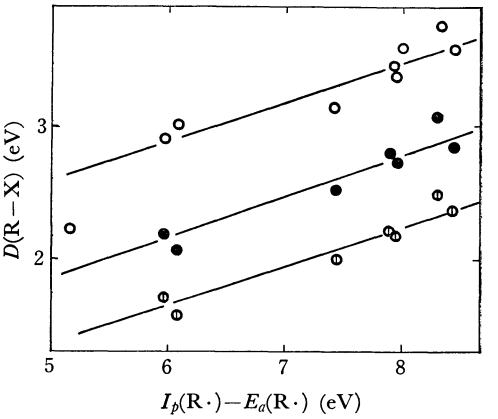


Fig. 10. Relation between the dissociation energy of alkyl halide and the value of $I_p(\mathrm{R}\cdot)-E_a(\mathrm{R}\cdot)$ of alkyl radical.
○, Chloride; ●, Bromide; ⓘ, Iodide

The empirical equation (23) was, then, obtained for the dissociation energy of alkyl chloride:

$$D(\mathrm{RCl}) = 0.3\{I_p(\mathrm{R}\cdot) - E_a(\mathrm{R}\cdot)\} + 1.1 \tag{23}$$

By substituting Eq. (23) into Eq. (22), the activation energy may be expressed in terms of $I_p(\mathrm{R}\cdot)$ and $E_a(\mathrm{R}\cdot)$:

$$\Delta E = C_7 + C_2(1.3 - C_3)I_p(\mathrm{R}\cdot) - 0.3E_a(\mathrm{R}\cdot) \tag{24}$$

On the other hand, from the plots of $E_a(\mathrm{R}\cdot)$ against $I_p(\mathrm{R}\cdot)$, as is shown in Fig. 11, $E_a(\mathrm{R}\cdot)$ is found to be approximately given by the following relations in the range of $7.8\leq I_p(\mathrm{R}\cdot)\leq 9.9$: for the conjugated alkyl radical:

$$E_a(\mathrm{R}\cdot) \fallingdotseq 2.0 \tag{25}$$

and for the non-conjugated alkyl radical:

$$E_a(\mathrm{R}\cdot) \fallingdotseq 0.45\, I_p(\mathrm{R}\cdot) - 3.0 \tag{26}$$

Hence, the activation energy may be written in these forms:

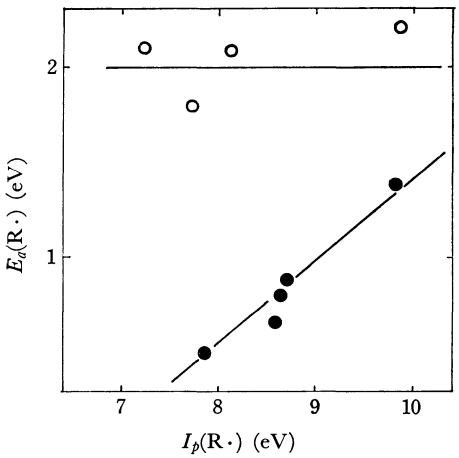

Fig. 11. Relation between electron affinity E_a(R·) and ionization potential I_p(R·) of alkyl radical.
○, conjugated alkyl radical
●, non-conjugated alkyl radical

for the conjugated alkyl radical:

$$\Delta E = (C_7 - 0.6) + C_2(1.3 - C_3)I_p(\mathrm{R}\cdot) \quad (27)$$

and for the non-conjugated alkyl radical:

$$\Delta E = (C_7 + 0.9) + C_2(1.17 - C_3)I_p(\mathrm{R}\cdot) \quad (28)$$

On the other hand, the rate constant is expressed by Eq. (29):

$$\ln k_i = \ln A - \Delta E/\boldsymbol{R}T \quad (29)$$

By substituting Eq. (27) or (28) into Eq. (29), Eqs. (30) and (31) were obtained for the conjugated alkyl radical:

$$\ln k_i = (0.6/\boldsymbol{R}T + C_8) + (C_2/\boldsymbol{R}T)(1.3 - C_3)I_p(\mathrm{R}\cdot) \quad (30)$$

and for the non-conjugated alkyl radical:

$$\ln k_i = (-0.9/\boldsymbol{R}T + C_8) + (C_2/\boldsymbol{R}T)(1.17 - C_3)I_p(\mathrm{R}\cdot) \quad (31)$$

If $1.17 < C_3 < 1.30$ and $C_2 > 0$, then:
for the conjugated alkyl radical:

$$1.3 - C_3 < 0 \quad (32)$$

and for the non-conjugated alkyl radical:

$$1.17 - C_3 > 0 \quad (33)$$

Therefore, if the values of C_3 and C_2 satisfy the above assumption, these considerations can explain the experimental results with the catalysts of conjugated and non-conjugated alkyl chlorides shown in Fig. 7.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 3524—3528 (1969)

The N→O Acetyl Migration of 5-Substituted-2-pyrrolidinemethanols*[1]

Hisayuki SAKURAI and Toshiyasu ISHIMARU

The Institute of Scientific and Industrial Research, Osaka University, Suita, Osaka

(Received May 21, 1969)

In order to obtain information about the stereochemistry of a fused-ring system, *cis* and *trans* isomers of 5-methyl- and 5-phenyl-2-pyrrolidinemethanols were synthesized and rate constants for their N→O acetyl migrations were measured. Each product was a mixture of *cis* and *trans* isomers. For both 5-methyl and 5-phenyl derivatives, it was observed that *trans* isomers migrated faster than *cis* isomers. The results were discussed in relation to stereochemistry.

The configuration of penicillin containing a fused-ring system consisting of 4- and 5-membered rings was determined by X-ray diffraction.[1] Very little, however, has been reported about the stereochemical studies of such a fused-ring system as penicillin because of the unstability of the 4-membered ring containing a lactam bond. Welsh proposed[2] that the N→O acyl migration of α-aminoalcohols, which has been studied in our laboratory, proceeds *via* an oxazolidine intermediate. The authors synthesized *cis* and *trans* isomers of 5-methyl- and 5-phenyl-2-pyrrolidinemethanol and examined their N→O acetyl migration rates in relation to configuration. This system is supposed to form during migration a fused-ring intermediate consisting of 5- and 5-membered rings.

*1 Paper IX, Stereochemistry of α-aminoalcohols and related compounds. For the previous paper in this series, see T. Ishimaru, *Nippon Kagaku Zasshi (J. Chem. Soc. Japan, Pure Chem. Sect.)*, **81**, 1592 (1960).

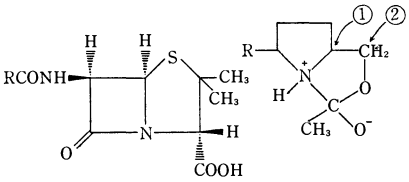

Fig. 1. Penicillin

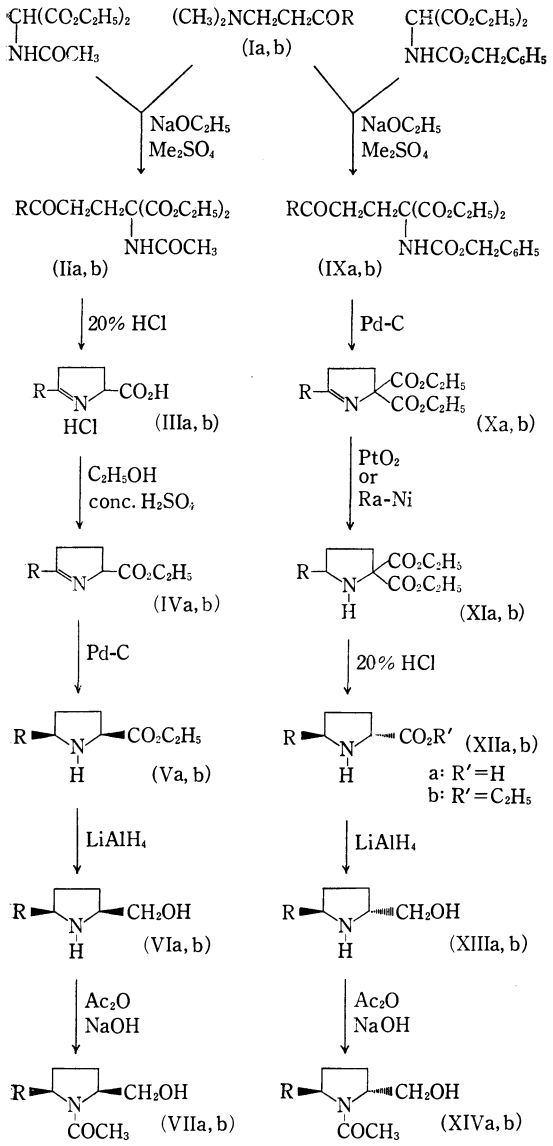
Since the free rotation of the bond between C_1 and C_2 (Fig. 1) is possible, it was expected that the difference between *cis* and *trans* isomers in the effects which the configuration of the substituent R would produce on the N→O acetyl migration would be very little. However, a considerable difference was observed. The results and stereochemical discussion are described.



Scheme 1. Synthetic route.

Experimental*2

Ethyl 5-Substituted-2-pyrrolidinecarboxylate (Va, b and XIIa, b). The compounds were prepared by the method reported by Sanno[3] (Table 1). Esterification of Δ^1-2-substituted-pyrroline-5-carboxylic acid hydrochlorides (IIIa, b) was carried out by the method of Leonard.[4]

5-Substituted-2-pyrrolidinemethanol (VIa, b and XIIIa, b). To an ice-cooled suspension of 2.5 g (0.066 mol) of lithium aluminum hydride in 50 cc of anhydrous tetrahydrofuran (THF), 11.0 g (0.05 mol) of Vb in 50 cc of anhydrous THF was added dropwise with stirring. After refluxing for 2 hr, 50 cc of THF containing 5 cc of water was added dropwise and the reaction mixture was refluxed for an hour with stirring. Precipitate was filtered and washed three times with THF. The filtrate and washings were combined and dried over anhydrous sodium sulfate. Distillation under reduced pressure gave 6.2 g (70 %) of VIb, bp 148—149°C/4.5 mmHg. Picrate, mp 138—138.5°C (EtOH). Other materials were obtained in the same manner as described above (Tables 2 and 3).

***N*-Acetyl-5-substituted-2-pyrrolidinemethanol (VIIa, b and XIVa, b).** To an ice-cooled and mechanically stirred solution of 2.9 g (0.025 mol) of VIa in 20 cc of acetone, 5 cc (0.053 mol) of acetic anhydride was added dropwise and the 2 N sodium hydroxide solution (containing 3.4 g of sodium hydroxide) was added. When necessary, an appropriate amount of sodium hydroxide solution was added to keep the reaction mixture alkaline. After concentration *in vacuo*, the residue was extracted with chloroform. The extract was dried over anhydrous sodium sulfate, concentrated *in vacuo* and distilled under reduced pressure. Three grams (75.8 %) of viscous oil, bp 153.5—154.5°C/5 mmHg was obtained. Other materials were prepared in the same manner as described above (Table 4).

Kinetic Procedure of N→O Acetyl Migrations. Measurement was carried out according to the method of Ishimaru[5] at 50±0.1°C in 15 cc of 90 % aqueous dioxane containing an equivalent amount of 0.1 N hydrochloric acid to the sample which was weighed accurately. At regular intervals, 2 cc of reaction mixture was pipetted into 10 cc of ice-cooled 20% aqueous acetone and titrated with 0.02 N barium hydroxide using bromophenol blue as indicator. The pH of the end point is about 3.5.

No linear relationship was shown on the second-order plots. Therefore rate constants were estimated from the gradients of the lines drawn over the first three points. Each constant is an average of 2-4 measurements.

Measurement of pK_a values. pK_a values of 5-substituted-2-pyrrolidinemethanols were measured by the method reported by Parke and Davis.[6] About 10 mg

of a sample was dissolved in 10 cc of water and 0.1 N hydrochloric acid (equivalent or a little more) was added. The solution was titrated with 2 N potassium hydroxide at 18°C. "Hitachi Horiba pH meter D-5" was used for the measurement.

Results and Discussion

The authors intended to obtain *cis* isomers, Va and Vb, from IVa and IVb by catalytic reduction. It was confirmed by gas chromatography that Va and Vb were pure respectively. However, *cis*-5-phenyl-2-pyrrolidinemethanol (VIb) obtained from Vb turned out to be a mixture of *cis* and *trans* isomers (*cis* : *trans*=8.5 : 1.5).[10] It is supposed

cis	C_6H_5	203—205/5	70.92 (71.21	8.06 7.81	6.24 6.39)
trans	C_6H_5	175—176/2	70.99 (71.21	8.00 7.81	6.32 6.39)
	H	139—142/2.1	58.48 (58.72	9.31 9.15	9.85 9.78)

that the presence of *trans* isomer in VIb is due to isomerization by heating during isolation since the *trans* peak of VIb increased after heating at about 180°C for 2 hr (*cis* : *trans*=6.6 : 3.4). *N*-Acetyl-*cis*-5-methyl-2-pyrrolidinemethanol (VIIa) was also recognized to be mixed with a little of *trans* isomer (*cis* : *trans*=9.0 : 1.0).

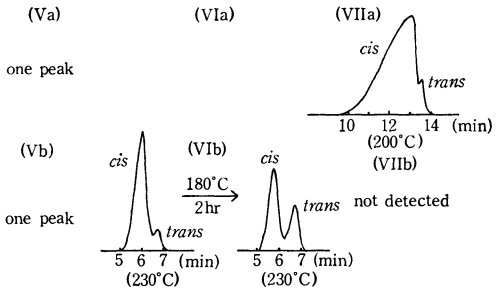

Fig. 2. Gas chromatograms of *cis* isomers.

It is considered that hydrolyses of XIa and XIb afford *trans* isomers, which are expected to be more stable thermodynamically, but *cis* isomers are also likely to be produced. As expected the ethyl esters of XIIa and XIIb were mixtures of *cis* and *trans* isomers (XIIa, *cis* : *trans*=1.0 : 9.0; XIIb, *cis* : *trans*=5.8 : 4.2). It was recognized that *trans*-5-phenyl-2-pyrrolidinemethanol (XIIIb) (*cis* : *trans* =5.6 : 4.4) and *N*-acetyl-*trans*-5-methyl-2-pyrrolidinemethanol (XIVa) (*cis* : *trans*=5.7 : 4.3) were also mixtures.

The reaction rate constants were calculated by second-order equation. (Table 5)

If it is assumed that each sample is pure, the ratio $k(trans)/k(cis)$ equals about 4–5. Considering the gas chromatographic results, it seems that the ratio $k(trans)/k(cis)$ is high in practice and *cis* isomers migrate much more slowly than *trans* isomers. Neglecting *cis* isomers, we obtained the initial concentrations of *trans* isomers from the results of gas chromatographic analyses and calculated the rate constants for *trans* isomers. The results of the calculations for two samples in which the ratios of isomers are different agree with each other. Thus the migration rates of *cis* isomers are considered to be negligible.

In *N*-acetyl derivatives there seem to be two forms, (A) and (B), which are in equilibrium. (A) is considered favorable for forming the intermediate proposed for N→O acyl migration (Fig. 1). Taking the steric hindrance into consideration, it

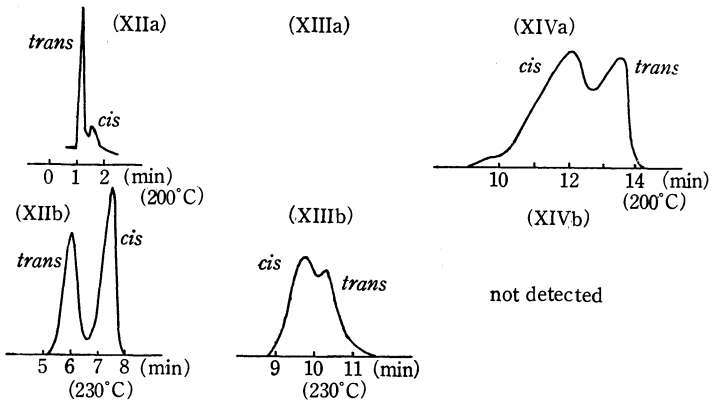

Fig. 3. Gas chromatograms of trans isomers.

Table 5. Migration rate constants

		k_2* mol l^{-1} sec^{-1}	k_2 mol l^{-1} sec^{-1}
5-CH_3	*trans*	7.22×10^{-4} a)	1.9×10^{-4}
	cis	1.48×10^{-4} b)	
5-C_6H_5	*trans*	5.86×10^{-4} c)	1.7×10^{-4}
	cis	1.51×10^{-4} d)	

* Rate constants when the samples are assumed to be pure. In practice a) *cis* : *trans*=5.7 : 4.3
b) *cis* : *trans*=9.0 : 1.0
c) *cis* : *trans*=5.6 : 4.4
d) *cis* : *trans*=8.5 : 1.5

seems that (B) predominates in *cis* and that the two forms can easily interchange in *trans*. Consequently, it is understood that *trans* isomers migrate faster than *cis* isomers.

It is difficult to discuss the difference of substituent effects between methyl and phenyl groups. The ratios of isomers were obtained on the basis of the results of gas chromatography, although isomerization may occur during the operation due to high temperature of the columns. In addition, in 5-phenyl derivatives gas chromatographic analyses were performed for 5-phenyl-2-pyrrolidinemethanols (VIb, XIIIb), and not for *N*-acetyl-5-phenyl-2-pyrrolidinemethanols (VIIb, XIVb).

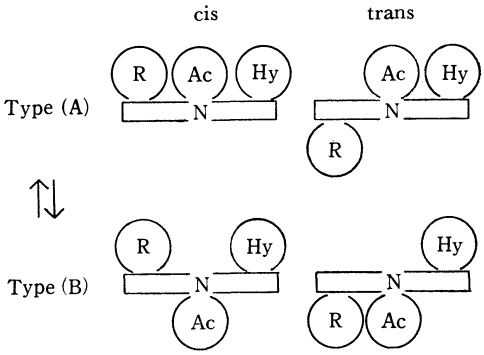

Fig. 4. *N*-Acetyl derivatives.
R=CH_3 or C_6H_5
Ac=$COCH_3$ Hy=CH_2OH

We were unsuccessful in synthesizing pure isomers, but we found from the measurements of their N→O acetyl migration that *trans* isomers migrated faster than *cis* isomers.

Alkaline Decomposition of Triarylsulfonium Halides with Various Bases[1)]

Shigeru OAE and Yong He KHIM

Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sumiyoshi-ku, Osaka

(Received May 24, 1969)

Alkaline decomposition of triarylsulfonium bromides with various bases was found to give different products depending on the nature of the bases. The reaction of triarylsulfonium bromide with either piperidide anion or thiophenoxide ion seems to proceed with the initial attack of piperidide anion or thiophenoxide ion of the carbon atom of C–S bond (S_N reaction on carbon atom), while the reaction of diarylethoxysulfonium tetrafluoroborate with thiophenoxide ion is presumed to involve the initial attack of thiophenoxide ion on the sulfur atom at low temperature (S_N reaction on sulfur atom). When triarylsulfonium bromide was subjected to the reaction with potassium hydroxide in aqueous ethanol, the main path was the alkaline decomposition which proceeds *via* the nucleophilic attack of the ethoxide ion on the sulfur atom. In the treatment with hydroxide ion in water, the decomposition appears to proceed mainly *via* two mechanistic routes, *i.e.*, the processes involving the nucleophilic attack of hydroxide ion on both aromatic carbon and the sulfur atoms. A free radical process cannot be excluded, but appears unlikely.

In a previous work,[2)] it was found that the alkaline decomposition reaction is presumably initiated by the attack of ethoxide ion on the sulfur atom of the sulfonium salts occured competitively along with S_N reaction of aromatic chloride.

In view of the formation of the various products in the treatment of triarylsulfonium salts with bases, the alkaline decompositions of triarylsulfonium salts seem to proceed *via* different routes depending on the nature of the bases. Namely, one portion undergoes a cleavage reaction *via* the initial attack on the sulfur atom (S_N reaction on sulfur atom), another involves a reaction *via* the attack on the aromatic carbon atom of C–S bond (S_N

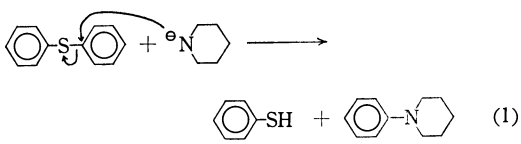
2) S. Oae and Y. H. Khim, *ibid.*, **42**, 1622 (1969).

reaction on carbon atom), and another proceeds through the initial removal of a proton to the sulfonio group followed by the subsequent elimination of sulfide group to form "benzyne" intermediate. In order to clarify the nature of the modes of alkaline decomposition of triarylsolfonium halides with various bases, the reactions of triarylsulfonium salts with piperidide anion, sodium arylthiolate, ethoxide and hydroxide ion have been carried out in various solvents. The details of alkaline decomposition and the mechanistic interpretation are presented in this paper.

Reaction of Triphenyl- and Tri-*p*-tolyl-sulfonium Bromides with Potassium Amide in Piperidine. When triphenylsulfonium bromide was reacted with potassium hydroxide in boiling piperidine under the conditions shown in Table 1, diphenyl sulfide, thiophenol and *N*-phenylpeperidine were obtained quantitatively.

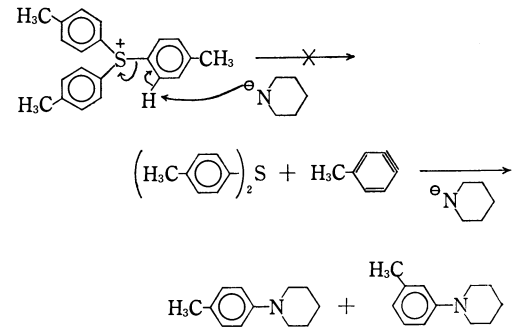
From analyses of the products, the alkaline cleavage reaction seems to proceed with the initial attack of piperidide anion on the carbon atom of C–S bond bearing sulfide group, while diphenyl sulfide formed reacts further with piperidide anion to give thiophenol and *N*-phenylpiperidine.

It has been suggested[3] that the cleavage reaction of diphenyl sulfide with sodium amide in boiling piperidine proceeds through the initial attack of peperidide anion on the carbon atom of diphenyl sulfide as follows.



(1)

However, since this particular reaction is performed between a positively charged species *i.e.* sulfonium salt and a very strong base in a heterogeneous system, there remains a possibility that the reaction proceeds through the initial abstraction of *o*-hydrogen followed by the subsequent elimination of sulfide group to form "benzyne" intermediate, to which piperidide anion adds to result in the final product as shown below.



(2)

In order to examine the "benzyne" mechanism tri-*p*-tolylsulfonium bromide was subjected to the alkaline decomposition reaction, since this mechanism requires the formation of both *meta*- and *para*-substituted *N*-*p*-tolylpiperidines. Identification of both *meta*- and *para*-*N*-tolylpiperidines can be easily performed by the comparison of their characteristic infrared absorption bands (*m*-derivative 10.5, 12.95 μ; *p*-derivative 12.32 μ) and also by gas chromatography. When the reaction was actually carried out under the conditions shown in Table 1, only the *para*-substituted compound was obtained, but

Table 1. The alkaline decomposition of triarylsulfonium bromide with potassium amide in piperidine

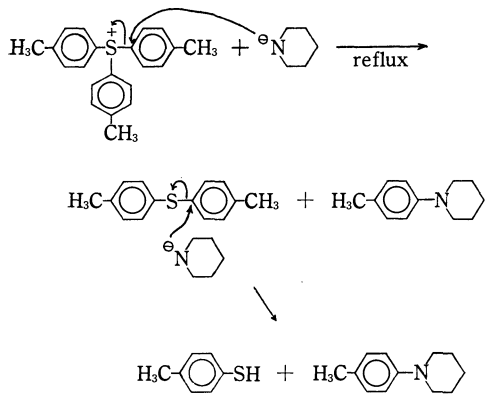
					$H_3CC_6H_4N$	80

a) The yield is a combined percentage of sulfide and thiophenol.
b) The yield was obtained based on the molar concentration of starting sulfonium salt.
c) The molar ratio of sulfonium and potassium amide was 1 : 4.

3) a) W. E. Truce, D. P. Tate and D. N. Burge, *J. Am. Chem. Soc.*, **82**, 2872 (1960). b) R. Otto, *Ber.*, **19**, 2425 (1886). c) S. Oae and R. Kiritani, This Bulletin, **38**, 765 (1965). d) N. Furukawa, H. Tanaka and S. Oae, *ibid.*, **41**, 1463 (1968).

no *meta-N*-tolylpiperidine.

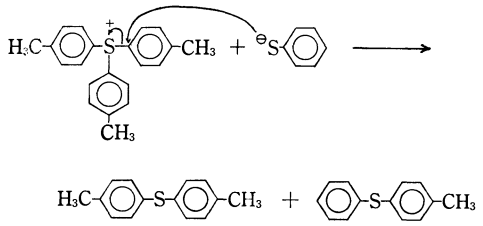
Thus the most plausible route for this reaction may be the one involving the aromatic S_N2 process.



(3)

Reaction of Triarylsulfonium Bromide and Ethoxy-diphenyl-sulfonium Tetrafluoroborate with Sodium Arylthiolate in Ethanol. Triarylsulfonium bromides were subjected to the alkaline decomposition with sodium arylthiolate in ethanol and the detailed analyses of the products formed in the reaction were undertaken in order to choose possible mechanistic pathways for the reaction. The solution of tri-*p*-tolylsulfonium bromide and sodium thiophenoxide in ethanol was gently refluxed in ethanol under the conditions given in Table 2. The products isolated were found to contain di-*p*-tolyl sulfide and phenyl- *p*-tolyl sulfide as the main products and a small amount of diphenyl disulfide as the minor product. The products and yields for other similar reactions are shown in Table 2. Identification and determination of the yields of products obtained were performed by means of quantitative vapor phase chromatography and by comparison of their infrared spectra with those of the authentic samples.

From the distribution of the whole products and their yields, the reaction (runs 1—4) seems to proceed *via* the nucleophilic attack on the carbon atom of C-S bond similarly to the case of the reaction of triarylsulfonium bromide with piperidide anion (Eq. (4)).



(4)

The formation of a small amount of diaryl disulfide (runs 1—4) undoubtedly results from the oxidation of sodium arylthiolate itself in boiling ethanol (Eq. (5)), because the yields of diaryl disulfides

(5)

do not differ much regardless of the absence or presence of the sulfonium salts in the reaction system (run 3), and the yield of diphenyl disulfide in the

a) The apparent yield is based on moles of sulfonium salt; the real yield from the cleavage reaction is 90%.

b) Without sulfonium salt, sodium thiophenoxide itself upon being acidified in the air gave diphenyl in ethanol.

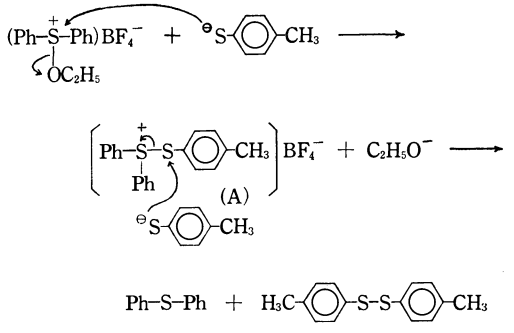
c) The moles of both diphenyl sulfide and ditolyl disulfide are almost same.

reaction with equimolar mixture of tri-*p*-tolylsulfonium bromide and sodium thiophenoxide (run 4) is much smaller than that in the case with a mixture in which the ratio of sodium thiophenoxide over sulfonium salt is three.

Another possible mechanism of S_N reaction on sulfur atom of triarylsulfonium salt may be considered. If the reaction proceeds *via* S_N reaction at sulfur atom, it should give toluene or benzene as in the case of the reaction of triarylsulfonium halide with phenyllithium, where the nucleophilic attack of phenyl anion on sulfur atom of sulfonium salt was actually detected.[4]

In no case, however, could the formation of any hydrocarbon be detected. Therefore, the S_N reaction on the sulfur atom can be ruled out.

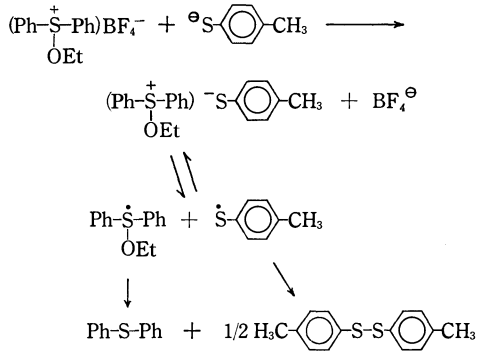
When diphenylethoxysulfonium tetrafluoroborate was subjected to the reaction with sodium *p*-toluenethiolate under the conditions shown in Table 2 (run 5, 6), the products isolated from the reaction were both diphenyl sulfide and ditolyl disulfide. From the products the reaction seems to proceed first *via* the attack of the nucleophile on the sulfur atom of the sulfonium salt with ethoxy group as the leaving group, involving the initial formation of an unstable *p*-tolylthiodiphenylsulfonium ion intermediate (A). It then seems to proceed through the attack of the same nucleophile on the S atom of *p*-tolylthio group of the intermediate sulfonium ion, with diphenyl sulfide as the leaving group as shown below.



(6)

Since the ethoxy group is a better leaving group than the diphenyl sulfide group, *p*-toluenethiolate ion may easily attack the sulfur atom in contrast to the aromatic substitution of tri-*p*-tolylsulfonium bromide with thiophenoxide ion in which diphenyl sulfide is the leaving group. The problem of attacking site of nucleophilic reagent in the S_N reaction of sulfonium salt can easily be explained by the relative ease and stability of the leaving group. Recently, Kice and his co-workers[5] have revealed that the scission of the sulfur-sulfur bond of aryl-hydroxy-arylthio-sulfonium ion in the reaction of aryl arylthiolsulfinate with nucleophilic reagents occurs at the sulfur atom of arylthio group, but not at the sulfur of aryl-hydroxysulfonio ion. Recently McEwen and Knapcyzyk[6] suggested that the reaction of triarylsulfonium halides with alkoxide ion in alcohol solbents proceeds *via* a radical process.

If the reaction of diphenyl-ethoxysulfonium bromide with *p*-toluenethiolate ion involves a radical process in which the electron transfer occurs, as in Eq. (7), the reaction between equimolar amounts of the sulfonium and *p*-toluenethiolate ion should give a mixture of an equimolar amount of diphenyl sulfide and a half molar amount of di-*p*-tolyl disulfide, while in the case of the usual S_N reaction on the sulfur atom, the decomposition of the sulfonium salt is expected to give equimolar mixture of both diphenyl sulfide and di-*p*-tolyl disulfide.



(7)

The results shown in runs 5 and 6 in Table 2, reveal that almost the same molar quantities of both sulfide and the disulfide were obtained. Therefore, the alkaline decomposition of the diaryl-ethoxysulfonium tetrafluoroborate with *p*-toluenethiolate ion in ethanol is presumed to proceed through the initial nucleophilic attack of the arylthiolate anion on the sulfur atom of the sulfonium compound.

Reaction of Triarylsulfonium Bromide with Potassium Hydroxide in Aqueous Ethanol and Water. The reaction of a triarylsulfonium bromide with potassium hydroxide in aqueous ethanol gave corresponding diaryl sulfide, hydrocarbon and resins as the main products and a small amount of ethyl aryl ether. A similar decomposition of the sulfonium salt in water under prolonged heating conditions at higher tempera-

	H_2O	KOH Ph-OH	160—180	50	(90),  (88)

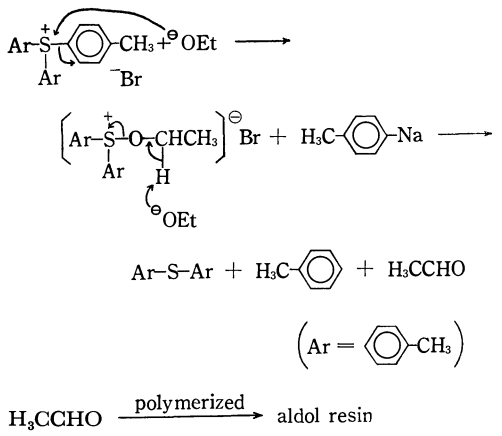
a) The reaction was carried out in an ampoul.
b) The molar ratio of starting sulfonium salt and potassium hydroxide is 1 : 8.
c) The formation of *p*-tolyl bromide could be explained in terms of the intramolecular decomposition. McEwen and Wiegand[7] demonstrated that triarylsulfonium halides might proceed *via* an intramolecular decomposition at 250°C to give sulfides and aryl halides.
d) The molar ratio of starting salt: KOH : phenol is 1 : 8 : 4.

ture as shown in Table 4 yielded the diaryl sulfide, the diaryl ether, phenol, and hydrocarbon compounds.

The results and the experimental conditions are tabulated in Tables 3 and 4. There is a big difference in the products and their yields between the alkaline decompositions of the triarylsulfonium salt in aqueous ethanol and that in water, although experimental conditions also somewhat differ from each other.

Considering the main products of sulfide, hydrocarbon compound and resins obtained from the reaction in aqueous ethanol, the decomposition of triarylsulfonium bromide with ethoxide ion seems to proceed mainly through the initial attack of the ethoxide ion on the sulfur atom of the sulfonium salt and the rest, through the process shown below.

7) G. H. Wiegand and W. E. McEwen, Tetrahedron Letters **1965**, 2639; *J. Org. Chem.*, **33**, 2671 (1968).



(8)

Since both hydroxide and ethoxide ions can exist in an equilibrium in aqueous ethanol, one could expect that the hydroxide ion should participate in the alkaline decomposition if the amount of water increases. From the products analyses of the reaction of the triphenylsulfonium bromide with potassium hydroxide from 1.6 to 97 mol % aqueous ethanol, the reaction seems to proceed mainly through the nucleophilic attack of only ethoxide ion on the sulfur atom of the sulfonium salt.

In a previous paper,[2] it was revealed that the alkaline decomposition of the triarylsulfonium bromide with ethoxide ion in 70% (vol%) aqueous ethanol obeys the second order kinetic rate low; first order with respect to both the sulfonium and potassium hydroxide concentrations.

Thus, the kinetic experiment of the alkaline decomposition was carried out in order to examine the solvent effect of various water and ethanol mixtures. The values of the rate constants for the alkaline decompositions in various aqueous ethanol solvents at 120°C are shown in Table 5. Figure 1 records a plot of the mol per cent of ethyl alcohol in water against the log of second order rate constant. The results indicate that the rate of the decomposition is increased about 10^6 fold by increasing the ethanol concentration (97.7 mol%) from 98.33 mol % of water.

Solvent (H_2O-C_2H_5OH) W% C_2H_5OH	Mol% C_2H_5OH	k_2 $mol^{-1}\,l\,sec^{-1}$
	0.96	——a)
6.25	1.77	2.90×10^{-6}
38.00	16.00	7.80×10^{-5}
46.50	26.80	2.95×10^{-4}
61.00	40.00	5.73×10^{-4}
81.00	63.50	1.39×10^{-3}
90.00	80.00	5.34×10^{-3}
97.00	93.00	2.38×10^{-1}
98.00	95.30	7.60×10^{-1}
99.00	97.70	9.32×10^{-1}

a) After the reaction mixture was heated for 48 hr, the starting sulfonium bromide was recovered almost quantitatively.

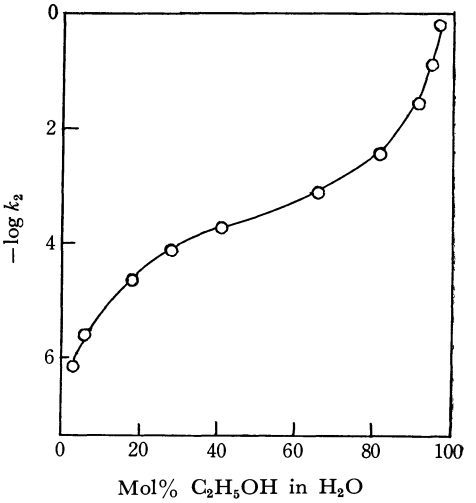

Fig. 1. Plot of mole percentage of ethyl alcohol in water against negative logarithm of k_2 ($mol^{-1}\,l\cdot sec^{-1}$) for the reaction of triphenylsulfonium bromide with potassium hydroxide.

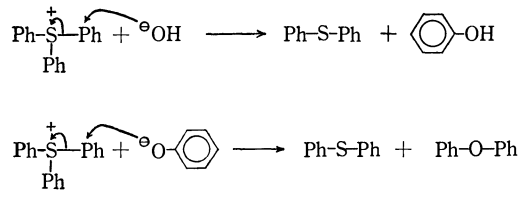
The curve in Fig. 1 is of a shape observed frequently in the solvent effect of the reaction in the reactions of the mixted solvents. Although the plot is almost linear from 30 to 80 mol % of ethyl alcohol the rates rise much more steeply at lower and higher concentrations. In the case of pure water, after the reaction mixture was heated at 120°C for 50 hr, the starting solfonium salt was quantitatively recovered. From the results obtained in the kinetic experiments, it may be concluded that ethoxide ion which is more nucleophilic than hydroxide ion attacks preferentially the sulfonium ion undergoing alkaline decomposition.

$$HO^{\ominus}\cdots HOH + HOC_2H_5 \rightleftarrows HO^{\ominus}\cdots HOC_2H_5 \rightleftarrows {}^{\ominus}OC_2H_5 + H_2O$$

When the triphenylsulfonium bromide was subjected to reaction with potassium hydroxide in water under severer conditions as shown in Table 4, the isolated compounds were diphenyl sulfide (87 %), diphenyl ether (27 %), phenol (25 %) and a small amount of benzene in contrast to the case of the similar reaction in aqueous ethanol. From the distribution of the products, the decomposition of triphenylsulfonium bromide with potassium hydroxide in water seems to involve the initial attack of hydroxide ion on the carbon atom of C-S bond to form phenolate ion, which in turn



attacks the carbon atom of the sulfonium salt yeilding diphenyl ether. Phenoxide ion may be more nucleophilic than hydroxide ion. In the presence of phenoxide ion, the alkaline decomposition of triphenylsulfonium bromide gave an equimolar mixture of both diphenyl sulfide and diphenyl ether quantitatively under the same condition as shown in Table 4.

Another possible mechanism of benzyne route is considered, because diphenyl sulfide, phenyl ether and phenol can be formed by the abstraction of *o*-hydrogen followed by the elimination of sulfide group to form benzyne intermediate.

Benzyne has been postulated as being an intermediate between the triarylsulfonium halides and a base in other reactions.[4] In order to examine the benzyne mechanism, tri-*p*-tolylsulfonium bromide was subjected to the reaction with hydroxide ion in water under the condition shown in Table 4, since this mechanism requires the formation of both *meta*- and *para*-ditolyl ether.

The compound isolated is only the *para* substituted compound *p,p'*-ditolyl ether, whose identification can be easily performed by the comparison of its characteristic IR.

Therefore, the possibility of the benzyne precess is ruled out.

It is noteworthy that the decomposition of triphenylsulfonium bromide with hydroxide ion in water gives a small amount of benzene whereas a similar reaction of tri-*p*-tolylsulfonium bromide with hydroxide ion affords a higher yield of toluene than that of benzene, especially at higher reaction temperature, though the experimental conditions are somewhat different. The reaction system of triphenylsulfonium salt is homogeneous, while that of tri-*p*-tolylsulfonium salt is heterogeneous and so requires a higher reaction temperature and longer time as shown in Table 4.

In the case of the alkaline decomposition of tritolylsulfonium bromide, the yield of toluene increases with the rise of reaction temperature and that of *p*-cresol and its derivatives decreases. It could be that in the case of tri-*p*-tolylsulfonium salt the heterogeneous reaction system and higher reaction temperature are preferable for a radical process.

It could be garued that the diaryl sulfide, diaryl ehter, phenol and hydrocarbon compounds also arise through a radical process[6] although it is not very likely.

The formation of phenol in this reaction could be explained by the following equations.

$$Ar_3\overset{+}{S}\overset{-}{Br} + {}^{\ominus}OH \rightarrow Ar_3\overset{+}{S}\overset{-}{OH} + Br^{\ominus} \rightleftarrows Ar_3SOH$$

$$\rightleftarrows [Ar_3\dot{S}\ \dot{O}H] \rightarrow Ar_2S + ArOH \qquad (9)$$

If the phenoxide ion formed by the dissociation of phenol obtained in the radical process would again attack the carbon atom of the C–S bond (S_N reaction on a carbon atom) analogous to hydroxide ion, diaryl ether should be obtained.

When the decomposition of a triarylsulfonium salts took place both in the presence and absence of oxygen, the ratio of all the phenol derivatives to diaryl sulfide produced did not differ. In the case of a radical process, a higher yield of phenol and phenol derivatives in the presence of oxygen than that in the absence of oxygen can be expected. However, at the present time a definite conclusion to these complicating reactions of the triarylsulfonium bromide with hydroxide ion in water can not be drawn.

Experimental

Triphenyl- and Tri-*p*-tolylsulfonium Bromide. The titled triarylsulfonium bormides were prepared from diarylethoxysulfonium tetrafluoroborate and aryl Grignard reagent according to the usual methods.[2]

The Reaction of Triphenylsulfonium Bromide with Potassium Amine in Piperidine. Sodium amide (0.5 g, 0.012 mol) which was washed with anhydrous *n*-hexane before use, was refluxed in piperidine (10 m*l*) for 30 min. To this solution was added triphenylsulfonium bromide (1 g, 0.003 mol) and the mixture was refluxed for about 5 hr. After cooling, the solution was quenched with ice water to decompose sodium amide. The aqueous solution was extracted with ether; the aqueous layer was carefully acidified with 1 N hydrochloric acid and extracted again with ether. After evaporation of ether, thiophenol (40 %) was obtained. The first ether layer was distilled and the distillate fractionated by vapor phase chromatography. Identification and determination of the yields of the products were performed using quantitative vapor phase chromatography and by comparison of their infrared spectra with those of authentic samples. The isolated compounds from the organic layer are diphenyl sulfide (50 %) and *N*-phenylpiperidine (90 %). The reaction of tri-*p*-tolylsulfonium bromide with potassium amide in piperidine was carried out similarly to that of triphenylsulfonium salt. The results are shown in Table 1.

The Reaction of Tri-*p*-tolylsulfonium with Sodium Thiophenoxide. Tri-*p*-tolylsulfonium bromide (2 g, 0.0026 mol) was dissolved in ethanol (30 m*l*). To this solution was added sodium thiophenoxide (2.08 g, 0.0104 mol) in ethanol (20 m*l*) with stirring. After the reaction mixture was refluxed for 4 hr, it was poured into ice water and acidified with dilute hydrochloric acid, extracted with ether, washed, dried over magnesium sulfate. The compounds isolated from the organic layer were di-*p*-tolyl sulfide (92 %) and phenyl *p*-tolyl sulfide (90 %) and a small amount of diphenyl disulfide. The purity and yields of the products were checked

with quantitative vapor-phase chromstography. Identification of these products was performed by comparison of their infrared spectra with those of authentic samples. Other reactions of triphenylsulfonium bromide with *p*-toluenethiolate and thiophenoxide ions were carried out similarly to the above reaction. All the results are summarized in Table 4.

