In the present experiment, the kinetics of water adsorption on the amorphous ferric oxide prepared by heating the ferric oxide gel at 200°C, and the effect of water on the semiconductivity of the oxide, were investigated in an attempt to elucidate the interaction between the oxide and the adsorbed water.

Experimental

Materials. Ferric oxide gel was prepared by mixing 54 ml of a 6N NH_4OH solution and 750 ml of a 0.1 M $Fe(NO_3)_3$ solution at 90°C. The pH of the solution in which the hydroxide gel was suspended was 9.05. The precipitate obtained as above was carefully washed with distilled water and dried for two days at room temperature and for 6 hr at 100°C in 20 mmHg. After drying, it was calcinated in air at a fixed heating rate of 10°C/min up to 200°C and kept at this temperature for 10 min. The sample to be studied was ground to a powder with a mesh size of 200—300. This oxide was found to be amorphous by X-ray diffraction examination, and its surface area was 162 m^2/g (BET method).

Measurements. The rate of the adsorption of water vapor was measured gravimetrically using a quartz spring microbalance and a cathetometer. The water vapor was supplied by a sulfuric acid solution placed in a constant-temperature bath, while the pressure was controlled by changing the concentration of the acid solution. Before the adsorption experiment, the specimen was evacuated at 150°C for 3 hr at 10^{-5} mmHg. The cell used for the measurement of the electrical conductivity was of the sandwich type, with two platinum electrodes (contact area, 0.95 cm^2) and a stainless-steel spring to press the oxide between electrodes at a pressure of 1 kg/cm^2. The voltage supplied across the cell was 10 V d. c., and the conducting current was measured in a vacuum of 10^{-6} mmHg at various fixed temperatures ranging from 5°C to 50°C. The conducting current was measured by an electrometer (Ohkura Electric Co.). Before the measurement of the conductivity, the specimen was subjected to the adsorption of water vapor in a desiccator containing the sulfuric acid solution for various periods of time in order to change the amount of adsorbed water which could be determined by weighing the specimen before and after the adsorption.

Results

Kinetics of Adsorption. Typical adsorption-time curves are shown in Fig. 1, in which the amount of water adsorbed, q, is represented in units of mg H_2O per m^2 of the oxide surface and the time, t, in minutes. The q values in the initial stage of the adsorption, *i.e.*, for 1 or 1.5 min after the introduction of water vapor into the adsorption chamber, are not so accurate as in the later stage because of the oscillation of the quartz spring.

To analyze these adsorption-time curves in the figure, q is plotted against $\log(t+t')$ in Fig. 2, where t' is chosen to linearize the q-$\log t$ relation by a

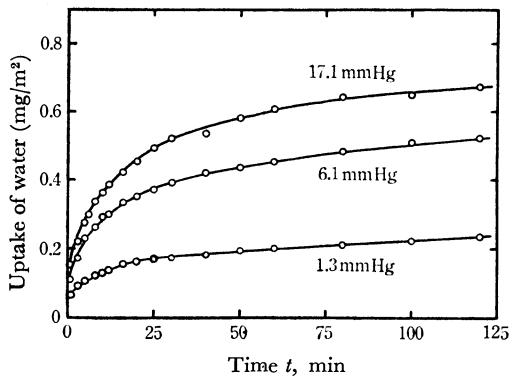

Fig. 1. Adsorption-time curves for amorphous ferric oxide at 30°C at various pressures.

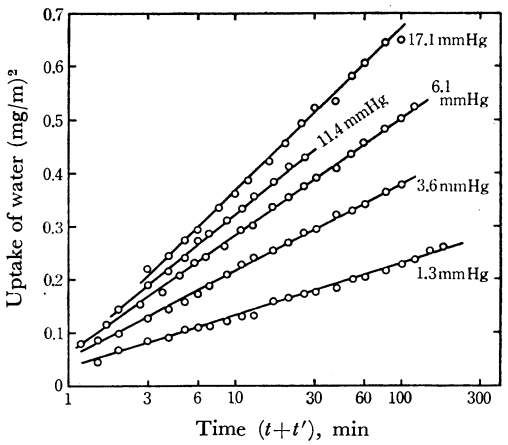

Fig. 2. Kinetics of the water vapor uptake at 30°C at various pressures.

trial-and-error method. It may be seen in Fig. 2 that the kinetics of water adsorption on the amorphous ferric oxide obeys the Rozinsky-Zeldovich or Elovich equation, which can be formulated as follows in the differential and integrated forms respectively:

$$dq/dt = k \exp(-\alpha q/\boldsymbol{RT}) \quad (1)$$

$$q = 2.303(\boldsymbol{RT}/\alpha)\log(t + \boldsymbol{RT}/\alpha k) - 2.303(\boldsymbol{RT}/\alpha)\cdot\log \boldsymbol{RT}/\alpha k \quad (2)$$

where k is the initial rate when q is zero and α is constant. The value of t' on the abscissa $\log(t+t')$ in Fig. 2, therefore, corresponds to the $\boldsymbol{RT}/\alpha k$ term, and the slope of the straight lines, to $2.303(\boldsymbol{RT}/\alpha)$ in Eq. (2). Accordingly, α and k can be calculated from the values of t' and the slope of the lines. However, it has been shown by Taylor and Thon[11] that the initial rate of adsorption, k, calculated t' is smaller than the experimentally-measured rate

11) H. A. Taylor and N. Thon, *J. Am. Chem. Soc.*, **74**, 4169 (1952).

in many cases. In the present paper, because of the difficulty in measuring the initial velocity, the calculated k has been assumed to be the initial rate of adsorption.

As may be seen in Fig. 2, the solpe of the line, that is $2.303(RT/\alpha)$ in Eq. (2), increases with the pressure of the water vapor, p. The slope of the line, when plotted as in Fig. 3, is seen to increase

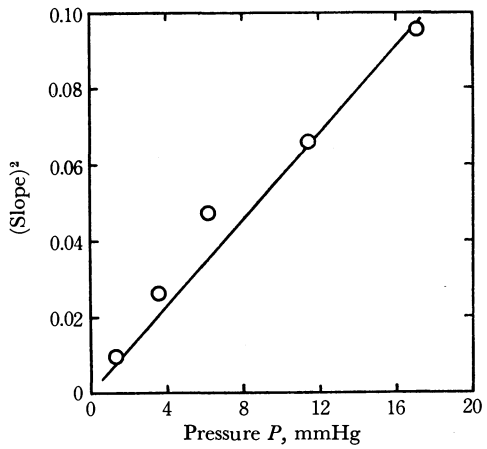

Fig. 3. Pressure dependence of the slope of lines in Fig. 2.

linearly with $p^{0.5}$, so α can be writted as $\alpha=\alpha'/p^{0.5}$. To examine the pressure-dependence of k, which can be calculated from Eq. (2), log k is plotted as a function of log p in Fig. 4. Thus, the relation

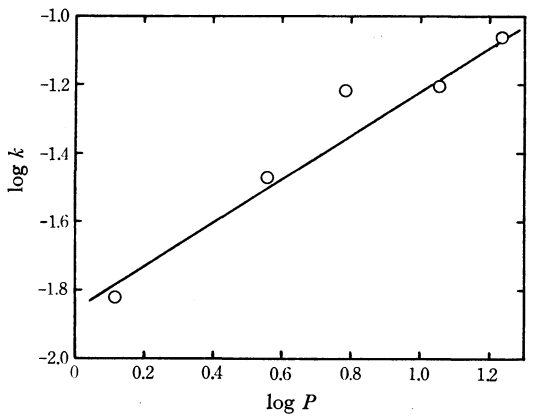

Fig. 4. Pressure dependence of the initial velocity calculated from the data in Fig. 2.

between k and p can be represented as $k=k'p^{0.63}$. The substitution of new pressure-dependent parameters, α and k, into Eq. (1) yields:

$$dq/dt = k'p^{0.63} \exp(-\alpha' q/RTp^{0.5}) \quad (3)$$

Electrical Conductivity. The results of the measurement of the electrical conductivity as a function of the temperature are shown in Fig. 5,

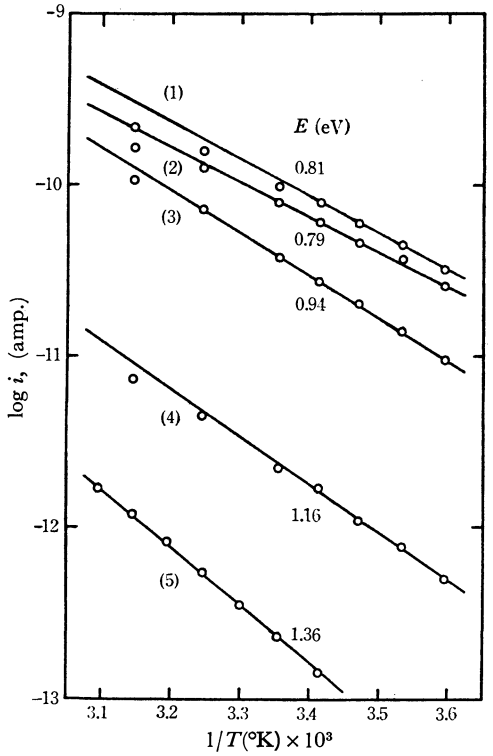

Fig. 5. Conductivity of amorphous ferric oxide as a function of temparature. Curves (1), (2), (3), (4) and (5) correspond, respectively, to the conductivity of samples containing 0, 4.9, 8.7, 12.0 and 14.5 wt% of adsorbed water.

in which the logarithm of the conducting current through the cell has been plotted against the reciprocal absolute temperature. Five curves, denoted in this figure by (1) to (5), represent the conductivity of specimens containing different amounts of adsorbed water, that is 0, 4.9, 8.7, 12.0 and 14.5 wt% of water respectively. The results in Fig. 5 show that the conducting current, i, at a given temperature, T, can be formulated by Eq. (4);

$$i = i_0 \exp(-E/kT) \quad (4)$$

where i_0 and E are constants and k, the Boltzman constant. Furthermore, it was found that, although no variation in the current with time occurred at 5°C in a vacuum, some decrease in the current did occur when air entered the conductivity cell. These results imply that the ferric oxides are n-type semiconductors. Accordingly, the slope of the lines Fig. 5 is considered to give the activation energy, E, for semiconduction. At higher temperatures the conducting currents of the wet oxides, as seen in Fig. 5, deviates downward from the stright line, probably because of the desorption of the adsorbed water.[10]

It may also be seen in Fig. 5 that as the amount of adsorbed water increases, E decreases and i

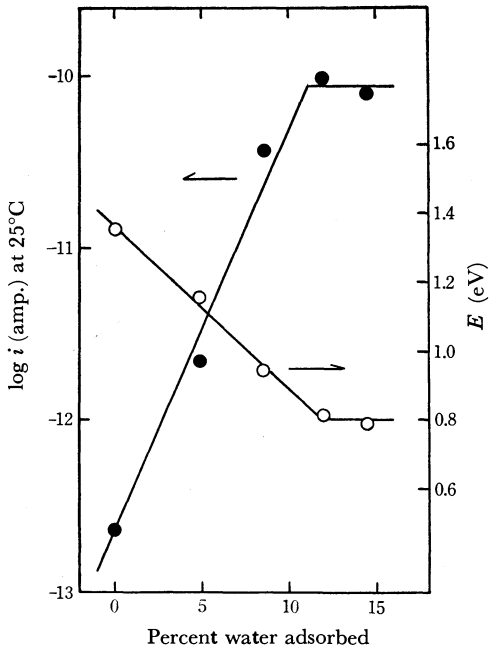

Fig. 6. Relation between conducting current at 25°C, activation energy and amount of adsorbed water.

increases in the temperature range examined. This is quantitatively shown in Fig. 6, in which the values of the conducting current at 25°C are given as examples. The change in the conducting current, i, with the amount of adsorbed water, q, at a fixed temperature is seen to obey the equation:

$$\log i = i' + aq \tag{5}$$

where i' and a are constants. Furthermore, the activation energy of semiconduction, E, can be expressed by:

$$E = E_0 - bq \tag{6}$$

where E_0 corresponds to the activation energy of the dried oxide and where b is constant.

From Eqs. (5) and (6) the relation:

$$\log i = \text{const.} - \text{const.} \times E \tag{7}$$

can be obtained. Equation (7) satisfies Mayer's rule,[12] which, in general, has been interpreted as follows: the activation energy of electronic conduction in semiconductors decreases with an increase in the concentration of carriers and donor centers. Accordingly, it may be concluded that the adsorbed water acts as a donor-type impurity in the oxide, the oxide being a semiconductor of the n type.

Discussion

As has been mentioned above, the amorphous ferric oxide is an n-type semiconductor and the adsorption of water on it causes the electrical conductivity to increase. Therefore, the adsorption which, in the present case, may be referred to as the cumulative or cationic chemisorption must be accompanied by the charge transfer. Hauffe, Morrison and Stone[13] have discussed the kinetics of the cationic adsorption on the basis of the boundary-layer theory of chemisorption. On the other hand, Eley and Leslie[14] postulated in their recent study that the adsorption kinetics of water vapor on proteins may be regarded as a two-stage process: the van der Waals adsorption and the charge-transfer adsorption, with the rate-determining step being the latter. On the basis of this adsorption model, they derived theoretically the equation indicated by Eq. (8) and gave a qualitative description of the rate of adsorption experimentally obtained (Eq. (9)):

$$dq/dt = K'N_{VW}p^{0.6}\exp[-(E_0 + \beta q - \gamma p)/RT] \tag{8}$$

$$dq/dt = Kp^{0.6}\exp(-\alpha' q/RTp) \tag{9}$$

where K, K', β, γ nad α' are constants; N_{VW}, the number of sites on the surface of the adsorbent, E_0, the energy barrier of the charge-transfer step at $q=0$. In Eq. (8), the activation energy, E, is assumed to increase linearly with the amonut of adsorbed water, the additional term, γp, is the contribution to E of the dipole moment of water molecules in the van der Waals adsorption state. By comparing Eq. (3) with Eq. (9), it can easily be seen that these two equations are almost the same except for a difference in the exponent of p in the exponential term. Accordingly, the adsorption of water on the amorphous ferric oxide may be explained by the two-stage model proposed for the adsorption on protein. On the basis of the above discussion, the adsorption process can be represented as follows:

$$H_2O + \text{oxide} \rightleftarrows [H_2O\cdots\text{oxide}]_{VW} \xrightarrow{-A\rightarrow} [H_2O \rightarrow {}^{-}\text{oxide}]_{CT}$$

Pearson and Bardeen[15] found, for boron in silicon, that the ionization energy, E_D, of the donors decreased with an increase in the concentration of the donors, n_D, in the semiconductor. Assuming the interaction energy between the impurity atoms to be inversely proportional to the average distance between these atoms, they derived this relation between E_D and n_D:

15) G. L. Peason and J. Bardeen, *Phys. Rev.*, **75**, 865 (1949).

$$E_D = E_{DC} - n_D^{1/3} \quad (10)$$

If it can be assumed that, as has been described above, the adsorbed water is acting as an impurity producing donor centers, and that the amount of adsorbed water, q, is proportional to n_D to the one-third power, the change of E with q in Eq. (6) can be interpreted in terms of the interaction between the adsorbed waters. Moreover, the conductivity[16] is given by the theory of the impurity mechanism of semiconduction:

$$\sigma = e\mu(4n_D)^{1/2}(2\pi mkT/h^2)^{4/3} \exp(-E_D/2kT) \quad (11)$$

where e is the electronic charge, and μ, the mobility, while the others are well-known symbols. By substituting Eq. (10) into Eq. (11), and by assuming $n_D^{1/3}$ to be proportional to q, the logarithm of σ can be given by:

$$\log \sigma = \text{const.} + \log q^{3/2} + \text{const.} \times q \quad (12)$$

Neglecting log $q^{3/2}$ term, Eq. (12) fits the relation between i and q in Eq. (5) obtained experimentally in the present investigation.

One of the authors (R. F.) especially wishes to thank the Sakkokai Foundation for his scholarship.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 2479—2485 (1969)

The Crystal and Molecular Structure of the High-melting-point Isomer of Bis-(1,2-diethoxycarbonyl-ethyl)tin Dibromide

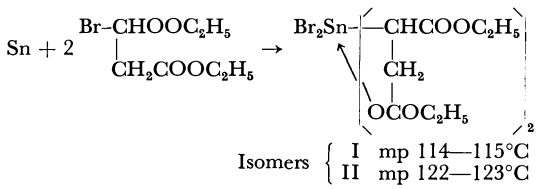
Toshihide KIMURA, Tatzuo UEKI,[*1] Noritake YASUOKA, Nobutami KASAI[*2] and Masao KAKUDO

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamada-Kami, Suita, Osaka

(Received February 20, 1969)

The high-mp isomer crystal of bis-(1,2-diethoxycarbonyl-ethyl)tin dibromide (mp 122—123°C) is monoclinic: $a=19.46$, $b=10.25$, $c=13.20$ Å, $\beta=121.1°$; space group $C2/c$; four molecules are contained in a unit cell. The molecule has the C_2 symmetry. The tin atom lies on the two-fold axis, and the coordination about the tin atom is nearly octahedral. Similar to the low-mp isomer, two bromine atoms attached to the tin atom are in *cis*-positions; also, two ligands, both 1,2-diethoxycarbonyl-ethyl groups, are bound to the tin atom by oxygen and carbon atoms, forming rather puckered five-membered rings. Both rings are in either the *d*- or *l*-form, instead of consisting of one *d*- and one *l*-form, as in the low-mp isomer.

Bis-(1,2-diethoxycarbonyl-ethyl)tin dibromide was prepared by a direct reaction between tin foil and diethyl bromosuccinate;[1] the two isomers thus



Isomers { I mp 114—115°C
II mp 122—123°C

isolated had mp's of 114—115°C and 122—123°C.

We undertook a three-dimensional structure analysis of these isomers by means of X-rays, and have already reported on the structure of I, the low-mp isomer.[2] In the present paper the molecular and crystal structure of II, the high-mp isomer, and the differences between the structure of these two isomers will be described.

Experimental

The crystals were obtained by recrystallization from an ethanol solution. They were colorless needles developed along the *c* axis. In order to determine the lattice parameters, oscillation and Weissenberg photographs were taken around the *b* and *c* axes. Debye lines of aluminum were superposed on the Weissenberg photographs for calibration.

For the intensity data collection, the layers from 0 through 7 around the *b* axis were recorded by the

multi-film equi-inclination Weissenberg technique, using nickel-filtered Cu$K\alpha$ radiation. The reflections of the layers from 0 through 2 around the c axis were also collected, mainly for the inter-layer scaling.

The intensities were estimated visually by using a calibrated standard scale. Lorentz and polarization corrections were carried out, but no absorption correction was made. In all, 1546 (1536 non-zero) reflections were obtained. The density was measured by the floatation method.

Crystal data are summarized in Table 1. For reference, those of the low-mp isomer are also shown in Table 1.

Determination and Refinement of the Structure

From the systematic absence of the reflections, the possible space group is either $C2/c$ or Cc. If the space group is $C2/c$, the general positions in the unit cell are eight-fold. In this case, however, four molecules are present, and the molecules must occupy special positions. Therefore, the molecule has either C_i or C_2 symmetry. In the case of Cc, the molecules lie on general positions. From these considerations, the following four possible cases may be considered:

1) the space group is $C2/c$, the molecule has the C_2 symmetry, and the two bromine atoms are in the *trans*-position;

2) the space group is $C2/c$, the molecule has the C_2 symmetry, and the two bromine atoms are in the *cis*-position;

3) the space group is $C2/c$, the molecule has the C_i symmetry, and the two bromine atoms are in the *trans*-position;

4) the space group is Cc, and the molecule has no symmetry.

The three-dimensional Patterson function was interpreted successfully in the case of 2), and so the space group was determined to be $C2/c$. The tin atom lies on the two-fold axis.

The crystal structure was established by the heavy-atom method. By starting with approximate parameters of tin and bromine atoms, the positions of all the light atoms except hydrogen were found in the three-dimensional Fourier maps. Successive block-diagonal least-squares refinement was carried out on a HITAC 5020E computer at the University of Tokyo, using a program written by Dr. T. Ashida. After two cycles of refinement for the heavy atoms, Sn and Br, the discrepancy factor, $R=\sum||F_o|-|F_c||/\sum|F_o|$, was reduced to 0.348. In this refinement, the unit weight was assigned for all reflections. Then, the refinement was made for all atoms except hydrogen. The following weighting scheme was applied: $w=(23.1/|F_o|)^2$ for $|F_o|>23.1$, $w=1.0$ for $23.1\geqq|F_o|\geqq1.0$, and $w=0.2$ for $|F_o|<1.0$. After three cycles, anisotropic temperature factors for the heavy atoms were introduced. Six cycles of refinement gave the R value of 0.167 for all reflections.

The atomic and thermal parameters are listed in Table 2, while the observed and calculated structure factors are listed in Table 3. The atomic scattering factors used in the structure-factor calculation were those of Hanson *et al.*[3]

Description of the Molecular Structure and Discussion

The molecular structure is shown in Fig. 1. The geometry around the tin atom is shown in Fig. 2,*3 while the bond lengths and angles in the environment of the tin atom are listed in Table 4. Such as in the low-mp isomer, the two bromine atoms attached to the tin atom are in *cis*-positions. The two ligands, both 1,2-diethoxycarbonyl-ethyl groups, are bound to the tin atom by carbon and oxygen atoms, and form rather puckered five-membered rings. The coordination about the tin atom is a six-coordinated, distorted octahedron. In the $(CH_3)_2Sn(C_9H_6NO)_2$ compound, it was found that, though the tin atom seems to be six-coordinated, the C–Sn–C angle is nearly tetrahedral (110.7°); Schlemper postulated a theory that the bonding involves sp^3 hybrid orbitals on the tin atom participating in two normal covalent bonds to the methyl groups and in two three-center bonds to the oxinate groups.[4] In the high-mp isomer, however, the C–Sn–C angle (147.4°) and the other angles around the tin atom take values different from those in the oxinate chelate.

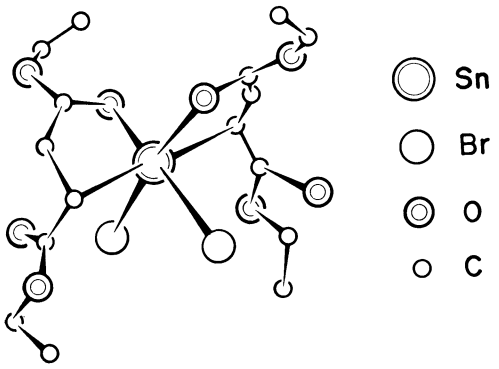

Fig. 1. The molecular structure of the high mp isomer of bis-(1,2-diethoxycarbonyl-ethyl)tin dibromide.

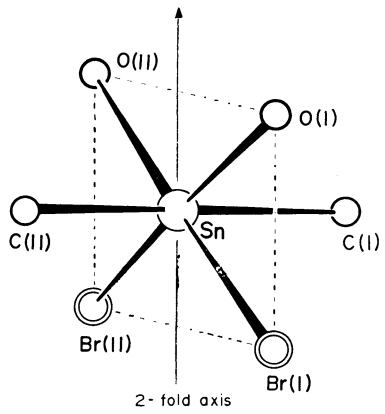

Fig. 2. The geometry around the tin atom.

*3 The Br(11), C(11), ···, C(18) and O(11), ···, and O(14) stand for the equivalent positions related by the two-fold axis at the $(0, y, 1/4)$ of Br(1), C(1),···, C(8) and O(1), ···, O(4) respectively.

Table 4. Bond lengths and angles in the environment of the tin atom

Bond length		Bond angle	
Sn–Br(1)	2.504 Å	Br(1)–Sn–Br(11)	101°
Sn–C(1)	2.24	Br(1)–Sn–C(1)	103
Sn–O(1)	2.49	Br(1)–Sn–O(1)	91
		Br(1)–Sn–C(11)	97
		Br(1)–Sn–O(11)	166
		C(1)–Sn–O(1)	72
		C(1)–Sn–C(11)	148
		O(1)–Sn–C(11)	83
		O(1)–Sn–O(11)	79

The estimated standard deviations of the bond lengths in Sn–Br is 0.005 Å, in Sn–C 0.03 Å, and in Sn–O 0.02 Å. Those for angles are all less than 2.5°.

The Sn–Br distance, 2.504 Å, is slightly shorter than the sum of the covalent radii of Sn and Br, 2.540 Å, and is also shorter than those in the low-mp isomer, 2.52 Å and 2.58 Å.[2] The Sn–Br distance of 2.507 Å observed in (4-bromo-1,2,3,4-tetraphenyl-*cis,cis*-1,3-butadienyl)dimethyltin bromide[5] is, however, close to this value. The Sn–C distance, 2.24 Å, is not much different from that in the low-mp isomer,[2] 2.26 Å, nor from that in (4-bromo-1,2,3,4-tetraphenyl-*cis*-1,3-butadienyl)dimethyltin bromide,[5] 2.24 Å. All these values are slightly longer than the sum of the covalent radii (2.17 Å) and also longer than those in $(CH_3)_3SnMn(CO)_5$[6] (2.16 Å) and those in $(CH_3)_2Sn(C_9H_6NO)_2$[4] (2.17 Å). The Sn–O bond distance, 2.49 Å, is considerably longer than the sum of the covalent radii (2.06 Å) and also longer than those in $(CH_3)_2Sn(C_9H_6NO)_2$[4] (2.10 Å) and those in $[\pi\text{-}C_5H_5Fe(CO)_2]_2Sn(ONO)_2$ (2.14 Å).[7] This suggests that the Sn–O bond is a weak coordination bond similar to that of the low-mp isomer (Sn–O, 2.45 Å). The bond angles shown in Table 4 are similar to those observed in the low-mp isomer.

The largest deviations from the least-squares planes, Br(1)–O(1)–O(11)–Br(11), Br(1)–C(1)–O(11)–C(11), and O(1)–C(1)–C(11)–Br(11), all centered by the tin, are 0.20 Å, 0.28 Å, and 0.24 Å respectively. These three planes make dihedral angles, 88°, 87°, and 87°, with each other.

The bond lengths and angles in the ligand, the

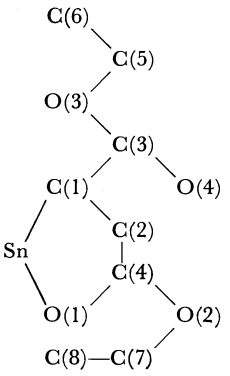
1,2-diethoxycarbonyl-ethyl group, are listed in Table 5.

TABLE 5. THE BOND LENGTHS AND ANGLES OF THE LIGAND GROUP



Bond length		Bond angle	
Sn-C(1)	2.24 Å	O(1)-Sn-C(1)	72°
Sn-O(1)	2.49	Sn-O(1)-C(4)	109
O(1)-C(4)	1.12	C(4)-O(2)-C(7)	118
O(2)-C(4)	1.39	C(3)-O(3)-C(5)	120
O(2)-C(7)	1.42	Sn-C(1)-C(2)	106
O(3)-C(3)	1.30	C(2)-C(1)-C(3)	116
O(3)-C(5)	1.43	C(1)-C(2)-C(4)	112
O(4)-C(3)	1.20	O(3)-C(3)-O(4)	129
C(1)-C(2)	1.54	O(3)-C(3)-C(1)	110
C(1)-C(3)	1.47	O(4)-C(3)-C(1)	120
C(2)-C(4)	1.41	O(1)-C(4)-C(2)	127
C(5)-C(6)	1.42	O(1)-C(4)-O(2)	120
C(7)-C(8)	1.42	O(2)-C(4)-C(2)	112
		O(3)-C(5)-C(6)	109
		O(2)-C(7)-C(8)	114

The estimated standard deviations for bond lengths are 0.02—0.08 Å, and for angles are 2.0—3.7°.

Each of the two ligands, both 1,2-diethoxycarbonyl-ethyl groups, has an asymmetric carbon atom, C(1) and C(11) respectively. In the low-mp isomer,[2] one of the two asymmetric carbons is in the *d*-form and the other, in the *l*-form. In the high-mp isomer, however, since the molecule has C_2 symmetry, both of them are in either the *d*-form or the *l*-form. The molecule must possess optical activity. Since there are glide planes in the unit cell (space group: $C2/c$), there are equal numbers of molecules of two optical antipodes (Fig. 3) in the crystal. The crystal exhibits no optical activity as a whole.

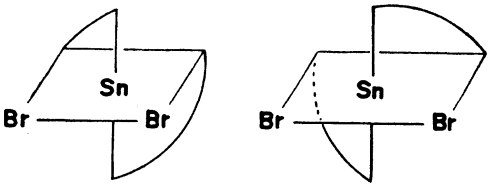


Fig. 3. Two optical antipodes.

Figure 4 shows the crystal structure of the high-mp isomer projected onto the (010) plane. Intermolecular atomic contacts of less than 4.0 Å are listed in Table 6. The shortest distances are O(4)-C(15)^{II}, 3.15 Å, O(4)-C(17)^{IV}, 3.16 Å, and C(7)-O(14),^{IV} 3.16 Å. These values are similar to those found in the low-mp isomer. However, the number of close intermolecular contacts in the high-mp isomer exceeds those in the low-mp isomer. Therefore, it seems that the molecules are packed more densely in the high-mp isomer than in the low-mp isomer. This is supported by the fact that the density of the high-mp isomer (D_m=1.82, D_x=1.83 g·cm^{-3}) is larger than that of low-mp isomer (D_m=1.80, D_x=1.80 g·cm^{-3}). The difference in the melting points of the two isomers, 8°C, may be

The Ultrasonic Study of Aqueous Solutions of Alkyl-Substituted Urea

Katsutaka SASAKI and Kiyoshi ARAKAWA

Research Institute of Applied Electricity, Hokkaido University, Sapporo

(Received February 22, 1969)

An ultrasonic investigation of aqueous solutions of alkyl-substituted urea was made by means of an ultrasonic pulse technique in order to study the influence of the solutes upon the structure of solvent. The ultrasonic velocity and absorption were measured in solutions of 1,3-dimethylurea and 1,3-diethylurea in the frequency range from 5 to 45 Mc/sec. The temperature was varied from 10 to 40°C, and the concentration from 0.2 to 4 mol/*l*. Within the range of frequency no relaxation frequency was observed for both solutions. From the data on absorption coefficent and viscosity, the magnitude of absorption due to structural relaxation was calculated. It was found that structural absorption in dimethylurea solutions is slightly larger, and in diethylurea solutions much larger than that of the urea solutions. From these results, it is concluded that 1,3-dimethylurea is a structure breaker for the open-packed structure in water, the ability being smaller than that of urea, and that, for the behavior of 1,3-diethylurea molecule in water, the structure-forming ability of the ethyl group is found to surpass the structure-breaking effect of the residual part of the molecule.

In the preceding paper[1] one of the authors reported the results of an ultrasonic study on aqueous solutions of urea, and stated from experimental grounds that urea behaves as a structure breaker for the "open-packed structure" or the "ice-like structure" in liquid water. Recently, H. S. Frank and coworker[2] have discussed the behavior of urea molecules in water and have concluded that urea is a structure breaker for water, based on a two state model of water,[3] which has been made clear

1) K. Arakawa and N. Takenaka, This Bulletin, **40**, 2739 (1967).

3) L. Hall, *Phys. Rev.*, **73**, 775 (1948).

by the authors[4] to be a useful model for thermodynamical behaviors of liquid water. Urea is well known as a typical reagent for the denaturation of protein.[5] The effect of the addition of urea in aqueous solutions of polymers is said to consist of two factors;[6] the direct interactions between polymer molecules and urea[7,8] and the influence upon the configuration of polymer molecules through the change of the structure of water caused by the addition of urea.[1,9]

We have studied the structure of water[4] and the influence of the various addends upon it.[1,10] It is interesting to investigate the behavior of alkyl-substituted urea in water in comparison with those of urea, aiming at the effect of alkyl-substitution, especially the change in the ability as structure breaker which is attributed to the introduction of alkyl group. We measured the ultrasonic velocity and absorption of aqueous solutions of alkyl urea.

The denaturation effect of Lysozyme by 1,3-dimethylurea has recently been investigated by Hamaguchi and Sasaki.[11] Concerning the influence of alkane molecules upon the structure of water, Wetlaufer *et al.* have studied the solubility of hydrocarbons in 7M urea and 4.9M guanidine hydrochloride solutions,[12] and appreciable differences have been observed between the behavior of methane and that of higher homologues. Thus we carried out an ultrasonic study of aqueous solutions of 1,3-dimethylurea and 1,3-diethylurea.

Experimental

An ultrasonic pulse method was used for the measurements of the sound velocity and of the absorption. The apparatus used and the procedure for the measurements were described in the preceding paper.[13] The absorption coefficient was determined over the fequency range of 15—45 Mc/sec and at temperatures from 10 to 40°C with 10°C intervals. The sound velocity was measured at 5 Mc/sec. The temperature was held constant to within ±0.1°C. The absorption data were reproducible within 2% and the velocity data within 1 m/sec. Two commercial samples, 1,3-dimethylurea*1 and 1,3-diethylurea,*2 were used without further purification. The melting points of the samples were 106.6 ±0.5°C and 103.8±0.5°C, respectively. The viscosity coefficient, η, was measured on the aqueous solutions by means of an Ostwald capillary viscometer (flow time for pure water 77.7 sec at 20°C). From the values of η the classical absorption (Stokes loss) was calculated.

Results

Ultrasonic Velocity. The results obtained for the aqueous solutions of 1,3-dimethylurea and of 1,3-diethylurea are plotted against temperature in Figs. 1(a) and (b), respectively. The sound velocity data obtained for pure water by Greenspan and Tschiegg[14] are also given. We see that the concentration dependence of the velocity *vs.* temperature curves is similar to that for urea solutions.[1]

Ultrasonic Absorption. The absorption coefficient, α, was measured for solutions of 1,3-dimethylurea in the concentration range, 0.2—4 mol/*l*, and for solutions of 1,3-diethylurea in the range, 0.5—2 mol/*l*. The frequency dependency of α is given

Concn., 1 mol/*l*

in Figs. 2(a) and (b) in the form of α/f^2 *vs.* $\log f$ relation, where f is frequency, for 2 mol/*l* solution of dimethyl urea and for 1 mol/*l* solution of diethyl urea, as examples. Both groups of curves are flat throughout the frequency range. This means that no relaxation frequency is observed.

In Figs. 3(a) and (b) the (α/f^2) *vs.* concentration curves are given for the solutions of dimethylurea and diethylurea, respectively. For solutions of diethylurea the magnitude of α/f^2 is seen to increase more rapidly than for solutions of dimethylurea with the increase in concentration. The (α/f^2) *vs.* concentration curves for aqueous solutions of urea, 1,3-dimethylurea, and 1,3-diethylurea at 20°C and 40°C are compared in Figs. 4(a) and (b). Concentrations are given in volume %. The dotted lines represent the magnitude of absorption,*3 which is attributed only to water as solvent when no structural change is assumed.

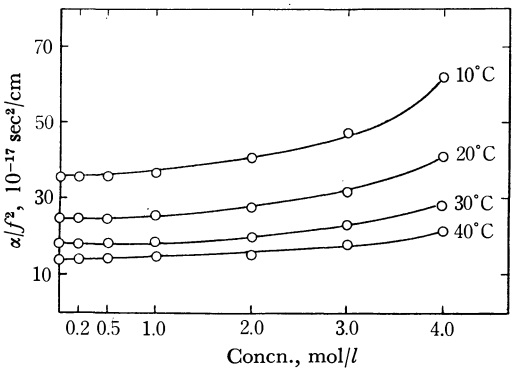

Fig. 3(a). α/f^2 *vs.* concn. relation 1,3-dimethylurea solution.

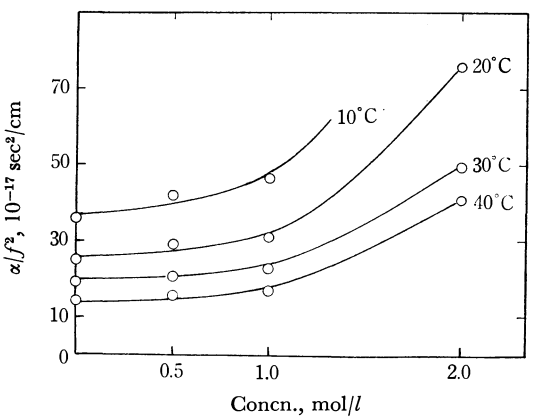

Fig. 3(b). α/f^2 *vs.* concn. relation 1,3-diethylurea solution.

In order to calculate the classical absorption $(\alpha/f^2)_\eta$, the viscosity coefficient η, was measured. The result is given in Fig. 5. The classical absorption is given by

$$(\alpha/f^2)_\eta = \frac{8\pi^2\eta}{3\rho V^3} \qquad (1)$$

*3 This is calculated according to the volume fraction of water as solvent from the absorption of pure water.

Discussion

The Influence of Solute Molecules upon the Structure of Liquid Water. Urea is known as hydrogen bond breaker. However, there is some ambiguity[15] about the behavior of urea in water. From recent studies by us[1] and by Hammes *et al.*,[9] it has been concluded that urea behaves as a structure breaker for the ice-like structure in liquid water. In the case of alkyl-substituted urea the situation is different, because, in addition to the effect of substitution of hydrogen attached to amino radical, the alkyl group is believed to cause iceberg-

15) M. Abu-Hamdiyyah, *J. Phys. Chem.*, **69**, 2720 (1965).

formation around it in water.[16,17] That is, alkyl-substituted urea has two opposite functions, *viz.*, as a structure breaker and as a structure former.

It is clearly seen from Figs. 6(a) and (b) that the magnitude of ultrasonic absorption due to structural relaxation becomes larger in the order 1,3-diethylurea > 1,3-dimethylurea > urea. As pointed out previously,[1] the absorption in urea solutions decreases with the addition of the solute to water, and becomes smaller than the absorption caused by water component only (shown by dotted curves as seen in Figs. 4(a) and (b)). It is similar in the case of structural absorption as seen in Figs. 6(a) and (b). This fact supports definitely the idea that the urea molecules behave as the structure breaker for the ice-like structure in liquid water. This also seems to be the case in 1,3-dimethylurea solutions. The absorption of the solution of 1,3-dimethylurea due to structural relaxation is nearly equal to that in the solutions of urea for a concentration less than about 10 vol%. The magnitude of $(\alpha/f^2)_{\text{struct.}}$ for dimethylurea solutions decreases first with the increase in concentration, and is nearly equal to or a little smaller than that shown by the dotted line for a concentration range of less than about 10 vol%. This behavior is similar essentially to that of urea solutions, though the features observed are not so striking. 1,3-Dimethylurea molecules may be said to act as the structure breaker for the ice-like structure in water, though that ability is supposed to be smaller than that of urea.

In the case of the 1,3-diethylurea solutions, the situations are definitely different. The structural absorption in the solution is found to be much larger than that in the dimethylurea solution within the whole range of concentration. The difference between diethylurea solutions and the other two solutions becomes appreciable in the range of concentration greater than 0.1 volume fraction. This difference is, of course, ascribed to the presence of ethyl groups in place of methyl groups. In order to investigate the change of ultrasonic absorption accompanying the increase in the number of carbon atoms in homologous series, the absorption data for various compounds are given in Table 1. No appreciable change of absorption is observed. It seems that the variation of ultrasonic absorption induced by the introduction of C_2H_5 group in place of CH_3 is not great. Therefore, from the absorption data given in Figs. 6(a) and (b), the fact that the absorption in diethylurea solutions is greater than that in dimethylurea solutions is explained by the structure-forming effect of C_2H_5 group in liquid water. This is in line with the suggestion given by Wetlaufer *et al.*,[12] based on the solubility data of hydrocarbons in urea and guanidine hydrochloride solutions. According to their data, an essential difference between CH_4 and C_2H_6 has been observed with respect to the interaction of alkane molecules with water around themselves. It has been suggested that, at temperatures above about 20°C, C_2H_6 molecules and those of higher homologues have a structure-forming effect upon water molecules around them, with the exception of CH_4. Thus we conclude that in the diethylurea solution the comparatively large absorption is attributed at least partly to the local water structure around C_2H_5 groups, and that the structure-forming effect of C_2H_5 groups may surpass the structure-breaking effect of residual groups in the diethylurea molecule.

Table 1. Ultrasonic absorption of various liquids

Summary and Conclusion

From the ultrasonic data obtained by means of a pulse technique, it is concluded that in the aqueous solution of 1,3-dimethylurea the solute molecules behave as a structure breaker for the ice-like structure in liquid water, though the structure-breaking ability is smaller than that of urea. For the aqueous solution of 1,3-diethylurea it may be said that the structure-forming ability of ethyl group surpasses the structure-breaking effect of the residual part in the solute molecule.

The authors wish to thank Mr. Nobuo Takenaka and Miss Yuko Endo for their cooperation in performing this study.

The Size and Shape of the Component Molecules as the Factors Determining the Electronic Structure of Crystal Complexes

Yoshio MATSUNAGA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo

(Received February 27, 1969)

The molecular complexes of six aromatic diamines with various acceptors were classified into those complexes having essentially non-bonding ground states and those having dative ground states on the basis of their vibrational spectra. A method to arrange the complexes by the difference between the ionization potential of the donor molecule and the electron affinity of the acceptor molecule was proposed to demonstrate how important the size and shape of the component molecules are as the factors determining the electronic structures of crystal complexes. The electrostatic energies per molecule in 1 : 1 crystal complexes were found to range from 2.3 to 2.6 eV.

On the basis of the electronic and vibrational spectra, it has been shown that most donor-acceptor crystal complexes can be rather sharply divided into two groups, namely, those having essentially non-bonding ground states and those having essentially dative ground states.[1,2] The complexes in the former group are often called as weak or non-ionic complexes and those in the latter group as strong or ionic complexes. In general, when the ionization potential of the donor molecule is low and the electron affinity of the acceptor molecule is high, the resulting complex tends to have a dative ground state. However, the formation of such a crystal complex must be governed not only by the energy needed to charge the molecules, but also by the electrostatic energy of the charged lattice. The latter quantity depends on the packing of the component ions, which in turn depends on the molecular size and on the shapes of the donor and the acceptor. The present work was started with the hope of demonstrating how important the molecular size and shape can be as factors determining the electronic structures of donor-acceptor crystal complexes.

The crystal complexes were characterized in the following way. If the vibrational spectrum of a complex is well approximated by a superposition of the spectra of the component compounds, the complex has a non-bonding ground state. There are slight shifts in frequency and some alternation of intensity, reflecting the molecular association; however, it is generally easy to point out the pattern due to each component.[3,4] When the vibrational spectrum consists of the spectra of the ionized components, namely, D^+ and A^- free-radical ions, the ground state of the complex is considered to be essentially dative. The difference in the vibrational spectrum between the D molecule and the D^+ ion or that between the A molecule and the A^- ion is generally so remarkable that the characterization of crystal complexes by their spectra is not difficult.[2]

The method of selecting the component compounds must be now mentioned. It is highly desirable to have component compounds of similar nature but with different molecular sizes and shapes. The following six aromatic diamines were thought to best fulfill these requirements: *N,N,N',N'*-tetramethyl-*p*-phenylenediamine (TMPD) (I), 1,6-diaminopyrene (II), *N,N,N',N'*-tetramethylbenzidine (III), diaminodurene (IV), 1,5-diaminonaphthalene (V), and *p*-phenylenediamine (VI). The donor I has the lowest ionization potential, and VI, the highest, among these compounds. Fortunately, even the latter is known to be able to form some authentic cation-radical salts with vibrational spectra comparable with those of the complexes. The donors II, III, and V represent diamines with pyrene, biphenyl, and naphthalene nuclei respectively. The donor IV, the ionization potential of which is presumably not far from that of I, was also included because of the higher stability of its crystal complexes. The acceptors must cover a range so wide that the diamine complexes with some acceptors have essentially non-bonding ground states, while those with some others have dative ground states. The following compounds were chosen: 2,3-dichloro-5,6-dicyano-*p*-benzoquinone (DDQ) (a), tetracyano-*p*-benzoquinodimethane (TCNQ) (b), tetracyanoethylene (TCNE) (c), 2,3-dicyano-α-naphthoquinone (d), 9-dicyanomethylene-2,4,7-trinitrofluorene (e), *p*-chloranil (f), *p*-fluoranil (g), 2,5-dichloro-*p*-benzoquinone (h), 2,4,7-

trinitrofluorenone (i), and dichloro-*p*-xyloquinone (j).

Experimental

All the crystal complexes were prepared by crystallization or by precipitation from solutions. The solvents used were mostly benzene and chloroform. The vibrational spectra in the NaCl region were recorded as Nujol mulls using a Hitachi EPI-S2 infrared spectrophotometer. The visible absorption spectra of systems containing combinations of appropriate amounts of the donors and acceptors dissolved in chloroform were measured with a Beckman DK2A spectrophotometer.

Results and Discussion

Earlier the present author discussed the ionic character and charge transfer in molecular complexes in terms of the electronegativity of the highest occupied orbital of the donor molecule and that of the lowest vacant orbital of the acceptor molecule.[5] The condition;

$$\varepsilon_i < (I_D - A_A)/2 \qquad (1)$$

was obtained in the case where the charge on each molecule, ρ, in a 1:1 crystal complex is less than one half and:

$$\varepsilon_i > (I_D - A_A)/2 \qquad (2)$$

in the case where $\rho > 1/2$. Here, ε_i is the electrostatic energy per molecule when there is a unit positive or negative charge on each molecule, I_D is the ionization potential of the donor molecule, and A_A is the electron affinity of the acceptor molecule. It is apparent that the condition (1) is fulfilled in complexes having essentially non-bonding ground states and the condition (2), in those complexes with essentially dative ground states.

If one could arrange complexes placing the ionization potentials of donors on the abscissa and the electron affinities of acceptors on the ordinate, lines with a slope of -1 would become the scale for $I_D - A_A$. Such an arrangement of complexes seems to be convenient for demonstrating how the electrostatic energy, ε_i, can vary with the kind of component molecules. Unfortunately, the ionization potentials and the electron affinities are not available in the desired accuracy.

The energy of the charge-transfer absorption, $h\nu_{CT}$, in a 1:1 single complex with an essentially non-bonding ground state may be given by:

$$h\nu_{CT} = I_D - A_A - C + W + R + R', \qquad (3)$$

where C is the electrostatic energy in the dative bond structure, W is the energy due to van der Waals interaction in the no-bond structure, and R and R' are the energy changes due to the resonance interaction between these two structures in the ground and excited states respectively.[6] In a series of complexes of a given acceptor with various donors, when A_A is constant, it has been well established that a plot of $h\nu_{CT}$ against I_D yields a straight line. Therefore, $C - W - R - R'$ is a relatively insensitive function of the donor, and one may write as a good approximation;[7]

$$h\nu_{CT} \fallingdotseq I_D - A_A - C'. \qquad (4)$$

Here the electrostatic energy, C, in Eq. (3) is supposed to make the major contribution to the term C'. The energy of charge-transfer absorptions in complexes of a given donor with various acceptors may also be approximated by Eq. (4). Consequently, the energy of the charge-transfer absorption in the *s*-trinitrobenzene complex, X, measured in a chloroform solution was taken in this experiment as a measure of the ionization potential, and that in the pyrene complex, Y, as a measure of the electron affinity. The complexes on line of $Y = -X +$ constant in Fig. 1 must all exhibit charge-transfer absorptions at nearly the same energy. For example, the upper line corresponds to an energy of 15kK, and

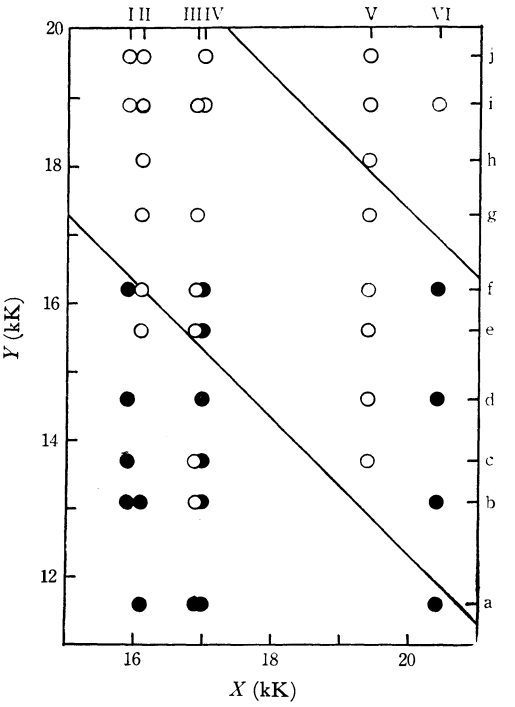

Fig. 1. Electronic structures of molecular complexes as revealed by the vibrational spectra. The complexes having non-bonding ground states are indicated by open circles and those having dative ground states by shaded circles. As to notations I—VI, a—f, and X and Y, see text.

the lower one, to 10 kK. To check the validity of this diagram, the energies of charge-transfer absorptions observed in a solution for possible combinations of the donors I—VI and the acceptors a—j were plotted against the energies read on the diagram. As Fig. 2 shows, the agreement is generally excellent.

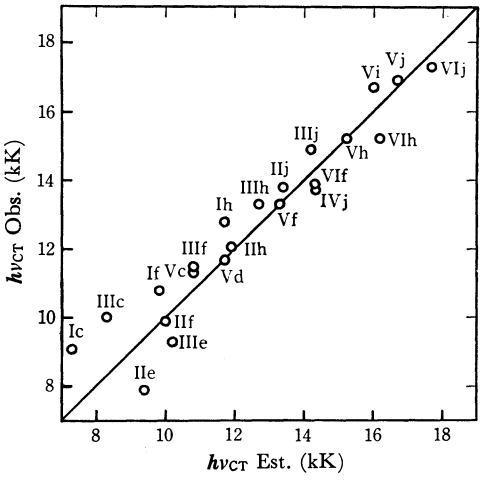

Fig. 2. Comparison between the observed energies of charge-transfer bands measured in solutions and the energies estimated by Fig. 1.

In Fig. 1 the complexes which were found to have essentially non-bonding ground states are indicated by open circles, and those found to have dative ground states, by shaded circles. The data for the DDQ (a) and *p*-chloranil (f) complexes were taken from the author's previous papers.[2,8] The independent characterization of some TCNQ (b) complexes is available in the literature.[9-11] Foster and Thomson have examined the visible absorption spectra of a number of TMPD (I) complexes and suggested that ionization by the complete transfer of an electron from the donor to the acceptor molecule occurs in the ground state of those complexes with several acceptors, including a, b, c, f, and h.[1] The present characterization by vibrational spectra is almost entirely consistent with theirs. Attempts to prepare well-defined complexes were not successful for the combinations missing from this figure. As expected, most of the complexes in the region where both X and Y are high are expressed by open circles, and those in the region where both X and Y are low, by shaded circles.

However, there are many exceptions which reflect the effects of the size and shape of component molecules on the electronic structure of the crystal complexes. Among these, *p*-phenylenediamine (VI), which is supposed to have the highest ionization potential, shows a strong tendency to form complexes with dative ground states, *e. g.*, the complex VIf. On the other hand, the tetramethylbenzidine (III) complexes tend to have non-bonding ground states in spite of the low ionization potential of the donor, *e. g.*, the complex IIIb. The difference in ε_i between these two extremes can be estimated using the following relations;

$$\varepsilon_i(\mathrm{VIf}) > [I_D(\mathrm{VI}) - A_A(\mathrm{f})]/2 \fallingdotseq [h\nu_{CT}(\mathrm{VIf}) + C']/2$$
$$\varepsilon_i(\mathrm{IIIb}) < [I_D(\mathrm{III}) - A_A(\mathrm{b})]/2 \fallingdotseq [h\nu_{CT}(\mathrm{IIIb}) + C']/2.$$

Although the crystal complex VIf has a dative ground state, the energy, $h\nu_{CT}$ (VIf), in the complex in solution can be measured using suitable solvents, or the value may be estimated by Fig. 1. Hence;

$$\varepsilon_i(\mathrm{VIf}) - \varepsilon_i(\mathrm{IIIb}) > [h\nu_{CT}(\mathrm{VIf}) - h\nu_{CT}(\mathrm{IIIb})]/2$$
$$= 3.3\,\mathrm{kK} \text{ or } 0.41\,\mathrm{eV}$$

Judging from the results presented in Fig. 1, this difference may be considered to be close to the maximum variation of ε_i.

One might feel that this difference is merely imaginary because, in the process of the estimation of ε_i, a possible change in the term C' in Eq. (4) was not taken into consideration at all. As will be discussed in the following paragraph, the electrostatic term in an ion pair in which the components are different in size and shape is generally smaller than that in which both the components are derivatives of benzene. If the doners to be compared are such as III and VI, the difference in X may be predicted to be smaller than that in I_D. Therefore, the above-mentioned value for ε_i (VIf) $-\varepsilon_i$ (IIIb) is rather underestimated.

It is very desirable to know even roughly how large ε_i itself can be. Taking the ionization potential of pyrene as 7.72 eV,[12] the following values were estimated by Eq. (4) using the energies of charge-transfer absorptions in the *s*-trinitrobenzene complexes; 7.0 eV for donor III and 7.5 eV for VI. The electron affinities were assumed to be 2.5 eV for the acceptor b and 2.2 eV for f following the discussion presented in a preceding paper.[5] Then, ε_i (VIf) $>$ 2.6 eV and ε_i (IIIb) $<$ 2.3 eV were obtained. Considering the uncertainties mentioned above, one may conclude that ε_i is of the order of magnitude of 2 eV. The electrostatic energy per molecule in a crystal, ε_i, is obtained by multiplying the Madelung constant by the electrostatic energy per molecule in an ion pair, C, in which the relative configuration is supposed to be kept the same.

This assumption does not seem to be strictly realized; however, the change in ε_t by the kind of component molecule may be nearly parallel to the corresponding change in C. The values of C were computed for combinations of benzene ion and three other hydrocarbon ions, locating a fractional point charge on each carbon atom. The charge distribution are those given by the Hückel MO theory. The molecular planes were assumed to be parallel to each other and to be separated by 3.40 Å. The results are presented in Fig. 3.

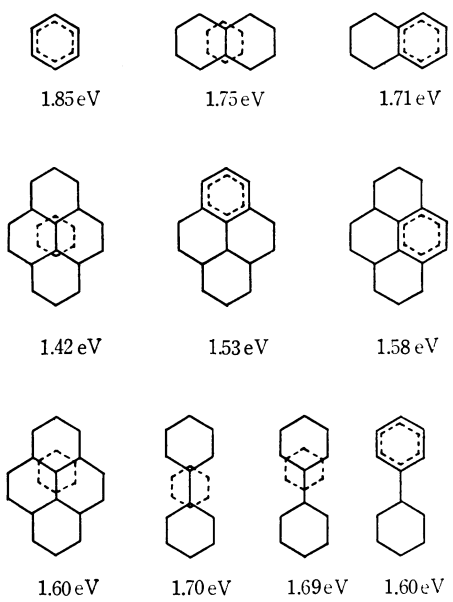

Fig. 3. The electrostatic energies per molecule in ion pairs consisting of aromatic hydrocarbon ions with a separation of 3.40 Å. All the C-C bonds were assumed to be 1.40 Å long.

The larger the difference in molecular size and shape, the smaller the electrostatic energy, C; therefore, one may expect a greater probability of finding complexes with non-bonding ground states. Although the component compounds used in the present work are not as simple as the hydrocarbons, the prediction is in fairly good agreement with the observed trends shown in Fig. 1. Assuming 1.85 eV for C in the complex VIf and 1.66 eV for C in the complex IIId, the Madelung constants were found in the range from 1.35 to 1.40. It may be worthwhile to note that these values are almost equal to the constant for a one-dimensional ionic lattice.

Most of the quinone complexes with electrical resistivities of 10^6 ohm cm or less were reported to have dative ground states. The only exceptions occurred in the case of 1,6-diaminopyrene-*p*-chloranil (IIf) and related molecular complexes.[8] On the basis of the results presented in Fig. 1, one may conclude that the complex IIf is located near the border line between 1,6-diaminopyrene complexes with non-bonding ground states and those with dative ground states. Furthermore, it has been established that the complex crystallized from benzene can be easily transformed into a new form exhibiting only a few ohm cm. The vibrational spectra indicated that, in this form, the electronic structure of the complex itself is intermediate between no-bond and dative.[13] The tetramethylbenzidine-*p*-chloranil (IIIf), which exhibits a resistivity of 10^6 ohm cm, is located near the 1,6-diaminopyrene complex. Thus, complexes with non-bonding ground states seem to exhibit relatively low resistivities only when the charge-transfer absorptions are in an exceptionally low-energy region. To prepare such complexes, the use of component compounds with a biphenyl or pyrene nucleus may be of great advantage. Attempts in this direction are now in progress.

The author wishes to express his thanks to Professor Hiroaki Baba of the Research Institute of Applied Electricity for the use of the Hitachi EPI-S2 infrared spectrophotometer, to Mr. Yoichi Iida for his help in the computation of the electrostatic energies presented in Fig. 3, and to Mr. Nobuhiko Miyajima for recording the infrared spectra.

Effects of Metallic Surfaces on the Thermal Decomposition of Ethane

Yoshiyuki NISHIYAMA

Chemical Research Institute of Non-Aqueous Solutions, Tohoku University, Sendai

(Received February 27, 1969)

The thermal decomposition of ethane was conducted in a static system at 700°C, using a silica vessel packed with a sheet of metal. Various sorts of metals were tested. The rate of ethylene formation decreased notably in the presence of metals as compared with the rate in an unpacked vessel, the decrease being larger at lower pressures. The activity of metals to reduce the rate was in order: Zr>Ti>Fe>Cu>W,Ag>Pt,Mo. The rate of methane formation did not change with the packing of metals. The main reactions were assumed to be radical reactions in the gas phase. From the observed order of reaction, it was concluded that the action of metal is to catalyze the recombination of hydrogen atoms and therefore to terminate the radical-chain reactions. A similar action was noted in hydrogen dissolved in a titanium sheet.

A metallic surface placed in hydrocarbon gases at a high temperature may catalyze the decomposition of the hydrocarbon on the surface. There is also another aspect of influence, which is the subject of the present report, *i. e.*, the metal surface may alter the rate of radical reactions in the gas phase by taking part in the formation and the quenching of radicals. This type of catalytic behavior of the reactor wall was first suggested by Rice and Herzfeld.[1] Laidler and Wojciechowski[2] attributed the change in the reaction order of ethane decomposition by the increase of the surface-to-volume ratio of quartz reactors to the termination process at the wall. Marshall and Quinn[3] made a kinetic analysis of ethane decomposition, assuming that homogeneous quadratic and heterogeneous linear termination occur simultaneously. The dependence of the rate of propane decomposition on the nature and the area of the surface was shown by Voevodsky.[4] However, no metallic surface seems to have been examined, so the present investigation was undertaken in order to clarify whether metals accelerate or retard the decomposition and to correlate the observed effects with the nature of the surface.

Experimental

Apparatus. The decomposition was carried out by a static method using a silica reaction vessel (shown in Fig. 1), which had a volume of 8.6 cc and an effective surface area of 31.6 cm². To see the effect of the metal, sheets of various metals, rectangular in shape and 0.1 mm thick, were bent and packed in turn into the vessel. Three different sizes of sheets were used: S-1, 1.0×7.0 cm²; S-2, 2.0×7.0 cm², and S-3, 4.0×7.0 cm². The packed states of the sheets are illustrated in Fig. 1. The packing of a silica plate was used for comparison. The reaction vessel was placed in an electric furnace and was maintained at 700±2°C for whole runs.

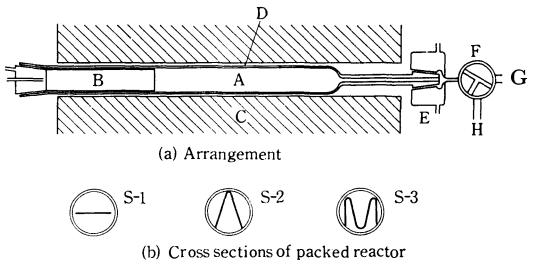

Fig. 1. Reaction vessel.

A: space for reaction, B: silica plug to exclude the space in temperature gradient, C: electric furnace, D: thermocouple, E: water-cooled joint, F: switching valve, G: piping connected to reservoir, H: piping connected to expansion bulb.

Materials. A research-grade ethane (>99.7%) was frozen in liquid air, and the non-condensable gases were removed by evacuation; then the ethane was evaporated slowly to leave the heavier impurities and was led into a reservoir. The metals used were obtained from commercial sources and were at least 99.9% pure, with the exception of titanium (99.3%). The pretreatment of metals will be individually described below.

Procedure. After the evacuation of the reaction vessel, ethane was introduced into the vessel and the pressure was equilibrated with that of the reservoir. This pressure will be referred to as the initial pressure of ethane, p_0. The reaction was stopped by expanding the gas in the reaction vessel into a pre-evacuated bulb

(320 cc), and then the product was compressed by the use of a Teopler pump into the sampling tube of the gas chromatograph and analyzed.

Four to eight runs were made at the same pressure of ethane. The reaction time was usually 2 to 10 sec, and less than 20% of the ethane was decomposed. The gas chromatograph was equipped with 1.5 m of an active alumina column at 30°C; helium was used as the carrier, and the amounts of hydrogen, methane, ethane, and ethylene were determined quantitatively.

Results

Main Course of Reaction. The gaseous products were composed of nearly equal moles of ethylene and hydrogen, a small amount of methane (4 to 10% of ethylene), and unreacted ethane. In the cases of titanium or zirconium packing, the yield of hydrogen was somewhat less than that of ethylene, perhaps because of the dissolution of hydrogen into the metal. Also, the weight of these metals increased slightly, indicating that about 4% of the reacted ethane was fixed in a form of carbide. As the rate of the carbide formation of these metals with ethane is no less than that with ethylene,[5] the surface decomposition may be supposed not to disturb the gaseous-product distribution. In the other metals, no measurable change in the weight was observed and a lustrous appearance was retained. From these facts and from a tendency of the results described below which seems reasonable, it was assumed that the course of the decomposition in the gas phase in the presence of metal surface was similar to that reported for the reaction in silica vessels, at least so far as the initial rates were concerned.

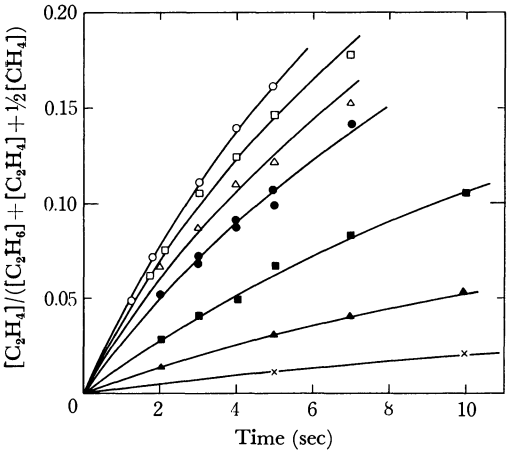

Fig. 2. Ethylene yield against time, in the presence of iron (S-2).
The p_0 values are: ○ 425, □ 288, △ 213, ● 153, ■ 73, ▲ 39, × 19 mmHg

The ethylene yield-time curve for each p_0 was similar to the reported pattern.[2] Typical plots are shown in Fig. 2. From the initial slope of the plots in Fig. 2, the initial rate of ethylene formation, r_0, was determined.[6] The initial rate of methane formation, r_0', was obtained in a similar manner. The rates so obtained have a probable error of about 10%, which is allowable for the present purposes.

Rate of Ethylene Formation. The rate of ethylene formation in the silica vessel is plotted against p_0 in the logarithmic scale in Fig. 3. This shows that the reaction is nearly first order with respect to ethane at higher pressures and 3/2 at

lower pressures, and that the order is altered slightly by the increase in the surface area, though the reaction rate is reduced somewhat.

The results for the cases of packing with iron sheets are shown in Fig. 4. Before use, the packed sheets were normally heated in 200 mmHg of hydrogen at 700°C for 30 min in order to reduce the oxidized surfaces. The same treatment was repeated frequently between the decomposition runs to keep the surface clean. A few runs were carried out using an iron sheet which had not been treated with hydrogen, but they showed essentially the same trend. The rate was decreased markedly by the packing of iron, and the order of reaction was 2 to 5/2 at 50 mmHg, the larger order for the larger sheet.

A check was made on the surface roughness by using an iron sheet abraded by Emery paper (#1). The results show a more pronounced decrease in the rate.

The titanium sheets were normally used without hydrogen treatment, for this is irrelevant to the reduction of oxide. The effect of hydrogen was tested by using titanium sheets packed in the reaction vessel and equilibrated with about 300 mmHg of hydrogen at 700°C (110 cc STP/g was absorbed). After this, the vessel was evacuated for 5 min and ethane decomposition conducted as usual.

The packing of titanium exerted an influence on the rate similar to that of iron, as is shown in Fig. 5, but the effect was more remarkable. The reaction order at 50 mmHg was from 2.1 to 3.0. It is interesting to note that titanium with dissolved hydrogen behaved as if the area of the sheet had been enlarged.

Various metals with the same dimensions are compared in Fig. 6. All the metals had smooth surfaces, and copper, silver, and platinum were treated with hydrogen, as iron had been. In every case, the rate was more or less reduced and the activity was in the order: Zr>Ti>Fe>Cu>W≅Ag>Pt≅Mo.

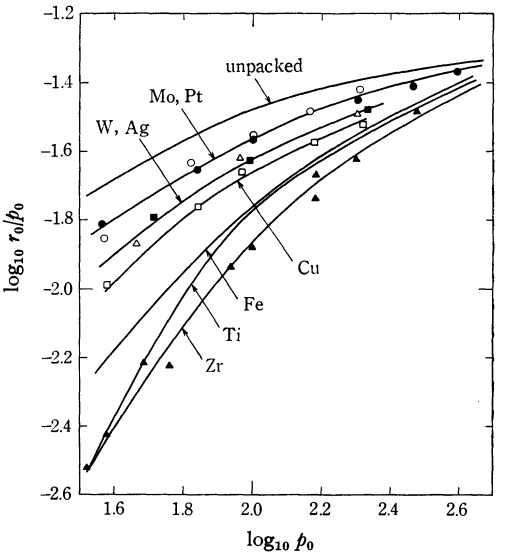

Fig. 6. Comparison of metals.
▲ Zr, □ Cu, △ W, ■ Ag, ○ Mo, ● Pt; S-2 for each

Rate of Methane Formation. The rates of methane formation in several cases are shown in Fig. 7. This figure indicates that the rates are only slightly affected by the presences of metallic surfaces, in contrast to the simultaneous large variation in the rate of ethylene formation. The reaction order was approximately 3/2 at higher pressures and increased to about 2 as the pressure was reduced.

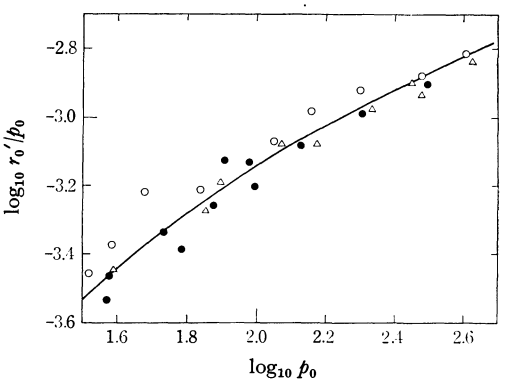

Fig. 7. Rate of methane formation.
○ unpacked, △ packed with iron S-2, ● Packed with titanium S-2 with dissolved hydrogen

Discussion

Kinetic Consideration of the Reaction Order. The thermal decomposition of ethane in the gas phase is usually explained on the basis of the radical mechanism as follows:

$$C_2H_6 \rightarrow 2CH_3\cdot \quad (1)$$

$$CH_3\cdot + C_2H_6 \rightarrow CH_4 + C_2H_5\cdot \quad (2)$$

$$C_2H_5\cdot \rightarrow C_2H_4 + H\cdot \quad (3)$$

$$H\cdot + C_2H_6 \rightarrow H_2 + C_2H_5\cdot \quad (4)$$

$$C_2H_5\cdot + C_2H_5\cdot \rightarrow C_4H_{10} \text{ or } C_2H_6 + C_2H_4. \quad (5)$$

The rate of methane formation is said to be a measure of the initiation step.[7] The order of this reaction was from 3/2 to 2 under the present condition; this order is in accord with the pressure-dependent nature of reaction (1).[7-9] The secondary production of methane from ethylene was noted in some cases,[10-12] but this is less important at present, for the rate of methane formation differed little among the cases in which the rate of ethylene formation differed remarkably.

The order of the decomposition of the ethyl radical is said to change from 1 to 3/2 as the pressure is reduced.[8,13] For the termination, the following processes involving hydrogen atoms were taken into account in addition to (5):

$$H\cdot + C_2H_5\cdot \rightarrow C_2H_6 \quad (6)$$

$$H\cdot + H\cdot \rightarrow H_2 \quad \text{(2nd order)} \quad (7)$$

$$H\cdot \rightarrow H_{ad} \text{ or } {}^1/_2\, H_2. \quad \text{(1st order)} \quad (8)$$

The reaction (6) is said to be quite slow in the gas phase.[8,14] The step (7) corresponds to a situation in which concentration of adsorbed hydrogen on the metal surface is relatively small and is in equilibrium with that in the gas phase. The step (8) reflects the situation either when the surface coverage of the adsorbed hydrogen is near unity and the recombination of hydrogen atoms occurs in the Rideal mechanism, or when every hydrogen atom is trapped by the surface when it collides.

For each case, the order of ethylene formation with respect to ethane was calculated, assuming the predominance of a particular termination step; the results are tabulated in Table 1.

Table 1. Calculated reaction order

Order of (1)	Order of (3)	Overall order for termination by (5)	(6)	(7)	(8)
3/2	1	3/4	5/4	7/4	5/2
3/2	3/2	5/4	3/2	7/4	5/2

2	3/2	3/2	7/4	2	3

The involvement of hydrogen in the termination increases the reaction order, as has been supposed by Marshall and Quinn[3] and others.[8,13] The present results seem to show clearly the contribution of hydrogen in termination. The highest order observed was 3 for titanium packing at lower pressures; it can be explained by the linear termination of hydrogen atoms. At higher pressures, termination by (6) seems to predominate. The order in the presence of iron indicates that the recombination of hydrogen is between linear and quadratic concentration dependence.

Other Possible Contributions of Metals. There is a possibility that the metallic wall initiates the radical chain. However, methyl radical formation seems not to occur on metal surfaces, as the rate of methane formation is scarcely affected by metals. Another mode of initiation might be the inverse step of (6), but this could play a role only at a very early stage of the decomposition, since the radical concentrations at the steady state favor recombination.

Also, the heterogeneous dehydrogenation of ethane might take place to some extent. However, at present this cannot be discriminated from homogeneous processes, as metallic surfaces exerted a stronger influence on termination, resulting in a reduction of the overall rate over the entire pressure range.

Effects of the Nature of the Surfaces. If the above explanation is correct, the negative catalytic activity of metals might have a close correlation with that of the recombination of hydrogen atoms in a hydrogen atmosphere. However, this activity would depend on the state of the surface. For a quantitative comparison, it is necessary to define the geometry of packing and to ascertain the rate of diffusion of each component. The metal surfaces in the present experiment were by no means clean and the crystallographic characteristics were not defined, so only a qualitative discussion is possible here. In spite of these imperfections, the present trend among metals seems reasonable and is, though only partly, in accord with that reported by Wood and Wise;[15] *i. e.*, the catalytic activity of metals for hydrogen-atom recombination is roughly in the order: Ti>(Ni)>

Cu>W>Pt. The packing of a nickel sheet was attempted in this study, but the reaction rate varied considerably from run to run, so it was impossible to determine the rate with the desired precision. Roughly speaking, however, the effect of nickel was in the same range as that of iron. The accordance except in the case of nickel seems to indicate that the catalytic action of metals for hydrogen recombination is relatively insensitive to the adsorbed hydrocarbons. The weak activity of molybdenum may be associated with the weak interaction of this with hydrogen.[16]

The above trend holds only for metals of similar appearance; alteration of the surface state by abrasion changed the activity, as is usual in catalysis.

The action of hydrogen dissolved in titanium can be interpreted by assuming that hydrogen atoms emerging from bulk metal combine much more easily with hydrogen from the gas phase. The enhanced activities of dissolved hydrogen were noted in the the recombination of hydrogen atoms[15] and in other reactions, for example, in the dehydrogenation of cyclohexane.[17]

The author is grateful to Professor Yasukatsu Tamai for his helpful discussions and encouragement.

The Effects of Tetraalkylammonium Salts on the Structure and the Temperature of the Maximum Density of Water

Goro WADA and Masako MIURA

Department of Chemistry, Nara Women's University, Nara

(Received March 1, 1969)

The effects of the tetraalkylammonium halides on the temperature of the maximum density of water were measured by means of dilatometry. Contrary to the expectation that the hydrophobic nature of the alkyl radicals would elevate the temperature of the maximum density of water, these salts lowered it, as other, more usual salts do, obeying the Despretz rule. Among the salts represented as R_4NBr, where R is either H or an *n*-alkyl radical, the Despretz constant, k_D, increases in the sequence: $H < CH_3 < C_2H_5 < n\text{-}C_3H_7 \ll n\text{-}C_4H_9$, while the deviation of k_D from k, which is a hypothetical constant of the ideal mixing where there is no interaction between the solute and the solvent, varies in the following sequence: $H \simeq CH_3 \simeq C_2H_5 \simeq n\text{-}C_3H_7 \ll n\text{-}C_4H_9$. The latter fact is attributable to the specific occurrence of a clathrate-like structure formed in the aqueous solution, only when R is $n\text{-}C_4H_9$. This is in accordance with another peculiarity of $(n\text{-}C_4H_9)_4NBr$ which shows a minimum in its partial molar volume at a certain concentration in water.

The phenomenon of the maximum density exhibited by water at 3.98°C under an atmospheric pressure is affected by the addition of a small amount of an electrolyte to it; this is in obedience to the Despretz rule,[1] which states that the lowering of the temperature of the maximum density (abbreviated as TMD) of water caused by a solute is linear with respect to its concentration. The rule has been almost uniformly confirmed by previous measurements of various electrolytes.[2] Recently, however, some alcohols, most markedly *t*-butyl alcohol, have been found to be in contradiction to the rule; their TMD is even elevated at dilute concentrations.[3] These observations have been interpreted as being attributable to the structure-promoting nature of the hydrophobic alkyl radicals bonded with the hydrophilic hydroxyl radical.

The present work has been undertaken in order to see how the tetraalkylammonium ions affect the TMD of water as the kind of the alkyl radicals is varied. As has been the recent trend, the characteristic properties of aqueous solutions of several

tetraalkylammonium salts have been investigated from various points of view——the partial molar volumes,[4-10] the adiabatic compressibilities,[4,6] the transport properties,[11-14] the heats of dilution,[15] the solubilities,[16,17] the near-infrared spectra,[18] and the association equilibria.[19,20] According to their experimental results, the alkyl radicals generally interact with water molecules, with a structure-promoting tendency through the hydrophobic bonds, which sometimes leads to the formation of a clathrate-like structure around the solute ions. Simply judging from the fact that the structure-breaking nature of ions lowered the TMD of water, as in the case of simple ions,[2] while, on the contrary, the structure-promoting nature of the hydrophobic radicals in non-electrolytes elevated it, as in the case of some alcohols,[3] one might expect a slight elevation of the TMD by tetraalkylammonium ions. However, this was not found to be the case, as will be described below.

Experimental

Materials. The crystals used were of a guaranteed reagent grade and were obtained from the Tokyo Kasei Kogyo Co., Ltd., Tokyo, or from the Nakarai Chemicals, Ltd., Kyoto. Commercial NaSCN, NH_4Br, $(CH_3)_4NBr$, $(C_2H_5)_4NBr$, and $(C_2H_5)_4NI$ were recrystalized from water, $(n\text{-}C_3H_7)_4NI$, from ethanol, and $(n\text{-}C_4H_9)_4NBr$, from ethyl acetate. Pure water was prepared by repeating twice the cycles of treatment with ion-exchange resin and distillation.

Procedure. The TMD values of solutions were determined by the use of a dilatometer especially made for the present purpose; it had a capacity of about 300 m*l*, thus enabling us to detect a volume change of 3×10^{-5}%, as has been described in detail elsewhere.[3]

The thermal expansion coefficients, α, and the molar volumes at 0°C, V_{S_0}, of the salts were determined by measuring the volumes of the crystals at various temperatures. In order to do that, a specific gravity bottle with a ground-in perforated glass stopper was used. In it a weighed amount of the crystal was put, after

which it was filled with an inert liquid, such as toluene or cyclohexane. The bottle was filled with the liquid under reduced pressure to prevent bubbles from being occluded in the small openings between the pieces of the crystal. The temperature variation of the molar volumes in the temperature range of about 2—25°C was linear and gave the α from the slope and the V_{S_0} from the intercept at 0°C, as calculated by the method of the least squares.

Results and Discussion

The observed shifts in the TMD from 3.98°C, ΔT, at various concentrations expressed in mole fractions, x, are listed in Table 1. Some of them agree well with the data appearing in the literature.[21,22] The good linear relationships between ΔT and x

for the individual salts may be seen in Fig. 1. Therefore, the Despretz constant, k_D, may be defined empirically as:

$$\Delta T = -k_D x \tag{1}$$

Its values for the salts are shown in Table 2.

When it is assumed that there is no interaction between the ions and the solvent molecules, and that, consequently, the resultant volume after the solute and the solvent have been mixed is the algebraic sum of the volumes of the components, the ideal depression of the TMD, ΔT_n, may be expressed as follows:[3]

$$\Delta T_n = -\frac{x}{1-x}\frac{\alpha}{2\beta}\frac{V_{S_0}}{V_{W_m}} \tag{2}$$

where V_{W_m} is the molar volume of water at 3.98°C, 18.016 ml/mol, and where β is also a constant, 7.80×10^{-6} deg^{-2}, related to the thermal expansion of water near the TMD, as defined by the equation:

$$V_W = V_{W_m}\{1+\beta(\theta-3.98)^2\} \tag{3}$$

in which θ is the temperature in Celsius. This equation is only applicable at temperatures close to the TMD of water. According to Eq. (2), ΔT_n is approximately linear with respect to x, with a proportional constant of $k=(\alpha/2\beta)(V_{S_0}/V_{W_m})$ at concentrations so dilute that $1-x$ can be regarded as being equal to unity. Then, the following relationship can be established:

$$\Delta T_n = -kx \tag{4}$$

For the calculation of k's, the values of α and V_{S_0}, tabulated in Table 2, are necessary.

Generally, the observed k_D and the calculated k do not coincide with each other; rather, the former predominates over the latter. Therefore, the difference between them, $\Delta k=k_D-k$ (shown in the last column of Table 2), is a useful clue for any discussion of the discrepancy from the ideal mixing.

In the present work, since experimental data on $(n\text{-}C_3H_7)_4NBr$ are lacking because of the difficulty of purifying it, $(n\text{-}C_3H_7)_4NI$ was used instead, with $(C_2H_5)_4NI$ as a reference.

TABLE 3. COMAPRISON OF THE VALUES OF k_D BETWEEN BROMIDES AND IODIDES

Cation	Br^-	I^-	Diff (I^-–Br^-)
Li^+ [2]	390	460	70
Na^+ [2]	820	950	130
K^+ [2]	740	860	120
$(C_2H_5)_4N^+$	596	726	130

Table 3 lists the values of k_D for the bromides and iodides of several common cations; it indicates that the differences between the bromides and iodides are almost constant unless the size of the cation is extremely small.

Because of this additive nature of ions, the k_D of $(n\text{-}C_3H_7)_4NBr$ can be roughly estimated as is shown in the parentheses in Table 2. The k value for the same salt can also be estimated by simply assuming that it may come in the middle between those for $(C_2H_5)_4NBr$ and $(n\text{-}C_4H_9)_4NBr$. Consequently, its Δk may be supposed to be approximately 400.

A survey of the Δk values of tetraalkylammonium bromides (R_4NBr) in Table 2 will show that Δk does not vary greatly so long as R corresponds to either H, CH_3, C_2H_5, or $n\text{-}C_3H_7$, but that it suddenly doubles when R is altered to $n\text{-}C_4H_9$.

According to the general tendency already found in the cases of simple salts, Δk is always positive and is larger for the stronger structure-breakers or for the weaker structure-formers. Water is considered to be an equilibrium mixture between the molecules of an ice-like structure (iceberg) and of a structure without hydrogen bondings.[23] When the ice-like structure is destroyed by ions, the TMD of water must be lowered to a larger extent than could be expected on the basis of k; this corresponds to the transition of the ice-like structure to a more packed one, because the water in the ice-like structure has a larger molar volume than otherwise. Since the alkyl radicals have a hydrophobic nature, and, since, therefore, they may be considered to promote the ice-like structure around them, the Δk's for tetraalkylammonium bromides have been expected to be negative, much as *t*-butyl alcohol really behaves.[3] However the facts found here are quite contrary to this expectation.

Among many tetraalkylammonium salts, only some tetra-*n*-butyl-ammonium salts are known to form clathrate hydrate crystals, such as $(n\text{-}C_4H_9)_4NBr\cdot 32.8H_2O$ and $(n\text{-}C_4H_9)_4N\text{-}C_6H_5COO\cdot 39.5H_2O$, in which the four $n\text{-}C_4H_9$ radicals are wrapped in individual polyhedral cages composed of water molecules and in which the nitrogen atom of the ammonium is located at the point of contact of these four cages.[24] Alkyl radicals smaller than the *n*-butyl do not form such clathrates because they are too small in comparison with the cage.

When the partial molar volumes of $(n\text{-}C_4H_9)_4NBr$ in its aqueous solutions are plotted against the square root of the concentrations, the curve exhibits a minimum value at the concentration of about 1 mol/*l*. The ratio of the number of moles of the solute to that of the solvent at this concentration corresponds to $(n\text{-}C_4H_9)_4NBr\cdot(60\pm 10)H_2O$.[25] In the cases of other simpler salts, no phenomenon like this is seen; in such cases there are only the monotonous curves of the partial molar volumes *vs.* the square root of the concentration approximately obeying the Debye-Hückel law.[26,27]

Therefore, the characteristic behavior of $(n\text{-}C_4H_9)_4NBr$ in exhibiting both an extraordinarily large value in Δk and a minimum value in the partial molar volume in aqueous solutions might be closely related to the fact that $(n\text{-}C_4H_9)_4NBr$ is the only one among the tetraalkylammonium bromides used that forms the clathrate hydrate. The number of water molecules involved in the clathrate-like structure in solution at the concentration of the minimum partial molar volume is approximately twice as many as in the crystal. Although the clathrate-like structure of $(n\text{-}C_4H_9)_4NBr$ in water is, therefore, in a less-established order than in the crystalline state, the water molecules around the $n\text{-}C_4H_9$ radicals are more ordered and more effectively packed than in the free water, similarly as the structure-breaking ions break the bulky, ice-like structure up into a more packed one. However, one important difference between the shrinks of the volumes due to the formation of the clathrate-like structure and to the destruction by the structure-breaking ions is that the former is accompanied by an increased order, but the latter, by an increased disorder.

The chemical shifts in the NMR signals due to the protons in the water molecules caused by the structure-promoting ions are usually negative, while they are positive upon the disappearance of the hydrogen bonds caused by the structure-breaking ions. The observed chemical shifts caused by the tetraalkylammonium ions are, on the contrary, positive, as if they were weak structure-breakers.[28] The tetraalkylammonium ions are large enough for them to be a likely kind of structure-breaker. However, the hydrophobic nature of the alkyl radicals must promote the structure around the ions by the so-called hydrophobic bonds.[29] This contradiction can be clearly interpreted by the fact that the covalent character of the hydrogen bonds in water causes a chemical shift towards a higher applied field of the water-proton resonance, as has been revealed by the measurements of the sodium alkyl sulfate solutions.[30]

Thus, in summary, the phenomena observed on the shifts in the TMD by the tetraalkylammonium ions may be said to be affected by three factors. First, the tetraalkylammonium ions are ions of such

large radii that they behave like structure-breakers, making k_D larger than k. Second, the alkyl radicals are hydrophobic and so are likely to have the effect of depressing k_D. Third, only the tetra-*n*-butylammonium ion specifically serves to form a clathrate-like structure, a structure which makes the apparent partial molar volume of water smaller; consequently, the k_D of $(n\text{-}C_4H_9)_4NBr$ is one of the largest k_D's among the salts of the 1 : 1 type. Sodium thiocyanate was chosen as a typical structure-breaking salt; it has the very high k_D value of 1095, as is shown in Table 2.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 2502—2505 (1969)

Catalytic Vapor-Phase Ammoxidation of Substituted Toluenes over Chromium Oxide[1]

Katsumasa SAKANISHI and Yoshiro OGATA

Department of Applied Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya

(Received March 1, 1969)

Ammoxidation of substituted toluenes over a chromium oxide catalyst has been studied in a flow system at atmospheric pressure. The reactions give satisfactory yields (*ca.* 70%) of corresponding nitriles at high conversion of toluenes. The rate constant for the reaction of substrate adsorbed on the catalyst surface, k^0_T, is independent of the substituent of substrate, while the adsorption equilibrium constant of gaseous substrate, K_T, depends on the substituent, affording Hammett's ρ of -0.9 for σ^+. These results support our mechanism reported previously for the analogous oxidation of toluene and ethylbenzene over Cr_2O_3, which involves an electron transfer from adsorbed hydrocarbons to dissociated oxygen.

In previous papers, we have reported the kinetic study on the ammoxidation of toluene[2] and ethylbenzene[3] over chromium oxide and interpreted the results in terms of the Langmuir-Hinshelwood mechanism.[2,3] The rate constant for the reaction of substrate on the catalyst surface, k°, and the adsorption equilibrium constants, K, were estimated and it is proposed that the rate-determining step is the reaction between adsorbed hydrocarbon and adsorbed oxygen in a dissociated form.[3] The present paper is an extention of the study to the ammoxidation of substituted toluenes over chromium oxide; the reaction gave satisfactory yields of substituted benzonitriles, the data being interpreted in terms of k°_T and K_T.

Experimental

Materials. Toluene (bp 110.6°C), ethylbenzene (bp 135.8—136.0°C), *o*-xylene (bp 144.0—144.5°C), *m*-xylene (bp 137.2—137.5°C) and *p*-xylene (bp 136.5—137.0°C) were purified as previously described.[2,3] *p*-*t*-Butyltoluene (bp 108.5°C/60 mmHg) was purified by rectification. Commericial *o*-chlorotoluene was employed. *m*-Chlorotoluene (bp 59.5—61.0°C/23 mmHg),[4] *p*-chlorotoluene (bp 160.8—161.1°C),[5] *o*-bromotoluene (bp 76.5—77.7°C/23 mmHg),[6] *m*-bromotoluene (bp 104°C/65 mmHg),[7] *p*-bromotoluene (bp 79.5—79.9°C/24 mmHg),[8] *o*-tolunitrile (bp 93—94°C/20.5 mmHg),[9] *m*-tolunitrile (bp 104—104.5°C/24 mmHg),[9] and *p*-tolunitrile (bp 105.5°C/23 mmHg)[9] were synthesized by well-known methods. Commercial ammonia, N_2 and O_2 were employed. The same catalyst as that in the previous papers[2,3] was used for kinetic studies. The catalyst of 5 wt% Cr_2O_3 on Al_2O_3, used for synthetic studies, was prepared by a method similar to that in the previous paper[2] and was allowed to age under reaction conditions for 35 hr in order to stabilize its activity.

Apparatus and Procedures. The apparatus and procedure for kinetic studies were similar to those employed before,[2] but a column of 30 wt% Silicone D.C. 550 on Chamelite CK 40 cm was used for gas chromatographic analysis of the substituted toluenes.

For synthetic purposes, a reactor of stainless steel, 19 mm inner diameter, with a concentric thermowell

(4 mm outer diameter), was immersed in a thermostated alkali nitrates bath. The substrates of *ca.* 2 m*l* were charged by a microfeeder, and introduced with the mixed reaction gas into the reactor for about 2 hr. When the reaction was over, N_2 gas was fed into the ractor for 30 min. The products were collected by a trap cooled by air and traps cooled by a freezing mixture. Recrystallized products were identified by means of their melting points as well as GLC analysis.

Results

Preparative Ammoxidation of Substituted Toluenes. Ammoxidation of substituted toluenes[10] to prepare benzonitriles were carried out over the stabilized catalyst of 40 m*l* at the standard composition of reaction gas, *i. e.*, partial pressure of substrate (p_T) was 1.3×10^{-2} atm, that of oxygen (p_0) 13.3×10^{-2} atm, and that of ammonia (p_A) 6.7×10^{-2} atm. Nitrogen gas was used as a diluent.

Table 1. Ammoxidation of substituted toluenes at bath temperature of 370°C with gas space velocity of 450 hr^{-1}

Substrate	Product	Yield (mol %)[a]
p-Chlorotoluene	*p*-Chlorobenzonitrile	68
m-Chlorotoluene	*m*-Chlorobenzonitrile	69
o-Chlorotoluene	*o*-Chlorobenzonitrile	72
p-Bromotoluene	*p*-Bromobenzonitrile	75
m-Bromotoluene	*m*-Bromobenzonitrile	69
o-Bromotoluene	*o*-Bromobenzonitrile	74
p-Tolunitrile	Terephthalonitrile	66
m-Tolunitrile	Isophthalonitrile	63
o-Tolunitrile	Phthalonitrile	36
	+Phthalimide	15
p-Xylene	Terephthalonitrile	45
m-Xylene	Isophthalonitrile	29
	+*m*-Tolunitrile	5.6
o-Xylene	Phthalonitrile	26
	+Phthalimide	10
Toluene	Benzonitrile	45
Toluene[b]	Benzonitrile	72
Ethylbenzene	Benzonitrile	36
	+Styrene	8.2
Ethylbenzene[c]	Benzonitrile	50
	+Styrene	20

a) Based on the fed substrate. The conversions of all substrates were 100%, except for footnote b and c.
b) The conversion of toluene was 86% at bath temperature of 356°C, with gas space velocity of 930 hr^{-1} and catalyst volume of 19.3 m*l*.
c) The conversion of ethylbenzene was 77% at bath temperature of 360°C with gas space velocity of 930 hr^{-1} and catalyst volume of 19.3 m*l*.

As shown in Table 1, *o*-, *m*- and *p*-chlorotoluenes, bromotoluenes, and *m*- and *p*-tolunitriles gave fairly high yields of corresponding nitriles (*ca.* 70%). Relatively low yields of nitriles were obtained in ammoxidation of xylenes and unsubstituted toluene at 370°C under these conditions. However, at moderate reaction conditions (footnotes b and c in Table 1), toluene gave higher yield of benzonitrile (72%), its selectivity being 84%, while ethylbenzene gave 50% benzonitrile and 20% styrene, their selectivities being 65% and 26%, respectively.

Kinetics of Ammoxidation of Substituted Toluenes. The reaction conditions for kinetics were as follows: p_T, $0.67-2.67\times10^{-2}$ atm; p_A, 6.7×10^{-2} atm; p_0, 13.3×10^{-2} atm; reaction temperature, 400°C; catalyst volume, 2.5 m*l*; and gas space velocity, 7200 hr^{-1}.

Treatment of experimental data was similar to that of our previous reports,[2,3] *i. e.*, the rate of consumption of substrate, v_T, is expressed as:

$$v_T = -\frac{d[\text{substrate}]}{dt} = -\frac{d\left(\frac{p_{T_0}(1-x_T)}{RT_0}\right)}{d\left(\frac{V}{F}\right)} = k_T p_T^{t}\cdot p_0^{n}\cdot p_A^{a} \quad (1)$$

$p_0 \gg p_T$ and $p_A \gg p_T$, and hence p_0 and p_A are virtually constant under experimental conditions. Therefore, integration of Eq. (1) leads to

$$p_{T_0}\cdot x_T \simeq k_T R T_0 p_{T_0}^{t}\cdot p_0^{n}\cdot p_A^{a}(V/F) \quad (2)$$

or

$$v_T \simeq \frac{p_{T_0}\cdot x_T}{RT_0\left(\frac{V}{F}\right)} \quad (3)$$

Hence, the t value (kinetic order in substrate) can be estimated from the slope of line in the plot of $\log(p_{T_0}x_T)$ *vs.* $\log(p_{T_0})$. Also, applying Langmuir-Hinshelwood mechanism, v_T is expressed as follows.[2,3]

$$v_T = k_T^{\circ}\frac{K_T p_0\sqrt{K_0 p_0}}{(1+K_T p_{T_0}+\sqrt{K_0 p_0})^2} \quad (4)$$

Introduction of Eq. (3) into Eq. (4) gives

$$x_T^{-1/2} = \{1+\sqrt{(K_0 p_0)}+K_T p_{T_0}\} \times \{k^{\circ}_T RT_0 K_T\sqrt{(K_0 p_0)}V/F\}^{-1/2} \quad (5)$$

Relative values of K_T and k°_T can be obtained by means of the plot of $x_T^{-1/2}$ *vs.* p_{T_0} at various p_{T_0} with constant and known p_0, p_A and V/F as shown in Fig. 1. Values of K_0 and $k^{\circ}_T RT_0$ were estimated by using the value of 0.15 atm^{-1} for K_0, as obtained previously.[2]

These values are shown in Table 2. The values of K_T, $k^{\circ}_T RT_0$ and t were comparable with those obtained previously.[2] The values of $k^{\circ}_T RT_0$ are

nearly constant except bromotoluenes. Values of K_T depend on the substituent of toluene. Hammett's plot of log K_T *vs.* Brown's σ^+ gave a straight line, from which the ρ value was estimated to be −0.9, except for bromotoluenes.

Discussion

Since the selectivities to nitriles are high at moderate reaction conditions (Table 1), kinetic data can clarify the mechanistic feature of the ammoxidation of substituted toluenes to the corresponding nitriles. As suggested previously,[3] the mechanism for the oxidation would be expressed as follows, where the rate is determined by step 8 or 9:

$$\mathrm{Hc\ (gas) + Catalyst^+ \overset{K_{Hc}}{\rightleftarrows} Hc^+(ads) + Catslyst} \quad (6)$$

$$\mathrm{O_2\ (gas) + 2\ Catalyst \overset{K_O}{\rightleftarrows} 2O^-(ads) + 2Catalyst^+} \quad (7)$$

$$\mathrm{Hc^+(ads) + O^-(ads) \underset{k_{-8}}{\overset{k_8}{\rightleftarrows}} [Hc^+(ads)O^-(ads)]\ I\ (transition\ state)} \quad (8)$$

$$\mathrm{[Hc^+(ads)O^-(ads)] \overset{k_9}{\longrightarrow} Intermediates\ or\ Products} \quad (9)$$

Here Hc means hydrocarbon and (ads) means adsorbed gas on the catalyst. Hence, $K_{Hc} \equiv K_T$ and $k°_T \equiv k_8 \cdot k_9/k_{-8}+k_9$.

The effect of substituent of toluenes on K_T gives ρ of −0.9 and the effect is expected from Eq. (6), where adsorbed hydrocarbons act as electron-donors to the catalyst. The relation between t and K_T in Table 2 implies that the stronger adsorption of substrate corresponds to the lower reaction order substrate.[3]

Equation (9) may be a hydrogen abstraction reaction. Factors influencing the selectivity in the hydrogen abstraction reaction are (i) the bond dissociation energy of the breaking C–H bond, (ii) the ionization potential of the formed radical, and (iii) the factor of entropy.[11] The transition state, I, seems to be resonating as follows.

$$\underset{II}{[(ads)^+ArCH_2{:}H\cdot O^-(ads)]} \leftrightarrow \underset{III}{[(ads)^+ArCH_2\cdot \dot{H}\cdot O^-(ads)]}$$

$$\leftrightarrow \underset{IV}{[(ads)^+ArCH_2{}^+\dot{H}{:}^-O^-(ads)]} \quad (10)$$

However, the contribution of the carbonium ion-type structure, IV, to stabilize the transition state may be negligible. Hence, the ionization potential of the substituted benzyl radical is not important for the reactivity of substrate. The bond dissociation energies of the substituted benzylic C–H bonds are almost constant.[12,13] Therefore, if the factor of entropy and others are nearly constant, $k°_T RT_0$ would not be affected by substituents. As shown in Table 2, the observed values of $k°_T RT_0$ are almost independent of substituent, except bromotoluene. This substituent effect on $k°_T RT_0$ and K_T supports the mechanism shown in Eqs. (6)—(9).

The unusual behavior of bromotoluenes may be explained as follows: The adsorption of substrates seems to need the charge transfer of π-donor type involving π- or pseudo π-electron and/or the charge transfer of n-donor type involving lone pair electron; in bromotoluenes, the latter may be more important and change the factor of entropy. Further, the decomposition of bromotoluenes may cause the intervention of Br· in the reaction system.[14]

Nomenclature

Photoconductive Properties of Organic Polyiodides

Toshihiko SANO,*1 Kenichi OKAMOTO, Shigekazu KUSABAYASHI and Hiroshi MIKAWA

Department of Chemical Technology, Faculty of Engineering, Osaka University, Yamadakami, Suita-shi, Osaka

(Received March 5, 1969)

The photoconductive properties of $(CH_3)_4N^+I_5^-$, $(CH_3)_3(C_6H_5)N^+I_5^-$, *N*-methylacridinium pentaiodide and *N*-methylquinolinium pentaiodide were investigated by both a sandwich type cell and a single crystal cell. In the former arrangement, the photoresponse observed was the overlap of photoconductive response and photovoltaic response. The single crystal gave pure photoconductive response. Tetramethylammonium pentaiodide was the most photoconductive among the polyiodides. Spectral dependence of the photocondutcivity of this compound revealed that the threshold is at about 1000 mμ (1.24 eV). This value is in good agreement with the band gap energy 1.36 eV obtained from the temperature dependence of the dark current and 1.20—1.26 eV from calculation. Semiconductive properties of the organic polyiodides are explained by applying the band model.

Semiconductive properties of thirteen organic polyiodides including tetramethylammonium, trimethylphenylammonium, *N*-methylpicolinium, and *N*-methylacridinium polyiodides were investigated.[1,2] Two inorganic polyiodides, caesium triiodide[3] and tetraiodide,[4] were investigated. The effect of X- and γ-irradiations on the electrical conductivity of tetramethylammonium pentaiodide was also investigated.[5] Specific resistivity of the polyiodides was of the order 10^5—10^{12} Ωcm and had close connection with the number of the iodine atoms of the polyiodide anion. The framework of the polyiodide anion in the crystal is, therefore, considered to be of primary importance in determining the electrical

conductivity of the crystals. Energy band calculation of tetramethylammonium pentaiodide was carried out by the simple LCAO approximation method.[6] Calculation of the energy band was carried out with caesium triiodide[3] and caesium tetraiodide (Cs_2I_8).[4] Although in these calculations only the iodine framework was considered, without taking into consideration the effect of cations, values of the energy gap were found to be nearly the same as the observed value. This fact confirmed again the primary importance of the iodine framework in determining the electrical properties of the polyiodides.