The Reaction of Diphenylethoxysulfonium Tetrafluoroborate with Sodium *p*-Toluenethiolate. Diphenyl sulfoxide (2 g, 0.01 mol) was dissolved in anhydrous methylene chloride (5 m*l*) containing triethyloxonium tetrafluoroborate (2 g). The reaction mixture was stirred for about 30 min, at room temperature and to the this solution 50 m*l* of anhydrous ether was added, then the methylene chloride-ether mixture was replaced by anhydrous ethanol (30 m*l*) by decantation. To this solution was slowly added sodium *p*-toluenethiolate (1.46 g, 0.01 mol) in anhydrous ethanol (20 m*l*) −5——10°C over a period of about 1 hr with stirring. After stirring was continued for 30 min, the reaction mixture was poured into ice water, acidified carefully with dilute cold hydrochloric acid, extracted with a large amount of ether, washed and dried over magneisum sulfate. From the ether layer, diphenyl sulfide (42%) and di-*p*-tolyl disulfide (40%) were isolated. The yields of products were determined by quantitative vapor phase chromatography.

Sodium *p*-Toluenethiolate. The compound was prepared by treating *p*-tolyl mercaptan (10 g, 0.08 mol) and sodium hydroxide (3.7 g, 0.078 mol) in benzene. The usual work up of the reaction mixture afforded 11 g of colorless sodium *p*-toluene thiolate in 94 % yield.

The Reaction of Triarylsulfonium Bromide with Potassium Hydroxide in Aqueous Ethanol and Water. A typical run is as follows. Triphenylsulfonium bromide (1 g, 0.003 mol) and potassium hydroxide (1.3 g, 0.0024 mol) were dissolved in water. The solution was sealed into a glass tube and heated for 50 hr at 150—160°C. After cooling, the sealed tube was broken and the content poured into water, acidified with dilute hydrochloric acid, extracted with ether, washed, dried over magnesium sulfate. The ether layer was fractionated by vapor phase chromatography. Identification and determination of the yields of the products were also done by IR, NMR and gas chromatography. All the results and those from other reaction are shown in Tables 3 and 4.

Kinetic Experiment. Kinetic measurement and the rate calculation of alkaline decomposition of triphenylsulfonium bromide with ethoxide ion in aqueous ethanol were performed with the use of the ultraviolet spectra of the diphenyl sulfide in the same method as described previously.[2)]

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 3535—3538 (1969)

Reaction of Ethyl Diazoacetate with Cupric Chloride

Takeo SAEGUSA, Yoshihiko ITO, Toyoji SHIMIZU and Shiro KOBAYASHI

Department of Synthetic Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received May 23, 1969)

The reaction of ethyl diazoacetate (**1**) with $CuCl_2$ was investigated. Ethyl chloroacetate (**2**), ethyl dichloroacetate (**3**) and a mixture of ethyl dichloromaleate (**4**) and ethyl dichlorofumarate (**5**) were produced. These products were explained by assuming 1-chloro-1-ehtoxycarbonylmethyl-copper complexes, (**10**) and (**11**). The reactions of **1** with $HgCl_2$ and $CoCl_2$ were examined in detail as reference reactions from the mechanistic view point.

The reaction of diazo compounds, especially diazomethane, with metal halides has been extensively studied, which provides a convenient method for the preparation of halomethylmetal compound.[1] Studies on the interaction between diazo compound and copper salts are restricted to the copper catalyzed decomposition of diazo compounds.[2]

This paper describes the reaction of ethyl diazoacetate (**1**) with $CuCl_2$. It has been found that $CuCl_2$ is distinguished from other copper salts. In equimolar reactions of **1** with cupric salts having negative groups of CN, SO_4 and NO_3 as well as cuprous chloride, only a mixture of ethyl maleate and fumarate was produced. On the other hand, the reaction of **1** with $CuCl_2$ produced ethyl chloroacetate (**2**), ethyl dichloroacetate (**3**), and a mixture of ethyl dichloromaleate (**4**) and ethyl dichlorofumarate (**5**). These products were explained by assuming ethoxycarbonyl-substituted chloromethyl-copper complexes, exemplified by **10** and **11**, as unstable intermediates. The reactions of **1** with $HgCl_2$ and $CoCl_2$ are described in more detail as reference reactions from the mechanistic view point. The reaction of diphenyldiazomethane with cupric chloride was also examined to complement mechanistic consideration.

b) Yields are calculated on the basis of the amount of ethyl diazoacetate.

Results and Discussion

Reactions of 1 with Copper Compounds. An equimolar reaction of **1** with CuCl took place smoothly at room temperature. A mixture of ethyl maleate and ethyl fumarate was produced in a quantitative yield (Table 1). Similarly, cupric salts having negative groups of CN, SO_4 and NO_3 gave a maleate-fumarate mixture. Its formation is explained by assuming the formation of ethoxycarbonylcarbene.[2)]

The reaction of **1** with $CuCl_2$ is quite different from that with other copper compounds. The products of an equimolar reaction at 15°C in acetonitrile were **2** (yield 16%), **3** (40%), a mixture of **4** and **5** (3%) and the maleate-fumarate mixture (30%). The maleate-fumarate mixture is probably produced also by the carbene reaction of **1**. It was not produced in the **1**-$CuCl_2$ reaction of 1 : 2 molar ratio. Here, $CuCl_2$ was reduced completely to CuCl. These findings can be rationalized by the assumption that the reaction of **1** with $CuCl_2$ is much faster than the carbene reaction of **1** induced by CuCl. In other words, the maleate-fumarate mixture is produced only after all $CuCl_2$ has been reduced to CuCl.

The production of considerable amounts of **3** is taken to differentiate $CuCl_2$ from other metal chlorides.

Reactions of 1 with $HgCl_2$ and $CoCl_2$. Nesmeyanov[3)] reported the reaction of **1** with $HgCl_2$ which produced **2** and organomercury compound (**6**).

$$4N_2CHCO_2Et + 3HgCl_2 \rightarrow \underset{(1)}{} \underset{(6)}{Hg\left(-\overset{Cl}{\overset{|}{C}}-CO_2Et\right)_2} + \underset{(2)}{2ClCH_2CO_2Et} \qquad (1)$$
HgCl

In order to characterize the **1**-$CuCl_2$ reaction and to elucidate its reaction mechanism, the reactions of **1** with $HgCl_2$ and $CoCl_2$ were examined as reference reactions. At room temperature, these metallic chlorides reacted with **1** only very slowly. At refluxing temperature (about 80°C), the reactions proceeded at considerable rates. In the **1**-$CoCl_2$ reaction, the heat-treated reaction mixture was separated into liquid and solid parts. From the liquid part, **2** was isolated by distillation. By glpc analysis, a trace of the **4**/**5** mixture and **9** was detected in the liquid part. The solid part did not dissolve in common solvents, and further purification without decomposition was impossible. However, the solid part showed an IR spectrum which was almost the same as that of the organomercury complex (**6**) prepared according to Nesmeyanov's procedure. Consequently, an organocobalt complex (**7**) corresponding to **6** can be assumed to be the essential constituent of the solid part of the **1**-$CoCl_2$ reaction mixture.

In the reaction of **1** with $HgCl_2$, a trace of the **4**/**5** mixture and **9** was detected in addition to the two products indicated in Eq. (1). These results are summarized in Table 2.

Table 2. Reaction of **1** with $HgCl_2$ and $CoCl_2$[a)]

3) A. N. Nesmeyanov and G. S. Powich, *Ber.*, **67**, B, 971 (1934).

It is interesting that **6** is comparatively inert towards $HgCl_2$ and $CoCl_2$ but easily decomposed by $CuCl_2$ to produce the **4/5** mixture and **9**. This finding has an important bearing upon the mechanism of the **1**-$CuCl_2$ reaction, especially the production of the **4/5** mixture.

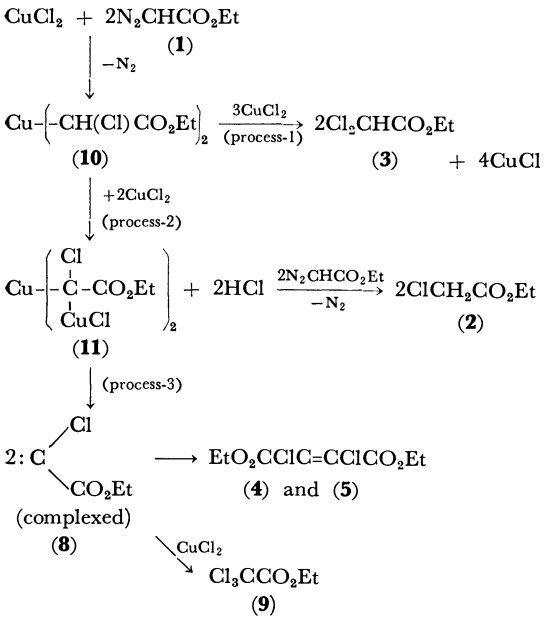
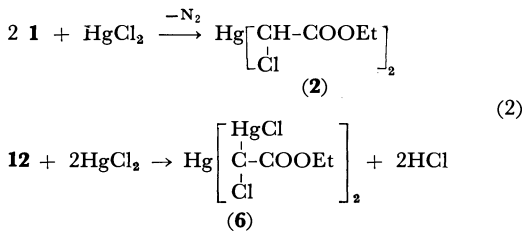
a) Reaction was carried out in 10 m*l* of acetonitrile at 80°C for 1 hr.
b) Yields are calculated on the basis of **6**.

Mechanism of Reaction of 1 with $CuCl_2$. The following scheme of reaction may explain the production of **3**, the **4/5** mixture and **9**. As the first unstable intermediate, 1-chloro-1-ethoxycarbonylmethylcopper complex (**10**) is postulated, whose reaction with $CuCl_2$ (process-1) will produce **3** and CuCl. Process-1 is the process of the chlorine ligand transfer from $CuCl_2$ to 1-chloro-1-ethoxycarbonylmethyl moiety, which seems to resemble the so-called ligand transfer[4] between organic free radical and the ligand of metal salt. As to the production of **2**, the origin of the second α-hydrogen atom is an essential problem.



In the **1**-$HgCl_2$ reaction, Nesmeyanov[3] proposed that **2** is produced from **1** and hydrogen chloride which is liberated by the mercuration of the acidic α-hydrogen of an organomercury compound (**12**).



In the **1**-$CuCl_2$ reaction of the present study, an experiment using α-deuterio-diazoacetate (**1**-*d*) was carried out. It has been established that the second hydrogen atom of **2** originates in another molecule of **1**. **1**-*d* of a degree of deuteration over 98% was prepared from **1** and deuterium oxide in the presence of triethylamine catalyst. The products **2** and **3** in the reaction of **1**-*d* with $CuCl_2$ under the regular reaction conditions were of the same degree of deuteration over 98% as that of **1**-*d*. Consequently it is clear that the α-hydrogen atom of **2** does not originate from acetonitrile or from water which might be present as an impurity.

This conclusion is supported by the reaction of diphenyldiazomethane (**13**) having no α-hydrogen with $CuCl_2$. The products of the reaction of **13** with excess $CuCl_2$ (molar ratio 1 : 2) were dichlorodiphenylmethane (yield 48%), benzophenone azine (34%) and tetraphenylethylene (9%). Diphenylchloromethane which corresponds to **2** in the reaction of **1** was not detected among the products.

In relation to Nesmeyanov's mechanism for the reaction of $HgCl_2$, the conversion of **10** by $CuCl_2$ to **11** (process-2) liberating hydrogen chloride may be cited as one possible mechanism of the elimination of hydrogen from **1**. In the reaction of **1** with $HgCl_2$, the species corresponding to **11** was actually isolated. In the **1**-$CuCl_2$ reaction, **11** was not isolated. This may be ascribed to the fact that **11** is much less stable due to the weakness of copper-carbon bond and that **11** is readily decomposed with $CuCl_2$. In addition, **11** is assumed to be a key intermediate in the course of reaction leading to the **4/5** mixture and **9**. The reaction of **11** with $CuCl_2$ producing the **4/5** mixture and **9** has been supported by reference experiments in which the mercury species corresponding to **11** was reacted with $CuCl_2$ to give the **4/5** mixture and **9**. Probably, the **4/5** mixture and **9** would be derived from the common precursor **8**. The process of the formation of **9** seems to correspond to that of **3** in the **1**-$CuCl_2$ reaction.

Recently, bis(diazoethoxycarbonylmethyl) mercury $Hg[C(N_2)CO_2Et]_2$ (**14**)[5] attracts much

Experimetnal

Reaction of Ethyl Diazoacetate (1) with CuCl. To a stirred mixture of CuCl (18.0 mmol) and acetonitrile, **1** (18.0 mmol) was added dropwise at 15°C. The reaction proceeded smoothly, evolving N_2 gas, and ceased in 30 min. The reaction mixture was filtered to remove an insoluble copper salt, and was subjected to distillation. A mixture of ethyl maleate and fumarate (80—85°C/30 mmHg) was obtained in 97% yield.

Reaction of Ethyl Diazoacetate (1) with $CuCl_2$. To a stirred mixture of $CuCl_2$ (16.4 mmol) and acetonitrile (10 m*l*), **1** (16.4 mmol) was added dropwise at 15°C. The N_2 gas evolution ceased in 30 min and the mixture turned to red-brown. The reaction mixture was filtered to remove the insoluble salt and subjected to distillation. The distillate of bp 60—100°C/20 mmHg was analyzed by glpc. The products were ethyl chloroacetate (**2**) (16%), ethyl dichloroacetate (**3**) (40%), a mixture of ethyl dichloromaleate (**4**) and ethyl dichlorofumarate (**5**) (3%) and a mixture of ethyl maleate and fumarate (30%). The products **2**, **3**, **4**, **5**, ethyl maleate and ethyl fumarate were identified by comparison of the glpc retention time and the IR spectrum with those of the corresponding authentic samples. The insoluble part was analyzed by IR and redox titration. The IR spectrum of the insoluble part showed no absorption band in the region of ordinary organic compounds. Thus, the salt did not contain any organic moiety. The valence of copper was measured by redox titration. $CuCl_2$ was completely reduced to CuCl after the reaction.

Reaction of Ethyl Diazoacetate (1) with $HgCl_2$. To a mixture of $HgCl_2$ (20 mmol) and acetonitrile (10 m*l*), **1** (10 mmol) was added slowly at 15°C and then the reaction mixture was heated at refluxing temperature (80°C) for 4 hr. The reaction mixture was filtered to remove the insoluble solid. The filtrate was distilled to give ethyl chloroacetate (41%). The organomercury compound (**6**) was isolated from the insoluble part according to Nesmeyanov's[3] procedure (yield 40%). IR of **6** (Nujol): $\nu_{C=O}$ 1660 cm^{-1}, ν_{C-O} 1200 cm^{-1}, ν_{C-Cl} 775 cm^{-1}.

Reaction of Ethyl Diazoacetate (1) with $CoCl_2$. A mixture of $CoCl_2$ (20 mmol), ethyl diazoacetate (**1**) (10 mmol) and acetonitrile (10 m*l*) was heated at 80°C for 4 hr. The solid and liquid parts were separated. From the liquid part, **2** was isolated by distillation (yield 31%). The solid part did not dissolve in common solvents. Further purification without decomposition was impossible. The amount of solid part was 0.86 g (IR (Nujol): $\nu_{C=O}$ 1665 cm^{-1}, ν_{C-O} 1205 sm^{-1}, ν_{C-Cl} 770 cm^{-1}).

Reaction of Diphenyldiazomethane (13) with $CuCl_2$. To a mixture of $CuCl_2$ (20 mmol) and acetonitrile (10 m*l*), a solution of **13** (10 mmol) in acetonitrile (5 m*l*) was added slowly at 15°C. The reaction proceeded smoothly evolving N_2 gas and ceased in about 15 min. The reaction mixture was filtered to remove a white solid. The filtrate was dried up *in vacuo*, and the residue was analyzed by column chromatography (silica gel, benzene-petroleum ether) to obtain dichlorodiphenylmethane (48%), benzophenone azine (34%) and tetraphenylethylene (9%). These three products were identified by comparison of the IR spectra and/or the melting points with those of the corresponding authentic samples.

Preparation of Ethyl α-Deuterio-diazoacetate (1-*d*.).[6] A heterogeneous mixture of **1** (4 m*l*), deuterium oxide (15 m*l*) and triethylamine (0.1 m*l*) was stirred for 1 hr. The layer of diazoacetate was separated and treated with deuterium oxide again. The diazoacetate layer was dried with anhydrous Na_2SO_4 and distilled to give ethyl α-deuterio-diazoacetate in 80% yield. The NMR spectrum analysis revealed that the α-position was deuterated to an extent over 98%.

Reaction of Ethyl α-Deuterio-diazoacetate (1-*d*) with $CuCl_2$. The reaction was carried out in the same way as that of the **1**-$CuCl_2$ reaction. The products of **2**, **3** and the **4/5** mixture were isolated by preparative glpc. By NMR spectrum, the extents of deuteration at α-hydrogen of **2** and **3** were found to be over 98%.

Reaction of $Hg\left(\begin{array}{l}-C(Cl)CO_2Et\\|\\HgCl\end{array}\right)_2$ (6) with $CuCl_2$. A mixture of **6** (5 mmol), $CuCl_2$ (15 mmol) and acetonitrile (10 m*l*) was heated at 80°C for 1 hr. The reaction mixture was filtered to remove the solid part. The filtrate was concentrated *in vacuo* and analyzed by glpc. The products were the **4/5** mixture (60%) and trichloroacetate (**9**) (27%).

Reaction of $Hg(N_2CCO_2Et)_2$[5a] (14) with $CuCl_2$. A solution of **14** (5 mmol) in acetonitrile (5 m*l*) was added dropwise to a mixture of cupric chloride (15 mmol) and acetonitrile (10 m*l*) at 0°C. After 1 hr, the reaction mixture was filtered to remove the insoluble solid.

The filtrate was analyzed by glpc to obtain ethyl trichloroacetate (10%) and a mixture of ethyl dichloromaleate and ethyl dichlorofumarate (33%).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 3539—3546 (1969)

Synthesis of Pyrrole Nucleosides by the Photo-dehydrogenation of Δ^3-Pyrroline Derivatives

Masajiro KAWANA and Sakae EMOTO

The Institute of Physical and Chemical Research, Yamato-machi, Kita-Adachi-gun, Saitama

(Received June 3, 1969)

1-(β-D-Glucopyranosyl)pyrrole (VI) was prepared by the photo-dehydrogenation of 1-(2′,3′,4′,6′-tetra-*O*-acetyl-β-D-glucopyranosyl)-Δ^3-pyrroline (IV) in the presence of oxygen and benzophenone, followed by deacetylation. The nucleoside (VI) was also derived directly from 1-(D-glucosyl)-Δ^3-pyrroline (III) by photochemical means. The synthesis of 1-(α-D-ribofuranosyl)-pyrrole (XI), its β-anomer (XII), and 1-(β-D-ribopyranosyl)pyrrole (XIII) was accomplished by photodehydrogenation of 1-(2′,3′-*O*-isopropylidene-D-ribosyl)-Δ^3-pyrroline, followed by the removal of the protecting group. The treatment of 1-(2′,3′-*O*-isopropylidene-α-D-ribofuranosyl)pyrrole (VIII) with 80% aqueous acetic acid afforded a novel α-cyclonucleoside, 1-(2-*C*,2′-*O*-isopropylidene-α-D-ribofuranosyl)pyrrole (XIV), besides XI—XIII. The formation of pyrrole by the photo-dehydrogenation of Δ^3-pyrroline (II) itself was confirmed by gas chromatography.

The photo-dehydrogenation of partially-hydrogenated nitrogen-heterocycles, such as tetraphenyl chlorin[1] and 2,3-dihydro-β-carbolines,[2] has been reported. Preobrazhenskaya,[3] Walton,[4] and their co-workers demonstrated that 1-(D-glycosyl)indoles were synthesized from the corresponding indolines using a reagent useful for dehydrogenation, 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ).

In the course of the step-by-step synthesis of pyrrole nucleosides, we found that 1-(2′,3′,4′,6′-tetra-*O*-acetyl-β-D-glucopyranosyl)-Δ^3-pyrroline (IV) could be photochemically dehydrogenated to yield 1-(2′,3′,4′,6′-tetra-*O*-acetyl-β-D-glucopyranosyl)pyrrole (V).[5] We wish now to present these results in detail, and to describe the photochemical formation of anomeric D-ribosylpyrroles and the formation of a novel α-cyclonucleoside by the migration of an isopropylidene group.

Results and Discussion

The synthesis of 1-(D-glucosyl)-Δ^3-pyrroline (III) was performed by heating a mixture of α-D-glucose (I) and crude Δ^3-pyrroline (II)[6] under conditions similar to those used for the synthesis of 1-(D-glucosyl) piperidine[7] (Fig. 1); the purification[8] of crude II was not necessary for the present purposes because only III was crystallized by the addition of acetone to the reaction mixture.

The structure of III was tentatively identified. The observed values for the elemental analysis of III were in good agreement with the theoretical values. The NMR spectrum in deuterium oxide (D_2O) exhibited two singlets, at τ 6.24 and 4.23, due to the methylene and olefinic protons of the Δ^3-pyrroline ring respectively.[8] The signals of the anomeric proton appeared in the τ 6.0—5.6 region,[9] but they were not sufficiently resolved for interpretation.

The treatment of III with acetic anhydride in pyridine gave IV in a 73% yield. Its IR spectrum was devoid of N–H, O–H, and *N*-acetyl carbonyl absorption bands. The NMR spectrum in deuterio-chloroform($CDCl_3$) revealed four singlets, at τ 7.99—7.93, for the acetyl protons, and two singlets, at τ 6.22 and 4.32, for the methylene and olefinic protons of the Δ^3-pyrroline ring respectively. The signal of the anomeric proton appeared as a doublet centered at τ *ca.* 5.7 with the coupling constant of *ca.* 8 cps; the values could not be accurately measured, however, because the high-field part of the doublet was overlapped by other signals.

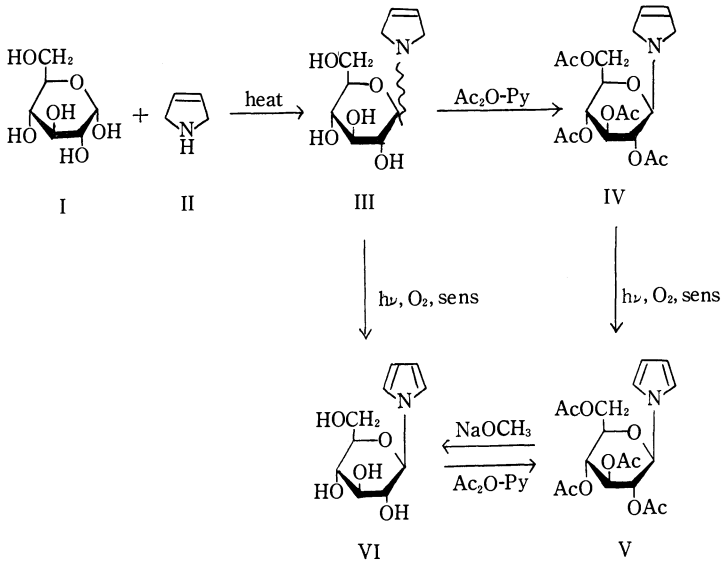

Fig. 1

This large coupling constant is indicative of a *trans*-diaxial relationship between H-1′ and H-2′, and it corresponds to the β-configuration.[10]

Further proof of the glucopsranosylamine structure of IV was obtained by the ready degradation[11] of IV with 0.7% aqueous formic acid to the known 2,3,4,6-tetra-*O*-acetyl-D-glucopyranose.[12]

When a benzene solution of IV was allowed to evaporate repeatedly in an open vessel, the thin-layer chromatographic analysis showed that IV was gradually converted into V. This conversion was markedly accelerated by the irradiation of UV light with a Pyrex filter, under bubbling oxygen, and in the presence of benzophenone as a sensitizer.[13] Under such conditions V was obtained as the main product: it was isolated by crystallization in a 85% yield. The dehydrogenation of IV with DDQ in the dark was also effective, producing V in a good yield.

The IR and UV spectra of V showed the presence of a pyrrole ring[14,15] (*cf.* Table 1 and the Experimental section). The NMR spectrum in $CDCl_3$ exhibited two pseudo-triplets of equal intensity, centered at τ 3.83 and 3.21 for the protons at C-3, 4 and C-2, 5 of the pyrrole ring respectively (Table 2).[16] The signal of the anomeric proton was not separated from the others.

The anomeric configuration of V was deduced by comparing the chemical shifts of the acetyl signals of IV and V in the NMR spectroscopy. Cushley *et al.*[17] have found that when the C-2′ acetyl group and the pyrimidine in acetylated pyranosyl pyrimidine nucleosides are in a *trans*-diequatorial relationship, there is a small but significant down-field shift (*ca.* 0.05 ppm) of the C-2′ acetyl signal upon the saturation of the 5, 6-double bond of the pyrimidine. In the case of acetylated β-ribo- and β-gluco-pyranosylindoline-indole systems, a large down-field shift (at least 0.29 ppm) of the C-2′ acetyl signal occurs upon the removal of the anisotropy due to the 2,3-double bond of the indole.[18] A similar down-field shift was observed in the present pyrrole nucleoside. The acetyl signals of V appeared at τ 7.99—7.93 as three singlets and at τ 8.15 as one singlet assignable to the C-2′ acetyl group; all would be in an area of positive shielding due to the anisotropy of the pyrrole ring.[19] Therefore, the

a) τ-Value (peak multiplicity, and coupling constant (cps)); see Experimental section.
b) The acetyl signals appeared at τ 8.15 (3H), 7.99, 7.95, and 7.93 as singlets.
c) The signal of H-2′ appeared as a quartet ($J_{1',2'}$=2.6 cps, $J_{2',3'}$=3.6 cps) centered at τ 5.58. Irradiation of H-1′ caused the quartet to collapse to a doublet ($J_{2',3'}$=3.6 cps), and irradiation of H-2′ caused a doublet due to H-1′ to collapse to a singlet.
d) Numbers in brackets refer to number of the protons obtained integration.
e) Letters in parentheses refer to singlet (s), doublet (d), triplet (t), pseudo-triplet (pt), quartet (q), and multiplet (m).
f) A poorly resolved doublet.
g) The signals disappeared by the addition of D_2O.
h) C-4′ OH.
i) C-2′, 3′, and 4′ OHs.
j) C-3′ OH.
k) H-3 (1H, $J_{3,4}$=3.0 cps, $J_{3,5}$=1.5 cps).
l) H-4 (1H, $J_{3,4}$=3.0 cps).
m) H-5 (1H, $J_{3,5}$=1.5 cps, $J_{4,5}$=2.4 cps).

C-2′ acetyl signal is shifted by at least 0.16 ppm down-field in changing from V to IV. This suggests that V has the β-configuration.

The deacetylation of V in the usual manner gave, after chromatography, analytically pure 1-(β-D-glucopyranosyl)pyrrole (VI) as a hygroscopic glass in a 76% yield. The paper and gas chromatographic analyses showed that the product was anomerically pure. The NMR spectrum of VI in D_2O revealed a doublet due to the anomeric proton with the large coupling constant of 8.4 cps, thus establishing the β-configuration.[10] Therefore, it was confirmed that the proposed sutrcture for V was correct and that the β-configuration of IV was retained in the course of the dehydrogenation with photochemical means as well as with DDQ.

Plisov[20] reported that when a mixture of glucose and pyrrole was heated the product, which consisted of two components, was obtained as a crystal (mp 190°C) after crystallization from pyridine. However, its structure was unsubstantiated by experimental details or physical data. Moreover, Plisov's product was not identical with VI, at least not in respect to their solubility in pyridine, in which the latter was readily soluble.

An alternative route to obtain VI is the direct photo-dehydrogenation of III. When a suspension of III in ethanol was irradiated under the conditions described above, analytically pure VI

20) A. K. Plisov, *Ukrainskii Khem. Zhur.*, **3**, 477 (1928); *Chem. Abstr.*, **23**, 3224 (1929).

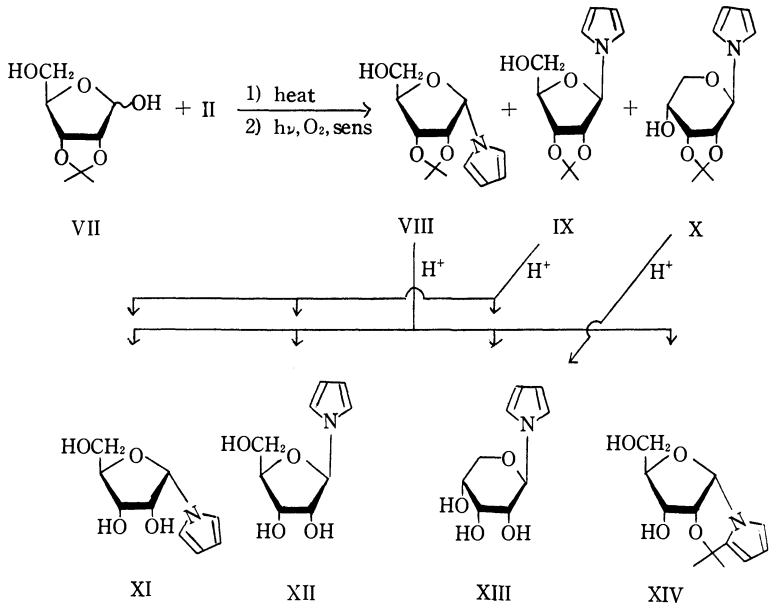

Fig. 2

was produced in a 62% yield after chromatography. The product was identical in every respect with a specimen prepared from V. Further, the acetylation of the product gave V in a 92% yield.

The preparation of the D-ribosylpyrrole nucleosides was undertaken starting with pure II[8] and 2′,3′-*O*-isopropylidene-D-ribose (VII)[21] (Fig. 2). Thus, a mixture of II and VII was heated to give syrupy products which could contain 1-(2′,3′-*O*-isopropylidene-D-ribosyl)-Δ^3-pyrroline. The irradiation of the syrup in ethanol under the conditions described above provided the isomeric nucleosides (40%), namely, 1-(2′,3′-*O*-isopropylidene-α-D-ribofuranosyl)pyrrole (VIII), 1-(2′,3′-*O*-isopropylidene-β-D-ribofuranosyl)pyrrole (IX), and 1-(2′,3′-*O*-isopropylidene-β-D-ribopyranosyl)pyrrole (X), in a ratio of approximately 1 : 8 : 1 (Table 1). Interestingly, the treatment of the syrup with DDQ produced these nucleosides (54%) in a ratio of approximately 7 : 2 : 1, the α-furanosyl anomer (VIII) being predominant.

The removal of the isopropylidene group of IX with 80% aqueous acetic acid, followed by column chromatography on Dowex 1 (OH^-),[22] gave 1-(α-D-ribofurayosyl)pyrrole (XI), 1-(β-D-ribofuranosyl)pyrrole (XII), and 1-(β-D-ribopyranosyl)-pyrrole (XIII) in 3.5, 87, and 2.5% yields respectively. This suggests that pyrrole nucleosides as well as indole nucleosides[3] isomerize under mild acidic conditions. The removal of the isopropylidene group of VIII also gave XI, XII, and XIII in 21, 22, and 3% yields respectively. In addition, 1-(2-*C*, 2′-*O*-isopropylidene-α-D-ribofuranosyl)pyrrole (XIV) was obtained in a 29% yield from VIII. It can be considered that XIV is formed by an acid-catalyzed intramolecular reaction similar to that of the substituted indole with the dimethyl ketal group.[23] To our knowledge, XIV is a new type of α-cyclonucleoside.[24] The removal of the protecting group of X provided only XIII in a 90% yield.

The analytical and spectroscopic data for VIII—XIV supported the assigned structres (Tables 1 and 2). The NMR spectra of VIII, IX, XI, and XII in deuterated dimethyl sulfoxide (DMSO-d_6)[25] showed a C-5′ hydroxyl proton as each triplet; these protons disappeared upon the addition of D_2O. This indicates that these nucleosides have the furanosyl structure. Therefore, VIII and IX as well as XI and XII are a pair of anomers; they can be assigned to the α- and β-configurations respectively on the basis of the following NMR data:

(1) The signals of the anomeric protons of the β-anomers, IX and XII, were found in a higher field than those of the α-anomers, VIII and XI respectively; Nishimura and Shimizu[26] have found that the anomeric protons of nucleosides occur in

26) T. Nishimura and B. Shimizu, *Chem. Pharm. Bull.*, **13**, 803 (1965).

a higher field when the C-1′ and 2′ substituents are *trans* than when they are *cis*.[27]

(2) The difference in the coupling constants of the anomeric protons between the β-anomers, IX and XII, was much greater than the difference in those between the α-anomers, VIII and XI; Jardetzky[28] has reported that when the ribofuranose ring is constrained by fusion with a second ring, the coupling constant of the anomeric proton of β-nucleoside is reudced.[29]

(3) The signals of the protons of the isopropylidene group for the α-anomer, VIII, appeared in a higher field than those for the β-anomer, IX, presumably because of the anisotropic effect of the pyrrole ring.[17-19,30]

(4) The signals of the C-5′ hydroxyl proton of the β-anomer, XII, appeared in a lower field than those of the α-anomer, XI, as has been observed in the case of the anomeric 7-D-ribofuranosyladenines.[27b]

Further, the order of elution from the anion-exchange column[22] supported these assignments; the α-anomer, XI, was eluted faster than the β-anomer, XII (see the Experimental section).[31]

The pyranosyl structure of X was proved by the appearance of a doublet due to the C-4′ hydroxyl proton in the NMR spectrum (in DMSO-d_6).[25] The signals of the anomeric protons of X and XIII appeared as doublets with large coupling constants, thus establishing the β-configurations.[10]

The NMR spectrum of XIV in DMSO-d_6 showed the presence of an isopropylidene group and a 1,2-disubstituted pyrrole ring. The signals of the C-3′ and 5′ hydroxyl protons appeared as a doublet (J= 6.0 cps) and a triplet respectively. In spin-decoupling experiments, the irradiation of the anomeric proton caused a quartet centered at τ 5.58 to collapse to a doublet (J=3.6 cps). This indicated that the quartet arises from H-2′ and that the C-2′ hydroxyl group is substituted.

The value for the coupling constant of the anomeric proton of XIV was 2.6 cps, a value which corresponded to a dihedral angle of H-$C_{1'}$-$C_{2'}$-H, 54° or 123°, according to the Karplus equation.[32] An examination of the Dreiding models showed that the former was suitable for the dihedral angle of the α-configuration, but that neither of them was suitable for that of the β-configuration. Additional support of the α-configuration of XIV was obtained by a comparison of the optical rotations of XI, XII, and XIV (Table 1); XI and XII obey the Hudson's isorotation rules,[33] and XI and XIV have the same sign of rotation.

An attempt was made to examine whether II itself was converted into pyrrole by photochemical means. A solution of crude II[6] in ethanol was irradiated under the conditions described above, and aliquots were examined by gas chromatography. A peak due to II disappeared after 2 hr, the formation of pyrrole being identified. The photo-dehydrogenation reaction in the presence of oxygen and benzophenone provides an alternative to a number of known pyrrole syntheses using II or its derivatives.[34,35]

Experimental

Some of the physical data for the pyrrole nucleosides are listed in Tables 1 and 2. All the melting points are uncorrected.

The irradiation of UV light was performed with a super-high-pressure mercury lamp (100 W, Matsuda SHL-100UV-1). The optical rotations were measured with a Perkin-Elmer 141 photoelectric polarimeter in a 1-dm tube. The IR spectra were obtained using a Perkin-Elmer 521 grating infrared spectrophotometer. The UV spectra were taken on a Cary 14 recording spectrophotometer.

The NMR spectra were determined on a Nippon Denshi C-60 spectrometer using sodium 2, 2-dimethyl-2-silapentane-5-sulfonate (tetramethylsilane for the $CDCl_3$ solutions) as the internal standard. The chemical shifts were recorded as ppm on the τ scale, with the coupling constants (the directly-measured line-spacings) as cps.

The gas chromatography (GC) was performed at 180°C with a Shimadzu GC-4A gas chromatograph equipped with a flame ionization detector using a glass column (1.8 m×4 mm) packed with 3% OV-17 on Shimalite W (80—100 mesh); nitrogen was used as the carrier gas (flow rate, 64 ml/min). The individual nucleoside was treated with a pyridine solution of hexamethyldisilazane and trimethylchlorosilane at room temperature, and the resulting solution was injected into the gas chromatograph.[36]

The thin-layer and paper chromatographies (TLC and PC) were run by the ascending technique on a silica gel G (E. Merck) plate and a filter paper No. 51

(Toyo Roshi) respectively. The following solvent systems were used as developers: (A) *n*-hexane - ethyl acetate (1 : 1); (B) ethyl acetate - isopropanol - water (65 : 30 : 5); (C) ethyl acetate - *n* - hexane - methanol (7 : 2: 1); (D) *n* - butanol - water (87 : 13). The spots were detected by iodine vapor or a 1% solution of *p*-dimethylaminobenzaldehyde[37] in methanol - concentrated hydrochloric acid (3 : 1).

1-(D-Glucosyl)-Δ^3-pyrroline (III). A mixture of I (1.8 g, 0.01 mol) and crude II[6] (1.4 g, 0.02 mol) was heated at 80—85°C (bath-temperature) for 15 min in a flask equipped with a tight stopper. To the cooled reaction mixture there was added acetone (50 m*l*). The syrupy product rapidly solidified on scratching. After being cooled overnight at 0°C, the product was filtered, washed with cold acetone, and dried. Recrystallization from acetone-methanol gave III (1.7 g, 73.9%): mp 130—135°C (decomp.); $[\alpha]_D^{20}$ −28.8° (4 min) → +13.0° (46 hr, constant, *c* 0.40, H_2O); IR, ν_{max}^{KBr} 3408, 3290, 2886, 2850, 1085, 1025 cm^{-1}; NMR (in D_2O), τ 6.24 (singlet, methylene protons of the Δ^3-pyrroline ring), 5.98, 5.88, and 5,75 (*ca.* 1.5H, broad peaks), 4.23 (2H, singlet, olefinic protons).

Found: C, 51.78; H, 7.14; N, 6.09%. Calcd for $C_{10}H_{17}O_5N$: C, 51.94; H, 7.41; N, 6.06%.

1-(2′,3′,4′,6′-Tetra-*O*-acetyl-β-D-glucopyranosyl)-Δ^3-pyrroline(IV). To a mixture of acetic anhydride (2.7 g, 26 mmol) and dry pyridine (4.1 g, 52 mmol), there was added III (1.16 g, 5 mmol) at −10—−5°C, and then the mixture was stirred for 1.5 hr. After the reaction mixture had been allowed to stand at −5°C for 24 hr, ethanol (1 m*l*) was added to decompose an excess of acetic anhydride, and then the pyridine was removed at room temperature *in vacuo*. The residue was dissolved in ether, and the solution was washed with water, aqueous sodium bicarbonate, and water successively and then dried over anhydrous magnesium sulfate. The evaporation of the ether gave a crystalline mass (1.67 g) which, after recrystallization from degassed *n*-hexane - isopropanol with charcoal treatment in the dark, afforded a crude material (1.51 g, mp 118—122°C). Further recrystallization from degassed *n*-hexane - ethanol in the dark gave IV (1.45 g, 72.5%): mp 121—122°C; $[\alpha]_D^{25}$ −23.7° (*c* 0.49, degassed $CHCl_3$); R_f(TLC, solvent A), 0.27; IR, ν_{max}^{KBr} 2892, 2850, 1753, 1738, 1380, 1240, 1038 cm^{-1}; NMR (in $CDCl_3$), τ 7.99, 7.97, 7.95, and 7.93 (12H, each singlet, acetyl protons), 6.22 (singlet, methylene protons of Δ^3-pyrroline ring), *ca.* 5.7 (doublet, $J_{1',2'}$=*ca.* 8 cps, anomeric proton), 4.32 (2H, singlet, olefinic proton).

Found: C, 54.10; H, 6.05; N, 3.51%. Calcd for $C_{18}H_{25}O_9N$: C, 54.13; H, 6.31; N, 3.51%.

Degradation of 1-(2′,3′,4′,6′-tetra-*O*-acetyl-β-D-glucopyranosyl)-Δ^3-pyrroline (IV). To a solution of IV (200 mg, 0.5 mmol) in degassed acetone (2 m*l*) there was added 0.7% aqueous formic acid (10 m*l*) at room temperature in the dark. After 15 min, the acetone was removed at 25°C *in vacuo*. The residue was extracted with chloroform, and the extract was washed with water, aqueous sodium bicarbonate, and water successively and dried over anhydrous magnesium sulfate. The evaporation of the chloroform at room temperature *in vacuo* gave 2,3,4,6-tetra-*O*-acetyl-D-glucopyranose as a syrup (145 mg, 83.3%) : $[\alpha]_D^{20}$ +76.6° (constant, *c* 1.44, 95% EtOH) (lit,[12a] $[\alpha]_D^{24}$ +80.2° (constant, *c* 3.37, 95% EtOH)). This product was identical with an equilibrated authentic sample[12b] in all respects (IR, NMR, and TLC).

1-(2′,3′,4′,6′,-Tetra-*O*-acetyl-β-D-glucopyranosyl)-pyrrole (V). *(A) Photo-dehydrogenation.* A mixture of IV (200 mg, 0.5 mmol) and benzophenone (13.7 mg, 0.075 mmol) in bezene (10 m*l*) was irradiated externally in a water-cooled Pyrex vessel under bubbling oxygen at 20°C for 1 hr. The evaporation of the benzene at 50°C *in vacuo* gave a crystalline mass which, after recrystallization from ethanol, afforded V (169 mg, 84.9%): R_f (TLC, solvent A), 0.50; IR, ν_{max}^{KBr} 3145, 3134, 3120, 3102, 1740, 1493, 740 cm^{-1}.

Found: C, 54.53; H, 5.73; N, 3.52%. Calcd for $C_{18}H_{23}O_9N$: C, 54.40; H, 5.83; N, 3.53%.

(B) Chemical dehydrogenation. All the experiments were carried out in the dark. To a suspension of DDQ (119 mg, 0.52 mmol) in dry benzene (5 m*l*), there was added a solution of IV (200 mg, 0.5 mmol) in dry benzene (4 m*l*). The reaction mixture was then allowed to stand at room temperature for 1 hr under occasional shaking. The resultant precipitates were filtered and washed with benzene. The removal of the benzene at 60°C *in vacuo* gave crystals which, after recrystallization from ethanol, afforded V (178 mg, 89.4%). The IR spectral comparison and a mixed-melting-point determination showed this material to be identical with the sample prepared by the method A.

(C) Acetylation of VI. A mixture of acetic anhydride (570 mg, 5.6 mmol) and dry pyridine (790 mg, 10 mmol) was stirred into a solution of VI (130 mg, 0.57 mmol) in dry pyridine (500 mg). After the stirring had been continued at this temperature for 1 hr, the reaction mixture was allowed to stand overnight at 0°C. Ethanol (0.5 m*l*) was added to decompose an excess of acetic anhydride, and the pyridine was removed at room temperature *in vacuo*. The resultant crystals were washed with water, filtered, and dried. Recrystallization from ethanol gave V (207 mg, 92.0%). The IR spectral comparison, a mixed-melting-point determination, and the TLC analysis showed this product to be identical with the sample prepared by the method A.

1-(β-D-Glucopyranosyl)pyrrole (VI). *(A) Deacetylation of V.* To a solution of absolute methanol (12 m*l*) containing sodium methoxide (54 mg, 1.0 mmol), there was added V (397 mg, 1.0 mmol), after which the mixture was stirred at room temperature for 50 min. After the removal of the methanol at 25°C *in vacuo*, the residue was dissolved in water (5 m*l*). The solution was treated with ion-excange resin (Dowex 50W, H^+ form)(1 g) for 1 min, the resin was then immediately filtered and washed with water. After the filtrate had been treated with charcoal, the evaporation of the water at 60°C *in vacuo* gave a glassy mass (193 mg). The product was chromatographed on a silica-gel (Merck)(24 g) column with ethyl acetate - ethanol (8 : 2), yielding VI (173 mg, 75.5%) : R_f, 0.66 (TLC, solvent B), 0.38 (PC, solvent D); retention time (GC), 24.1 min; IR, ν_{max}^{KBr} 3400, 1491, 738 cm^{-1}.