The authors have already pointed out that some of the organic polyiodides have photoconductive response. In the present investigation, the photoconductive properties of tetramethylammonium pentaiodide (I), trimethylphenylammonium pentaiodide(II), *N*-methylquinolinium pentaiodide(III) and *N*-methylacridinium pentaiodide (IV) are reported. The threshold wavelength of the photoconductivity of I is in agreement with the band gap energy from the dark conductivity and the calculated band gap energy.

Experimental

Materials. The pentaiodides (I—IV) were prepared by the method reported[1,2] and used as the samples for photoconductivity measurement after recrystallizing repeatedly from water-alcohol (I, II, III) or alcohol-tetrahydrofuran (IV).

Sandwich-type Cell. The sandwich type cell (0.3—0.6 cm^2 in area and 10^{-2} cm in thickness) was made by melting and solidifying the polyiodide material between two nesa quartz plates (Fig. 1). The polyiodide materials sandwiched were in polycrystalline state.

Single Crystal Cell. The single crystal cell was made by putting between two quartz plates a single crystal (1.5 mm in width, 1 mm in thickness and 4 mm in length) with the electrodes attached by using silver paste (Fig. 1). The light illumination was effected perpendicular to the cleavage plane (*ab*-plane) of the crystal. To prevent the incident light from reaching the electrodes area an appropriate screen was attached to the single crystal cell. The sample was shut out from air with a paraffin seal between the two quartz plates, as shown in Fig. 1.

A monochromatic light from a 500 W xenon lamp with the intensity distribution shown in Fig. 2 was used, its intensity being controlled by neutral filters. Electrical measurements were carried out as usual at 20°C. In measuring the photocurrent, the dark current was potentiometrically compensated when necessary.

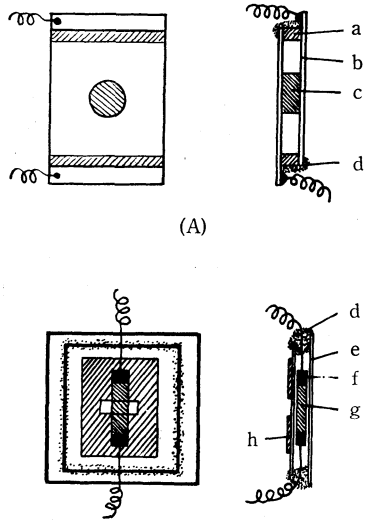

Fig. 1. Sandwich cell (A) and Single crystal cell (B).
a mica sheet, b nesa coated glass or quartz, c sample (melted and solidified), d paraffin, e glass or quartz, f silver paste, g crystal, h mask for the light

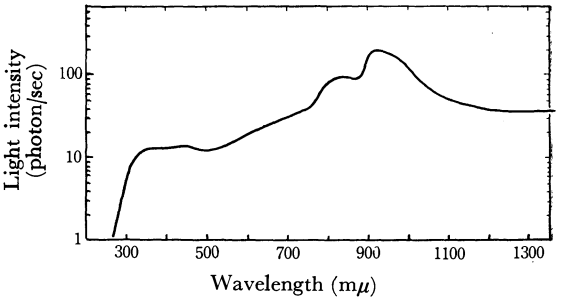

Fig. 2. Energy distribution of the light of the xenon lamp measured by a thermopile (Reedeer 8858 USA) using a monochrometer. For light of 300—320 mμ and 500—1200 mμ the slit width was kept 2 mm and 0.48 mm respectively. For 320—500 mμ the width of the wave length was kept 10 mμ. Absolute intensity of the light with this wave length width at 350—450 mμ region is 3.3×10^{14} photon/sec, when measured at the outlet of the monochrometer.

Results and Discussion

With the sandwich type cell the photoresponse consisted of both photoconductive response and photovoltaic response. It was revealed that the photoresponse of tetramethylammonium pentaiodide (I) is two to three orders of magnitude larger than the other three pentaiodides (II—IV). The photoresponse of I is very large when the positive side is illuminated, and small when illuminated at the negative side. Then sign of this rectifying effect in photoconductivity is in agreement with the positive sign of the thermoelectric power.[1] The predominant carrier in this material seems to be a hole rather

6) S. Kusabayashi and H. Mikawa, This Bulletin, **39**, 736 (1966); S. Kusabayashi, H. Mikawa, M. Konda and M. Hayashi, *ibid.*, **39**, 1383 (1966).

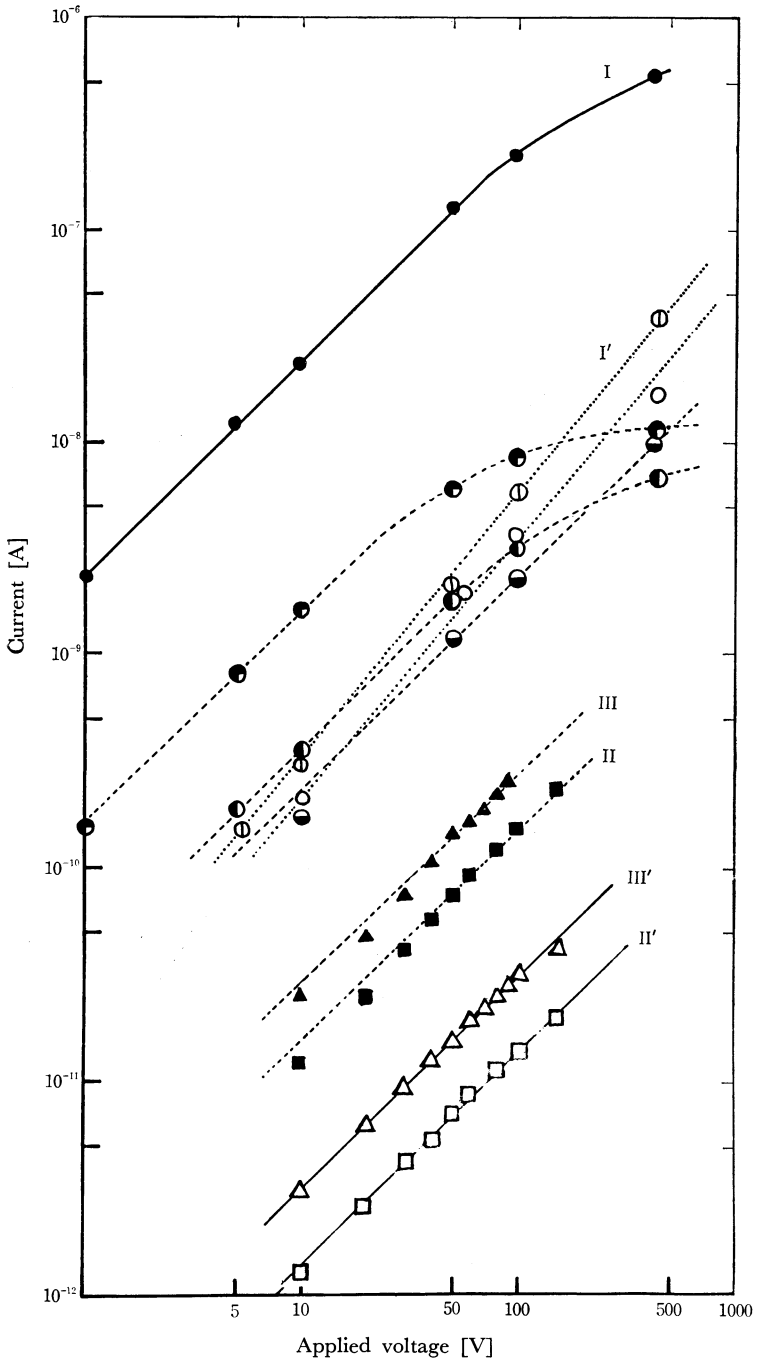

Fig. 3. Voltage dependence of the dark current I, II and III and the photocurrent I′, II′ and III′.
Tetramethylammonium pentaiodide (I and I′) with the monochromatic light of ◔ 850 mμ, ◐ 700 mμ, ◒ 600 mμ, ◑ 450 mμ, ○ 350 mμ. Trimethylphenylammonium pentaiodide (II and II′) and *N*-methylquinolinium pentaiodide (III and III′) with the light from a 500 W xenon lamp with the filter passing the light longer than 550 mμ. All values of the photocurrent are not normalized for the light intensity.

than an electron. At the higher applied voltage region, the photocurrents of II, III and IV are very small in comparison with the dark current, and the photocurrent due to the photovoltaic effect seems to be predominant.

With the single cyrstal cells no photoresponse was observed when illuminated with no applied potential. Under applied potential the steady state photocurrent with comparatively sharp rise and decay characteristics was observed with the light on or off. As the contact area between the electrode and the material is not illuminated in the single crystal cell, it might be concluded that the polyiodide materials are photoconductive. Photoresponse was in the order I $\gg$ II, III, IV, being in the same order as for the sandwich type cell.

The photocurrent with the monochromatic light was very small for the compounds II, III and IV, when compared with the dark current, being in the order of 10^{-11}—10^{-12} A. Total light with $\lambda > 550$ mμ was, therefore, used to measure the voltage dependence of the photocurrent of these compounds. Both the dark current and the photocurrent thus measured were proportional to the applied voltage, as shown by the curves II, II′, III and III′ in Fig. 3. The dark current and the photocurrent of compound I was nearly proportional to the applied voltage, as shown by the curves I and I′ in Fig. 3. As the photocurrent of this compound is rather large, monochromatic light was used. When illuminated with the light of the longer wavelength (700 mμ and 850 mμ), saturation of the photocurrent occurs in the higher voltage region. As the length of the single crystal was about 4 mm, the field strength remained within several hundred volt per cm even when 100 V was applied.

The light intensity dependence of the photocurrent changes as shown in Fig. 4 and Table 1 according to the applied voltage and the wave-

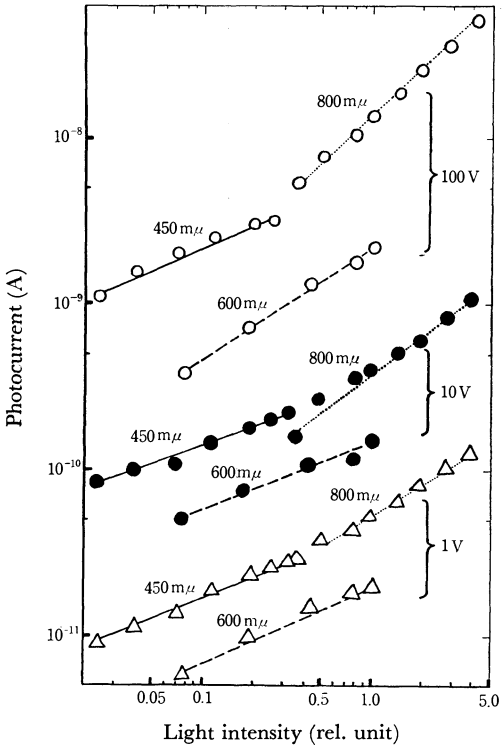

Fig. 4. Dependence of the photocurrent of tetramethylammonium pentaiodide on light intensity. Voltages shown in the figure are the potentials applied across the crystal of *ca.* 4 mm length.

Voltage		Wavelength mμ		
		$\lambda<500$	$500<\lambda<700$	$700<\lambda$
High	(100—450 V)	0.5	0.5—1.0	1.0
Low	(1—100 V)	0.4—0.5	0.5—0.7	0.7—0.9

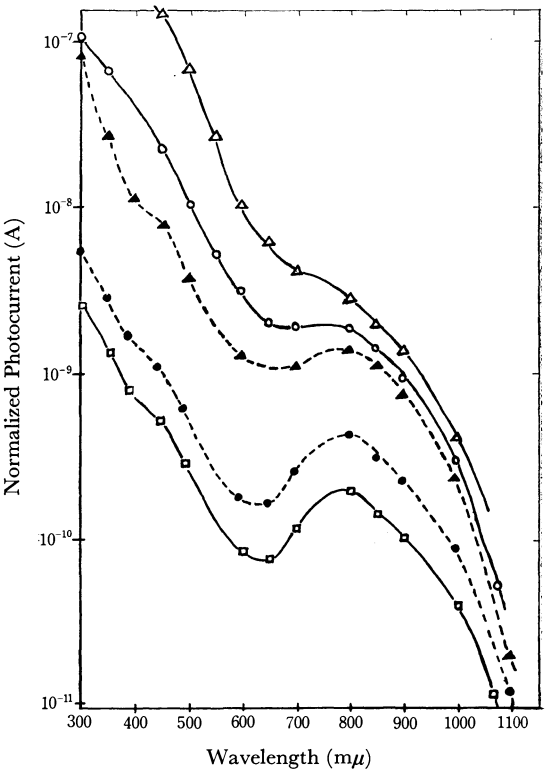

Fig. 5. Spectral dependence of the photocurrent of tetramethylammonium pentaiodide normalized for light intensity. Voltages shown in the figure are the potentials applied across the crystal of *ca.* 4 mm length.

—△— 450 V —○— 100 V
—▲— 50 V ------●------ 10 V
—□— 5 V

length. When illuminated with the light shorter than 500 mμ, the photocurrent was proportional to the 0.5 power of the light intensity, probably because the photocurrent was recombination limited in this region, the light being strongly absorbed, generating the carriers in very high concentration at the crystal surface. On the other hand the wavelength longer than 700 mμ is absorbed weakly, generating the carriers penetrating rather deep in the bulk of the crystal. This condition gives $n=1.0$. In the intermediate region from 500—700 mμ, n becomes 0.5—1.0.

The wavelength dependence of the photocurrent normalized for the light intensity L is shown in Fig. 5. The normalization was made by assuming the relation $I_{ph} \propto L^{1.0}$, the current at 600 mμ being taken as the standard. As the photocurrent is proportional to the light intensity in the region longer than 700 mμ at 100—450 V as shown in Fig. 4, this normalization may be reasonable at least in this region.

The apparent quantum yield of the photocurrent of tetramethylammonium pentaiodide was calculated to be 1.5×10^{-5} at 1000 mμ under 450 V. The threshold of the photocurrent seems to be about 1000 mμ. If the mechanism of the photoconduction is to be explained by the band model, the energy of the threshold (1.24 eV) must be equal to the band-gap energy. This value is in good agreement with the band-gap energy value 1.36 eV[1] estimated from the temperature dependence of the dark current and the band-gap energy value 1.20—1.26 eV estimated from the calculation.[6] These facts suggest that the band model is applicable to the photoconduction of the tetramethylammonium pentaiodide. Moreover, this result gives additional support to our previous suggestion that the iodine framework in the crystal structure is of primary importance in determining the conductivity of polyiodides.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 2509—2513 (1969)

The Bond Character of the Sn–Cl Bonds in the Hydrates of Tin(IV) Chloride

Hisao NEGITA, Tsutomu OKUDA and Mitsuo MISHIMA*1

Department of Chemistry, Faculty of Science, Hiroshima University, Higashi-Senda-machi, Hiroshima

(Received March 7, 1969)

Several hydrates of tin(IV) chloride, *e.g.*, $SnCl_4 \cdot xH_2O$ ($x=2$, 3, 4 and 5) and $SnCl_4 \cdot yD_2O$ ($y=3$, 4 and 5), were investigated by means of the nuclear quadrupole resonance (NQR) due to ^{35}Cl and the Mössbauer effect due to ^{119}Sn. The NQR-frequencies were observed at the temperature of liquid nitrogen and room temperature; they were found to range from 17.656 to 21.439 MHz. The Mössbauer effect was investigated only at the temperature of liquid nitrogen; it resulted in isomer shifts ranging from 0.275 to 0.350 mm/sec. The NQR-frequency and the isomer shift decreased with an increase in the number of water molecules in the hydrates, and the relationship between the NQR-frequency and the isomer shift was nearly linear. This relation was interpreted in terms of the transfer of the *s*-electrons of the tin atom to the chlorine atoms. Furthermore, it was revealed that there was a significant difference between the Sn-Cl bond of the hydrates and that of ammonium chlorostannate.

It is well-known that tin(IV) chloride forms various hydrates but their structures have not been determined by any means except the Raman spectra.[1] Tin(IV) chloride and its hydrates are suitable for investigating the Sn–Cl bond, since the electronic structures of the tin and chlorine atoms can be investigated by means of the Mössbauer effect due to ^{119}Sn and the nuclear quadrupole resonance due to ^{35}Cl.

The molecular complexes of tin(IV) chloride with organic or inorganic compounds containing oxygen or nitrogen atoms have thus far investigated by means of NQR[2,3] and the Mössbauer effect.[4–8]

*1 Present address: Department of Chemistry, Faculty of Literature and Science, Shimane University, Matsue.

1) H. S. Brune and W. Zeil, *Z. Physik. Chem. Neue Folge*, **32**, 384 (1962).

2) D. Biedenkapp and A. Weiss, *Z. Naturforsch.*, **19a**, 1518 (1964).

3) B. Haas, Thesis, Technischen Hochschule Karlsruhe (1965).

However, the hydrates of tin(IV) chloride was investigated at the temperature of liquid nitrogen.[2,3,9] Only the pentahydrate $SnCl_4 \cdot 5H_2O$ has been investigated by means of the Mössbauer effect[6,10–16] at both the temperature of liquid nitrogen and room temperature. A variety of values have been reported for the isomer shift of the hydrate, ranging from 0.2 to 0.3 mm/sec with respect to tin(IV) oxide except for the value of 0.09 mm/sec observed by Lees and Flinn.[17] These authors observed a small quadrupole splitting for that hydrate, although others did not. Our value for the isomer shift of the hydrate is 0.275 mm/sec, while the value for $SnCl_4 \cdot 5D_2O$ is 0.300 mm/sec.

Brune and Zeil[1] investigated several hydrates of tin(IV) chloride, $SnCl_4 \cdot xH_2O$ ($x=2$, 3, 4, 5 and 8) and $SnCl_4 \cdot yD_2O$ ($y=5$ and 8) by Raman spectroscopy. They concluded from the spectra that chlorine atoms are arranged octahydrally around the central tin atom and that two of the hydrated water molecules occupy the *trans*-position, that is, the hydrate molecules possess the D_{4h} symmetry in the liquid state and in solution. This is consistent with the conclusion drawn from the NQR-frequencies in the solid state.

The molecular configuration described above will be ascertained in this paper. The ionic character of the Sn–Cl bonds increases with the number of water molecules in the hydrates, and the bond character of the Sn–Cl bond in a similar compound, such as ammonium chlorostannate, is different from those of the hydrates.

Experimental

Materials. The hydrate of tin(IV) chloride was prepared by mixing tin(IV) chloride and light or heavy water in a proper molar ratio and in a sealed tube, but attempts to prepare the dihydrate, $SnCl_4 \cdot 2D_2O$, were unsuccessful. Ammonium chlorostannate was prepared by a method reported previously.[18]

Measurements. The NQR-spectrometer used for measuring the ^{35}Cl resonance consisted of a superregerative oscillator, an amplifier, and a detector. The resonance frequencies were determined at both room temperature and the temperature of liquid nitrogen.

The Mössbauer apparatus employed was essentially the same as that described previously.[4] Tin(IV) oxide containing 0.6 mCi of ^{119m}Sn was used as the γ-radiation source; it was kept at room temperature. The hydrate of tin(IV) chloride was mounted as an absorber; for tin it was about 15 mg/cm^2 thick and was cooled with liquid nitrogen.

Results and Discussion

Nuclear Quadrupole Resonance. The hydrates, $SnCl_4 \cdot 2H_2O$, $SnCl_4 \cdot 3H_2O$, and $SnCl_4 \cdot 3D_2O$, have a single resonance line due to ^{35}Cl at both room temperature and at the temperature of liquid nitrogen. The pentahydrates, $SnCl_4 \cdot 5H_2O$ and $SnCl_4 \cdot 5D_2O$, have two resonance lines at room temperature. The resonance of the latter hydrates could not be measured at the temperature of liquid nitrogen because of the piezo effect which appeared on cooling. The resonance lines in the tetrahydrates, $SnCl_4 \cdot 4H_2O$ and $SnCl_4 \cdot 4D_2O$, could not be found. The NQR-frequencies and the ionic characteristics found for the rest of the hydrates

TABLE 1. THE NQR-FREQUENCIES DUE TO ^{35}Cl FOR THE HYDRATES OF TIN(IV) CHLORIDE AND THE IONIC CHARACTER

Hydrate	Resonace frequency, MHz		Ionic character[a] %
	77°K	293°K	
$SnCl_4 \cdot 2H_2O$	21.439	21.039	55
$SnCl_4 \cdot 3H_2O$	20.384	20.173	57
$SnCl_4 \cdot 5H_2O$		18.054 17.656	62
$SnCl_4 \cdot 3D_2O$	20.438	20.208	57
$SnCl_4 \cdot 5D_2O$		18.102 17.735	62

a) The percent ionic character was obtained by neglecting the double bond character and the asymmetry parameter.

are summarized in Table 1. The ionic character is determined by neglecting the double-bond character and by estimating the *s*-electron character of the chlorine atom is 15%. As may be seen in Table 1, the NQR-frequency decreases with an increase in the number of water molecules; that is, the ionic character of the Sn–Cl bonds in the hydrates increases with the number of water molecules. In general, the hydrates of tin(IV) chloride with heavy water show slightly higher frequencies than those with light water. This result, however, shows no appreciable difference in the ionic character between the corresponding hydrates.

The atomic arrangement around the central tin atom in the dihydrates, $SnCl_4 \cdot 2H_2O$ and $SnCl_4 \cdot 2D_2O$, seems to be coordinated octahedrally by sp^3d^2-hybridization. If this is the case, the two water molecules must occupy either the *cis*- or the *trans*-position of an octahedron, as is shown in Fig. 1.

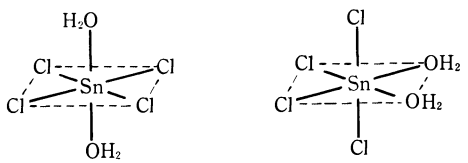

Fig. 1. The configuration of the dihydrate, $SnCl_4 \cdot 2H_2O$.
(a) *trans*-form (b) *cis*-form

From the fact that only a single NQR line was observed in the hydrates, the two water molecules may be considered to occupy the *trans*-position, since all the Sn–Cl bonds must be equivalent. Brune and Zeil suggested that the dihydrate takes the octahedral configuration in the liquid state.[1] Consequently, the D_{4h} symmetry of the dihydrate is preserved in the solid state.

The trihydrates, $SnCl_4 \cdot 3H_2O$ and $SnCl_4 \cdot 3D_2O$, also exhibit a single resonance line. Consequently, it may be assumed that two of the three water molecules are bonded to the central tin atom and occupy the *trans*-positions of the octahedron. The influence of non-coordinated molecules on the Sn–Cl bonds is quite significant, since the resonance frequency of the trihydrate, $SnCl_4 \cdot 3H_2O$, is considerably lower than that of the dihydrate, $SnCl_4 \cdot 2H_2O$, the difference being 1.055 MHz at the temperature of liquid nitrogen. The difference in ionic character between the two hydrates is 2%.

In the pentahydrates, the two resonance lines are situated close together; the difference between them is 0.398 MHz for $SnCl_4 \cdot 5H_2O$ and 0.367 MHz for $SnCl_4 \cdot 5D_2O$. This indicates the existence of two non-equivalent Sn–Cl bonds in the pentahydrates. The findings on the Raman spectra for the hydrates, $SnCl_4 \cdot xH_2O$ and $SnCl_4 \cdot yD_2O$, show that all the hydrates possess the D_{4h} symmetry with regard to the arrangement of the atoms bonded to the central tin atom in the liquid state. If the atomic configuration around the tin atom is the *cis*-form in the pentahydrates, the symmetry class must be C_{2v}. This contradicts the results of the Raman spectra. Consequently, it may be concluded that the small deviation in the resonance frequencies is not caused by the *cis*-form, but is brought about by the crystal field due to the three non-coordinated water molecules as well as the neighboring octahedrons.

In addition, the resonance frequencies of the pentahydrates, $SnCl_4 \cdot 5H_2O$ and $SnCl_4 \cdot 5D_2O$, are considerably lower than those of the dihydrate and trihydrates. Taking into account this lowing and the appearance of the two lines in the pentahydrate, the influence of the non-coordinated water molecules on the Sn–Cl bonds seems to be significant. On the other hand, the resonance frequencies of all the hydrates are much lower than those of pure tin(IV) chloride, 24.294, 24.226, 24.140, and 23.179 MHz at 77°K. The four chlorine atoms are spatially directed to the corners of a distorted tetrahedron in the crystal state, forming sp^3-hybrid orbitals, although Sn–Cl bonds have an ionic character of 48% if the double-bond character is disregarded. According to Haas[3] and Schawlow,[19] the ionic character is estimated to be 41 and 38% respectively. When tin(IV) chloride is hydrated, the atoms around the tin atom are arranged almost octahedrally, forming sp^3d^2-hybrid orbitals quite ionic in character. The *d*-electrons necessary for this hybridization are brought from the lone-pair electrons of the oxygen atoms of water molecules. The Sn–Cl bonds in the hydrates are more ionic than those of pure tin(IV) chloride, since the resonance frequencies of the former are lower than those of the latter.

Mössbauer Effect. The results of the Mössbauer effect are summarized in Table 2. The values of the isomer shift at the temperature of liquid nitrogen are shown with respect to tin(IV) oxide. These values fall in a range from 0.275 to 0.350 mm/sec and decrease with an increase in the number of water molecules in the same way as do the NQR-

Table 2. The Mössbauer effect due to ^{119}Sn of the hydrates of tin(IV) chloride

Hydrate	δ,[a] mm/sec	Hydrate	δ,[a] mm/sec
$SnCl_4 \cdot 2H_2O$	0.350		
$SnCl_4 \cdot 3H_2O$	0.325	$SnCl_4 \cdot 3D_2O$	0.350
$SnCl_4 \cdot 4H_2O$	0.300	$SnCl_4 \cdot 4D_2O$	0.330
$SnCl_4 \cdot 5H_2O$	0.275	$SnCl_4 \cdot 5D_2O$	0.300

a) δ is the isomer shift at liquid nitrogen temperature relative to the source of SnO_2 crystal. The accuracy is $\pm 5\%$ in the measurement.

19) A. L. Schawlow, *J. Chem. Phys.*, **22**, 1211 (1954).

frequencies. It may be noted again that the values for the hydrates of light water are slightly smaller than those of the hydrates of heavy water, but this fact will not be taken into account. From the tendency of the isomer shift, it is evident that the *s*-electron density at a tin nucleus decreases with an increase in the number of water molecules. The decrease in the *s*-electron density is caused by either losing *s*-electrons directly to other atoms or by receiving *p*- and/or *d*-electrons, the shielding effect of which decreases the *s*-electron density indirectly. The latter theory would mean an increase in the covalent character, and this is in conflict with the NQR results. Therefore, the tin atom is becoming a complete stannic ion with an increase in the number of water molecules. The increase in the ionic character results in a decrease in the covalent character and bring about a variation in the shielding effect.

According to the NQR results, the increase in the number of water molecules causes an increase in the electron density around the chlorine nucleus. Supposing that the *s*-electrons in the tin atom move to the chlorine atoms, the *s*-electron density at the tin nucleus should decrease, and hence the isomer shift should be diminished. This interpretation fits well with the findings on the Mössbauer effect.

The $(x-2)$ non-coordinated water molecules in the hydrates, $SnCl_4 \cdot xH_2O$, affect the nature of the Sn–Cl bonds significantly. However, these molecules do not take part directly in the decrease in the electron density at the tin nucleus, since they are located outside the octahedron centered about the tin nucleus. They seem to affect the tin atom through the coordinated chlorine atoms and/or water molecules, which may form hydrogen bonds with one another.

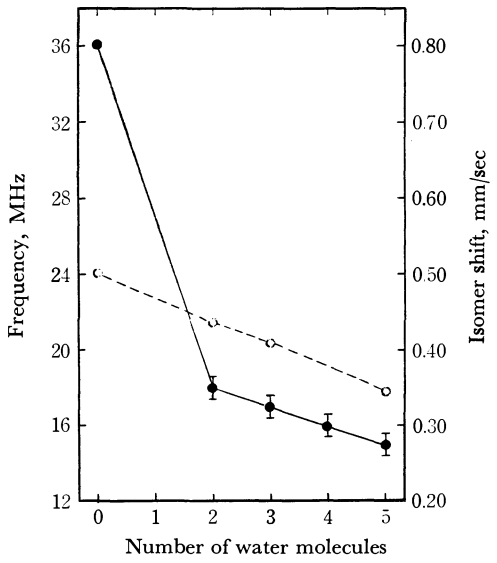

Fig. 2. The relation between the number of water molecules and the NQR-frequency or the isomer shift for the hydrate $SnCl_4 \cdot xH_2O$ at 77°K.

○: NQR-frequency ●: isomer shift

Figure 2 shows how the isomer shift and the NQR-frequency vary with the number of water molecules in the hydrate; the literature values of the pure tin(IV) chloride, 0.7,[6] 0.78,[20] 0.8,[7] 0.85,[13] and 0.9[15] mm/sec, have been averaged. It is apparent that there is a sudden decrease in the isomer shift from $x=0$ to $x=2$. This seems to be attributable to the shielding due to the *d*-electrons and to the increased ionic character of the tin atom. The gradient of the curve of the NQR-frequency *versus* the number of water molecules from $x=0$ to $x=2$ is almost the same as that from $x=2$ to $x=5$. The NQR-frequency of pentahydrates at the temperature of liquid nitrogen was roughly estimated from the value at room temperature. Taking the gradual decrease in the NQR-frequency into consideration, the sudden decrease of the isomer shift from $x=0$ to $x=2$ can be attributed to the shielding effect due to the *d*-electrons.

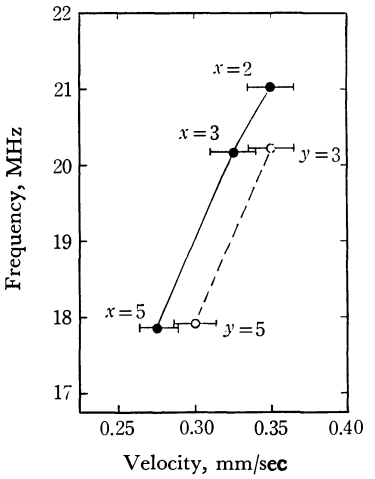

Fig. 3. The isomer shift at 77°K *versus* the NQR-frequency at 293°K for the hydrates, $SnCl_4 \cdot xH_2O$ and $SnCl_4 \cdot yD_2O$.

Figure 3 shows that the NQR-frequency increases almost linearly with the isomer shift in the two series of hydrates, $SnCl_4 \cdot xH_2O$ and $SnCl_4 \cdot yD_2O$. From this relation it may be concluded that the *s*-electrons of the tin atom move to the chlorine atoms. In other words, the less the isomer shift due to ^{119}Sn, the more ionic is the Sn–Cl bond. The resonance frequencies of the tetrahydrates, $SnCl_4 \cdot 4H_2O$ and $SnCl_4 \cdot 4D_2O$, which could not be observed in the present investigation are assumed

20) A. Yu. Aleksandrov, N. N. Delyagin, N. P. Mitrofanov, L. S. Polak and L. S. Shpinel, *Zh. Eksperim. i Teor. Fiz.*, **43**, 1242 (1962); *Soviet Phys. JETP*, **16**, 879 (1963).

to be as follows: The frequency for $SnCl_4 \cdot 4H_2O$ lies in the immediate neighborhood of 19 MHz, while that for $SnCl_4 \cdot 4D_2O$ is about 0.05 MHz higher than this value.

Ammonium hexachlorostannate, $(NH_4)_2SnCl_6$, shows two resonance lines at the temperature of liquid nitrogen, *i.e.*, 15.61 and 15.65 MHz. The value of the isomer shift for this compound is 0.475 mm/sec with respect to tin(IV) oxide in our experiment, although its literature values are 0.3,[15] 0.40,[14] 0.42,[16] 0.49,[21] and 0.50.[13] The crystal structure was analyzed by X-ray diffraction.[22] The tin atom is surrounded octahedrally by six equivalent chlorine atoms, but the NQR results show that two groups of slightly different bonds exist. The atomic arrangement around the tin atom in the hydrates can be obtained by substituting water molecules for chlorine in the hexachlorostannate ion. The NQR-frequencies reveal that the chlorine atoms in the ammonium hexachlorostannate are more ionic than that in the dihydrate. On the other hand, the Mössbauer effect reveals that the *s*-electron density at the tin nucleus in the chlorostannate is greater than in the dihydrate. Consequently, the tin atom is not as ionic as we had expected, although anions are coordinated to the tin atom. In other words, the Sn–Cl bonds in the chlorostannate are quite covalent. The conclusion that the more ionic the chlorine atoms, the more ionic is the tin atom does not apply to ammonium hexachlorostannate. $[SnCl_6]^{2-}$ ion has two minus charges distributed among the six chlorine atoms almost uniformly, while each chlorine atom has a charge of $-1/3$. Assuming that most of these charges participate in the ionic bond with an ammonium ion, the charges do not have a great influence upon the tin atom. This assumption is consistent with the NQR results and the Mössbauer effect.

The Sn–O bond is expected to be more ionic than the Sn–Cl bond in the dihydrate since the oxygen atom is more electronegative than the chlorine atom, and the isomer shift due to the ^{119}Sn of the dihydrate is smaller than those of $M^{I}_2SnCl_6$ or $M^{II}SnCl_6$ (M^{I}=H, K, NH_4; M^{II}=Mg, Ca, Ni), which are reported to be 0.42—0.49 mm/sec.[10,20]

The authors wish to express their thanks to Miss T. Shimazu for her help in checking some of the results.

Measurement of Negative Ions Formed by Electron Impact. IV. Negative Ion Mass Spectra and Ionization Efficiency Curves of Negative Ions of *m/e* 17 and 16 from *n*-Propyl and Isopropyl Alcohols

Satoru TSUDA, Akira YOKOHATA and Michihiro KAWAI

Department of Chemisrty, Faculty of Engineering, University of Hiroshima, Senda-machi, Hiroshima

(Received March 10, 1969)

The negative ion mass spectra of *n*- and iso-propyl alcohols, with emphasis on their relative yields to the positive ions under 80 eV, 40 eV and 15 eV electron energies, and the ionization efficiency (IE) curves of OH^- and O^- ions to the extent of 50 eV electron energies were measured. In both cases, the electron impacts of 80 eV and 40 eV gave almost the same negative ion mass spectra, in which the relatively strong peaks of *m/e* 16 (O^-), *m/e* 17 (OH^-) and *m/e* 25 (C_2H^-) ions except for the decrement of C_2H^- ions in 40 eV for isopropyl alcohol were characteristic. For *n*-propyl alcohol, the ratio of the yield of CH_2OH^+ ions to that of O^- ions (CH_2OH^+/O^-) gave the values of 6.9×10^4 and 1.9×10^5 in 80 eV and 40 eV. For isopropyl alcohol the values of $C_2H_4OH^+/OH^-$ were 3.3×10^4 and 6.4×10^4 in 80 eV and 40 eV, respectively. The comparison of the yield of negative ion in 10 eV with that of positive ion in 15 eV gave $CH_2OH^+/O^-=2.0\times10^4$ and $C_2H_4OH^+/OH^-=2.3\times10^3$. Each appearance potential observed in IE curves is well interpreted by the following reactions. [OH^- ions], for the first process C_3H_7OH(*n*- or iso-)$+e^-\rightarrow OH^-+C_2H_4+CH_2+H$, for the second process C_3H_7OH(*n*- or iso-)$+e^-\rightarrow OH^-+CH_3+CH_2+CH_2^++e^-$ or $OH^-+C_2H_4+CH_2+H^++e^-$. [O^- ions], for the first process C_3H_7OH(*n*- or iso-)$+e^-\rightarrow O^-+C_2H_5+CH_3$, for the second process C_3H_7OH(*n*- or iso-)$+e^-\rightarrow O^-+C_2H_4+CH_3+H$ or $O^-+C_2H_3+CH_3+H_2$ and for the third process C_3H_7OH(*n*- or iso-)$+e^-\rightarrow O^-+C_3H_7$(*n*- or iso-)$+H^++e^-$ or $O^-+C_3H_5+H_2+H^++e^-$.

Recently, several studies have been reported on the measurement of negative ion mass spectra by the electron impact method.[1-6] However, they were only made for limited kinds of compounds. Furthermore, data of the ionization efficiency (IE) curves of negative ions are very limited.[7-9] On the other hand, the role of negative ions is attracting increasing attention in the field of radiation chemistry. Compounds containing oxygen atom are of particular interest. Warman *et al.*[10,11] have pointed out the occurrence of the negative ion-molecule reactions containing O^- ions.

The authors reported previously the results of measurement of negative ion mass spectra obtained from nitroalkanes in relation to electron energies,[12] and of IE curves of NO_2^-, O^-, $CH_2NO_2^-$,[12] CN^- and CNO^-[13] ions.

This work was extended to *n*- and iso-propyl alcohols. Emphasis was placed on the relative yields of negative ions to the positive ions and on the measurement of the IE curves of OH^- and O^- ions.*1

*1 Recently, the measurement of ethyl alcohol was reported. However, no detailed discussion was made. (H. Hotta, T. Sugiura and H. Kurihara, The 11th Meeting of Radiation Chemistry, Tokyo (1968)).

Experimental

Experiments were performed on a Hitachi RMU-6D mass spectrometer equipped with the T-2M ion source having a rhenium filament. The ion detection circuit consisted of a ten stage electron multiplier and of a Faraday collector. Conditions for the experiment and the method for correction of the electron energy scale were the same as those described previously[12] except for the use of accelerating voltage of 2.4 kV and electron multiplier voltage of 1.8 kV. The compounds used were of research grade and no further purifications were made.

Results and Discussion

Negative Ion Mass Spectra. Figures 1 and 2 show the negative ion mass spectra for *n*- and iso-propyl alcohols in 80 eV, 40 eV and 10 eV electron energies, in relation to the positive ion mass spectra in 80 eV, 40 eV and 15 eV.*2

For the electron impact of 80 eV and 40 eV, the peaks of negative ions obtained commonly in both samples are as follows; *m/e* 12 (C^-), *m/e* 13 (CH^-), *m/e* 14 (CH_2^-), *m/e* 16 (O^-), *m/e* 17 (OH^-), *m/e* 24 (C_2^-), *m/e* 25 (C_2H^-), *m/e* 41 (C_2HO^-), *m/e* 43 ($C_2H_3O^-$), *m/e* 57 ($C_3H_5O^-$) and *m/e* 59 ($C_3H_7O^-$).

The formation of *m/e* 41, 43, 57 and 59 ions shows that loss of hydrogen by negative ion formation is almost entirely restricted to that of an odd

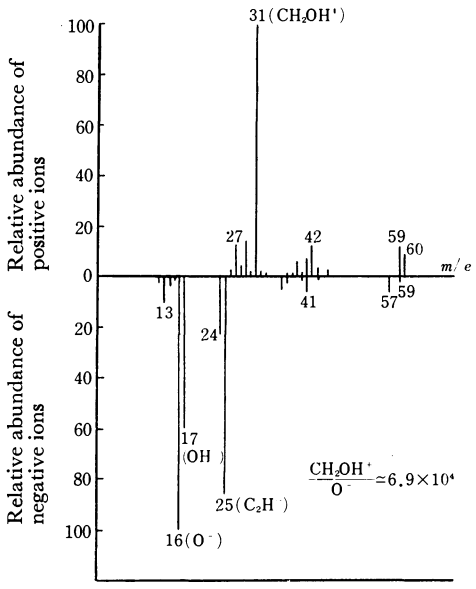

Fig. 1a.

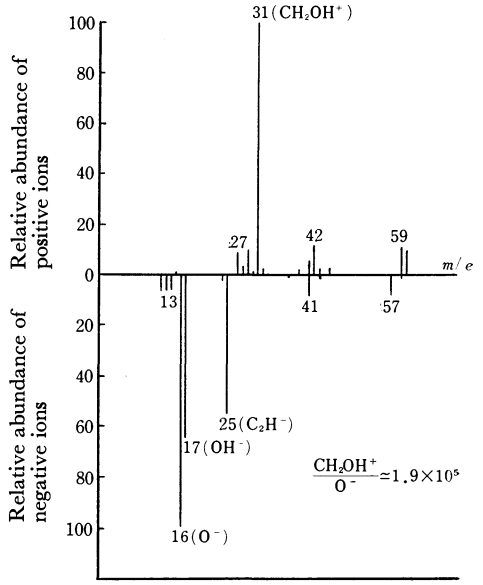

Fig. 1b.

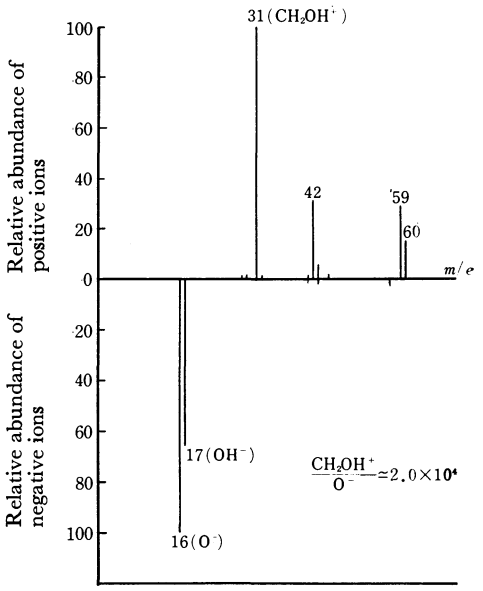

Fig. 1c.

Fig. 1. Positive and negative ion mass spectra of *n*-propyl alcohol.
(a) 80 eV
(b) 40 eV
(c) 15 eV for positive ions, 10 eV for negative ions

number of hydrogen atoms.

The most intense peaks were O^- ions for *n*-propyl alcohol and OH^- ions for isopropyl alcohol. A relatively large change in their relative yields with electron energies (80→40 eV) was found especially in C^-, C_2^- and C_3^- ions for *n*-propyl alcohol, and O^-, C_2^-, C_2H^-, C_3^- and C_2O^- ions for isopropyl alcohol. The general patterns of spectra in 80 eV

*2 Since the positive ions obtained in 10 eV electron energies are very limited, the data for 15 eV were conveniently used for comparison with the yield of negative ions in 10 eV.

showed a relatively good consistency with those obtained by Melton[1] in 90 eV except for a smaller peak of $C_3H_7O^-$ ions for the two samples.

The comparsion of the yield of O^- ions with of CH_2OH^+ ions (the most intense peak among the positive ions) for *n*-propyl alcohol and of OH^- ions with $C_2H_4OH^+$ ions (the most intense peak among the positive ions) for isopropyl alcohol gave $CH_2OH^+/O^-=6.9\times10^4$ and $C_2H_4OH^+/OH^-=3.3\times10^4$ for 80 eV electron energies, $CH_2OH^+/O^-=1.9\times10^5$ and $C_2H_4OH^+/OH^-=6.4\times10^4$ for 40 eV electron energies respectively.

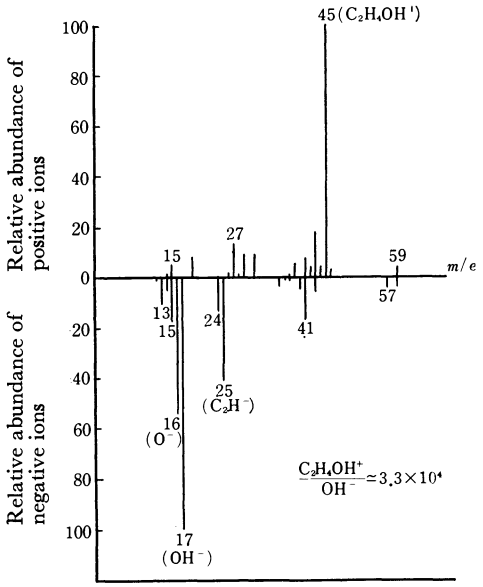

Fig. 2a.

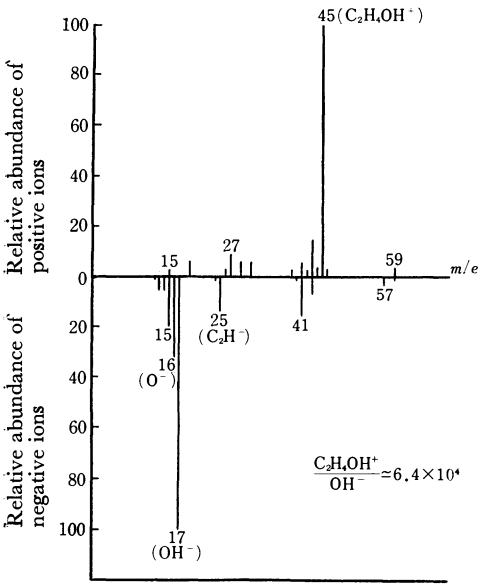

Fig. 2b.

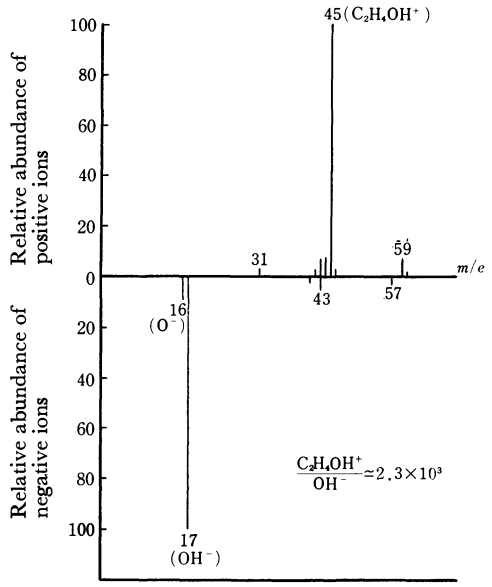

Fig. 2c.

Fig. 2. Positive and negative ion mass spectra of isopropyl alcohol.
(a) 80 eV
(b) 40 eV
(c) 15 eV for positive ions, 10 eV for negative ions

In 10 eV electron energies, O^- and OH^- ions for *n*-propyl alcohol and OH^- ions for isopropyl alcohol predominated other negative ions. When the yields of O^- and OH^- ions in 10 eV electron energies are compared with those of positive ions of the most intense peak obtained in 15 eV electron energies, $CH_2OH^+/O^-=2.0\times10^4$ for *n*-propyl alcohol and $C_2H_4OH^+/OH^-=2.3\times10^3$ for isopropyl alcohol were obtained respectively.

Since the data were taken at a pressure of $\sim10^{-6}$ mmHg, the possibility of ions induced by ion-molecule reactions would be ruled out.

The differences in negative ion mass spectra in both samples, especially of O^- and OH^- ions, will be also discussed later in relation to electron energies on the basis of measurement results of IE curves.

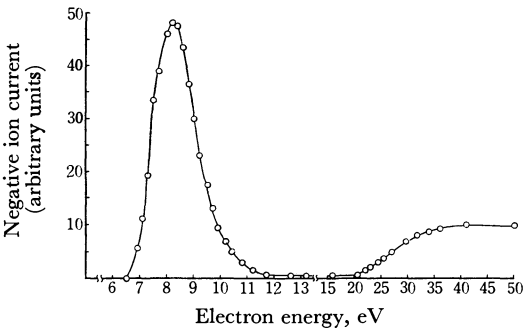

Fig. 3. Ionization efficiency curve of OH^- ions from *n*-propyl alcohol.

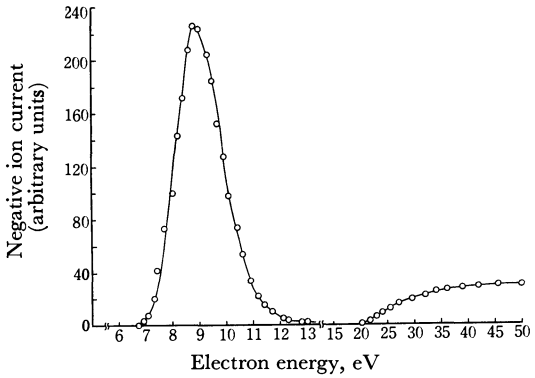

Fig. 4. Ionization efficiency curve of OH^- ions from isopropyl alcohol.

IE Curves. *OH^- Ions.* Figures 3 and 4 show the IE curves for *m/e* 17 (OH^-) ions obtained from *n*- and iso-propyl alcohols respectively. It can be understood that in both cases two processes contribute to their formation. The first process appears at ~6.5 eV for *n*-propyl alcohol and at ~6.7 eV for isopropyl alcohol. The second process appears at ~20.5 eV and ~20.1 eV. The shape of IE curves suggests clearly the dissociative electron capture for the first process and the ion pair formation for the second process.

Generally speaking, the appearance potential (AP) of reaction (1) can be experssed by Eq. (2), if the kinetic energies of fragment are ignored and the ions formed are in ground state.

$$XYZ + e^- \rightarrow X^- + Y + Z \quad (1)$$

$$AP_{calc} = \Delta H = \Delta H_f(X^-) + \Delta H_f(Y) + \Delta H_f(Z) - \Delta H_f(XYZ) \quad (2)^{*3}$$

In the case of ion pair formation ($Y \rightarrow Y^+$), the following equation holds.

$$AP_{calc} = \Delta H = \Delta H_f(X^-) + \Delta H_f(Y^+) + \Delta H_f(Z) - \Delta H_f(XYZ) \quad (3)$$

From Eqs. (2) and (3), the schemes of the most plausible reactions expected to occur at the onset values of each AP_{obs} were sought.

For the first process, the following reactions may be considered.

$$n\text{-}C_3H_7OH + e^- \rightarrow OH^- + C_3H_7 \quad (AP_{calc}=2.22\ eV) \quad (4)$$

$$\rightarrow OH^- + CH_3 + C_2H_4 \quad (AP_{calc}=3.19\ eV) \quad (5)$$

$$\rightarrow OH^- + C_2H_5 + CH_2 \quad (AP_{calc}=4.86\ eV) \quad (6)$$

$$\rightarrow OH^- + CH_2 + H + C_2H_4 \quad (AP_{calc}=6.56\ eV) \quad (7)$$

$$\rightarrow OH^- + CH_3 + 2CH_2 \quad (AP_{calc}=7.65\ eV) \quad (8)$$

*3 $\Delta H_f(X)$: heat of formation of X.

In the estimation of AP_{calc}, the values of ΔH_f (*n*-C_3H_7OH) = −2.70 eV, $\Delta H_f(OH^-)$ = −1.44 eV,*4 $\Delta H_f(C_3H_7)$ = 0.96 eV, $\Delta H_f(CH_3)$ = 1.39 eV, $\Delta H_f(C_2H_4)$ = 0.54 eV, $\Delta H_f(C_2H_5)$ = 1.10 eV, $\Delta H_f(CH_2)$ = 2.5 eV and $\Delta H_f(H)$ = 2.26 eV were used.[14] Among reactions (4)—(8), the reaction (7) is strongly expected because the consistency of AP_{calc} with AP_{obs} (~6.5 eV) is best for reaction (7).

For the second process,*5 the following reactions may be considered.

$$n\text{-}C_3H_7OH + e^- \rightarrow OH^- + C_3H_7^+ + e^- \quad (AP_{calc}=10.91\ eV) \quad (9)$$

$$\rightarrow OH^- + CH_3^+ + C_2H_4 + e^- \quad (AP_{calc}=13.03\ eV) \quad (10)$$

$$\rightarrow OH^- + C_2H_5^+ + CH_2 + e^- \quad (AP_{calc}=13.64\ eV) \quad (11)$$

$$\rightarrow OH^- + C_2H_4^+ + CH_3 + e^- \quad (AP_{calc}=13.70\ eV) \quad (12)$$

$$\rightarrow OH^- + CH_2^+ + C_2H_5 + e^- \quad (AP_{calc}=16.76\ eV) \quad (13)$$

$$\rightarrow OH^- + CH_3^+ + 2CH_2 + e^- \quad (AP_{calc}=17.49\ eV) \quad (14)$$

$$\rightarrow OH^- + CH_2^+ + CH_3 + CH_2 + e^- \quad (AP_{calc}=19.55\ eV) \quad (15)$$

$$\rightarrow OH^- + H^+ + CH_2 + C_2H_4 + e^- \quad (AP_{calc}=20.16\ eV) \quad (16)$$

A relatively good consistency of AP_{calc} of reaction (16) with AP_{obs} (~20.5 eV) suggests the possibility of the occurrence of reaction (16). A small allowance of the excess kinetic energies of the fragment ions, however, may also permit the possibility of reaction (15). In the present stage when their details are not well known, it is difficult to discuss this problem further.

The same reactions would also be assigned for the first and second processes in isopropyl alcohol, in which the use of ΔH_f(*i*-C_3H_7OH) = −2.84 eV is required.*6

O^- Ions. Figures 5 and 6 show the IE curves for *m/e* 16 (O^-) ions obtained from *n*- and iso-propyl alcohols respectively. The two samples gave similar curves except for a small peak at ~11.2 eV for *n*-propyl alcohol. If this peak is ignored, we see that the first process appears at ~6.2 eV and ~6.4 eV, the second process at the same value,

*4 To be estimated from $\Delta H_f(OH)$ = 0.39 eV and EA(OH) = 1.83 eV (L. M. Branscob, *Phys. Rev.*, **148**, 11 (1966)).

*5 For the value of $H_f(Y^+)$, see Ref. 14.

*6 In some cases, rearrangement should be taken into consideration.

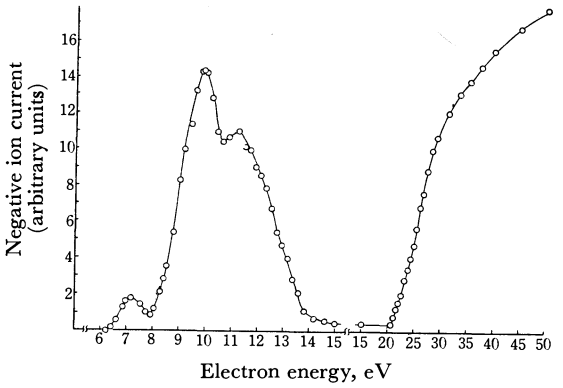

Fig. 5. Ionization efficiency curve of O^- ions from *n*-propyl alcohol.

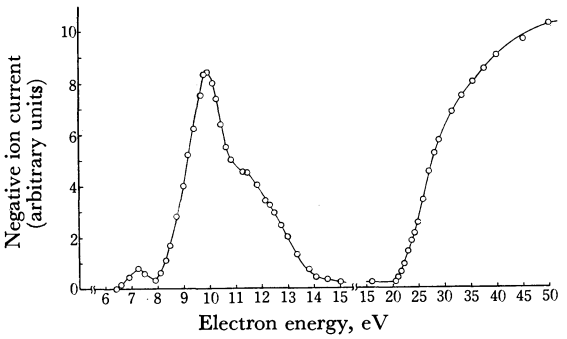

Fig. 6. Ionization efficiency curve of O^- ions from isopropyl alcohol.

~7.9 eV*[7] and the third process at ~20.8 eV and ~20.5 eV.

In the same manner as OH^- ions, the reaction schemes which correspond to each AP_{obs} value were sought by using $\Delta H_f(O^-)=1.09$ eV*[8] and the known values of ΔH_f(products).[14] For the first process, the following reactions may be considered.

$$n\text{-}C_3H_7OH + e^- \rightarrow O^- + C_3H_6 + H_2 \quad (AP_{calc}=4.00\ eV) \quad (17)$$

$$\rightarrow O^- + C_2H_5 + CH_3 \quad (AP_{calc}=6.28\ eV) \quad (18)$$

For the second process,

$$n\text{-}C_3H_7OH + e^- \rightarrow O^- + C_3H_7 + H \quad (AP_{calc}=7.01\ eV) \quad (19)$$

$$\rightarrow O^- + C_3H_5 + H_2 + H \quad (AP_{calc}=7.35\ eV) \quad (20)$$

$$\rightarrow O^- + C_2H_4 + CH_3 + H \quad (AP_{calc}=7.98\ eV) \quad (21)$$

$$\rightarrow O^- + C_2H_3 + H_2 + CH_3 \quad (AP_{calc}=8.01\ eV) \quad (22)$$

$$\rightarrow O^- + C_3H_6 + 2H \quad (AP_{calc}=8.52\ eV) \quad (23)$$

$$\rightarrow O^- + C_3H_4 + H_2 + 2H \quad (AP_{calc}=10.23\ eV) \quad (24)$$

For the third process,

$$n\text{-}C_3H_7OH + e^- \rightarrow O^- + CH_3^+ + H + C_2H_4 + e^- \quad (AP_{calc}=17.82\ eV) \quad (25)$$

$$\rightarrow O^- + C_2H_4^+ + H + CH_3 + e^- \quad (AP_{calc}=18.49\ eV) \quad (26)$$

$$\rightarrow O^- + H^+ + C_3H_7 + e^- \quad (AP_{calc}=20.61\ eV) \quad (27)$$

$$\rightarrow O^- + H^+ + C_3H_5 + H_2 + e^- \quad (AP_{calc}=20.95\ eV) \quad (28)$$

Among these reactions, the possibility of reaction (18) for the first proc of reaction (21) or (22) for the second process ar of reaction (27) or (28) for the third process can be strongly expected because their AP_{calc} values are almost consistent with each AP_{obs} value of ~6.2 eV, ~7.9 eV and ~20.8 eV respectively. For the same reason as described in the case of OH^- ions, however, we cannot exclude the possibility of reactions (19), (20) or (25) and (26). The same interpretation is also applied for isopropyl alcohol. Reaction (24) might correspond to the process appearing at ~11.2 eV of the third peak observed for *n*-propyl alcohol. This is, however, a tentative interpretation and still open to question.

The yield of negative ions (OH^-, O^- ions) depends on the cross section of formation process of negative ions. Figures 3 and 4 show that the maximum yield of OH^- ions is obtained at 8.2 eV for *n*-propyl alcohol and at 8.7 eV for isopropyl alcohol and is larger in isopropyl alcohol. The cross section of reaction (7) expected to occur at 8.2 eV and 8.7 eV electron energies is larger by a factor of 5 in isopropyl alcohol. On the other hand, Figs. 5 and 6 show that the maximum yield of O^- ions is obtained at almost the same electron energies, ~10 eV in the range of zero to 30 eV, and their yield is larger by a factor of ~1.6 in *n*-propyl alcohol.

It should be noted that (1) O^- ions for *n*-propyl alcohol and OH^- ions for isopropyl alcohol showed always the most intense peaks irrespective of electron energies used, (2) their yields under 80 eV and

*[7] Since the tailing due to the first process might overlap with the appearance of the second process, the exact determination of appearance potential of the second process is difficult. In this work, the minimum values in IE curves have been taken into consideration (G. J. Schulz, *Phys. Rev.*, **113**, 816 (1959)).

*[8] $\Delta H_f(O^-)=\Delta H_f(O)-EA(O^-)=2.56-1.47=1.09$ (eV) (L. M. Baranskob, D. S. Burch, S. J. Smith and S. Geltman, *Phys. Rev.*, **111**, 504 (1958)).

40 eV electron energies were lower by a factor of 10^5—10^4 than those of positive ions, (3) even if the energy is decreased to 10 eV, their yields were still lower by a factor of 10^4—10^3 compared with those of positive ions in 15 eV, and (4) contrary to our expectation, the simple dissociative electron capture and ion pair processes such as reactions (4) and (9)*[9] could not be found.

*[9] An apparatus with extremely high sensitivity seems to be required for the detection of reaction (9), $C_3H_7^+ + OH^- + e^-$. The cross section of this reaction appears to be extremely small. (S. Tsuda and W. H. Hamill, *Advan. Mass Spectry.*, **3**, 249 (1965))

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 2519—2523 (1969)

Bond Lengths of Dimethylacetylene as Determined by Gas Electron Diffraction

Mitsutoshi TANIMOTO, Kozo KUCHITSU and Yonezo MORINO

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo

(Received March 14, 1969)

The bond distances of dimethylacetylene have been determined by electron diffraction to be r_g(C–C)$=1.467_5\pm0.001_3$ Å, r_g(C≡C)$=1.213_5\pm0.001_3$ Å, r_g(C–H)$=1.115_8\pm0.005_9$ Å, and ∠C–C–H$=110.7\pm0.4°$, the uncertainties representing the limits of experimental error. The carbon-carbon single bond length has been found to be in good agreement with that in butadiene, as was qualitatively to be expected from Stoicheff's empirical rule. The carbon-carbon triple bond length appears to be longer than that of acetylene and shorter than that of diacetylene by a few thousandths of an angstrom. The dependence of the triple-bond lengths on the environment is discussed in terms of the change in conjugation and hyperconjugation.

Abundant experimental data from spectroscopy and electron diffraction accumulated over three decades are of basic importance to a systematic understanding of molecular structure. A marked dependence of the carbon-carbon single bond lengths on environment was first recognized by Herzberg *et al.*[1] in 1937. A distinct but less conspicuous difference in C=C double bond lengths in allene and ethylene was later shown by Overend and Thompson.[2] A subsequent analysis of the available data led Stoicheff[3] to determine empirical regularities for the "normal" behavior of C–C and C=C bond lengths, which vary nearly linearly with the number of atoms attached to the carbon atoms in question. While a majority of the C–C and C=C lengths in hydrocarbons seem to follow his rule to 0.005 Å, this does not necessarily preclude an appreciable deviation due to adjacent heteroatoms, *i.e.*, a "secondary" effect, about which little is known at present. Recently a series of molecules with C–C bonds adjacent to two double bonds (butadiene, acrolein and glyoxal) were studied by Kuchitsu, Fukuyama, and Morino,[4] who demonstrated a systematic variation of the single-bond lengths. A similar difference was observed in the C–C bonds adjacent to two triple bonds (cyanogen[5] and diacetylene[6]). The purpose of the present study is to extend such investigations to C≡C triple-bond systems.

The lengths of ordinary C≡C bonds have been supposed to be insensitive to their environment. For example, the C≡C lengths (r_0) in acetylene, methylacetylene, and cyanoacetylene were found to be nearly equal (1.207 Å),[7] so that any increase in the length due to conjugation or hyperconjugation should be extremely small (probably not over 0.005 Å),[8] whereas Stoicheff remarked a slight decrease when halogen atoms were adjacent to a C≡C bond.[3] The constancy of the C≡C length

has had practical utility in the spectroscopic determination of molecular structure; when the number of independent structural parameters exceeded that of rotational constants available, the r_0(C≡C) length has often been set equal to that in simple acetylenic compounds, say, 1.206 Å, since this assumption was one of the most plausible. The r_s(C≡C) distances in a number of molecules measured by Costain and others seem to offer further support for this invariance, since they range from 1.205 Å (cyanoacetylene)[9] to 1.209 Å (tert-butylacetylene).[10]

However, if one intends to study the dependence of the bond lengths on the environment more carefully (say, with an accuracy better than 0.005 Å), one has to investigate the equilibrium or average distances instead of the r_0 or r_s distances. Since the latter parameters for polyatomic molecules are based on only operational definitions, they are not always suitable for such a critical comparison of bond lengths.

In this connection, the structure of diacetylene was examined in our laboratory. The *thermal average* C≡C length determined by electron diffraction was found to be r_g(C≡C)$=1.217_6\pm0.001_4$ Å,[6] about 0.006 Å longer than the corresponding value in in acetylene, r_g(C≡C)$=1.212\pm0.001$ Å.[6] This suggests that the *equilibrium* bond lengths (r_e) also differ by a similar amount, so that a further experimental study of molecules with C≡C bonds seems to be worthwhile.

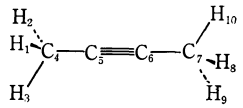

Fig. 1. The structure and numbering convention of dimethylacetylene.

The bond lengths in dimethylacetylene (2-butyne) have been investigated by gas electron diffraction in the present study. The structure of this molecule was first studied by means of electron-diffraction measurements by Pauling *et al.*,[11] who gave r(≡C–C≡)$=1.47\pm0.02$ Å on the assumptions that the other bond lengths were r(C≡C)$=1.20$ Å and r(C–H)$=1.09$ Å. The rotational constant, B_0, was determined by Callomon and Stoicheff[12] on the basis of an analysis of their pure rotational Raman spectrum. They could not, however, determine the dimensions of dimethylacetylene since they obtained the B_0 constant of the normal species alone. From a comparison of the observed moment of inertia with that calculated from the methylacetylene parameters, which was significantly smaller than the observed value, they concluded that at least one of the carbon-carbon bonds was longer than in the closely related molecule, methylacetylene.

Experimental

Two millilitres of a 99% pure liquid sample of dimethylacetylene were purchased from the Tokyo Kagaku Seiki Co., Ltd., and were used after vacuum distillation. Diffraction photographs were taken at room temperature using an apparatus with an r^3-sector.[13] The accelerating voltage (about 40 kV), stabilized to within 0.01%, was monitored during the exposure and was further calibrated with reference to the C=O length of carbon dioxide.[5] Four plates were chosen from each camera distance (107.78 ± 0.02 mm or 243.23 ± 0.02 mm), and their photographic densities, measured by a microphotometer, were analyzed in order to obtain the molecular intensities.

Analysis

The molecular intensities were analyzed by a conventional least-squares method[14] with some modifications.[4] The alterations involved a choice of independent parameters and corrections for vibrational effects. The calculations were made by using the HITAC 5020E at the Computer Centre of the University of Tokyo.

As a result of molecular vibration, the r_g distances determined by electron diffraction are not additive. The so-called shrinkage effect[15] should disappear in regard to the r_α distances, which are obtained from r_g by subtracting the perpendicular and centrifugal contributions:[16]

$$r_\alpha = r_g - \frac{\langle \Delta\rho^2 \rangle}{2r_e} - \delta r. \qquad (1)$$

Since the r_α structure represents the thermal-average positions of constituent atoms,[4] it corresponds to the equilibrium symmetry of the molecule. In other words, provided the molecular symmetry is known from spectroscopy, the number of distance parameters (r_α) can be decreased by assuming the symmetry as a constraint. In the present analysis, the bond lengths, r(C–H), r(C–C) and r(C≡C), and the angle θ(CCH) with regard to the r_α structure were taken as independent parameters.

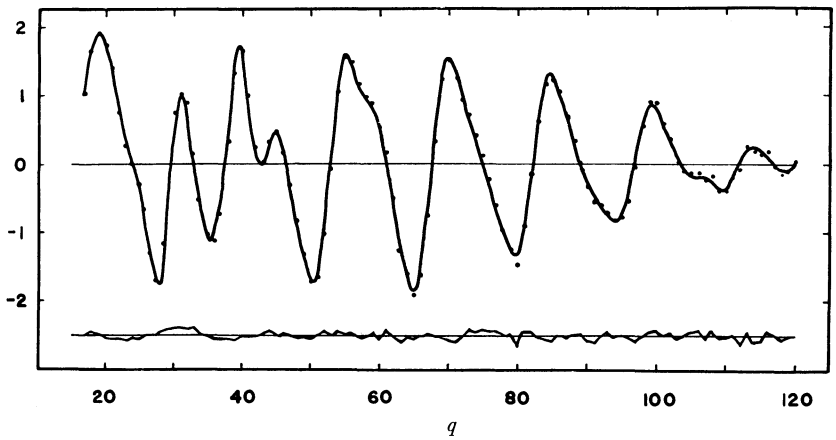

Fig. 2. Reduced molecular intensity curves (dots for observed values and the solid curve calculated from the best-fit model) and the residuals (below)

Since longer nonbonded H···H atom pairs contribute only a negligible amount to the reduced molecular intensity in the observed q range, the reduced molecular intensity is insensitive to the internal rotation of the methyl groups. Since the infrared spectra lead us to believe that the two methyl groups undergo a nearly free internal rotation,[17] the present analysis was based on the assumption of free rotation.

The asymmetry parameters, κ, were calculated by the diatomic approximation[18] to be 2.0×10^{-5} Å^3 for the CH bonded pairs and 8×10^{-7} Å^3 for the C≡C and C–C bonded pairs. The parameters for the other atom pairs were ignored since their effects were unimportant.

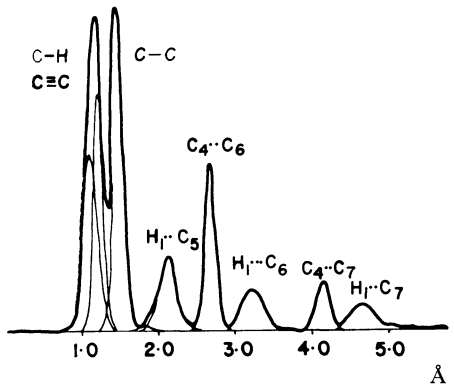

Fig. 3. Radial distribution curve. The atom pairs contributing to individual peaks are shown.

Table 1 lists the values of independent parameters obtained in the above analysis, together with their estimated limits of error (2.5 times the random standard errors plus systematic errors). The observed mean amplitudes given in Table 2 agree with the parallel amplitudes calculated by a conventional method[19] within the range of experimental error.

Discussion

Average Structure. The distances between the atoms in the vibrational ground state, r_a^0, were

17) D. Papoušek, J. Adams and K. N. Rao, Symposium on Molecular Structure and Spectroscopy O6, Columbus, Ohio, 1968.

18) K. Kuchitsu, This Bulletin, **40**, 498 (1967).

19) Y. Morino and E. Hirota, *J. Chem. Phys.*, **23**, 737 (1955).

obtained from the r_a distances by:[20]

$$r_a^0 = \lim(T \to 0°K) r_a$$
$$= r_a - (\langle \Delta z \rangle_T - \langle \Delta z \rangle_0), \quad (2)$$

where $\langle \Delta z \rangle = \langle \Delta r \rangle - (\langle \Delta x^2 \rangle + \langle \Delta y^2 \rangle)/2r_e$. The $\langle \Delta r \rangle$ term was calculated by assuming a Morse-type potential function for a bond, the anharmonicity parameter being taken from the corresponding diatomic molecule. The generalized mean amplitudes, $\langle \Delta x^2 \rangle$, $\langle \Delta y^2 \rangle$, and $\langle \Delta z^2 \rangle$, were calculated by the use of the quadratic force constants.[21] The values of the r_a^0 distances are given in Table 1.

The rotational constant, B_z, calculated from the r_a^0 structure was compared with the ground-state rotational constant, B_0, by correcting for vibration-rotation interactions.[20] The correction, -3×10^{-5} cm^{-1}, was an order of magnitude smaller than the experimental error. The rotational constant, B_0, calculated from the diffraction structure was 0.1116 $\pm$0.0002 cm^{-1}, which was 0.5$\pm$0.2% smaller than the spectroscopic B_0 constant,[12] 0.1122$\pm$0.0002 cm^{-1}.

This difference is probably due to the systematic error in the rotational-Raman measurement, since, for similar molecules[22-25] listed in Table 3, the

TABLE 3. ROTATIONAL CONSTANTS B_0 DERIVED FROM RAMAN AND INFRARED SPECTROSCOPY (in cm^{-1} units)

c) Estimated.

rotational constants obtained from the Raman spectra are about 3×10^{-4} cm^{-1} larger than those derived from the infrared spectra, the difference exceeding their limits of error. The origin of the discrepancy for cyanogen was ascribed by Maki[26] to the Raman measurement biased by overlapping lines due to molecules in the low-lying vibrational excited states. If this is also the case for dimethylacetylene, a proper spectroscopic B_0 value should be smaller than the observed value[12] by about 5×10^{-4} cm^{-1}; it is thus estimated to be 0.1117$\pm$0.0002 cm^{-1}, in reasonable agreement with the present diffraction result.

Comparison of Bond Lengths. As was recently discussed by Kuchitsu,[27] distance parameters can be compared most conveniently in terms of the thermal-average (r_g) distances, since the differences in r_g for analogous molecules correspond to those in r_e within the range of experimental error; the effect of thermal vibration ($r_g - r_e$) on a certain bond distance should be essentially equal to its counterparts for analogous molecules. The r_g parameters determined above afford a clue to the problem set up in the introduction, *i. e.*, the effect of the environment on carbon-carbon triple and single bond lengths.

The change in multiple bond lengths by conjugation has been discussed from a theoretical point of view. Mulliken[28] argued that the multiple-bond length should increase only slightly since π-electrons delocalized into adjacent bonds as a result of conjugation should return to the original bonds because of mutual repulsion. In consideration of the effects of hybridization and electron delocalization on the CC bond lengths, Bak and Hansen-Nygaard[29] estimated a multiple-bond lengthening of a few thousandths of an angstrom from the corresponding shortening of the neighboring bonds. A number of experimental data indicating such lengthenings in multiple-bonds were given; those data were in rough agreement with what they expected. At the same time, however, they stressed the usefulness of further, more accurate experiments in order to make the structure comparison less ambiguous.

The present study has confirmed that the C≡C bond length in dimethylacetylene is significantly shorter than that in diacetylene[6] and longer than that in acetylene[6] (Table 4). Furthermore, the value for dimethylacetylene is in good agreement with the bond length in vinylacetylene.[30] The

above results are consistent with simple intuition in terms of the effect of conjugation and hyperconjugation on bond lengths. According to Mulliken,[31] the effect of conjugation should be larger than that of hyperconjugation. Thus, the C≡C distance in dimethylacetylene should fall in between those of diacetylene and acetylene. For a number of other molecules the lengths of CC triple bonds have been reported in terms of r_s distances. (For example, see Ref. 9). Presumably the r_s(C≡C) distances are shorter than the r_g(C≡C) distances by a few thousandths of an angstrom.

The C–C distance (r_g) determened in this study, $1.467_5 \pm 0.001_3$ Å, is equal to that in butadiene[32] (r_g(C–C) = 1.465±0.003 Å) within the range of experimental uncertainty. This observation agrees qualitatively with Stoicheff's rule, which says they should be identical. The C–C bond length in methylacetylene is also expected to be similar to those in dimethylacetylene and butadiene, whereas the r_s(C–C) distance was reported by Costain[9] to be 1.4589 Å. An electron-diffraction study of this molecule is now in progress.

The r_g(C–H) distance determined above (r_g(C–H) = $1.115_8 \pm 0.005_9$ Å) seems to be slightly longer than the CH bond length in ethane (r_g(C–H) = $1.110_8 \pm 0.002$ Å[27,33]), but the large limit of error attached to the former bond length forbids a quantitative comparison. The CCH angle in dimethylacetylene, 110.7±0.4°, appears to be only slightly smaller than that in ethane[27] (111.5±0.3°). A similar value has been reported for methylacetylene[9] (110.2° in r_s structure).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 2523—2531 (1969)

The Chemistry of Protactinium. VIII. Synergistic Effect of Di-isobutyl Carbinol on the Pa(V)-TTA-Benzene Solvent Extraction System

Shin SUZUKI and Yasushi INOUE

The Research Institute for Iron, Steel and Other Metals, Tohoku University, Katahira-cho, Sendai

(Received January 8, 1969)

For the purpose of understanding the behavior of protactinium in a perchloric acid solution toward TTA-benzene extraction, the effect of di-isobutyl carbinol (DIBC) on the extraction was studied. A marked synergism was observed. As a result of a detailed investigation of such things as the effects of the TTA concentration, of the DIBC concentration, and of the acidity, the unified mechanism of TTA-benzene and TTA-DIBC-benzene extraction is considered to be a series of successive reactions, (1) through (4), with an increase in the DIBC concentration:

$PaO_m(OH)_n^{5-2m-n} + 4HT = Pa(OH)_2T_3(HT) + (m+n-2)H_2O + (5-2m-n)H^+$

$Pa(OH)_2T_3(HT) \rightarrow PaOT_3(HT)$ (slow, irreversible) (1)

$PaO_m(OH)_n^{5-2m-n} + 4HT + B = Pa(OH)_2T_3(HT)B + (m+n-2)H_2O + (5-2m-n)H^+$

$Pa(OH)_2T_3(HT)B \rightarrow PaOT_3(HT)B$ (slow, irreversible) (2)

$PaO_m(OH)_n^{5-2m-n} + 3HT + B = Pa(OH)_2T_3B + (m+n-2)H_2O + (5-2m-n)H^+$

$Pa(OH)_2T_3B \rightarrow PaOT_3B$ (slow, irreversible) (3)

$PaO_m(OH)_n^{5-2m-n} + 3HT + 2B = Pa(OH)_2T_3B_2 + (m+n-2)H_2O + (5-2m-n)H^+$

$Pa(OH)_2T_3B_2 \rightarrow PaOT_3B_2$ (slow, irreversible) (4)

The slow, irreversible reaction in each step indicates the irreversible formation of unstrippable species in the organic phase with aging. The absorption spectral measurements gave results consistent with this conclusion.

It was stated earlier[1] that when the protactinium concentration was lower than 10^{-6}M and the perchloric acid concentration was 0.3—2.0M, the reaction of TTA extraction of protactinium from a perchloric acid solution proceeded as:

$$PaO_m(OH)_n^{5-2m-n} + 4HT = Pa(OH)T_4 + (m+n-1)H_2O + (5-2m-n)H^+ \quad (1)$$

where $2m+n$ is 3 and 4, or as:

1) S. Suzuki and Y. Inoue, This Bulletin, **39**, 1705 (1966).

$$PaO_m(OH)_nT^{4-2m-n} + 4HT = PaT_5 + (m+n)H_2O + (4-2m-n)H^+ \quad (2)$$

where $2m+n$ is 2 and 3.

We have been unable to distinguish between the two reactions from the experimental evidence. Reaction (1) may, however, be considered to be more probable than reaction (2) because of the very low solubility of TTA in the aqueous phase. In any case, protactinium(V) in a perchloric acid solution is present as species which have +2 and +1 charges. $Pa(OH)T_4$, which is used in Eq. (1) to represent the extracted species, is not the only form which it is possible to deduce from the experimental results. In general, the addition compounds of HT should be taken into account. Thus the extracted form may generally be written as $PaO_p(OH)_qT_{5-2p-q}(HT)_d$, where $2p+q-d$ is unity. That is, $PaOT_3(HT)$ or $Pa(OH)_2T_3(HT)$, $PaO(OH)T_2(HT)_2$ or $Pa(OH)_3T_2(HT)_2$ and $Pa(OH)_4T(HT)_3$, $PaO_2T(HT)_3$ or $PaO(OH)_2T(HT)_3$, ··· are possible as well as $Pa(OH)T_4$, depending on the d value, which cannot be determined by a simple TTA extraction experiment. In the above investigation, discussion has been restricted to the qualitative aspect because the reproducibility of the experimental data is not good enough to provide quantitative information. One of the reasons for this irreproducibility has been considered to be the complex behavior of TTA extraction, which depends greatly on the method of preparing the perchloric acid solution of protactinium. In order to elucidate the complex behavior more clearly, an elaborate investigation was carried out. Definite differences in the extraction behavior were observed among four kinds of the solutions which were prepared by different methods. Moreover, it was shown that a stripping equilibrium was established only when a freshly-prepared protactinium solution in TTA-benzene was used. Unstrippable species are formed when the Pa-TTA-benzene stands for a long period.[2]

The investigation of a synergistic effect is one of the means to determine the d values mentioned above. Guillaumont[3] studied the synergistic effect of TBP on the extraction of protactinium by TTA-benzene. The mechanism of the effect was understood by the following reaction:

$$Pa(OH)_3T_2(HT)_2 + 2TBP = Pa(OH)_3T_2(TBP)_2 + 2HT \quad (3)$$

and the extraction mechanism of protactinium by TTA was:

$$Pa(OH)_3^{2+} + 4HT = Pa(OH)_3T_2(HT)_2 + 2H^+ \quad (4)$$

As a result of the investigation of the synergism by *n*-amyl alcohol in the TTA extraction system, Kolarich and his co-workers[4] concluded that the extracted species was $PaOT_3(HT)$.

In the present investigation, the effect of di-isobutyl carbinol (DIBC) on the TTA-benzene extraction of protactinium has been examined; a marked synergism was observed. The consideration of the mechanism of the synergistic effect enables us to determine the d value and to make a hypothesis concerning the reasons for the irreversible change of the protactinium species in the TTA-benzene solution.

Experimental

Reagents and Apparatus. ^{231}Pa *and* ^{233}Pa. Stock solutions of these isotopes in hydrochloric acid and hydrofluoric acid mixtures were prepared by a method reported previously.[5] The concentration of protactinium in the ^{231}Pa solution was determined by gravimetry as protactinium pentoxide. The benzene was purified by distillation, and doubly-distilled water was used throughout this experiment. The acidity of the solution was determined by titration with a standard sodium hydroxide solution. The highest-purity-grade lithium perchlorate was used for the adjustment of the ionic strength, and the concentration of its solution was determined gravimetrically as lithium sulfate. The other chemicals, such as thenoyl trifluoroacetone, perchloric acid and di-isobutyl carbinol, were also all of the highest purity.

For the solvent-extraction procedure, an Iwaki universal mechanical shaker, Model V-S, was used. A Kôbe Kôgyo Model PS-400 well-type scintillation probe coupled with a Kôbe Kôgyo Model SA-400 scaler was used for the γ-ray measurement. For the measurement of the absorption spectra, a Hitachi Model EPS-3 recording spectrophotometer with a 1 cm photometric cell was used.

Procedure. All the experiments were carried out at room temperature. Ordinary separatory funnels made of glass were used for the solvent extraction. To eliminate distortions of the experimental results arising from adsorption on glass, the walls of the funnels were preliminarily saturated with protactinium by shaking the test solution for a time sufficient for adsorption equilibrium to be reached. Care was taken to ascertain the material balance in each experiment, and each value given was the average of the results of at least two determinations. For all solvent extractions except with Fomin's method,[2,6] 5 m*l* portions of the aqueous and of the organic phase were used; after the separation of the two phases, a 2 m*l* aliquot of each phase was taken into a polyethylene test tube and counted for γ radioactivity. The distribution ratio was calculated by means of the usual relationship:

$$D = \frac{\gamma \text{ activity per 1 m}l \text{ of the organic phase}}{\gamma \text{ activity per 1 m}l \text{ of the aqueous phase}}$$

Forward Extraction. The protactinium solution in 1M perchloric acid for the forward extraction experiments was prepared as follows.

Aliquots of ^{231}Pa and of ^{233}Pa stock solutions (a total of 5 m*l*) and a small amount of hydrofluoric acid were transferred into a platinum dish and evaporated almost to dryness, initially on a hot plate and finally on a water bath. The residue was dissolved in 5M perchloric acid with slight heating and diluted to make the protactinium concentration 10^{-7}M.

Backward Extraction. A protactinium solution in the organic solvent for the backward extraction was prepared by the following procedure.

Aliquots of ^{231}Pa and of ^{233}Pa stock solutions were transferred into a platinum dish and heated to dryness on a hot plate. The residue was dissolved in 0.64 m*l* of 1.17M hydrofluoric acid, and then 0.99 m*l* of 5.05M perchloric acid and 1.7 m*l* of a 1.33M aluminum perchlorate solution were added, in this order. The resulting solution was diluted to 50 m*l* with distilled water. This solution was then placed in contact with 200 m*l* of a DIBC-TTA-benzene solution of a suitable composition for 20 min. The concentration of protactinium in the TTA-DIBC-benzene solution thus prepared was 0.99×10^{-7}M.

Absorption Spectra. A ^{231}Pa solution containing 6.17×10^{-6} Mole was transferred into a platinum dish and heated to dryness on a water bath. The residue was dissolved in 0.96 m*l* of 1.17M hydrofluoric acid, and then 0.53 m*l* of 4.71N sulfuric acid and distilled water were added to make 25 m*l*. This solution was then transferred into a separatory funnel containing 25 m*l* of a 0.5M TTA-benzene solution and 25 m*l* of a 0.136M aluminum perchlorate solution. Then the separatory funnel was shaken with a mechanical shaker for 15 min. The organic phase was withdrawn from the funnel and an aliquot of the solution was diluted with DIBC-benzene of a suitable concentration. This solution was used for the absorption spectral measurement. The protactinium concentration was about 2.5×10^{-5}M.

Results

The Effect of Contact Time in the Forward Extraction. The effect of the contact time on the distribution ratio of protactinium in 1M perchloric acid was investigated as a function of the DIBC concentration, as is shown in Figs. 1a and 1b. When the DIBC concentration is lower than 0.1% (the concentration of DIBC is represented by volume%), the distribution ratio reaches constant after about 10 min of contact, whereas the extraction rate becomes slower with an increase in the concentration of DIBC. Longer than an hour's contact is necessary for the extractant 1% in DIBC to reach a constant distribution ratio.

The Effect of Aging on the Distribution Ratio in the Forward Extraction. The effect of aging time on the distribution ratio was investigated for the forward extraction of protactinium in a 1M perchloric acid solution by both 2×10^{-2}M TTA-0.07%DIBC and 5×10^{-2}MTTA-0.02%DIBC in benzene solutions. Curves similar to that of

No. 1 in Fig. 3 of the 7th report of this series[2] were obtained; that is, the distribution ratio remains constant for about a week after the preparation of the sample, and then it begins to decrease. This constant value coincides with

one obtained from the backward distribution of the fresh protactinium solution in TTA-DIBC-benzene. The conditions used in the preparation of the protactinium solution are as suitable as those used for No. 1 in a previous report.[2] The reason why the No. 1 preparation method has not been used is that in it the control of the acidity is very difficult.

The Relation between the Distribution Ratio and the TTA Concentration. The influence of the TTA concentration on the distribution ratio was investigated for a 1M solution in perchloric acid at various DIBC concentrations. The logarithm of the distribution ratio was plotted as a function of the logarithm of the TTA activity in the benzene phase, as is shown in Fig. 2. Provided the nature of TTA is not affected by the presence of DIBC at such low concentrations as 1%, the activity of TTA in the benzene phase at equilibrium can be calculated from its initial concentration by the following equations:

$$\frac{(HT)_I}{(HT)_B} = 1.02 + 10^{-8}/(H^+)^{7)} \quad (5)$$

$$f_{HT} = 1 - 0.25(HT)_B^{0.48\ 8)} \quad (6)$$

where f_{HT} is the activity coefficient of TTA in benzene; $(HT)_B$, the final concentration in benzene when equilibrated with an equal volume of an aqueous phase, and $(HT)_I$, the initial concentration. It is clear from Fig. 2 that the log-log plot of the distribution ratio and the activity of TTA shows a good linearity, with varying slopes, depending on the DIBC concentration, over a wide range of TTA concentrations. As Table 1 shows, the slope is about 4 when the DIBC concentration is lower than 0.0003% and decreases with an increase in the DIBC concentration from 0.0003% upwards.

The Relation between the Distribution Ratio and the DIBC Concentration. The effect of the DIBC concentration on the distribution ratio was examined in 1M perchloric acid solution, with the TTA concentration kept constant. The logarithm of the distribution ratio was plotted as a function of the logarithm of the DIBC concentration in the benzene phase, as is shown in Fig. 3. Though the protactinium in the 1M perchloric acid solution was not extracted at all, even by pure DIBC, the distribution ratio increases remarkably upon the addition of a small amount of DIBC; that is, synergism is observed. The linear relationship does not hold between the log of the distribution ratio and that of the DIBC concentration, but the curves asymptotically approach straight lines with an increase in the DIBC concentration. When the concentrations of TTA were 0.02M, 0.05M, and 0.1M, the slopes of the curves approached 1.0, 1.4 and 1.8 respectively.

ion concentration of 1.5M, the log-log plots of the distribution ratio and the hydrogen ion concentration show a linear relationship with a slope of −1.7, except in the case of No. 5, as is clearly shown in Fig. 4. In the case of Curve 5, with TTA and DIBC concentrations of 0.1M and 0.0004% respectively, an exact linearity does not hold.

The Effect of Contact Time in the Backward Extraction. The effect of the contact time on the backward extraction carried out by using a freshly-prepared protactinium solution in 0.05M TTA and 0.02% DIBC-benzene was investigated; the results are shown in Fig. 5. The stripping solution was 1.0M perchloric acid. It is apparent from the figure that about an hour's contact is necessary to get a constant distribution ratio.

The Effect of Time of Standing of a Protactinium Solution in TTA-DIBC-Benzene on the Distribution Ratio. A protactinium solution in TTA-DIBC-benzene was stored in a brown bottle in the dark, and the change in the distribution ratio during the standing was followed. The protactinium in a 0.05M TTA-0.02% DIBC-benzene solution was stripped by 1M perchloric acid for 1.5 hr. It is apparent from Fig. 6 that, at first, the distribution ratio remained constant for about several hours and then gradually increased, finally reaching a constant 5 days after the preparation. The curve was analyzed by Fomin's method. As is shown in Fig. 7, the P value (the percentage of unstrippable species which are not in rapid equilibrium with the strippable species) observed for a fresh Pa-TTA-DIBC solution was only a few percent. It increases remarkably with the standing, however, and reaches a constant value of about 40% after 10 days of standing. The distribution ratio of strippable species does not change with standing, so that the increase in distribution ratio can be explained on the basis of the formation of unstrippable species alone.

Absorption Spectra of Protactinium in TTA-DIBC-Benzene Solution. The absorption spectra of protactinium in the TTA-DIBC-benzene mixture were measured from 340 to 650 mμ in relation to the DIBC concentration, as is shown in Fig. 8. The concentrations of protactinium and of TTA are *ca.* 2.5×10^{-5}M and 0.05M respectively. It is observed that, in the absence of DIBC, an absorption maximum appears at 408 mμ; it shifts to a shorter wavelength with an increase in the DIBC

Discussion

If the species extractable into the organic phase are considered to have no charge, the general equation for the TTA-DIBC extraction reaction can be written as:

$$\mathrm{PaO}_m(\mathrm{OH})_n^{5-2m-n}(\mathrm{aq.}) + (5-q-2p+d)\mathrm{HT}(\mathrm{org.}) + b\mathrm{B}(\mathrm{org.}) = \mathrm{PaO}_p(\mathrm{OH})_q(\mathrm{HT})_d\mathrm{T}_{5-2p-q}\mathrm{B}_b(\mathrm{org.}) + (m+n-p-q)\mathrm{H_2O} + (5-2m-n)\mathrm{H^+}(\mathrm{aq.}) \quad (5)$$

where HT, T^-, and B are used to denote the TTA molecule, the dissociated TTA anion, and the di-isobutyl carbinol molecule respectively. The equilibrium constant of this reaction can then be defined as:

$$K_{m,n,p,q,d} = \frac{[\mathrm{PaO}_p(\mathrm{OH})_q(\mathrm{HT})_d\mathrm{T}_{5-2p-q}\mathrm{B}_b][\mathrm{H_2O}]^{m+n-p-q}[\mathrm{H^+}]^{5-2m-n}}{[\mathrm{PaO}_m(\mathrm{OH})_n^{5-2m-n}][\mathrm{HT}]^{5-q-2p+d}[\mathrm{B}]^b} \quad (6)$$

where brackets have been used to represent the activities of the enclosed species. (The designation of the phase in which each species exists has been omitted in order to simplify the writing of the equation.) A distribution ratio expressed in terms of activities is defined as the sum of the activities of the protactinium species in the benzene phase divided by the sum of the activities of the protactinium species in the aqueous phase:

$$K_d = \frac{\sum_{p,q,d,b}[\mathrm{PaO}_p(\mathrm{OH})_q(\mathrm{HT})_d\mathrm{T}_{5-2p-q}\mathrm{B}_b]}{\sum_{m,n}[\mathrm{PaO}_m(\mathrm{OH})_n^{5-2m-n}]} \quad (7)$$

If the activity coefficients of TTA and DIBC are independent of the concentrations of DIBC and TTA respectively, one can derive the following relationships by the same procedure as was used before:[1]

$$-\frac{\partial \ln K_d}{\partial \ln [\mathrm{HT}]} = 5 - \sum(2p+q-d)f_{p,q,d,b} \quad (8)$$

$$\frac{\partial \ln K_d}{\partial \ln [\mathrm{H^+}]} = -\sum(5-2m-n)f'_{m,n} \quad (9)$$

$$\frac{\partial \ln K_d}{\partial \ln [\mathrm{B}]} = \sum bf_{q,p,d,b} \quad (10)$$

where $f_{p,q,d,b}$ is the fraction of the total activity of the protactinium species in the benzene phase contributed by the $\mathrm{PaO}_p(\mathrm{OH})_q(\mathrm{HT})_d\mathrm{T}_{5-2p-q}\mathrm{B}_b$ species, and $f'_{m,n}$ is that in the aqueous phase contributed by the $\mathrm{PaO}_m(\mathrm{OH})_n^{5-2m-n}$ species.

Hence,

$$\sum_{p,q,d,b} f_{q,p,d,b} = 1 \quad (11)$$

$$\sum_{m,n} f'_{m,n} = 1 \quad (12)$$

If the activity coefficients of the protactinium species and of the hydrogen ion are assumed to be constant over the entire range of acidity when the ionic strength of a solution is kept constant, the distribution ratio (D) obtained empirically can be replaced by the thermodynamic distribution ratio (K_d) expressed in terms of activity; no appreciable error should be introduced by this assumption. As is clearly shown in Fig. 4, a linear relationship with a slope of -1.7 holds between the logarithm of the distribution ratio and the logarithm of the hydrogen-ion concentration.

Therefore,

$$-5 + \sum(2m+n)f'_{m,n} = -1.7 \quad (13)$$

$$\sum(2m+n)f'_{m,n} = 3.3 \quad (14)$$

Therefore, in agreement with the results of the TTA extraction,[1] the protactinium in a perchloric acid solution may be found in the forms of $\mathrm{Pa(OH)_3^{+2}}$ or $\mathrm{PaO(OH)^{+}}$ and of $\mathrm{Pa(OH)_4^{+}}$, $\mathrm{PaO(OH)_2^{+}}$, or $\mathrm{PaO_2^{+}}$.

If the activity coefficients of the protactinium species are assumed to be constant, irrespective of the TTA concentration, the distribution ratio (D) obtained empirically can be replaced by the thermodynamic distribution ratio (K_d) in terms of activity; no appreciable error should be introduced by this assumption.

If DIBC is absent,

$$5 - \sum(q+2p-d)f_{p,q,d,b} = 4$$

$$\sum(q+2p-d)f_{p,q,d,b} = 1 \quad (15)$$

When DIBC is added, the slope of the log-log plot of the distribution ratio and the TTA activity in the organic phase changes from 4 to 3, depending on the DIBC concentration.

Thus,

$$3 \leqq 5 - \sum(q+2p-d)f_{p,q,d,b} \leqq 4$$

that is,

$$2 \geqq \sum(q+2p-d)f_{p,q,d,b} \geqq 1 \quad (16)$$

holds. In this experiment, we can not determine the d value. Depending on the postulated d value, one can obtain the following relationships:

When

$$d = 0 \quad 2 \geqq \sum(q+2p)f_{p,q,0,b} \geqq 1 \quad (17)$$

$$d = 1 \quad 3 \geqq \sum(q+2p)f_{p,q,1,b} \geqq 2 \quad (18)$$

$$d = 2 \quad 4 \geqq \sum(q+2p)f_{p,q,2,b} \geqq 3 \quad (19)$$

$$d = 3 \quad \sum(q+2p)f_{p,q,3,b} = 4 \quad (20)$$

In Eq. (20), the value of $\sum(q+2p)f_{p,q,3,b}$ over 4 is impossible because an improbable assumption must be made concerning the degree of hydrolysis, which is higher in the organic phase than in the aqueous phase. For the same reason, a d value of over 3 is impossible.

Next, in Eq. (10), if the activity coefficients of the protactinium species are assumed to be constant over the entire range of DIBC concentration, the

distribution ratio (D) obtained empirically can be replaced by the thermodynamic distribution ratio (K_d) expressed in terms of activity. As is clear from Fig. 3, the relation:

$$0 \leqq \sum bf_{p,q,a,b} < 2 \qquad (21)$$

holds. When the DIBC concentration is very low, the distribution ratio is independent of the DIBC concentration, whereas the dependence of the distribution ratio on the TTA concentration is of the power of 4. When the concentration of DIBC is extremely high as compared with the concentration of TTA, the slope of the log-log plot of the distribution ratio and the DIBC concentration is 1.8. At such a high concentration of DIBC, it is clear from Fig. 3 that the TTA dependence on the distribution ratio is of the power of 3. From the above considerations, the possibilities for the species extracted into the organic phase in relation to the concentration of DIBC may be summarized as is shown in Table 2.

The degree of the hydrolysis of the extracted protactinium species may not increase with an increase in the DIBC concentration, for synergism is observed in spite of the decrease in the TTA dependence with an increase in the DIBC concentration. Nor does it decrease, for it is difficult for the less basic DIBC to replace the more basic hydroxy anion. This implies that the change in the extracted species with an increase in the DIBC concentration occurs from the left to the right of the same row in Table 2. These considerations naturally obviate the possibility of the first row. The series of reactions described in the third row was also not warranted, for the following reasons. In this case, two molecules of TTA are assumed to be combined loosely with the chelate. If this is the case, the TTA dependency of 2 should be easily attained with an increase in the DIBC concentration. This is, however, contrary to observation. The same argument is applicable in the case of the series of reactions in the last row. Accordingly, the most probable species extracted into the organic phase are those listed on the second row.

On the second row, two series of the extracted species are possible, depending on p or q, but their values cannot be determined from the experimental results. If one compares the species containing $Pa(OH)_2^{3+}$ and PaO^{3+}, the former is considered to be more hydrophilic than the latter. On the other hand, it is known that, in a benzene solution saturated with water, 11% of TTA is present as the hydrate and that, in a benzene solution which has been neither dried nor equilibrated with water, there is present 3% hydrate. The rate of conversion of the enole form to ketohydrate is very slow, taking 2 or 3 days to reach equilibrium.[9] As the two phases were in contact for only thirty minutes in the preparation of the protactinium solution in TTA-DIBC-benzene, the equilibrium between the enole and ketohydrate forms is not attained. Therefore, the benzene solution has the potentiality of absorbing water. For this reason or for another, if one considers that the forms composed of $Pa(OH)_2^{3+}$, which will participate in the extraction equilibrium, undergo dehydration to form that composed of PaO^{3+}, the irreversible formation of unstrippable species in the organic phase with the time of standing can be well understood. The same is applicable to the interpretation of the similar findings in the TTA extraction reported in the previous report.[2] The difference in the amount of irreversible species formed during a long period of standing between the TTA and the TTA-DIBC extractions (80% and 40% respectively) is attributable to the difference in the TTA concentration used. This irreversible change in the extraction behavior cannot be attributed to the polymerization of the extracted TTA chelate, nor to the decomposition of the chelate by some such means as thermal or radiation decomposition, as has been pointed out previously.[2] These arguments do not violate the validity of the hypothesis mentioned above.