Found: C, 52.15; H, 6.38; N, 6.09%. Calcd for $C_{10}H_{15}O_5N$: C, 52.39; H, 6.60; N, 6.11%.

(B) Photo-dehydrogenation of III. A suspension of III (462 mg, 2.0 mmol) in 99.5% ethanol (15 m*l*) containing

37) F. Feigl, "Spot Test in Organic Analysis," translated by R. E. Oesper, Elsevier Publishing Co., Amsterdam and Maruzen Co., Tokyo (1960), p. 289.

benzophenone (55 mg, 0.3 mmol) was irradiated externally in a water-cooled Pyrex vessel under bubbling oxygen at 19°C for 1 hr. After the ethanol had been removed at 30°C *in vacuo*, the residue was chromatographed on a Dowex 1-X2 (OH^- form) (10 g) column (2× 8.5 cm). The elution with water - methanol (7 : 3) gave a slightly contaminated product (313 mg). Further purification by silica-gel (Merck) (24 g) column chromatography with ethyl acetate - ethanol (8 : 2) afforded analytically-pure VI (284 mg, 62.0%). This product was identical with a specimen prepared by the method A in all respects (optical rotation, TLC, PC, GC, IR, UV, and NMR).

1-(2′,3′-*O*-Isopropylidene-α-D-ribofuranosyl)pyrrole (VIII), 1-(2′,3′-*O*-isopropylidene-β-D-ribofuranosyl)pyrrole (IX), and 1-(2′,3′-*O*-isopropylidene-β-D-ribopyranosyl)pyrrole (X). *(A) Photo-dehydrogenation.* A mixture of VII[21] (571 mg, 3.0 mmol) and pure II[8] (249 mg, 3.6 mmol) was placed in a flask equipped with a tight stopper and heated at 95—100°C (bath-temperature) for 3 hr. After being cooled immediately, the reaction mixture was diluted with absolute ethanol (15 m*l*), after which benzophenone (55 mg, 0.3 mmol) was added. The mixture was irradiated externally in a water-cooled Pyrex vessel under bubbling dry oxygen at 18°C for 2 hr. The evaporation of the ethanol at 30°C *in vacuo* gave a syrup, which was then dissolved in ether (80 m*l*). The ethereal solution was washed with water (4×10 m*l*), dried over anhydrous sodium sulfate, and concentrated at below 30°C *in vacuo*. The resultant syrup was chromatographed on a silica-gel (Merck) (100 g) column using *n*-hexane - ethyl acetate (6 : 4). Three products were obtained in the following sequence: IX (230 mg, 32.0%); X (22 mg, 3.1%); a mixture (7 mg, 1.0%, *ca.* 6 : 4) of VIII and X, and VIII (25 mg, 3.5%).

The α-anomer (VIII) was analyzed without further purification: R_f (TLC, solvent A), 0.30; IR, $\nu_{max}^{CHCl_3}$ 3640, 3158, 3100, 1488 cm^{-1}.

Found: C, 60.26; H, 7.12; N, 5.81%. Calcd for $C_{12}H_{17}O_4N$: C, 60.24; H, 7.16; N, 5.85%.

Recrystallization of IX from *n*-hexane - benzene gave the analytical samples as colorless crystals: R_f (TLC, solvent A), 0.59; IR, ν_{max}^{KBr} 3454, 3128, 3112, 1490, 742 cm^{-1}.

Found: C, 60.02; H, 7.22; N, 5.88%. Calcd for $C_{12}H_{17}O_4N$: C, 60.24; H, 7.16; N, 5.85%.

The recrystallization of X from *n*-hexane - benzene gave the analytical sample as colorless crystals: R_f (TLC, solvent A), 0.38; IR, ν_{max}^{KBr} 3478, 3134, 3118, 3102, 1489, 726 cm^{-1}.

Found: C, 60.37; H, 6.99; N, 5.93%. Calcd for $C_{12}H_{17}O_4N$: C, 60.24; H, 7.16; N, 5.85%.

(B) Chemical dehydrogenation. A mixture of VII[21] (761 mg, 4.0 mmol) and pure II[8] (332 mg, 4.8 mmol) was heated under the conditions described above. The cooled reaction mixture was then suspended in dry benzene (5 m*l*). This suspension was stirred, drop by drop, into a mixture of DDQ (908 mg, 4.0 mmol) and dry benzene (20 m*l*) at room temperature. After the addition had been completed, the stirring was continued for 5 min. The resultant precipitates were filtered and washed with benzene, and the filtrate was diluted with ether (50 m*l*). The solution was wased with dilute aqueous sodium carbonate and water successively, dried over anhydrous sodium sulfate, and concentrated at below 30°C *in vacuo*. The residue gave, after chromatography on a silica-gel (Merck) (150 g) column using *n*-hexane - ethyl acetate (6 : 4), IX (115 mg, 12.0%), X (29 mg, 3.0%), crude VIII (114 mg, 11.9%) slightly contaminated with X, and VIII (263 mg, 27.5%) in sequence. The IR and NMR spectral comparison, a mixed-melting-point determination, and the TLC analysis showed these products to be identical with the specimens prepared by the method A.

1-(β-D-Ribofuranosyl)pyrrole (XII). A solution of IX (239 mg, 1.0 mmol) in 80% aqueous acetic acid (2 m*l*) was heated at 100°C (bath-temperature) for 40 min. After the acetic acid and the water had been removed by repeated evaporation with ethanol (50 m*l*, total) at 60°C *in vacuo*, the residue was chromatographed on a column (2×14 cm) of Dowex 1-X2 (OH^- form) (20 g). Elution was effected with water - methanol (7 : 3), 10-m*l* fractions being collected.

Fractions 4—6 contained the starting material (2 mg).

Fractions 7—9 contained an unknown substance (1 mg).

Fractions 12—15 and 18—25 contained XIII (5 mg, 2.5%) and XI (7 mg, 3.5%) respectively; these products were identified by a color reaction[37] with *p*-dimethylaminobenzaldehyde on developed TLC plates.

Fractions 25—47 were combined; the evaporation of the solvents gave XII (174 mg, 87.4%): R_f, 0.50 (TLC, solvent C) (color reaction,[37] purple), 0.67 (PC, solvent, D); retention time (GC), 8.9 min.

Found: C, 54.01; H, 6.31; N, 7.08%. Calcd for $C_9H_{13}O_4N$: C, 54.26; H, 6.58; N, 7.03%.

1-(α-D-Ribofuranosyl)pyrrole (XI) and 1-(2-*C*,2′-*O*-Isopropylidene-α-D-ribofuranysyl)pyrrole (XIV). A solution of VIII (200 mg, 0.84 mmol) in 80% aqueous acetic acid (1.8 m*l*) was heated at 100°C bath-temperature) for 1 hr. The solvents were then removed in a manner similar to that described above. The residue was chromatographed on a column (2× 14 cm) of Dowex 1-X2 (OH^- form) (20 g) using water - ethanol (7 : 3), 10-m*l* fractions being collected.

Fractions 4—5 contained an unknown substance (2 mg).

Fractions 6—11 were combined and the solvents were removed to afford syrupy products, which contained a small amount of the starting material. Further purification by column chromatography on a silica-gel (Merck) (15 g) column with *n*-hexane - ethyl acetate (2 : 8) gave XIV (58 mg, 29.0%) as a glass which crystallized when scratched: R_f, 0.57 (TLC, solvent C) (color reaction,[37] reddish purple); IR, ν_{max}^{KBr} 3568, 3390, 3130, 3100, 1483, 717 cm^{-1}.

Found: C, 60.28; H, 7.29; N, 5.74%. Calcd for $C_{12}H_{17}O_4N$: C, 60.24; H, 7.16; N, 5.85%.

Fractions 15—21 contained XIII (*ca.* 5 mg, 3%) and an unknown substance (*ca.* 5 mg); the former was identified by color reaction[37] with *p*-dimethylaminobenzaldehyde on a developed TLC plate.

Fractions 24—32 were combined and the solvents removed to yield XI (35 mg, 21.0%): R_f, 0.43 (TLC, solvent C) (color reaction,[37] orange), 0.61 (PC, solvent D); retention time (GC), 9.6 min.

Found: C, 54.22; H, 6.36; N, 7.11%. Calcd for $C_9H_{13}O_4N$: C, 54.26; H, 6.58; N, 7.03%.

Fractions 40—68 contained XII (36 mg, 21.6%), the NMR spectrum of which was identical with that of a specimen prepared from IX.

1-(β-D-Ribopyranosyl)pyrrole (XIII). A solution of X (24 mg, 0.1 mmol) in 80% aqueous acetic acid (0.5 m*l*) was heated at 100°C (bath-temperature) for 15 min. The solvents were removed in a manner similar to that described above. The residue was chromatographed on a column (2×8.5 cm) of Dowex 1-X2 (OH^- form)(10 g) with water - methanol (7 : 3), 10-m*l* fractions being collected. Fractions 7—11 were combined and the solvents removed to yield XIII (18 mg, 90.0%): R_f, 0.40 (TLC, solvent C) (color reaction,[37] brownish purple), 0.56 (PC, solvent D); retention time (GC), 9.0 min.

Found: N, 6.82%. Calcd for $C_9H_{13}O_4N$: N, 7.03%.

Photo-dehydrogenation of Δ^3-Pyrroline (II). A solution of crude II[6] (69 mg, 1.0 mmol) in dry benzene (10 m*l*) containing benzophenone (14 mg, 0.077 mmol) was irradiated under conditions similar to those used for the preparation of V. Aliquots were examined by the GC (stainless steel column (3 m×3 mm) packed with 3% OV-17 on Shimalite W (80—100 mesh), flow rate 18 m*l*/min, column temperature 60°C). After 2 hr, a broad peak (retention time, 13 min) due to II disappeared and a new peak (retention time, 8.1 min) was observed. Under the same conditions, the pyrrolidine remained unchanged.

We are grateful to Drs. K. Isono and H. Kuzuhara and to Mr. H. Ohrui for their valuable suggestions and discussions, to Dr. H. Homma and his staff for the elemental analyses, to Mr. H. Ogawa for the IR spectra, to Mr. J. Uzawa for the NMR spectra, and to Miss K. Sano for her helpful assistance.

Preparation of Vinyl Ethers by Transetherification in the Presence of Molecular Sieves

Heimei YUKI, Koichi HATADA, Kazuhiko NAGATA and Ken-ichi KAJIYAMA

Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka

(Received June 4, 1969)

The interchange reaction: $CH_3OCH{=}CH_2 + ROH \rightleftarrows ROCH{=}CH_2 + CH_3OH$, which is catalyzed by $Hg(OAc)_2$, has been studied. It was found that the equilibrium could be smoothly shifted toward the product by the selective absorption of the produced methanol on molecular sieves of the type 4A (MS-4A) and that the yield of the desired vinyl ether could be increased. According to this method, we prepared various vinyl ethers, including ethyl, isopropyl, isobutyl, *t*-butyl vinyl ether, and benzyl vinyl ethers. The yields of the alkyl vinyl ethers decrease as their alkyl groups become more electron-donating. The effects of the reaction conditions and the pretreatment of the molecular sieves have been investigated.

The vinyl transetherification catalyzed by mercuric salt is known to have a wide utility in the preparation of various vinyl ethers.[1] As the reaction is reversible, it is necessary to drive the reaction to

$$ROCH{=}CH_2 + R'OH \rightleftarrows ROH + R'OCH{=}CH_2$$

completion by appropriate methods. One is the fractionation of a desired vinyl ether out of the reaction mixture in order to shift the reaction continuously toward the product. Another is the equilibration of a mixture of vinyl ether in excess alcohol and a catalyst, and the subsequent freezing of the equilibrium by the flash-stripping of the volatile components or by inactivating the catalyst. The former method, however, has restrictions related as to the boiling points of the components, while the latter gives a lower yield.

In this work we studied this transetherification reaction, using methyl vinyl ether (MVE) as a starting vinyl ether and mercuric acetate ($Hg(OAc)_2$) as the catalyst, and found that the reaction could be smoothly shifted toward the product by the absorption of the methanol produced selectively on molecular sieves of the type 4A (MS-4A). Molecular sieves have been used by several investigators[2-4] for shifting the chemical equilibria by the selective absorption of one of the products. We prepared vinyl ethers, including ethyl, isopropyl isobutyl, *t*-butyl, vinyl ether and benzyl vinyl ethers, and studied the effects of the reaction conditions as

well as those of the pretreatment of the molecular sieves.

Experimental

Materials. Gaseous methyl vinyl ether was purified by passing it successively through a saturated aqueous solution of potassium hydroxide and a column packed with potassium hydroxide pellets, it was collected over calcium hydride in a cold trap cooled at −78°C. Then it was distilled under reduced pressure and stored over lithium aluminum hydride. The ether thus purified was redistilled under a vacuum just before use.

All the alcohols used were purified by refluxing them over calcium oxide and by subsequent distillation, they were stored under nitrogen pressure.

The triethylamine was purified by the usual method. The mercuric acetate used as the catalyst was commercially obtained and was used without further purification. The molecular sieves were products of the Union Carbide Corporation and were predried at the desired temperature under a high vacuum for 2 hr just before use.

Preparation of Vinyl Ether. A typical example of the method of preparing isobutyl vinyl ether will now be described. A 100 m*l* two-necked flask, equipped with a special reflux condenser for low-boiling liquid[5] and a thermometer, was flushed with dry nitrogen and charged with 20.0 g of MS-4A (1/16 inch pellets) which had been heated at 200°C for 2 hr under a high vacuum. Then 5.8 g (0.1 mol) of methyl vinyl ether, 7.4 g (0.1 mol) of isobutyl alcohol, and 0.5 g (0.0016 mol) of mercuric acetate were introduced into the flask under a nitrogen atmosphere. The reaction was carried out at 0°C for 1 hr with occasional shaking and was then stopped by adding one gram of anhydrous potassium carbonate. The reaction mixture was flash-distilled under a high vacuum. The distillate was shown by a gas chromatographic analysis to contain 6.0 g of isobutyl vinyl ether, 1.8 g of methyl vinyl ether, 2.3 g of isobutyl alcohol, and a trace of methanol The fractional distillation of this distillate gave 5.2 g of isobutyl vinyl ether; bp 82.5—83.0°C, $n_D^{20}=1.3962$. The non-volatile residue of the reaction contained a small amount of the polymeric product. This was shown by NMR spectroscopy to be predominantly poly(isobutyl vinyl ether); it seems to have resulted from the cationic polymerization of the isobutyl vinyl ether by the catalytic action of the molecular sieves. The amount of this polymeric product was estimated roughly by means of the difference between the amount of the residue and the total amount of molecular sieves, mercuric acetate, potassium carbonate used and the methanol adsorbed on the sieves.

Analytical Procedures. The distillate from the reaction mixture was inspected on a Shimazu Seisakusho gas-liquid chromatograph equipped with a column (2 m long, 4 mm i.d.) containing 30% dioctyl phthalate on Shimalite B and operated at 80°C with a helium-carrier gas stream of 68 m*l*/min. The calibration curves were used for determining the product compositions, employing toluene as the intensity standard.

The properties of the molecular sieves preheated at various temperatures were investigated in the following manner. One gram of the predried sieves was suspended in 25 ml of conductivity water and stirred for 24 hr under dry nitrogen pressure at 20°C. The pH value of the supernatant liquid was then measured with a pH meter (Yanagimoto Mfg. Co.) at 20°C under dry nitrogen.

Results

Reaction of MVE and Isobutyl Alcohol (*i*-BuOH) Catalyzed by $Hg(OAc)_2$ in the Presence of MS-4A. The reaction between MVE and *i*-BuOH was carried out in the presence of MS-4A (1/16 inch pellets), using $Hg(OAc)_2$ as the catalyst. The results are summarized in Table 1. In the reactions without the sieves, the yields of isobutyl vinyl ether(*i*-BVE) were lower. The use of the molecular sieves gave a higher yield of the vinyl

ether as a result of the selective adsorption of methanol. A longer reaction time increased the yield of *i*-BVE at both 0 and 30°C, although it also increased the polymeric product at 30°C. The yield of *i*-BVE was lower when the amount of the sieves was decreased. The reaction without $Hg(OAc)_2$ gave no *i*-BVE even in the presence of molecular sieves. The use of benzene or diethyl ether as a solvent caused a decrease in the rate of the reaction.

The addition of a small amount of triethylamine to the reaction mixture strongly decreased the yield of the vinyl ether. The results are shown in Table 2.

Effect of the Character of Molecular Sieves on the Transetherification of MVE and *i*-BuOH. The reactions of MVE and *i*-BuOH were carried out at 0°C for 1 hr with MS-4A preheated at various temperatures for 2 hr under a high vacuum. The results are shown in Fig. 1. The maximum yield of *i*-BVE was obtained when sieves preheated at 200°C were used. The amounts of the polymeric products decreased with an increase in the preheating temperature of the sieves, nearly reaching zero when the temperature was 300°C.

When the powdered MS-4A was used, a lower yield of *i*-BVE and a higher yield of polymer were obtained than in the case of the pellet type (Table 3). The molecular sieves 3A and the beads of the MS-4A also gave a lower yield of *i*-BVE.

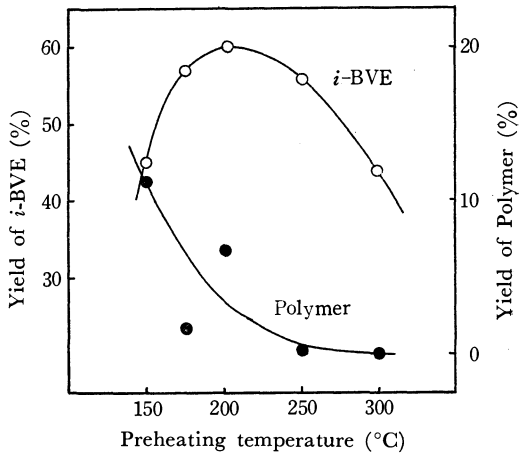

Fig. 1. Effect of the preheating temperature of MS-4A on the transetherification reaction of MVE and *i*-BuOH.

Reaction conditions: MVE 0.1 mol, *i*-BuOH 0.1 mol, $Hg(OAc)_2$ 0.0016 mol, Temp. 0°C, Time 1 hr, MS-4A was preheated for 2 hr under high vacuum.

Preparation of Other Vinyl Ethers. Transetherification reactions of MVE and various alcohols were carried out at 30°C for 1 hr with and without MS-4A. The results are shown in Table 4. The reactions proceeded smoothly in the presence of the sieves, and this technique for transetherification was proved successful for various combinations including various other aliphatic and aromatic alcohols with MVE. The yields of the desired alkyl vinyl ethers decreased, and the fractions of the polymeric product against the reacted MVE increased, as their alkyl groups were more electron-donating.

The reaction of MVE and *t*-butyl alcohol gave no *t*-butyl vinyl ether in the absence of molecular sieves, but a fairly good yield of *t*-butyl vinyl ether was obtained in the reaction with the sieves. The use of diethyl ether as a solvent reduced the fraction of the polymeric product, although the yield of the vinyl ether was also decreased. A prolonged reaction time resulted in a remarkable increase in the fraction of the ploymer.

Properties of Molecular Sieves Preheated at Various Temperatures. The pH value of a water suspension of MS-4A is shown in Fig. 2. With an increase in the temperature at which the sieves are preheated, the pH value increases; it passes through a maximum value of 9.96 at 200°C and then gradually falls off.

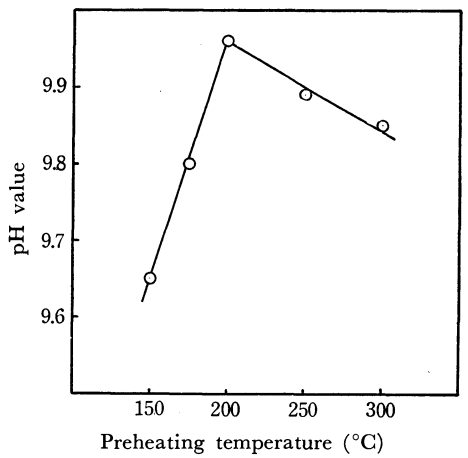

Fig. 2. pH Value of water suspension of MS-4A preheated at various temperatures.

Discussion

It has been ascertained that the equilibrium:

$$CH_3OCH{=}CH_2 + ROH \rightleftarrows ROCH{=}CH_2 + CH_3OH \quad (A)$$

was rapidly established by the $Hg(OAc)_2$ catalyst.[6] In this work we found that the reaction goes *smoothly* toward the right-hand side by the absorption of methanol selectively on MS-4A. The molecular sieves of the type 4A permit the reaction of MVE with any alcohol. The sieves of the type 3A work similarly, although the yield of vinyl ether is lower than in the case of the type 4A. The sieves of the type 5A, 10X or 13X have no absorption selectivity for methanol and produce a large amount of the polymeric product because of their higher catalytic activities for cationic polymerization.

The equilibration of the interchange reaction of MVE and *i*-BuOH is rapidly attained at 30°C, and the equilibrium constant is 0.570.[6] On the other hand, the absorption capacity of 20 g of MS-4A for methanol is about 0.09 mol at 30°C. From these data it may be expected that the reaction between 0.1 mol of MVE and *i*-BuOH catalyzed by $Hg(OAc)_2$ will go nearly to completion in the presence of 20 g of MS-4A. However, the actual conversion in the reaction is 83% for 3 hr. This appears to result from the occlusion of the molecular sieves with a polymeric product of *i*-BVE.

The only disadvantage of this ether-interchange technique is the decrease in the yield of the desired ether because of the polymer formation on the surface of the molecular sieves, as has been mentioned above. The attempt to prevent the polymerization of the resulting ether by the addition of a

6) H. Yuki, K. Hatada and K. Nagata, *Kogyo Kagaku Zasshi (J. Chem. Soc. Japan, Ind. Chem. Sect.)*, **73**, No. 4 (1970), in press.

small amount of triethylamine was not successful because of the decrease in the yield of the ether. The added amine may inactivate the mercuric acetate catalyst.

In the interchange reaction of MVE and alcohol with molecular sieves, lower yields of vinyl ethers were obtained when the alkyl groups of the resulting ethers were more electron-donating. This result may arise from the fact that the reactivity of the resulting vinyl ether for the cationic polymerization is higher,[7] as the alkyl group, R, in the reaction (A) is more electron-donating. The use of MVE as a starting vinyl ether is favorable for this technique because of its low polymerizability and the ease of its separation from the product by fractional distillation.

As is shown in Fig. 2, a water suspension of MS-4A preheated at temperatures from 150°C to 300°C had a pH value between 9.65 and 9.96, the maximum pH being obtained when the sieves were preheated at 200°C. This correlation resembles that between the yield of vinyl ether in the transetherification with molecular sieves and the preheating temperature of the sieves given in Fig. 1. However, the true significance of this interrelation is not certain at the present time.

The authors wish to express their deep thanks to Mr. T. Emura for his help in the laboratory work.

Resolution of Amino Acids. IX. Studies on the Preparation of β-Hydroxyasparagines and Configuration of Natural Hydroxyasparagine[1—3]

Hideo Okai[4] and Nobuo Izumiya[5]

Laboratory of Biochemistry, Faculty of Science, Kyushu University, Hakozaki, Fukuoka

(Received June 5, 1969)

Crystalline *threo-* and *erythro*-β-hydroxy-L-asparagine were prepared *via* asymmetric hydrolysis of the corresponding hydroxy-L-aspartic acid diamide by leucine aminopeptidase. The isomers of hydroxy-L-asparagine obtained were compared with the natural hydroxyasparagine isolated from human urine with respect to optical rotation and chromatography. From the results it is concluded that the spacial configuration of the natural product is that of *erythro*-β-hydroxy-L-asparagine. Additional studies were also carried out to prepare *threo-* and *erythro*-β-hydroxy-DL-asparagine from the corresponding hydroxy-DL-aspartic acid diamide without the enzyme.

Tominaga and his colleagues isolated 116 mg of a crystalline new amino acid from 200 *l* of human urine of normal male adults.[6] They presumed it to be β-hydroxyasparagine since it had produced β-hydroxyaspartic acid by acid hydrolysis. However, its spacial configuration has not been determined. Recently the four optical isomers of β-hydroxyaspartic acid were synthesized,[1,7] and their spacial configurations were established.[7] If the natural compound from human urine is one of possible four optical isomers of β-hydroxyasparagine, the compound may produce one of the four optical isomers of β-hydroxyaspartic acid by acid hydrolysis. However, it has been reported that the heating of either *threo-* or *erythro*-β-hydroxyaspartic acid in hydrochloric acid resulted in an interconversion of the diastereomers.[8] Therefore, we attempted

to determine the spacial configuration of the natural product by the comparison with synthetic *threo*- and *erythro*-β-hydroxy-L-asparagine.

This paper describes the preparation of *threo*- and *erythro*-β-hydroxy-L-asparagine *via* asymmetric hydrolysis of the corresponding hydroxy-L-aspartic acid diamide by LAPase and the comparison of the natural product with the isomers of hydroxy-L-asparagine in respect to optical rotation and column chromatography. Attempts were made to prepare *threo*- and *erythro*-hydroxy-DL-asparagine without using the enzyme.

Several isomers (L-, DL-*threo* and L-, DL-*erythro*) of hydroxyaspartic acid diamide were synthesized in the conventional manner. As an example, the reaction sequence for the synthesis of *erythro*-hydroxy-L-aspartic acid diamide is shown in Fig. 1.

Preparation of *threo*- and *erythro*-hydroxy-L-asparagine was attempted by LAPase treatment on the diamides synthesized. As an example, the two schemes for the preparation of *erythro*-hydroxy-L-asparagine are presented in Fig. 2. Prior to preparation of optical active hydroxyasparagines by LAPase, the rates of hydrolysis were determined to estimate the susceptibility of the diamides for the enzyme, the results being shown in Table 2. It was reported that L-cysteic acid amide was hydrolyzed especially slowly by LAPase among the substrates tested.[9] However, it was observed that the diamides of hydroxyaspartic acid were hydrolyzed more poorly (Table 2). The low susceptibility of these diamides is considered to be due to their β-hydroxy group. It was observed that

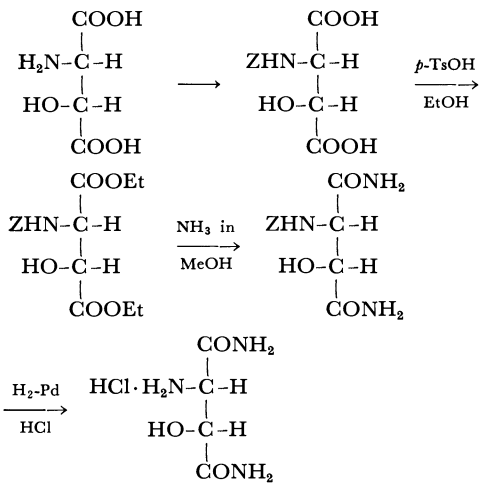

Fig. 1. Synthesis of *erythro*-hydroxy-L-aspartic acid diamide.

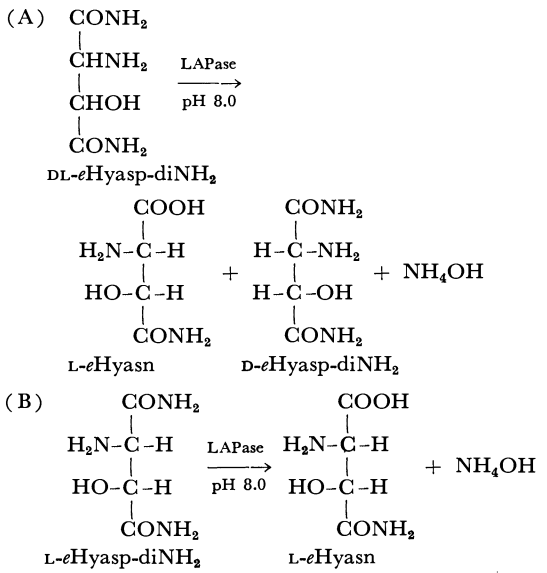

Fig. 2. Two schemes for preparation of *erythro*-hydroxy-L-asparagine.

the susceptibility of the *erythro*-L-diamide was slightly lower than that of the *threo*-L-diamide (Table 2). Thus a very high activity of LAPase was necessary for the effective hydrolysis of the diamides, and the highly purified enzyme preparation[10] was employed in this experiment.

For the determination of the rates of hydrolysis of *threo*- and *erythro*-DL-diamide, the course of hydrolysis in an incubation mixture of the substrate with the enzyme at pH 8.0 was followed by measuring the ammonia evolved. Contrary to expectation, it was observed that the amount of ammonia measured was greater than the theoretical 50% after 15—20 hr. The analysis of the mixture at 15—20 hr incubation by an amino acid analyzer and paper chromatography revealed the presence of hydroxyaspartic acid and other by-products in small amounts besides the major products, hydroxy-L-asparagine and hydroxy-D-aspartic acid diamide. The hydroxyaspartic acid and the by-products might be produced through the spontaneous degradation of the diamide and hydroxyasparagine at pH 8.0. The reason for the ammonia evolution more than the theoretical amount was further clarified by the observation that the diamide at pH 8.0 without the enzyme evolved ammonia gradually as shown in Fig. 5-b.

For the preparation of pure *threo*- and *erythro*-hydroxy-L-asparagine in preparative scale, the corresponding L-diamide was incubated with a large amount of the highly purified enzyme. This

Table 1. Specific rotations at 20°C of hydroxyasparagines

Compound	in H_2O[a)]	in 5 N HCl[b)]
L-*t*Hyasn (synthetic)	−29.6°	−28.0°
L-*e*Hyasn (synthetic)	+48.4	+63.0
Hyasn (natural)	+48.0	+61.6

a) *c* 0.5. b) *c* 1.0.

time, it was found that occurrence of the by-products was negligible even after the substrate was hydrolyzed completely. The crystalline *threo*- and *erythro*-hydroxy-L-asparagine were isolated from the incubation mixture in good yields by the use of Dowex 50 and 1 columns.

The synthetic hydroxyasparagines were compared with the natural product isolated from human urine. The values of specific rotation of *erythro*-hydroxy-L-asparagine and the natural product concurred within experimental error as shown in Table 1. A mixture of both the compounds afforded a single peak on co-chromatography by the amino acid analyzer as shown in Fig. 3. These data permit the conclusion that the spacial configuration of the natural product is that of *erythro*-β-hydroxy-L-asparagine. In this connection, it would be of interest to note that *erythro*-β-hydroxy-L-aspartic acid has been obtained by the action of a transaminase on dihydroxyfumaric acid and L-glutamic acid.[11)]

We attempted to prepare hydroxyasparagine through spontaneous degradation of the diamides in acid and alkaline mediums because it had been found that the diamides degraded spontaneously in the buffer solution at pH 8.0. Treatment of the diamides in dilute hydrochloric acid for 24 hr at 38°C afforded a mixture of many products including hydroxyasparagine. The chromatographic pattern by the amino acid analyzer are shown in Fig. 6-B. However, isolation of hydroxyasparagine from the reaction mixture was not attempted. In an alkaline treatment of the diamide for 5 hr at 38°C, the chromatographic patterns of degradation products in *threo*- and *erythro*-DL-diamide were different; *threo*-hydroxyasparagine was produced from the corresponding DL-diamide in considerable amount as shown in Fig. 6-C. The crystalline *threo*-hydroxy-DL-asparagine was isolated from the reaction mixture in a yield of 32%.

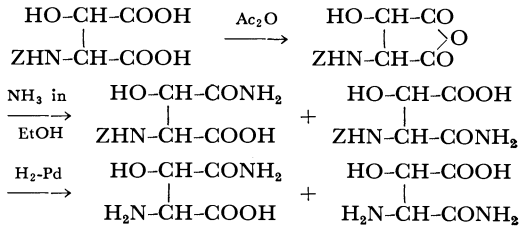

Fig. 4. Scheme for preparation of a mixture of hydroxyasparagine and hydroxyisoasparagine.

We attempted to prepare hydroxyasparagine *via* ammonolysis of benzyloxycarbonyl-hydroxyaspartic acid anhydride as shown in Fig. 4. It should be noted that Ressler and her colleagues prepared pure L-asparagine and L-isoasparagine from benzyloxycarbonyl-L-aspartic acid in a similar reaction sequence as shown in Fig. 4.[12)] The chromatographic patterns of the hydrogenated material are given in Fig. 6-D in which *erythro*-hydroxyasparagine is eluted as a single peak while *threo*-hydroxyasparagine is overlapped with other by-product. The crystalline *erythro*-hydroxy-DL-asparagine was isolated from the hydrogenated material derived from benzyloxycarbonyl-*erythro*-hydroxy-DL-aspartic acid in a yield of 33%. It seems that the preparation of the hydroxy-L-asparagines with the use of LAPase is preferable to that without the enzyme which is described in this paper.

Experimental

Synthesis of Compounds. *N-Benzyloxycarbonyl-threo-hydroxy-DL-aspartic Acid.* To a solution of DL-*t*Hyasp[1] (1.49 g, 10 mmol) and sodium bicarbonate (3.18 g, 36 mmol) in water (30 ml) was added a solution of benzyloxycarbonyl chloride (2.22 g, 13 mmol) in ether, and the reaction mixture was stirred for 4 hr at room temperature. After the reaction mixture was extracted with ether, the aqueous layer was acidified with 5 N hydrochloric acid and then extracted with ethyl acetate thrice (40 ml each). The extract was dried over sodium sulfate and evaporated *in vacuo*. The residual oil solidified after the addition of petroleum ether. It was recrystallized from ethanol-ether-petroleum ether. Yield, 2.12 g (75%); mp 186—187°C.

Found: C, 50.93; H, 4.74; N, 4.92%. Calcd for $C_{12}H_{13}O_7N$: C, 50.88; H, 4.63; N, 4.95%.

N-Benzyloxycarbonyl-threo-hydroxy-L-aspartic Acid. This was prepared from L-*t*Hyasp[1] as has been described for the preparation of Z-DL-*t*Hyasp. Yield, 86%; mp 106—107°C; $[\alpha]_D^{17}$ −8.0° (*c* 1, DMF).

Found: C, 50.93; H, 4.78; N, 4.83%.

N-Benzyloxycarbonyl-erythro-hydroxy-DL-aspartic Acid. This was prepared from DL-*e*Hyasp[1] as described for the preparation of Z-DL-*t*Hyasp. Yield, 85%; mp 155—156°C.

Found: C, 50.85; H, 4.85; N, 4.86%.

N-Benzyloxycarbonyl-erythro-hydroxy-L-aspartic Acid. This was prepared from L-*e*Hyasp.[1] Yield, 83%; mp 143—144°C; $[\alpha]_D^{17}$ +17.5° (*c* 1, DMF).

Found: C, 50.90; H, 4.86; N, 4.91%.

N-Benzyloxycarbonyl-threo-hydroxy-DL-aspartic Acid Diethyl Ester (Z-DL-tHyasp-diOEt). This compound was prepared according to the procedure of Kato *et al.*[13] for the preparation of benzoyl-DL-serine ethyl ester. A solution of Z-DL-*t*Hyasp (2.83 g, 10 mmol) and *p*-toluenesulfonic acid monohydrate (0.02 g) in a mixture of ethanol (20 ml) and carbon tetrachloride (100 ml) was refluxed for 64 hr, and the water liberated was removed as an azeotropic mixture. The reaction mixture was concentrated *in vacuo*, and the residual oil was dissolved in ethyl acetate (40 ml). The solution was washed with 4% sodium bicarbonate, 2% hydrochloric acid and water, and dried over sodium sulfate. The filtrate was evaporated *in vacuo*, and an oily residue was obtained. Yield, 3.36 g (99%); R_f 0.85.[14]

Z-L-tHyasp-diOEt, Z-DL-eHyasp-diOEt and Z-L-eHyasp-diOEt. These esters were also obtained as oily substance in nearly quantitative yields as described above.

N-Benzyloxycarbonyl-threo-hydroxy-DL-aspartic Acid Diamide. Z-DL-*t*Hyasp-diOEt (1.62 g, 4.7 mmol) was dissolved in methanol (80 ml) previously saturated with dry ammonia at 0°C, and the solution was kept at room temperature for 3 days and then concentrated *in vacuo* to dryness. The residual crystals were collected with the aid of a mixture of methanol and acetone. It was recrystallized from hot methanol. Yield, 1.01 g (77%); mp 209—211°C; R_f 0.66.[14]

Found: C, 51.25; H, 5.44; N, 14.71%. Calcd for $C_{12}H_{14}O_5N_3$: C, 51.42; H, 5.03; N, 14.99%.

N-Benzyloxycarbonyl-threo-hydroxy-L-aspartic Acid Diamide. This was prepared from Z-L-*t*Hyasp-diOEt as desbribed above. Yield, 66%; mp 194—196°C; $[\alpha]_D^{17}$ −25.5° (*c* 1, DMF).

Found: C, 51.15; H, 5.36; N, 14.65%.

N-Benzyloxycarbonyl-erythro-hydroxy-DL-aspartic Acid Diamide. This was prepared from Z-DL-*e*Hyasp-diOEt. Yield, 86%; mp 204—205°C.

Found: C, 51.38; H, 5.00; N, 14.61%.

N-Benzyloxycarbonyl-erythro-hydroxy-L-aspartic Acid Diamide. This was prepared from Z-L-*e*Hyasp-diOEt. Yield, 75%; mp 198—199°C; $[\alpha]_D^{17}$ +42.0° (*c* 0.5, DMF).

Found: C, 51.48; H, 5.48; N, 14.72%.

threo-Hydroxy-DL-aspartic Acid Diamide Hydrochloride. A solution of Z-DL-*t*Hyasp-diNH_2 (1.12 g, 4 mmol) in acetic acid (80 ml) was treated with hydrogen in the presence of palladium black. The catalyst was removed by filtration, and the filtrate was evaporated *in vacuo*. The residual oil was dissolved in N hydrochloric acid (4.2 ml) and the solution was evaporated *in vacuo* to dryness. The residue was recrystallized from methanol-ether. Yield, 0.86 g (93%); mp 190—192°C (decomp.).

Found: C, 26.36; H, 5.40; N; 22.84%. Calcd for $C_4H_9O_3N_3 \cdot HCl$: C, 26.17; H, 5.49; N, 22.90%.

threo-Hydroxy-L-aspartic Acid Diamide Hydrochloride. This was obtained by the hydrogenolysis of Z-L-*t*Hyasp-diNH_2 as described above. Yield, 91%; mp 190—192°C (decomp.); $[\alpha]_D^{17}$ −20.5° (*c* 1, H_2O).

Found: C, 25.96; 5.57; N, 22.82%.

erythro-Hydroxy-DL-aspartic Acid Diamide Hydrochloride. This was obtained by the hydrogenolysis of Z-DL-*e*Hyasp-diNH_2. Yield, 92%; mp 195—196°C (decomp.).

Found: C, 26.07; H, 5.47; N, 22.73%.

erythro-Hydroxy-L-aspartic Acid Diamide Hydrochloride. This was obtained by the hydrogenolysis of Z-L-*e*Hyasp-diNH_2. Yield, 90%; mp 193—194°C (decomp.); $[\alpha]_D^{17}$ +87.0° (*c* 0.5, H_2O).

Found: C, 25.80; H, 5.50; N, 22.86%.

Hydrolysis of Hydroxyaspartic Acid Diamide by LAPase. *Hydrolysis of DL-tHyasp-diNH_2 and DL-eHyasp-diNH_2.* A highly purified LAPase solution of step 6 by Smith was prepared following the method given in literature.[10] The enzyme solution was made to contain 4 mg protein per ml. One milliliter of the enzyme solution was dissolved in 0.4 M Tris buffer (0.5 ml) at pH

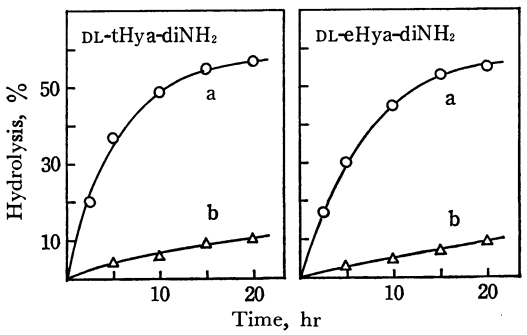

Fig. 5. Time-course of hydrolysis of *threo-* and *erythro*-hydroxy-DL-aspartic acid diamide with (a) without (b) LAPase.

8.0 and 0.12 M manganese chloride (0.5 ml). The solution was preincubated for 1 hr at 38°C to obtain maximal activation. This was named as an activated enzyme solution. A solution of DL-*t*(or *e*)Hyasp-diNH$_2$·HCl(0.1 mmol) in the activated enzyme solution (0.5 ml)

Table 2. Susceptibility of amino acid amides by lapase

Compound	C_1	Relative rate
L-Leu-NH$_2$	63	100
L-Asp-diNH$_2$	1.8	2.8
L-cysteic acid diamide		0.1[a]
L-*t*Hyasp-diNH$_2$	0.0069	0.011
L-*e*Hyasp-diNH$_2$	0.0049	0.0078

a) The datum is cited from literature.[9]

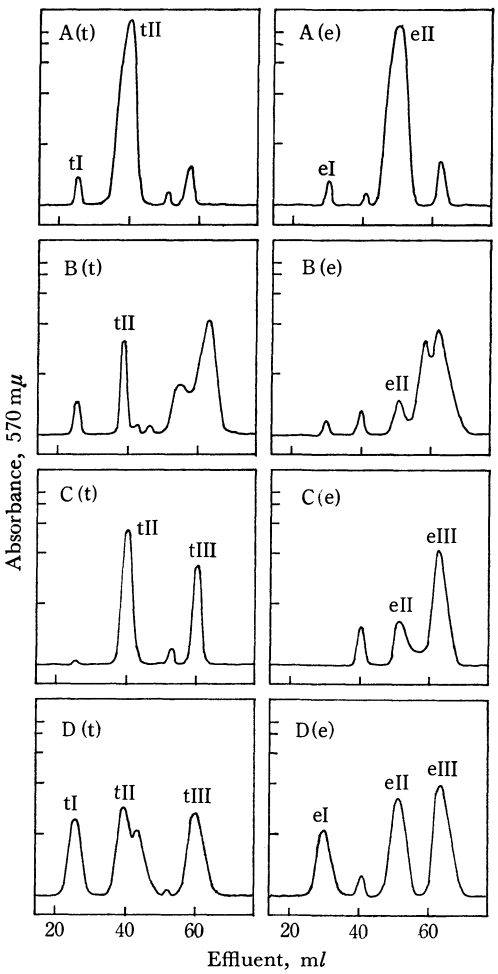

Fig. 6. Elution patterns of mixtures derived from hydroxyaspartic acid diamide and Z-hydroxyaspartic acid. (t), *threo*; (e), *erythro*; A, L-Hyasp-diNH$_2$ with LAPase; B, DL-Hyasp-diNH$_2$ with HCl; C, DL-Hyasp-diNH$_2$ with NaOH; D, hydrogenated material from Z-DL-Hyasp; I, Hyasp; II, Hyasn; III, Hyisoasn.

and 0.1 M Tris buffer (1.5 ml) at pH 8.0 was incubated at 38°C for 20 hr. The process of hydrolysis was followed by means of Conway's microdiffusion method[15] to determine ammonia (Fig. 5-a) and by paper chromatography. Analysis by an amino acid analyzer[16] of an aliquot after 20 hr incubation indicated the presence of hydroxyaspartic acid and other by-products as minor products. As a control experiment, a solution of DL-*t* (or *e*) Hyasp-diNH$_2$·HCl (0.1 mmol) in 0.1 M Tris buffer (2 ml) at pH 8.0 without the enzyme was incubated at 38°C and the amount of ammonia was determined. The results are given in Fig. 5-b.