The continuous change in the slope of the log-log plot of the distribution ratio and the TTA acitivity

9) E. L. King and W. H. Reas, *J. Am. Chem. Soc.*, **73**, 1806 (1951).

with the change in the DIBC concentration can be understood if we consider the extracted species to be a mixture of forms containing four TTA and three TTA, the mixing ratio continuously changing with the concentration of DIBC. In the study of the synergism of the UO_2^{2+} -TTA extraction system by TBP, Healy and his co-workers[10,11] showed that the absorption spectra of $UO_2(TTA)_2$ and $UO_2(TTA)_2TBP$ are essentially the same. In view of this fact, it can naturally be assumed that the solvation of DIBC to the protactinium TTA chelate does not affect the absorption spectrum of protactinium in the organic phase; that is, the spectra depend only on the number of TTA present in the extracted species. If we consider Curve No. 1 in Fig. 8 to be the spectrum of the protactinium species containing four molecules of TTA, and Curve No. 7 to be that of the species containing three molecules of TTA, as the spectrum does not change with an increase in the DIBC concentration above 1%, the intermediate curves can be constructed by an appropriate combination of the two curves, No. 1 and No. 7. Therefore, we can estimate the mixing ratio of the species containing three and four molecules of TTA from the absorption spectra. This calculation was done by the method of successive approximation, as is shown in the second and third columns of Table 1. From these values, the slope of the log-log plot of the distribution ratio and the TTA activity can be estimated. The results of the calculation, listed in the fourth column of Table 1, agree well with the empirical value presented in the same table.

In conclusion, one can say in summary that reactions (22) through (25) proceed in this order with the increase in the DIBC concentration:

$$PaO_m(OH)_n^{5-2m-n} + 4HT = Pa(OH)_2T_3(HT) + (m+n-2)H_2O + (5-2m-n)H^+$$
$$Pa(OH)_2T_3(HT) \rightarrow PaOT_3(HT) \quad \text{(slow, irresversible)} \tag{22}$$

$$PaO_m(OH)_n^{5-2m-n} + 4HT + B = Pa(OH)_2T_3(HT)B + (m+n-2)H_2O + (5-2m-n)H^+$$
$$Pa(OH)_2T_3(HT)B \rightarrow PaOT_3(HT)B \quad \text{(slow, irreversible)} \tag{23}$$

$$PaO_m(OH)_n^{5-2m-n} + 3HT + B = Pa(OH)_2T_3B + (m+n-2)H_2O + (5-2m-n)H^+$$
$$Pa(OH)_2T_3B \rightarrow PaOT_3B \quad \text{(slow, irreversible)} \tag{24}$$

$$PaO_m(OH)_n^{5-2m-n} + 3HT + 2B = Pa(OH)_2T_3B_2 + (m+n-2)H_2O + (5-2m-n)H^+$$
$$Pa(OH)_2T_3B_2 \rightarrow PaOT_3B_2 \quad \text{(slow, irreversible)} \tag{25}$$

where $2m+n=3$ and 4.

Kinetics of Multidentate Ligand Substitution Reactions. VI. The Substitution Reaction of Diethylenetriaminepentaacetic Acid with the Nitrilotriacetato Nickelate(II) Chelate

Mutsuo KODAMA

Department of Chemistry, Ibaraki University, Mito, Ibaraki

(Received June 20, 1969)

The kinetics of the substitution reaction of diethylenetriaminepentaacetic acid (DTPA) with the nitrilotriacetato nickelate(II) chelate have been studied polarographically in both acid and alkaline media. The reaction was found to be first-order with respect to DTPA and also first-order with respect to the nitrilotriacetato nickelate(II) chelate with 1-to-1 composition. In an acid solution the reaction proceeds mainly through tervalent and quadrivalent DTPA anions. On the other hand, in an alkaline solution the reaction proceeds through quadrivalent and quinquevalent DTPA anions. The heat of activation and the entropy of activation for the three elementary reactions were estimated, and the effect of the protonation of the quinquevalent DTPA anion on the reaction rate was discussed.

In previous investigations,[1-4] kinetic studies of the nucleophilic substitution reactions between Eriochrom Black T (BT) and cobalt(II)- and nickel(II)-aminopolycarboxylate chelates were carried out spectrophotometrically. From a comparison of the rate constants of the reactions with chelates of *N*-(2-hydroxyethyl)-ethylenediamine, *N*,*N*′,*N*′-triacetic acid (EDTA-OH), cyclohexanediaminetetraacetic acid (CyDTA), and diethylenetriaminepentaacetic acid (DTPA) with those of the corresponding reactions involving EDTA chelates, a detailed reaction mechanism was formulated, and the steric effect was quantitatively discussed on the basis of the proposed reaction intermediates.

It now seems to be important and necessary to extend the study to the investigation of the effect of various ligands on the reaction mechanism and the rate of the nucleophilic substitution reaction involving the metal(II) aminopolycarboxylate chelate. This paper will describe a polarographic study of the kinetics on the reaction of diethylenetriaminepentaacetic acid with the nitrilotriacetato nickelate(II) chelate.

Experimental

Reagents. The nickel (II) nitrate solution was prepared by dissolving a known amount of metallic nickel (99.99% pure) in dilute nitric acid (1+1) and by removing the excess nitric acid by distillation under reduced pressure. The standardization of the concentration of nickel (II) solution was described in a previous paper.[2] The recrystallization of nitrilotriacetic acid (NTA) and DTPA and the preparation of their solutions were also described previously.[2,4] The other reagents were of analytical-reagent grades and were used without further purification.

Apparatus and Experimental Procedure. All the polarograms and the current-time curves were obtained with a Yanagimoto PA-102 pen-recording polarograph, using a dropping mercury electrode which had an *m* value of 0.837 mg/sec and a drop time of 4.02 sec in an air-free acetate buffer solution (total concentration of acetate ions=0.10M, μ=0.20) with a pH of 4.80 at 25°C at −0.50 V *vs.* SCE at the mercury height of 75 cm. The experimental procedures were the same as have previously been described by Tanaka, Kato and Tamamushi.[5] In this study, all the measurements were conducted in solutions with an ionic strength of 0.20 ($NaClO_4$). In the pH range from 4.50 to 5.80, an acetate buffer was employed. In the alkaline region (8.50<pH <10.00), however, no buffer reagent was used, for sample solutions contained a large excess of uncomplexed NTA and so had a sufficient buffer capacity already. Uncomplexed DTPA develops a well-defined anodic wave over the entire pH range covered,[6] so the rate of the reaction was followed by measuring the change in the diffusion current of DTPA with the time. In the potential range where the anodic wave due to the uncomplexed DTPA can be observed, nickel (II)-DTPA and NTA chelates are non-reactive in the polarographic electrolysis. Therefore, neither nickel (II) chelate has any effect on the determination of the concentration

of uncomplexed DTPA.[6] As the reaction rate was determined in this study by measuring the wave height of the uncomplexed DTPA, DTPA is also consumed by the polarographic electrolysis. However, the amount of DTPA consumed by the polarographic electrolysis is negligibly small as compared with that consumed by the substitution reaction with the nickel(II)-NTA chelate. The contribution of the polarographic electrolysis to the whole DTPA concentration change is only 0.05%, even under the experimental conditions where the present reaction proceeds at its slowest rate. In the polarographic electrolysis, a small amount of the mercury(II)-DTPA chelate is also formed at the electrode surface. However, the formation of the mercury(II)-DTPA chelate may be expected to give no effect on the rate of the substitution reaction, because the amount of mercury(II)-DTPA chelate formed is negligible as compared with those of the chemical species involved in the substitution reaction, and also because its stability constant is much greater than that of the nickel(II)–DTPA chelate.[7] This prediction was also confirmed experimentally by adding a small amount of the mercury-(II)-DTPA chelate (2×10^{-6}M). The presence of the mercury(II)-DTPA chelate had no effect on the rate of reaction.

Results and Discussion

All the exchange reactions were studied in solutions containing a large excess of complexed and uncomplexed NTA. Therefore, the exchange reaction (Reaction (1)) can be treated as a pseudo-first-order reaction.

$$H_nZ^{n-5} \underset{k^-}{\overset{k^+}{\rightleftharpoons}} \begin{cases} NiZ^{3-} + nH^+ \\ NiHZ^{2-} \end{cases}$$

where H_nZ^{n-5} denotes the incompletely-deprotonated DTPA anion and NiZ^{3-} and $NiHZ,^{2-}$ normal and protonated nickel(II)-DTPA chelates respectively.

The stability constants of nickel(II)-DTPA chelates are much greater than those of the corresponding nickel(II)-NTA chelates.[7] Therefore, the apparent rate constant of the forward reaction, k^+, must be much greater than that of the backward reaction, k^-, hence, it seemed that rate of the backward reaction may be neglected as compared with that of the forward reaction. This theory was examined experimentally. The presence of the 10.0 mM nickel(II)-DTPA chelate was found to have no effect on the rate of the substitution reaction of DTPA with the nickel(II)-NTA chelate. Consequently, if the present reaction proceeds through simultaneous reaction pathways which involve the dissociation of the nickel(II)-NTA chelate as well as the second-order nucleophilic substitution reactions involving completely- and incompletely-dissociated DTPA anions, the rate of the disappearance of uncomplexed DTPA should be a function of the uncomplexed DTPA concentration and the apparent rate constant, k^+, in a solution of a given pH and with given concentrations of the nickel(II)-NTA chelate and uncomplexed NTA will be given by:

$$k^+ = k_\alpha + \frac{k_\beta}{[\mathrm{DTPA}]_f} \quad (2)$$

where $[\mathrm{DTPA}]_f$ indicates the concentration of uncomplexed DTPA and where the k's are constants.

Consequently, the rate law for the disappearance of uncomplexed DTPA can be expressed as:

$$-\frac{d[\mathrm{DTPA}]_f}{dt} = k^+[\mathrm{DTPA}]_f = k_\alpha[\mathrm{DTPA}]_f + k_\beta \quad (3)$$

By integrating Eq. (3), we obtain:

$$-\ln\left([\mathrm{DTPA}]_f + \frac{k_\beta}{k_\alpha}\right) = -k_\alpha \cdot t - \ln\left([\mathrm{DTPA}]_f^0 + \frac{k_\beta}{k_\alpha}\right) \quad (4)$$

where $[\mathrm{DTPA}]_f^0$ and $[\mathrm{DTPA}]_f$ are the concentrations of uncomplexed DTPA at time=0 and t respectively.

As was reported previously,[6] the limiting current of the anodic wave due to uncomplexed DTPA is proportional to the concentration of uncomplexed DTPA over the entire pH range studied. Therefore, Eq. (4) can be rewritten as:

$$-\log\left(i_t + \frac{k_\beta \cdot k}{k_\alpha}\right) = \frac{k_\alpha}{2.303} - \log\left(i_0 + \frac{k_\beta \cdot k}{k_\alpha}\right) \quad (5)$$

where i_0 and i_t are the wave heights of DTPA at $t=0$ and $t=t$ respectively and where k is the constant,

Concentration of Ni(II)-NTA chelate=6.90 mM
Concentration of uncomplexed NTA=9.53 mM
Concentration of acetate ion=9.15×10^{-2}M
Initial concentration of DTPA=0.453 mM
pH=5.00, μ=0.20, at 25°C
A. $k_\beta k/k_\alpha=1.00$, B. $k_\beta k/k_\alpha=0$

7) L. G. Sillen and A. E. Martell, "Stability Constants of Metal-Ion Complexes," The Chemical Society, London (1964), pp. 507, 693.

defined as $i=k\cdot[\mathrm{DTPA}]_f$.

If the present reaction mechanism does not involve the dissociation of the nickel(II)-NTA chelate, $k_\beta\cdot k/k_\alpha$ in Eq. (5) should be zero. Equation (5) was examined by using typical experimental data. As is illustrated in Fig. 1, the log-plot gave a linear relationship only when $k_\beta\cdot k/k_\alpha$ was zero over the entire pH range covered in this study. This fact clearly indicates that the reaction of DTPA with the nickel(II)-NTA chelate does not involve the dissociation of the nitrilotriacetato nickelate(II) chelate. This conclusion could also be confirmed by the fact that the k_α value determined from the slope of the linear relationship of $-\log i_t$ *versus* t was independent of the concentration of uncomplexed DTPA. The results obtained in the acid media (acetate buffer) are shown in Table 1.

TABLE 1. DEPENDENCE OF THE SLOPE ON THE DTPA CONCENTRATION

Concentration of uncomplexed NTA=9.53 mM
Concentration of nickel(II)-NTA chelate=6.90 mM
Concentration of acetate ion=9.15×10^{-2}M
μ=0.20, 25°C, pH=5.00

Initial concentration of DTPA, mM	Slope sec^{-1}
0.275	6.12×10^{-3}
0.453	6.12×10^{-3}
0.641	6.10×10^{-3}

With regard to the k_α value estimated from the above linear relationship, the following facts can also be established in acid media ($4.50<\mathrm{pH}<5.80$):
1) In solutions of a given pH and with given concentrations of acetate ion and uncomplexed NTA, k_α is proportional to the concentration of the nickel(II)-NTA chelate (Table 2).

TABLE 2. DEPENDENCE OF THE SLOPE ON THE CONCENTRATION OF NICKEL(II)-NTA CHELATE

Concentration of uncomplexed NTA=9.53 mM
Initial concentration of DTPA=0.453 mM
Concentration of acetate ion=9.15×10^{-2}M
μ=0.20, 25°C, pH=5.00

Concn. of Ni(II)-NTA, mM	Slope sec^{-1}	Concn. ratio	Slope ratio
6.90	6.12×10^{-3}	1.00	1.00
10.35	9.10×10^{-3}	1.50	1.49
13.80	$12.2_5\times10^{-3}$	2.00	2.00

2) In solutions of a given pH and with given concentrations of uncomplexed and complexed NTA, k_α is independent of the concentration of the acetate ion (Table 3).
3) In solutions of a given pH and with given concentrations of the acetate ion and the nickel(II)-NTA chelate, k_α is independent of the concentration of uncomplexed NTA (Table 4).

TABLE 3. DEPENDENCE OF THE SLOPE ON THE CONCENTRATION OF ACETATE ION

Concentration of uncomplexed NTA=9.53 mM
Concentration of nickel(II)-NTA chelate=6.90 mM
Initial concentration of DTPA=0.453 mM
μ=0.20, 25°C, pH=5.00

Concentration of acetate, ion, M	Slope, sec^{-1}
4.57×10^{-2}	6.12×10^{-3}
9.15×10^{-2}	6.12×10^{-3}
1.32×10^{-1}	6.15×10^{-3}

TABLE 4. DEPENDENCE OF THE SLOPE ON THE CONCENTRATION OF UNCOMPLEXED NTA

Concentration of nickel(II)-NTA chelate=6.90 mM
Concentration of acetate ion=9.15×10^{-2}M
Initial concentration of DTPA=0.453 mM
μ=0.20, 25°C, pH=5.00

Concentration of NTA, mM	Slope, sec^{-1}
9.53	6.12×10^{-3}
14.30	6.10×10^{-3}
19.10	6.10×10^{-3}

4) In solutions with given concentrations of the acetate ion and complexed and uncomplexed NTA, the plot of $k_\alpha\cdot(\alpha_H)_Z/[\mathrm{H}^+]$ against $[\mathrm{H}^+]$ gives a linear relationship (Fig. 2). Here, $(\alpha_H)_Z$ is the (α_H) value of DTPA.

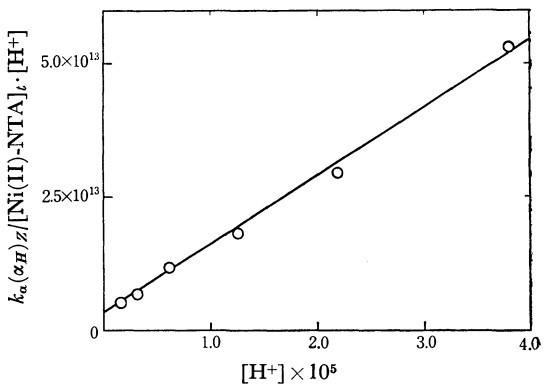

Fig. 2. The plot of $k_\alpha(\alpha_H)_Z/[\mathrm{Ni(II)\text{-}NTA}]_t\cdot[\mathrm{H}^+]$ against $[\mathrm{H}^+]$
Concentration of Ni(II)-NTA chelate=6.90 mM
Concentration of uncomplexed NTA=9.53 mM
Concentration of acetate ion=9.15×10^{-2}M
Initial concentration of DTPA=0.453 mM
μ=0.20, at 25°C

Thermodynamic calculation reveals that nickel (II) ions in solutions with pH's from 4.50 to 5.80 containing 10 mM uncomplexed NTA form only the chelate with a 1-to-1 composition, that the

predominant uncomplexed DTPA species are tervalent and quadrivalent anions, and that their concentrations are given by $[DTPA]_f[H^+]^2/k_5 \cdot k_4$ and $[DTPA]_f[H^+]/k_5$ respectively. Here, k_4 and k_5 denote the fourth and fifth dissociation constants of DTPA. Therefore, the above facts indicate that the present substitution reaction proceeds mainly through the following two simultaneous reaction pathways in the pH range from 4.50 to 5.80:

$$\text{i)}\quad NiX^- + H_2Z^{3-} \overset{k_1^+}{\rightleftharpoons} NiZ^{3-} + H^+ + HX^{2-}$$
$$\Big\Updownarrow \text{rapid}$$
$$NiHZ^{2-}$$

$$\text{ii)}\quad NiX^- + HZ^{4-} \overset{k_2^+}{\rightleftharpoons} NiZ^{3-} + HX^{2-}$$
$$\Big\Updownarrow \text{rapid}$$
$$NiHZ^{2-}$$

where NiX^- is the nickel(II)-NTA chelate with a 1-to-1 composition; HZ^{4-} and H_2Z^{3-}, quadrivalent and tervalent DTPA anions respectively, and HX^{2-}, the doubly-deprotonated NTA anion. On the basis of the above reaction mechanism, k_a in an acid medium can be written as:

$$k_a = \left(\frac{k_2^+[H^+]}{k_5} + \frac{k_1^+ \cdot [H^+]^2}{k_4 \cdot k_5}\right)\frac{[Ni(II)\text{-}NTA]_t}{(\alpha_H)_Z} \qquad (6)$$

In an alkaline medium ($8.50 < pH < 10.00$), as is illustrated by Tables 5 and 6, the k_a value determined from the linear relationship between $\log i_t$ and t was also found to be proportional to the total concentration of the nickel(II)-NTA chelate, but to be inversely proportional to the value of $1+k_{NiX_2} \cdot [X]_f/(\alpha_H)_X$, provided that the other experimental conditions are kept constant. Here, K_{NiX_2}, $(\alpha_H)_X$ and $[X]_f$ have the same meanings as have been used previously.[2] The above facts clearly indicate that the k_a value is linearly proportional to the concentration of the nickel(II)-NTA chelate with a 1-to-1 composition. $[X]_f$ was calculated from the total concentrations of NTA and nickel(II) ions with the aid of Eq. (2) of Ref. 2. As was found in the acid medium, k_a was also independent of the DTPA concentration (these results are not shown here). This fact clearly indicates that, in the pH range from 8.50 to 10.00, the substitution reaction of DTPA with the nitrilotriacetato nickelate(II) chelate does not proceed through the reaction pathway in which the dissociation of the nickel(II)-NTA chelate is involved.

The k_a value was also a function of the hydrogen ion concentration, and there was a linear relationship between $k_a \cdot (\alpha_H)_Z[1+k_{NiX_2} \cdot [X]_f/(\alpha_H)_X]/[Ni(II)NTA]_t$ and the hydrogen ion concentration, $[H^+]$ (Fig. 3). Here, $[Ni(II)NTA]_t$ indicates the total concentrations of nickel(II)-NTA chelates. All the facts stated above clearly indicate that, in an alkaline solution, the present reaction mainly proceeds through the following two reaction pathways.

Table 5. Dependence of the slope on the total concentration of nickel(II)-NTA chelate

Concentration of uncomplexed NTA=11.7 mM
Initial concentration of DTPA=0.453 mM
μ=0.20, 25°C, pH=9.50

Total concn. of Ni(II)-NTA, mM	Slope, sec^{-1}	Concn. ratio	Slope ratio
6.90	8.50×10^{-3}	1.00	1.00
10.35	12.8×10^{-3}	1.50	1.51
13.80	16.7×10^{-3}	2.00	1.97

Table 6. Dependence of the slope on the $[1+K_{NiX_2}[X]_f/(\alpha_H)_X]$ value

Initial concentration of DTPA=0.453 mM
Total concentration of nickel(II)-NTA chelate=6.90 mM
μ=0.20, 25°C, pH=9.50

Concn. of uncomplexed NTA, mM	Slope, sec^{-1}	Slope$\times[1+K_{NiX_2}[X]_f/(\alpha_H)_X]$
11.70	8.50×10^{-3}	1.19
27.3	3.58×10^{-3}	1.25
37.7	2.68×10^{-3}	1.21

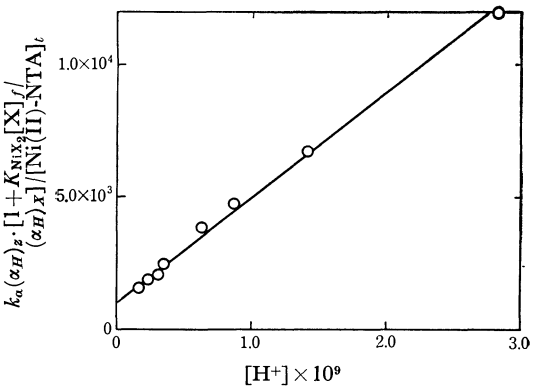

Fig. 3. The plot of $k_a(\alpha_H)_Z \cdot [1+K_{NiX_2}([X]_f/(\alpha_H)_X]/[Ni(II)\text{-}NTA]_t$ against $[H^+]$
Total concentration of nickel(II)-NTA chelate=6.90 mM
Total concentration of NTA=28.0 mM
Initial concentration of DTPA=0.453 mM
μ=0.20, at 25°C

$$\text{ii)}\quad NiX^- + HZ^{4-} \overset{k_2^+}{\rightleftharpoons} NiZ^{3-} + HX^{2-}$$
$$\Big\Updownarrow \text{rapid}$$
$$NiX_2^{4-}$$

$$\text{iii)}\quad NiX^- + Z^{5-} \overset{k_3^+}{\rightleftharpoons} NiZ^{3-} + X^{3-}$$
$$\Big\Updownarrow \text{rapid}$$
$$NiX_2^{4-}$$

where NiX_2^{4-} indicates the nickel(II)-NTA chelate with a 1-to-2 composition. Therefore, k_a in Eq. (5) can be written as:

$$k_a = \left(k_3^+ + k_2^+ \cdot \frac{[H^+]}{k_5}\right) \times \frac{[\text{Ni(II)-NTA}]_t}{(\alpha_H)_Z \cdot [1 + K_{NiX_2} \cdot [X]_f/(\alpha_H)_X]} \quad (7)$$

From the slopes and intercepts shown in Figs. 2 and 3, k_1^+, k_2^+ and k_3^+ were determined at 25°C. The k_2^+ value determined from the slope in Fig. 3 agreed well with that obtained from the intercept in Fig. 2. This agreement strongly supports the proposed reaction mechanism.

Similar results were also obtained in the experiments at 18°C and 9°C. The k^+ value determined at 18°C and 9°C are given in Table 7, along with

TABLE 7. RATE CONSTANTS, HEAT OF ACTIVATION AND ENTROPY OF ACTIVATION FOR REACTIONS i), ii) AND iii)

k^+ value	Temperature, °C 9.0	18.0	25.0	ΔH^{++} kcal/mol	ΔS^{++} e.u.
k_1^+	0.499	0.175	1.78	12.2	−16.5
k_2^+	2.77×10^1	7.24×10^1	3.06×10^2	19.3	20.5
k_3^+	3.1×10^2	7.0×10^2	9.1×10^2	10.0	−11.2

the results obtained at 25°C. Linear relationships were found between the log k^+ value and $1/T$ for three elementary reactions, i), ii) and iii); this made it possible to calculate the heat and entropy of activation. The results are given in Table 7. The k^+ values given in Table 7 are much greater than the corresponding rate constants for the reaction of the nickel(II)-NTA chelate with EDTA-OH,[8] lending strong support to the present author's conclusion that the exchange reaction of DTPA with the nickel(II)-NTA chelate proceeds predominantly through three simultaneous reaction pathways, all of which involve a second-order nucleophilic substitution reaction without any dissociation of the nickel(II)-NTA chelate. The greater rate constants probably mean that the present exchange reaction proceeds by a mechanism which involves a reaction intermediate more stable than that for the nickel-(II)-NTA-EDTA-OH reaction.

On the basis of the conclusion reached by Rorabacher and Margerum concerning the reaction of nickel(II)-polyamine complexes with EDTA,[9] the reaction intermediate expected for the present exchange reaction may involve the DTPA anion, all three nitrogen groups of which are coordinated to the nickel(II) ion, as well as the tervalent NTA anion. If the DTPA anion in the reaction intermediate forms only two nickel(II)-nitrogen bonds or less, the k^+ values of the present reaction should be smaller than the corresponding rate constants for the nickel(II)-NTA–EDTA-OH reaction, because the less stable reaction intermediate due to the larger steric effect of DTPA would make the reaction more sluggish.

It is also interesting to note that the heat of activation for the elementary reaction ii) is much larger than those for i) and iii) reactions, and that the entropy of activation for the ii) reaction is positive, whereas those for the i) and iii) reactions are negative. Generally, the entropy of activation for a second-order nucleophilic substitution reaction involving a multidentate ligand may be expected to be negative, because the conformational, translational, and rotational freedom of an entering multidentate ligand would be lost in the formation of a mixed ligand intermediate chelate. The negative entropy for the elementary reaction iii) may be responsible for this effect. An NMR study of the protonation of the quinquevalent DTPA anion (Fig. 4) in an aqueous solution[10] gave the conclu-

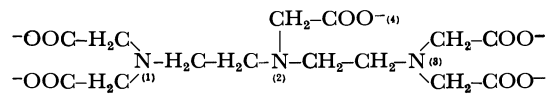

Fig. 4. Quinquevalent DTP Aanion.

sion that, after the addition of one proton equivalent, the terminal nitrogen groups, (1) and (3), are each protonated 26% of the time each; the central nitrogen group (2) is protonated 41% of the time, and the central acetate group (4) is protonated 7% of the time, while the terminal acetate groups are not protonated to any detectable extent. On the other hand, when a second proton equivalent is added, the two terminal nitrogen groups are each protonated 85% of the time, the central nitrogen group (2) is protonated only 15% of the time, and four terminal acetate groups are protonated 4% of the time. The fact that the first proton is almost equally bonded among the three nitrogen groups of the DTPA anion probably indicates that the intramolecular hydrogen bonding arranges the DTPA anion in a favorable position to form the reaction intermediate. Thus, less conformational and rotational freedom is lost in the formation of the mixed ligand intermediate chelate, corresponding to the positive entropy of activation for the e ementary reaction ii). The tervalent DTPA anion, H_2Z^{3-}, where the two terminal nitrogen groups are almost completely-protonated and where the central nitrogen group is protonated only 15% of the time, may have a conformation less favor-

able to the formation of the reaction intermediate, because the electrostatic repulsion between the positively-protonated sites would prevent the DTPA anion from having a favorable conformation to react with the nickel(II)-NTA chelate. Thus, a remarkable decrease in entropy for the elementary reaction i) can be expected.

Finally, it can also be mentioned that, with an increase in the extent of the protonation of the central nitrogen and acetate groups, the heat of activation becomes greater. This probably suggests that the deprotonation of these groups is inherently required for the formation of a mixed ligand chelate intermediate, through which the exchange reaction of the nickel(II)-NTA chelate with DTPA proceeds. The importance of the conformation of the attacking group will be discussed in a subsequent paper.

The present author wishes to express his hearty thanks to Mr. Tomohiko Noda and Miss Yayoe Tominaga for their help during this experiment.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 2537—2543 (1969)

Role of the Solvent in the Distribution of the Zinc-TTA Chelate and the Adduct Formation with TBP

Kenichi AKIBA, Nobuo SUZUKI and Takuji KANNO

Research Institute of Mineral Dressing and Metallurgy, Tohoku University, Sendai

(Received January 28, 1969)

The distributions of the zinc chelate with thenoyltrifluoroacetone (TTA) between an aqueous solution and twelve inert organic solvents were investigated. After it had been confirmed that the distributed species were ZnA_2, the distribution coefficients of the chelate (P_M) and those of TTA (P_{HA}) were compared; it was found that there is a correlation which can be expressed as $\log P_M = n \log P_{HA} + \text{const.}$ When TTA and TBP are in the extraction system, the adduct formation constants of chelate were obtained. The activities of all the species which take part in the adduct formation were evaluated on the basis of the regular solution theory. It was found that the adduct formation constant in terms of activity (K_S°) is constant in all the organic solvents; namely, $\log K_S^\circ$ was found to be 4.05. Finally, the role of the solvent in the synergistic extraction system is explained systematically by a combination of the regularity in the distribution and that in the adduct formation.

The extraction processes of metal complexes have been studied qualitatively in several extraction systems, but there have been few works on the role of organic solvents in connection with the physical chemistry of a solution. The properties of solvents governing the distribution coefficient have never been clarified, and the solvents have been chosen empirically without even a qualitative measure.

In the previous papers the relation between the distribution coefficient and the solubility parameter of solvents was examined on the basis of the regular solution theory;[1] the regularities in the distributions of β-diketones and their scandium chelates have thus been explained in the various solvent systems.[2-6] A similar treatment is applicable not only to β-diketone but to a distributed species in general; the distribution coefficients of oxine and its derivatives have been explained in relation to the solubility parameter.[7]

However, the regularity in the distribution can be hardly explained in the same manner when such organic-phase reactions as adduct formation, dimerization, and solvation take place. A synergism on the distribution of the metal chelate has been observed in several extraction systems, but no general explanation of the role of the solvent has

been given. The physicochemical properties of the solvent will, however, influence both the distribution coefficients and the equilibrium constants of the organic-phase reactions. The synergistic effect should be discussed in relation to not the over-all extraction constant but the equilibrium constants of the organic-phase reactions.

This work was undertaken in order to clarify the role of the organic solvent in the distribution of the chelate and in the adduct formation with a neutral ligand. The distribution coefficients of the zinc-TTA chelate between an aqueous perchlorate medium and several organic solvents are determined, and the relation between the distribution coefficients of TTA is examined. The adduct formation constants of the zinc-TTA chelate with tributyl phosphate (TBP) are obtained by the distribution method.

The activity coefficients of the species related to the organic-phase reaction are estimated with the aid of the regular solution theory,[8] and the adduct formation constants are correlated to changes in the activity coefficients. The role of solvents in synergistic extraction may be explained systematically by the regularity in the distribution and that in the adduct formation.

Experimental

Reagents. The zinc-65 was obtained from the New England Nuclear Corp. (USA) as a hydrochloric acid solution. After a portion of this solution had been dried on a water bath, the tracer was taken in 0.1M perchloric acid; the concentration of zinc ions was controlled by the addition of an inactive zinc solution.

TTA was purified as before.[6]

TBP was refluxed for 5 hr with an equal volume of a 0.5M sodium hydroxide solution on the water bath; the TBP phase was washed with water and dried over anhydrous sodium sulfate, and the washed product was distilled under reduced pressure.

All the solvents were purified by ordinary methods.

The apparatus used was the same as that described previously.[4]

Distribution Ratio of TTA (D_{HA}). The desired organic solution of TTA was shaken for 16 hr with an aqueous perchloric acid solution with an ionic strength of 0.1. After centrifuging, a portion of the aqueous phase was pipetted out, and the concentration of TTA was determined spectrophotometrically. An aqueous solution saturated with an organic solution free from TTA was used as a reference for the measurement of the absorbance.

Distribution Ratio of Zinc (D_M, $D_{M,S}$). An organic solution containing TTA was agitated for 20 hr with an acetate buffer solution (pH 3.5—5.5) containing ^{65}Zn. The ionic strength was adjusted to 0.1 with sodium perchlorate. After the two phases had been separated, the γ-activity of each phase and the pH of the aqueous phase were measured.

All the experiments were carried out at 25°C.

Concentration of Acetate Ions. The distribution ratios of zinc decreased slightly with an increase in the concentration of acetate ions up to about 0.05M, but they were constant below 0.01M. Accordingly, the concentration of acetate ions was kept at 0.002M.

Concentration of Zinc Ions. As the distribution ratios are independent of the zinc-ion concentration below about 5×10^{-6}M, the concentration of zinc was kept at 10^{-6}M. The recovery of the total γ-activity was always checked, and the losses of zinc were found for a few paraffinic solvents. To avoid the loss of zinc, the concentration of zinc was held constant at 10^{-7}M for these solvents.

Results and Discussion

The extraction processes of the zinc-TTA chelate may be expressed as follows:

$$Zn^{2+}_{aq} + nA^{-}_{aq} \overset{\beta_n}{\rightleftharpoons} ZnA^{(2-n)+}_{n,aq} \quad (1)$$

$$ZnA_{2,aq} \overset{P_M}{\rightleftharpoons} ZnA_{2,org} \quad (2)$$

$$ZnA_{2,org} + jHA_{org} \overset{K_j}{\rightleftharpoons} ZnA_2\cdot jHA_{org} \quad (3)$$

$$ZnA_{2,org} + mS_{org} \overset{K_{S,m}}{\rightleftharpoons} ZnA_2\cdot mS_{org} \quad (4)$$

where HA and S stand for the undissociated TTA and the neutral ligand respectively. The subscripts aq and org refer to the aqueous and organic phases.

The distribution of zinc in the absence of the neutral ligand, D_M, is given by:

$$D_M = \frac{P_M\beta_2[A^-]^2_{aq}\{1 + \sum K_j[HA]^j_{org}\}}{1 + \beta_n[A^-]^n_{aq}} \quad (5)$$

If no mixed adduct complexes, $ZnA_2\cdot jHA\cdot mS$, are formed, and distribution ratio in the presence of the neutral ligand, $D_{M,S}$, is written as:

$$D_{M,S} = \frac{P_M\beta_2[A^-]^2_{aq}\{1+\sum K_j[HA]^j_{org}+\sum K_{S,m}[S]^m_{org}\}}{1+\sum\beta_n[A^-]^n_{aq}} \quad (6)$$

The extraction of zinc complexes with the neutral ligand alone is negligibly small. If the undissociated TTA does not react with the chelate and if the only adduct with S is predominant, the following equation is obtained from Eqs. (5) and (6):

$$K_S = \frac{D_{M,S}}{D_M}\cdot\frac{1}{[S]^m_{org}} \quad (7)$$

where K_S is the overall adduct formation constant.

Distribution of the Zinc Chelate. The extraction mechanism of the zinc-TTA chelate has been studied for a few solvent systems, and it has been shown that bivalent zinc is extracted into the organic phase as the formally neutral species

ZnA_2.[9-11] In this study it was important to confirm that the distributed species is the same one for all solvents. Plots of log D_M measured at various pH values against pA ($=-\log[A^-]_{aq}$) gave a series of straight lines with a slope of -2. As an example that for benzene is given in Fig. 1; the same line

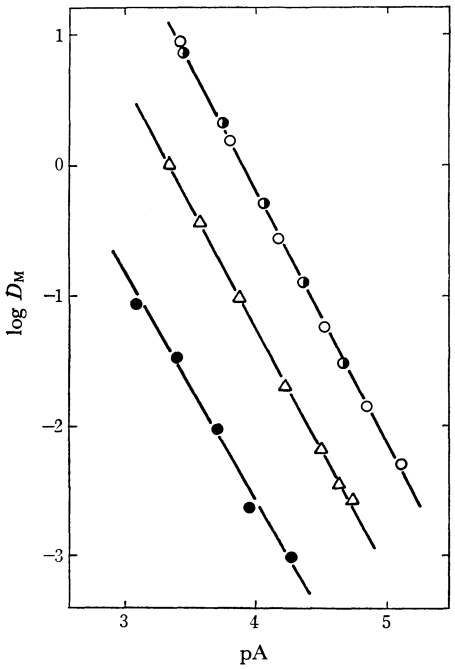

Fig. 1. Distribution ratio of zinc-TTA chelate as a function of pA.
Ionic strength, 0.10; $[HA]_{org,\,init.}=0.1M$
●, *n*-hexane; △, carbon tetrachloride;
○, benzene; ◑, benzene (pH=5.08)

was obtained at different concentrations of HA. In all cases, the distributed species is ZnA_2 and there is no additive compound with HA. The concentration of the dissociated TTA anion (A^-) in the aqueous phase can be calculated by the following equation:

$$[A^-]=\frac{[HA]_{org,init.}}{(P_{HA}+1)[H^+]/K_a+1} \qquad (8)$$

where K_a represents the apparent dissociation constant of TTA, $K_a=6\times10^{-7}$,[12] and where P_{HA} is the distribution coefficient of TTA. When the concentration of zinc is over 10^{-6}M, losses of radioactivities were observed in *n*-hexane, *n*-heptane, and cyclohexane. Even in this case, however, the distribution ratios are independent of the zinc concentration and the same straight lines, log D_M *vs.* pA, are obtained. After the two phases were discarded, the extracting tube was washed with an organic solvent other than the paraffinic solvent or with an acidic aqueous solution; a great portion of the lost activity could be thus recovered. It seems that both the phases were saturated with such complexes as $ZnA_2\cdot nH_2O$ and that a portion of the complexes was removed from the system as a precipitate. The possibility of the formation of the higher complexes, $ZnA_n^{(2-n)+}$ ($n>2$), seems to be eliminated. The measured distribution ratio may be regarded as a contribution of only one species, that shown as ZnA_2. The distribution coefficients of the chelate are too large to be measured experimentally. As the distribution ratio written in Eq. (5) is expressed as a simple function of pA, the distribution ratio is proportional to the distribution coefficient at a definite pA. The distribution ratios at pA 4.0 for each solvent are given in Table 1. The following relation

between the distribution coefficients of the chelating agent and those of the metal chelate has been derived from the regular solution theory[2] (the distributions of scandium β-diketonates were satisfactorily explained in the various solvent systems):[2,4-6]

$$\log P_M=\frac{V_M}{V_{HA}}\log P_{HA}+\text{const.} \qquad (9)$$

where V_{HA} and V_M denote the molar volume of the chelating agent and that of the metal chelate respectively. This relation is expected to hold for the zinc chelate also. Plots of log D_M at pA 4.0

against log P_{HA} give a straight line with a slope of 2.1, as is shown in Fig. 2. It is reasonable that the ratio of the molar volume of the chelate to that of TTA is about two, because two molecules of TTA combine with zinc ion.

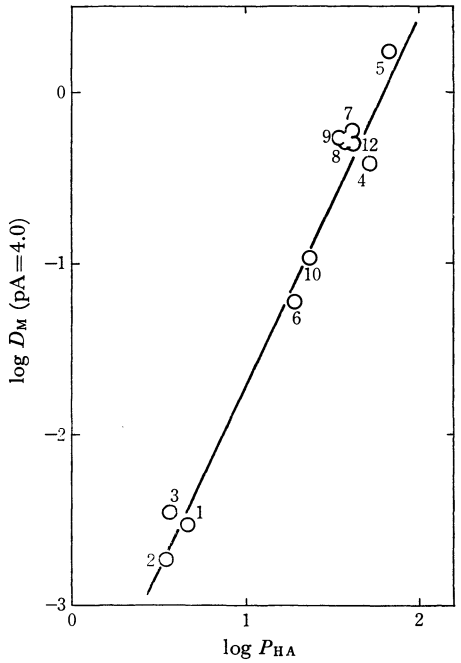

Fig. 2. Correlation between the distribution coefficient of TTA and that of zinc chelate.
The numbers in Figs. 2, 6 and 7 correspond to those in Table 1.

Distribution of Zinc Chelate in the Presence of the Neutral Ligand. When a formally neutral donor (S) is added to the chelate extraction system, the extraction is extremely enhanced.[9-11] The distribution behavior was examined in the presence of TBP in order to obtain a reliable adduct formation constant. At first, the distribution ratio of TTA was measured with the change in the concentration of TBP in order to examine whether or not TBP affects TTA; the results are shown in Fig. 3. The distribution ratios of TTA are independent of the TBP concentration up to 0.01M for *n*-hexane, 0.02M for carbon tetrachloride and benzene, and 0.1M for chloroform. In these concentration ranges of TBP, the UV spectra of TTA are essentially the same as those in the absence of TBP. At higher TBP concentrations, the distribution ratio increases with an increase in the concentration of TBP; the rate of increase is different for each solvent, being especially remarkable for *n*-hexane. It can be considered that the distributed species of TTA is affected by TBP. TTA exists almost entirely as the enol form in the inert solvent or at low TBP concentrations, while the ratio of the keto form increases with an increase in the cocentration of TBP. Therefore, the TBP concentration ranges where there is no effect of TBP were employed. As the distribution coefficients of TBP between the aqueous and the organic phases are very large,[13] the initial concentration of TBP may be regarded as the equilibrium concentration.

In order to examine the contribution of TBP to the adduct formation, the change in the distribution ratio of zinc ($D_{M,S}$) with the change in the concentration of TBP was examined as in Fig. 4.

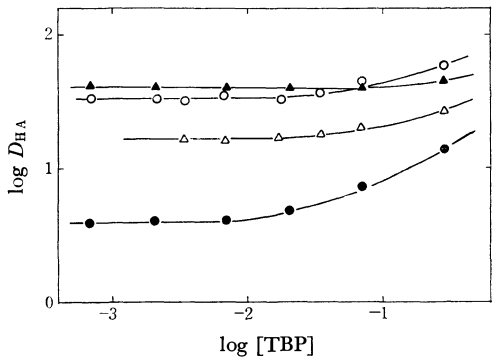

Fig. 3. Distribution ratio of TTA as a function of TBP concentration.

13) K. Alcock, S. S. Grimley, T. V. Healy, J. Kennedy and H.A.C. McKay, *Trans. Faraday Soc.*, **52**, 39 (1956).

The limiting slope was unity for each solvent. It seems that one molecule of TBP adds to one molecule of chelate; there is no evidence that two or more molecules of TBP add to the zinc chelate. The deviation from the straight line with a slope of 1 is evident at low concentrations of TBP, especially in the case of chloroform, because the assumption that the adduct is predominant is not applicable at low concentrations of TBP.

The plots of log $D_{M,S}$ against pA at a constant [TBP] gave a series of straight lines with a slope of -2, as is shown in Fig. 5. It is clear that the

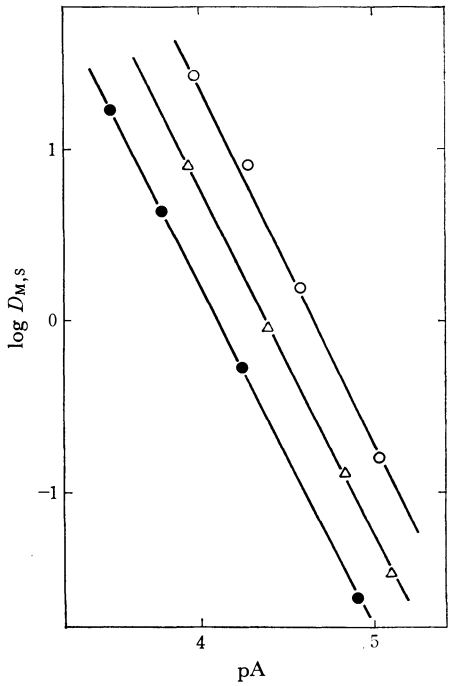

Fig. 5. Distribution ratio of zinc complex in the presence of TBP.

○, benzene

adduct is predominant as compared with the case of no TBP, and that the adduct formation constant can be obtained from D_M and $D_{M,S}$.

The log K_S values are given in Table 1; they are close to the values obtained by Sekine and Dyrssen, 2.69 for chloroform and 4.34 for carbon tetrachloride.[9] Although there is a tendency toward large K_S values for simple paraffinic solvents and small ones for halogen-substituted solvents, the values of K_S are very different for each solvent. This means that the adduct formation constants are strongly influenced by the nature of the organic solvent, and that the role of the solvent in synergism is complicated. One can not simply relate the K_S values to the physicochemical properties of the solvent. The change in the activity with the solvent nature plays a very important role in the adduct formation. Therefore, the activity coefficients of all the species in the organic phase must be taken into account. Up to the present, it has been sometimes assumed that the activity coefficient of the species in the organic phase is close to unity, and there has been no consideration of the change in the activity with the nature of the solute and/or the solvent.

The interaction among the molecules in the organic solution should be estimated as the activity coefficient for each species. The overall adduct formation constant, expressed in terms of activities defined as K_S°, is:

$$K_S^\circ = \frac{a_{ZnA_2\cdot mS}}{a_{ZnA_2}a_S^m} = K_S\frac{\gamma_{ZnA_2\cdot mS}}{\gamma_{ZnA_2}\gamma_S^m} \tag{10}$$

where a represents the activity; γ, the activity coefficient, and the subscripts, chemical species. When the activity coefficient of a pure component is assumed to be unity, as is standard, the K_S° values do not depent on the medium. If the activities of all species can be evaluated in several organic solvents, the applicability of Eq. (10) may be considered. The activities of TBP have been measured in several organic solvents,[13,14] but those of the others have never been established. We have insufficient data on these organic solutions to evaluate the activity.

As the solvents used in this work may be regarded as so-called inert solvents, it seems that there are no specific interactions among the components of the solutions. These solutions are usually considered to be reasonably regular. It is practical to evaluate the activity according to the equation of Hildebrand-Scott:[8]

$$\begin{cases} \boldsymbol{R}T\ln a_A = \boldsymbol{R}T\ln x_A + V_A\varphi_B^2(\delta_A-\delta_B)^2 & \text{(11a)} \\ \boldsymbol{R}T\ln a_A = \boldsymbol{R}T\left[\ln\varphi_A + \varphi_B\left(1-\frac{V_A}{V_B}\right)\right] + V_A\varphi_B^2(\delta_A-\delta_B)^2 & \text{(11b)} \end{cases}$$

where the subscripts A and B denote the components A and B respectively, and where x represents the mole fraction; V, the molar volume, φ, the volume fraction, and δ, the solubility parameter. If the entropy of mixing is ideal, Eq. (11a) is appropriate. Where the molar volumes of components A and B are quite appreciably different, it seems that Eq. (11b) is more reasonable,[8] so Eq. (11b) is used in this study. The solubility parameters of the solvents have been listed in a monograph, or they can be calculated from the thermodynamic quantity.[8] However, as there are no fundamental data on, *e. g.*, the heat of vaporization and the solubility for the chelate and the adduct, it is difficult to evaluate the solubility parameter.

As for the chelate, the correlation between the

14) S. Siekierski, *J. Inorg. Nucl. Chem.*, **24**, 205 (1962).

distribution coefficients of TTA and of chelate shown in Fig. 2 would lead us to suppose that the molar volume of the chelate is twice that of TTA and that the solubility parameter of chelate is equal to that of TTA. Consequently, the activity of the chelate may be calculated from the two values V_M 320 m*l* and δ_{ZnA_2} 9.9. Next, the activity of adduct must be assessed one way or another. Here, taking into account that the concentration of the component A is sufficiently low, A and B represent the molecules of the solute and the solvent respectively in Eq. (11b). If the difference in the ratio of the molar volume of the solute to that of the solvent is small for each solvent, Eq. (11b) can be put into a simpler form:

$$\log \gamma_A = C + D(\delta_A - \delta_B)^2 \qquad (12)$$

where C and D are constants. When the activity coefficients of the component A, γ_A, or the values which are proportional to γ_A are plotted against the solubility parameters of the solvents, δ_B, the curve which indicates a minimum at $\delta_A=\delta_B$ will be drawn. Accordingly, the solubility parameter of the component A can be obtained at the minimum in the curve. Equation (10) can be rewritten as by adopting $m=1$:

$$\gamma_{ZnA_2\cdot S} = K_S^\circ \cdot \frac{\gamma_{ZnA_2}\gamma_S}{K_S} \qquad (13)$$

The combination of Eq. (12) ($ZnA_2\cdot S$ was taken as A) and Eq. (13) leads to Eq. (14):

$$\log \frac{\gamma_{ZnA_2}\gamma_S}{K_S} = C' + D(\delta_{ZnA_2\cdot S} - \delta_B)^2 \qquad (14)$$

where C' is a constant. The values of γ_{ZnA_2} may be calculated as above. Alcock and his co-workers[13] reported that TBP forms an ideal solution up to about a 1% TBP solution with paraffinic solvents and up to 10% with benzene and others. In calculating the activity coefficient of TBP, the experimental data on a 1% solution of TBP were used for *n*-hexane, *n*-heptane, and cyclohexane,[13] while those on a 5% solution obtained by Siekierski[14] were used for most of the solvents. The relation of Eq. (14) is shown in Fig. 6. The solubility parameter of the adduct was obtained as 9.4. The molar volume of the adduct may be got from the curvature of Fig. 6, but it is hard to get the accurate value because of an insufficient number of the experimental data on the solvents with large solubility parameters. In the present study the molar volume of the adducts was assumed to be equal to the algebraic sum of the molar volume of the chelate and that of TBP. This seems a reasonable assumption because Eq. (4) is the addition reaction, and, practically, the effect of the small difference in molar volume on the activity coefficient is small except when value of $|\delta_A-\delta_B|$ is large. Accordingly, the activity coefficient of the adduct can also be calculated from the two values $\delta_{ZnA_2\cdot S}$ 9.4 and $V_{ZnA_2\cdot S}$ 593 m*l*.