Hydrolysis of L-*tHyasp-diNH$_2$ and* L-*eHyasp-diNH$_2$.* For determination of the accurate rate of hydrolysis of the L-Hyasp-diNH$_2$, an increased amount of LAPase was used. The occurrence of the by-products through spontaneous degradation was found to be negligible. A solution of L-*t*(or *e*)Hyasp-diNH$_2$·HCl (0.05 mmol) in the activated enzyme solution (1 ml) and 0.1 M Tris buffer (1 ml) at pH 8.0 was incubated 38°C. The patterns given by the amino acid analyzer with the samples of 10 hr incubation are shown in Fig. 6-A. The proteolytic coefficients (C_1) of the diamides are shown in Table 2, the C_1 of amides of L-leucine, L-asparagine and L-cysteic acid[9] being included for comparison. The C_1 values are calculated from $C_1=k/e$, where $k=(1/\text{min})\log[100/(100-\%\text{ hydrolysis})]$ and e is the protein concentration in mg of protein N per ml of test solution.

Preparation of L-*t*Hyasn and L-*e*Hyasn by LAPase. *L-tHyasn.* L-*t*Hyasp-diNH$_2$·HCl (92 mg, 0.5 mmol) was dissolved in a mixture of the activated enzyme solution (10 ml) and water (30 ml), the pH of the solution being adjusted to 8.0 with N sodium hydroxide. After being kept 8 hr at 38°C, the incubation mixture indicated complete hydrolysis of the diamide producing hydroxyasparagine through the assays by the amino acid analyzer and paper chromatography. The mixture was adjusted to pH 5 with acetic acid and warmed with a small amount of charcoal to remove protein. The filtrate was put on a column (0.9×20 cm) of Dowex 1×8 (OH^- form), and the column was washed with water and eluted with 0.5 N acetic acid. Ninhydrin positive fractions were collected and evaporated *in vacuo*. The residual crystals were collected with the aid of ethanol and recrystallized from water-ethanol. Yield, 53 mg (71%); mp 246—248°C (decomp.); R_f 0.15.[17]

Found: C, 32.10; H, 5.45; N, 18.57%. Calcd for $C_4H_8O_4N_2$: C, 32.44; H, 5.44; N, 18.79%.

L-eHyasn. This was obtained from L-*e*Hyasp-diNH$_2$·HCl (0.5 mmol) in the same way as has been described for the preparation of L-*t*Hyasn except for the incubation time being 12 hr. Yield, 50 mg (68%); mp 230—

15) R. B. Johnston, M. J. Mycek and J. S. Fruton, *J. Biol. Chem.*, **185**, 629 (1950).

16) The analyzer used was a Hitachi amino acid analyzer (Model KLA-3B) with spherical resin. The conditions were as follows: 0.9×50 cm column; 0.2 M standard citrate buffer of pH 3.25; flow rate, 60 ml/hr; jacket temperature, 55°C.

17) The R_f value refers to the paper chromatography with the solvent system of *n*-butanol - acetic acid - pyridine - water (4 : 1 : 1 : 2, v/v). It was observed that R_f for L-*t*Hyasp and L-*t*Hyasp-diNH$_2$·HCl are 0.13 and 0.22 respectively.

232°C(decomp.);[18] R_f 0.15.[17]

Found: C, 32.08; H, 5.44; N, 18.63%.

Comparison of Synthetic L-Hydroxyasparagines and the Natural Product. The three samples were employed for the measurements of optical rotation, using water and 5 N hydrochloric acid as solvent. As recognized from Table 1, the values of specific rotation of synthetic L-*e*Hyasn and the natural product are identical within experimental error. The three samples afforded the same R_f values in paper chromatography.[17] However, the L-*e*Hyasn and the natural product gave a peak at the same place while the L-*t*Hyasn gave one at a different place according to the amino acid analyzer (Fig. 3).[19] Furthermore, a mixture of the L-*e*Hyasn and the natural product afforded a single peak on the co-chromatography (Fig. 3). Thus, it is concluded that the spacial configuration of the natural product is that of L-*e*Hyasn.

Spontaneous Degradation of DL-Hyasp-diNH$_2$ in Acid Solution. DL-*t*(or *e*)Hyasp-diNH$_2$·HCl (18.4 mg, 0.1 mmol) was dissolved in 0.1 N hydrochloric acid (2 m*l*). After the solution had been allowed to stand for 24 hr at 38°C, an aliquot was analyzed by the amino acid analyzer, the patterns being shown in Fig. 6-B. Although *t*(or *e*)Hyasn was produced in a small amount, its isolation from the solution was not attempted.

Spontaneous Degradation of DL-Hyasp-diNH$_2$ in Alkaline Solution and Preparation of DL-tHyasn. *Preliminary Studies.* DL-*t*(or *e*)Hyasp-diNH$_2$·HCl (0.1 mmol) in 0.1 N sodium hydroxide (2 m*l*) was treated in the same way as above for 5 hr at 38°C. The patterns given by the amino acid analyzer are shown in Fig. 6-C. It was observed that the amount of DL-*t*Hyasn produced was much greater than that of DL-*e*Hyasn as shown in Fig. 6-C. Thus the separation of DL-*t*Hyasn from the reaction mixture was attempted as follows.

DL-tHyasn. DL-*t*Hyasp-diNH$_2$·HCl (368 mg, 2 mmol) in 0.1 N sodium hydroxide (40 m*l*) was allowed to stand for 5 hr at 38°C. After the solution was neutralized to pH 7, it was evaporated *in vacuo* to dryness. The residue was dissolved in a small amount of dilute acetic acid, and was applied on a column (1.8×150 cm) of Amberlite CG-120 (type III, Na^+ form). The column was eluted with 0.2 M sodium citrate buffer of pH 3.25 at a flow rate of 60 m*l*/hr; the fractions of 220—380 m*l* were confirmed to contain DL-*t*Hyasn. The fractions combined were put on a column of Dowex 1 (OH^- form), and the column was washed with water and eluted with 0.5 N acetic acid. After the eluate was evaporated *in vacuo*, the crystals were collected with the aid of ethanol and recrystallized from water-ethanol. Yield, 95 mg (32%); mp 228—232°C (decomp.); R_f 0.15.[17]

Found: C, 32.16; H, 5.62; N, 18.89%. Calcd for $C_4H_8O_4N_2$: C, 32.44; H, 5.44; N, 18.79%.

Preparation of DL-eHyasn through Z-DL-eHyasp Anhydride. *Preliminary Studies.* A solution of Z-DL-*t*(or *e*)Hyasp (142 mg, 0.5 mmol) in acetic anhydride (2 m*l*) was allowed to stand for 6 hr at 50°C. After evaporation *in vacuo* to dryness, the residue was dissolved in N ethanolic ammonia (5 m*l*) at 0°C. The solution was left for 30 min at 0°C, then 2 hr at room temperature, and evaporated to dryness. The residue was dissolved in acetic acid (3 m*l*) and hydrogenated in the presence of palladium black. An aliquot of the filtrate was analyzed by the amino acid analyzer (Fig. 6-D). It was assumed that a compound in peak *t*III or *e*III in Fig. 6 was β-hydroxyisoasparagine, however, conclusive evidence could not be obtained.[20] As shown in Fig. 6-D, it appeared that the *e*Hyasn might be isolated from the reaction mixture. The separation of DL-*e*Hyasn was attempted as follows.

DL-eHyasn. Two millimoles (566 mg) of Z-DL-*e*Hyasp were treated as described avove. Acetic acid in the hydrogenated material was removed by evaporation, and the residue was dissolved in a small amount of water. It was treated with a Amberlite CG-120 column (1.8× 50 cm) and 0.2 M sodium citrate buffer of pH 3.25 as had been described for the separation of DL-*t*Hyasn. The fractions of 120—155 m*l* were treated with a Dowex 1 column as described and yielded crystalline DL-*e*Hyasn. Yield, 98 mg (33%); mp 232—235°C(decomp.); R_f 0.15.[17]

Found: C, 32.51; H, 5.38; N, 18.62%. Calcd for $C_4H_8O_4N_2$: C, 32.44; H, 5.44; N, 18.79%.

We wish to express our thanks to Dr. Fumio Tominaga of Takeda Chemical Industries, Ltd. for supplying the natural hydroxyasparagine from human urine.

18) The mp of the natural hydroxyasparagine was determined to be 231—234°C (decomp.).

19) A sample each of 0.5 μmol with respect to one component was subjected to the analyzer.

20) The fractions of a peak *t*III or *e*III were collected in an experiment of preparative scale, however, the evaporation procedure *in vacuo* yielded Hyasp instead of Hyisoasn because of unstability of a compound (presumably, Hyisoasn) in *t*III or *e*III.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 3556—3558 (1969)

Electronic Spectra of *O*-Alkyl Thiobenzoates and Their Derivatives

Atsuyoshi OHNO, Tamotsu KOIZUMI, Yutaka OHNISHI
and Gen-ichi TSUCHIHASHI

Sagami Chemical Research Center, Onuma, Sagamihara

(Received June 5, 1969)

The absorption spectra of *O*-methyl and -ethyl thiobenzoates and their *p*- and *m*-methoxy, methyl and chloro derivatives have been studied. The substituent effect on the $n\rightarrow\pi^*$ transition of thiocarbonyl group has been discussed with the use of the Hammett relationship.

Among many organic compounds, thiocarbonyl compounds have received little attention until recently. Studies on the electronic spectra of thiocarbonyl compounds are not exceptions. The substituent effect on the spectra of thiobenzophenone was first published by Burawoy and co-workers only with electron-releasing substituents,[1,2] and then by de Boer and co-workers with a variety of substituents.[3] However, some of these compounds are unstable and it is difficult to obtain reliable spectra for the discussion on the substituent effect. *O*-Alkyl thiobenzoates and their derivatives are, on the other hand, stable in air and suitable for spectroscopic studies.

The purpose of this paper is mainly to gather reliable electronic spectral data on *O*-alkyl thiobenzoates and their derivatives and then to discuss the effect of substituents on the electronic transitions of thiocarbonyl group.

Results and Discussion

O-Methyl and -ethyl thiobenzoates and their *p*- and *m*-methoxy, methyl and chloro derivatives were synthesized and subjected to spectrometry.[4] The purity of materials was confirmed by VPC. The spectra were recorded in cyclohexane solution.

The electronic spectra of *O*-alkyl thiobenzoates have two regions of absorption (Fig. 1). The absorption at around 420 mμ is attributable to the $n\rightarrow\pi^*$ transition in the thiocarbonyl group. This characterization is verified by the fact that the intensity of the absorption is low, that a blue-shift of the absorption can be observed on transferring to a more polar solvent (λ_{max}=418 mμ, ε=98 in 95% aq. ethanol for *O*-methyl thiobenzoate) and that electron-releasing substituents cause the blue-shift (*vide infra*). The absorption at around 280—290 mμ can be regarded as the $\pi\rightarrow\pi^*$ transition in the arylthiocarbonyl group by the intensities and effects of substituents and solvents (λ_{max}=288 mμ, ε=9,812 in 95% aq. ethanol for *O*-methyl thiobenzoate). However, since the absorption of this region is accompanied by a shoulder(s) in several compounds, the origin of the transition is not unequivocally assigned. Some of *O*-alkyl thiobenzoates have another absorption at around 230 mμ.

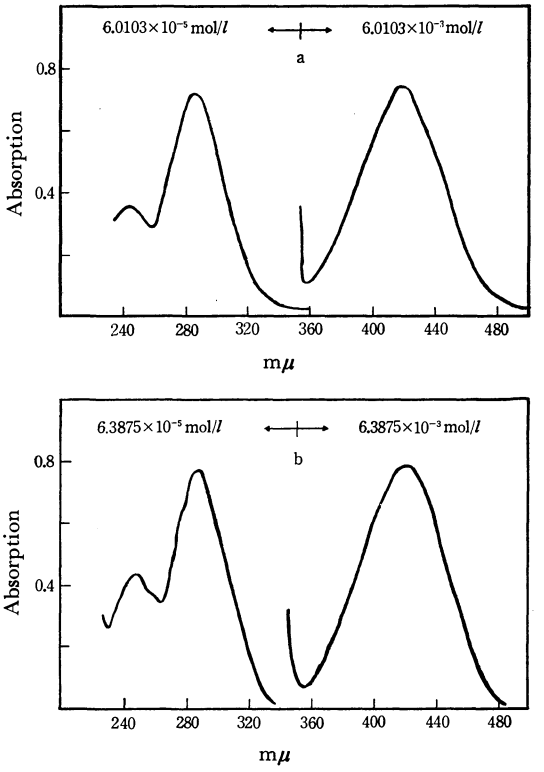

Fig. 1. The absorption spectra of (a) *O*-methyl thiobenzoate and (b) *O*-ethyl thiobenzoate.

a) In cyclohexane.

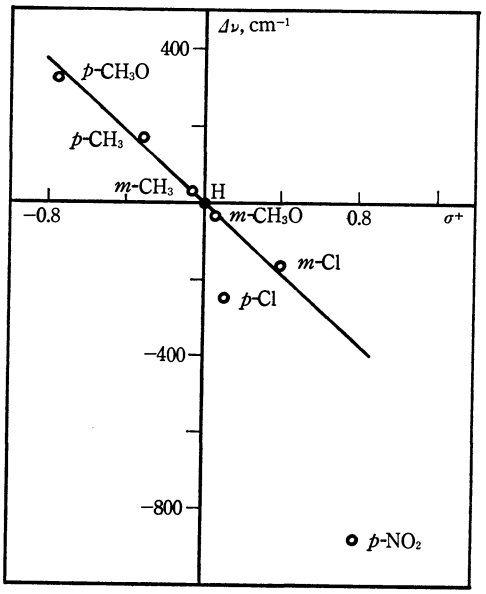

Fig. 2. Hammett relationship for the $n\rightarrow\pi^*$ transition of *O*-methyl thiobenzoates.

This is probably due to the interaction between the substituent and the phenyl-ring. The absorption maxima and the molar extinction coefficients are listed in Tables 1 and 2. In Table 1, the shifts in wave numbers of thiocarbonyl absorption band of substituted *O*-alkyl thiobenzoates relative to the corresponding unsubstituted thioesters are also listed.

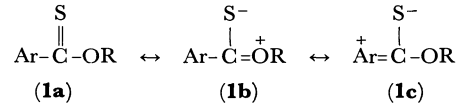
A remarkable substituent effect can be observed in the $n\rightarrow\pi^*$ transition: the Hammett plot, according to the equation.

$$\Delta\nu = \nu_X - \nu_H = \rho\sigma^+$$

is shown in Fig. 2 for the $n\rightarrow\pi^*$ transition of *O*-methyl thioesters. The *O*-ethyl thioesters behave similarly.

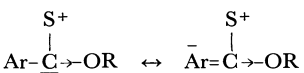
Obviously, electron-withdrawing substituents at the *p*-position exert different effect from the others on the transition. Let us assume that this is due to larger conjugative effect of such substituents in the n, π^* excited state of the thioester than in its ground state.

It will be interesting to compare the substituent effect in the thioester and that in thiobenzophenone or in 2,4,6-trimethylthiobenzophenone, where electron-releasing and -withdrawing substituents each give lines with different slopes regardless the position of substituents.[3a)] In series of substituted thiobenzophenones, it has been assumed that, as a consequence of an electronic influence by an electron-withdrawing substituent in *p*-position, the phenyl or even the 2,4,6-trimethylphenyl group reaches a greater degree of coplanarity with the thiocarbonyl group than the *p*-substituted phenyl group. Therefore, only the inductive effect of the substituent can act upon the transition. Thus, there exists a distinct difference in the conjugative effects of electron-withdrawing substituents between thioesters and thiobenzophenones. This difference might be interpreted as follows: since



(**1a**) (**1b**) (**1c**)

the thiocarbonyl group is highly polarized in its ground state,[5-7] the contribution of the structure **1b** is fairly important in the ground state of the thioester.[7] On the other hand, since the polarization of the thiocarbonyl group is reverse in the n, π^* exited state[8] to that in the ground state, the resonance effect of the oxygen atom no more operates. As a consequence, the importance of the structure (**2b**) increases in the n, π^* excited state.



(**2a**) (**2b**)

Although the limited number of substituents do not allow to estimate the relative importance of the resonance effect quantitatively, the present results show that electron-releasing substituents can conjugate with the thiocarbonyl group in the ground state, whereas electron-withdrawing substituents interact with the thiocarbonyl group in the n, π^* excited state. It should be noted that the phenyl group in thiobenzophenone or the mesityl group in 2,4,6-trimethylthiobenzophenone has ability to conjugate with the thiocarbonyl group both electron-releasingly and -withdrawingly.

Unfortunately, the susceptibility of the substituent effect to the thiocarbonyl group cannot be compared with that to the carbonyl group, because the absorption due to the $n\rightarrow\pi^*$ transition in benzoates are completely hidden by an intense band of the $\pi\rightarrow\pi^*$ transition.

For the $\pi\rightarrow\pi^*$ transition, the difference of absorption maxima between p- and m-positions for each substituents correlates well to the value of $\Delta\sigma=\sigma_p-\sigma_m$. This fact indicates that the absorption in this region is largely affected by a resonance effect of substituents.[9] The plot is shown in Fig. 3 for the O-methyl thioesters. The linear correlations of $\Delta\nu$ with σ and σ_R is also found for m- and p-substituted thioesters, except for the p-nitro derivative, respectively, as has been found for the system of 2,4,6-trimethylthiobenzophenone.[3a]

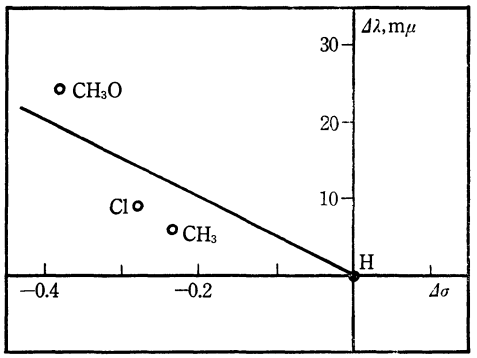


Fig. 3. The correlation of $\Delta\lambda$ *vs.* $\Delta\sigma$ for the $\pi\rightarrow\pi^*$ transition of O-methyl thiobenzoates.

Experimental

Materials. As previously reported,[10] the thioesters were prepared from the corresponding orthoesters[11] or from the corresponding imido ethers.[12,13] The purities were confirmed by IR, NMR and VPC. The results of elemental analyses were satisfactory for each compound.

Spectrometry. Spectra were obtained on a Cary-14 Spectrophotometer using spectrograde cyclohexane as solvents. The concentrations of solutions were adjusted so as to obtain the spectra, in which the maxima of a band had around 70—80% absorption. These were 6×10^{-3} M for visible and 6×10^{-5} M for UV revion, respectively. The estimated error in wavelength is ±1 mμ.

Oxidation Reactions of 2,4,6-Tri-*t*-butylaniline

Renji OKAZAKI, Takeo HOSOGAI, Masayoshi HASHIMOTO and Naoki INAMOTO

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received June 30, 1969)

Oxidation reactions of 2,4,6-tri-*t*-butylaniline with lead tetraacetate (LTA), lead tetrabenzoate (LTB), peroxybenzoic acid (PBA) and benzoyl peroxide (BPO) were studied and mechanisms of these reactions were briefly discussed. In the reaction with LTA, 4-acetoxy-1-imino-2,4,6-tri-*t*-butyl-2,5-cyclohexadiene (I), 2-acetamido-3,5-di-*t*-butylphenol (II) and 2-acetylimino-3,5-di-*t*-butyl-3,5-cyclohexadienone(III) were produced. Oxidation with LTB gave 4-benzoyloxy-1-imino-2,4,6-tri-*t*-butyl-2,5-cyclohexadiene (VI, major product) and 2-benzamido-3,5-di-*t*-butylphenol (VII). The reaction products with PBA were 2,4,6-tri-*t*-butylnitrosobenzene (VIII) and VII. In addition to the last two compounds, VI and 2,2′,4,4′,6,6′-hexa-*t*-butylazobenzene (XI) were obtained in the case of BPO.

2,4,6-Tri-*t*-butylaniline (TBA) has been studied by many workers who expected unusual properties due to the steric effects of the bulky *t*-butyl groups. There have been only a few reports on the chemical reactions, although there have been several investigations on the physical properties such as basic strength,[1-3] IR,[2] UV[2] and NMR[4] spectra. The reactions reported so far are conversion *via* diazotization[1,5] and preparation of the *N*-acyl and the *N*-alkyl derivatives.[2a]

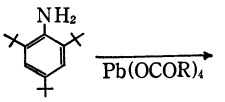
Oxidation reactions of TBA were focused only on the ESR studies of the corresponding anilino radical,[6] although Cauquis *et al.* have isolated some products in the electrochemical oxidation.[7]

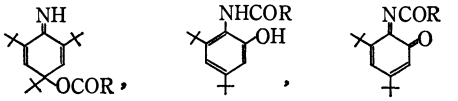
We have studied the reactions of TBA with some oxidizing agents such as lead tetraacetate (LTA), lead tetrabenzoate (LTB), peroxybenzoic acid (PBA) and benzoyl peroxide (BPO), and found that the reactions are different in many respects from those of sterically unhindered anilines.

Results

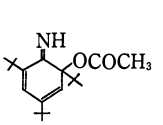
The structures of the reaction products were determined by elemental analyses, IR and NMR spectra.

Reactions with LTA or LTB. TBA reacted with LTA in benzene at 5°C to give 4-acetoxy-1-imino-2,4,6-tri-*t*-butyl-2,5-cyclohexadiene (I, 47%), 2-acetamido-3,5-di-*t*-butylphenol (II, 11%) and 2-acetylimino-3,5-di-*t*-butyl-3,5-cyclohexadienone (III, 8%).

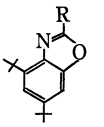




I: R=CH_3 II: R=CH_3 III: R=CH_3
VI: R=C_6H_5 VII: R=C_6H_5



IV



V: R=CH_3
X: R=C_6H_5

Although an isomeric structure (IV) is possible for I, IV was ruled out by the NMR spectrum which exhibited five singlets (τ 9.10, 9H, *t*-butyl protons at 4-position; 8.72, 18H, *t*-butyl protons at 2- and 6-positions; 8.05, 3H, acetyl protons; 4.04, 2H, olefinic protons; 0.48, 1H, imino proton), for the NMR spectrum of IV would be expected to show three kinds of the *t*-butyl protons, and AB type quartet of the olefinic protons.

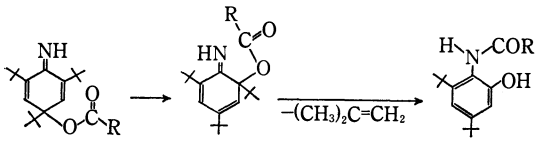
The imine (I) deccmposed about 150°C into II and isobutylene. The reaction proceeds presumably *via* an intermediate (IV) as shown below.



I, VI IV II, VII

The structure of II was confirmed by comparison with that of an authentic sample, which was synthesized by the acetylation of 2-amino-3,5-di-*t*-butylphenol.

The hydrolysis of II by hydrochloric acid gave 4,6-di-*t*-butyl-2-methylbenzoxazole (V) instead of expected 2-amino-3,5-di-*t*-butylphenol.

The reduction of III with lithium aluminum hydride yielded II, and conversely, the oxidation of II with LTA gave III.

LTB oxidized TBA in dichloromethane at room temperature to yield 4-benzoyloxy-1-imino-2,4,6-tri-*t*-butyl-2,5-cyclohexadiene (VI, 65%) and 2-benzamido-3,5-di-*t*-butylphenol (VII, 1.4%). Their characterization will be described later.

Reaction with PBA. The oxidation of TBA with two mole equivalents of PBA at 0°C gave 73% of 2,4,6-tri-*t*-butylnitrosobenzene (VIII) and a trace of VII. Use of excess PBA or higher temperatures produced 2,4,6-tri-*t*-butylnitrobenzene as by-product. On the other hand, use of an equimolar amount of PBA enhanced the yield of VII; VIII and VII being produced in 18 and 10% yields, respectively. The formation of *o*-*N*-acylaminophenols has not yet been observed for the ordinary anilines.

Furthermore, II was produced instead of VII, in the case of the reaction with an equimolar amount of PBA in the presence of a large excess of acetic acid. Oxidation of TBA with 30% hydrogen peroxide in acetic acid by the procedure of Holmes and Bayer[8] produced no nitroso compound.

The nitrosobenzene (VIII) is emerald-green crystals and monomeric even in the solid state.[9]

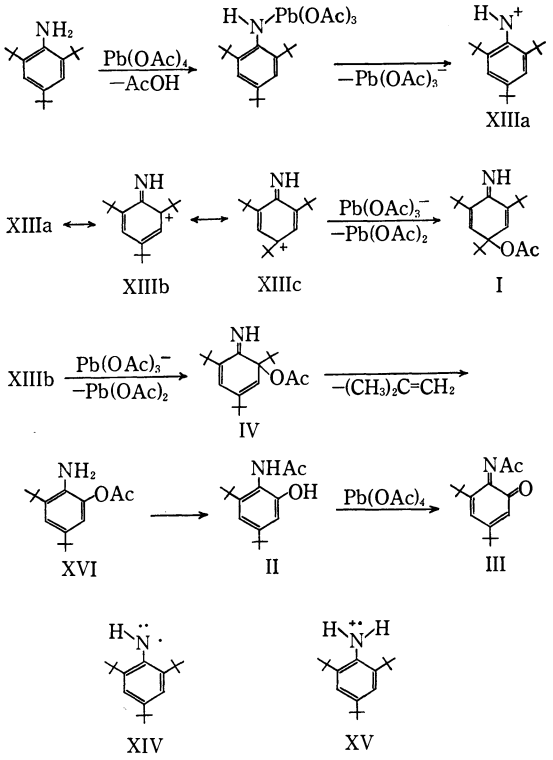
The structure of VII was characterized by comparison with that of an authentic sample, which was prepared by benzoylation of 2-amino-3,5-di-*t*-butylphenol. The phenol (VII) was converted into the methyl ether (IX) by diazomethane and cyclized to 2-phenyl-3,5-di-*t*-butylbenzoxazole (X) by hydrochloric acid as in the case of II.

Reaction with BPO. TBA reacted with BPO in benzene at room temperature to yield VIII, VII, VI and 2,2′,4,4′,6,6′-hexa-*t*-butylazobenzene (XI) in 2, 49, 38 and 2% yields, respectively.

The imine (VI) was undistilled even under high vacuum owing to its facile decomposition into VII at about 100°C. Moreover, it could not be purified by column chromatography on silica gel, because of easy decomposition into VII (37%) and 4-benzoyloxy-2,6-di-*t*-butylaniline (XII, 39%). However, petroleum ether soluble part of the reaction products, after extraction of benzoic acid by aqueous alkali, was almost pure VI.

Discussion

It is known that the reactions of the primary aromatic amines with LTA produce azo compounds in poor yields.[10] Products other than azo compound were obtained in the case of TBA. The difference can be attributed to the steric hindrance around the amino group of TBA. The following mechanism is considered to account for the results, although a homolytic mechanism involving anilino



8) R. R. Holmes and R. P. Bayer, *J. Am. Chem. Soc.*, **82**, 3454 (1960).

10) K. H. Pausacker and J. G. Scroggie, *J. Chem. Soc.*, **1954**, 4003; E. Baer and A. L. Tosoni, *J. Am. Chem. Soc.*, **78**, 2857 (1956).

radical (XIV) or aniline radical-cation(XV) cannot be ruled out. Rearrangement of *O*-acetylated aminophenols such as XVI into the corresponding *N*-acetylated aminophenols is well known.[11]

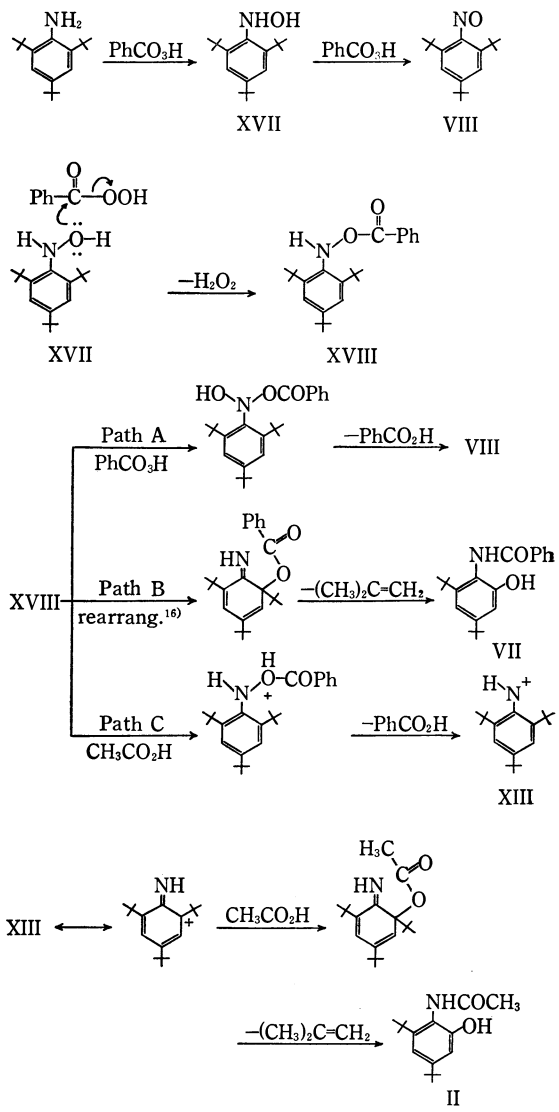
In the reactions of the ordinary anilines the intermediate anilino cations readily attack the unchanged anilines followed by further oxidation to give azobenzenes, while the intermediate (XIII) generated from TBA cannot react with another TBA molecule owing to the steric hindrance by the *t*-butyl groups.

Reaction with LTB is likely to proceed *via* the same mechanism as that with LTA. It is different, however, in two respects; the product ratio of the aminophenol (VII or II) to the imino compound (VI or I) is rather low and no *o*-benzoquinone acylimine analogous to III is produced. The low product ratio in the case of LTB is obviously due to the more bulky attacking species such as $Pb(OCOPh)_3^-$.

It is known that the reaction products of primary aromatic amines with peroxyacids are different depending upon the kinds of peroxyacids and the reaction conditions.[12] Caro's acid oxidizes the anilines to the nitroso compounds in usually poor yields. Oxidation with peroxyacetic acid affords nitrosobenzenes, nitrobenzenes and/or azoxybenzenes depending upon the reaction conditions; higher temperatures favor the production of the latter two and lower temperatures that of the former.[8,13] For PBA there have been a few investigations[14] which have dealt with the reaction only qualitatively except for the study by Horner and Kirmse, who reported azobenzene and azoxybenzene as the reaction products with aniline.[15]

However, PBA oxidized TBA into the nitroso compound (VIII) in a high yield.[9] This is because the bulky *t*-butyl groups at *ortho*-positions disturb the condensation of the unchanged TBA with the corresponding nitroso or hydroxylamino compound produced.

As for formation of VII and II under various conditions, the following scheme is plausible, although not conclusive.



The unusual formation of VII is likely to be due to the steric hindrance which makes the rate of the reaction XVII→XVIII comparable to that of the reaction XVII→VIII, for the steric congestion around the oxygen atom in XVII is fairly less than that around the nitrogen atom.

Horner and Kirmse have concluded that the reactions of the anilines with BPO proceed by both homolytic and heterolytic mechanisms.[17]

Our results for TBA are also explicable by the following mechanism involving both homolytic and heterolytic reactions, the former being predominant. The imine (VI), the benzamidophenol (VII) and the azobenzene (XI) are products *via*

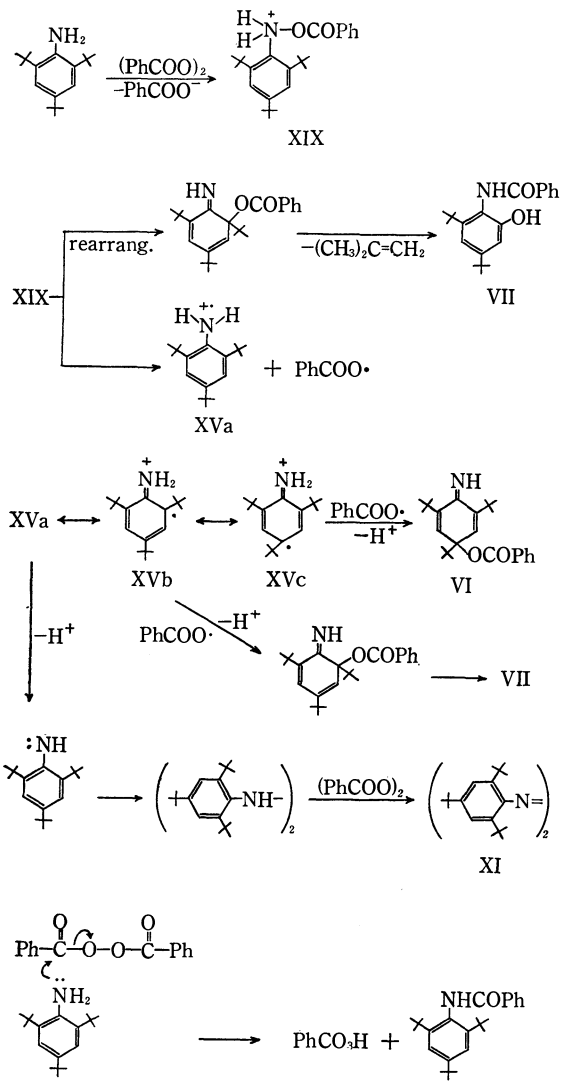
homolytic processes and the nitroso compound (VIII) is that *via* heterolytic one.



The formation of the nitrosobenzene (VIII) is reasonably explained by oxidation of TBA with PBA which is yielded by aminolysis of BPO, although the full characterization of the benzamide was unsuccessful (see Experimental).

A high product ratio of VII to VI as compared with that in the case of LTB suggests the existence of another route to VII probably *via* rearrangement of an intermediate (XIX).

Experimental

Melting points and boiling points are uncorrected. The NMR spectra were taken on a Japan Electron Optics Laboratory spectrometer Model JNM-C-60H using tetramethylsilane as an internal standard. Unless otherwise indicated, the solvent was carbon tetrachloride, and the signals were singlet. The electronic and the infrared spectra were recorded on a Hitachi spectrophotometer Model EPS-3 and EPI-G2, respectively.

2,4,6-Tri-*t*-butylaniline,[2a] lead tetraacetate,[18] lead tetrabenzoate[19] and peroxybenzoic acid[20] were prepared by the reported methods.

Reaction of 2,4,6-Tri-*t*-butylaniline (TBA) with Lead Tetraacetate (LTA). To a solution of TBA (9.2 g, 0.035 mol) in 250 m*l* of dry benzene, was added LTA (18.7 g, 0.042 mol) in 250 m*l* of benzene with stirring at 5°C. The mixture was stirred successively for 3 hr. After filtration of lead diacetate (10.6 g, 0.033 mol), the filtrate was shaken with 300 m*l* of water, and the benzene layer was dried over anhydrous sodium sulfate. After removal of benzene *in vacuo* below 50°C, petroleum ether (100 m*l*) was added and the insoluble crystals were recrystallized from chloroform to yield 2-acetamido-3,5-di-*t*-butylphenol (II, 1.0 g, 11%) as white solid, mp 214—216°C, which was identical with a compound obtained from acetylation of 2-amino-3,5-di-*t*-butylphenol (see below).

Found: C, 72.77; H, 9.62; N, 5.26%. Calcd for $C_{16}H_{25}NO_2$: C, 72.96; H, 9.57; N, 5.32%. Mol wt (Rast method) Found: 261. Calcd: 263.

The petroleum ether solution was chromatographed on silica gel. An oily material (5.3 g, 47%), eluted with petroleum ether, was purified by distillation to give 4-acetoxy-1-imino-2,4,6-tri-*t*-butyl-2,5-cyclohexadiene (I, 3.4 g, 31%), bp 90°C (0.28 mmHg). NMR: τ 0.48 (1H, broad), 4.04 (2H), 8.05 (3H), 8.72 (18H) and 9.10 (9H). IR (neat): 3330(N-H) and 1745 cm^{-1} (C=O).

Found: C, 75.38; H, 10.34; N, 4.54%. Calcd for $C_{20}H_{33}NO_2$: C, 75.19; H, 10.41; N, 4.38%.

Another material eluted with benzene was recrystallized from 70% ethanol to give 2-acetylimino-3,5-di-*t*-butyl-3,5-cyclohexadienone (III, 0.7 g, 8%) as orange-red crystals, mp 81—85°C. NMR: τ 3.29 (1H), 3.90 (1H), 7.86 (3H), 8.65 (9H) and 8.77 (9H).

Found: C, 73.26; H, 9.04; N, 5.27%. Calcd for $C_{16}H_{23}NO_2$: C, 73.53; H, 8.87; N, 5.36%.

Pyrolysis of I and 4-Benzoyloxy-1-imino-2,4,6-tri-*t*-butyl-2,5-cyclohexadiene (VI). Cyclohexadiene (I, 1.00 g, 3.1 mmol) was heated to 148°C in the course of 15 min in a test tube connected to a trap cooled with Dry Ice - ethanol mixture. The sample suddenly solidified with evolution of gas. The solid was washed with petroleum ether and recrystallized from methanol to give II (0.56 g, 70%), mp 215—217°C. To the liquid collected in the trap was added bromine in carbon tetrachloride to yield isobutylene dibromide (0.38 g, 57%), the amount of which was determined by means of VPC (succinic polyester of diethylene-glycol).

The cyclohexadiene (VI, 1.09 g, 2.86 mmol) obtained in the reaction of TBA with BPO was pyrolyzed by the same procedure to give isobutylene (47%) and 2-benzamido-3,5-di-*t*-butylphenol (VII, 0.57 g, 62%), which was identical with an authentic sample synthesized from benzoylation of 2-amino-3,5-di-*t*-butylphenol. VI began to decompose at about 100°C and decomposed vigorously at 130°C.

20) G. Braun, "Organic Syntheses," Coll. Vol. 1, p. 431 (1956).

Oxidation of II. To a solution of II (0.5 g, 1.9 mmol) in 10 m*l* of dry benzene was added LTA (1.0 g, 2.3 mmol) in 30 m*l* of dry benzene at room temperature, and the mixture was allowed to stand at room temperature overnight. After filtration of lead diacetate (0.7 g, 2.2 mmol) and removal of benzene, petroleum ether was added and insoluble LTA was filtered off. The filtrate was chromatographed on silica gel with benzene-ether (9 : 1) to give III (0.3 g, 60%), mp 81—85°C.

Reduction of III. To a solution of lithium aluminum hydride (0.1 g, 2.6 mmol) in 6 m*l* of anhydrous ether was added dropwise III (0.1 g, 3.8 mmol) in 5 m*l* of ether at room temperature with stirring. After usual working up, II (0.02 g, 20%), mp 214—216°C, was obtained.

Preparation of 2-Amino-3,5-di-*t*-butylphenol. To 3,5-di-*t*-butyl-2-nitrophenol[21] (10 g, 0.040 mol) in 20 m*l* of ethanol, was added sodium hydroxide (2 g, 0.050 mol) in 20 m*l* of water and then sodium hydrosulfite (14 g, 0.080 mol) in 100 m*l* of water was added dropwise at room temperature. Another sodium hydroxide (3 g, 0.075 mol) was added in portions to keep the mixture slightly alkaline, and the solution was stirred overnight. The reaction mixture was poured into 2 *l* of water and neutralized with dilute hydrochloric acid. The precipitate (10 g) was recrystallized from carbon tetrachloride to give 2-amino-3,5-di-*t*-butylphenol (2 g, 23%), mp 165—167°C. IR: 3330, 3430 (N-H) and 3110 cm^{-1} (O-H).

Found: C, 75.85; H, 10.25; N, 6.26%. Calcd for $C_{14}H_{23}NO$: C, 75.97; H, 10.47; N, 6.33%.

Acetylation and Benzoylation of 2-Amino-3,5-di-*t*-butylphenol. To a mixture of 2-amino-3,5-di-*t*-butylphenol (0.44 g, 2.0 mmol) and triethylamine (1.36 g, 3.6 mmol) in 5 m*l* of ether, acetyl chloride (0.16 g, 2.0 mmol) in 5 m*l* of ether was added with stirring at room temperature. After usual working up, II (0.1 g, 20%), mp 212—214°C, was obtained.

Found: C, 72.93; H, 9.56; N, 5.56%. Calcd for $C_{16}H_{25}NO_2$: C, 72.96; H, 9.57; N, 5.32%.

The benzoyl derivative (VII) was prepared by a similar method in 42% yield, mp 231—232°C (from chloroform).

Found: C, 77.21; H, 8.38; N, 4.36%. Calcd for $C_{21}H_{27}NO_2$: C, 77.50; H, 8.36; N, 4.30%.

4,6-Di-*t*-butyl-2-methylbenzoxazole (V). II (1.2 g, 4.6 mmol) was refluxed for 7 hr in 50 m*l* of absolute methanol under a stream of dry hydrogen chloride. After usual treatment, crude product was purified by column chromatography on alumina with petroleum ether to yield V (0.85 g, 77%), mp 45—46°C. UV: λ_{max}^{MeOH} 240 (log ε 4.11), 271 (3.65) and 280 mμ (3.62). The UV spectrum was in good agreement with that of 2-methylbenzoxazole.[22]

Found: C, 78.37; H, 9.68; N, 5.89%. Calcd for $C_{16}H_{23}NO$: C, 78.32; H, 9.45; N, 5.71%.

Reaction of 2,4,6-Tri-*t*-butylaniline (TBA) with Lead Tetrabenzoate (LTB). A mixture of TBA (13 g, 0.050 mol), LTB (36 g, 0.052 mol) and dichloromethane (400 m*l*) was stirred for 2 hr at room temperature and then allowed to stand overnight. After removal of dichloromethane, ether was added in order to precipitate lead dibenzoate (21 g, 94%) (Found: C, 36.95; H, 2.51; N, 0%). After evaporation of the solvent from the filtrate and addition of petroleum ether, resulting white precipitates were shaken with aqueous sodium carbonate to leave insoluble VII (0.23 g, 1.4%), which was identified by comparison of the IR spectrum with that of an authentic sample described above. Acidification of the aqueous layer gave benzoic acid (6.33 g, 101%). The petroleum ether soluble products (16.21 g) were found by the NMR spectrum to be a mixture of unchanged TBA and VI (12.0 g, 65%). For characterization of VI, see the reaction with BPO.

Oxidation of TBA with Peroxybenzoic Acid (PBA). a) PBA (0.148 mol) in 100 m*l* of ether was added to an ethereal solution (100 m*l*) of TBA (19.5 g, 0.0747 mol) cooled with ice-water, and the mixture was kept at 0°C overnight. After usual working up, the crude material was purified by means of column chromatography on alumina or silica gel. 2,4,6-Tri-*t*-butylnitrosobenzene (VIII), first eluted with petroleum ether, was recrystallized from ethanol as emerald-green crystals. The yield was 16.2 g (73%), mp 166—168°C. The molecular weight was found to be 303 (Rast method) or 244 (Beckmann method in benzene); Calcd for $C_{18}H_{29}NO$: 275. NMR: τ 2.75 (2H), 8.65 (9H) and 8.80 (18H).

Found: C, 78.25; H, 10.81; N, 5.09%. Calcd for $C_{18}H_{29}NO$: C, 78.49; H, 10.61; N, 5.09%.

b) To TBA (5.2 g, 0.020 mol) in 20 m*l* of dichloromethane was added PBA (0.020 mol) in 20 m*l* of dichloromethane under cooling with ice-water, and the mixture was kept at 0°C overnight. After usual working up, the remaining solid was dissolved in petroleum ether. 3,5-Di-*t*-butyl-2-benzamidophenol (VII, 0.6 g, 10%) was obtained as white solid insoluble in this solvent, and recrystallized from chloroform and then from methanol, mp 231—232°C. IR (in Nujol): 3340 (N-H), 3110 (O-H) and 1630 cm^{-1} (C=O).

Found: C, 77.38; H, 8.48; N, 4.59%. Calcd for $C_{21}H_{27}NO_2$: C, 77.50; H, 8.36; N, 4.30%.

A product soluble in petroleum ether was VIII (1.0 g, 18%) and some TBA (1.5 g, 29%) was recovered.

c) To TBA (5.0 g, 0.019 mol) in 50 m*l* of ether, 30 m*l* of glacial acetic acid and then PBA (0.020 mol) were added under cooling with ice-water. After being kept at 0°C overnight, the reaction mixture was neutralized with aqueous sodium carbonate and dried over anhydrous sodium sulfate. After removal of the solvent the residue was dissolved in petroleum ether. II (5 mg, 0.1%) was obtained as a material insoluble in this solvent. The structure was confirmed to be identical with that of an authentic sample by the IR spectrum. The yield of VIII was 2.2 g (42%).

Methyl Ether of VII (IX). To a solution of VII (0.6 g, 2 mmol) in 100 m*l* of ethanol, about 1 g (24 mmol) of diazomethane in ether - ethanol was added at 0°C. The mixture was maintained at 0°C for two days. The solvents and excess diazomethane were removed, and recrystallization of the residual solid from methanol yielded methyl ether (IX, 0.3 g, 50%), mp 245.0—245.5°C. NMR (in $CDCl_3$ at 56°C): τ 1.95—3.20 (m, 7H), 6.27 (3H), 8.62 (9H) and 8.69 (9H). IR (in Nujol): 3270 (N-H), 1640 (C=O) and 1043 cm^{-1} (OCH_3).

Found: C, 77.55; H, 8.84; N, 4.11%. Calcd for $C_{22}H_{29}NO_2$: C, 77.84; H, 8.61; N, 4.13%.

4,6-Di-*t*-butyl-2-phenylbenzoxazole (X). To a solution of VII (1.0 g, 3.2 mmol) in 50 m*l* of ethanol, 50 m*l* of 8 N hydrochloric acid was added, and the solution was refluxed at 110—120°C for 4 hr. After usual working up, to the viscous oil thus obtained was added 100 m*l* of petroleum ether. After filtration of the precipitated starting material (0.1 g, 10%) and removal of the solvent, the residue (0.8 g) was purified by column chromatography on alumina with petroleum ether. The yield was 0.6 g (57%). Mp 82—84°C.
NMR: τ 1.59—2.00 (m, 2H), 2.40—2.90 (m, 5H), 8.40 (9H) and 8.60 (9H). IR (in Nujol): 1595 cm^{-1} (C=N). UV: λ_{max}^{EtOH} 232 (log ε 4.20), 299 (4.49), 301 (4.50) and 321 mμ (4.21). The UV spectrum was in good agreement with that of 2-phenylbenzoxazole.[22]

Found: C, 81.96; H, 8.43; N, 4.51%. Calcd for $C_{21}H_{25}NO$: C, 82.04; H, 8.20; N, 4.56%.

Reaction of TBA with Benzoyl Peroxide (BPO). A mixture of TBA (13 g, 0.050 mol) and BPO (13 g, 0.054 mol) in 200 m*l* of benzene was allowed to stand overnight at room temperature. After a large amount of white crystals (ppt-1, 2.75 g) were filtered off, the reaction solution was shaken with aqueous sodium carbonate to remove benzoic acid (5.5 g, 83%) and then dried over anhydrous sodium sulfate. Again white crystals (ppt-2, 1.79 g) precipitated, after filtration of which the benzene was evaporated under reduced pressure and petroleum ether was added. After precipitates thus obtained (ppt-3, 3.40 g) were filtered off, the solvent was removed completely under reduced pressure, leaving slightly reddish oily material (7.66 g). The IR spectra of ppt-1, ppt-2 and ppt-3 (7.94 g, 49% in total) were in entire agreement with that of VII.

The slightly reddish oil, VI, showed satisfactory analytical result without further purification. IR (neat): 3310 (N–H) and 1720 cm^{-1} (C=O). NMR: τ 8.93 (9H), 8.55 (18H), 3.83 (2H), 2.35—2.70 (m, 3H), 1.75—2.10 (m, 2H) and 0.60 (1H, broad).

Found: C, 78.50; H, 9.70; N, 3.30%. Calcd for $C_{25}H_{35}NO_2$: C, 78.68; H, 9.25; N, 3.67%.

The oily material (5.6 g) was chromatographed on silica gel. 2,2′,4,4′,6,6′-Hexa-*t*-butylazobenzene (XI, 0.33 g, 2%), 2,6-di-*t*-butyl-4-benzoyloxyaniline (XII, 1.76 g, 39%) and VII (1.69 g, 37%), mp 230—232°C, were eluted with petroleum ether, benzene and ether, respectively.

The azobenzene (XI) was identified by comparison of the UV spectra (λ_{max}^{EtOH}, 470 (ε 617) and 314 mμ (14, 200)), and the melting point (237—238°C) with data of an authentic sample.[7]

The aniline (XII) was a white solid and recrystallized from petroleum ether, mp 134—135°C. NMR: τ 8.51 (18H), 5.95 (2H), 2.95 (2H), 2.25—2.55 (m, 3H) and 1.50—1.85 (m, 2H).

Found: C, 77.82; H, 8.66; N, 4.09%. Calcd for $C_{21}H_{27}NO_2$: C, 77.50; H, 8.36; N, 4.30%.

When a mixture of ppt-2 and ppt-3 was chromatographed on alumina, a trace of white crystals was eluted with dichloromethane. It melted at 256—258°C after recrystallization from carbon tetrachloride. The IR spectrum showed strong bands at 3280 and 1638 cm^{-1}. It was tentatively identified as 2,4,6-tri-*t*-butylbenzanilide.

Found: C, 81.10; H, 10.02; N, 4.33%. Calcd for $C_{25}H_{35}NO$: C, 82.14; H, 9.65; N, 3.83%.

From the petroleum ether-soluble oil obtained by another experiment using 5.0 g (0.019 mol) of TBA and 5.0 g (0.021 mol) of BPO, VIII (0.1 g, 2%) was isolated by sublimation under vacuum, mp 167—170°C.

The authors are grateful to Professor Osamu Simamura for his kind guidance and helpful discussions.

Triazene Rearrangement. III.*[1] A Kinetic Study of the Rearrangement of *N*-Methyldiaryltriazenes

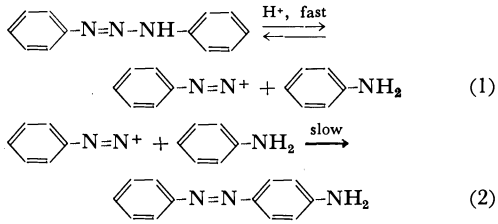
Takashi YAMADA*[2]

Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto

(Received July 22, 1969)

The rate constants of the hydrochloric acid-catalyzed rearrangement of *N*-methyldiaryltriazenes were determined in 95% aqueous ethanol in the presence of *N*-methylaniline. Electron-donating substituents on the diazo-part in triazene promoted the rearrangement. A Hammett plot of the rate constants gave a good straight line. The negative ρ-value (−3.63 at 30.0°C) and the large positive values of the entropy of activation suggested that the rate-determining step in this rearrangement is the dissociation of protonated triazene; this is in contrast with the case of the Friswell-Green mechanism. This theory was suppoted by such a solvent effect as that the rate decreased a little as the polarity of the solvent increased. The kinetic behavior of triazenes in the absence of *N*-methylaniline, and the incorporation of *N*-methyl-*o*-toluidine into the product in the rearrangement of 1-*p*-chlorophenyl-3-methyl-3-phenyltriazene (Id), were also discussed in connection with the above mechanism.

On the mechanism of the triazene rearrangement, several product studies[1] have thus far been presented. As a result, Friswell-Green's mechanism[2] prevails, though a few objections[3] have been offered against it.



(1)

(2)

In our previous papers,[4] Friswell-Green's mechanism was supported by the quantitative analyses of the products, which were found to contain the added amine in the rearrangement.

However, there have been few kinetic studies of the mechanism of the triazene rearrangement; Goldschmidt *et al.*[5] determined the order of reaction in the rearrangement of 1,3-diphenyltriazene, but they could not clarify the details of the reaction mechanism. Yokojima[6] insufficiently examined the effect of amines upon the reaction rate in ethanol.

In this paper, the author will report on the substituent effect, the solvent effect, and the thermodynamics of activation and will discuss the mechanism of the triazene rearrangement in more detail.

Results

Reaction in Ethanol. The rearrangement of triazenes (Ia—f) was carried out in 95% aqueous ethanol in the presence of hydrochloric acid; the first-order rate plots of the reaction are shown in Figs. 1 and 2. The line for Ib (X=*p*-CH_3) is linear, whereas the line for Ia (X=*p*-OCH_3) is concave and the others are convex. Yokojima[6] observed a similar curve for the rearrangement of 1,3-diphenyltriazene in ethanol. This behavior of the lines can be ascribed to the difference in basicity between triazenes (I) and aminoazobenzenes (II),

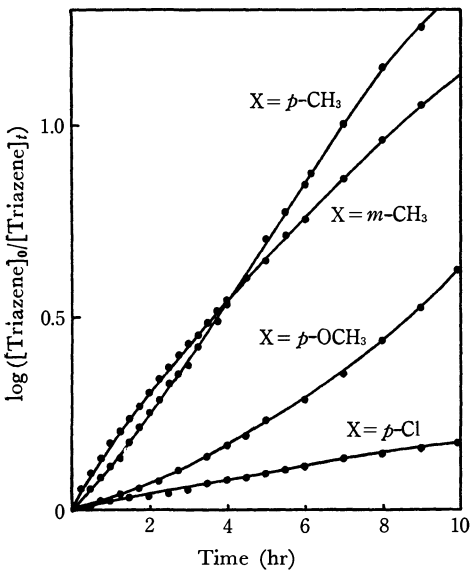

Fig. 1. First-order plots for the rearrangement of triazenes (Ia—d) in 95% aqueous ethanol at 30.0°C.
[Triazene]=5.0×10^{-3} M, [HCl]=0.5×10^{-3} M

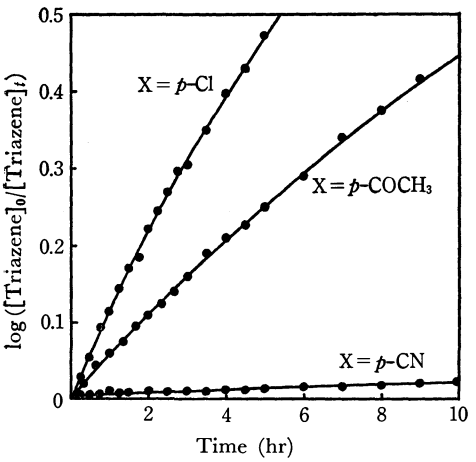

Fig. 2. First-order plots for the rearrangement of triazenes (Id—f) in 95% aqueous ethanol at 30.0°C.
[Triazene]=5.0×10^{-3} M, [HCl]=2.5×10^{-3} M

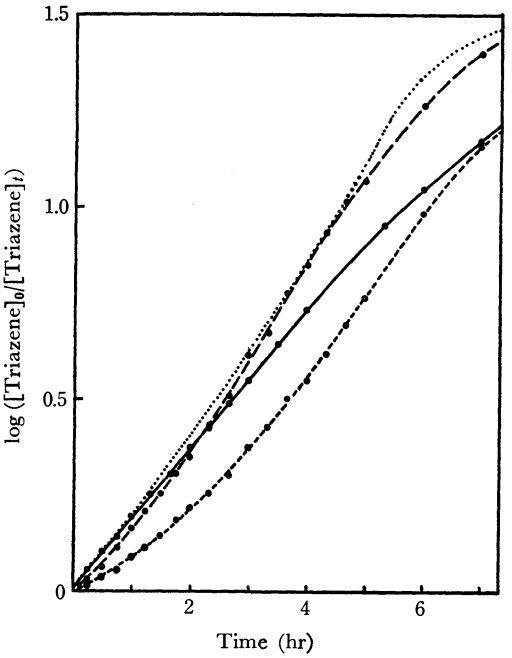

Fig. 3. First-order plots for the rearrangement of triazene (Ia) in the presence of various quantity of *N*-methylaniline.
[Triazene]=5.0×10^{-3} M, [HCl]=1.0×10^{-3} M
[*N*-Methylaniline] = 0 (- - -), 2.5×10^{-3} M (— —), 5.0×10^{-3} M (·····), 10×10^{-3} M (——)

for the first-order plots became linear when the reaction was carried out in the presence of *N*-methylaniline, which seemed to be a stronger base than either Ia—f or IIa—f (Fig. 3). Consequently, the curves of Figs. 1 and 2 suggest that, regarding basicity, Ia>IIa, Ib≒IIb, and I<II for the others.

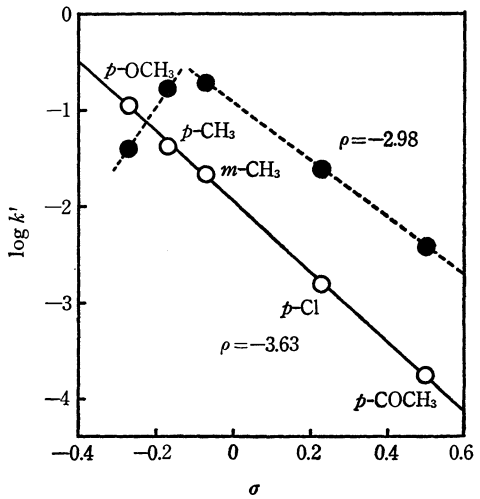

Fig. 4. Hammett's plots for the rearrangement of *N*-methyldiaryltriazene in the presence (—○—) and absence (- -●- -) of *N*-methylaniline. (in 95% aq. EtOH, at 30.0°C).

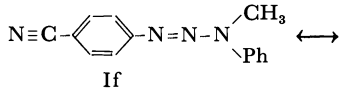
In Figs. 1 (except for Ia) and 2, it is qualitatively shown that the rearrangement is accelerated by the electron-donating substituents on the diazo-part of triazenes. A Hammett plot of the initial rate constants also shows it (Fig. 4). This acceleration is against the expectation from the mechanism proposed by Friswell and Green, in which the rate-determining step is the *C*-coupling reaction (Eq. (2)).

It is noteworthy that the initial rate of the rearrangement of Ia in the absence of *N*-methylaniline was lower than that of Ib and Ic, and that a Hammett plot was concave (Fig. 4), whereas the initial rate of Ia increased upon the addition of *N*-methylaniline to become greater than the rates of Ib and Ic in the presence of the amine (Figs. 3 and 4).

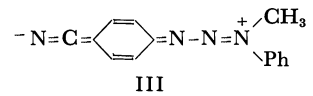
Rearrangement in the Presence of *N*-Methylaniline. The first-order rate plot was made linear by the addition of *N*-methylaniline of twice as much molar quantity as triazenes, even in the rearrangement of Ia, which may be the strongest base among the Ia—f and IIa—f (Fig. 3). Besides, the presence of the amine may favorably exclude the variation in the relative rate because of the difference in the basicities among I's or among II's, and prevent the decomposition of triazenes.[3]

The rearranaement of I in ethanol containing *N*-methylaniline in the presence of hydrochloric acid was a second-order reaction; *i.e.*, it was first-order with respect to triazene and to the acid (Table 1). The same is true for the case of 1,3-diphenyltriazene in aniline.[5]

Table 2 shows that electron-donating substituents on the diazo-part of triazene promote the rearrangement. A Hammett plot of the rate constants at 30.0°C gives a good straight line (Fig. 4, $\rho=-3.63$, $r=0.999$). In the plot of the rate constants at 40.0°C against σ, the point for *p*-CN deviated from a straight line. This deviation may be attributed to the fact that the protonation of triazene may be inhibited by such additional conjugation as that of III in the ground state of triazene (If).



If



III (4)

Table 3 summarizes the activation parameters calculated from the values in Table 2. It is interesting that the entropies of activation ($\Delta S^{\neq}$) were large positive values.

* not optimum yield.
** II was not detected by TLC.

it was observed by thin-layer chromatography (TLC) that the crude products contained a small amount of aminoazo compounds (II). Therefore, in order to clarify the competition between *C*-coupling and *N*-coupling, the II content in the crude products was examined in the reaction of aryldiazonium with *N*-methylaniline (Table 5) (Eq. (5)).

The total yield of products increased with the electron-withdrawing property of the substituents, as was expected.[8] The formation of only a small amount of II showed that *N*-coupling is much more rapid than *C*-coupling. The introduction of the electron-withdrawing substituent resulted in a small but appreciable increase in the ratio of II to I. When the kinetic results in Table 2 are taken into account, it seems that the formation of II may be not through the rearrangement of triazene, but by a direct *C*-coupling competing with *N*-coupling.

Incorporation of Amine in the Rearrangement. When triazene (Id) was rearranged with hydrochloric acid in the presence of 1 equiv. of *N*-methyl-*o*-toluidine (IV), two products were detected by TLC: IId, the product expected from Id, and V, expected from the incorporation of the added amine (IV) (Eq. (6)).

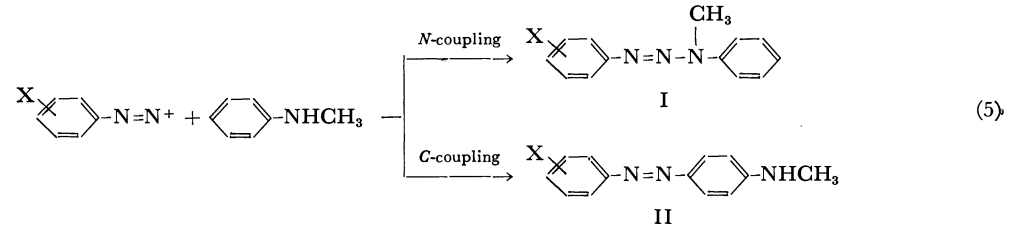
The fact that the yield of V was 56% evidently shows a very efficient incorporation of the added amine into the product and, thus, the intermolecular aspect of this reaction.

It is interesting to note that the ratio IId/V (33/67) roughly agrees with the ratio of the incorporation of *o*-toluidine into the amine-part of the products in the reaction showin in Eq. (7)(35/65).[4]

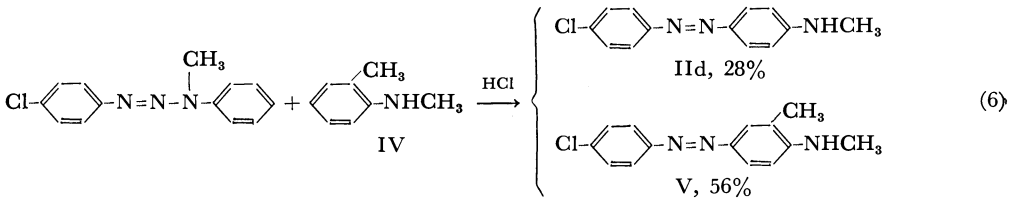
Discussion

On the basis of the above results, it seems reasonable to assume as follows regarding the rearrangement of *N*-methyldiaryltriazene:

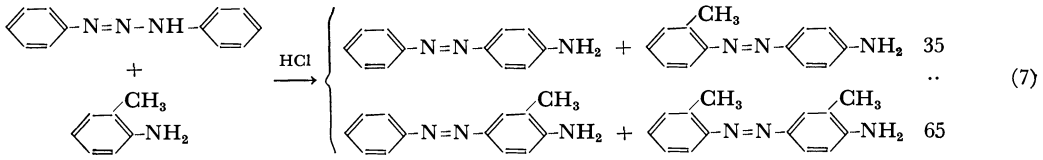
(1) The reaction process consists of three steps, in accordance with Friswell-Green's mechanism on the rearrangement of 1,3-diphenyltriazene: the protonation of triazene, the dissociation of the



(5)



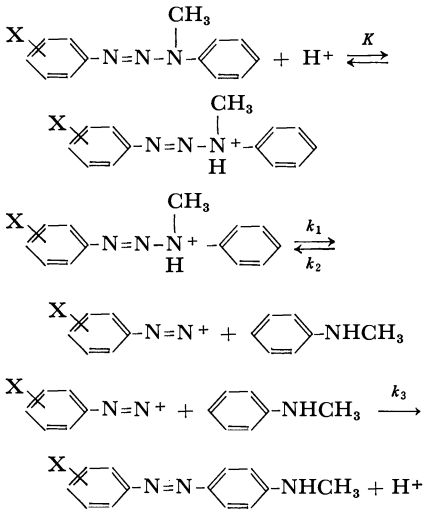
(6)



(7)

8) M. J. S. Dewar, "The Electronic Theory of Organic Chemistry," Oxford University Press, Oxford(1949), p. 183.

protonated triazene to the diazonium ion and amine, and the subsequent *C*-coupling of those moieties.



(2) However, the negative ρ-value (Fig. 4) and the large positive entropies of activation (Table 3) show that, in contrast with Friswell-Green's mechanism for 1,3-diphenyltriazene, the rate-determining step in the rearrangement of *N*-methyldiaryltriazene (I) is not the *C*-coupling step but the dissociation step of the protonated triazene to the diazonium ion and amine, *i.e.*, $k_1 < k_3 \ll k_2$. Although a negative ρ-value may also be expected from the substituent effect in the protonation of triazene, the protonation is probably not rate-determining, for it is reasonably assumed to be much more rapid than the dissociation of protonated triazene. If the protonation of triazene were the rate-determining step, $\Delta S^{\neq}$ might be expected to have a negative value.

According to Ingold's criterion,[9] the above consideration is supported by the solvent effect; the increase in the solvent polarity resulted in a small decrease in the rate (Table 4).

(3) As has been remarked above, unusual behavior was observed in the rate plot of the rearrangement of Ia in the absence of *N*-methylaniline (Figs. 1 and 3), and a Hammett plot of the initial-rates was concave (Fig. 4). These results may be interpreted as follows.

In the rearrangement of Ia in the absence of *N*-methylaniline, the *C*-coupling of diazonium with amine may be the rate-determining step (*i.e.*, $k_3 < k_1 \ll k_2$), whereas in the rearrangemnet of Ic—f the rate-determining step may be the dissociation of protonated triazene, even in the absence of the amine ($k_1 < k_3 \ll k_2$) and Ib may have an intermediate character. Such a change in the rate-determining step may cause the curve of a Hammett plot to be concave.

The increase in the basicity of triazene caused by the electron-donating substituent undoubtedly results in the rate decrease. The difference in ρ-values shown in Fig. 4 (-3.63 in the presence of *N*-methylaniline and -2.98 in its absence) is probably due to this effect. However, the decrease in Ia is too large to be ascribed to the same effect.

The enhancement of the initial-rate observed when a small quantity of *N*-methylaniline was added may be because the rate-determining step lies in the *C*-coupling.

(4) In our previous papers,[4] we supported Friswell-Green's mechanism because, judging from the results of the product analysis, the rate-determining step of the triazene rearrangement seemed to be the *C*-coupling reaction.

However, the efficient incorporation of the added amine, *N*-methyl-*o*-toluidine, into products was also observed in the rearrangement of Id in which the rate-determining step was clearly, on the basis of the kinetic results, the dissociation of protonated triazene. That is, the incorporation might well occur if the relative rate were $k_3 \ll k_2$ whether the rate-determining step is the *C*-coupling or the dissociation of protonated triazene. Therefore, on the rearrangement of the 1,3-diphenyltriazene previously discussed on the basis of only the product studies of the incorporation reaction,[4] further kinetic study is desirable.

Experimental*3

Materials. *The triazenes (I)* were prepared by the reaction of the corresponding aryldiazonium chlorides and *N*-methylaniline by the usual procedure;[10] they were purified by several recrystallizations from ethanol. The triazene (If) was purified by elution chromatography over activated alumina, using benzene as an eluent, and by recrystallization from ethanol.

azene and 1.0×10^{-3} mol of *N*-methylaniline was placed in a 100-m*l* measuring flask covered with aluminum foil in order to exclude all light; it was then kept at an appropriate reaction temperature in a thermostated water bath. After about an hour, 5 m*l* of aqueous hydrochloric acid was pipetted into this solution, and the entire solution was made up to volume with ethanol. Aliquots (1 m*l* each) were removed at intervals and put into 10-m*l* measuring flasks containing a sodium hydroxide solution (1 m*l*) in concentrations enough to neutralize the catalytic acid. The solution was made up to volume with ethanol, and, further, the solution was diluted ten times with ethanol to be used as the sample for the optical density measurements. All these samples were kept in the dark.

The optical densities were measured at two different wavelengths, 343—365 mμ (λ_{max} for I) and 400—440 mμ (λ_{max} for II) (see Table 8); the data were then treated in the manner previously described[15] to give the concentrations of the triazene remaining and of the aminoazobenzene produced. The reaction rate constants were evaluated by the graphical method. A typical example is shown in Fig. 5. As the rate constants of the disappearance of I were found to agree with those

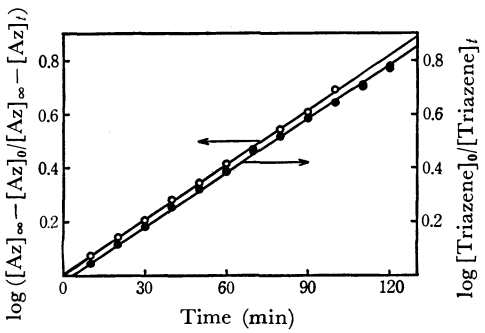

Fig. 5. Typical first-order plots for the rearrangement of triazene (Ib) in 95% aqueous ethanol at 50.0°C. (Az=aminoazobenzene (IIb)) [Triazene]$=5.0\times10^{-3}$ M, [HCl]$=0.5\times10^{-3}$ M, [*N*-Methylaniline]$=10\times10^{-3}$ M

of the formation of II, the former are summarized in Table 2.

Competition between *N*-Coupling and *C*-Coupling. A solution of the diazonium salt prepared in the usual way from 0.01 mol of the corresponding aniline (in 15 m*l* of water), 3 m*l* of the concentrated hydrochloric acid, and 0.67 g of sodium nitrite (in 3.5 m*l* of water at 0— −2°C was added to a cold solution of *N*-methyl-aniline (1.07 g, 0.01 mol) in 6% aqueous hydrochloric acid (6 m*l*). The mixture was stirred for 10 min at −3——5°C. Then, to this mixture, a solution of 4.5 g (0.033 mol) of crystalline sodium acetate dissolved in 10 m*l* of water was added, and the stirring was continued for 30 min, keeping the temperature below 0°C. The precipitate of triazene produced was filtered, washed with cold water, and then dried over calcium chloride in a desiccator for a day.

The ratios of I to II in the products not still purified were obtained by the spectrophotometric method described above (Table 5).

Incorporation of *N*-Methyl-*o*-toluidine in the Rearrangement of Triazene (Id). Id (248 mg, 10^{-3} mol) was rearranged by the action of 0.1 N aqueous hydrochloric acid (2 m*l*) in ethanol (50 m*l*) containing *N*-methyl-*o*-toluidine (121 mg, 10^{-3} mol) at 40°C for several days. After TLC showed that all the triazene had been consumed, the reaction mixture was neutralized with a 0.05 N aqueous sodium hydroxide solution (5 m*l*). TLC (Merck silica gel G, *n*-hexane-benzene (3 : 1)) showed two main products, namely, IId and V, and a trace of two products which might be *ortho*-rearranged products. 2′,3-Dichloro-4-aminoazobenzene (VI) was added to the solution as an internal standard. Each component was separated by TLC on silica gel and was extracted with ethanol. The yield was determined from the intensity of the maximum absorption of each extract in an electronic spectrum. The extinction coefficients used were: Id $\varepsilon_{411\ m\mu}=30300$, V $\varepsilon_{412\ m\mu}=30200$, and VI $\varepsilon_{397\ m\mu}=25700$ (in ethanol).

The author wishes to thank Professor Ryōzō Gotō for his helpful discussions and encouragement throughout this work. He is also indebted to Professors Aritsune Kaji and Jun-ichi Hayami for their valuable discussions.

n–π^* Electronic Spectra of 2-Methyl-1,4-naphthoquinone in the Vapour Phase

G. D. BARUAH, S. Nath SINGH and R. S. SINGH

Spectroscopy Department, Banaras Hindu University, Varanasi-5, India

(Received January 13, 1969)

The visible emission glow of 2-methyl 1,4-naphthoquinone has been excited by an uncondensed transformer discharge in the presence of flowing vapour of benzene. The vapour absorption spectrum of the molecule has also been investigated in the region 4900—3800 Å at different temperature.

The wide occurrence of quinones in nature and their essential role in photochemistry makes the understanding of their electronic structure a most important matter. In recent years many interesting papers have appeared, both experimental and theoretical, on spectroscopic investigations of quinones. We have undertaken studies of quinone, and the sensitized emission spectra involving n–π^* electronic transitions of p-benzoquinone,[1] 1,4-naphthoquinone[2] and 9,10-anthraquinone[3] molecules in the vapour phase have already been reported.

The near ultraviolet absorption spectrum of 2-methyl-1,4-naphthoquinone (2-MeNQ) in solution[4] and vapour[5] phases have been studied and the absorption maxima at 40804 and 30294 cm^{-1} reported. The phosphorescence spectrum of the molecule in methyl cyclohexane at 77°K has been studied by Kuboyama.[6] He reported a system consisting of seven peaks at 20115, 19737, 18970, 18513, 18062, 17386 and 16858 cm^{-1} and assigned it to n–π^* (triplet-singlet) transition. However, no work in the vapour phase of the molecule has been done so far in the visible region. This paper deals with the electronic emission and absorption spectra in the vapour phase.

Experimental

The emission spectrum of 2-MeNQ vapour was excited by an uncondensed transformer discharge in the presence of the flowing vapour of benzene employing π-type discharge tube. The bright yellowish glow was photographed by a Fuess Glass Spectrograph employing Kodak IF plates in six hours. The absorption spectrum was also photographed on the same spectrograph employing HP-3 plates with slit width of 40 μ. The absorption cell used was a quartz to Pyrex graded seal cell of length 120 cm enclosed in an electric furnace. A tungsten filament lamp was used as the source of continuum in the visible region. All the bands were measured on a Hilger L-76 comparator.

Results

The emission spectrum lies in the region 22078—14663 cm^{-1} and consists of 35 bands. The observed bands are broad, diffuse and intense. The important feature observed is the irregular intensity distribution of bands like that of other p-quinones.[1-3] The bands in the region 22215—20825 cm^{-1} are weak as compared to those in the region 20827—17236 cm^{-1} and intensity abruptly falls again on the longer wavelength side. The spectrogram is shown in Fig 1. The entire absorption spectrum in the visible region lies in the region 20257—26659 cm^{-1} and is divided into two groups, developing at different temperatures with the same cell length of 120 cm. At about 150°C one system of bands develops in the region 22215—27019 cm^{-1} and while increasing the temperature up to 190°C three broad and very diffuse bands develop in the region 20402—22215 cm^{-1}. The bands in the former region are also diffuse but distinct. The observed spectrum is shown in Fig. 2. The analyses of the bands observed in emission and absorption spectra are given in Tables 1 and 2 respectively. Table 3 includes the comparison of the ground and excited state frequencies with those of Raman and infrared.[7]

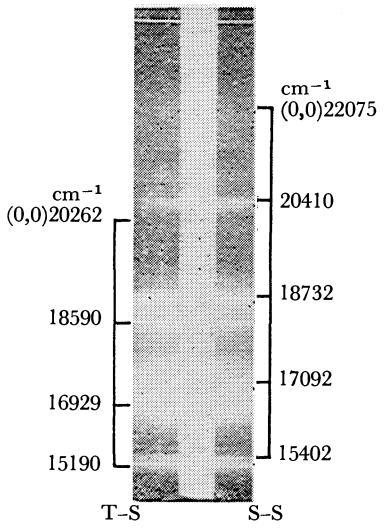

Fig. 1. Emission spectrum of 2-ethylnaphthoquinone.

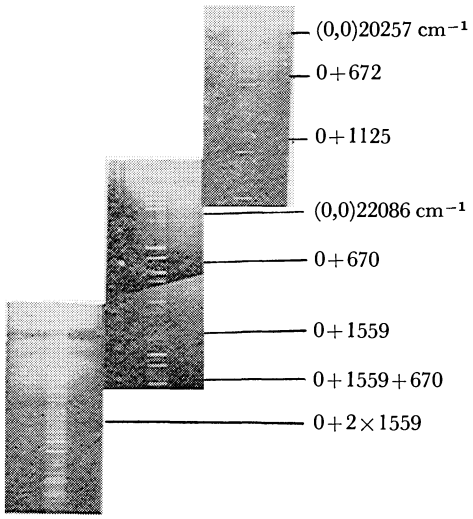

Fig. 2. Absorption spectrum of 2-methylnaphthoquinone.

Analysis and Discussion

The molecular symmetry C_{2v} of 1,4-naphthoquinone is reduced to C_s when a CH_3 group lying in the plane of the molecule replaces a hydrogen atom in its 2-position. Assuming C_s symmetry for the molecule both in the ground as well as in the excited state, the analyses of emission and absorption spectra have been given below.

In emission spectrum, the medium strong band at 22075 cm^{-1} on the shorter wavelength side of the spectrum has been taken as the (0−0) band of the system, corresponding to that of NQ[2] at 21945 cm^{-1}. This band in the absorption spectrum is identified at 22086 cm^{-1}. On the lower frequency side to this there are three more bands

i. p.=in-plane; o. p.=out-of-plane.

extending upto 20262 cm^{-1} and seems to belong to some other electronic transition. Since this latter system does not have any vibrational structure, an adequate analysis is not possible. However these bands will be discussed along with the phosphorescence bands. The medium strong band at 21701 cm^{-1} in the emission spectrum is associated with a frequency 374 cm^{-1} which corresponds to the Raman line 380 cm^{-1}. The excited state counterpart of this vibration is obsered in the absorption spectrum at 22449 cm^{-1} with a separation of 363 cm^{-1} from the (0-0) band. This frequency is suggested to be a C=O bending mode of vibration in the molecular plane. The strong band at 21383 cm^{-1} involves the ground state frequency 692 cm^{-1} in the emission and at 22756 cm^{-1} with a corresponding excited state frequency 670 cm^{-1} in the absorption spectrum. In the Raman spectrum this frequency is found to be 698 cm^{-1} and assigned to ring breathing mode of vibration. Another moderately intense band at 20793 cm^{-1} with a difference of 1282 cm^{-1} from the (0-0) band in the emission spectrum may be correlated to Raman frequency 1306 cm^{-1}. The excited state frequency is observed to be 1258 cm^{-1} associated with a strong band at 23344 cm^{-1} in the absorption spectrum. In the emission spectrum the strong band at 20410 cm^{-1} is due to excitation of a totally symmetric C=O stretching mode of vibration with value 1665 cm^{-1}. This frequency forms the progression in the spectrum and appears up to four quanta as well as in combinations with other frequencies.

The bands with two and three quanta of C=O stretching mode of vibrations are more intense than those of one and four quanta, indicating the increase in the equilibrium internuclear distance for the excited electronic state. On this account, the (0-0) band is weak and intense bands result, corresponding to the transition to the higher vibrational sublevels of the ground state rather than the lower ones. The difference between the successive bands involving the higher quanta of this vibration decreases in magnitude and gives the evidence of the anharmonicity in C=O vibration. The excited state counterpart of this vibration is found to be associated with a band at 23645 cm^{-1} having a separation of 1559 cm^{-1} from the (0−0) band in the absorption spectrum. Most of the other bands observed in the emission and absorption spectra are explained as combinations, overtones and quanta of this vibration. In regard to the nature of electronic transition involved, the system may be assumed to be due to n–π^* ($^1A'$–$^1A'$) transition agreeing with n–π^* (singlet-singlet) transition of NQ.[3] This is further confirmed by a blue shift of 130 cm^{-1} in the (0−0) band on 2-methyl substitution in NQ.

Comparison with Phosphorescence Bands. It has been observed that some of the bands in the present work agree well with those reported from phosphorescence in rigid glass solution and it is therefore worthwhile to compare them. Assuming the first intense band of the phosphorescence spectrum at 20115 cm^{-1} as the origin of the system, the band at 20262 cm^{-1} in the vapour emission spectrum may be taken to correspond to it, in the light of which a vibrational analysis has been suggested for these bands and shown in Table 4.

The totally symmetric vibrations 378 cm^{-1} (C=O bending), 1145 cm^{-1} (C-H bending) and 1672 cm^{-1} (C=O stretching) are found to be superposed on this (0−0) band of the new electronic system. The assignment of this new system was considered preferable for interpreting the unusual intensity distribution associated with the bands at 20262, 18590 and 16929 cm^{-1} analysed as $0-n\times 1665-144$, where $n=1, 2, 3$ respectively in the S–S system. In the case this system can be identified with the one observed in phosphorescence, it is due to (S–T) transition. The C=O stretching mode of vibration in both S–T vapour emission and phosphorescence spectra are prominent and appears strongly in combination and overtones.

The life time of the phosphorescence glow has been reported to be 0.001 sec which is favourable for a triplet-singlet emission under the present experimental conditions. Thus as presumed in

A Thermodynamic Formulation of Reaction Rates

Naokata TAKEYAMA

Faculty of Science and Engineering, Saga University, Honjyo-machi, Saga

(Received January 8, 1969)

The purpose of this note is to show a thermodynamical method to formulate a correct expression for the reaction rate proposed by Horiuti *et al.*[1]

In the current theory of rate processes,[2] except for that of Horiuti, the reaction rate is assumed to be c_*/τ, where c_*=concentration of activated complex and τ=lifetime. By equating this rate to that of the kinetic expression kc_Ac_B we obtain

$$k = \frac{1}{\tau}\cdot\frac{c_*}{c_Ac_B} = \frac{K^*}{\tau}, \tag{1}$$

where k=rate constant, and c_A, c_B=concentration of reactant. K^* is interpreted as an equilibrium constant for the formation of an activated complex M* from A and B. However, if we formulate K^* according to the equilibrium theory, we should have

$$K^* = \frac{c_*^{(e)}}{c_A^{(e)}c_B^{(e)}} \tag{2}$$

and

$$\text{reaction rate} = \left\{\frac{1}{\tau}\cdot\frac{c_*^{(e)}}{c_A^{(e)}c_B^{(e)}}\right\} c_Ac_B, \tag{3}$$

where the concentration of each species in an equilibrium state is distinguished from that in a non-equilibrium state by a superscript (e). The difference between the concentrations of a reactant in equilibrium and non-equilibrium states should be reasonably taken into account.

Let us take a reversible reaction

$$\nu_AA + \nu_BB \rightleftarrows \nu_CC + \nu_DD, \tag{4}$$

where ν_X is the stoichiometric coefficient of a species X.

Reactants are supposed to be immersed in a large heat bath of temperature T which stays in equilibrium irrespective of energy exchange with the reactants. Considering the processes of the formation of an activated complex

$$\nu_AA + \nu_BB \rightarrow M^* \quad \text{(in initial state)} \tag{5.a}$$

and

$$\nu_CC + \nu_DD \rightarrow M^* \quad \text{(in final state)}, \tag{5.b}$$

we introduce the corresponding variables of progress by means of a unilateral variation

$$\vec{\delta}\xi_I = \vec{\delta}c_* = -\nu_A^{-1}\vec{\delta}c_A = -\nu_B^{-1}\vec{\delta}c_B \tag{6.a}$$

and

$$\vec{\delta}\xi_F = \vec{\delta}c_* = -\nu_C^{-1}\vec{\delta}c_C = -\nu_D^{-1}\vec{\delta}c_D, \tag{6.b}$$

where the arrow on the variation notation denotes the unilaterality.

We should mention that the ordinary progress variable for reaction (4) is

$$\begin{aligned}\delta\xi &= -\nu_A^{-1}\delta c_A = -\nu_B^{-1}\delta c_B \\ &= \nu_C^{-1}\delta c_C = \nu_D^{-1}\delta c_D (\gtrless 0),\end{aligned} \tag{7}$$

whose bilaterality comes from

$$\delta\xi = \vec{\delta}\xi_I - \vec{\delta}\xi_F. \tag{8}$$

With respect to the rate of reaction (5.a) or (5.b), we have to express a unidirectional rate of reaction in terms of chemically observable entities restricted to the reactants in (5.a) or (5.b). So, even from phenomenological consideration, we cannot neglect the probability factor for activation multiplied by the term c_*/τ. The activation probability will be obtained by applying Boltzmann's entropy principle as follows.

When we designate the initial or final state by α=I or α=F, and the occupation probabilities that the system under consideration exists in the unactivated and activated states in an α state by W° and W^*, respectively, the activation probability can be written in the form

1) G. Okamoto, J. Horiuti and K. Hirota, *Sci. Papers Inst. Phys. Chem. Res.*, **29**, 223 (1936); J. Horiuti, "Chemistry of Catalysis," (in Japanese), Asakura Book Co., Tokyo (1953).

The author would like to express his sincere thanks to the referee, who kindly informed him that a presupposition in Horiuti's theory was in line with the present result, but was more general. The present treatment seems to enlighten the thermodynamical background of the presupposition on a very elementary level.

2) S. Glasstone, K. J. Laidler and H. Eyring, "The Theory of Rate Processes," McGraw-Hill Book Co., Inc., New York (1941), pp. 13, 187, 286, 348, 402.

$$\left(\frac{W^*}{W^\circ}\right)_\alpha = \exp\left(\frac{\Delta_\alpha S}{R}\right), \tag{9}$$

where $\Delta_\alpha S$ is total entropy change in the activation of (5.a) or (5.b) which may be calculated by

$$\Delta_\alpha S \equiv \left\{\left(\frac{\partial S}{\partial \xi_\alpha}\right)\Delta\xi_\alpha\right\}_{\Delta\xi_\alpha=+1} = \frac{\partial S}{\partial \xi_\alpha}. \tag{10}$$

Here the total entropy S is expressed by

$$S = S_b(T) + \sum_X n_X\left(s_X^\circ - \frac{u_X^\circ}{T} - R\ln c_X\right) + n_*\left(s_*^\circ - \frac{u_*^\circ}{T} - R\ln c_*\right), \tag{11}$$

where $S_b(T)$ is a part in the entropy of heat bath invariant against energy exchange with reactants under energy conservation, whose influence upon the entropy is expressed in terms of $-(\sum_X n_X u_X^\circ/T + n_* u^\circ_*/T)$, where n_X is the number of moles of a reactant X(=A, B, C and D), n_* is the number of moles of M*, and s° and u° are the standard entropy and internal energy per mole of each species. Here the activity of a species to be used in logarithmic term is approximated by concentration.