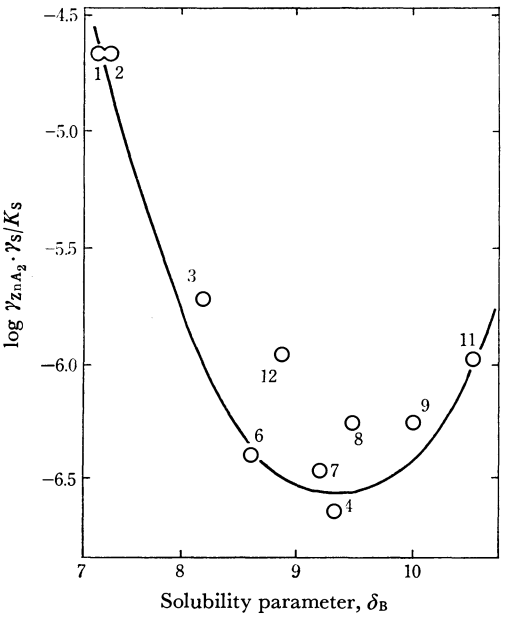

Fig. 6. Relation between the activity coefficient and the solubility parameter of solvent.

Since the activity coefficients of all the species were evaluated, the relation of Eq. (10) is illustrated in Fig. 7. The plots of log K_S against the logarithm of the activity coefficients are close to a straight line with a slope of −1 for most of the solvents, as was to be expected. The deviations from the

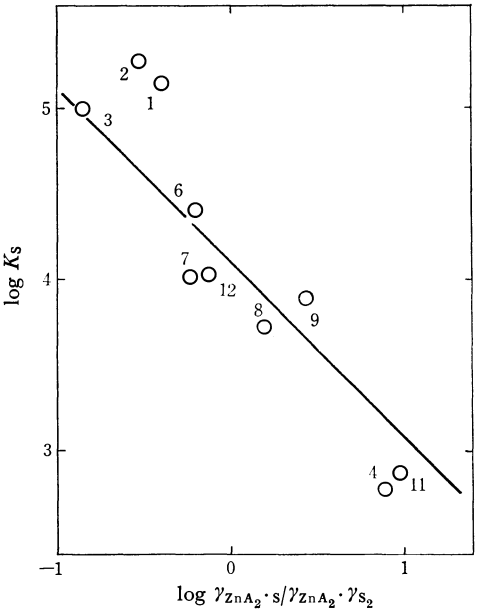

Fig. 7. Relation between the adduct formation constant and the activity coefficients in the organic phase.

line for *n*-hexane and *n*-heptane with large $|\delta_A-\delta_B|$ values appears to be due to the uncertainty concerning the molar volume of adduct. If the molecules of the chelate and TBP form a more compact adduct than the postulated one, the deviations are small. The value of $\log K_S^\circ$ was obtained as 4.05. Although the activity coefficients have been estimated on the base of a simplifing assumption, it is significant that the adduct formation constant in terms of activity is constant for each solvent. If the K_S value is measured for one solvent, that for the other can be estimated by considering the activity coefficient of the species.

Eq. (7) can be related to Eq. (10) as follows:

$$D_{M,S} = K_S^\circ D_M [S]_{org}^m \frac{\gamma_{ZnA_2}\gamma_S^m}{\gamma_{ZnA_2 \cdot mS}} \quad (16)$$

The distribution ratio in the presence of a neutral ligand can be pre-estimated from that in the absence of one according to Eq. (16). In this manner the role of the solvent in the synergistic extraction system can be explained systematically by a combination of the regularity as in the distribution of the metal chelate and that in the adduct formation.

The authors are grateful to Dr. T. Wakabayashi for his interest during this study. Thanks are also due to Miss H. Asano for her assistance in the experimental work.

(Received February 21, 1969)

Many new palladium(II) complexes (abbreviated as M(X-SAL·R)$_2$) of Schiff bases obtained from substituted salicylaldehydes and alkyl and aryl amines were prepared as yellow-orange or red crystals, where X denotes H, 3-CH_3O and 5,6-benzo. For R=*n*-alkyl and aryl groups, the complexes Pd(X-SAL·R)$_2$ in non-donor solvents consist of square-planar molecules. The complexes of the type Pd(X-SAL·*t*-C_4H_9)$_2$ show electronic spectra which are different from those of the complexes of the type Pd(X-SAL·*n*-alkyl)$_2$, but all these complexes are diamagnetic. This difference between the two kinds of complexes is discussed in connection with the bonding in, and the structure of, the complexes on the basis of the spectral and magnetic properties. The results for the palladium(II) complexes are compared with those for the corresponding nickel(II) complexes.

Many detailed studies have been reported on nickel(II) complexes (Fig. 1) with Schiff bases

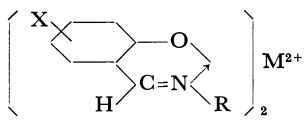

Fig. 1. M(X-SAL·R)$_2$

obtained from substituted salicylaldehydes.[1-3] Having a d^8 configuration, the palladium(II) ion forms complexes which are similar to the nickel(II) complexes, but there are also many examples of palladium(II) complexes which are remarkably different from the corresponding nickel(II) complexes. On the palladium(II) complexes with the Schiff bases, however, only a few papers have so far been published,[4,5] and systematic studies in particular seem to be lacking.

The present paper deals with preparation of the palladium(II) complexes with the Schiff bases and examination of their stereochemistry for comparison with the results about the corresponding nickel(II) complexes. It is also one of the purposes of the present work to examine the effect of steric hindrance of various degrees on the stereochemistry of these palladium(II) complexes.

	t-C_4H_9				55.55	6.35	5.19

and 2, were prepared according to methods similar to those previously reported.[5] A typical example of preparation is as follows. To a solution of potassium tetrachloropalladate(II) (0.01 mol) and potassium hydroxide (0.02 mol) in a small amount of water were added a solution of salicylaldehyde or substituted salicylaldehyde (0.02 mol) in ethanol and an appropriate amine. The resulting solution was stirred at about 50°C for about one hour. The precipitate was collected by filtration and recrystallized from ethanol, chloroform or benzene.

The complexes $Pd(H\text{-}SAL\cdot R)_2$ with R=CH_3, C_2H_5, *n*-C_3H_7 and *n*-C_4H_9, which were first reported by Sacconi and others,[4] were prepared in the present work as previously reported.[5]

* The notation Ph denotes a phenyl group.

All these palladium(II) complexes are yellow or yellowish orange, with the exception of the *N*-*t*-butyl-substituted complexes, which are brownish red. They are insoluble in water but soluble in methanol, ethanol, chloroform, benzene and acetone.

Analytical data of the new compounds are given in Tables 1 and 2.

Measurements. The electronic absorption spectra of the compounds in solution were determined with a Shimadzu MPL-50 and a Shimadzu QR-50 spectrophotometer.

Diamagnetism of the complexes was detected by the Gouy method.

Results and Discussion

Many new compounds, which are listed in Tables 1 and 2, have been prepared in the present work. Sacconi and others[4] formerly prepared the complexes of the type $Pd(H\text{-}SAL\cdot R)_2$ with R=CH_3, C_2H_5, *n*-C_3H_7 and *n*-C_4H_9, and concluded them to be *trans*-planar. Moreover, it is well known that the palladium(II), in general, takes a planar, four-coordinated configuration. It seems, therefore, to be most likely that the complexes of the type $Pd(X\text{-}SAL\cdot n\text{-}alkyl)_2$ prepared in the present work may also be planar. Electronic spectra of these complexes, as shown in Figs. 2 and 3, are quite

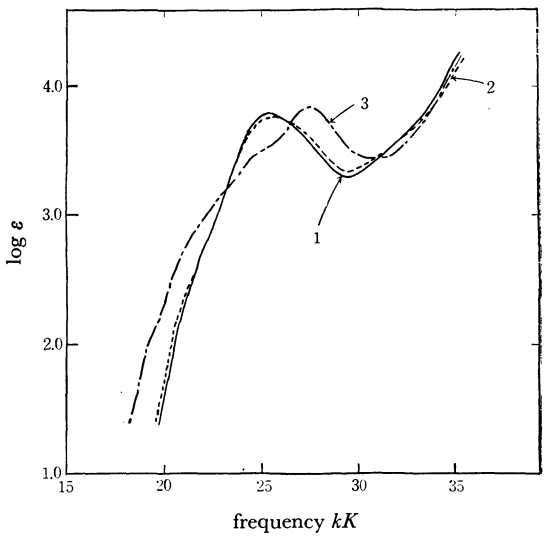

Fig. 2. Electronic absorption spectra of $Pd(H\text{-}SAL\cdot R)_2$ in chloroform; 1, R=*n*-C_4H_9 (——); 2, R=*i*-C_3H_7 (----); 3, R=*t*-C_4H_9 (— — —).

similar to each other, showing that their configuration is all alike. The absorption peak at about 25.5 kK may be due to an electronic transition within the ligand bound with the palladium(II) ion. The ligand field bands mainly due to the palladium(II) ion are considered to be hidden by the strong absorption bands of other origins. In a similar way, it is considered that the planar configuration is most likely for the complexes of the type $Pd(H\text{-}SAL\cdot R)_2$ with R=phenyl and substituted phenyl groups.

It is to be noted that Beer's law holds for all these palladium(II) complexes, so that no association of the square-planar complexes occurs in solution, in contrast to the behavior of the correspond-

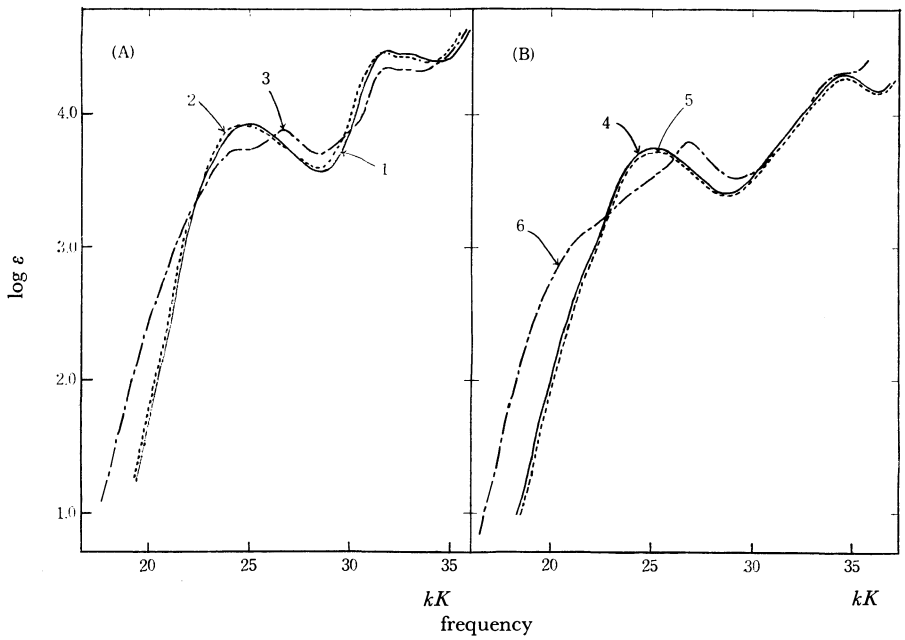

Fig. 3. Electronic absorption spectra in chloroform of (A) Pd(5,6-benzo-SAL·R)$_2$; 1, R=*n*-C_4H_9; 2, R=*i*-C_3H_7; 3, R=*t*-C_4H_9 and (B) Pd(3-CH_3O-SAL·R)$_2$; 4, R=*n*-C_4H_9; 5, R=*i*-C_3H_7; 6, R=*t*-C_4H_9.

ing nickel(II) complexes. This finding is in agreement with the current view that the tendency of palladium(II) to take coordination number larger than four is extremely low and, in fact, much lower than that of nickel(II).

With Pd(H-SAL·2,6-$(CH_3)_2$Ph)$_2$, the steric condition is not quite favorable for the square-planar configuration. However, since the corresponding nickel(II) and copper(II) complex have been found to be square-planar,[6] the square-planar configuration may also be most likely for Pd(H-SAL·2,6-$(CH_3)_2$Ph)$_2$ in spite of the possible steric hindrance. This is borne out by the electronic spectrum of this palladium(II) complex, which is quite similar to those of Pd(H-SAL·CH_3Ph)$_2$ and related complexes, as shown in Fig. 4.

For Pd(X-SAL·*i*-C_3H_7)$_2$, the steric condition is not quite favorable for the square-planar configuration. However, these complexes are diamagnetic, and their electronic spectra are similar to those of Pd(X-SAL·*n*-alkyl)$_2$, as may be seen in Figs. 2 and 3. It is, therefore, presumed that all these complexes are square-planar. It is to be noted that this is not the case with the corresponding nickel(II) complexes. The nickel(II) complexes of the type Ni(X-SAL·*i*-C_3H_7)$_2$ are square-planar or distorted-tetrahedral, depending upon the nature of X.[3,7]

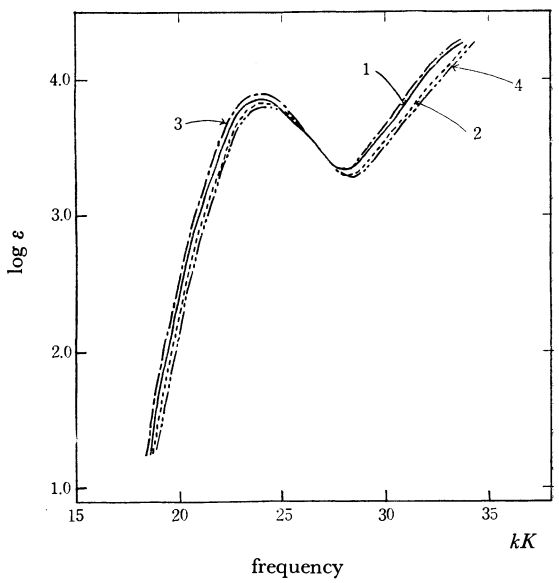

Fig. 4. Electronic absorption spectra of Pd(H-SAL·R)$_2$ in chloroform; 1, R=Ph (——); 2,R=*o*-CH_3Ph (– – –); 3, R=*p*-CH_3Ph (— — —); 4, R=*o*, *o*′-$(CH_3)_2$Ph (— · — · —).

For Pd(X-SAL·*t*-C_4H_9)$_2$, the steric condition is considered to be highly unfavorable for the planar configuration. Their electronic spectra are apparently different from those of the complexes of the type Pd(X-SAL·*n*-alkyl)$_2$, as clearly seen in Figs. 2 and 3. This difference in the spectrum between the complexes of the above two types may

6) S. Yamada, H. Nishikawa and E. Yoshida, This Bulletin, **39**, 994 (1966).

7) S. Yamada and H. Nishikawa, *ibid.*, **36**, 755 (1963).

be ascribed to either of the following two possibilities.

(1) The configuration of Pd(X-SAL·t-C_4H_9)$_2$ is distorted from the planar one.

(2) In Pd(X-SAL·t-C_4H_9)$_2$, the coordination configuration of the palladium(II) ion, namely [Pd(N)$_2$-(O)$_2$], is planar, but the remarkable steric hindrance in this case is exerted to the ligands, giving rise to considerable perturbation in the electronic state of the ligand.

Since the present work reveals that all these palladium(II) complexes are diamagnetic, the latter possibility seems to be higher than the former. The diamagnetism fo Pd(X-SAL·t-C_4H_9)$_2$, however, might also be explained, if we assume that the deviation from the planar coordination of [Pd(N)$_2$-(O)$_2$] is so small that the energy separation between the highest $d_{x^2-y^2}$ and the next highest d orbital of the palladium(II) ion is still large enough to allow the spin-paired state to remain the lowest. Definite conclusion on the precise configuration of the complexes Pd(X-SAL·t-C_4H_9)$_2$ must await X-ray examination.

The conclusion on the configurations of Pd(X-SAL·t-C_4H_9)$_2$ and Pd(X-SAL·i-C_3H_7)$_2$ is found to be different in many respects from that obtained previously about the corresponding nickel(II) complexes. This difference may be considered to arise from the following two points.

(1) The ionic radius of the palladium(II) ion is known to be considerably larger than that of the nickel(II) ion.

(2) The stability of the planar configuration *vis-a-vis* the tetrahedral one is higher for the palladium(II) than for the nickel(II) ion.

The spectra of all these Schiff base palladium(II) complexes in a donor-solvent like pyridine are nearly the same as those of the same complexes in non-donor solvents. It is, therefore, most likely that their configuration in non-donor solvents may be retained in pyridine, namely that the coordination of the pyridine molecule with the palladium(II) ion does not take place. It was previously shown that this was not the case with the nickel(II) complexes.[8] This difference between the nickel(II) and the palladium(II) complexes seems to show that the palladium(II) ion has less tendency to form sexa-coordination than the nickel(II) ion, as was also observed with related ligands as well as many others.[9]

In these respects, the platinum(II) ion is similar to the palladium(II) ion, and the difference between the platinum(II) and the nickel(II) ion is known to be even more marked than that between the palladium(II) and the nickel(II) ion. Therefore, with the platinum(II) complexes Pt(H-SAL·R)$_2$, a similar result to that with the corresponding palladium(II) complexes may be expected. This is borne out by the electronic spectra of these platinum(II) complexes. Thus the spectrum of Pt(H-SAL·n-alkyl)$_2$ is similar to that of Pt(H-SAL·i-C_3H_7)$_2$ but different from that of Pt(H-SAL·t-C_4H_9)$_2$.[5] The details of this phase of the study will be published later.

We wish to thank Mrs. Kayo Fujita for her experimental assistance at the earlier stage of the present work. Financial assistance of the Education Ministry of Japan is also gratefully acknowledged.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 2547—2549 (1969)

The Viscosities of Aqueous Solutions Containing Metal Complexes. II. *trans*-1,2-Cyclohexanediaminetetraacetato Complexes*1

Motoo YASUDA

Department of General Education, Nagoya University, Chikusa-ku, Nagoya

(Received March 5, 1969)

The viscosities of aqueous solutions containing metal chelate formed with *trans*-1,2-cyclohexanediaminetetraacetic acid (H_4cydta) were measured with a Cannon-Fenske capillary viscometer. Measurements were made in a Shibata viscosity bath maintained at 25±0.01°C. The Jones-Dole viscosity *B*-coefficient of the cydta^{4-} chelates is larger than that of the corresponding ethylenediaminetetraacetato (edta^{4-}) chelates, as may be expected. The *B*-value of the Co(III) chelate [Co cydta]$^-$ is much smaller than that of any of the divalent metal cydta^{4-} chelates studied. This fact, the same as in the case of the edta^{4-} chelates, may indicate that the Co(III) chelate has a marked stable hexa-coordinated structure, while divalent metal chelates do not have such a stable hexa-coordinated structure as the Co(III) chelate.

In part I of this series,[1] the viscosities of aqueous solutions containing several cobalt complexes were measured with a capillary viscometer. The results showed that there was a distinct difference between the *B*-coefficients of Co(II) and Co(III) chelates formed with ethylenediaminetetraacetic acid (H_4edta); this suggested that there might be a marked difference between the structures of [Co edta]$^{2-}$ and [Co edta]$^-$ ions. In order to confirm this, a viscosity study was made of aqueous solutions of metal chelates formed with 1,2-cyclohexanediaminetetraacetic acid (H_4cydta), whose structure is very similar to that of H_4edta.

Experimental

Measurements. The viscosity *B*-coefficients of Co(III) and eleven divalent metal chelates were determined with a Cannon-Fenske capillary viscometer with an efflux time of *ca.* 240 sec for distilled water. The viscosities and densities of the solutions were measured in a Shibata viscosity bath maintained at 25±0.01°C.

Complexes. Potassium (cyclohexanediaminetetraacetato)cobaltate(III) trihydrate was obtained as red-violet crystals following the method in the literature.[2] However, divalent metal chelates were not isolated as crystals. Instead, solutions of these chelate were made up using metal nitrate (or chloride) and K_4cydta stock solutions. The concentrations of the metal nitrate (or chloride) solutions were determined by chelatometric titrations. The concentration of the K_4cydta stock solution, made from Dotite H_4cydta and potassium hydroxide, was also determined by chelatometric titration.

Calculations. For each of the chelates studied, the variations in the viscosity with the solute concentration was expressed by the Jones-Dole equation:[3]

$$\frac{\eta}{\eta_0} = 1 + A\sqrt{C} + BC \qquad (1)$$

where η and η_0 are the viscosities of the solution and of water respectively; and where *A* and *B* are constants characteristic of the solute. Only the *B*-coefficient will be discussed in this paper, for the *B*-coefficient seems to be a manifestation of the hydrated ionic volume; this is supported by the linearity of the *BC* term in the concentration. On the other hand, the *A*-coefficient, which is thought to represent the amount of the interionic electrostatic forces, will not be discussed here, for the *A*-values are very small compared with the *B*-values and are almost independent of the metal included in the chelate.

Results and Discussion

The viscosity and density data for K_2[Cu cydta] (+2KNO_3) and K[Co cydta] are listed in Tables 1 and 2. Table 3 contains the *B*-values of cydta^{4-} complex anions at 25°C, together with the stability constants for these complex ions reported by Anderegg.[4]

The solubility of the lead chelate, which was the least soluble in water of the metal chelates studied, was only 0.01 mol/*l*; thus, the *B*-value of

* J. H. Holloway and C. N. Reilly, *Anal. Chem.*, **32**, 249 (1960).

[Pb cydta]$^{2-}$ is the least accurate.

Now it may be very interesting to compare the B-values of the cydta^{4-} chelates with those of the edta^{4-} chelates, reported by Charles[5] and by the present author.[1] Their relation is shown in Fig. 1; the ordinates are the B-values of the cydta^{4-} chelates, and the abscissas, those of the edta^{4-} chelates. The rather good agreement of all the points except those for Mg^{2+} and Mn^{2+} chelates with the straight line may indicate that Mcydta^{n-} and Medta^{n-} chelates have similar structures.

5) R. G. Charles, *J. Am. Chem. Soc.*, **78**, 3946 (1956).

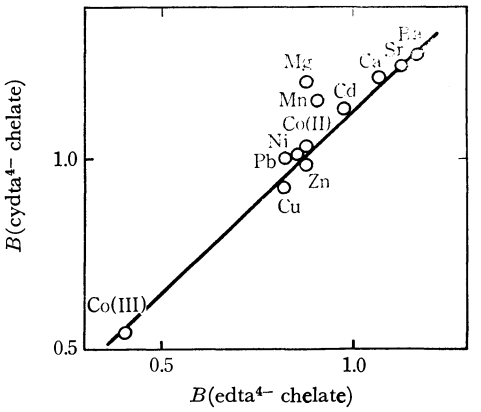

Fig. 1. Relation between the B-coefficients of cydta^{4-} and edta^{4-} Chelates

Next, Einstein's equation,[6] derived for the viscosity of the solution, must be taken into account. According to Einstein, the viscosity of a solution which contains, in suspension, rigid spherical particles which are large compared with the size of the solvent molecules is given by the following equation;

$$\eta = \eta_0(1 + 2.5\,\phi) \tag{2}$$

where ϕ is the volume-fraction occupied by the particles.

If it is assumed that his theory can be applied to large molecules in solution,*2 Eq. (3) is obtained from Eqs. (1) and (2);

$$A\sqrt{C} + BC = 2.5\,\phi \tag{3}$$

The volume fraction, ϕ, may then be expressed by:

$$\phi = CV \tag{4}$$

where V is the molar volume of the solute, including an attached solvent (in l/mol). Further the $A\sqrt{C}$ term is very small in comparison with BC, and so it can safely be neglected. Accordingly, we obtain:*3

$$B = 2.5\,V \tag{5}$$

Eq. (5) leads to:

$$v_h = \frac{4000\,B}{6.02}\ \text{Å}^3 \tag{6}$$

where v_h is the volume of the hydrated solute. Thus, the average radius can be calculated from the B-coefficient. The values obtained for the Co(II) and Co(III) chelates of edta^{4-} and cydta^{4-} are listed in Table 4.

6) A. Einstein, *Ann. Phys.*, **19**, 289 (1906); **34**, 591 (1911).

*2 This was confirmed by Fuoss and Tuan and by Stokes and Mills for $C(CH_2OH)_4$, Bu_4N^+, Ph_4B^-, *etc.*

*3 This relation was derived by Stokes and Mills; R. H. Stokes and R. Mills, "Viscosity of Electrolytes and Related Properties," Pergamon Press, Oxford (1965).

Table 4. *B*-Coefficients and average radii (r) of the Co chelates

	$[Co\ edta]^{2-}$	$[Co\ edta]^{-}$	$[Co\ cydta]^{2-}$	$[Co\ cydta]^{-}$
B	0.85	0.41	1.03	0.54
r(Å)	5.1	4.0	5.5	4.4

As may be seen from Table 4, the radius of the Co(III) chelate is about 1 Å smaller than that of the corresponding Co(II) chelate. Co-N interatomic distances have been measured for several Co(II) and Co(III) complexes derived from ligands with nitrogen donors. Since there are few data available on the Co(II)-N interatomic distance, it may be improper to draw a conclusion concerning the difference between the Co(II)- and Co(III)-N distances. However, it may be safely assumed that there is no marked difference between them. Further, since the $cydta^{4-}$ chelates have very large stability constants, it may be assumed that there is no apprreciable change in the viscosity of the solution due to the dissociation of the chelate. Accordingly, the large difference between *B*-coefficients of Co(III) and divalent metal chelates may imply that the structure of the Co(III) chelate is different from that of divalent metal chelates, as with the $edta^{4-}$ chelates. Thus, it may be assumed that the Co(III) chelate has a markedly stable hexa-coordinated structure, but that the divalent metal $cydta^{4-}$ chelates, not having so stable a hexa-coordinated structure as the Co(III) chelate, are present as a penta-coordinated chelate or as an equilibrium mixture of hexa- and penta-coordinated structures.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 2549—2551 (1969)

Dioxouraniun(VI) Complexes of Schiff Bases Obtained from Substituted Salicylaldehydes and Alkyl Amines[1)]

Shoichiro YAMADA and Akira TAKEUCHI

Institute of Chemistry, College of General Education, Osaka University, Toyonaka, Osaka

(Received March 5, 1969)

Dioxouranium(VI) complexes have been examined with Schiff bases obtained from substituted salicylaldehydes and alkyl amines. Many new complexes of the type abbreviated as $UO_2(NO_3)_2$(X-SAL·R·H)$_2$ have been prepared as orange-red crystals. The notation X denotes H, 5,6-benzo and 3-CH_3O, and R represents alkyl groups. Infrared spectra indicate that there is no uncoordinated nitrate ion, and that the nitrate ions are coordinated with the uranium(VI) ion as unidentate ligands in these complexes. It is to be noted that the molecules, and not anions, of the Schiff bases are coordinated with the metal ions, as in many other dioxouranium(VI) complexes.

A number of studies have been carried out on the Schiff base complexes of various metal ions.[2-4] These studies, however, were mainly concerned with the 3*d* transition elements, and comparatively little has been reported on the corresponding complexes of the heavier transition elements.

In the present work, dioxouranium(VI) ion has been taken up, and its complexes (Fig. 1) with

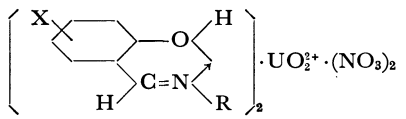

Fig. 1. $UO_2(NO_3)_2$(X-SAL·R·H)$_2$.

Schiff bases*1 obtained from substituted salicylaldehydes have been examined. The dioxouranium(VI) complexes are interesting, particularly in that the coordination number exceeding six may normally be expected for the uranium(VI) ion. Only a few papers[2,3,5)] have so far been published about dioxouranium(VI) complexes with the Schiff bases, and systematic studies were thought to be desirable.

Experimental

Materials. Dinitratobis(*N*-alkyl-salicylideneimine)-, dinitratobis(*N*-alkyl-5,6-benzosalicylideneimine)- and dinitratobis(*N*-alkyl-3-methoxysalicylideneimine)-dioxouranium(VI) complexes of the general formula $UO_2(NO_3)_2(X\text{-}SAL\cdot R\cdot H)_2$ were prepared according to the methods (a) and/or (b) given below. The notation X denotes H, 5,6-benzo and 3-CH_3O, and R represents alkyl groups. The elemental analyses of these complexes are given in Table 1.

(a) To a luke-warm solution of dioxouranium(VI) nitrate hexahydrate (0.01 mol) in ethanol (200 m*l*) was added a solution of a substituted salicylaldehyde (0.02 mol) in ethanol (100 m*l*). The solution immediately changed colour from orange-yellow to red. To this solution was added with stirring drop by drop a solution of an appropriate amine (0.02 mol) in ethanol (50 m*l*). The resulting red solution was allowed to stand for a few hours at about 30°C to 40°C. The orange-red crystals, which separated out, were collected by filtration and washed with ethanol.

(b) To a solution of dioxouranium(VI) nitrate hexahydrate (0.01 mol) in ether-ethanol (1 : 1, 300 m*l*) was added a solution of an appropriate Schiff base (0.02 mol) in ethanol (150 m*l*) with stirring at room temperature. The resulting solution was allowed to stand at about 5°C for a few hours. The orange-red crystals, which separated out, were collected by filtration, and washed with ethanol.

These dioxouranium(VI) complexes, the elemental analyses of which are given in Table 1, are slightly soluble in methanol, ethanol, chloroform and benzene, and a little more soluble in pyridine. Recrystallization from methanol, ethanol or chloroform was sometimes successful, but some of these complexes were so unstable against heat that they often underwent thermal decomposition during the process of recrystallization.

Measurements. The electronic absorption spectra of these complexes in solution were determined with a Shimadzu QR-50 spectrophotometer and a Shimadzu MPS-50 spectrophotometer. The infrared spectra in the region from 700 to 4000 cm^{-1} were measured with a Hitachi-EPI-2 infrared spectrophotometer using the Nujol mull technique.

The diamagnetism of the dioxouranium(VI) complexes in the solid state was detected by the Gouy method at room temperature.

Results and Discussion

Many new complexes of the type $UO_2(NO_3)_2(X\text{-}SAL\cdot R\cdot H)_2$, as shown in Table 1, have been prepared in the present work. They are stable against light and atmosphere in a solid state, and are all diamagnetic.

The infrared spectra of these complexes show no absorption band near about 1380 cm^{-1}, where the free nitrate ion is known to absorb. It is concluded, therefore, that there is no nitrate ion which is not bound with the uranium(VI) ion. Since these complexes show absorption peaks at about 1480 cm^{-1} and 1280 cm^{-1}, which are assigned to the ν_1 (NO stretching) and ν_4 (NO_2 asymmetric stretching) vibration, respectively,[6] it is presumed that in these complexes the nitrate ions are coordinated with the metal ion as unidentate ligands. It is thus found that the uranium(VI) ion takes an eight-coordination. A considerable number of dioxouranium(VI) complexes were previously reported which have nitrate ions coordinated with the uranium(VI) ion.[7] It is also to be noted that in the complexes of the type $UO_2(NO_3)_2(X\text{-}SAL\cdot$

6) E. P. Bertin, R. B. Penland, S. Mizushima, C. Curran and J. V. Quagliano, *J. Am. Chem. Soc.*, **81**, 3818 (1959); J. E. Fleming and H. Lynton, *Chem. Ind. (London)*, **1963**, 1416; C. C. Addison and W. B. Simpson, *J. Chem. Soc.*, **1965**, 598; A. B. Lever, *Inorg. Chem.*, **4**, 1042 (1965).

7) L. Sacconi and G. Giannoni, *J. Chem. Soc.*, **1954**, 2751; F. J. Frere, *J. Am. Chem. Soc.*, **55**, 4362 (1933).

$R\cdot H)_2$ the *neurtal molecules*, and not anions, of the Schiff bases are considered to be coordinated with the metal ion. Such was the case previously reported with dioxouranium(VI) complexes of 8-hydroxyquinoline, β-diketones and so on, in which the ligand *molecules* were considered to be bound with the metal ion.[7]

The electronic spectra of these dioxouranium(VI) complexes in the same solvent are all alike, independent of the nature of R, if comparison is made for the complexes with the same substituent X. The spectra of the complexes in chloroform are quite similar to those of the benzene solutions. In these solvents, Beer's law is found to hold, and it is most likely that these complexes may exist as eight-coordinated molecules, no decomposition or dissociation taking place. Since their solubility in organic solvents was considerably low, the absorption curves for the lower molar extinction coefficient was not very accurate. The absorption curves in Figs. 2 and 3 are regarded as superposition of the absorption due to the dioxouranium(VI) group[8] and that mainly due to the Schiff base molecules bound with the metal ion. The absorption of the former type is much stronger than that of the latter type, which is considered to be hidden by the former. Precise assignment of the absorption bands of these complexes is not possible at the present stage.

The electronic spectra of the methanol and the ethanol solution are different from those of the chloroform and the benzene solution. Some of the typical spectra in different solvents are also shown in Figs. 2 and 3. It is most likely that in methanol or in ethanol there occurs dissociation of the nitrate ions, and subsequent combination of the methanol or the ethanol molecule with the uranium(VI) ion. Incidentally, the combination of the methanol or the ethanol molecule with the uranium(VI) ion has often been observed, and indeed the alcohol adducts have been isolated as crystals, for example, with the dioxouranium(VI) complexes of the Schiff bases.[2,9]

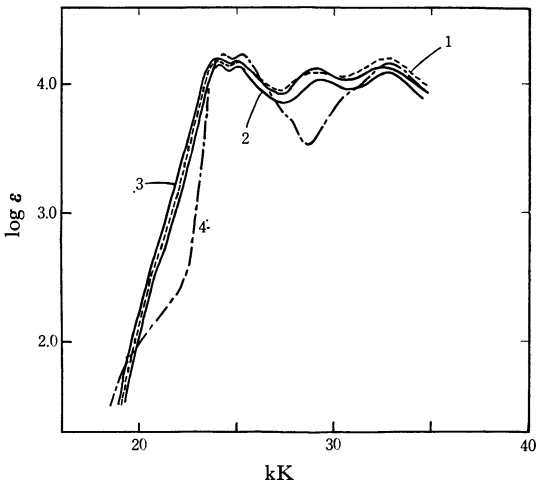

Fig. 3. Electronic absorption spectra of $UO_2(NO_3)$-(5,6-benzo-SAL·R·H)$_2$ in solution.
1, R=C_2H_5, in chloroform; 2, R=t-C_4H_9, in chloroform; 3, R=n-C_4H_9, in chloroform; 4, R=n-C_4H_9, in methanol

It is to be noted that the complexes of the type $UO_2(NO_3)_2$(X-SAL·t-C_4H_9·H)$_2$ were readily prepared and that their properties resemble those of the corresponding complexes with n-alkyl groups for R, all having an eight-coordinated configuration. This finding seems to be significant, particularly because it is known that the steric effect arising from the t-butyl group often favors the geometry which is different from that of the corresponding complex having an n-alkyl group instead of the t-butyl group.[10–12]

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 2552—2555 (1969)

The Syntheses and the Structure of Triethanolamine Complexes with Cobalt(II) and Nickel(II)[1)]

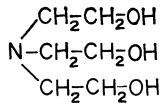
Yoshio KUGE*[1] and Shoichiro YAMADA

Institute of Chemistry, College of General Education, Osaka University, Toyonaka-shi, Osaka

(Received March 18, 1969)

Triethanolamine complexes with cobalt(II) and nickel(II) have been synthesized as crystals and examined on the basis of analytical data, electronic absorption spectra, and magnetic moments. A complex, $Ni\{N(CH_2CH_2OH)_3\}(ClO_4)_2$, which is formed with $Ni(ClO_4)_2$, is concluded to have a six-coordinated configuration, similar to that previously reported for the corresponding chloride, bromide, and nitrate complexes. In cobalt(II) complexes, $Co\{N(CH_2CH_2OH)_2(CH_2CH_2O)\}X$, which are formed with CoX_2 ($X=Cl^-$, Br^-, or NCS^-), the cobalt(II) ion is concluded to take a five-coordinated configuration.

A number of papers have been published concerning the behavior of metal complexes with triethanolamine (Formula I) in solution, but little



Formula I

is known about these complexes in the solid state.[2–4)]

Examining these complexes in the solid state by magnetic, spectroscopic, and X-ray powder techniques, Hughes and Rutt[5)] recently reached some significant conclusions about their stoichiometry and stereochemistry. Independently, the present authors have also carried out a similar study of this subject. Many of our conclusions agree with the conclusions of the earlier reports, but our study has also yielded some conclusions which are different from those in the previous works, or which seem to be of a more conclusive nature than those of the previous papers. Moreover, among the previous workers there has been some disagreement event about the stoichiometry of the solid compounds. The present paper is concerned with the syntheses and the structures of the triethanolamine complexes with cobalt(II) and nickel(II), but emphasis will be placed upon the new and more significant results and on those of our conclusions which are different from those of the previous papers.

Experimental

Materials. Since the composition of the solid complexes reported in the present paper markedly depends upon the precise conditions of preparation, it seems wise to give here a detailed account of the preparation.

Cobalt(II) complexes of triethanolamine were prepared as purple crystals in the following manner. Into a solution of $CoX_2 \cdot 6H_2O$ ($X=Cl^-$, Br^-, or NCS^-) (0.0125 mol) in 95% ethanol (100 m*l*), triethanolamine (0.025 mol) was stirred at room temperature. Purple crystals immediately began to separate out in the solution. After the solution had been stirred for about 30 min, the purple crystals of $Co\{N(CH_2CH_2OH)_2(CH_2CH_2O)\}X$ were collected by filtration, washed with cold ethanol, and dried overnight in a vacuum desiccator.

The solubility of these complexes in solvents like water, methanol and ethanol is quite low.

Employing a method essentially the same as that described above, Duff and Steer[4)] obtained crystals of the same compositions as ours, but Hughes and Rutt[5)] reported compounds with the $[Co\{N(CH_2CH_2OH)_3\}_2]X_2$ formula.

Nickel(II) complexes of triethanolamine of the $[Ni\{N(CH_2CH_2OH)_3\}_2]X_2$ formula ($X=Cl^-$, Br^-, NO_3^-, or ClO_4^-), were prepared as pale-blue crystals in the present work. The former three ($X=Cl^-$, Br^-, or NO_3^-) had been reported previously,[2,3,5)] but the complex with $X=ClO_4^-$ had not been.

The method in the present work was as follows. Into a solution of $NiX_2.6H_2O$ ($X=Cl^-$, Br^-, NO_3^-, or ClO_4^-) (0.025 mol) in 95% ethanol (100 m*l*), we stirred triethanolamine (0.055 mol) in small portions at about 60°C. After being kept at this temperature

* μ: magnetic moment at room temperature in B. M.
** The notaiton, TEA', represents an anionic ligand, $N(CH_2CH_2OH)_2(CH_2CH_2O)$.

for about 30 min, the solution was allowed to stand overnight at room temperature. A pale-blue precipitate which was formed in the solution was recrystallized from methanol. Pale-blue crystals of $[Ni\{N(CH_2CH_2OH)_3\}_2]X_2$ were thus obtained.

These complexes with $X=Cl^-$, Br^-, or NO_3^- are slightly soluble in methanol, but are almost insoluble in other solvents. The complex with $X=ClO_4^-$ is more soluble in methanol than are the othet three complexes.

With $X=ClO_4^-$, Hughes and Rutt[5] isolated a solid complex with a complicated formula.

Elemental analyses of those cobalt(II) and nickel(II) complexes whose composition remains still in dispute are given in Table 1.

Measurements. The electronic absorption spectra of the complexes in the solid state were determined with a Shimadzu QR-50 and a Shimadzu MPS-50L spectrophotometer. The measurement of the solution spectrum was possible only with $[Ni\{N(CH_2CH_2OH)_3\}_2](ClO_4)_2$. The solubilities of the other complexes in suitable solvents were too low for any accurate determination of the solution spectrum.

The X-ray diffraction diagrams were obtained with a Toshiba ADX-103 X-ray diffractometer.

The magnetic moments of the complexes were determined by the Gouy method at room temperature.

Results and Discussion

It was previously concluded, from the electronic spectra,[5] that the nickel(II) complexes $[Ni\{N(CH_2CH_2OH)_3\}]X_2$ with $X=Cl^-$, Br^-, or NO_3^- consisted of six-coordinated complex-ions.

The new complex, $[Ni\{N(CH_2CH_2OH)_3\}_2](ClO_4)_2$, in the solid state shows a spectrum which is quite similar to those of the corresponding complexes with $X=Cl^-$, Br^-, and NO_3^-, as is shown in Fig. 1. Since all these nickel(II) complexes in the solid state show absorption bands at nearly the same frequencies, they may be considered to take a quite similar configuration. The absorption bands at about 11.0, 16.7, and 26.5 kK may be assigned to $^3T_{2g}\leftarrow{}^3A_{2g}$, $^3T_{1g}(F)\leftarrow{}^3A_{2g}$, and $^3T_{1g}(P)\leftarrow{}^3A_{2g}$ in the scheme of the O_h-field symmetry. As has also been concluded previously,[5] it is most likely that triethanolamine normally acts as a

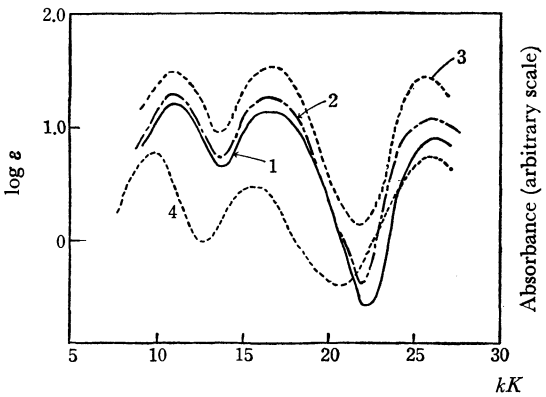

Fig. 1. Electronic absorption spectra of $[Ni\{N(CH_2CH_2OH)_3\}_2]X_2$.
1, $X=Br^-$, reflectance; 2, $X=NO_3^-$, reflectance; 3, $X=ClO_4^-$, reflectance; 4, $X=ClO_4^-$, in methanol. The scale on the right hand side refers to the curves 1, 2, and 3, and the scale on the left hand side the curve 4.

terdentate ligand with one hydroxyl-group remaining uncoordianted, although this ligand is structurally related to β,β',β''-triaminotriethylamine, which can function as a quadridentate ligand.

The absorption spectrum of $[Ni\{N(CH_2CH_2OH)_3\}_2](ClO_4)_2$ in methanol is found to be consistent with the octahedral configuration, but the band maxima in the solution spectrum are shifted toward much lower frequencies, indicating that the configuration of $[Ni\{N(CH_2CH_2OH)_3\}_2](ClO_4)_2$ in methanol may be considerably distorted compared with that in the solid state as well as with the regular octahedron.

The cobalt(II) complexes, $Co\{N(CH_2CH_2OH)_2(CH_2CH_2O)\}X$ ($X=Cl^-$, Br^-, and NCS^-), show quite similar spectra, as is shown in Fig. 2. It is found that these spectra cannot be consistently interpreted in terms of tetrahedral or an octahedral configuration.[6] Instead, they are similar to the

6) S. Buffagni and T. M. Dunn, *Nature*, **188**, 937 (1960); D. L. M. Goodgame, M. Goodgame and F. A. Cotton, *J. Am. Chem. Soc.*, **83**, 1161 (1961).

spectra of some cobalt(II) complexes of high-spin type, for which a five-coordinated structure has been established with certainty.[7]

The magnetic moments of these cobalt(II) complexes, as shown in Table 1, seem to be too low for the six-coordinated cobalt(II) complexes,

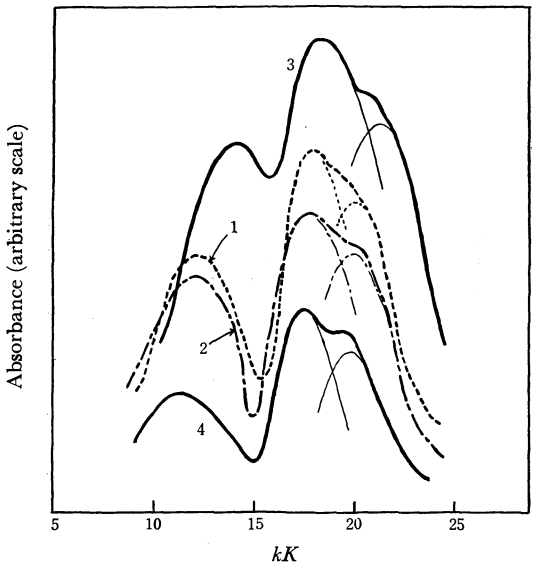

Fig. 2. Electronic absorption spectra of Co{N-$(CH_2CH_2OH)_2(CH_2CH_2O)$}X (compound I) and [Co(Me$_4$daeo)NCS]NCS (compound II) in the solid state. The notation Me$_4$daeo denotes a molecule of O{$CH_2CH_2N(CH_3)_2$}$_2$.
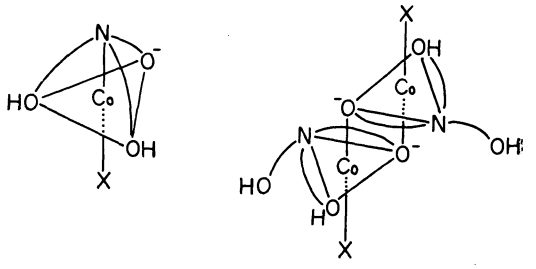
1, compound I, X=Cl$^-$; 2, compound I, X=Br$^-$; 3, compound I, X=NCS$^-$; 4, compound II. The curve 4 is taken from Ref. 7 in the text.

but they lie in a range which may reasonably be expected for the moments of the five-coordinated cobalt(II) complexes with ligands of this kind.[7] It may, therefore, be presumed that in the Co{N-$(CH_2CH_2OH)_2(CH_2CH_2O)$}X complexes (X=Cl$^-$, Br$^-$, or NCS$^-$), the cobalt(II) ion takes a five-coordinated configuration.

The close similarity of the spectra of these cobalt(II) complexes seems to indicate that they have a similar configuration, one in which the cobalt(II) ions take five-coordination. In agreement with this may be the fact that the X-ray powder diagram of Co{$N(CH_2CH_2OH)_2(CH_2CH_2O)$}Cl has been found in the present work to be quite similar to that of the bromide analogue.*2

For the configuration of the five-coordinated cobalt(II) complexes, the (A) configuration in Fig. 3 might at first sight be considered to be possible. This configuration, however, seems to be unlikely, since it is more likely that the ligand, $N(CH_2CH_2OH)_2(CH_2CH_2O)$, is a terdentate rather than a quadridentate ligand, judging from the findings on the corresponding nickel(II) complexes. The presence of one negatively-charged alcoholate group in the ligand suggests that these cobalt(II) complexes are binuclear or polynuclear, with bridging oxygen in the alcoholate group and with the chloride ion also coordinated to the cobalt(II) ion. The binuclear structure (B) in Fig. 3, like that found for



(A) (B)

Fig. 3. Some possible configurations of Co{$N(CH_2CH_2OH)_2(CH_2CH_2O)$}X, in which the cobalt(II) ion takes a five-coordination.

the cobalt(II) complex with *N*-methylsalicylideneiminate,[8] may be considered to be one of the most probable for the present cobalt(II) complexes. Any final conclusion about the precise configuration must, however, await further studies, based, for example, upon the X-ray crystal analysis.

It should be noted that a difference is observed between the cobalt(II) and the nickel(II) ion in the stereochemistry of their triethanolamine complexes. This difference seems to be in agreement with previous studies showing that the stability of the five-coordinated configuration *vis-à-vis* the six-coordinated configuration is higher for the cobalt(II) than for the nickel(II) ion.[9]

It is also interesting to compare the triethanolamine complexes with the corresponding complexes of N{$CH_2CH_2N(C_2H_5)_2$}$_3$. The present work reveals that NiX_2 (X=Cl$^-$, Br$^-$, or NO_3^-) forms six-coordinated complexes with the former ligand, while it has previously been shown[7] that five-coordinated complexes are formed with the latter ligand. The former and the latter ligands are found to function as terdentate and quadridentate

ligands, respectively. The difference between the two ligands lies only in the terminal groups, the ability of the OH-group to combine with the metal ion being considered to be lower than that of the NR_2-group.

The present authors wish to thank the Ministry of Education for its financial support.

Shielding Effect of *Ortho*-Substituents on Magnetic Moments and d–d Bands in Chloro-*N*-phenylsalicylideneiminatocopper(II)[*1]

Michinobu KATO,* Yoneichiro MUTO,** Hans B. JONASSEN,*** Kyoko IMAI,* Kazuko KATSUKI** and Seishi IKEGAMI**

(Received March 20, 1969)

Complexes with the formula, $Cu(\overset{1}{O}\cdot C_6H_4\cdot \overset{2}{C}H{=}N\text{-}Ph\text{-}X)Cl$, where Ph-X is a mono- or di-substituted phenyl group, were prepared. A dimeric structure was postulated for these complexes based on the observed subnormal magnetic moments and the chemical formula. For these complexes, a linear relation was observed to exist between the magnetic moments, $\mu_{eff}^{25°C}$, and the d–d band positions, $\tilde{\nu}_{max}$. The d–d bands of the dimeric complexes with *o*-substituents appeared at shorter wavelengths than those with *m*- or *p*-substituents irrespective of the polar nature of the substituents. A similar *ortho*-effect was also observed for the magnetic moments; complexes with *o*-substituents were observed to have smaller moment values than those with *m*- or *p*-substituents. The *ortho*-effect was also observed in the d–d bands of the monomeric bis-complexes $Cu(\overset{1}{O}\cdot C_6H_4\cdot \overset{2}{C}H{=}N\text{-}Ph\text{-}X)_2$ and their d–d bands when X=*o*-substituents appeared at shorter wavelengths than those with *m*- or *p*-substituents. These *ortho*-effects decreased for the solution spectra of the monomeric complexes.