The unidirectional rate of reaction is defined by

$$\frac{\vec{d\xi_\alpha}}{dt} \equiv \frac{c_*}{\tau}\left(\frac{W^*}{W^\circ}\right)_\alpha = \frac{c_*}{\tau}\exp\left(\frac{\Delta_\alpha S}{R}\right). \tag{12}$$

By means of the relation

$$\Delta_\alpha S = s_*^\circ - \frac{u_*^\circ}{T} - R\ln c_* - \sum_{X\in\alpha}\nu_X\left(s_X^\circ - \frac{u_X^\circ}{T} - R\ln c_X\right), \tag{13}$$

it follows that

$$\frac{\vec{d\xi_\alpha}}{dt} = \frac{1}{\tau}\cdot\exp\left\{\frac{1}{R}(s_*^\circ - \sum_{X\in\alpha}\nu_X s_X^\circ)\right\} \times \exp\left\{-\frac{1}{RT}(u_*^\circ - \sum_{X\in\alpha}\nu_X u_X^\circ)\right\}\prod_{X\in\alpha} c_X^{\nu_X}$$

$$= \frac{1}{\tau}\cdot\exp\left\{-\frac{1}{RT}(f_*^\circ - \sum_{X\in\alpha}\nu_X f_X^\circ)\right\}\prod_{X\in\alpha} c_X^{\nu_X}$$

$$= \frac{1}{\tau}\cdot\exp\left\{-\frac{1}{RT}(f_*^\circ - \sum_{X\in\alpha}\nu_X f_X)\right\}, \tag{14}$$

where $\sum_{X\in\alpha}$ and $\prod_{X\in\alpha}$ show the summation and multiplication referring to the reactants X (=A and B, or C and D) belonging to an α (=I or F) state. $f_X^\circ = u_X^\circ - Ts_X^\circ$ is the standard Helmholtz energy per mole of X, and $f_X = f_X^\circ + RT\ln c_X$.

It should be noted that the rate expression of (14) is derived without using explicitly any condition of "activation equilibrium", that is, $c_* \neq c_*^{(e)}$, and $c \neq c^{(e)}$ for all of X. However, if we use the condition of the equilibrium of activation given by $\Delta_\alpha S = 0$, or

$$\ln\frac{c_*^{(e)}}{\prod_{X\in\alpha}(c_X^{(e)})^{\nu_X}} = \frac{1}{R}(s_*^\circ - \sum_{X\in\alpha}\nu_X s_X^\circ) - \frac{1}{RT}(u_*^\circ - \sum_{X\in\alpha}\nu_X u_X^\circ), \tag{15}$$

the rate expression may be transformed into

$$\frac{\vec{d\xi_\alpha}}{dt} = \left\{\frac{1}{\tau}\cdot\frac{c^{(e)}}{\prod_{X\in\alpha}(c_X^{(e)})^{\nu_X}}\right\}\prod_{X\in\alpha} c_X^{\nu_X}. \tag{16}$$

Finally, with the aid of Eq. (8), the net rate of reaction may be expressed in the form

$$\frac{d\xi}{dt} = \frac{\vec{d\xi_I}}{dt} - \frac{\vec{d\xi_F}}{dt} = \frac{1}{\tau}\cdot\exp\left(-\frac{f_*^\circ}{RT}\right)\left\{\exp\left(\frac{\sum_{X\in I}\nu_X f_X}{RT}\right) - \exp\left(\frac{\sum_{X\in F}\nu_X f_X}{RT}\right)\right\}. \tag{17}$$

In conclusion the present formulation gives a thermodynamical basis to the theory of transition state.

Effects of Temperature and of Mixing on Dielectric Constants of Several Organic Solvents

Etsuo NIKI, Yoshio KAMIYA and Nobuto OHTA

Department of Fuel Engineering, University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received March 26, 1969)

It is known that the dielectric constants of the organic solvents are dependent on temperature[1] and that those of binary mixtures are not usually equal to the calculated average values.[2] In other words, the curve obtained by plotting the dielectric constants of mixtures against the molar fraction of one of the components usually shows some curvature. Although much data have been obtained for organic solvents and their binary mixtures at different temperatures, relatively little has been reported on hydrocarbons, inert solvents and their mixtures, which are often used for studies on autoxidation. In the course of our study on the solvent effects in autoxidation,[3,4] we have determined the dielectric constants of tetralin, several inert solvents and their mixtures at temperatures from 25°C to 70°C.

The measured dielectric constants for several pure liquids at different temperatures are summarized in Table 1 together with the values in literature.[5] As a whole, the observed values show good agreement with the reported values. Table 1 shows that the dielectric constants for 9 out of 10 liquids decrease with an increase in temperature. The only exception is that for butyric acid, which increases with an increase in temperature.

Lowry and Jessop[6] found that the following correlation exists between the dielectric constants of liquids and temperature.

$$D = D_0 \exp(-LT) \tag{1}$$

where D_0 and L are constants characteristic for each liquid. The equation

$$\log(D_1 D_2) = L(T_2 - T_1)/2.303 \tag{2}$$

is derived from Eq. (1). In Fig. 1, the logarithm of D_1/D_2 is plotted as a function of $(T_2 - T_1)$ using the measured dielectric constants in Table 1 assuming T_1 to be 298°K. Figure 1 shows that Eq. (2) holds for all the solvents measured. The calculated values of L from the slope of the lines in Fig. 1 for each liquid are given in the last column of Table 1. The value of L varies with solvents by a factor of more than 7. The liquid with high

and downward convex curves. In Table 3 are summarized the dielectric constants for the systems of tetralin-nitrobenzene-solvents at 70°C. These values again gave convex curves when plotted as a function of the tetralin concentration.

Experimental

Tetralin, *n*-decane and chlorobenzene were washed successively with sulfuric acid, water, alkali, and water, dried with calcium chloride, and then distilled under reduced pressure of nitrogen. Anisole and nitrobenzene were washed with alkali and water, dried and distilled under reduced pressure. Diethyl maleate and acetophenone were fractionally distilled. Butyric acid and butyl stearate of guaranteed grade were used without further purification. The water content in butyric acid was less than 0.1%.

The dielectric constants were measured at 2Mcps of frequencies using a Dielectric Analyzer Model FAM-3A, Yamato Scientific Instrument Co. Two kinds of dielecric cells were used, one for the solution of low dielectric constant (smaller than 20) and the other for the high dielectric solution (larger than 20). The cell constants for the two cells were determined with several solvents as standard. Since the same apparatus and technique have been used in this study, errors in the measurements will be relative and will not affect the general nature of the conclusion drawn.

μ-Peroxobis(pentacyano)dicobaltate(III) as an Oxidizing Agent

Toshihiko ASAI and Tadashi HARA

Department of Chemical Engineering, Doshisha University, Kamikyo-ku, Kyoto

(Received April 9, 1969)

It has been reported by Haim and Wilmarth[1] that the pentacyanocobaltate(II) (PC-II) is oxidized with oxygen at 0°C to form μ-peroxobis(pentacyano)dicobaltate(III)(POPC), which is decomposed with sulfuric acid to produce hydrogen peroxide.

There have also been several reports concerning the direct epoxidation of acrolein with hydrogen peroxide[2] and of propylene with organic hydroperoxide[3,4] or organic peracid.[5]

Since the possibility of the epoxidation of acrolein and propylene was expected on the basis of the above reports, an attempt was made to epoxidize them with POPC, but the results obtained were negative.

The present paper deals with spectrophotometric and polarographic investigations of the chemical behaviors of POPC to clarify the reason for the negative results.

Experimental

Preparation of POPC. POPC was prepared by oxidizing PC-II with oxygen at 0°C or by dropping a cobalt(II) nitrate solution into a potassium cyanide solution under the passage of oxygen gas at the same temperature. POPC in an aqueous solution was reddish brown and precipitated as crystalline brown needles by addition of methanol. POPC was determined by treating with sulfuric acid and by titrating the hydrogen peroxide produced iodometrically. The yield reached 95.5% under the following conditions; 1150 m*l* oxygen gas/min, 0°C, 30 min (dropping time), 5 : 1 mol ratio (0.1 M Co^{2+}), and 50 m*l* total volume.

Apparatus. A Shimadzu QR-50 spectrophotometer, a Yanagimoto P-8-D polarograph, a Yanagimoto GC-220 gas chromatograph, *etc.* were used.

Results and Discussion

POPC in an aqueous solution was stable for a long time in air or nitrogen atmosphere at 0°C,

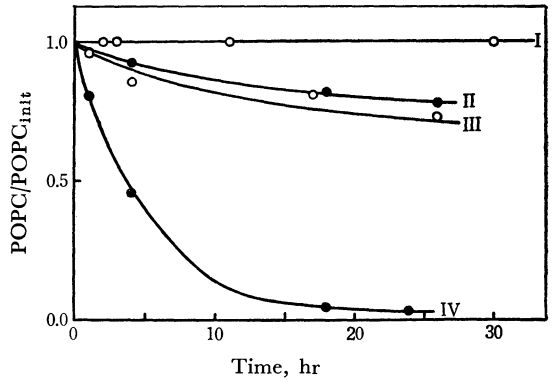

Fig. 1. Thermal stability of POPC.
I $POPC_{init}$: 2.47×10^{-2} M, temperature: 0°C
II $POPC_{init}$: 2.57×10^{-2} M, temperature: 25°C
III $POPC_{init}$: 2.72×10^{-2} M, temperature: 30°C
IV $POPC_{init}$: 2.57×10^{-2} M, temperature: 50°C

but it was decomposed markedly with the rise of temperature to produce pentacyanocobaltate(III) (PC-III) (Fig. 1).

The absorption spectra of POPC, PC-II, PC-III and hexacyanocolaltate(III)(HC-III) are shown in Fig. 2. The absorption of PC-II and PC-III at 310 mμ is so small that the absorption maximum at the same wavelength is attributed to the formation of POPC. There is a linear relationship between the absorbance and the concentration of POPC which was determined by iodometry (Fig. 3).

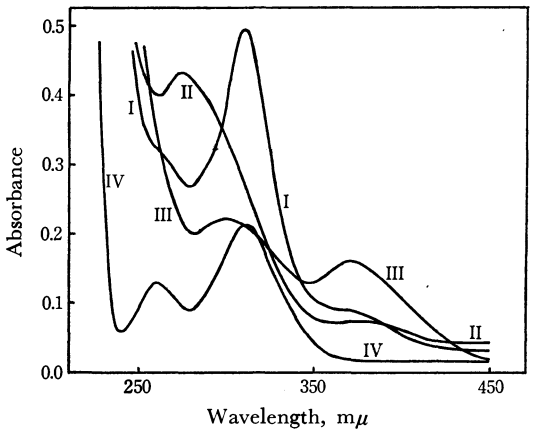

Fig. 2. Absorption spectra.
I POPC; cobalt: 2.50×10^{-4} M
II PC-II; cobalt: 2.50×10^{-4} M
III PC-III; cobalt: 1.00×10^{-3} M
IV HC-III; cobalt: 1.00×10^{-3} M
pH: 12.5, temperature: 0°C

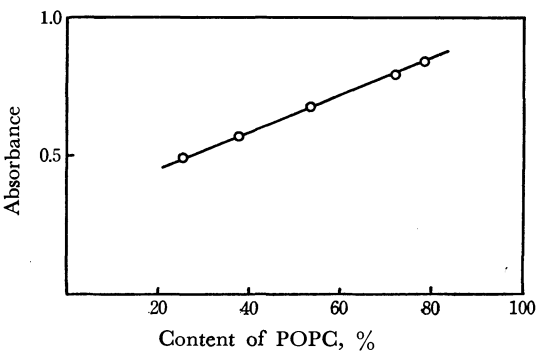

Fig. 3. Calibration curve of POPC at 0°C.
cobalt: 2.50×10^{-4} M, pH: 12.5, wavelength: 310 mμ

The following results were obtained by spectrophotometric investigation: 1) The absorption spectra of POPC solutions prepared by the above-mentioned methods are identical with each other; 2) the absorption spectra of the solutions obtained by treating POPC with sulfuric acid or by heating POPC agree not with that of PC-II but of PC-III; 3) the same absorption spectrum as that of HC-III is obtained by adding potassium cyanide to PC-III and by heating. A schematic diagram from the results is given in Fig. 4. It is easily supposed from 2) that POPC is not produced successively since an oxygen molecule can not coordinate to PC-III.

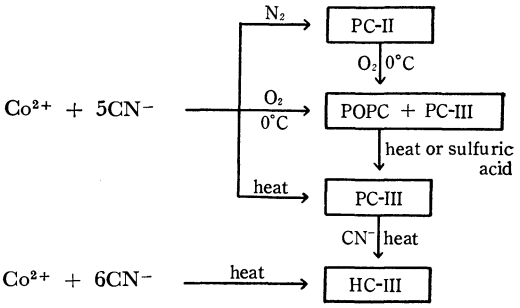

Fig. 4. The schematic diagram for cobalt cyanide complexes.

Table 1. The half wave potentials and the wave heights measured
Concentration of cobalt $=2.50\times10^{-3}$ M, pH=12.5, Temperature=0°C

		Half wave potential (V)	Wave heights (μA)
PC-III		−1.65	7.45
PC-II		−1.59	4.00
POPC	a	−1.66	8.30
	b	−1.68	10.7
O_2	1st step	−0.20	
	2nd step	−1.30	
H_2O_2		−1.19	

a, content 23%
b, content 88%

The polarographic reduction waves of POPC, PC-II, PC-III, hydrogen peroxide and oxygen were recorded with the use of a dropping mercury and saturated calomel electrode couple, and the results are shown in Table 1. As can be seen, the half wave potential of POPC is more negative than that of hydrogen peroxide in spite of the fact that POPC reacts with sulfuric acid to give hydrogen peroxide. This shows that POPC is quite different from hydrogen peroxide. Though there seemed to be two paths as the reduction mechanism of POPC and two waves were expected, only a single wave was observed. This means that the respective reactions in the two reduction paths proceed very fast.

$$\mathrm{CoOOCo} \begin{cases} \xrightarrow{2e} \mathrm{Co^{+} + O_2^{2-}} \\ \xrightarrow{e} \mathrm{Co^{3+} + OH^{-}} \end{cases} \begin{cases} \xrightarrow{e} \\ \xrightarrow{2e} \end{cases} \mathrm{Co^{+} + OH^{-}}$$

The wave height estimated on the basis of the above reduction mechanism and the concentration of POPC agreed well with that of POPC in a polarogram.

Epoxidation. Acrolein and propylene were treated with POPC under the conditions: pH 8—12, 1.5—30°C, and 40—180 min (reaction time).

The reaction mixtures were examined by a gas chromatograph. No epoxide was found. Acrolein was treated similarly with a solution obtained by adjusting the pH to 8—9 after acidfication of POPC solution with sulfuric acid. The gas chromatogram obtained showed a peak of glycidaldehyde.

The failure in the direct epoxidation with POPC is attributed to the inertness of POPC to olefins.

Studies on Reactions of Isoprenoids. VI.[1] Synthesis of *cis*-Homochrysanthemic Acid and Its Derivatives from Δ^3-Carene

Tadashi SASAKI, Shoji EGUCHI, Masatomi OHNO and Takeshi OYOBE

Institute of Applied Organic Chemistry, Faculty of Engineering, Nagoya University, Furo-cho, Chikusa-ku, Nagoya

(Received April 18, 1969)

In 1965, Matsui *et al.*[2] reported the synthesis of *trans*-chrysanthemic acid from Δ^3-carene (I) *via* the keto-aldehyde (II) through several steps. Considering the presence of a cyclopropylacetaldehyde in II, it seemed reasonable to attempt the synthesis of homochrysanthemic acid (VII) from II. This paper deals with our results, though our objective (VII) was already prepared from *cis*-chrysanthemic acid by utilizing the Arndt-Eistert homologation in low yields.[3] Since the communication by Matsui *et al.*[2] did not describe the detailed experimental conditions for the preparation of II,[4] we checked the oxidation conditions in three methods. Method 1 involved ozonolysis of I following Semmler and Schiller[4a] to II which was not isolated by Matsui *et al.*[2] We adopted a somewhat modified procedure.[4b] By decomposing the ozonized mixture with hydrogen peroxide in refluxing aqueous acetic acid for 10 hr, 3,3-dimethyl-2-(2-oxopropyl)cyclopropylacetic acid (III) was directly obtained from I in about 10% yield. Method 2 involved a new procedure adopted by Pappas and Keaveney[5] using dimethyl sulfide for decomposition of the intermediated ozonide was applied. The yield of II was 52%. II was readily convertible to III by potassium permanganate in 65% yield. This method seems to be superior to method 1 and the following method 3. Method 3 utilized direct oxidation of I with potassium permanganate in acetone at 10°C; the yield of III was only 15%, many side-products being formed, which were hardly separated from III by repeated *vacuum* distillation.

The conversion of 2-oxopropyl group into isobutenyl was fulfilled by applying the selective Grignard reaction to III and VI followed by dehydration. The keto-ester (VI), obtained from III by the acid-catalyzed esterification or by methylation with diazomethane, was treated with one mole of methylmagnesium iodide and work-up gave methyl 3,3-dimethyl-2-(2-methyl-2-hydroxypropyl)cyclopropylacetate (V). V was also prepared by the methylation of the corresponding IV which was similarly prepared in a 90% yield by the selective Grignard reaction of the keto-acid (III) with two moles of methylmagnesium iodide following the reverse-addition procedure (see Experimental). The results are summarized in Chart 1.

The last step is the dehydration of the hydroxy acid (IV) or hydroxy ester (V). Dehydration of the tertiary hydroxy group in IV and V was very likely to yield isobutenyl group, since a conjugation of the produced double bond with a cyclopropane might favor the desired dehydration,[6] though in IV, simultaneous cyclopropane-ring-opening according to the mechanism proposed by Matsui *et al.*[7] might afford γ-lactone especially in an acidic condition. In fact, when treated with the catalytic amount of *p*-toluenesulfonic acid, IV afforded the known γ-lactone, 4,4-dimethyl-3-(3-methylbut-1-enyl)butanolide (IX);[3] the structure was confirmed by means of analytical and spectral data. A *cis*-relation of the lactone ring to

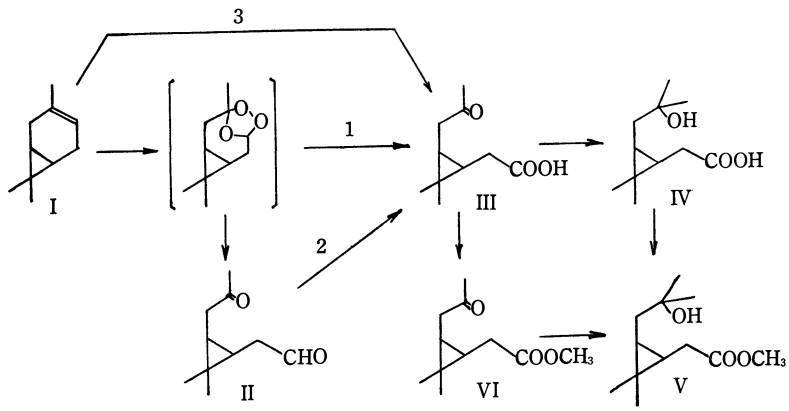

Chart 1

the isopropyl group was demonstrated by the coupling constants of two vinyl protons at 4.53 τ (J= 6.0 and 7.5 Hz) in its NMR spectrum ($CDCl_3$).[8] However, when IV was treated with phosphorus oxychloride in dry pyridine at 0°C, the product was characterized as a seven-membered lactone X on the basis of analytical and spectral data. The formation of IX was also recognized on treatment with phosphorus oxychloride even when a small amount of pyridine was used. At all events, homochrysanthemic acid seems more labile against acid than chrysanthemic acid, and the direct conversion of IV to homochrysanthemic acid was unsuccessful. From the results, dehydration of the hydroxy-ester (V) was investigated. When V was treated with *p*-toluenesulfonic acid in refluxing toluene for 4 hr,

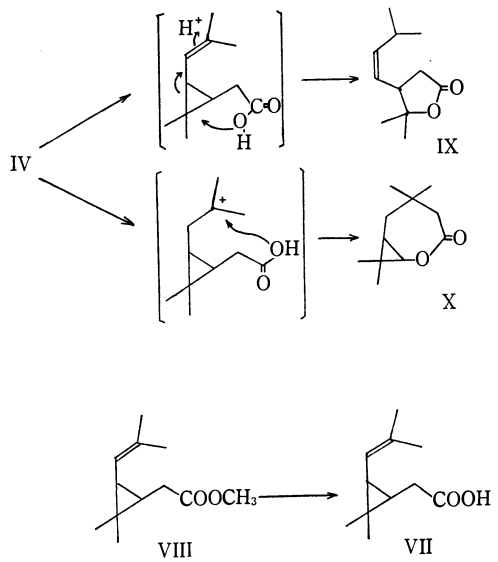

Chart 2

the product was found to be a mixture of methyl homochrysanthemate (VIII) and homochrysanthemic acid (VII) produced by hydrolysis of the former. The best method for dehydration of V to VIII was the treatment of V in dry pyridine with phosphorus oxychloride at 0°C. Pure VIII was obtained in a 51% yield. The acid (VII) was obtained by the alkaline hydrolysis of VIII in an 85% yield. The results are summarized in Chart 2.

Experimental

All melting points were measured on a Yanagimoto micromelting point apparatus and are uncorrected. Boiling points were also not corrected. The microanalyses were performed on a Yanagimoto CHN Corder, Model MT-1, while the IR spectra were obtained on a JASCO Model IR-S spectrophotometer. The NMR spectra were recorded with a Varian A-60 and/or a Jeolco MINIMAR spectrometer using TMS as an internal standard. Chemical shifts were reported in τ values, designating singlet signals as s, doublet as d, triplet as t, multiplet as m. Ozonization was carried out with a Nippon-Ozone Ozonyzer, Model 0-1-2, controlling the reaction with bromination test and thin layer chromatography (TLC).

Oxidation of Δ^3-Carene. *Method 1.* Freshly distilled Δ^3-carene (I), bp 66—66.5°C/23.5 mmHg, n_D^{21} 1.4727 (34 g, 0.25 mol) was dissolved in a mixture of 200 m*l* of acetic acid and 10 m*l* of water and ozone was passed through this solution for 10 hr at 8—10°C. After the reaction was over, 200 m*l* of water and 6.33 m*l* of 30% hydrogen peroxide were added and the mixture was refluxed for 2 hr. After cooling, it was extracted with methylene chloride (100 m*l*×5) and the combined extract was washed with water (300 m*l*×3) and dried (Na_2SO_4). Removal of the solvent and distillation afforded 3 g (10%) of 3,3-dimethyl-2-(2-oxopropyl)-acetic acid (III): bp 135—137°C/0.25 mmHg, n_D^{25} 1.4700 (lit,[4b] bp 145—146°C/2 mmHg, n_D^{20} 1.4688).

Method 2. Ozone was passed through a solution of I (68 g, 0.5 mpl) in 300 m*l* of methanol for 17 hr at −60°C under cooling with a dry ice-methanol mixture until bromination test was found negative. After the reaction was over, nitrogen gas was bubbled into the reaction mixture for 5 min at the same temperature and

8) N. S. Bhacca and D. H. Williams, "Application of NMR Spectroscopy in Organic Chemistry," Holden-Day, Inc., San Francisco (1964), p. 85.

52 ml (43.5 g, 0.7 mol) of dimethyl sulfide was added with stirring under nitrogen atmosphere. The reaction temperature was allowed to rise gradually to room temperature after removing the cooling bath while stirring was continued. Benzene (500 ml) was added after concentration of methanol solution to *ca.* 100 ml and the benzene layer was wahed with water and dried (Na_2SO_4), and the residue obtained by removal of the solvent was distilled to afford 35 g (40%) of 3,3-dimethyl-2-(2-oxopropyl)cyclopropylacetaldehyde (II) as an oil with a bp 80—83°C/1 mmHg, n_D^{20} 1.4600 (lit,[4b] bp 92-94°C/2 mmHg, n_D^{20} 1.4601).

Method 3. To a stirred solution of I (13.6 g, 0.1 mol) in 100 ml of acetone and 25 ml of water, potassium permanganate (11 g) was added little by little at 5—10°C. After reaction was over, 5 ml of ethanol was added to the reaction mixture in order to decompose the excess potassium permanganate and the resulting precipitates were filtered and washed with acetone (50 ml). The combined filtrate and washings were concentrated and the residue obtained was distilled to give 1.95 g (15%) of III with bp 145—148°C/2 mmHg, n_D^{20} 1.4688 (lit,[4b] bp 145—146°C/2 mmHg).

Oxidation of 3, 3-Dimethyl-2-(2-oxopropyl)cyclopropylacetaldehyde (II) to Keto-carboxylic Acid (III). To a mixture of II (26 g, 0.15 mol), acetone (200 ml), and water (50 ml) was added 22 g of potassium permanganate in small portions with stirring at 5—10°C during 3 hr. Excess potassium permanganate was decomposed with addition of ethanol and the resulting precipitates were filtered and washed with acetone (50 ml). The combined filtrate and washings were concentrated *in vacuo* to *ca.* 100 ml. The residue obtained was extracted with ether after addition of water (100 ml) and the ether layer was dried (Na_2SO_4). Removal of ether gave crude acid (III) which was distilled to afford 17.5 g (65%) of pure III with bp 110—115°C/0.5 mmHg, n_D^{20} 1.4670 (lit,[4b] bp 145—146°C/2 mmHg, n_D^{20} 1.4688).

Reaction of the Keto-carboxylic Acid (III) with Methylmagnesium Iodide. Magnesium (1.366 g, 0.055 g atom) was suspended in 100 ml of dry ether and to this was added an ethereal solution of methyl iodide (7.8 g, 0.055 mol in 50 ml) according to general procedures for preparation of methyl Grignard reagent. To a stirred solution of III (4.6 g, 0.025 mol) in 50 ml of ether was added the Grignard reagent at room temperature very slowly in 3 hr. Stirring was continued overnight, and water was added to produce a turbid solution, to which aqueous ammonium chloride was added. This was acidified with 10% hydrochloric acid and the ether layer was separated and dried (Na_2SO_4). Removal of the solvent left crystalline solids which were recrystallized from *n*-hexane to give 4.51 g (90%) of 3,3-dimethyl-2-(2-methyl-2-hydroxypropyl)cyclopropylacetic acid (IV) as colorless needles with a mp of 87—88°C. IR (KBr) cm^{-1}: 3300 (OH), 3000—2500 and 1680 (COOH) 1150 (-C(-OH)-). NMR ($CDCl_3$)τ : 2.90 (2 H, s, COOH and OH), 7.07 (2 H, d, J=7.0 Hz, $-CH_2-$), 8.54 (2 H, d, J=6.0 Hz, $-CH_2-$), 8.72 (6 H, s, $-(HO)C(C\underline{H}_3)_2$), 8.90 and 9.08 (each 3 H, each s, $C(CH_3)_2$), and 9.00—9.32 (*ca.* 2 H, m, cyclopropane ring protons).

Found: C, 65.68; H, 10.01%. Calcd for $C_{11}H_{20}O_3$: C, 65.97; H, 10.07%.

Esterification of the Hydroxy-carboxylic Acid (IV) to (V). A solution of IV (1 g, 0.005 mol) in ether was treated with an ethereal solution of diazomethane which was prepared from 2 g of nitrosomethylurea and 6 ml of 50% aqueous potassium hydroxide in 50 ml of ether. After standing overnight, ether and excess diazomethane were removed to give pure ester (V) in almost quantitative yield. IR (neat) cm^{-1}: 3550 and 1170 (-C(-OH)-), 1740 and 1029 ($COOCH_3$), and 2910, 1450, 910 and 770. NMR($CDCl_3$) τ: 6.22 (3 H, s, $COOCH_3$), 7.65 (2 H, d, J=7.0 Hz, $-C\underline{H}_2COOCH_3$), 8.24 (1 H, s, OH), 8.53 (2 H, d, J=7.0 Hz, $-CH_2-$), 8.71 (6 H, s, $-(HO)C(C\underline{H}_3)_2$), 8.86 and 9.10 (*ca.* 6 H, each s, $C(CH_3)_2$), and 9.00—9.40 (*ca.* 2 H, m, cyclopropane ring protons).

Found: C, 67.55; H, 10.76%. Calcd for $C_{12}H_{22}O_3$: C, 67.25; H, 10.35%.

Preparation of the Keto-ester (VI). Treatment of III (8.3 g, 0.045 mol) with an excess diazomethane in ether at room temperature afforded crude (VI) which was distilled to give 8.1 g (92%) of pure VI with a bp of 83—85°C/1 mmHg, n_D^{20} 1.4518 (lit,[4b] bp 98—99°C/2 mmHg, n_D^{20} 1.4518). Treatment of III in refluxing methanol in the presence of a catalytic amount of sulfuric acid afforded also VI in a 50% yield, though some decomposition reactions were unavoidable.

Grignard Reaction of Keto-ester (VI). To a stirred solution of VI (8 g, 0.043 mol) in 50 ml of ether was added slowly the Grignard reagent prepared from 0.945 g (0.043 g atom) of magnesium and 6.11 g (0.043 mol) of methyl iodide in 100 ml of ether. Stirring was continued for 3 hr at room temperature and aqueous ammonium chloride was added to the reaction mixture which was neutralized with 10% hydrochloric acid. The ether layer was separated and the water layer was extracted with ether (30 ml×2). The combined ether layer and extracts were washed with water and dried (Na_2SO_4). After removal of ether, the oily residue was distilled to give 7.74 g of the hydroxy-ester (V), bp 76—80°C/2 mmHg, n_D^{20} 1.4560. Its infrared spectrum (neat) was superimposable on that of V prepared from IV.

Dehydration of the Hydroxy-carboxylic Acid (IV). *a) With p-Toluenesulfonic Acid.* A mixture of 0.5 g (0.0025 mol) of IV and 50 mg of *p*-toluenesulfonic acid was dry-distilled to give an oil with a bp of 115—120°C/1 mmHg, which was further purified by chromatography on a silica-gel (Mallinckrodt, 100 Mesh) column eluting with methylene chloride to give 300 mg (66%) of γ-lactone (IX). IR (neat) cm^{-1}: 2980 (CH), 1780 (γ-lactone), and 1660 (C=C). NMR ($CDCl_3$)τ : 4.46 and 4.60 (2 H, q, J=6.5 and 7.5 Hz, -CH=CH-, *cis*), 7.00—7.80 (4 H, m, CH_2 and CH), 8.52 and 8.72 (each 3 H, each s, $C(CH_3)_2$), and 8.96 (6 H, d, J=6.5 Hz, $CH(CH_3)_2$).

Found: C, 72.58; H, 9.99%. Calcd for $C_{11}H_{18}O_2$: C, 72.49; H, 9.96%.

b) With Phosphorus Oxychloride and Pyridine. To a stirred solution of IV (0.3 g, 0.0015 mol) in 5 ml of dry pyridine was added 0.55 ml of phosphorus oxychloride at 0°C during 30 min and the mixture was stirred for another 2.5 hr. After confirming the termination of reaction by TLC, the reaction mixture was poured onto ice-water and extracted with chloroform (20 ml× 5). The combined chloroform extracts were washed with 5% hydrochloric acid, and then with water several times and dried (Na_2SO_4). Removal of chloroform *in vacuo* afforded 160 mg (59%) of needles of the ε-lactone derivative (X), mp 40—41°C. IR (KBr) cm^{-1}: 2900 (OH), 1712 (ε-lactone) and no OH and C=C bands.

NMR ($CDCl_3$)τ: 6.98—8.20 (4 H, complex m, $-CH_2-\times 2$), 8.49 and 8.55 (6 H, eash s, $-O-C(CH_3)_2$), 8.90 (6 H, s, $C(CH_3)_2$), and *ca.* 8.90—9.21 (*ca.* 2 H, m, cyclopropane ring protons).

Found: C, 72.49; H, 10.22%. Calcd for $C_{11}H_{18}O_2$: C, 72.49; H, 9.96%.

When the amount of pyridine decreased or in the absence of pyridine, the exothermic reaction occurred in the above reaction to result in the formation of the γ-lactone derivative (IX) which was confirmed by infrared specral comparison with a specimen prepared as above.

Dehydration of the Hydroxy-ester (V). *a) With p-Toluenesulfonic Acid.* A solution of V (4.8 g, 0.022 mol) and *p*-toluenesulfonic acid (20 mg) in 50 m*l* of dry toluene was refluxed for 4 hr to give a red solution. Purification of the products by distillation and chromatography on a silica-gel column afforded 0.84 g (24%) of methyl *cis*-homochrysanthemate (VIII) as an oil with a bp of 55—60°C/0.3 mmHg and 2.4 g (50%) of *cis*-homochrysanthemic acid (VII) with a bp of 110—115° C/0.1 mmHg, n_D^{20} 1.4652, both of which were confirmed by infrared spectral comparison with the respective specimen prepared by the following procedure.

b) With Phophorus Oxychloride and Pyridine. Similar procedure to the dehydration of IV was carried out on V (1 g, 0.0046 mol) in 10 m*l* of dry pyridine and phosphorus oxychloride (0.6 m*l*) at 0°C for 3 hr. After pouring onto ice-water, the reaction mixture was extracted with benzene. The benzene extracts were chromatographed on a silica-gel column to give 0.47 g (51%) of methyl *cis*-homochrysanthemate, n_D^{20} 1.4658 (lit.,[3] n_D^{20} 1.4663). IR (neat) cm^{-1}: 1740 and 1065 ($COOCH_3$), 1650 and 840 (CH=C). NMR ($CDCl_3$)τ: 5.18 (1 H, broad d, J=7.5 Hz, -CH=C), 6.37 (3 H, s, $COOCH_3$), 7.37 (2 H, d, J=7.0 Hz, $-C\underline{H}_2-COOCH_3$), 8.07 (*ca.* 1 H, superimposed t, J=*ca.* 7.5 Hz, allylic cyclopropane ring proton), 8.27 and 8.32 (*ca.* 6 H, overlapped s, $C=C(CH_3)_2$), 8.86 and 9.05 (*ca.* 6 H, each s, $C(CH_3)_2$) and *ca.* 8.80—9.23 (*ca.* 1 H, complex m, cyclopropane ring proton).

Found: C, 73.26; H, 10.36%. Calcd for $C_{12}H_{20}O_2$: C, 73.43; H, 10.27%.

***cis*-Homochrysanthemic Acid (VII) by Hydrolysis of Its Ester (VIII).** A suspension of VIII (200 mg) in 5 m*l* of 5% sodium hydroxide was stirred at room temperature for 12 hr. The mixture was acidified with 10% hydrochloric acid and extracted with chloroform (20 m$l\times$5). The combined chloroform extract was washed with water and dried (Na_2SO_4). Removal of the solvent *in vacuo* afforded 160 mg (85%) of VII as an oil. IR (neat) cm^{-1}: 3100—2729 and 1703 (COOH), 1648 and 840 (CH=C). NMR ($CDCl_3$)τ: -1.25 (1 H, s, COOH), and other signals were almost the same as those of VIII.

Found: C, 72.36; H, 9.90%. Calcd for $C_{11}H_{18}O_2$: C, 72.49; H, 9.96%.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 3585—3588 (1969)

The Syntheses and Properties of Molybdenum(VI)-Amino Acids Complexes

Hiroshi EGUCHI, Toshio TAKEUCHI, Akira OUCHI and Akiko FURUHASHI*1

Department of Chemistry, College of General Education, The University of Tokyo, Komaba, Meguro-ku, Tokyo

(Received April 19, 1969)

New compounds of the $Mo(VI)_2O_7H_3(Am)_n$-type (where HAm=glycine, DL-alamine, DL-Methionine, or L-Leucine) were obtained from an acidic aqueous solution (pH=1) containing sodium molybdate and amino acid. These compounds seem to be isostructural with each other, and all are diamagnetic. Their infrared spectra show characteristic ν(Mo=O) bands.

The ethylenediaminetetraacetato chelates of molybdenum(VI) and (V) have already been studied potentially,[1-3] while studies of the amino acid chelates of molybdenum have appeared only recently. Spence and Lee have studied the solution chemistry of the molybdenum-hystidine system.[4] The molybdenum-cystein complex was obtained in the solid state very recently,[5] and the X-ray structural analysis data[6] as well as its infrared spectral data[7] have also been reported. However the molybdenum chelates of other amino acids are not very stable in a neutral aqueous solution and the solid products have not yet been obtained. The authors found that some amino acids, such as glycine,

alanine, leucine and methionine, give a very stable product in acidic aqueous media; the solid complexes were thus obtained. They are insoluble in water or organic solvents and consist of two molybdenum atoms per amino acid molecule. From the properties of these complexes, they are expected to be of the polymer type.

Experimental

Instruments. The infrared spectra were obtained by the Nujol or hexachloro-1,3-butadiene mull method using a DS-301 infrared spectrophotometer of the Japan Spectroscopic Co., Ltd. The magnetic susceptibilities of the products were measured with a Gouy balance at room temperature (20°C).

Synthesis of the Complex. *Methoioninato Dimolybdenum (VI)*, $Mo(VI)_2O_7H_3(C_5H_{10}NO_2S)$. One and a half grams (10 mM) of DL-methionine were dissolved into a minimum quantity of 1 N hydrochloric acid. In a separate flask 4.80 g (20 mM) of sodium molybdate dihydrate were dissolved into 10 m*l* of water. The two solutions were mixed and the pH of the supernatant of the mixture was adjusted to about 1 by adding 6 N hydrochloric acid. The mixture was heated and boiled for several minutes, and the original precipitate was dissolved then gradually a fine powder appeared which tended to cling to the wall of the vessel. After the reaction had been completed, the product was filtered off and washed with 0.1 N hydrochloric acid, water, ethanol, and diethyl ether in that order.

The complex thus obtained was dried in a vacuum dessicator for about 24 hr at room temperature. It was pale yellow and was insoluble in water or usual organic solvents, but soluble in an alkaline aqueous solution (in which it decomposed). Although attempts at recrystallization have not yet been successful, this product seems to be a simple compound and not a mixture, because even when the mole ratio of the starting material was changed from 4 : 1 to 1 : 4, the product was found to be identical not only on the basis of the analytical data but also on the basis of the infrared spectra. Moreover, this is supported by the fact that the isostructural complexes were also obtained from other amino acids by the same method.

The glycine, DL-alanine, and L-leucine compounds were obtained by almost the same synthetic method, but they were all white, not yellowish, in color. Using other amino acids, such as glutamic acid, aspartic acid, valine, phenyl-alanine, and histidine, this type of complex has not yet been obtained.

Results and Discussion

The analytical data for these compounds are given in Table 1. These complexes are all diamagnetic at room temperature. The infrared spectral data for the complexes are summarized in Table 2, together with those of several related compounds.

The infrared spectra of amino acid and their metal complexes have already been reported in many papers.[7–10] The assignments of the bands shown n the table were deduced from t hese references and are only tentative. The ν(N–H) bands near 3200 cm^{-1} of the amino acid complexes of the usual first series of transition elements are rather sharp and in a higher frequency region than those of the free ligand. The bands of these molybdenum(VI) complexes are weak and broad, and the wave number of the peak is less than 3200 cm^{-1}. This is probably due to the fact that the molybdic acid part of the compound makes a strong hydrogen bond with the amino group of an amino acid. The antisymmetric and symmetric stretching bands of $-COO^-$ in the region of 1600—1400 cm^{-1} show a little shift from those of free ligands as usual metal complexes of amino acid, and then the oxygen of the carboxyl group of an amino acid seems to make the coordination bond with the central molybdenum atom in these complexes. The $\delta(-NH_2)$ or $\delta(-NH_3^+)$ peaks can also be recognized in these regions. It seems that the strong bands in the region of 1000—900 cm^{-1} and near 760 cm^{-1} can be identified as ν(Mo=O) and ν(Mo–O–Mo) bands respectively by comparing them with the infrared data of acid complexes of molybdenum reported by many authors;[7,11–16] the rocking band of the methyl group of bands caused by amino acid may also appear near here, but, if so, they should be far less intense. The strong peak near 950 cm^{-1} is likely a band of the terminal Mo=O bond which has almost pure double bond character; however, as there are

Mo_2(Met), for example, shows the methionine complex having the composition shown in Table 1.

some other bands of lower frequencies in this region too, Mo-O bonds with less of a double-bond character may also exist.[7,12,14,16] The band near 760 cm^{-1} seems to be due to the Mo–O–Mo bridge,[12,15] this Mo–O bond should have rather a single-bond character.

The results of the alkalimetry of the methionine complex are shown in Fig. 1.*2 After the mole ratio of NaOH : Mo_2A (where Mo_2A means the complex) exceeds 2 : 1, the suspended solid begins to dissolve into the solution; after the alkaline standard solution had been added, it takes a few minutes until a stabilized pH value is observed. At the point where the ratio is 4 : 1 all the solid is dissolved and a clear solution is obtained: the pH of the solution suddenly rises there.

As (1) the solid complexes are obtained from an acidic aqueous solution of about pH=1, (2) these complexes are insoluble in water, and (3) the mole ratio of molybdenum and the amino acids in the complexes is 2 : 1, these complexes are probably in the polymer form. However, the behavior of these complexes in alkalimetry is a little different from those of isopolymolybdate, as the reaction with alkali in an aqueous solution is faster and as a big pH change is observed at the point where NaOH : Mo_2A=4 : 1.

The complex seems to be less stable than usual isopolymolybdate. Moreover, in an alkaline solution the presence of polymolybdate ions or complex anions is not probable, as the metal molybdate precipitated immediately from the solution when barium or lead salt was added and as the attempt to isolate the sodium salt of the complex by adding organic solvents to the solution was not successful. On the basis of these results, Fig. 2

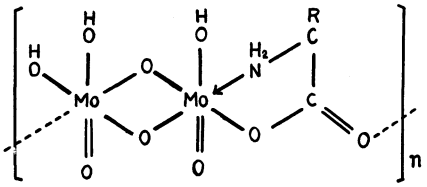

Fig. 2. Structure of molybdenum(VI)-amino acid complexes.

shows a tentative model of these complexes, though the exact structure must be determined by a subsequent X-ray structural analysis.

The authors wish to thank Professors Yasumasa Hayakawa and Yukichi Yoshino and the colleagues of our laboratories for their helpful discussions. A part of this research was carried out with a Scientific Research Grant from the Ministry of Education, to which the authors thanks are due.

*2 0.1 mM sample suspended in 100 m*l* of water was titrated by 0.1 N sodium hydroxide. Almost the same results were obtained by the other three complexes, too (at 20°C).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 3588—3590 (1969)

The Kinetics of the Ligand Substitution Reaction of Copper(II)-nitrilotriacetate and -nitrilo(diacetic)propionate Complexes with *trans*-1,2-Cyclohexanediaminetetraacetate Ions*[1]

Masaru KIMURA*[2]

Department of Applied Chemistry, Yamagata University, Yonezawa-shi

(Received April 28, 1969)

Previous studies[1,2] have shown that the rate of the reaction of some nickel(II) complexes with *trans*-1,2-cyclohexanediaminetetraacetate (CyDTA) ions was independent of the concentrations of CyDTA and proceeded by means of the complete dissociation of the nickel(II) ion from the nickel(II) complex. Although CyDTA did not affect the rate of the dissociation of the nickel ion from the complex, the hydrogen ion promoted the dissociation reactions.[1,2] The same behavior was shown in the reaction of copper(II) complexes with CyDTA ions. In the present study, the rate constants of the dissociation reaction of copper(II)-nitrilotriacetate (NTA) and -nitrilo(diacetic)propionate (NDAP) complexes were determined and compared with those of the other metal complexes. The acid dissociation constant of the ligand and/or the formation constant of the complex is used in most methods when the rate constant is determined.

*2 Correspondence to be addressed to: c/o Prof. I. M. Kolthoff, Department of Chemistry, University of Minnesota, Minneapolis, Minn. 55455, USA.

1) M. Kimura, This Bulletin, **42**, 2841 (1969).

2) M. Kimura, *ibid.*, **42**, 2844 (1969).

However, this method of determining the dissociation rate constant using CyDTA as an indicator of the rate is abvantageous in that the rate constant can be determined without using any other constants.

Experimental

A solution of copper(II) nitrate was prepared by dissolving a known amount of pure copper metal in reagent-grade nitric acid. A chelating agent, NDAP, was synthesized by the same procedures as have been reported by Uehara *et al.*[3] All the other chemicals and apparatus used were the same as those described in previous papers.[1,4] The temperature was maintained at 25°C, and the ionic strength was adjusted to 0.2 with potassium nitrate.

Derivation of the Rate Equation

The overall substitution reaction of the copper-NTA or copper-NDAP complex with CyDTA can be expressed as follows:

$$CuX^- + \left\{\begin{matrix}Cy^{4-}\\ \updownarrow\\ \vdots\\ \updownarrow\\ H_4Cy\end{matrix}\right\} \underset{k^-}{\overset{k^+}{\rightleftharpoons}} CuCy^{2-} + \left\{\begin{matrix}X^{3-}\\ \updownarrow\\ \vdots\\ \updownarrow\\ H_3X\end{matrix}\right\} \quad (1)$$

where X^{3-} denotes a tervalent NTA or NDAP anion, and Cy^{4-}, a quadrivalent CyDTA anion.

The rate of the forward reaction (1) was confirmed to be independent of the initial concentrations of CyDTA and also of NTA or NDAP. Therefore, the rate equation can be expressed as:

$$-\frac{d[CyDTA]}{dt} \equiv -\frac{d[CuX^-]}{dt} = k^+[CuX^-] - k^-[CuCy^{2-}] \quad (2)$$

The concentration that can be determined polarographically is [CyDTA] which is given by:

$$[CyDTA] = \sum_{j=0}^{4}[H_jCy^{(4-j)-}] \quad (3)$$

By integrating Eq. (2), we obtain:

$$\ln([CuX^-] - [CuX^-]_e) = -(k^+ + k^-)t + \ln([CuX^-]_i - [CuX^-]_e) \quad (4)$$

where the subscripts i and e represent the initial and the equilibrium states respectively. At the equilibrium of the reaction, the following relation may be satisfied:

$$k^+/k^- = [CuCy^{2-}]_e/[CuX^-]_e = (K_{CuCy}/K_{CuX}) \times ([Cy^{4-}]_i/[X^{3-}]_i) \fallingdotseq 10^8 \quad (5)$$

Therefore, the relations of $k^- \ll k^+$ and $[CuX^-]_e \ll [CuX^-]_i$ are satisfied, and k^- and $[CuX^-]_e$ can be neglected under the present experimental conditions. Consequently, Eq. (4) was simplified to:

$$\ln[CuX^-] = -k^+t + \ln[CuX^-]_i \quad (6)$$

Equation (6) shows that the plots of its left-hand side against t should give a straight line and that the value of k^+ can be obtained from the slope.

Results and Discussion

Figure 1 shows examples of a current-time curve and a plot of the left-hand side in Eq. (6) against the time, a plot which was obtained for the reaction of the copper-NTA complex with CyDTA. The

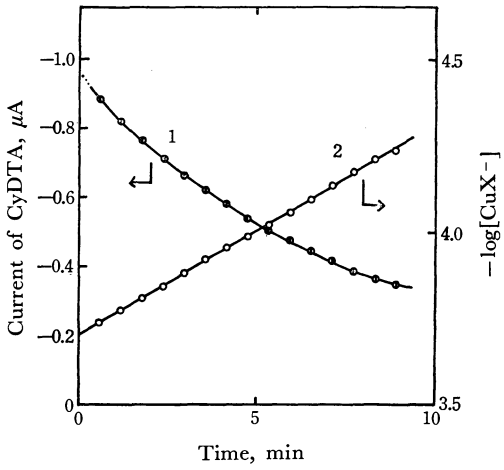

Fig. 1. A current-time curve (curve 1) and the left-hand side of Eq. (6) as a function of time (curve 2). The reaction is that of copper(II)-NTA complex with CyDTA. Measurement was made at +0.22V *vs.* SCE and was in acetate-buffer solution of pH 5.82 containing 0.04 M acetate ion at ionic strength 0.2 and at 25°C. Initial concentrations are: $[Cunta^-]_i = 2.01 \times 10^{-4}$ M, $[NTA]_i = 2.7 \times 10^{-5}$ M and $[CyDTA]_i = 2.25 \times 10^{-4}$ M.

plot gives a straight line, as may be expected from Eq. (6). The values of k^+ were not affected by the change in the initial concentrations of the copper-NTA complex, CyDTA, and NTA. The same behavior was also found in the reaction of the copper-NDAP complex with CyDTA. The plots of k^+ *versus* $[H^+]$ showed a straight line (see Fig. 2).

These results indicate that the overall reaction (1) proceeds through the following reaction paths:

$$CuX^- \underset{k_a^-}{\overset{k_{CuX}}{\rightleftharpoons}} Cu^{2+} + X^{3-} \quad (7)$$

$$CuX^- + H^+ \underset{k_b^-}{\overset{k^H_{CuX}}{\rightleftharpoons}} Cu^{2+} + HX^{2-} \quad (8)$$

$$Cu^{2+} + \left\{\begin{matrix}Cy^{4-}\\ \updownarrow\\ \vdots\\ \updownarrow\\ H_4Cy\end{matrix}\right\} \underset{}{\overset{k_j^+}{\rightleftharpoons}} CuCy^{2-} + jH^+ \quad (9)$$

3) A. Uehara, E. Kyuno and R. Tsuchiya, This Bulletin, **41**, 2385 (1968).

4) M. Kimura, *Nippon Kagaku Zasshi (J. Chem. Soc. Japan, Pure Chem. Sect.)*, **89**, 1209 (1968).

where the relation:

$$\sum_{j=0}^{4} k_j^{+}[H_jCy^{(4-j)-}] \gg k_a^{-}[X^{3-}] + k_b^{-}[HX^{2-}] \quad (10)$$

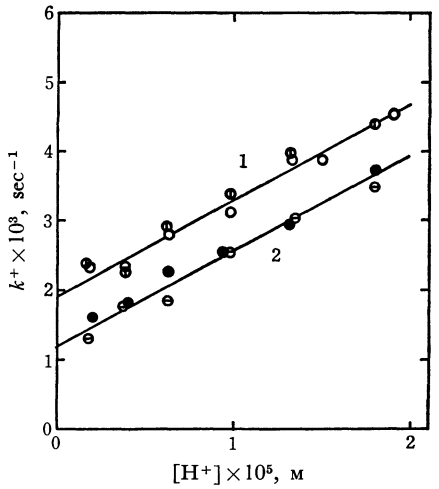

Fig. 2. k^+ as a function of the hydrogen ion concentration at ionic strength 0.2 and 25°C. Measurement was made in acetate-buffer solution containing 0.04 M acetate ion. The reactions are those of Cu(II)-NTA (curve 1) and Cu(II)-NDAP (curve 2) complexes with CyDTA.
Initial concentrations for curve 1:
$[Cu\mathit{nta}^-]_i = 2.01 \times 10^{-4}$ M, $[NTA]_i = 2.7 \times 10^{-5}$ M, $[CyDTA]_i = 3.37 \times 10^{-4}$ M (◐) and 2.25×10^{-4} M (○)
Initial concentrations for curve 2:
$[CyDTA]_i = 2.25 \times 10^{-4}$ M, $[Cu\mathit{ndap}^-]_i = 1.31 \times 10^{-4}$ M (⊖) and 2.62×10^{-4} M (●), $[NDAP]_i = 1.1 \times 10^{-5}$ M (⊖) and 2.2×10^{-5} M (●).

is satisfied under the present experimental conditions. (However, the condition of Eq. (10) can not be satisfied near the final stage of the reaction because the concentration of CyDTA gradually decreases according to the progress of the forward reaction, while that of NTA (or NDAP) increases according to the reaction process.) From the reaction mechanism, the rate of the forward reaction (1) is represented by Eq.(11):

$$(\text{Rate}) = k^{+}[CuX^{-}] = (k_{CuX} + k^{H}_{CuX}[H^{+}])[CuX^{-}] \quad (11)$$

The rate constants in Eq.(11) were determined from the plots of Fig. 2; they are given in Table 1.

Table 1. Rate constants of the dissociation reactions (7) and (8), at an ionic strength of 0.2 at 25°C

$k_{Cu(nta)}$	1.9×10^{-3} sec^{-1}
$k_{Cu(ndap)}$	1.2×10^{-3} sec^{-1}
$k^{H}_{Cu(nta)}$	1.4×10^{2} l mol^{-1} sec^{-1}
$k^{H}_{Cu(ndap)}$	1.4×10^{2} l mol^{-1} sec^{-1}

The value of $k_{Cu(nta)}$ was about twice that of $k_{Cu(ndap)}$. A similar tendency was also found in the nickel(II) complexes with NTA and NDAP, as have been reported previously.[1,2]

The author wishes to thank the Ministry of Education for the financial support granted for this research.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 3591 (1969)

Two Phenol Ethers and an Aliphatic Ketone of the Essential Oil of the Kusunoki (*Cinnamomum camphora*, Sieb.)

Shûichi HAYASHI, Katsumi YANO*1 and Tamon MATSUURA

Department of Chemistry, Faculty of Science, Hiroshima University, Hiroshima

(Received April 30, 1969)

In previous papers,[1,2] the constituents of the sesquiterpene fraction of commercial camphor blue oil were reported. A continuous investigation of the sesquiterpene alcohol fraction was attempted more precisely. Three compounds, 2-pentadecanone, 2,3-methylenedioxynaphthalene, and piperonyl acrolein, were newly obtained in small amounts.

Experimental

The sesquiterpene alcohol fraction (bp 120—160°C/4 mmHg, 456 g) of commercial camphor blue oil was fractionated and divided into 19 fractions.

2-Pentadecanone. Fraction 5 (bp 124—126°C/4 mmHg) was chromatographed on silica gel with chloroform. White crystals were isolated from the first eluate and recrystallized (mp 35—37°C, GC pure) from ethanol. This melting point corresponds to that of 2-pentadecanone.[3] The IR spectrum indicated that this compound was an aliphatic ketone having a CH_3-CO-CH_2-group ($\nu_{C=O}$ 1710, $\delta_{CH_2-C=O}$ 1405 and $\delta_{CH_3-C=O}$ 1355 cm^{-1}). The main peaks (*m/e* 43 (CH_3-CO)$^+$, 58 (base peak) (CH_3-CO-CH_2+H)$^+$, 59 (CH_3-CO-CH_2+2H)$^+$, 71 (CH_3-CO-CH_2-CH_2)$^+$, 85 (CH_3-CO-CH_2-CH_2-CH_2)$^+$ and 226 M$^+$) were observed in the mass spectrum. From the above evidence, this compound can be said to be 2-pentadecanone.

2,3-Methylenedioxynaphthalene. From the second eluate group, white crystals were obtained and sublimed; mp 96—97°C (TLC pure). The UV spectra of this compound and naphthalene were similar to each other; the first band had the absorption maximum at λ_{max}^{EtOH} 227 mμ (ε 35000); the second band had the fine structure at 266 mμ (ε 3500), 275 mμ (ε 3700) and 286 mμ (ε 3100), and the third band at 313 mμ (ε 1900) and 325 mμ (ε 2300) showed a bathochromic shift in comparison with that of naphthalene. These bands indicated that this compound had the skeleton of β-substituted naphthalene. Moreover, this UV spectrum was much the same as that of 2-methyl-6,7-methylenedioxynaphthalene.[4] The IR spectrum showed the existence of the condensed aromatic nucleus ($\nu_{C=C}$ 1610, $\nu_{C=C}$ 1490 and $\nu_{C=C}$ 1470), the 1,2,4,5-tetrasubstituted benzene ring (δ_{CH} 857 cm^{-1}), and the methylenedioxy group (ν_{CH_2} 2790, $\nu_{=C-O-C}$ 1264, $\nu_{=C-O-C}$ 1049 and ν_{-O-CH_2-O-} 947 cm^{-1}). Therefore, the methylenedioxy group combines with naphthalene at the 2,3-positions. The mass spectrum showed peaks of *m/e* 14, 28, 44, 114, and 172 (base peak) M$^+$; molecular formula $C_{11}H_8O_2$ was deduced from p+1 (12.01%) and p+2 (1.20%) against M$^+$ (100%).[5] From the above evidence, this compound was determined to be 2,3-methylenedioxynaphthalene.

Piperonyl Acrolein. Fraction 9 (bp 132—134°C/4 mmHg) was chromatographed on alumina III with benzene. Pale yellow crystals were isolated from the middle eluate and recrystallized (mp 84—85°C, TLC pure) from ethanol This melting point corresponds to that of piperonyl acrolein.[6] The IR spestrum showed the existence of the 1,2,4-trisubstituted benzene ring (δ_{CH} 818 and δ_{CH} 877 cm^{-1}), the methylenedioxy group (ν_{CH_2} 2785, $\nu_{=C-O-C}$ 1267, $\nu_{=C-O-C}$ 1040 and ν_{-O-CH_2-O-} 932 cm^{-1}) combined with the aromatic nucleus, and the -CH=CH-CHO group (ν_{CH} 2821, ν_{CH} 2707, $\nu_{C=O}$ 1665, $\nu_{C=C}$ 1618, $\nu_{C=C}$ 1595 and δ_{CH} 975 cm^{-1}). The NMR spectrum showed the signals of aromatic protons at 6—8 ppm (3H, m, AB_2 type), methylene protons of the methylenedioxy group at 6.02 ppm (2H, s), olefinic protons of the *trans* disubstituted double bond at 7.39 ppm (1H, d, J=16.0 cps) and 6.53 ppm (1H, d-d, J=16.0 and 8.0 cps), and the aldehyde proton at 9.66 ppm (1H, d, J=8.0 cps). The mass spectrum showed peaks of *m/e* 147 (M-CHO)$^+$, 175 (M-H)$^+$, and 176 (base peak) M$^+$. Judging the above evidence, this compound is a derivative of benzene which combines with the methylenedioxy group at the 1,2-positions and with the -CH=CH-CHO group at the 4-position. Thsu, this compound can be said to be piperonyl acrolein.

Synthesis of a Fragment (Pentapeptide) of *E. Coli* Acyl Carrier Protein Apoprotein

Yoshiro MIURA and Shuichi SETO

Chemical Research Institute of Non-Aqueous Solutions, Tohoku University, Katahira-cho, Sendai

(Received May 23, 1969)

Various peptides have been synthesized rapidly and in higher yield by the solid phase method.[1-3] We have synthesized by this method, a nonapeptide of melittin[4] and a heptapeptide[5]. Acyl carrier protein has recently been found to be essential for saturated fatty acid biosynthesis, amino acid sequence of which has been reported.[6,7]

Acyl carrier protein holoprotein (holo-ACP) synthetase which transfers 4′-phosphopantetheine from reduced CoA to apo acyl carrier protein (apo-ACP) to form holo-ACP and 3′,5′-adenosine diphosphate has been shown in *E. Coli B*.[8] It seemed interesting to study the smallest fragment of apo-ACP to be utilized as a substrate of this enzyme, and we tried to synthesize a pentapeptide having a serine residue to which 4′-phosphopantetheine is bound. We wish to report the synthesis of a fragment of apo-ACP, H-Gly-L-Ala-L-Asp-L-Ser-L-Leu-OH, by the solid phase method. Synthesis of a pentapeptide was carried out according to the procedure described by Marshall and Merrifield[3] for the solid phase method, using an automatic instrument which we constructed[5].

The peptide was synthesized stepwise, beginning with 1.7 mmol of *t*-butyloxycarbonyl (*t*-Boc)-L-leucine esterified to 10 g of the cross-linked polystyrene resin (copolymerized with 2% divinylbenzene). *t*-Boc-amino acids with protected side chains were *O*-benzyl-L-serine and *β*-benzyl-L-aspartic acid.

Coupling was mediated by *N*, *N*′-dicyclocarbodiimide (DCC). *t*-Boc groups were removed with 1 N hydrogen chloride in glacial acetic acid. Neutralization of the hydrochloride was carried out with triethylamine in dimethylformamide (DMF).

The total time required for the sysnthesis was 28 hr. The peptide was cleaved from the resin with hydrogen bromide in trifluoroacetic acid. The reagent also cleaved the ether bond in the *O*-benzyl-L-serine residue and the ester bond in the *β*-benzyl-L-aspartic acid residue. Paper chromatography of the crude peptide showed one major ninhydrin positive spot and a few minor spots. The pure pentapeptide was obtained through purification of the crude peptide by gel filtration on a column of Sephadex G-10 using 0.1 M acetic acid as the solvent and gave the correct amino acid ratios on acid hydrolysis. The over-all yield from the first leucine residue was 19.6%. Its homogeneity was shown by paper chromatography using two different solvent systems and by electrophoresis.

Experimental

Solvents used for ascending paper chromatography on Toyo Roshi No. 50 paper were a) *n*-butanol - acetic acid - water(BAW) (4 : 1 : 1) and b) *n*-butanol - acetic acid - pyridine - water (BAPW) (15 : 3 : 10 : 12). Paper electrophoresis was carried out using a pH 7.76 buffer (KH_2PO_4-Na_2HPO_4), on Toyo Roshi No. 50 paper at 500V/38 cm for 2 hr.

***t*-Boc-L-leucyl Resin.** A solution of 3.06 g (13.25 mmol) of *t*-Boc-L-leucine and 1.34 g (13.25 mmol) of triethylamine in 14 m*l* of absolute ethanol and 7 m*l* of chloroform was added to 10.0 g of chloromethylcopolystyrene-2% divinylbenzene which contained 6.61% chlorine. The reaction mixture was stirred at reflux temperature for 48 hr. The esterified resin was filtered off and washed with absolute ethanol (three times), water (three times), and methanol (three times). The esterified resin was then dried *in vacuo* over KOH pellets; yield, 11.5 g. Amino acid analysis of an acid hydrolysate (dioxane-12 N HCl, 1 : 1) showed the product to contain 0.602 mmol of leucine/g of esterified resin.

***t*-Boc-glycyl-L-alanyl-*β*-benzyl-L-aspartyl-*O*-benzyl-L-seryl-L-leucyl-Resin.** The *t*-Boc-L-leucyl (2.82 g) was placed in the reaction vessel. The following cycle of de-protection, neutralization, and coupling was carried out for the introduction of each residue: (1) three washings with 26 m*l* portions of glacial acetic acid; (2) cleavage of the *t*-Boc group by treatment with 1 N HCl in glacial acetic acid (30 m*l*) for 30 min at room temperature; (3) three washings with 26 m*l* portions of glacial acetic acid; (4) three washings with 33 m*l* portions of absolute ethanol; (5) three washings with 24 m*l*

portions of DMF; (6) neutralization of the hydrochloride salt with 2.6 m*l* of triethylamine in 26 m*l* of DMF; (7) three washings with 24 m*l* portions of DMF; (8) three washings with 28 m*l* portions of methylene chloride; (9) addition of 6.80 mmol of the appropriate *t*-Boc-amino acid dissolved in 20 m*l* of methylene chloride and mixing for 10 min; (10) addition of 6.80 mmol of DCC in 16 m*l* of methylene chloride, followed by a reaction period of 3.0 hr at room temperature. For the *t*-Boc-*O*-benzyl-L-serine cycle the reaction time was 3.5 hr; (11) three washings with 28 m*l* portions of methylene chloride; (12) three washings with 33 m*l* portions of absolute ethanol.

After step 12 following the incorporation of the *t*-Boc-glycine, the protected peptide resin compound was further washed with methylene chloride, absolute ethanol and dried *in vacuo* over KOH pellets overnight; yield, 3.7 g.

Crude Glycyl-L-alanyl-L-aspartyl-L-seryl-L-leucine. The protected peptide resin (2.90 g) was suspended in 20 m*l* of trifluoroacetic acid, and a stream of hydrogen bromide was bubbled through the suspension with occasional shaking for 90 min. The resin was removed by filtration and washed with 4 m*l* of trifluoroacetic acid. The combined filtrates were evaporated on a rotary evaporator *in vacuo* at 25°C and the syrupy product obtained was triturated with dry ether. Ether was removed by decantation and the residue was washed with ether. The amorphous powder was collected; yield, 810 mg.

Paper chromatography in BAW showed a major spot at R_f 0.21 when sprayed with ninhydrin reagent and traces of materials at R_f 0.11, R_f 0.42, and R_f 0.62, and also in BAPW, a major spot at R_f 0.45 and traces of materials at R_f 0.52 and R_f 0.79.

Paper electrophoresis showed two spots when sprayed with ninhydrin reagent.

Purification of Crude Pentapeptide. A portion (18 mg) of the crude peptide was placed on a 1.2×68 cm column of Sephadex G-10 equilibrated with 0.1 M acetic acid. The column was then developed with the same solvent. Aliquots (0.1 m*l*) from 2 m*l* fractions were alanyzed by ninhydrin reagent. Fractions 6-19 contained only the major compound and were pooled and lyophilized; yield, 2.7 mg. This presents an overall yield 19.6% based on the amount of leucine initially esterified to the resin.

By paper chromatography we obtained R_f 0.20 (BAW), R_f 0.45 (BAPW). Paper electrophoresis of the pentapeptide showed a single ninhydrin positive spot. Amino acid ratios found were: Asp, 0.95; Ser, 0.98; Gly, 1.02; Ala, 1.00; Leu, 1.03. $[\alpha]_D^{23}$ −59.3 (*c* 0.73, H_2O).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 3593—3596 (1969)

Effect of Particle Size on Infrared Spectra of Inorganic Powders*1,*2

Kimitaka SATO, Fumio KUROSAWA and Ōhiko KAMMORI

Tokyo Research Institute, Yawata Iron and Steel Co., Ltd., Ida, Kawasaki

(Received May 28, 1969)

In our studies of the analysis of the inclusions in iron and steel by infrared absorption spectroscopy,[1-7] it was found that the effect of the particle size of inorganic powders is remarkable in its quantitative measurement. The effect is, of course, also connected with the physical properties of iron and steel as well as with the quantitative investigation of these substances. One effect of the particle size in the infrared spectra of inorganic powders had already been studied by the Liege investigators,[8-10] who proposed a theoretical formula. At that time, it was, however, difficult to separate inorganic powders into different particle sizes according to the order of micron. Lejeune and co-worker[8] identified each particle size of powders by means of a microscope. Since then, the problem on the particle size has not been discussed, because no

technique for separating powders has been developed.

A new method of separating particles with ultrasonic waves was recently developed in our laboratory,[11] and it was applied to the study of the effect of the particle size on the infrared spectra of inorganic powders. The present paper will describe the variation in the absorption bands in the infrared spectra of several inorganic powders separated by means of the new screening method mentioned above.

Experimental

Materials. Three inorganic powders, α-SiO_2, $CaCO_3$, and α,β-Si_3N_4, were used as samples, since they have more absorption bands than the other metal oxides, carbides, nitrides and sulfides reported on in our previous papers.[1,6]

Separation of Powders with Particles of Different Sizes. The three inorganic powders were separated into each particle size according to the order of micron by means of a new apparatus with ultrasonic waves developed in our laboratory.[11] The outline of the technique is as follows. The inorganic powders used are uniformly suspended in methanol with ultrasonic waves and are then filtered with metal sieves. In this experiment, the powdered samples were separated into four particle sizes by using sieves of 2, 10, and 20 μ. A micrograph of the 5 μ sieve is shown in Photo. 1.

Measurement. The spectra were obtained using a Perkin Elmer model 521 grating spectrometer with the KBr disk technique over the 400—1400 cm^{-1} region. The KBr powders were prepared by pulverizing single crystals into particle sizes smaller than 300 mesh, and the amount of KBr in the disk for one sample (about 0.5 mg) was unified to 300 mg in a disk preparation. The disk prepared was about 1 mm thick and 13 mm in diameter.The thickness of the disk was not measured exactly in this experiment. We spent 15—20 min mixing inorganic powder with KBr powder in an agate mortar, according to the method described in our previous papers.[5,7]

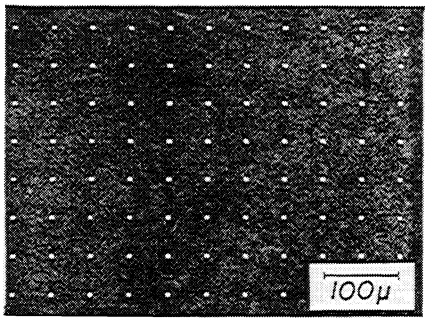

Photo. 1. An exampe of 5 μ sieve used in this experiment.

Results and Discussion

The micrograph of $CaCO_3$ separated into four ranges of particle sizes by the screening method with ultrasonic waves is shown in Photo. 2 as an example. It seems to be nicely separated by particle size. The infrared spectra of $CaCO_3$ for each particle size are shown in Fig. 1, which shows that each absorption band becomes sharper and its spectral intensity stronger as the particle size becomes smaller. Figure 2 shows the variation in the infrared spectrum for each particle size of α-SiO_2. The absorption band at about 800 cm^{-1} hardly splits at all in the larger particle size, while it separates remarkably into two bands in the sizes smaller than 2 μ. For the 460 cm^{-1} band with a shoulder at 512 cm^{-1} in the sample of a particle size larger than 2 μ, the 512 cm^{-1} band is separated remarkably

in the particles smaller than 2 μ. We observed a similar phenomenon for the 371 and 397 cm^{-1} bands. Si_3N_4 cannot be separated into α- and β-forms, so it was used as a mixture. The variation in the infrared spectra in each particle size of α,β-Si_3N_4 is shown in Fig. 3. In the case of larger particle sizes, each absorption band is hardly split at all, while the separation of each band is fine in the sizes less than 2 μ.

In the infrared spectra of inorganic powders, each absorbance at characteristic absorption bands varies according to its particle size, as has been mentioned above. In general, the smaller the particle size, the larger its absorbance. In some particles of the smaller size, it seems that the tendency of absorbance becomes definite; this finding agrees with Duyckaerts'.[9] In the separation of each particle size of a mixture, there is still a difference in the particle size of each component. Therefore, when a mixture involves substances in different particle-size meshes, the spectrum for each mesh may show something unusual. The corresponding examples are the 1090 cm^{-1} band in the spectrum of 2μ up-separated $CaCO_3$ and the 1030 cm^{-1} band in α-SiO_2 with sizes between 2 and 10μ. Accordingly, we must pay attention to the point of the spectral abnormality. At the same time, it is indispensable that a sample be very pure in a study of the variation in the infrared spectrum for inorganic powders of different particle sizes.

On the other hand, it is very useful to separate powders into each size of particle when the iron ores, the corrosion product of steel, and the non-metallic inclusion in steel are used as the samples for separation. In the present technique, only the sieves with meshes larger than 2μ can be manufacutured; it is difficult to make a mesh less than this size.

In any case the study of infrared spectra by the separation of powders into each particle size is important not only for a quantitative analysis but also for a study of the properties of an inorganic substance.

The authors are grateful to Dr. San-ichiro Mizushima, the Director of the Institute, for his interest in this work.

Photoisomerization of 1,2-Diphenyl-6-methyl-2,3-dihydro-4-pyridone

Choji KASHIMA, Makoto YAMAMOTO, Yoshiaki SATO and Noboru SUGIYAMA

Department of Chemistry, Tokyo Kyoiku University, Otsuka, Bunkyo-ku, Tokyo

(Received May 30, 1969)

There have been many papers about the photochemical isomerization and dimerization of 2-cyclohexenones.[1] Yates reported that 2,6-dimethyl-2,3-dihydro-4-pyrone was dimerized by light.[2] Recently we have found a method of synthesizing 2,3-dihydro-4-pyridones from β-diketones and Schiff bases.[3] As an analogy with cyclohexenone and 2,3-dihydropyrone, the photochemistry of 2,3-dihydro-4-pyridone is of interest.

A solution of 1,2-diphenyl-6-methyl-2,3-dihydro-4-pyridone (I) in benzene or methanol was irradiated with a high-pressure mercury lamp through a Pyrex filter. No apparent change was observed after irradiation for a week. However, by the irradiation of a methanol solution of I with a low-pressure mercury lamp through a Vycor filter, three products (II, III, and IV) were obtained. Figure 1 shows the change in I and in the production of II, III, and IV with the time.

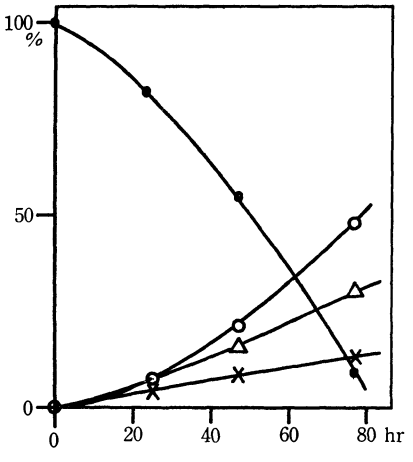

Fig. 1. The change of I and the production of II, III and IV with time.

lation of the 2,3-dihydro-4-pyridone structures in II and III. In the NMR spectra of II and III, the signals of the ABX pattern at τ 7.1 and 5.1, which are assignable to the 2-methine proton and the 3-methylene protons, were observed. Though the olefinic proton signal at τ 4.81 was not found, new singlet signals were observed at τ 5.13 and 5.18 which were changed by deuterium exchange. These results suggest that II is 2,5-diphenyl-6-methyl-2,3-dihydro-4-(1H)-pyridone and that III is 2,6-diphenyl-5-methyl-2,3-dihydro-4-pyridone.

However, IV did not show the characteristic absorption bands of 1,3-dihydro-4-(1H)-pyridone in the IR and UV spectra. In the NMR spectrum of IV, the singlet of one olefinic proton and a pair of doublets of two olefinic protons were observed at τ 4.80, 3.50, and 2.58. The singlet at τ −3.17, which disappeared upon the deuterium exchange, was assigned to the NH proton signal. These facts and the elemental analyses indicated that the structure of IV was 5-anilino-1-phenyl-1,4-hexadien-3-one. This was further confirmed by the fact that IV was identical with the condensation product of 2-anilino-2-penten-4-one and benzaldehyde after it had been treated with sulfuric acid.

Experimental

Materials. 1,2-Diphenyl-6-methyl-2,3-dihydro-4-pyridone (I) was synthesized from acetylacetone and benzylideneaniline in liquid ammonia;[3] mp 85°C. The spectral data are shown in Table 1.

Irradiation. Through the Vycor filter, a solution of 500 mg of I in 5 m*l* of methanol was irradiated by a high-pressure mercury lamp (450 W), and the reaction products were detected. However the photoproduct was not detected from a methanol or benzene solution of I through a Pyrex filter in a week. By the irradiation of a solution of 200 mg of I in 10 m*l* of methanol with a low-pressure mercury lamp (80 W) through a Vycor filter, I was isomerized to II, III, and IV. The change was monitored with the NMR spectrometer shown in Fig. 1.

Products II, III, and IV. After the irradiation of a solution of 300 mg of I in 10 m*l* of methanol for 100 hr, the colorless crystals which formed were filtered out and washed with cold methanol; mp 257°C.

Found: C, 82.00; H, 6.49; N, 5.27%. Calcd for $C_{18}H_{17}NO$: C, 82.10; H, 6.51; N, 5.32%.

The filtrate was concentrated under reduced pressure, and the residue was passed through a silica-gel (Merck 7734) column with a benzene - ethyl acetate (2 : 1 v/v) mixture. A yellow fraction and a pale yellow fraction were collected separately. The former fraction contained IV, and the latter contained III, showing R_f 0.85 and 0.44 on silica-gel (Wako-gel B-5) thin-layer chromatography with a benzene - ethyl acetate (2 : 1 v/v) mixture. The spectral data of II, III, and IV are summarized in Table 1.

5-Anilino-1-phenyl-1,4-hexadiene-3-one (IV). To 200 m*l* of liquid ammonia containing 2.1 g of potassium amide there were added 3 g of 2-anilino-2-penten-4-one at −33°C. After the mixture had been stirred one hour, 2 m*l* of benzaldehyde was added and stirring was continued for 2 hr. After the removal of the solvent at room temperature, the residue was acidified with concentrated hydrochloric acid. The product was extracted with chloroform, and the organic layer was washed with aqueous ammonia and then with water. The solvent was evaporated, and the residue was dissolved in 20 m*l* of concentrated sulfuric acid at room temperature. After 20 min, the solution was poured onto crashed ice and extracted with chloroform. The organic layer was washed with an aqueous sodium bicarbonate and with water, and then dried over calcium chloride. After the removal of the solvent, the residue was passed through a silica-gel (Merck 7734) column. The yellow fraction was collected, and the slovent evaporated. The residue was recrystallized from *n*-hexane, mp 101°C, which was identified with the above its R_f value of 0.44.

Found: C, 81.89; H, 6.72; N, 5.41%. Calcd for $C_{18}H_{17}NO$: C, 82.10; H, 6.51; N, 5.32%.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 3598—3600 (1969)

On the Stability of Silver(I) Complexes with an Imidazole and Its Derivatives

Shigeo NAKATSUJI, Riichiro NAKAJIMA and Tadashi HARA

Department of Chemical Engineering, Faculty of Engineering, Doshisha University, Kamikyo-ku, Kyoto

(Received June 2, 1969)

No report seems to have been given on the formation constant of the complexes between silver(I) ion and imidazole derivatieves except for poly-*N*-vinylimidazole[1] and *N*-methylimidazole.[2] The present paper deals with the stability of silver(I) complexes with imidazole derivatives, in which the consecutive formation constants of the silver complexes were estimated and the influences of the substituent upon the stability of the silver complexes were discussed. The molecular diagram of the imidazole derivatives was calculated and the nitrogen atom as a donor was determined. The infrared spectra of the silver complexes are also recorded and discussed.

The consecutive formation constants were estimated by applying the pH measurement and Bjerrum's methods.[3] An imidazole and its derivatives were of guaranteed-grade. The solution containing imidazole or imidazole derivatives, nitric acid and potassium nitrate (the ionic strength : 1) was titrated with a standard sodium hydroxide solution at 25°C.[4,5] The readings in the pH meter were corrected by the activity coefficients, and the dissociation constants of an imidazole and its derivatives were estimated, followed by calculation of the consecutive formation constants. From the formation curves for the imidazole derivatives, all the values of $\bar{n}$ were found to be less than 2. This is compatible with the following equilibrium.

$$\left.\begin{aligned} Ag^+ + Im &\overset{k_1}{\rightleftharpoons} AgIm^+ \\ AgIm^+ + Im &\overset{k_2}{\rightleftharpoons} AgIm_2^+ \end{aligned}\right) \quad (1)$$

Hence, the consecutive formation constants are given by

$$k_1 = \frac{[AgIm^+]}{[Ag^+]\cdot[Im]}, \quad k_2 = \frac{[AgIm_2^+]}{[AgIm^+]\cdot[Im]}, \quad (2)$$

where Im means imidazole or imidazole derivatives. According to Bjerrum's assumption, the values of p[Im] at $\bar{n}=1/2$ and 3/2 on the formation curve correspond to those of $\log k_1$ and $\log k_2$. The values of $[Ag^+]$, $[AgIm^+]$ and $[AgIm_2^+]$ were calculated using the values of k_1 and k_2. However, Bjerrum's assumption[3] was not valid. Approximate calculation was repeated until the values of k_1 and k_2 converged. The final results are shown in Table 1 with those of pyridine derivatives. The

13	β-Picoline	5.68	2.35	4.35	2
14	γ-Picoline	6.26	2.24	2.46	7
15	2,4-Lutidine	6.99	2.47	2.41	7

relations between pK_a and $\log k_1$ or $\log k_2$ are shown in Figs. 1 and 2. These results show that the affinity of an imidazole and its derivatives to silver ion increases with an increasing affinity to hydrogen ion. The same tendency is also found in cadmium complexes,[8] but not in copper complexes.[9] It is characteristic that $\log k_1$ is smaller than $\log k_2$ in the silver complexes, while the opposite is the case in the complexes of copper, cadmium and zinc. As the formation constants of the silver complexes with 2,4-dimethyl and 2-ethyl-4-methylimidazoles are larger than those with 2-methyl and 2-ethylimidazoles, the methyl group at the 4-position makes the silver complexes very stable. This seems to come from a larger increase of electron density at the 3-position than at the 1-position since the 3-position is structurally nearer the 4-position than the 1-position. On the other hand, the vinyl group at the 1-position makes the complexes unstable. There has been conflict concerning the nitrogen atom as a donor, Edsall[10] and Gold[1] proposing the coordination of the pyrrole-type nitrogen atom, while Bauman[2] and Li[5] that of the pyridine-type one. The molecular diagram of the imidazole derivatives was calculated by the simple LCAO method[11] (Table 2). The difference between our

TABLE 2. MOLECULAR DIAGRAM OF IMIDAZOLE DERIVATIVE

Ligand	1-Position	3-Position
Imidazole	0.549	−0.277
Imidazole[12]	0.41	−0.35
2-Ethylimidazole	0.421	−0.336
2,4-Dimethylimidazole	0.475	−0.392
4-Methylimidazole	0.479	−0.414
N-Methylimidazole	0.963	−0.506

values and those obtained by Orgel[12] seems to be responsible for the different selection of parameters. The fact that the nitrogen atoms at the 1- and 3-positions are assigned with the positive and negative charges supports the dissociation[13-15] of hydrogen atom on the pyrrole-type nitrogen atom and the coordination with the pyridine-type nitrogen. It is understandable that the value of formation constants increases with an increasing negative charge at the 3-position. The absorption bands at 1667 ($\nu_{C=NH}$), 1440, and 1095 cm^{-1} in the infrared spectrum of the silver imidazole complexes

The Fries Rearrangement of 2-Ethyl-5-acetyloxybenzofuran

Teruo NAKANISHI, Kazuhiko KIMURA, Kiyoshi ITŌ, Masahiko IKEMOTO and Yoshitaka ŌISHI

Research Laboratory, Kakenyaku-Kako Co., Ltd., Ōtsu

(Received June 2, 1969)

The reaction of acyl ester of phenol with aluminum chloride is known with respect to the conversion of ester into isomeric *o*- or *p*-hydroxy ketone. It is an important route in synthesis of ketones from phenols.[1] Fries discovered this rearrangement during his study on coumaranones.[2] Thereafter this type of rearrangement has been examined on coumarin derivatives. Little has been done, however, on the study of coumarones, *i.e.*, benzofuran derivatives[3] in which only one compound was separated as a rearrangement product. In the present paper we report the Fries reaction of 2-ethyl-5-acetyloxybenzofuran which resulted in the isolation of three new isomeric products.

2-Ethyl-5-acetyloxybenzofuran (I) in nitrobenzene was stirred in the presence of aluminum chloride at room temperature for 16 hr, the reaction mixture was decomposed with water, and submitted to steam distillation. After a run of nitrobenzene, a yellow oil was distilled to give a precipitate on standing. Recrystallization from petroleum ether gave yellow needles (II), mp 120—122°C. The mother liquor gave yellow plates (III), mp 75—76°C. The residue on steam distillation was recrystallized from ethanol to yield colorless prisms (IV), mp 177—178°C.

Elementary analysis revealed that the three compounds were the rearranged isomeric products of I. The IR measurement of the reaction products showed no absorption of ester. However, the absorption due to the presence of a ketonic group was distinctly observed. Absence of absorption due to hydroxyl group in II and III was explained by the influence of intramolecular hydrogen bonding to the ketonic group formed in the rearrangement reaction, whereas the absorption of hydroxyl group was observed with IV.

Signals of protons in benzofuran ring in the NMR spectra were assigned in the usual manner. The proton at position 3 in II was assigned δ 6.57 in a singlet, which appears to be a fine splitting peak due to a long range coupling of the protons at positions 3 and 7 in benzofuran ring.[4] The doublet peaks at δ 6.80 and δ 7.51 are of one proton respectively. A signal with fine splitting peak at lower magnetic field (δ 7.51) was assigned to proton at position 7. The relatively greater coupling constant ($J_{6,7}=9.0$ cps) indicates that the coupling is *o*-coupling,[5] and the doublet at higher magnetic field was assigned to proton at position 6.

The hydroxyl proton of position 5 was assigned to a singlet at δ 12.92, which supported the presence of intramolecular hydrogen bonding to adjacent carbonyl group.[6] Based on these evidences, the acetyl group in I is considered to be rearranged to position 4, and II is formed as the rearrangement product.

A singlet (δ 6.32) was assigned to the proton of position 3 in benzofuran ring of III and the remaining two peaks (δ 6.97 and δ 7.71) were assigned to two protons in the benzene ring, which showed scarcely any coupling with each other. Thus they

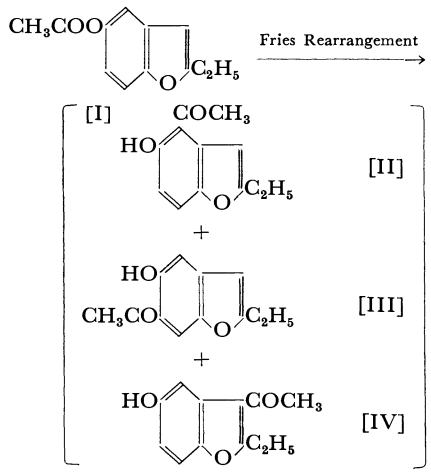
must be situated at *p*-position,[5] *i.e.*, positions 4 and 7. As the protons at positions 3 and 7 in the benzofuran ring show a long range coupling, a signal with a fine splitting peak at δ 7.71 was assigned to position 7. The assignment of the hydroxyl proton at position 5 of III (δ 12.12) was the same as in the case of II. From these results, it is concluded that the acetyl group in I is rearranged to position 6, resulting in the formation of III.

Since IV is slightly soluble in chloroform, the corresponding acetate was derived to use in NMR measurement. No absorption at about δ 6.4 proved the absence of proton at position 3. One-proton peaks belonging to the benzene ring were recognized at δ 7.67, 7.01 and 7.43, respectively. A quartet at δ 7.01 was assigned to the proton at position 6 which arose through unequal coupling with protons at positions 4 and 7. The proton at position 7 was assigned to the doublet at δ 7.43 which has a greater *o*-coupling constant with proton at position 6 (*o*-coupling: $J_{6,7}=9.0$ cps). The remaining signal which appeared at δ 7.67 was assignable to the proton at position 4 (*m*-coupling: $J_{4,6}=2.1$ cps). Thus it is concluded that the acetyl group of I is rearranged to position 3 to produce IV.

Based on these results, a scheme of the rearrangement is presented as follows:



One interesting point in the Fries reaction is that the variation in the ratio of both ortho- and para-isomers depends on experimental conditions. In order to investigate the variation, we performed gas chromatography on benzofuran derivatives.[7] Raw products obtained on decomposition with water for 5 hr and 16 hr were submitted to gas chromatography. Intensity of the peaks on gas chromatogram indicated the preparation ratio of II : III : IV to be approximately 1 : 1 : 1.5 at 5 hr and 1 : 1 : 1 at 16 hr. A peak appearing immediately after the peak of IV was recognized to be due to 2-ethyl-3-acetyl-5-acetyloxybenzofuran (V). The compounds are not known. Hence we synthesized them through another route, and used them for standard sample on gas chromatography. Formation of V during the reaction suggested that the present rearrangement was intermolecular.