In a previous paper,[1] it was reported that, despite the wide variation in the polar nature of the substituents in dimeric pyridine *N*-oxides copper(II) chloride complexes a linear relation exists between the magnetic moments, $\mu_{eff}^{25°C}$, and the d–d band positions, $\tilde{\nu}_{max}$. No such correlation, however, is found between the polar nature of the substituents in terms of Hammett's σ constants and the magnetic moments of the d–d band positions. The breakdown of Hammett's rule in these dimeric systems was correlated to a steric effect of the substituents on the central metal atom overlapped by their polar effect. The substituents in the aromatic ring which rotates around the N–C bond perpendicular to the coordination plane, will, depending on their size or positions, shield the fifth coordinating site of the central metal atom from the influences of other molecules or ions. This type of shielding effect makes the d–d bands shift towards shorter wavelengths and lowers the magnetic moments compared to those of the parent complexes.

In order to test the validity of these observations for other dimeric complexes, we have prepared copper(II) complexes with the formula, Cu(Sal·N–Ph–X)Cl[*2] and studied their magnetic and spectral properties. Spectral measurements were also made for the parent bis-complexes $Cu(Sal\cdot N\text{-}Ph\text{-}X)_2$.

* Ph-X=mono- or di-substituted phenyl group with substituent X.
Indications in the parentheses in the first column are the solvent molecules combined with the complexes for the chemical formula.

The present study also compares the difference in the pathways of polar effect transmittance in pyridine *N*-oxide and *N*-phenylsalicylaldimine complexes, and the magnetic interactions between copper(II) ions in a dimer.

Experimental

Materials. Salicylaldehyde, various aryl amines and anhydrous cupric chloride (Fisher certified reagent) were obtained commercially.

Preparation of the Copper(II) Complexes. *a) Parent Bis(N-phenylsalicylideneiminato)copper(II) Complexes.* These were prepared by the general method.[2,3] In most cases, methanol or ethanol was used as solvent but in the preparation of complexes with *o*-chloro or *o*-nitro group, dimethylformamide was employed instead of alcohols to elevate the reaction temperature. The purity of the recrystallized complexes was checked by copper analysis.

b) Chloro Copper(II) Complexes. In a typical preparation, a filtered solution of anhydrous cupric chloride in ethanol was added to one of the recrystallized parent complexes in a flask. The mole ratio of cupric chloride to each complex was 1.1 : 1, *i. e.*, ten percent excess of $CuCl_2$ over the stoichiometric quantity was used. The alcoholic mixture in the flask equipped with a condenser was stirred on a hot plate for two hours. The precipitated product was filtered off from solvent on a glass filter, washed several times with ethanol and once with ether, and dried at 70—80°C. The analytical data are listed in Table 1.

Magnetic Susceptibility Determinations. These data were obtained by the Gouy method at room temperature. The effective magnetic moment, μ_{eff}, per copper atom was calculated from the expression $\mu_{eff}=2.83\sqrt{\chi_M\cdot T}$ B.M., where χ_M is the molar susceptibility corrected using Pascal's constants,[4,5] for the diamagnetism of all the atoms in the compounds. The temperature-independent paramagnetism associated with the copper ions was not included in the calculation of μ_{eff} throughout this work. The magnetic moments observed at room temperature were corrected for minor room temperature variations to those at 25°C, $\mu_{eff}^{25°C}$, by using Bleaney and Bowers' equation assuming $g=2.2$.[6,7] These results are given in Table 2.

Spectral Measurements. These were made in 340—2000 mμ region on the automatic recording Hitachi EPS-3T spectrophotometer. The diffuse reflectance spectra of the parent bis-complexes and the copper(II) chloride complexes were measured with a reflectance attachment. Magnesium oxide or lithium fluoride of optical grade was used as the standard of light reflectance. Instead of diluting the compounds with the reference material, appropriate absorbancy ranges were selected by controlling the sensitivity knobs on the spectrophotometer. The band maxima of these complexes are recorded in Tables 3 and 5. Spectral measurements were also made for some of the paren bis-complexes in chloroform. The data of these solution

spectra are given in Table 4. The bands listed in these tables may be resolved into more than one component.

Results and Discussion

Parent Monomeric Complexes. The parent monomeric complexes give rise to several bands in 340—2000 mμ region in the diffuse reflectance spectra (*cf.* Tables 3 and 4). Many of these bands are not well characterized. The bands at wave-

lengths shorter than about 500 mμ can probably be attributed to charge-transfer or intra-ligand transition.[8,9] The bands recorded at wavelengths longer than about 1200 mμ, are difficult to assign[10] and do not seem to be important in this discussion. The bands appearing around 700 mμ are the most distinct (marked with an asterisk in Tables 3 and 4), and most of these are considered to be the well-known d–d bands of the planar type of copper(II) complexes.[7–12]

Those of the complexes with a substituent in the *ortho*-position appeared at shorter wavelengths than those with a substituent at the *meta*- or *para*-position, *i. e.*,

$$\lambda_{max}\ (o\text{-}) < \lambda_{max}\ (m\text{-}) \sim \lambda_{max}\ (p\text{-})$$

The difference in λ_{max} between *meta*- and *para*-complexes is small compared to that between the *ortho*- and *meta*- or *para*-complexes. This is illustrated by the spectral curves of the complexes with methyl group in Fig. 1. On the other hand, essentially no difference in λ_{max} of d–d bands was observed among complexes with different substituents at the same ring positions. Figure 2 shows this for the absorption bands of complexes with *m*-Cl, *m*-CH_3 and *m*-NO_2, all at about 740—745 mμ.

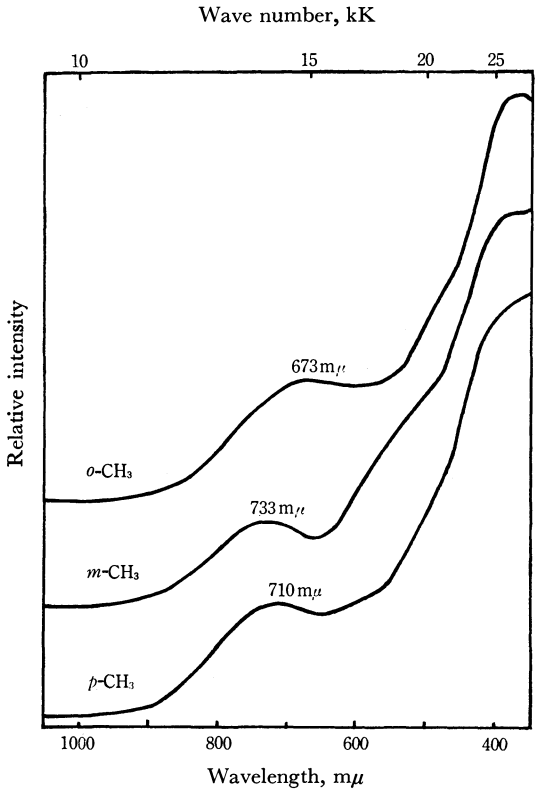

Fig. 1. Diffuse reflectance spectra of Cu(Sal·N-Ph-CH_3)$_2$.

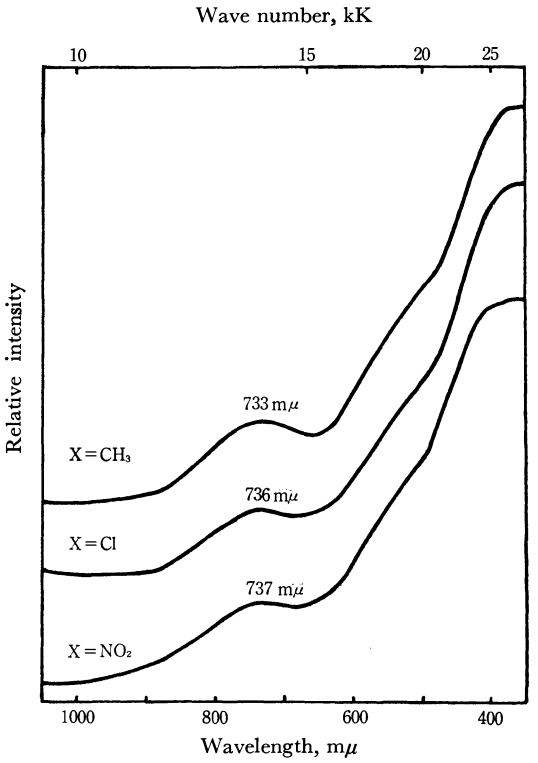

Fig. 2. Diffuse reflectance spectra of Cu(Sal·N-Ph-X)$_2$ with X=*m*-CH_3, *m*-Cl, and *m*-NO_2.

An X-ray analysis of the parent compound, bis(*N*-phenyl-salicylideneiminato)copper(II)[13] has shown that the plane of the *N*-phenyl group is nearly perpendicular to the $\begin{pmatrix}O\\N\end{pmatrix}Cu\begin{pmatrix}N\\O\end{pmatrix}$ plane. Under such conditions, substituents attached in the *ortho*-position of the phenyl group should have a great tendency to shield the fifth coordination site of the copper(II) ions. Such shielding effect is said to stabilize the complexes and to produce the observed "blue shift" of the d–d band.[1,14–17]

The "blue shift" effect of *ortho*-substituents on the d–d bands in chloroform solution was apparently retained even though it decreased compared to

that in the solid state (*cf.* Fig. 3).

In solid complexes the vacant coordination sites of the copper(II) ion are subjected to the influences of adjacent atoms, ions, or molecules. However, in solutions of weak-coordinating solvents such as chloroform, these influences should decrease as the distances between the complexes increases. Since the solvent molecules display a kind of shielding effect, it is then quite probable that the shielding effect due to the steric condition of the *ortho*-substituents is much decreased. Since the copper(II) ion has one unpaired electron, a continuous variation in the influence of the ligand field or in the stereochemistry, seems to be possible.[18] The *ortho*-substituent effect for the di-substituted complexes, was retained in some cases (those with methyl group) but in other cases it became obscure (those with the chloro group) (*cf.* Table 3). This may be due to an additional steric effect which interferes with the existence of stable planar complex due to the preparatory method used for the solid complexes.[1,8,18,19]

Dimeric Chloro Copper(II) Complexes. No X-ray analysis for dimeric chloro copper(II) complexes similar to those we prepared has been reported. On the basis of the chemical formula of these complexes which contain only three coordinating atoms, and of the observed low magnetic moments,

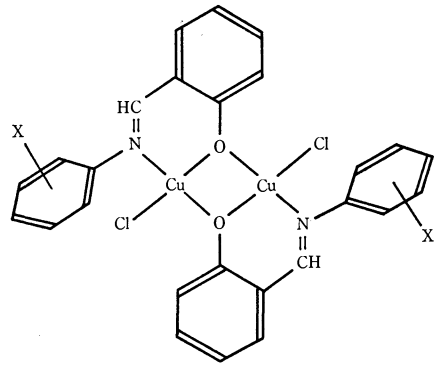

Fig. 4. The assumed dimeric structure of Cu(Sal·N-Ph-X)Cl.

we have assumed a dimeric structure of the type given in Fig. 4. Of the three types of coordinating atoms in the dimeric complexes, the phenolic oxygen atom is most probably the bridging atom because (1) the imino-nitrogen atom can not span the copper(II) ions because of steric hindrance of the *N*-phenyl group, and (2) a low magnetic moment of 1—1.5 B.M. recorded for these dimeric complexes has never been observed in copper(II) complexes with chlorine-bridges.[20]

a) Diffuse Reflectance Spectra. The diffuse reflectance spectra of the chloro copper(II) complexes revealed several bands in the 340—2000 mμ region similar to the parent monomeric complexes (*cf.* Table 5). The main d–d band which corresponds to that of the parent complexes can easily be distinguished from the other bands. The d–d band maximum occurs at a much longer wavelengths (800—900 mμ) than that of the monomeric complexes suggesting a distorted planar or pseudo-tetrahedral structure for these complexes.[8–10,19,21–23] Sacconi found that the salicylideneiminato-copper(II) of pseudo-tetrahedral type are maroon,[8] and these dimeric copper(II) chloride complexes are all maroon or brown. Chloro(*N*-alkylsalicylideneiminato)copper(II) complexes which we studied previously[*1-b,24] are closely related to chloro(*N*-phenylsalicylideneiminato)copper(II); they also are brown. They showed three bands in the 340—1500 mμ range with essentially the same spectral features as those of bis(*N*-alkylsalicylideneiminato)-

copper(II) with pseudo-tetrahedral structure.[8,21] The magnetic moments and the main d–d band positions of these chloro copper(II) complexes with *N*-alkyl groups fall in the range of 1—1.4 B.M. and of 800—900 mμ respectively, the same ranges as those observed for the dimeric complexes with *N*-phenyl groups of the present study.

Each copper(II) ion in these dimeric complexes is effectively surrounded by three coordinating atoms, one of which is the chloride ion which has a position in the early part of the spectrochemical series.[25] The ligand field strength is therefore much weaker than that of the monomeric complexes. The diffuse reflectance spectra of the dimeric complexes with mono-substituted *N*-phenyl group, showed a "blue shift" effect of *ortho*-substituents just as the parent monomeric complexes (*cf.* Fig. 5 and Table 5). This suggests that a structural

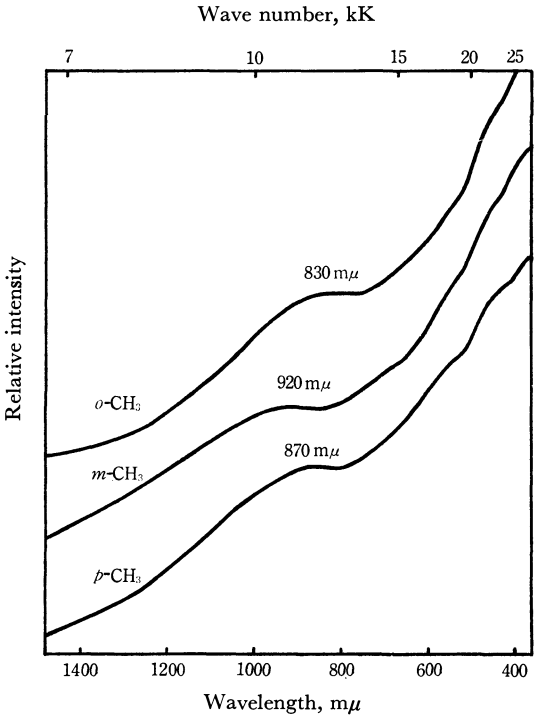

Fig. 5. Diffuse reflectance spectra of Cu(Sal·N-Ph-CH_3)Cl.

feature important in bis(*N*-phenylsalicylideneiminato)copper(II), namely the upward rotation of the *N*-phenyl group perpendicular to the coordination plane, is substantially retained in these dimeric complexes. The same type of *ortho*-substituent effects was observed in the d–d bands and in the magnetic interaction between copper(II) ions in a pair[1] for the dimeric copper(II) chloride complexes with pyridine *N*-oxides. The structure of the parent copper(II) chloride complex with pyridine *N*-oxide shows that the pyridine ring is rotated about the O–N bond such that its plane is essentially perpendicular to the coordination sphere of a distorted square-planar geometry.[26,27]

In the dimeric chloro copper(II) complexes with *N*-phenylsalicylaldimines, as for copper(II) chloride complexes with pyridine *N*-oxides, no correlation was observed to exist between Hammett's σ constants of substituents and the d–d band positions.

b) Magnetic Moments. For the complexes with a disubstituted *N*-phenyl group, the *ortho*-substituent effect of "lowering at magnetic moment" was observed in these dimeric complexes (*cf.* Table 2), with a few exceptions

$$\mu_{\mathrm{eff}}^{25^\circ\mathrm{C}}(o\text{-}) < \mu_{\mathrm{eff}}^{25^\circ\mathrm{C}}(m\text{-}) \sim \mu_{\mathrm{eff}}^{25^\circ\mathrm{C}}(p\text{-})$$

However, no correlation exists between the polar nature of the substituents in terms of Hammett's constants and the moments. These observations are the same as those in copper(II) chloride complexes with pyridine *N*-oxides.[1]

c) Linear Relation between d–d Band Positions and Magnetic Moments. Even though no correlation exists between Hammett's σ constants of substituents and the d–d band positions, $\tilde{\nu}_{\max}$, or the magnetic moments corrected to those at 25°C, $\mu_{\mathrm{eff}}^{25^\circ\mathrm{C}}$, a linear relation between $\tilde{\nu}_{\max}$ and $\mu_{\mathrm{eff}}^{25^\circ\mathrm{C}}$ (*cf.* Fig. 6) is found, the same relation observed for the copper(II) chloride complexes with pyridine *N*-oxides.[1,28] In the postulated structure of [Cu(Sal·N-Ph-X)Cl]$_2$ (Fig. 4) the magnetic interac-

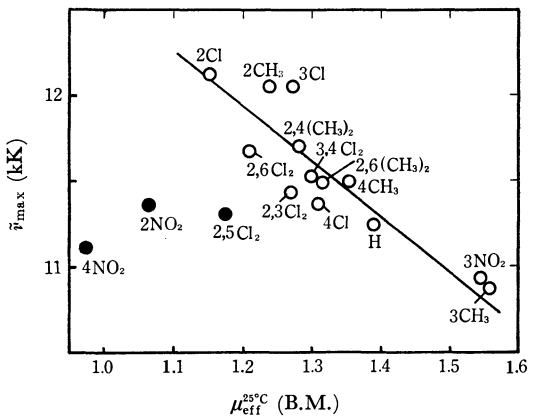

Fig. 6. The plot of the wave number ($\tilde{\nu}_{\max}$ in kK) of d–d bands of Cu(Sal·N-Ph-X)Cl against the corrected magnetic moments ($\mu_{\mathrm{eff}}^{25^\circ\mathrm{C}}$ in B.M.).

tion between copper(II) ions in a dimeric molecule will most probably occur by a superexchange mechanism through the bridging phenolic oxygen atoms.[29–32] Since the orbital overlap scheme of relevant orbitals for the superexchange interaction should essentially be the same for these two systems, a σ type and a π type pathway for the superexchange interaction are possible. The σ type seems to be more important for the same reason as that given for copper(II) chloride complexes with pyridine *N*-oxides.[1]

In the dimeric complexes with pyridine *N*-oxides, the polar effect of substituents transmits directly to the oxygen atoms which are in the superexchange pathway. On the other hand in $[Cu(Sla\cdot N\text{–}Ph\text{–}X)Cl]_2$, the substituent effect should transmit to the coordinating nitrogen atoms not in the superexchange pathway. Despite such difference in the transmittance of substituent-polar effect, the steric effect of the substituents appears to be more important in the determination of physicochemical properties of these complexes than the electronic effect of the substituents.

The anomalous properties of *o*-NO_2 and *p*-NO_2 complexes may be due to a different structure (*cf.* Table 2 and Fig. 6). These compounds have magnetic moments smaller than those expected from the linear relation between $\tilde{\nu}_{max}$ and $\mu_{eff}^{25°C}$; furthermore, whereas the other complexes are brown, these two complexes are greenish-orange in color and their d–d bands are broad. The *o*-NO_2 and *p*-NO_2 compounds are thus seemingly quite similar to the orange one of the two modifications of $Cu(Sal\cdot N\text{–}CH_3)Cl$*[1-b,24]; the orange compound has a moment of 0.9 B.M. and the brown one a moment of 1.47 B.M. at room temperature. The spectral curves of these two modifications are given with those of *p*-NO_2 and *m*-NO_2 compounds in Fig. 7. The compound with *m*-NO_2 group is brown and its spectral feature is essentially the same as that of all other complexes.

The reason for the deviation from linearity for the 2,5-Cl_2 compound is not clear at present. However, it is one of the disubstituted compounds and its d–d band is composed of two bands in contiguity (double peak).

The extent of magnetic interaction found in $[Cu(Sal\cdot N\text{–}Ph\text{–}X)Cl]_2$ ranges from 1 to 1.5 B.M. This is weaker than that observed for the copper(II) chloride complexes with pyridine *N*-oxides (0.2—1 B.M.). On the basis of the p*K* values of ligand

molecules[33–36] the Cu–O coordinate bonds in the bridging framework is considered to be stronger in salicylideneiminato-complexes than in pyridine *N*-oxide complexes.

In the preceding paper, we suggested that the most important factor in the determination of the electron exchange is the bond angle rather than the bond strengths in a pathway, because an effective electron exchange requires a successive overlapping of the relevant orbitals of atoms in a superexchange pathway.[37]

A comparison of the total coordinate bonds in the two complexes shows in $[Cu(PyO)Cl_2]_2$*[3] one

*3 PyO=pyridine *N*-oxide or its derivatives.

Cu–O (PyO–O) and two Cu–Cl bonds *versus* one Cu–O (phenolic-O), one Cu–N (imino-N) and one Cu–Cl bond for $[Cu(Sal\cdot N\text{–}Ph\text{–}X)Cl]_2$. This would indicate greater total covalent bond strength in the latter, however, their d–d bands are practically at the same energy (760—900 mμ) for $[Cu(PyO)Cl_2]_2$ and (830—900 mμ) for $[Cu(Sal\cdot N\text{–}Ph\text{–}X)Cl]_2$. This seeming contradiction can be resolved if it is postulated that the stereochemistry of the $[Cu(Sal\cdot N\text{–}Ph\text{–}X)Cl]_2$ complexes has a greater tetrahedral distortion than $[Cu(PyO)Cl_2]_2$.[8,21,22]

This assumption is consistent with the lower range of magnetic moments (0.2—1 B.M.) in the pyridine *N*-oxide and with the higher range (1—1.5 B.M.) in *N*-phenylsalicylideneiminato-complexes. On the basis of the assumed pathways the orbital overlap effective for the superexchange interaction should be weaker in the system with a greater pseudo-tetrahedral framework than in that with greater planar framework.

A linear relationship between d–d band position and magnetic moments in dimeric $[Cu(Sal\cdot N\text{–}Ph\text{–}X)Cl]_2$ has been established similar to that found previously for dimeric $[Cu(PyO)Cl_2]_2$. It holds even though in the two complexes there is a difference in the position of the coordinate bonds through which the substituent polar effect is transmitted in the superexchange pathway.

A shielding effect of the substituents on d–d band position and magnetic moments has also been observed which is greatest for *ortho* substitution (*ortho*-effect) even though a change in polarity of the substituents has no effect on either d–d band position or magnetic moments.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 2562—2566 (1969)

Metal Complexes of Schiff Bases Obtained from Substituted Salicylaldehydes and 2-Aminopyridine Derivatives[1)]

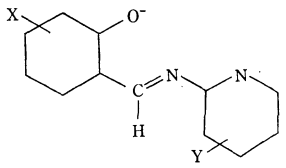
Shoichiro YAMADA and Kuniko YAMANOUCHI

Institute of Chemistry, College of General Education, Osaka University, Toyonaka, Osaka

(Received March 28, 1969)

Numerous metal complexes (abbreviated as $M(X\text{-}SAL\cdot R)_2\cdot nH_2O$) of Schiff bases obtained from substituted salicylaldehydes and 2-aminopyridine derivatives were prepared as crystals, where X=H, 5,6-benzo, 5-Cl, 5-Br, 5-NO_2 and 3-CH_3O, R=2-pyridyl, 2-(3-methylpyridyl), 2-(4-methylpyridyl) and 2-(6-methylpyridyl), and M=Co(II), Ni(II), Cu(II), Zn(II) and Pd(II). It is concluded, mainly from the electronic absorption spectra, that the cobalt(II) complexes are tetrahedral, with one exception, which has an octahedral configuration with two water molecules coordinated to the cobalt(II) ion. The nickel(II) complexes are octahedral, and the copper(II) and the palladium(II) complexes are planar. In these metal complexes, the Schiff bases are bidentate, except bis(*N*-2-(6-methylpyridyl)-salicylideneiminato)nickel(II), in which the ligand functions as a terdentate.

Ligands represented by Formula I*[1] contain three atoms capable of coordinating to one metal ion, but the steric condition does not seem to be favorable for them to act as terdentate ligands. However, there still remains a possibility that these ligands behave as terdentate ligands, and it seems interesting to examine in what compounds this may, in fact, occur. The present work concerns the preparation of Schiff base complexes with some transition metal ions and examination of their structure in relation to the coordination mode of these ligands.



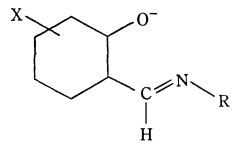
Formula I

1) Presented, in part, at the 18th Symposium on Coordination Chemistry, Kyoto, October, 1968.

*[1] Abbreviated as X-SAL·2-Py for Y=H and as X-SAL·CH_3-Py for Y=CH_3.

Experimental

Materials. Schiff base metal complexes newly prepared in the present work are shown in Tables 1, 2 and 3. The cobalt(II) complexes with the ligands



Formula II

represented by Formula II*[2] were prepared as previously reported,[2,3] either from cobalt(II) acetate tetrahydrate, substituted salicylaldehydes and amines, or from bis-(substituted salicylaldehydato)cobalt(II) and amines. One of the typical methods is given below for Co-(H-SAL·2-Py)$_2$ as an example. To a solution of cobalt-(II) acetate tetrahydrate (0.005 mol) in ethanol (10 m*l*) was added a solution of a Schiff base (0.01 mol) in ethanol (10 m*l*). The reaction was continued at about 65°C for about one hour. When the solution was cooled, crude product of the complex separated out. The pure compound was obtained as red crystals by recrystallization of the crude product from such solvents as chloroform, acetone, ethanol and benzene.

Table 1. Analytical data of Co(X-SAL·2-Py)$_2$

* μ: magnetic moment in Bohr magneton at room temperature

The other cobalt(II) complexes were obtained in a similar way. Nickel(II), copper(II) and zinc(II) complexes given in Tables 2 and 3, were prepared by methods similar to those for the cobalt(II) complexes described above. Some of the cobalt(II) and nickel(II) complexes were obtained as dihydrate, which may be recrystallized from benzene or chloroform without decomposition.

Table 2. Analytical data of M(X-SAL·2-Py)$_2$

M	X	Calcd %			Found %		
		C	H	N	C	H	N
Cu*	H	62.94	3.96	12.23	63.31	3.77	12.11
	5,6-Benzo	68.87	3.97	10.04	68.49	3.73	9.70
	3-CH_3O	60.30	4.09	11.21	60.28	4.29	10.82

	5,6-Benzo	63.92	3.69	9.32	62.94	3.42	9.86

* The Cu(II) complexes are brown or dark-brown.
** The Zn(II) and the Pd(II) complexes are orange.

Palladium(II) complexes given in Table 2, were prepared by a method similar to that previously reported.[4]

All these complexes are insoluble in water, but soluble in methanol, ethanol, chloroform, dichloromethane and benzene, except Co(5-NO_2-SAL·2-Py)$_2$, which is almost insoluble in these organic solvents.

Measurements. The electronic absorption spectra of these complexes in solution and in the solid state were determined with a Shimadzu QR-50 and a Shimadzu MPS-50L spectrophotometer. In Tables 4 and 5 are listed only those data of the solution spectra, for which Beer's law was confirmed to hold.

The X-ray powder diagrams were obtained with a Toshiba ADX-103 diffractometer. The magnetic moments were determined at room temperature by the Gouy method using $CoHg(SCN)_4$ as a standard.

Results and Discussion

Cobalt(II) and Zinc(II) Complexes. The complexes of the type Co(X-SAL·2-py)$_2$ are paramagnetic with magnetic moments ranging from 4.17 to 4.50 B.M., the values which lie in the range expected for tetrahedral cobalt(II) complexes of a high-spin type. The octahedral cobalt(II) complexes with the related Schiff bases are known to have magnetic moments near 5.0 B.M.,[2] which are evidently larger than the values for the tetrahedral complexes.

The electronic absorption spectra of these cobalt-(II) complexes in the solid state and in non-donor solvents, as shown in Fig. 1 and Table 4, are typical

sh: shoulder

of the tetrahedral cobalt(II) complex and different from that of the octahedral complex.[2,5] It is, therefore, concluded that the complexes of the type, Co(X-SAL·2-Py)$_2$, are tetrahedral with a high-spin. It is to be noted that the spectrum of Co-H-SAL·2-Py)$_2$ is quite similar to that of Co(H-SAL·Ph)$_2$,*3 which was previously concluded to be tetrahedral.[2] The absorption band at about 8.1 kK with a small shoulder at about 11 kK may be assigned to the transition $^4T_1 \leftarrow {}^4A_2$. It is also found that the configuration of these cobalt(II) complexes is tetrahedral, irrespective of the nature of the substituent X.

In all these cobalt(II) complexes, the ligands X-SAL·2-Py are found to act as bidentate ligands and not as terdentate ligands, the nitrogen atom in the heterocyclic ring not being bound with the metal ion. It is considered that the steric condition is not favorable for these ligands to act as terdentate ligands.

For R=4-CH_3-Py and 6-CH_3-Py, complexes of the type Co(H-SAL·R)$_2$ were obtained. It is concluded, from the electronic spectra, that they are tetrahedral with a high-spin. On the contrary, for R=3-CH_3-Py, a similar method yielded Co(H-SAL·R)$_2$(H_2O)$_2$ instead of Co(H-SAL·R)$_2$. The electronic spectra, as shown in Table 5, indicate that this complex in the solid state and in non-donor solvents consists of octahedral cobalt(II) with the two water molecules bound to the cobalt(II) ion. The magnetic moment of 4.79 B. M. for this complex may be understood on the basis of the octahedral configuration, although the value seems to be a little too low.

The electronic spectra, as shown in Tables 4 and 5, and Fig. 1, also indicate that, when dissolved in pyridine, these cobalt(II) complexes exist as bis-(pyridine)-complexes Co(X-SAL·R)$_2$(*py*)$_2$, where *py* denotes a pyridine molecule. This behavior is similar to that with the corresponding complexes for R=phenyl and substituted phenyl groups.[2]

It is known that the complexes of the type Zn(X-SAL-R)$_2$, in general, take a similar configuration to that of the corresponding cobalt(II) complexes. It may be, therefore, reasonable to assume that the zinc(II) complexes prepared in the present work also take a tetrahedral configuration. This seems to agree with the finding that the X-ray powder diagram of Zn(H-SAL·2-Py)$_2$ is quite similar to that of Co(H-SAL·2-Py)$_2$, showing that these two complexes are isomorphous with each other.

Complexes of Nickel(II) and Other Metal Ions. For R=2-Py, all the methods, which have been applicable to the synthesis of complexes of the other ions, proved to be unsuccessful for isolating the nickel(II) complexes of the type Ni(X-SAL·2-Py)$_2$. Thus those methods only yielded crystals of nickel(II) complexes with a complicated composition.

For R=3-CH_3-Py and 4-CH_3-Py, the nickel(II) complexes of the type Ni(H-SAL·R)$_2$(H_2O)$_2$ were obtained. They are all of a high-spin type with a magnetic moment ranging between 3.10 and 3.17 B.M. The electronic absorption spectra indicate, as shown in Fig. 2 and Table 5, that these nickel(II) complexes are octahedral in the solid state and in non-doner solvents. It is most likely that the two water molecules are bound with the nickel(II) ion.

*3 The notation Ph represents a phenyl group.

5) S. Yamada, *Coordin. Chem. Rev.*, **2**, 83 (1967).

Heating these complexes at about 100°C for many hours gave rise to neither decomposition nor loss of the water molecules. This indicates that the linkage of the water moleculrs with the nickel(II) ion may be considerably strong.

For R=6-CH$_3$-Py the nickel(II) complex Ni(H-SAL·R)$_2$ was obtained. This complex is paramagnetic with a magnetic moment of 3.25 B.M., which corresponds to a moment expected for the nickel(II) complex of a high-spin type. The electronic spectra indicate, as shown in Fig. 2 and Table 5, that this nickel(II) complex is octahedral in the solid state and in non-doner solvents. Since Beer's law holds for this as well as the other complexes, the association of the planar molecules in solution may be excluded for this complex. The band maxima lie in much lower frequency regions than the mixima of the related nickel(II) complexes, as may be seen in Table 5. The low frequency of the d-d band maxima, together with the comparatively high magnetic moment, seems to indicate that the configuration of Ni(H-SAL·6-CH$_3$-Py)$_2$ may be considerably distorted from the regular octahedron. It is to be noted that the ligand in this complex functions as a terdentate ligand with the nitrogen atom in the heterocyclic ring coordinated to the nickel(II) ion. It is also concluded, from the electronic spectrum, that this nickel(II) complex, when dissolved in pyridine, forms an octahedral pyridine adduct Ni(N-SAL·6-CH$_3$-Py)$_2$-(py)$_2$ in which the ligand H-SAL·6-CH$_3$-Py acts as a bidentate ligand.

The palladium(II) ion is similar to the nickel(II) ion in the sense that both ions have a d^8 configuration. Difference between these two ions, however, is remarkable in some respects; the palladium(II) ion forms stable quadri-coordinated planar complexes with various ligands, and the tendency of the palladium(II) ion to take coordination number exceeding four is much lower than that of the nickel-(II) ion. In the present work, the complexes of the type Pd(X-SAL·2-Py)$_2$ were obtained. Since the complexes of the type Pd(X-SAL·R)$_2$ so far obtained are known to have a square-planar con-

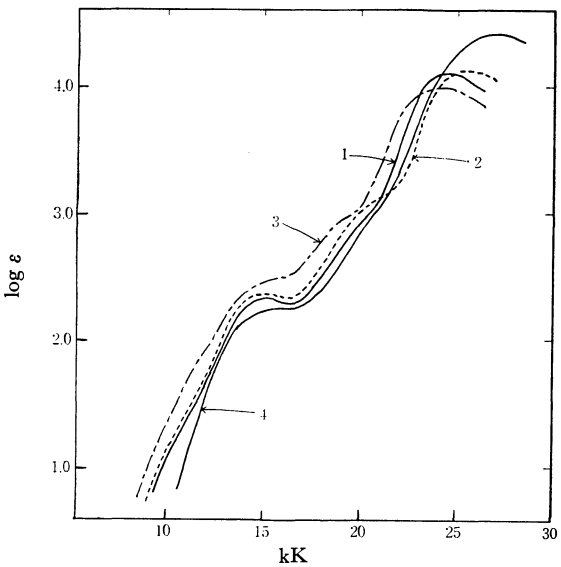

Fig. 3. Electronic absorption spectra of Cu(X-SAL·R)$_2$ in solution.
1 X=H, R=Ph, in chloroform

4 X=H, R=3-CH$_3$-Py, in dichloromethane

figuration for R=*n*-alkyl and aryl groups, it is most likely that the palladium(II) complexes may also be planar. In fact, the electronic spectrum of Pd(H-SAL·2-Py)$_2$ in solution is similar to that of Pd(H-SAL·Ph)$_2$ in solution, with a band at about 23.6 kK (log ε 3.8).

In contrast to the nickel(II) complexes, the copper(II) complexes of the type Cu(X-SAL·R)$_2$ were readily obtained as crystals. Since, for R=*n*-alkyl and aryl groups, the complexes of the type Cu(X-SAL·R)$_2$ so far obtained, in general, are known to take an essentially planar configuration,*4 it is expected that the copper(II) complexes obtained in the present work may also be planar. This seems to agree with the finding that the electronic absorption spectrum of Cu(H-SAL·2-Py)$_2$ is quite similar to that of Cu(H-SAL·Ph)$_2$, which was previously concluded to be planar, as shown in Fig. 3. The spectra of the other copper(II) complexes prepared in the present work are also found to be quite similar to the spectrum of Cu(H-SAL·2-Py)$_2$.

It is found that the ligands of the types X-SAL·2-Py and H-SAL·CH$_3$-Py function as bidentate ligands in the metal complexes prepared in the present work, with the exception of one nickel(II) complex, in which the ligand might act as a terdentate ligand. The steric condition does not seem to be favorable for these ligands to function as terdentate ligands, since in this case there should be formed the unstable four-membered ring containing the metal ion and the nitrogen atom in the pyridine ring. In this connection, it is interesting to note that for R=(2-pyridyl)-methyl Oehmke and Bailar[6] obtained a compound of a formula Ni(H-SAL·R)$_2$, in which the nickel(II) ion has coordination number six. The steric condition is obviously favorable for this ligand to act as a terdentate ligand.

Support of this work by the Ministry of Education is gratefully acknowledged.

*4 Some complexes are also known to form associated species in the solid state, yielding five-coordinated copper(II) complexes.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 2566—2570 (1969)

Reactions of Thiamine Disulfide Monosulfoxides with Mercaptans[1)]

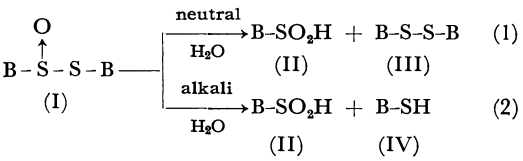
Goro Tsukamoto, Toshio Watanabe and Isamu Utsumi

Pharmaceutical Research Laboratory, Tanabe Seiyaku Co., Ltd., Kashima-cho, Higashiyodogawa-ku, Osaka

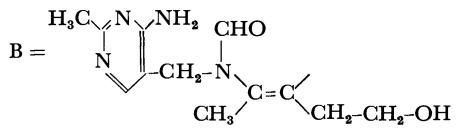
(Received September 16, 1968)

It was found that the reaction of thiamine disulfide monosulfoxide (I) with mercaptan is a competitive reaction between the so-called mercaptan-thiolsulfinate reaction and the apparent oxidation reduction reaction. This reaction offers an excellent method for the preparation of the mixed disulfides of thiamine and *t*-mercaptan or the unstable mixed disulfides, such as thiamine-glutathione disulfides.

In a previous paper,[2)] we showed that thiolsulfinate-type thiamine (I) gave 2-(2-methyl-4-amino-5-pyrimidyl)methylformamido-2-pentene-3-sulfinic acid (II, hereinafter called hypothiaminic acid) in alkaline or neutral hydrolysis as represented by



where



Yurugi *et al.* obtained thiamine butyl disulfide (VI, R=C_4H_7) in low yield on the oxidation of thiamine disulfide (III) in acetic acid with hydrogen peroxide, followed by reaction with butyl mercaptan in alkaline condition, and they suggested an intermediate in this reaction to be thiolsulfinate-type thiamine (I).[3)] In the meantime, we reported that

1) Part XXXII in a series on "Studies on Thiamine Disulfide."

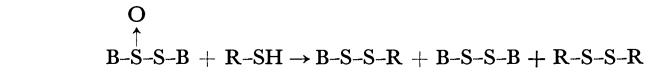
2) I. Utsumi, T. Watanabe, K. Harada and G. Tsukamoto, *Chem. Pharm. Bull.* (*Tokyo*), **15**, 1485 (1967).

3) S. Yurugi, H. Kawasaki and S. Noguchi, *Yakugaku Zasshi* (*J. Pharm. Soc. Japan*), **75**, 498 (1955).

the oxidation of III with hydrogen peroxide did not give the corresponding thiolsulfinate (I).[4,5] This result and the observation described in this paper suggest that thiamine butyl disulfide produced in Yurugi's experiment is formed not through thiolsulfinate (I) but through an other mechanistic route,[6] which will be reported in near future. In this paper, we would like to report the reaction of I with mercaptans.

Result and Discussion

When thiolsulfinate (I) is allowed to react with mercaptans as reported for the reaction of alkyl alkanethiolsulfinate with thiamine in thiol form (IV),[7] compound I is expected to produce the unsymmetrical disulfide-type thiamines (VI). In fact, compound I reacts smoothly and very rapidly with mercaptans at room temperature to give the unsymmetrical disulfides (VI) within a few minutes.



(I) (V) (VI) (III) (VII)

However, it was also found that symmetrical disulfides (III, VII) are concomitantly formed even under a stream of nitrogen.

It has been proposed that one mole of thiolsulfinate reacts with two moles of mercaptan to give two moles of unsymmetrical disulfide.[8] Whereas, Schöberl and Grafje, and Carson and Wong have suggested that a part of sulfenic acid, which is presumably formed in the reaction of thiolsulfinate with mercaptan, gives rise to disproportionation to give mercaptan and sulfinic acid.[9] If a similar reaction takes place in this case, the formation of hypothiaminic acid (II) and thiamine in thiol form (IV) would be observed.[2] However, these compounds (II, IV) can not be detected by paper electrophoresis[2] in the reaction solution.

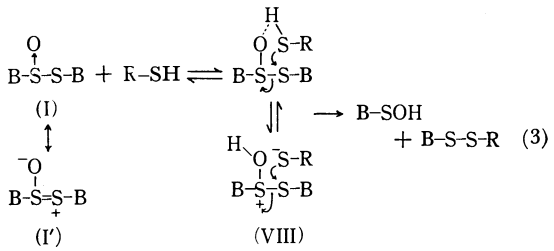
The product analyses were carried out in detail by means of paper partition and gas chromatography, and the formation of the following compounds were observed: (1) in the case of molar ratio, V/I=2, three compounds, *i. e.*, unsymmetrical disulfide (VI) and symmetrical disulfides (III, VII), (2) in the case of V/I <2, starting compound (I) in addition to these three compounds, (3) in the case of V/I $\gg 2$, thiamine (IV) and thiothiamine (3-(2-methyl-4-amino-5-pyrimidyl)methyl-4-methyl-5-β-hydroxyethylthiazoline-2-thione) as the secondary decomposed products.

The yield of thiamine propyl disulfide obtained from the reaction of I with propyl mercaptan in 80% ethanol are listed in Table 1.

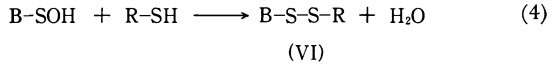
Table 1. Effect of amount of PrSH on yield of BSSPr

PrSH/I	1.0	1.2	1.4	1.6	1.8	2.0	2.1	3.0
Yield(%) of BSSPr	29	37	46	51	58	65	55	trace
PrSH(%) used in the formation of BSSPr	56	61	64	63	63	62	51	—

The reaction was carried out in 80% ethanol, and the main features of the reaction were the same even in absolute ethanol and acetic acid. Therefore, the predominant form of mercaptan should be undissociated acid which would either protonate or hydrogen-bond with sulfinate oxygen in the ground or transition state of the reaction, depending on the acidity of mercaptan.



(I) (I') (VIII)



(VI)

Both protonation and hydrogen bonding would make the sulfinyl group a better leaving group which would favor the nucleophilic attack of mercaptan on sulfenyl sulfur resulting in the formation of sulfenic acid and unsymmetrical disulfide.

The symmetrical disulfides (III, VII) were produced in the same ratio as indicated in Table 2. The production of III suggests the possibility that III might be formed through oxidation-reduction reaction between I and mercaptan in accordance with the previous report in which the thiolsulfinate (I) and its *O*-benzoyl ester (IX, OH in structure I is $OCOC_6H_5$) were proved to behave as an

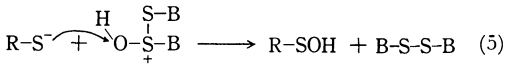
a) *t*-BuSSBu-*t* (yield: 5%) produced in this case was detected by gas chromatography (Retention time under the same condition as abvove: 3.8 min).

oxidizing reagent.[5,12]

In connection with the forgoing results, Tables 2 and 3 show that the mercaptans of higher acidity are oxidized more readily to the symmetrical disulfide (VII) than those of lower acidity, while the mercaptans of lower acidity yield a larger amount of unsymmetrical disulfide (VI) than the mercaptans of higher acidity. *O*-Benzoylthiamine disulfide monosulfoxide (IX) and thiamine benzyl disulfide monosulfoxide (ester of thiamine in thiol form (IV) and benzyl thiolsulfinic acid)[13] also showed similar reactivities to those of I.

The formation of the symmetrical disulfides (III, VII) would be dependent on the following reaction initiated by the attack of mercaptan to protonated oxygen. However, the attacking site of mercaptan is thought to be protonated oxygen and sulfinyl sulfur in the transition state (VIII). Namely, mercaptan attacks protonated oxygen to give symmetrical disulfides (III) and the corresponding sulfenic acid of the attacking mercaptan.

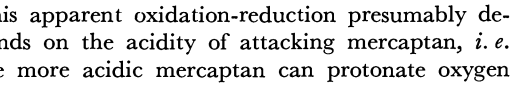


$$R\text{-}S^- + \overset{H}{\underset{+}{O}}\text{-}\overset{S\text{-}B}{\underset{+}{S}}\text{-}B \longrightarrow R\text{-}SOH + \underset{(III)}{B\text{-}S\text{-}S\text{-}B} \quad (5)$$

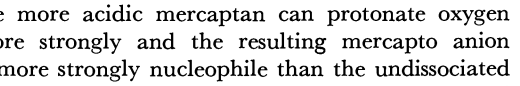
$$R\text{-}SOH + R\text{-}SH \longrightarrow \underset{(VII)}{R\text{-}S\text{-}S\text{-}R} + H_2O \quad (6)$$

This apparent oxidation-reduction presumably depends on the acidity of attacking mercaptan, *i. e.* the more acidic mercaptan can protonate oxygen more strongly and the resulting mercapto anion is more strongly nucleophile than the undissociated mercaptan. Similar trends have also been observed in the oxidation of mercaptan by sulfoxide to give disulfide, in which the order of reactivity of mercaptan is ArSH>$ArCH_2SH$>alkylSH.[14]

An important question remains as to the possible disproportionation reaction of the disulfides (VII, III) as follows:



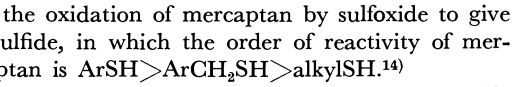
$$B\text{-}S\text{-}S\text{-}R + R\text{-}SH \longrightarrow B\text{-}SH + R\text{-}S\text{-}S\text{-}R \quad (7)$$



$$\overset{O}{\uparrow}\ B\text{-}S\text{-}S\text{-}B + B\text{-}SH \longrightarrow B\text{-}SOH + B\text{-}S\text{-}S\text{-}B \quad (8)$$

This must certainly be important when mercaptan is used more than two moles as indicated in Table 1.

Therefore, it can be concluded that the reaction of thiolsulfinate (I) with mercaptans is competitive reactions between the so-called mercaptan-thiolsulfinate reaction (Eq. (9)) and the apparent oxidation reduction (Eq. (10)).



$$\underset{(I)}{\overset{O}{\uparrow}\ B\text{-}S\text{-}S\text{-}B} + 2\ \underset{(V)}{R\text{-}SH} \begin{cases} \longrightarrow 2\ \underset{(VI)}{B\text{-}S\text{-}S\text{-}R} + H_2O & (9) \\ \longrightarrow \underset{(III)}{B\text{-}S\text{-}S\text{-}B} + \underset{(VII)}{R\text{-}S\text{-}S\text{-}R} + H_2O & (10) \end{cases}$$

It is of interest to note that these thiolsulfinate remained unchanged after four years at room temperatures. This pronounced stability which seems unusual for this type of compound would be due to the conjugation of $-S(O^-)=S^+-$ double bond with both sides of olefinic double bonds.

Up to the present time, a number of thiamine alkyl disulfides have been prepared by a variety of methods,[15] but hardly any are suitable for the preparation of the mixed disulfides of thiamine and *t*-mercaptan. In contrast, the reaction of I with *t*-mercaptan offers an excellent method for the preparation of the mixed disulfides.

Reduction of the mixed disulfides of thiamine and *t*-mercaptan by sulfhydryl compounds to

thiamine in thiol form proceeds with some difficulty in comparison with thiamine *n*-alkyl disulfides. This observation of biological interest will be reported elsewhere.

In addition to the preparation of the mixed disulfides, this reaction is also suitable for preparing unstable unsymmetrical thiamine disulfides such as thiamine-glutathione disulfide[16] and thiamine pyridylmethyl disulfide derivatives.[17]

Experimental

Melting points are not corrected. Infrared absorption spectra were measured with a Hitachi Infrared Spectrophotometer, EPI-S_2. Gas chromatographic analyses were carried out with a Shimadzu Model GC-1C.

Since thiamine disulfide (III), which was formed when thiolsulfinate (I) was allowed to react with mercaptans, could not be isolated quantitatively as crystals, it was measured as follows: Amounts of thiamine disulfide in the filtrates were determined by thiochrome method after the filtrates, from which unsymmetrical disulfides of thiamine (VII) were filtered off, were proved to contain only thiamine disulfide (III).

An Alternative Method for Preparation of Thiolsulfinates (I, VIII). The following procedure for the preparation of thiolsulfinates is favorable in comparison with that described previously.[5]

To a stirred solution of thiamine disulfide or its O-benzoyl ester (0.10 mol) dissolved in 2N H_2SO_4 (500 m*l*) was added peracetic acid (0.12 mol) under cooling with ice-water. The reaction mixture was allowed to stand overnight at room temperature. The adjustment of the reaction solution to pH 6—7 with Na_2CO_3 or $NaHCO_3$ gave the corresponding thiolsulfinates (I, IX), free from other oxidation product contaminants, as pale yellow crystals in satisfactory yield (80—85%).

Reaction of Thiolsulfinate (I) with Propyl and Butyl Mercaptans. *i) With Propyl Mercaptan.* To a suspension of I (580 mg) in 80% ethanol (10 m*l*) was added molar equivalent of propyl mercaptan (Table 1) with stirring under a stream of nitrogen at room temperature, and the mixture was allowed to stand for 10 min. The reaction solution, in which the mole ratio of the thiolsulfinate to the mercaptan was 1 : 1—1.8, was filtered and the filtrates were condensed under reduced pressure. The resulting residues to which water (5 m*l*) was added were allowed to stand for a day at room temperature to give colorless prisms in yields shown in Table 1. The crystals obtained were confirmed to be nearly pure by thin layer chromatography. Recrystallization of the crystals from benzene gave colorless prisms, mp 128—129°C, which were identical in infrared spectrum with the authentic thiamine propyl disulfide prepared by the known method.[6]

The reaction solutions, in which the mole ratio of the thiolsulfinate to the mercaptan was 1 : 2.0, 2.1, were similarly treated without having been filtered.