It has been reported[8] that under high reaction temperature in the usual Fries reaction the production rate of an *o*-derivative is predominant. Accordingly we conducted the rearrangement reaction at 110°C for 1 hr, but the ratio of II : III : IV in reaction products as estimated by gas chromatography was 1 : 1 : 1 or the same as that in the previous reaction.

Experimental

Apparatus and gas chromatographic conditions. A Shimadzu Model GC-1C gas chromatograph fitted with hydrogen flame ionization detector was employed. The U-shaped stainless steel column 1.1 m×3 mm i.d. containing 20% Apiezon GL by weight on 40/60 Neosorb NC. Conditions for chromatography: Column temperature, 190°C. Nitrogen (carrier), 20 ml/min.

2-Ethyl-5-acetyloxybenzofuran (I). To 2-ethyl-5-hydroxybenzofuran[9] (16.2 g) in pyridine (40 ml) was added dropwise acetic anhydride (20.4 g) with ice-cooling and stirring. After being stirred at room temperature for about 3 hr, the reaction mixture was poured with vigorous stirring into HCl-containing ice-water. The white precipitate thus formed was filtered and recrystallized from petroleum ether to give colorless needles (17 g), mp 54—55°C: IR (KBr) showed C=O aryl-acetate at 1758 cm^{-1}.

Found: C, 70.49; H, 6.10%. Calcd for $C_{12}H_{12}O_3$: C, 70.58; H, 5.92%.

2-Ethyl-4-acetyl-5-hydroxybenzofuran (II). To 2-ethyl-5-acetyloxybenzofuran (5 g) in nitrobenzen (50 ml) was added by portions anhydrous $AlCl_3$ (10 g) with ice-cooling and stirring. After being stirred at room temperature (20—25°C) for about 16 hr, the mixture was poured into ice-water to decompose. Steam distillation gave, after a run of nitrobenzene, a yellow precipitate, which was filtered and recrystallized from petroleum ether to yield yellow needles (0.8 g), mp 120—122°C. IR (KBr) showed no hydroxyl band, but intramolecular chelated aryl-ketone band at 1620 cm^{-1}.

Found: C, 70.61; H, 5.91%. Calcd for $C_{12}H_{12}O_3$: C, 70.58; H, 5.92%.

2-Ethyl-5-hydroxy-6-acetylbenzofuran (III). Removal of most of the mother liquor (petroleum ether) caused precipitation of yellow plates (III) (0.2 g), mp 75—76°C (from ethanol). IR (KBr) showed no hydroxyl absorption, but intramolecular chelated aryl-ketone band at 1630 cm^{-1}.

Found: C, 70.63; H, 5.75%. Calcd for $C_{12}H_{12}O_3$: C, 70.58; H, 5.92%.

2-Ethyl-3-acetyl-5-hydroxybenzofuran (IV). The residue on steam distillation was collected to recrystallize from ethanol to give colorless prisms (IV) (1.3 g),

177—178°C. IR (KBr) showed hydroxyl band at 3200 cm^{-1}, and intermolecular hydrogen bonded aryl-ketone band at 1625 cm^{-1}.

Found: C, 70.65; H, 6.07%. Calcd for $C_{12}H_{12}O_3$: C, 70.58; H, 5.92%.

2-Ethyl-3-acetyl-5-acetyloxybenzofuran (V). 2-Ethyl-5-hydroxybenzofuran (2.4 g) in CS_2 (40 m*l*) was cooled at 0—5°C, and to this was added acetyl chloride (2.4 g), and then dropwise $SnCl_4$ (8.1 g) with stirring. After being stirred at 5—10°C for about 5 hr, the reaction mixture was poured into HCl-containing ice-water and stirred vigorously. The CS_2 layer was dried, evaporated, and the residue was recrystallized from petroleum ether to give colorless needles (2.7 g), mp 88—89°C: arly-ketone at 1645 cm^{-1}, aryl-acetate at 1740 cm^{-1}.

Found: C, 68.45; H, 5.94%. Calcd for $C_{14}H_{14}O_4$: C, 68.28; H, 5.73%.

The authors wish to express their sincere thanks to Professor K. Onodera, Kyoto University, for his kind suggestion and encouragement.

Polymerization of Methyl Methacrylate by Amide-Carbon Tetrachloride System

Kyoji KAERIYAMA

Research Institute for Polymers and Textiles, Sawatari, Kanagawa-ku, Yokohama

(Received June 4, 1969)

Some systems consisting of amide and halide, dimethylaniline - benzyl chloride[1] and pyridine-carbon tetrachloride in liquid sulfur dioxide,[2] for example, are known to initiate the polymerization of vinyl monomers. It has been found that the amide-carbon tetrachloride system induces the polymerization of vinyl monomers.

The results of the polymerization of methyl methacrylate (MMA) in the presence of various components are shown in Table 1. It can be seen from Table 1 that the acetamide-carbon tetrachloride system initiates the polymerization of MMA. Other chlorides, such as *n*-butyl chloride and chloroform, can not take the place of carbon tetrachloride. Pyridine has little effect on polymerization. DPPH and benzoquinone inhibit the polymerization. This suggests that the polymerization proceeds according to a radical mechanism.

Polymerization was carried out in the presence of various amides. It can be seen from Table 2 that formamide, acetamide, and urea are active as initiators, but that dimethylated amide, dimethyl acetamide, dimethylformamide are inactive.

Table 3 summarizes the data on the polymerisation of several vinyl monomers. The initiator system is selective for monomers. It can initiate the polymerization of acryl ester and amide, but it can not polymerize styrene. This characteristic is

* 1.4 g acrylamide
Solvent: 2.5 ml DMSO+2.5 ml pyridine

similar to that of the dimethylaniline - benzyl chloride system.[1]

Figure 1 shows the conversion of the monomer as a function of the mole fraction of amide to carbon tetrachloride. In the case of acetamide, the maximum conversion is observed at the mole fraction of 0.667. In the case of malonamide, it is at the equimolar fraction. This implies that two amide groups and one carbon tetrachloride molecule participate in the initiation of the polymerization of MMA.

Grafting onto polyacryl amide, which had been polymerized by potassium persulfate as an initiator, was attempted. The polymerizing mixture, which consisted of 1.90 g of polyacryl amide, 14.0 ml of DMSO, 1.0 ml of carbon tetrachloride, and 5.0 ml

—○— Acetamide+CCl_4=27.3 mmol
DMSO: 6.0 ml; MMA: 2.0 ml
Polymerization: at 60°C for 20 hr
—△— Malonamide+CCl_4=18.2 mmol
DMSO: 14 ml; MMA: 4.0 ml
Polymerization: at 70°C for 20 hr

of MMA, was maintained at 60°C for 20 hr. The conversion amounted to 27.7%, but polymethyl methacrylate was completely extracted from the product with acetone. No graft-copolymer was obtained by these means. It is clear that polymerization is not initiated by a radical which has been formed by the cleavage of a bond in the amide molecule.

Experimental

Acetamide and acrylamide were recrystallized from a hot benzene solution. Malonamide was purified by pouring an aqueous solution into tetrahydrofuran. Urea was purified by pouring an aqueous solution into dioxane. Dimethyl sulfoxide, formamide, dimethylformamide, dimethylacetamide, and monomers were distilled under reduced pressure just prior to use. Polymerization was carried out in the dark according to the procedure described previously.[3]

The author is grateful to Mr. J. Ueda and Dr. A. Okada for their interest in this work. The author is also grateful to Dr. M. Suzuki.

Competition between Photo-Ionization and Photo-Dissociation of Aromatic Compounds

Hiroshi TSUBOMURA

Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka-shi, Osaka

(Received June 9, 1969)

Since the pioneering work of Lewis,[1] Porter[2] and their collaborators, it has been widely accepted that the ultraviolet irradiation of substituted aromatics yields their cations or radicals, the latter being formed by the fission of the β-bond of the substituent group. Thus, *p*-phenylenediamine, for instance, forms its cation almost exclusively. Anisole or phenol, on the other hand, forms mainly phenoxyl radical. For some compounds, the assignment of the products by Lewis and Porter was only tentative and lacked conclusive evidence. As far as the author is aware, reasons for such differrences in the photo-chemical behaviors of various aromatics do not seem to have been discussed.

We have studied the photo-products of several substituted aromatics irradiated in organic matrices at 77°K.[3-6] In these studies, the assignment of unstable species formed by the ultraviolet irradiation has been reconfirmed using more elaborate techniques. Some new data have also been added.

Some of the results on mono-substituted and *p*-disubstituted benzenes are summarized in Table 1. In the last two columns are indicated the main products formed by the ultraviolet irradiation of these compounds (or ions) in the 77°K matrices. For example, as already mentioned, *p*-phenylenediamines (**1** and **2**) form cations almost exclusively. Hence, for these two compounds, the column headed by "photo-ejection" is marked by + and the column headed by "dissociation" is marded by −, indicating that the main process for these compounds is the photo-ejection of an electron from the parent compound to the matrix.

In the case of *p*-dimethylamino-phenolate anion (**3**), studied in ethanol containing sodium hydroxide, the main process is also the photo-ejection of an electron yielding neutral *p*-dimethylamino-phenoxyl radical. Photo-ejection also prevails in the cases of **4**, **5** and **6**. As for *N*,*N*-dimethylaniline (**7**) and *N*-methylaniline (**8**), our detailed study of the absorption spectra of the photo-products confirmed that both the cation and the β-fission product are formed in the matrix, the former being more abundant in polar matrices such as ethanol. In the case of *p*-dimethoxybenzene (**9**), there is no indication of photo-ionization in ordinary organic solvents. However, we have found that it formed its cation when it is irradiated in a matrix composed of one part acetic acid and one part sulfuric acid at 77°K.[4a] This conclusion was later confirmed by a detailed study of the absorption spectrum of the cation prepared by other methods.[10] In the last three cases, hydroquinone,[4] anisole,[2] and phenol,[2] photo-dissociation is the main process and there was no indication that any cation was formed.

The compounds in the table are tabulated in the order of increasing gas-phase ionization potentials of the parent compounds, I_G. It is evident that the species formed depend strongly on I_G. T shows the (0–0) energy of the lowest triplet level. $I_G - T$ corresponds to the energy necessary for the second step of the photo-ionization. (See next paragraph.) S designates the energy of the first excited singlet state, or, speaking more precisely, gives the approximate absorption edge of the first absorption band. It should be noted that the photo-ejection is prevalent when $S-(I_G-T)$ is positive, and the photo-dissociation prevails when the value is negative. In cases where the value is nearly zero, both processes occur.

12	OH	H	8.52[9]	3.7	4.8	4.4	−0.4	−	+	1

* Energies are given in eV.

It has been established that the photo-ionization of aromatics by the near-ultraviolet light is accomplished by the two-step excitation, with the lowest triplet state as the stepping stone.[3,11] The vertical ionization potential of the aromatics in the matrix is only a few tenth eV smaller than I_G, and is almost independent of the polarity of the matrix. Both the photo-ionization and the photo-dissociation processes seem to have small quantum yields, because it takes at least several minutes of strong irradiation to obtain spectra of the products to a measurable amount.

The dissociation energies of the β-bond in the substituted aromatics may be estimated to be about 4 eV, which is about the same order of magnitude as the energies of the S levels and much less than the I_G values. Hence the possibility of one-photon dissociation of aromatics directly from the S states cannot be excluded. Our recent investigation has revealed that in some substituted aromatics, photo-dissociation by ultraviolet light mainly occurs by the two-step biphotonic excitation.[12] Anyway it is evident that photo-dissociation needs much less energy per quantum than photo-ionization. That photo-ionization is dominant over photo-dissociation in the compounds with low ionization potentials shows that the latter is a process having much less quantum yields than the former. Thus, only in cases where the former process is energetically forbidden, the products of the latter process will be accumulated.

Based on these arguments, the empirical rule mentioned above concerning the dependence of the products on $S-(I_G-T)$ may be explained in the following way. In the case where $S-(I_G-T)$ is positive, the molecule (or ion) in the triplet state can get ultraviolet light having sufficient energy to excite them to the energy region above the ionization limit. In the case where it is negative, the molecules in the triplet state cannot absorb photons having energies enough to excite them above the ionization limit, because the parent molecule, still abundant in the solution, will screen the light in such regions. In the case where it is almost zero, photoionization may occur to such an extent that it can compete with the photo-dissociation processes.

Validity of the present theory is based on the following facts: 1) the high-pressure mercury lamp used as the light source has considerable intensity even in the wavelength region shorter than 2530 Å (4.8 eV), and 2) the equilibrium concentration of the solute molecules in the triplet state at the time of irradiation is much smaller than that in the ground state. Of course, $S-(I_G-T)$ should be taken as a rough measure, particularly because S is a quantity difficult to define rigorously. More quantitative study is planned in our laboratory for the improvement of the present theory.

N-Alkylation of Primary and Secondary Amines by Alkyl Halides and Lithium Naphthalene

Kyoichi SUGA, Shoji WATANABE, Tsutomu FUJITA and Tsu Pai PAN

Department of Applied Chemistry, Faculty of Engineering, Chiba University, Yayoi-cho, Chiba

(Received June 10, 1969)

Alkylation of trivalent nitrogen can be effected in a variety of ways, such as the action of alcohol on ammonia or an amine for the preparation of the lower amines, and for higher amines by the action of an alkyl halide on ammonia in the liquid phase. Certain organoalkali compounds are used under various conditions. Lithium dialkylamides can be made from dialkylamine and phenyllithium. Lithium diethylamide reacts with phenyl halide in ether to form diethylaniline.[1] This paper deals with a new convenient procedure for the alkylation of various higher amines.[2]

Recently, the authors have reported that lithium naphthalene in tetrahydrofuran solution is an excellent agent for the ethynylation of α,β-unsaturated ketones,[3] and for the oligomerization of various dienes.[4,5] To a solution of lithium naphthalene in tetrahydrofuran, dibenzylamine (I) was added. *n*-Butyl bromide was added to this solution and the mixture was allowed to react in the usual way to give dibenzylbutylamine (II) in good yeild. Identity was confirmed by elementary analyses, titration and spectral data. From the combination of other various amines and alkyl halides, high conversion into the corresponding alkylamines was achieved by this method. Typical results are presented in Table 1. When authentic samples were available, identity was also confirmed by com parison of the infrared absorption spectra and the retension time of gas chromatography with those of authentic samples. The effect of reaction variables on the alkylation of dibenzylamine has been examined, and typical results are presented in Table 2. Alkylation products are obtained in higher yields with organic bromides than with organic chlorides. Both metallic sodium and potassium gave lower yields of *N*-alkylated products than in the case where lithium was used. Other products were obtained. The results indicate that lithium naphthalene can be applicable for selective *N*-alkylation of various higher primary and secondary amines.

Experimental

Materials. Commercial tetrahydrofuran was purified by drying with metallic sodium and distilling over metallic sodium under nitrogen. Naphthalene was recrystallized from benzene. All amines, organic halides and other compounds were distilled before use. All the experiments were carried out in a dry apparatus under purified nitrogen.

Alkylation of Amines. *Dibenzylbutylamine.* To a mixture of 0.05 mol (6.5 g) of naphthalene and 100 m*l* of tetrahydrofuran, 0.1 mol (0.7 g) of metallic lithium cuttings was added, and the mixture was agitated at room temperature in an atmsphere of dry nitrogen.[3,4] After 1 hr, 0.1 mol (19.7 g) of dibenzylamine was added slowly. The reaction mixture was stirred for an additional 2 hr 0.1 mol (13.7 g) of *n*-butyl bromide was gradually added, and the mixture was stirred for an additional 1 hr at room temperature. The reaction mixture was decomposed with methanol, the insoluble matter was dissolved in water, and the organic material was transferred into isopropyl ether. The isopropyl ether extracts were washed with water, dried over anhydrous sodium sulfate, and distilled to give the following fractions: (a) bp 74—80°C/4 Torr, yield 6.7 g; (b) bp 121—158°C/4 Torr, yield 7.0 g; and (c) bp 158—160°C/4 Torr, yield 15 g. Gas-liquid chromatography of fraction (a) with a column (2 m) of Reoplex 400 on Celite 545 at a temperature of 140°C with Helium as a carrier gas (40 m*l*/min) showed two peaks: peak No. 1 (1, 4-dihydronaphthalene), retention time 23 min, peak area ratio 50%; and peak No. 2 (naphthalene), retention time 35 min, peak area ratio 50%. Quantitative data were obtained by comparison of peak areas to those of internal standard of known concentration. Fraction (b) was dibenzylamine. Fraction (c) was redistilled to give pure dibenzylbutylamine, bp 159—160°C/4 Torr, n_D^{20} 1.5681, infrared (IR); 2960, 1600, 1460, 1120, 740 and 695 cm^{-1}; nuclear magnetic resonance (NMR) (δ, ppm): 0.8 ($C\underline{H}_3$-, 3H), 1.5 (-$C\underline{H}_2$-$C\underline{H}_2$-, 4H), 2.4 (-$C\underline{H}_2$-N-$C\underline{H}_2$-ph, 2H), 3.5 (ph-$C\underline{H}_2$-N-$C\underline{H}_2$-ph, 4H), 7.3 (aromatic protons, 10H), molecular weight from titrimetric procedure 240 (Calcd for $C_{18}H_{23}N$: 253).

Found: C, 85.24; H, 9.22; N, 5.43%. Calcd for $C_{18}H_{23}N$: C, 85.23; H, 9.15; N, 5.53%.

* Elementary nitrogen analyses and neutral equivalents of these amines agreed with the calculated data.
** Melting point.

Alkylation of other amines by organic halides and lithium naphthalene was performed and the products were identified in a similar way. Structures were confirmed by elementary nitrogen analyses and titrimetric procedure. Attempted butylation of *N,N*-dimethylaniline by butyl bromide and lithium naphthalene was carried out similarly as mentioned above. A mixture of isomeric butylnapthalenes was obtained, but not a butylated product of *N,N*-dimethylaniline. Alkylation of other tertiary amines by our method was unsuccessful.

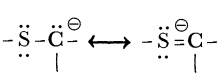
Solvent Effect in the Base-catalyzed Hydrogen Isotopic Exchange Reaction of α-Deuteriodiphenylthioacetal[1]

Isao MINAMIDA, Kenji UNEYAMA, Waichiro TAGAKI[2] and Shigeru OAE

Applied Chemistry, Faculty of Engineering, Osaka City University, Sugimotocho, Sumiyoshi-ku, Osaka

(Received June 16, 1969)

Effect of Phenylthio Group. Recently, we have shown that the divalent sulfide group assists the formation of α-carbanion due to its 3d-orbital resonance effect as shown below.[3-5]



However, the effect of solvent on these α-thiocarbanion forming reactions has not received much attention, and deserves to be investigated in detail. This paper will describe the H-D exchange reactions of α-deuterio-1, 1-di(phenylthio)ethane (I) and α-deuterio-1,1-di(ethylthio)ethane (II) in MeOH-MeONa, EtOH-EtONa, *t*-BUOH - *t*-BuOK and *t*-BuOH - DMSO - *t*-BuOK in order to obtain clear-cut information on the solvent effect and also to compare the carbanion stabilizing effect of the phenylthio group with that of the ethylthio group. Each kinetic run for the hydrogen isotopic exchange was carried out in a solution containing 0.1 M of a base and 0.2 M of the substrate, while the rates were followed by measuring the intensity of the stretching frequency of the C-D bond by means of IR spectroscopy. The results are listed in Tables 1 and 2.

1,1-Di(phenylthio)ethane (I) reacts 1.4×10^2 times faster than 1,1-di(ethylthio)ethane (II) in *t*-BuOH - *t*-BuOK. This trend is consistent with that found in the triethanolamine-catalyzed decarboxylation of 1,1-di(phenylthio)propionic acid(III) and 1,1-di(ethylthio)propionic acid(IV).[4] In the base-catalyzed elimination, β-chloroethyl phenyl sulfide reacts only 2.4 times faster than β-chloroethyl ethyl sulfide. This difference presumably comes from that of the carbanion character in the transition states of the two different reactions. In the former two reactions, the carbanion character develops substantially but in less extent in the elimination reaction, since this elimination is a typical E2 reaction.[5] The relatively large electron-withdrawing effect of the phenylthio group arises undoubtedly both from the electron-withdrawing inductive effect of the phenyl ring and substantial delocalization of the lone pair electrons of α-carbanion into the phenyl ring. The appreciable Hammett ρ value (2.0) of the base-catalyzed decarboxylation of the substituted 1,1-di(phenylthio)acetic acids in DMSO also suggests this.[6]

b) Relative rate at 158°C
c) DMSO : *t*-BuOH=1:1 in mole

Solvent Effects. Solvents used were MeOH, EtOH, *t*-BuOH and DMSO. In alcohols the rate increases with the increase of base strength. The addition of DMSO to *t*-BuOH also enhances the rate markedly. This result is in line with those observed in both the base-catalyzed E2 reaction of β-chloroethyl phenyl[5] sulfide and the base-catalyzed decarboxylation of 1,1-di(phenylthio)acetic acid.[7] Potassium *t*-butoxide in *t*-butanol is a stronger base than sodium ethoxide in ethanol, hence the proton-removal from the substrate takes place faster in *t*-butanol with *t*-butoxide than in ethanol with ethoxide. Addition of DMSO to *t*-BuOH makes potassium butoxide more basic in this reaction medium, thus enhancing the rate.[8] The lone electron pair on the α-carbon should be sufficiently delocalized both into the divalent sulfur atoms and phenyl ring due to the 3d orbital resonance, since the carbanion developing in the transition state is substantially stabilized by the two phenylthio groups. The carbanion is considered to be one of the soft bases as proposed by Pearson and Edwards.[9,10] Thus the α-thio carbanion may be solvated well in the transition state by a dipolar aprotic solvent such as dimethyl sulfoxide.

Experimental

Preparation of 1-deuterio-1, 1-di(phenylthio)ethane (I) and 1-deuterio-1,1-di(ethylthio) ethane (II) and kinetics were carried out in the same way as described previously.[3]

$$DCN + DCl + C_2H_5OD \rightarrow DC(=ND\cdot DCl)(OC_2H_5)$$

$$\xrightarrow{C_2H_5OH} D\text{-}C(OC_2H_5)_3 \quad (V)$$

$$(V) \xrightarrow{CH_3MgI} D\text{-}C(CH_3)(OC_2H_5)_2 \xrightarrow{\text{PhSH}} (I)$$

$$\xrightarrow{\text{EtSH}} (II)$$

Compounds (I) and (II) were finally distilled through an efficient column under reduced pressure. The boiling points of I and II are 168—169°C/1.7 mmHg and 79°C/15 mmHg respectively. Content of α-deuterium was analyzed by NMR spectra and both I and II were shown to be deuterated by 95%.

Preparation of Sterically Hindered Nitrosobenzenes

Renji OKAZAKI, Takeo HOSOGAI, Eiko IWADARE, Masayoshi HASHIMOTO and Naoki INAMOTO

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

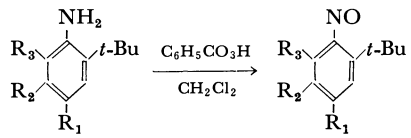
(Received June 30, 1969)

It is well known that most aromatic nitroso compounds exist as colorless or pale yellow dimers in the solid state and dissociate into green or bluish green monomers on solution or melting.[1] Some nitrosobenzenes having *p*-substituent such as dimethylamino, methoxy or iodo group, however, have been reported to be green or bluish green crystals and hence to be monomeric even in the solid state. The stabilization of these monomers has been attributed to the resonance interaction between the nitroso group and the *p*-substituent.[2]

It has been generally concluded that, regardless of the state, the green color (the presence of the n-π^* band) is an evidence of the monomer, and lack of color (the absence of the n-π^* band) indicates the dimer.[1,2]

This paper describes the preparation of a new group of nitrosobenzenes which exist as monomers even in the solid state for steric reasons.

Oxidation of 2,4,6-tri-*t*-butyl-,[3] 2,4-di-*t*-butyl-6-methyl-,[4] 2,5-di-*t*-butyl-,[5] 2,4-di-*t*-butyl-[6] and 4-benzoyloxy-2,6-di-*t*-butylaniline[7] with two molar amount of peroxybenzoic acid in dichloromethane at 0°C gave the corresponding nitroso compounds in good yields.



I: $R_1=R_3=t$-Bu, $R_2=H$
II: $R_1=t$-Bu, $R_2=H$, $R_3=CH_3$
III: $R_1=R_3=H$, $R_2=t$-Bu
IV: $R_1=OCOC_6H_5$, $R_2=H$, $R_3=t$-Bu
V: $R_1=t$-Bu, $R_2=R_3=H$

Among them I, II, III and IV were green crystals, and V was green liquid which solidified at dry-ice temperature to give green solid. Their yields, melting points, analytical data and electronic spectra are summarized in Table 1.

From studies on electronic spectra of a number of aromatic nitroso compounds, Nakamoto,[2a] Havinga[2b] and Lüttke[2c] have concluded that electron-donating groups in the *para*-position enhanced the stability of the monomers, and steric hindrance due to the *ortho*-substituents stabilized the dimer.[8] As an example, 2,4,6-trimethyl- and 2,4,6-trichloronitrosobenzenes are colorless dimers in the crystalline state, and the dimer exists in the extent of 70% and 20% in 0.1 M solution at 20°C, respectively.[2c] Accordingly, the extinction coefficients of their n-π^* absorption maxima exhibit appreciable change with varying concentration.[2b]

Contrary to anticipation that *ortho*-substituents would stabilize the dimers, nitrosobenzenes I—V having more bulky *ortho*-*t*-butyl groups seem to be monomeric even in the solid state, because they are highly colored in that state. In order to eliminate the possibility that they are mixtures of the monomer and the dimer, their electronic spectra were measured at various concentrations for I—IV, for the values of their extinction coefficients would increase upon dilution if they contain the dimeric species. As shown in Table 2 their extinction coefficients were almost invariable, no regular change being exhibited.

On the basis of the results described above, it is reasonably concluded that I—V are so sterically hindered by the bulky *t*-butyl groups that they cannot dimerize even in the solid state unlike methyl- or halogeno-substituted nitrosobenzenes.

In the course of our investigation of the oxidation of sterically hindered anilines to the corresponding nitrosobenzenes, we have found that peroxybenzoic

acid is the best reagent.[10] Oxidation of 2,4,6-tri-*t*-butylaniline with Caro's acid and peroxyacetic acid,[11] which are common oxidizing agents[1] for changing anilines to nitrosobenzenes, was unsuitable to give the corresponding nitrosobenzene.

Experimental

Melting points are uncorrected. The electronic spectra were recorded on a Hitachi recording spectrophotometer Model EPS-3.

General Preparation of Nitrosobenzenes. To ice-cooled dichloromethane solution of anilines was added dropwise with stirring two molar amount of peroxybenzoic acid in the same solvent. After being kept at 0°C overnight, the reaction mixture was shaken with aqueous sodium carbonate to remove benzoic acid. The organic layer was dried over anhydrous sodium sulfate, and then the solvent was evaporated. The crude product thus obtained was purified by means of column chromatography on silica gel; nitrosobenzenes were eluted with petroleum ether. In the case of 2,4,6-tri-*t*-butylnitrosobenzene (I) alumina was preferable because of good separation of nitrosobenzene from nitrobenzene as a by-product. (I) was recrystallized from methanol. Yields, melting points, electronic spectra and analytical data of purified nitrosobenzenes are summarized in Table 1.

The authors are grateful to Professor O. Simamura for his kind guidance and helpful discussions.

10) As for peroxybenzoic acid there have been a few investigations[12] dealing with the reaction only qualitatively except for the studies by Horner,[12c] who reported azobenzene and azoxybenzene as the reaction products with aniline.

SHORT COMMUNICATIONS

Substitution Reaction of 1-Bromoadamantane in Dimethyl Sulfoxide: Simple Synthesis of 1-Azidoadamantane[1]

Tadashi SASAKI, Shoji EGUCHI and Takeshi TORU

Institute of Applied Organic Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya

(Received July 25, 1969)

Recent interest in the chemistry of adamantane[2] and the biological activity of its derivatives[3] has given stimulus to synthesize many adamantylamine derivatives[4] including adamantylhydrazine.[5] We wish to report a simple synthesis of 1-azidoadamantane (II), a good precursor of adamantylnitrene. For this purpose, the direct substitution reaction of 1-bromoadamantane (I) with sodium azide in dipolar aprotic solvents has been examined, though direct substitution reactions of I in strongly acidic conditions have been well established.[6]

A mixture of I (0.43 g) and sodium azide (1.3 g) in dry dimethyl sulfoxide (20 m*l*) was heated with stirring at 100°C for 2 days. The mixture was poured onto ice-water to give colorless precipitates which afforded fine needles (0.105 g, 29.6%) with a mp of 80—81°C after recrystallization twice from aqueous methanol. This product was characterized as 1-azidoadamantane (II) from analytical (Found: C, 67.38; H, 8.65; N, 23.37%. Calcd for $C_{10}H_{15}N_3$: C, 67.76; H, 8.53; N, 23.71%) and infrared spectral data (ν_{N_3} 2110 cm^{-1}). Compound II afforded 1-aminoadamantane on treatment with lithium aluminium hydride in ether, which was identified by the same retention time with that of an authentic sample[7] on g.l.c. analysis,[8] and by the superimposable infrared spectrum on that of an authentic sample.[7] The yields of II in other conditions are summarized in Table 1, in which the best yield was 35.2%. From the water layer,

$$\underset{\text{I}}{\text{Ad-Br}} + \text{NaN}_3 \rightarrow \underset{\text{II}}{\text{Ad-N}_3} + \text{NaBr}.$$

$$\underset{\text{III}}{\text{Ad-O-S}^+(\text{CH}_3)_2\text{Br}^-} \qquad \text{Ad-} = 1\text{-adamantyl}$$

1-hydroxyadamantane (IV) was isolated in *ca.* 30% yield as the main by-product. Similar reaction in dimethylformamide or in hexamethylphosphoramide gave no II, most of the strating material being recovered. A facile substitution of I in dimethyl sulfoxide suggests a characteristic interaction of I with the solvent to give an intermediate salt like III[9] which could give II with azide anion and IV on hydrolysis. Although the yields are not satisfactory as yet, the facile preparation of II might make it possible to explore the chemistry of adamantylnitrene.

TABLE 1

Solvent	React. time (days)	React. temp. (°C)	Yield of II (%)

The Reaction of Cholest-4-en-3β-ol (Allocholesterol) with the Dichlorobis(triphenylphosphine)platinum(II)-Stannous Chloride Complex

Yoshiyuki ICHINOHE, Noriyuki KAMEDA and Masaharu KUJIRAI

Department of Chemistry, Faculty of Science and Engineering, Nihon University, Narashinodai, Funabashi, Chiba

(Received August 23, 1969)

Recently it has been reported that a noble metal complex acts as an efficient selective catalyst in the homogeneous hydrogenation of some steroids.[1] We now wish to report a new fact observed in the hydrogenation of steroids containing an allylic alcohol system with a dichlorobis(triphenylphosphine)platinum(II)-stannous chloride hydrate complex.[2]

Cholest-4-en-3β-ol (allocholesterol) (I) gave 5α-cholest-3-ene (II) and $\Delta^{2,4}$-cholestadiene (III) upon treatment with the complex at room temperature under a hydrogen pressure of 30 kg/cm² in a benzene-methanol (vol. ratio 3 : 2) solution. 5α-Cholestan-3β-ol (IV) was found in a very poor yield after a prolonged reaction, and no 5α-cholestane (V) was isolated. The results of reactions under various conditions are summarized in Table 1.

II was obtained in the maximum yield of 46.6% when the co-catalyst was used in a molar ratio to the catalyst of ten to one; this agrees with the finding reported by Tayim and Bailar.[3] When the reaction was carried out without stannous chloride, only cholest-4-en-3-one (VI) was yielded in spite of the presence of molecular hydrogen. Also accompanied by a small amount of a hydrogenolysis product, cholest-4-ene (VII), VI was afforded through the reaction performed in benzene as the only solvent. It is worthy of note that I was converted to II and III, but not to VI, by the reaction carried out under a nitrogen instead of a hydrogen atmosphere.

These experimental data have a strong resemblance to the results of the formation of acrolein from allyl alcohol or of *cis*-2-butene, butadiene and methyl vinyl ketone from 3-hydroxy-1-butene in the reactions with the same complex system.[4]

The consumption of methanol in the reaction course was confirmed by the identification of formaldehyde (characterized as the dimedone derivative). Accordingly, it may be considered that the above-mentioned complex system was reduced to a hydrido compound with methanol; the reduced complex then acts as the reducing agent in the course of reaction I to II. Attempts to cause a reaction using isopropyl alcohol and *t*-butyl alcohol as hydrogen sources were unsuccessful. It is of interest that the stereoisomer of I, cholest-4-en-3α-ol (epiallocholesterol) (VIII), was inert to the reaction with the platinum-tin complex. The structures of the above-mentioned compounds were confirmed by means of mp, $[\alpha]_D$, IR, NMR, TLC, VPC, *etc.*

A study of the hydrogenation with a dichlorobis (trialkylphosphine)platinum(II)-stannous chloride complex is in progress and will be reported on shortly.

TABLE 1

Farnesenes Isolated from the Volatile Oil of *Perilla frutscens f. viridis* Makino

Tsutomu SAKAI and Yoshio HIROSE

The Institute of Food Chemistry, Dojimanaka, Kita-ku, Osaka

(Received September 19, 1969)

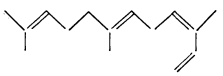
Three farnesene isomers, *cis*-α-farnesene (I), *trans*-(C_{10})- and *cis*(C_{10})- allofarnesenes (II and III), together with β-farnesene and farnesol, were isolated from the sesquiterpene fraction of the volatile oil now obtained from *Perilla frutscens f. viridis* Makino (Ao-shiso in Japanese) for the first time.

These three hydrocarbons (I, II and III) all had the same molecular formula, $C_{15}H_{24}$ (from MS data), and the same mother skeleton, farnesane (by hydrogenation).

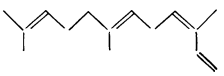
cis-α-Farnesene (I): IR; ν_{max}^{film} 1590, 3085, 985, 900, 1635, 830 cm^{-1}. NMR; δ^{CCl_4} 1.60, 165, 1.69 (12H, 3 s.), δ 2.00 (4H, unresolved d.), δ 2.78 (2H, t., J=7.0 Hz), δ 6.74 (1H, qua.), δ 4.95—5.25 (5H, complex m.). UV; λ_{max}^{EtOH} 238 mμ (ε=11300).

Cavill *et al.*[1] reported the isloation and characterization of α-farnesene from Dufour's gland in the ant *Aphenogaster longiceps* (F. Sm.); they identified it with that from the natural coating of "Grannyl Smith" apples isolated by Huelin and Murray.[2] They also showed that the α-farnesene from the ant and apples has a *trans*-conjugated diene. The lone proton in the R–CH=CH_2 system in the α-farnesene from the ant appears as a signal centered at δ 6.3 in the NMR spectrum, and its UV absorption maximum is at 232 mμ (ε=36400). On the other hand, our α-farnesene has the following values: δ 6.73; λ_{max}^{EtOH} 238 mμ (ε=11300). According to Ohloff *et al.*,[3] the proton at C_7 in the isomeric β-ocimene has a signal centered at δ 6.30 in *trans*-β-ocimene (IVb) and at δ 6.73 in *cis*-β-ocimene (IVa). Moreover, they reported an UV absorption maximum at 232 mμ (ε=27600) for *trans*-β-ocimene and one at 237 mμ (ε=21000) for *cis*-β-ocimene.

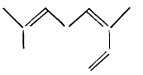
Therefore, it may be concluded that α-farnesene from the ant and from apples is *trans*-α-farnesene (V), while that from Perilla is *cis*-α-farnesene (I).



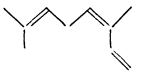
(I)



(V)



(IVa)



(IVb)

trans(C_{10})-Allofarnesene (II): IR; ν_{max}^{film} 960 cm^{-1}. NMR; δ 1,60, 1.63, 1.79 (15H, 3 s.), δ 2.06, 2.11 (4H, 2 s.), δ 5.07—7.44 (5H, complex m.). UV; λ_{max}^{EtOH} 270 mμ (ε=26800), 281 mμ (ε=35700), 292 mμ (ε=26700).

cis(C_{10})-Allofarnesene (III): NMR; δ 1.60, 1.67, 1.75 (15H, 3 s.), δ 2.05, 2.10 (4H, 2 s.), δ 5.08—6.25 (5H, complex m.). UV; λ_{max}^{EtOH} 266 mμ (ε=28300), 277 mμ (ε=36700), 288 mμ (ε=29400).

Naves[4] characterized the allofarnesene obtained from the dehydration of farnesol and nerolidol; he also identified the sesquiterpene hydrocarbon isolated from ylang-ylang oil and also "sesquicitronellene" with allofarnesene. However, the allofarnesene used for the structural analysis was a mixture of *trans*- and *cis*-isomers. The spectral data of allofarnesene reported by Naves resemble those of our *cis*(C_{10})-allofarnesene (III). O'Connor and Goldblatt[5] reported the UV absorption maxima at 270 mμ (ε=31319), 278 mμ (ε=39874), and 289 mμ (ε=30542) for *trans*(C_4)-*trans*(C_6)-alloocimene, and those at 265 mμ (ε=32872), 273 mμ (ε=42,871), and 285 mμ (ε=33757) for *trans*(C_4)-*cis*(C_6)-alloocimene.

Therefore, it may be concluded that the hydrocarbon II (Kovats index 1758)*1 is *trans*(C_8)-*trans*(C_{10})-allofarnesene and that the hydrocarbon III (Kovats index 1783) is *trans*(C_8)-*cis*(C_{10})-allofarnesene.

Preparation of Cyclic Phosphates of Uranium(VI)

Mutsukazu KAMO*1 and Shigeru OHASHI

Department of Chemistry, Faculty of Science, Kyushu University, Hakozaki, Fukuoka

(Received September 27, 1969)

Cyclic phosphates of uranium(VI) have not been prepared so far. When sodium trimetaphosphate reacts with uranyl nitrate in an aqueous solution, a precipitate of uranyl triphosphate is formed.[1] This shows that a hydrolytic ring-opening reaction of trimetaphosphate ion is remarkably accelerated by uranyl ion.

The present investigation was undertaken to know whether uranyl trimeta- or tetrametaphosphate can be prepared by the precipitation reaction in an alcoholic aqueous solution. The results indicate that uranyl trimetaphospate cannot be prepared by this method, but disodium uranyl tetrametaphosphate trihydrate, $Na_2UO_2P_4O_{12}\cdot 3H_2O$ can be precipitated from an ethanol-water solution of sodium tetrametaphosphate and uranyl nitrate.

Preparation of disodium uranyl tetrametaphosphate trihydrate was carried out as follows. To 25 m*l* of a 0.1M aqueous solution of sodium tetrametaphosphate 25 m*l* of a 0.1M aqueous solution of uranyl nitrate was added with stirring. After 5 min 45 m*l* of ethanol was added with stirring to the mixture. The precipitate was filtered, washed with 100 m*l* of 50% (v/v) ethanol in water and dried for about 24 hr in a vacuum desiccator over calcium chloride.

It was revealed by paper chromatoraphy that the product was tetrametaphosphate containing a very small amount of its hydrolytic products. The analytical results of the product are as follows.

Found: UO_3, 41.8%; P_2O_5, 41.4%; Na_2O, 8.9%; H_2O, 7.9% (by difference). Calcd for $Na_2UO_2P_4O_{12}\cdot 3H_2O$: UO_3, 41.58%; P_2O_5, 41.27%; Na_2O, 9.30%, H_2O, 7.85%.

The infrared spectrum of the product was similar to that of sodium tetrametaphosphate except for the peaks due to uranyl ion. This indicates that the major component of the precipitate is disodium uranyl tetrametaphosphate trihydrate.

From a comparison of the reaction of trimetaphosphate with that of tetrametaphosphate, it can be concluded that tetrametaphosphate ion is more stable than trimetaphosphate ion against hydrolysis in the presence of uranyl ion.

This work was supported in part by grant-in-aid from the Ministry of Education.

Polarography of the Dicyano Cobalt(III) Complexes

Nobufumi MAKI

Department of Chemistry, Faculty of Engineering, Shizuoka University, Johoku, Hamamatsu

(Received September 30, 1969)

It has been found that several kinds of penta-cyano- and tetracyano-cobaltate(III) complexes can be reduced to or through the cobalt(I) state in an aqueous solution at the dropping mercury electrode (DME).[1] The stabilization of the cobalt (I) state can certainly be ascribed to the contribution of the "back donation" at the bonds of four or five cyanide ligands.

In the present communication, however, the dicyano-tetrammine- and bis(ethylenediamine)-cobalt(III) complexes have been found still to undergo a step-by-step reduction of $Co^{III} \rightarrow Co^{II} \rightarrow Co^{I} \rightarrow Co^{0}$, as it were, at the DME in dimethyl sulfoxide (DMSO); it has hitherto been considered impossible for the cobalt(I) states of these complexes with only two cyanides to exist in solution during the course of reduction. That is, the complex ions, *cis*- and *trans*-$[Co^{III}(CN)_2en_2]^+$, and *trans*-$[Co^{III}(CN)_2(NH_3)_4]^+$, gave rise to well-defined waves of three steps in DMSO (100%) containing 0.1 M $[(C_2H_5)_4N]ClO_4$. The waves, each corresponding to an acceptance of one electron, represent the reductions of $Co^{III} \rightarrow Co^{II}$, $Co^{II} \rightarrow Co^{I}$, and $Co^{I} \rightarrow Co^{0}$ respectively.

Each of the limiting currents was proportional to the concentration of the complex in the range of 10^{-4}—10^{-2} M, and also proportional to the square root of the mercury pressure on the DME; the values of $i_l/\sqrt{h_{corr.}}$ are almost constant, irrespective of the mercury pressure. The instantaneous current-time curves during a one-drop growth of the DME at a constant potential exhibit a normal shape except that of the third step for the tetrammine complex; the current varies with time to the powers of 0.19—0.22 at the potentials, at which potential the current reaches a limiting plateau. This result, combined with the finding in relation to the mercury head, supports the conclusion regarding the diffusion-controlled features of all the waves except that of the third step for the ammine complex. The third wave for the tetrammine complex, involving a somewhat kinetic character in its current, expresses the partial disruption of the cobalt(I) complex during the reduction of $Co^{I} \rightarrow Co^{0}$ at the DME.

The following processes of the electrode reaction are considered to be the most probable:

$$[Co^{III}(CN)_2(NH_3)_4]^+ \xrightarrow{e}$$

$$[Co^{II}(CN)_2(NH_3)_4] \xrightarrow{e} [Co^{I}(CN)_2(NH_3)_4]^-$$

$$[Co^{I}(CN)_2(NH_3)_{4-n}(dmso)_n]^- \xrightarrow{e} Co(\textit{metal}).$$

Table 1 summarizes the half-wave potentials of the dicyano cobalt(III) complexes in DMSO. The addition of a small amount of water to the DMSO solution immediately causes the disruption of the cobalt(II) complex, thus permitting further direct reduction to the metal to take place; no cobalt(I) state can exist upon the reduction in water.

TABLE 1. THE HALF-WAVE POTENTIALS OF THE DICYANO COBALT(III) COMPLEXES IN THE DMSO (100%) CONTAINING 0.1 M $[(C_2H_5)_4N]ClO_4$ (25°C)