In a case where the mole ratio of the thiolsulfinate to the mercaptan was 1 : 3.0, a similar treatment of the reaction solution to the above-mentioned method afforded colorless needles (50 mg), mp 233—234°C (decomp.). Recrystallization from water gave colorless needles, mp 237—238°C (decomp.), which were identical in infrared spectrum with authentic 3-(2-methyl-4-amino-5-pyrimidyl)methyl-4-methyl-5-β-hydroxyethyl-thiazoline-2-thione. The mother liquor was condensed under reduced pressure to remove water and the resulting residue was dissolved in ethanolic HCl to afford colorless needles (560 mg), mp 246—247°C (decomp.), which were found to be identical with authentic thiamine hydrochloride by infrared spectrum.

ii) With n-Butyl Mercaptan. The procedure was the same as above. The reaction of I (580 mg) with *n*-butyl mercaptan (180 mg) gave 0.55 g (75%) of colorless prisms, mp 139—140°C. Recrystallization of the crystals from benzene gave colorless prisms, mp 135—136°C, which were found by infrared spectrum to be identical with authentic thiamine butyl disulfide prepared by the known method.[7]

iii) With s-Butyl Mercaptan. The procedure was the same as above except that the reaction time was 30 min. The reaction of I (580 mg) with *s*-butyl mercaptan (180 mg) yielded 640 mg (86%) of colorless prisms, mp 121—123°C. Recrystallization of the crystals from ethyl acetate gave thiamine *s*-butyl disulfide as colorless prisms, mp 121—123°C.

Found: C, 47.44; H, 6.73; N, 13.75%. Calcd for $C_{16}H_{27}O_2N_4S_2Cl$: C, 47.22; H, 6.69; N, 13.77%.

iv) With t-Butyl Mercaptan. The procedure was the same as above except that the reaction time was 1 hr. The reaction of I (580 mg) with *t*-butyl mercaptan (180 mg) gave 660 mg (90%) of colorless prisms, mp 151—152°C. Recrystallization from ethyl acetate gave thiamine *t*-butyl disulfide as colorless prisms, mp 151—152°C.

Found: C, 51.84; H, 7.06; N, 15.09; S, 16.79%. Calcd for $C_{16}H_{26}O_2N_4S_2$: C, 51.88; H, 7.08; N, 15.13; S, 17.28%.

IR ν_{max}^{Nujol} cm^{-1}: 3310, 3150, 1670, 1060.

Hydrochloride: Colorless needles (ethanol-ether), mp 182—184°C.

Found: C, 47.48; H, 6.80; N, 13.87%. Calcd for $C_{16}H_{27}O_2N_4S_2Cl$: C, 47.22; H, 6.69; N, 13.77%.

Reaction of Thiamine Benzyl Disulfide Monosulfoxide with Trityl Mercaptan. To a solution of thiamine benzyl disulfide monosulfoxide (420 mg) in 80% ethanol (10 m*l*) was added trityl mercaptan (550 mg) and the mixture was stirred at 50°C for 30 min. After the reaction, the reaction solution, in which oily precipitate separated, was condensed to dryness under reduced pressure and the resulting residue which was washed with petroleum ether was crystallized from ethanol to give crystals, 400 mg, mp 171—173°C. Recrystallization from ethanol gave thiamine trityl disulfide as colorless prisms, mp 171—173°C.

Found: C, 67.15; H, 5.93; N, 10.13; S, 11.40%. Calcd for $C_{31}H_{32}O_2N_4S_2$: C, 66.88; H, 5.79; N, 10.06; S, 11.52%.

IR ν_{max}^{Nujol} cm^{-1}: 3275, 3175, 1660, 1065, 730, 700.

This compound was found by infrared spectrum to be identical with authentic thiamine trityl disulfide prepared by the reaction of I with trityl mercaptan.

Reaction of I with Benzyl Mercaptan. To a stirred suspension of I (580 mg) in 80% ethanol (10 m*l*) was added benzyl mercaptan (248 mg) in nitrogen at room temperature, and a clear solution was immediately obtained. The reaction solution was condensed under reduced pressure. Water (5 m*l*) was added to the resulting residue and left to stand for a day to give crystals, 570 mg. After the crystals were dried under reduced pressure, they were washed with ether to give crystals, 470 mg (58%). Recrystallization from ethyl acetate gave 450 mg of thiamine benzyl disulfide as colorless prisms, mp 152°C, which were found to be identical with authentic samples by infrared spectrum.

Evaporation of the washed ether solution gave crystals, 100 mg (41%), mp 71—72°C, undepressed on admixture with authentic dibenzyl disulfide.

Reaction of I with Phenyl Mercaptan. The reaction between I (580 mg) and phenyl mercaptan (220 mg) was carried out with a similar procedure to that described in the reaction of I with benzyl mercaptan.

Ethanol as solvent of the reaction mixture was removed under reduced pressure and to the resulting residue was added water (5 m*l*) to separate crystals, which were extracted with chloroform. The chloroform solution was dried over sodium sulfate and chromatographed over alumina (10 g). The column was eluted with chloroform-ethanol (99 : 1) tracing with Dragendorff's reagent. The first fraction which is negative toward the reagent was condensed to dryness under reduced pressure to yield crystals (178 mg, 80%), mp 61—62°C, which were found to be identical with authentic diphenyl disulfide by infrared spectrum. The second fraction which is positive toward the reagent was treated similarly. The residue thus obtained was crystallized from benzene to yield colorless crystals (115 mg, 15%), mp 137°C (decomp.), which were found to be identical with authentic thiamine phenyl disulfide by infrared spectrum.

Reaction of I with *p*-Nitrophenyl Mercaptan. To a stirred suspension of I (580 mg) in 80% ethanol (10 m*l*) was added *p*-nitrophenyl mercaptan (310 mg). Separated colorless needles, 300 mg, mp 181—182°C, were filtered. Recrystallization from ethanol gave colorless needles, mp 182°C, which were found to be identical with authentic di-*p*-nitrophenyl disulfide by infrared spectrum.

The mother liquor from which di-*p*-nitrophenyl disulfide was filtered off was submitted to paper partition chromatography, which showed two spots, one R_f 0.37 assignable to thiamine disulfide and the other R_f 0.72 presumed to be thiamine *p*-nitrophenyl disulfide.

The authors are indebted to Professor S. Oae and Assistant Professor W. Tagaki of Osaka City University for their valuable discussions and their kindness to read the manuscript.

Alkoxysilanes. III. Preparation of Alkoxysiloxyaminosilane and Some of Its Reactions

Yoshimoto ABE and Ichiro KIJIMA

Department of Industrial Chemistry, Faculty of Engineering, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo

(Received September 19, 1968)

Bis(tri-*t*-butoxysiloxy)diaminosilane was prepared by the reaction of the corresponding dichlorosilane with ammonia. It was also obtained by the reaction of silicon tetrachloride with tri-*t*-butoxysilanol in the presence of pyridine as a dehydrochloric acid agent, followed by the subsequent reaction of the mixture with ammonia. The alcoholysis, transamination reaction, hydrolysis, and acetolysis of this compound with *n*-butyl alcohol, phenol, aniline, *n*-butylamine, water, and acetic acid led to the formation of the corresponding bis(tri-*t*-butoxysiloxy)silane derivatives. In these reactions, the measurement of the ammonia evolved made it possible examine the relative reactivity of the reactants. An attempt to isolate the triaminosilane by the reaction of tri-*t*-butoxysiloxytrichlorosilane with ammonia resulted in the formation of tetraaminocyclotetrasilazane and a polymeric substance containing the silicon-nitrogen bond.

It has been previously established that the hydroxy or amino group attached to the silicon atom in alkoxy or alkylsilanes is apt to be susceptible to condensation to form a siloxane or silazane bond,[1] but these groups are stabilized in the silicon com-

1) P. Fessenden and J. S. Fessenden, *Chem. Revs.*, **61**, 316 (1961).

pounds containing two or three secondary or tertiary alkyl groups.[2,3]

We have reported that the hydroxy group can be stabilized remarkably by introducing the tributoxysiloxy group into silicon compounds; thus silanediol and even-triol can be obtained.[4] Therefore, it was also expected that the introduction of this substituent into silicon compounds would stabilize the amino groups and permit the isolation of di- or triaminosilane with tributoxysiloxy groups.

In the present work, the preparation of the aminosilanes and its reactions with alcohols, amines water, and acetic acid were investigated.

Results and Discussion

Bis(tri-*t*-butoxysiloxy)diaminosilane was prepared in about an 80% yield by the reaction of bis(tri-*t*-butoxysiloxy)dichlorosilane with ammonia. The same compound was also obtained in about a 65% yield by the reaction of silicon tetrachloride with tri-*t*-butoxysilanol in the presence of pyridine, followed by treatment of the reaction mixture with ammonia;

$$[(Bu^tO)_3SiO]_2SiCl_2 \xrightarrow{NH_3} [(Bu^tO)_3SiO]_2Si(NH_2)_2$$

$$SiCl_4 + 2(Bu^tO)_3SiOH + 2C_5H_5N \xrightarrow{NH_3} [(Bu^tO)_3SiO]_2Si(NH_2)_2 + 2C_5H_5NHCl$$

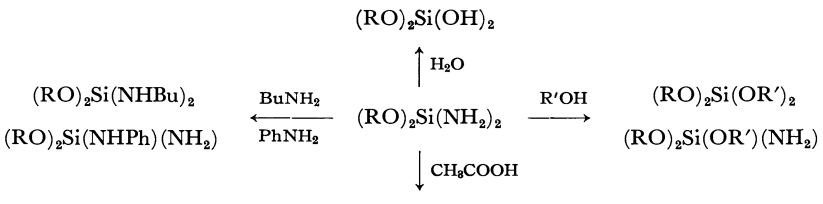
It could be distilled as a white crystalline solid without condensation, and it had a low melting point (55—57°C) and a high solubility in common organic solvents.

The diaminosilane reacted easily with water and acetic acid to give the corresponding silanediol and diacetoxysilane. However, alcoholysis and transamination reaction appear to occur step by step, for the reaction of the diaminosilane with phenol and *n*-butyl alcohol afforded only monobutoxy and monophenoxy derivatives when *n*-hexane was used as a solvent, whereas diphenoxy and dibutoxy derivatives were obtained by the reaction at the boiling point of each reactant. Similar results were obtained from transamination; the reaction of the diaminosilane with *n*-butylamine and aniline under the reflux of each reactant gave di-*n*-butylaminosilane and monoanilinosilane, but the further replacement of the amino group by aniline was difficult under the present conditions (Scheme 1).

Results similar to our findings that alcoholysis takes place step by step had been reported by Miner *et al.*,[2] who investigated the reaction of di-*t*-butoxydiaminosilane with alcohols and suggested that the reaction depends on the steric effect of the alkyl group of the alcohol. Therefore, the formation of mono-substituted derivatives when *n*-hexane is used as the solvent seems attributable to the steric effect of the *n*-butyl or phenyl group. Figure 1 shows the relative rates of transamination and alcoholysis determined by measuring the ammount of ammonia evolved. Apparently the reaction rate of *n*-butyl amine is faster than that of aniline, but the readiness of alcoholysis is not always in the phenol $>$ *n*-butyl alcohol order since the reaction temperatures are not taken into consideration.

In order to obtain tri-*t*-butoxysiloxytriaminosilane, the reaction of the corresponding trichlorosilane with ammonia was carried out. This reaction afforded, instead of the desired compound, a cyclosilazane containing a free amino group, which was identified as tetraaminotetra(tri-*t*-butoxysiloxy)cyclotetrasilazane $[(Bu^tO)_3SiOSi(NH_2)(NH)]_4$. Identification was made on the basis of the evidence from elemental analysis, the molecular-weight determination, and the infrared absorption peaks at 3450 and 3350 (ν_{NH}), 1530 (δ_{NH_2}), 1050 ($\nu_{Si-O-Si}$), and 950 ($\nu_{Si-N-Si}$) cm^{-1}.

In general, the reaction between trichlorosilane and ammonia leads to the formation of silsesquiazene;[5] nevertheless, in this case the cyclosilazane containing free amino groups was obtained.



where R=$(BuO)_3Si$ and R'=Bu or Ph

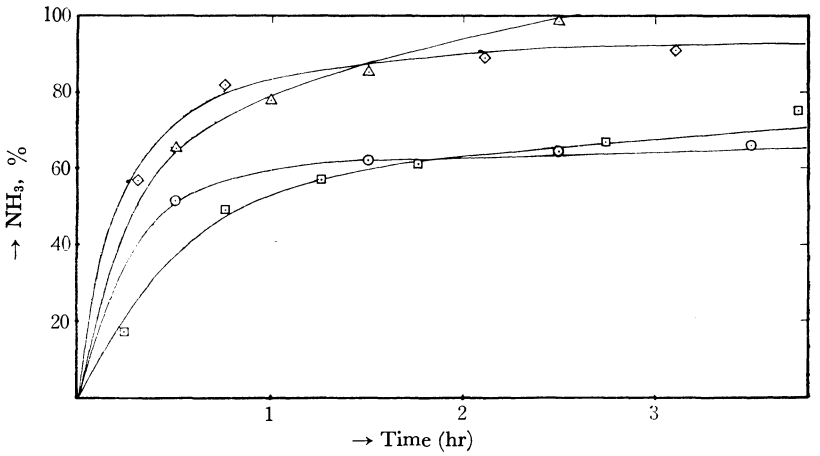

Fig. 1. The relative rate of the reaction of diaminosilane with *n*-butyl alcohol (⊡), aniline (⊙), phenol (◇), and *n*-butylamine (△). Reaction temperature, boilling points of reagents

This unexpected result is probably due to the large steric effect of tri-*t*-butoxysiloxy groups.[6,7]

In the couse of the distillation of the cyclosilazane, a solid was obtained as a residue; it was then purified to give a white powder (mp 240—243°C). Its IR spectrum was essentially identical with that of the cyclosilazane except for the absence of the absorption peaks at 1354 and 860 cm^{-1}. This product seems, therefore, to be a polymer formed by the condensation of the amino group in the cyclosilazane.

Experimental

All the experiments were carried out in a dry atmosphere or nitrogen. The melting points and boilling points were uncorrected.

Materials. The alcohols and amines were dried on calcium oxide or sodium hydroxide and were purified by distillation. The acetic acid was purified by fractional distillation. Bis(tri-*t*-butoxysiloxy)dichlorosilane and tri-*t*-butoxysiloxytrichlorosilane were prepared by a method previously described.[4]

Preparation of Bis(tri-*t*-butoxysiloxy)diaminosilane. To a solution of bis(tri-*t*-butoxysiloxy)dichlorosilane (28 g) in 200 m*l* of benzene, dry ammonia gas was introduced at 0—5°C with stirring. After the completion of the absorption of the ammonia, the mixture was refluxed for 1 hr. This treatment was repeated, and then the ammonium hydrochloride was filtered out and washed with benzene. The solvent was reomved, and the residue was distilled under reduced pressure to give 20 g of a crystalline solid (76.5%), bp 150°C/1 mmHg, mp 55—57°C. Found: C, 49.11; H, 9.96; N, 4.48; Si, 14.32%. Calcd for $C_{24}H_{58}O_8N_2Si_3$: C, 48.48; H, 10.40; N, 4.77; Si, 14.36%.

The preparation of the diaminosilane from silicon tetrachloride and tri-*t*-butoxysilanol proceeded in the following way: to a mixture of 74.6 g (0.283 mol) of silanol, 22.4 g (0.283 mol) of pyridine, and 400 m*l* of benzene, 23.8 g (0.141 mol) of silicon tetrachloride in 100 m*l* were stirred in, drop by drop, at about 0°C. The mixture was refluxed for 1 hr. Then the combined solution was cooled at about 0°C and ammonia gas was introduced. The distillation of the filtrate gave 53.8 g (64.0%) of the diaminosilane, 154°C/1 mmHg. IR: 3400 and 3350 (doublet, w, ν_{NH}), 1535 (m, δ_{NH_2}), 1385 and 1362 (doublet, *t*-butyl group), 1065 (s, $\nu_{Si-O-Si}$) cm^{-1}.

The Reaction of Diaminosilane with *n*-Butyl Alcohol. A solution of 3.4 g of *n*-butyl alcohol in 20 m*l* of *n*-hexane was added to a solution containing 15.2 g of diaminosilane. The mixture was refluxed for 1.5 hr with stirring, and the ammonia thus evolved

was trapped by introducing it into a sulfuric acid solution. The ratio of the recovery of ammonia was 47.4%. The removal of the solvent, followed by fractional distillation *in vacuo*, gave 14.6 g (88.1%) of a liquid; bp 156—157°C/0.6 mmHg, n_D^{20} 1.4125. Found: N, 2.07; Si, 12.93%. Calcd for $C_{28}H_{65}O_9NSi_3$: N, 2.17; Si, 13.00%. IR: 3400 and 3350 (doublet, w, ν_{NH}), 1530 (w, δ_{NH_2}) cm^{-1}.

Dibutoxy derivatives were obtained when the above reaction was carried out without any solvent; the diaminosilane (10.5 g) was heated with *n*-butyl alcohol (4.5 g) at 140—150°C for 10 hr under stirring (93%, ammonia evolved). The reaction mixture, on fractionation, gave 9.9 g (79.0%) of a pale yellow solid; bp 164—165°C/1 mmHg, mp 38—40°C (recrystallized with acetone). Found: C, 54.49; H, 11.22; Si, 12.03%. Calcd for $C_{32}H_{72}O_{10}Si_3$: C, 54.82; H, 10.30; Si, 11.87%. NMR: 8.71 (singlet, Bu^t), 6.32 (triplet, CH_2), 9.10 (doublet, CH_3) τ.

The Reaction of Diaminosilane with Phenol. To a solution of 13.4 g of diaminosilane in 50 m*l* of *n*-hexane, a solution of 4.4 g of phenol in 20 m*l* of *n*-hexane was added. The combined solution was then refluxed for 1.5 hr with stirring (45.6%, ammonia evolved). After the solvent had been removed, the residue was fractionated to give 9.9 g of a viscous liquid (75.7%); bp 182—183°C/1 mmHg, n_D^{20} 1.4361. Found: N, 1.74; Si, 12.78%. Calcd for $C_{30}H_{61}O_9NSi_3$: N, 2.16; Si, 12.80%.

The reaction was carried out without any solvent to obtain a diphenoxy derivative; a mixture of 16.0 g of diaminosilane and 7.7 g of phenol was heated at 170—180°C for 3.5 hr with stirring (94.0%, ammonia evolved). The residue was submitted to fractional distillation; this gave 15.6 g of a pale yellow solid (77.6%), bp 230—231°C/1 mmHg, mp 74—76°C (recrystallized with petroleum ether). Found: C, 57.10; H, 9.02; Si, 11.17%. IR: 1595, 1490, and 750 (m, phenyl group) cm^{-1}. NMR: 8.74 (singlet, Bu^t), 2.94 (single, phenyl protons) τ.

Hydrolysis of Diaminosilane. To 150 m*l* of a sulfuric acid solution (5%), 17.0 g of diaminosilane in 50 m*l* of *n*-hexane were added, drop by drop, at 7—8°C with agitation. The oily layer was separated, washed with a sodium bicarbonate solution and then water, and dried over anhydrous sodium sulfate. After the removal of the solvent, the residue was distilled *in vacuo*, giving 13.0 g (76.0%) of a white solid, bis(tri-*t*-butoxysiloxy)silanediol,[4] bp 154—155°C/1 mmHg.

The Reaction of Diaminosilane with Acetic Acid. Into a solution of 16.2 g of diaminosilane in 100 m*l* of *n*-hexane, a solution of 6.7 g of acetic acid in 50 m*l* of *n*-hexane was stirred, drop by drop, at 5—10°C for 45 min. The mixture was further stirred at room temperature for 1.5 hr, and then the ammonium acetate was filtered out. The removal of the solvent from the filtrate gave a solid, which was then dissolved into 20 m*l* of *n*-hexane. A white crystal was obtained from the solution when it was left standing under cooling; yield, 13.3 g (71.5%), mp 57—62°C. Found: C, 49.73; H, 9.29; Si, 12.30%. Calcd for $C_{28}H_{60}O_{12}Si_3$: C, 49.97; H, 8.98; Si, 12.52%. IR: 1734 (s, calbonyl group) cm^{-1}. NMR: 8.70 (Bu^t), 9.79 ($OCOCH_3$) τ.

Transamination Reaction of Diaminosilane with Aniline. A mixture of diaminosilane (13.7 g) and aniline (8.7 g) was heated at 140—150°C for 2.5 hr under stirring (54.5%, ammonia evolved). After the removal of the excess aniline, the mixture was distilled under reduced pressure, giving 13.0 g (80.7%) of a pale yellow liquid, bp 190.5°C/0.5 mmHg. The product partially solidified at room temperature. Found: C, 54.60; H, 10.10; N, 4.09; Si, 12.54%. Calcd for $C_{30}H_{62}O_8N_2Si_3$: C, 54.35; H, 9.42; N, 4.32; Si, 12.72%. IR: 3450 and 3350 (doublet, w, ν_{NH}), 1530 (w, δ_{NH_2}), 1487, 1590, and 750 (m, phenyl group) cm^{-1}. NMR: 8.66 (Bu^t), 5.75 (NHPh), 3.13 and 3.16 (doublet, phenyl protone) τ.

Transamination Reaction of Diaminosilane with *n*-Butylamine. A mixture of 6.5 g of *n*-butylamine and 13.1 g of diaminosilane was refluxed for 2.5 hr with stirring. The mixture was fractionally distilled under reduced pressure, giving 9.2 g (65.0%) of a pale yellow liquid, which solidified at room temperature; bp 192—193°C/0.5 mmHg, n_D^{20} 1.4217. Found: C, 54.45; H, 10.99; N, 3.73; Si, 11.86%. Calcd for $C_{32}H_{74}O_8N_2Si_3$: C, 54.97; H, 10.66; N, 4.01; Si, 11.86%. IR: 3350 (w, ν_{NH}) cm^{-1}. NMR: 9.12 (doublet, CH_3), 8.72 (Bu^t), 7.22 (quartet, CH_2) τ.

The Reaction of Tri-*t*-butoxysiloxytrichlorosilane with Ammonia. To a solution of 22.6 g of tri-*t*-butoxysiloxytrichlorosilane in 300 m*l* of dry ethyl ether, dry ammonia gas was introduced at −5 to −10°C for about 1 hr with agitation. After the absorption of ammonia had ceased, the mixture was stirred for 30 min at room temperature. After the above treatment had been repeated, ammonium hydrochloride was filtered out and the product washed with ehter. The evaporation of the solvent *in vacuo* gave a transparent, colorless, viscous liquid (14.3 g). This residue was submitted to analysis without further purification. Found: C, 44.47; H, 9.81; N, 8.36; Si, 17.30%, mol wt 1190, n_D^{20} 1.4270. Calcd for $(C_{12}H_{15}O_4N_2Si_2)_n$: C, 44.86; H, 9.39; N, 8.69; Si, 17.41%, mol wt 1289 (n=4).

This residue (7.9 g) was distilled *in vacuo* to give a transparent, highly viscous liquid (4.0 g); bp 220—222°C/0.5 mmHg, n_D^{20} 1.4250. Found: C, 44.58; H, 9.91; N, 7.68; Si, 17.30%, mol wt 1280. IR: 3450 and 3350 (doublet, m, ν_{NH}), 1530 (m, δ_{NH_2}), 1050 (vs, $\nu_{Si-O-Si}$), 950 (s, $\nu_{Si-N-Si}$) cm^{-1}.

After the distillation of the above product, 3.0 g of a white solid remained as a residue. The solid was further purified by the following procedure: to 50 m*l* of vigorously-stirred methanol, 3.0 g of the solid dissolved in 10 m*l* of benzene was added, drop by drop; then the precipitate was filtered and dried *in vacuo*, giving 2.6 g of a white powder, mp 240—243°C. Found: C, 43.02; H, 9.17; N, 6.07; Si, 19.90%. IR: 3450 and 3350 (w, ν_{NH}), 1050 (vs, $\nu_{Si-O-Si}$), 950 (s, $\nu_{Si-N-Si}$) cm^{-1}.

The authors wish to thank Professor Yojiro Tsuzuki for his helpful advice, and Mr. Takeo Takeuchi for his assistance in the experiments. Acknowledgement is also made to the Ministry of Education for its financial support.

Metal-Containing Initiator Systems. XVI. Radical Polymerization with Metal Carboxylates

Shuzo Aoki, Seitaro Matsumura and Takayuki Otsu

Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sugimoto-cho, Sumiyoshi-ku, Osaka

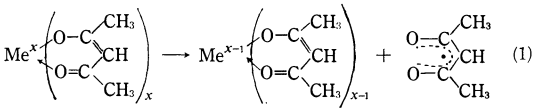
(Received October 3, 1968)

The polymerization of vinyl monomers with metal carboxylates has been investigated in benzene at 60°C. Cobalt(III) cyclohexanecarboxylate behaved as an effective initiator of the polymerization, and its activity was higher than that of corresponding salts of manganese (III) and copper(II), and than that of cobalt(III) acetylacetonate in the polymerizations of styrene (St) and methyl methacrylate (MMA). It was found that the overall rate of polymeriaztion (R_p) of MMA with cobalt(III) cyclohexanecarboxylate was expressed by the following equation, indicating that the polymerization proceeded through a free redical intermediate:

$$R_p = k[\mathrm{MMA}]^{1.4}[\mathrm{Co(III)}]^{0.5}$$

The free radical propagation of this polymerization was also supported by the results of the copolymerizations of St with MMA and with vinyl acetate; *i.e.*, the resulting copolymer composition curves agreed with the typical free radical ones. It was assumed that the initiation of polymerization occurred by means of a radical produced by the homolysis of the metal-oxygen bond in the carboxylate. The reaction order with respect to MMA in the above equation, which was higher than unity, suggested the participation of the MMA molecule in initiating the radical formation.

It is well known that some metal acetylacetonates can act as free radical initiators of vinyl polymerization. The initiation of polymerization has been considered to take place with a ligand radical resulting from the homolysis of the metal-oxygen bonds in metal acetylacetonates (Eq. (1)).[1-3]



(1)

In previous papers,[3-5] the initiation of vinyl polymerizations by various metal acetylacetonates and copper(II) ethyl acetoacetate was investigated, and it was suggested that it occurs *via* the participation of the monomer used.

It can be predicted that certain metal carboxylates which consist of a similar structure of metal acetylacetonates may serve in a similar manner to initiate the vinyl polymerization. Indeed, lead tetraacetate[6] and ferric laurate[7] have been found to initiate the polymerization of methyl methacrylate (MMA).

The present paper will describe the polymerization of vinyl monomers with metal cyclohexanecarboxylates, especially that of MMA with cobalt(III) cyclohexanecarboxylate.

Experimental

Materials. The monomers and the solvents were purified by ordinary methods and were redistilled before use.

Copper(II) cyclohexanecarboxylate was prepared by the reaction of sodium cyclohexanecarboxylate with copper sulfate. Cobalt(III) cyclohexanecarboxylate was obtained through the reaction of sodium cyclohexanecarboxylate with cobalt sulfate in the presence of hydrogen peroxide, much as in the preparation of cobalt(III) acetylacetonate.[8] Manganese(III) cyclohexanecarboxylate was also prepared according to the method used for the preparation of manganese(III) acetylacetonate;[9] *i.e.*, sodium cyclohexanecarboxylate was reacted with manganese chloride in the presence of potassium permanganate. All of the metal cyclohexanecarboxylates

obtained were thoroughly washed with water; they were then dried in a vacuum desiccator:

$Cu(OCOC_6H_{11})_2$; light blue powder, Cu (calcd) 20.0%, Cu (found) 20.7%.

$Co(OCOC_6H_{11})_3$; dark green powder, Co (calcd) 13.4%, Co (found) 13.8%.

$Mn(OCOC_6H_{11})_3$; dark brown powder, Mn (calcd) 12.6%, Mn (found) 13.3%.

Analytical-grade cobalt(III) acetylacetonate was used without further purification. Azobisisobutyronitrile was recrystallized from ethanol.

Polymerization. The polymerization was carried out in a sealed glass tube without diffused light in a thermostat maintained at given temperatures. The resulting polymer was isolated by pouring the polymerization mixture into a large amount of methanol.

The number-average molecular weight ($\bar{M}_n$) of the resulting polymers was determined from the intrinsic viscosity measurements in benzene at 30°C by using the following equations:[10]

$$[\eta] = 8.69 \times 10^{-5}\bar{M}_n^{0.76} \text{ for poly (MMA)}$$

$$[\eta] = 1.13 \times 10^{-4}\bar{M}_n^{0.73} \text{ for polystyrene}$$

Results and Discussion

Initiating Activity of Metal Cyclohexanecarboxylates. Styrene and MMA were polymerized by using copper(II), cobalt(III) and manganese(III) cyclohexanecarboxylates as initiators in bulk at 60°C. The results are shown in Table 1. Cobalt(III) cyclohexanecarboxylate was observed to show the highest initiating activity among these cyclohexanecarboxylates. For the MMA polymerization the activity decreased in the order: $Co^{III} > Mn^{III} > Cu^{II}$; this order agreed with that of the redox potential of the corresponding metal ions in aqueous solutions.[11]

Table 1. Bulk polymerizations of styrene and MMA with metal cyclohexanecarboxylates at 60°C

Carboxylate (1×10^{-2} mol/l)	Monomer	Time (hr)	Yield (%)	$\bar{M}_n\times10^{-5}$
Cu^{II}	Styrene	8	1.2	7.34
	MMA	5	trace	—
Co^{III}	Styrene	8	2.7	6.68
	MMA	2.5	6.6	8.55
Mn^{III}	Styrene	8	trace	—
	MMA	5	2.3	8.94

As can be seen from Table 2, the initiating activity of cobalt(III) cyclohexanecarboxylate was found to be higher than that of cobalt(III) acetylacetonate in the polymerizations of the vinyl monomers used. However, in the polymerization of butadiene, the initiating activity of cobalt(III) cyclohexanecarboxylate was very low.

Table 2. Bulk polymerizations of vinyl monomers with Co(III) cyclohexanecar boxylate and Co(III) acetylacetonate at 60°C

Monomer	Initiator	Time (hr)	Yield (%)
MMA	Carboxylate	5	11.0
	Acetylacetonate	5	2.2
Styrene	Carboxylate	5	1.9
	Acetylacetonate	5	1.0
Acrylonitrile[b]	Carboxylate	5	2.9
	Acetylacetonate	5	trace
Vinyl acetate	Carboxylate	2	2.0
	Acetylacetonate	2	trace
Butadiene[c]	Carboxylate	15	trace

a) Initiator 30 mg and monomer 10 ml were used.
b) Polymerized in 50 vol% benzene solution.
c) Polymerized in 70 vol% benzene solution using 100 mg of the carboxylate at 80°C.

Polymerization of MMA with Cobalt(III) Cyclohexanecarboxylate. The course of the MMA polymerization with cobalt(III) cyclohexanecarboxylate was investigated kinetically in bulk or in a benzene solution.

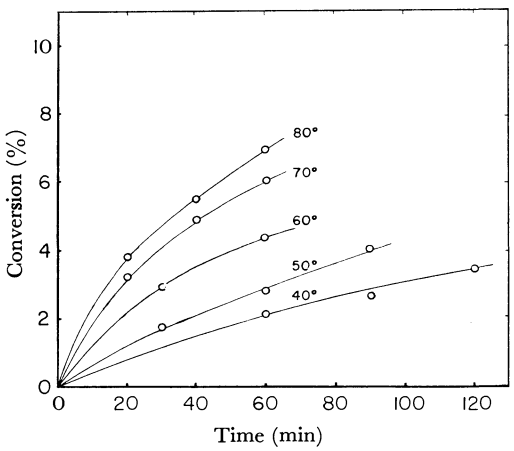

Fig. 1. Time-conversion curves in the bulk polymerization of MMA with cobalt(III) cyclohexanecarboxylate ([Co]=6.8×10^{-3} mol/l).

Figure 1 shows the time-conversion relations in the bulk polymerization of MMA at different temperatures. The linear relationship between the polymer yield and the time was not observed even at the initial stage of the polymerization, and the rate of polymerization decreased gradually with the time, much as in the MMA polymerization with lead tetraacetate.[6] Therefore, as a matter of convenience, the rate of polymerization was estimated approximately from the ratio of the polymer yield and the time at about a 5% polymer yield.

10) "Polymer Handbook," J. Brandrup and E. H. Immergut Ed., Interscience, New York (1966).
11) "Handbook of Chemistry," N. A. Lange Ed., McGraw-Hill, New York (1961).

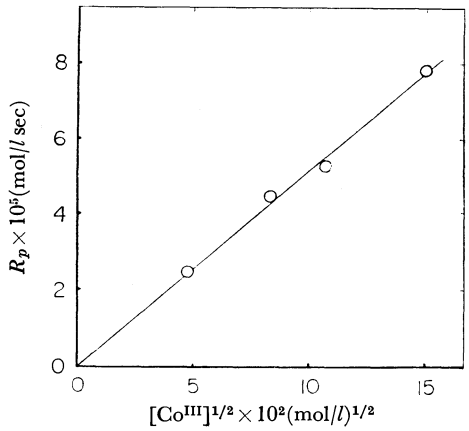

Fig. 2. Relationship between R_p and $[Co^{III}]^{1/2}$ at 60°C ([MMA]=4.7 mol/l in benzene).

Figure 2 shows the straight-line relationship between the rate of polymerization and the square-root concentration of the initiator at a constant MMA concentration in benzene at 60°C. Figure 3

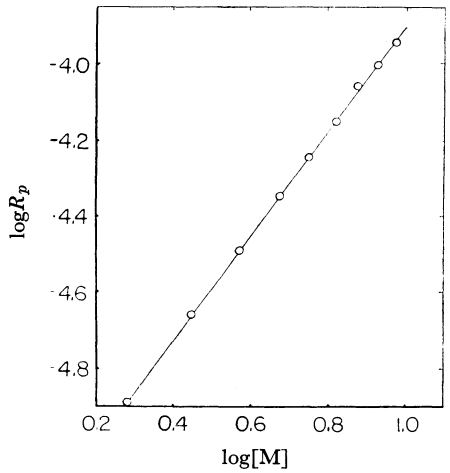

Fig. 3. Relationship between R_p and [MMA] in benzene at 60°C ($[Co^{III}]=6.8\times10^{-3}$ mol/l).

shows the log-log plot between the rate of polymerization and the monomer concentration at a constant initiator concentration in benzene at 60°C. From this figure, the kinetic order with respect to the MMA concentration was found to be 1.4.

Therefore, the overall rate of polymerization (R_p) of MMA with cobalt(III) cyclohexanecarboxylate was expressed by the following equation:

$$R_p = k[\text{MMA}]^{1.4}[\text{Co}]^{0.5} \quad (2)$$

The observed order with respect to the initiator concentration in Eq. (2) indicated that this polymerization proceeded through a free radical intermediate. The order of the MMA concentration, which was higher than unity, suggests that the MMA molecule participates in the radical formation from the cobalt(III) initiator.

The poly(MMA) obtained by using the metal cyclohexanecarboxylates showed the same infrared spectra as the typical radical polymer, indicating that there was no difference in stereoregularity between them.

Copolymerization of Styrene with MMA or Vinyl Acetate. Styrene (M_1) was copolymerized with MMA or vinyl acetate by using cobalt(III) cyclohexanecarboxylate as an initiator in bulk at 60°C. The monomer-copolymer composition curves obtained are shown in Fig. 4. From this figure

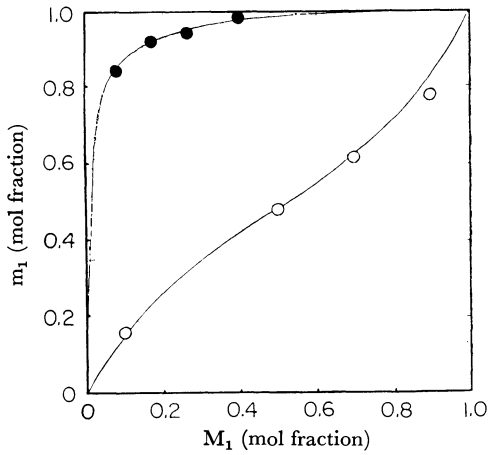

Fig. 4. Monomer-copolymer composition curves in the copolymerizations of styrene (M_1) with MMA (—○—) and with vinyl acetate (—●—) at 60°C.

the monomer reactivity ratios in these copolymerization systems were determined to be $r_1=0.40$ and $r_2=0.50$ for the styrene-MMA system, and $r_1=55$ and $r_2=0$ for the styrene-vinyl acetate system. These values were in accordance to those obtained by using peroxides and azo compounds as radical initiators,[10] indicating that this cobalt(III) initiator did not influence the propagation step of the radical polymerization.

Absorption Spectra of Cobalt(III) Cyclohexanecarboxylate. Cobalt(III) cyclohexanecarboxylate showed the characteristic absorption maximum at about 650 mμ based on the Co^{III} ion.

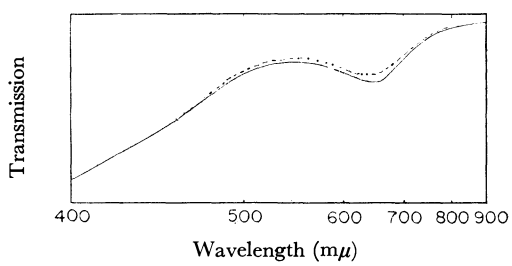

Fig. 5. Absorption spectra of cobalt (III) cyclohexanecarboxylate in benzene-MMA mixture (9 : 1). (——): Before heating, (-----): After heating

The intensity of this absorption peak did not change upon heating in benzene at 80°C for 18 hr. As can be seen from Fig. 5, however, it decreased slightly upon being heated in a benzene-MMA mixture. This result indicates that cobalt(III) cyclohexanecarboxylate does not decompose in benzene, much like cobalt(III) acetylacetonate,[12] but it decomposes in the presence of the MMA monomer.

Chain Transfer to Cobalt(III) Cyclohexanecarboxylate. Figure 6 shows the plot between the rate of the polymerization of MMA and the reciprocal degree of polymerization ($1/\bar{P}_n$) of the polymer obtained. Although this plot gave a straight line when azobisisobutyronitrile was used as an initiator, that obtained by using cobalt(III) cyclohexanecarboxylate showed a concave curve, indicating that considerable chain transfer to the cobalt(III) initiator occurred. According to the treatment by Tobolsky *et al.*,[13] the apparent chain transfer constant of this initiator toward the poly(MMA) was estimated to be 0.06.

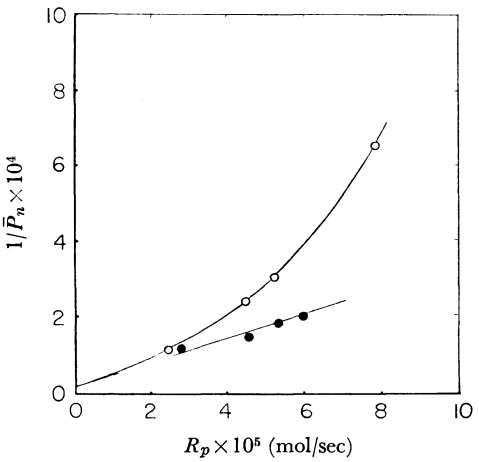

Fig. 6. $1/\bar{P}_n$ *vs.* R_p.
(—○—): Polymerized with cobalt(III) cyclohexanecarboxylate,
(—●—): Polymerized with azobisisobutyronitrile
(Polymerization conditions were the same with in Fig. 2.)

Conclusions

The following conclusions were derived from the results presented above: (i) cobalt(III) cyclohexanecarboxylate could serve as an effective free radical initiator of the MMA polymerization; (ii) this carboxylate did not influence the propagation step in the radical polymerization of MMA, and (iii) this carboxylate decomposed to produce the initiating radical species when the MMA monomer participated.

The initiation with cobalt(III) cyclohexanecarboxylate in the MMA polymerization might resemble that of metal acetylacetonates.[4,5] The polymerization was thought to be initiated with a radical produced by the homolysis of the metal-oxygen bond in metal carboxylate, with the participation of the MMA monomer, as follows:

$$Me^{x}\text{-}(\text{-O-}\overset{\overset{O}{\|}}{C}\text{-R})_x + M \rightarrow Me^{x-1}\text{-}(\text{-O-}\overset{\overset{O}{\|}}{C}\text{-R})_{x-1} + R\text{-}\overset{\overset{O}{\|}}{C}\text{-O-M}\cdot \text{ (or R-M}\cdot\text{)}$$

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 2578—2583 (1969)

Kinetic Features of the Redox-polymerization of Acrolein with the Potassium Persulfate - Silver Nitrate System

Tsutomu KAGIYA, Shigeru MORITA and Kenichi FUKUI

Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received November 4, 1968)

The polymerization of acrolein initiated by the potassium persulfate-silver nitrate redox system in water was studied at 0°C from the point of view of kinetics. The potassium persulfate concentration was varied over the range from 15.75 to 157.5 mmol/*l*, and that of the initial monomer, from 0.462 to 2.675 mol/*l*, while the concentration of silver nitrate was 31.5 mmol/*l*. Both the polymerization rate and the molecular weight of the polymer were found to increase with the reaction time in the early stage, while in the stage of higher conversion the polymerization rate was gradually reduced and the molecular weight remained constant. In the early stage of the polymerization, the polymer yield showed a first-order dependence on the potassium persulfate and initial monomer concentrations. The molecular weight of the polymer was proportional to the monomer concentration, independent of the catalyst concentration. From these results, the kinetic features were discussed.

Some detailed studies of the redox-polymerization with potassium persulfate-silver nitrate catalyst system have been reported, especially focused on the polymerization of a monomer such as acrolein[1] and methyl vinyl ketone.[2] Little attention, however, has been paid to the kinetic mechanism of these polymerizations. In order to make clear the mechanism of the redox-type polymerization, the acrolein polymerization with the potassium persulfate - silver nitrate system was studied. The purpose of this report is to describe the characteristic features of this polymerization.

Experimental

Materials. Commercial acrolein was distilled under nitrogen, using a 50-cm column, immediately before use; boiling point, 52.5°C/760 mmHg. Commercial potassium persulfate and silver nitrate (G. R. Grade) were used without purification. The water was purified through ion-exchange resin.

Polymerization Procedure. Definite amounts of potassium persulfate and water were placed into a glass ampoule; then, after cooling to 0°C, acrolein and an aqueous solution of silver nitrate were added to this system under a nitrogen atmosphere. The ampoule was sealed and maintained at 0°C for a definite reaction time. The product was poured into a large quantity of water, separated by filtration or centrifuge, and washed with water. In order to remove the silver salts, the filter cake was dispersed in an aqueous sodium thiosulfate solution of 1 wt%. After several hours, it was filtered, washed several times with water, and finally dried *in vacuo* at room temperature.

Characterization of the Polymer. The infrared spectrum was measured with a Shimadzu Infrared Spectrophotometer (Model IR-27) on KBr pellets. For the viscosity measurements, 100 mg of polyacrolein were mixed with 5 m*l* of a 10% aqueous sulfur dioxide solution in a 10 m*l* volumetric flask. This was allowed to stand overnight at room temperature and then filled to the mark with a 10% aqueous sodium chloride solution. Using this solution, the specific viscosity was measured at 25°C with an Ostwald viscometer. The number-average molecular weight was calculated by using the equation determined with the date reported by Schulz,[3] the η_{sp}/C ranging from 0.02 to 0.10 *l*/g:

$$\bar{M}_n = 16.8 \times 10^5(\eta_{sp}/C) - 2.8 \times 10^4$$

For the quantitative determination of the aldehyde group, the polyacrolein was reacted quantitatively with phenylhydrazine by the usual method.[4,5] The nitrogen content of the product (polyacrolein-phenylhydrazone) was also measured. In order to determine the C–C double-bond content, the polyacrolein was reduced with sodium borohydride, $NaBH_4$, to give a soluble polymer of polyallylalcohol,[6,7] and then the product was hydrogenated with hydrogen in the presence of platinum

dioxide in acetic acid.[8] The amount of hydrogen consumed was also measured.

Results and Discussion

Characterization of the Polymer. The polymer is a white powdery amorphous solid insoluble in organic solvents at room temperature. The infrared spectrum of the polymer showed the peaks characteristic of the vinyl-type polymer $(-CH_2-\underset{\underset{CH=O}{|}}{CH}-)_n$[9] and was very similar to that of the polymer formed by radical initiators (Fig. 1.). The elementary analysis of the product by the reaction of polyacrolein with phenylhydrazine showed that the polymer contains 97.5 mol% vinyl-type units (N 18.93, H 6.80, C 73.65%). Since there was no hydrogen absorption in the reaction product with $NaBH_4$, it can be said that the C–C double bond was not present in this system. From these results, it can be concluded that not the aldehyde-type polymer but only the vinyl-type polymer is formed by the redox-pair potassium persulfate-silver nitrate system.

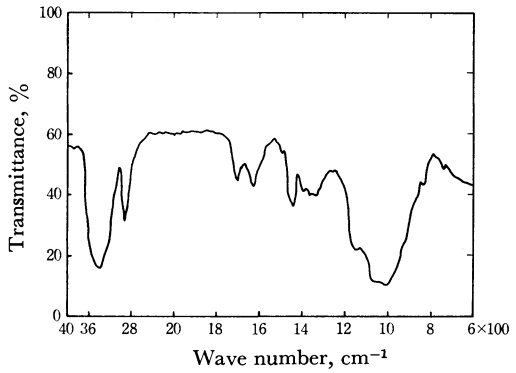

Fig. 1. Infrared spectrum of the polyacrolein formed with the redox system $AgNO_3/K_2S_2O_8$

Characteristic Effects of the Monomer and Potassium Persulfate Concentrations. The effect of the monomer concentration on the polymer yield and the molecular weight of the polymer was investigated; the results are shown in Table 1. Figure 2 indicates that the polymer yield at a constant time increases proportionally with the monomer concentration. The number-average degree of polymerization at a constant time is plotted against the monomer concentration in Fig. 3. It can be seen that the increase in the degree of polymerization with the monomer concentration becomes more pronounced with the reaction time; namely, the polymerizations in the earlier period (until 20 min) are characterized by a proportional increase in the degree of polymerization with the monomer concentration, while in the latter period (after 20 min) the exponent of the monomer concentration becomes more than unity.

Table 1. Effect of monomer concentration and time on polymer yield and molecular weight

Monomer concn. mol/l	Reaction time hr	Polymer yield mol/l	Molecular weight $\bar{M}_n \times 10^{-3}$
2.675	0.17	0.040	13.5
2.675	0.33	0.11	28.5
2.675	0.5	0.21	45.0
2.675	1.0	0.66	69.5
2.675	2.0	1.44	72.0
2.675	3.0	1.84	71.0

the increase becomes less pronounced. It is noted that the degree of polymerization at a constant time is almost independent of the catalyst concentration.

Classification of the Polymerization.[10] The polymer yields at various monomer concentrations are plotted against the reaction time in Fig. 5. In each of several monomer concentrations, S-shape curves are obtained; in the early stage (until 0.5—1.0 hr), there is a marked acceleration in rate, while the polymerization rate is gradually reduced in the later stage.

Figure 6 shows the variation in the molecular weight of the polymer formed with the reaction time. It is a characteristic phenomenon that, in the early stage, the molecular weight of the polymer formed increases proportionally with the reaction time, as does the rate acceleration. In the later stage, however, the molecular weight is shown to remain constant, independently of the reaction time.

The rate acceleration in the early stage shows the accumulation of propagating species. The initiation reaction may, therefore, be considered to occur continuously in the course of the polymerization; that is, this system is a polymerization with a slow initiation. Since the mole of the propagating species increases with the reaction time, the non-stationary state is realized in this case. Moreover, from the fact that the number-average degree of polymerization increases with the reaction time in the early stage, this stage is a successive polymerization.

On the other hand, the polymerization in the later stage is a chain polymerization, for the degree of polymerization is independent of the reaction time. In order to determine whether the polymerization in the later stage has a rapid or a slow initiation, and whether it has a stationary or a non-stationary state, the following experiments were carried out. At first, it was shown that the addition of excess amounts of sodium chloride inhibits the polymerization reaction completely. Three-fold sodium chloride, NaCl, of silver nitrate, $AgNO_3$, was added at various times in the course of the reaction, while the total reaction time was five hours. We term the reaction before and after the adding of NaCl period I and period II respectively. Table 3 shows that the increase in

Table 3. Results of two-stage polymerization by the addition of NaCl[a)]

5.0	0	0.279	0.297	−0.018

a) Reaction conditions: T = 0°C; $[K_2S_2O_8]_0$ = $[AgNO_3]_0$=31.5 mmol/*l*; initial monomer concentration: 0.462 mol/*l*; total reaction time: 5 hr; $NaCl/AgNO_3$=3.0 (molar ratio).
b) Overall polymerized monomer was obtained by subtracting the theoretical amount of AgCl (31.5 mmol/*l*) from the total yield.
c) The first-stage polymerization (Period I) was carried out as a blank polymerization in the same reaction conditions as that described above.
d) Polymerized monomer in Period II was obtained by subtracting the polymer yield in Period I from the overall polymer yield.

the polymer yield in period II was not observed in any case. This fact indicates that NaCl reacts with the Ag^+ ion to form a precipitate of AgCl, and that the formation of a new radical is stopped because of the disappearance of the reductant. The lack of any increase in the polymer yield in period II also leads to the consideration that there is a termination of the propagating species which had already been formed before the addition of sodium chloride.

In order to make clear the termination reaction, the polymerization was carried out by a two-stage monomer addition method as follows. The definite monomer was divided into two parts (14.7% and 85.3%). In the first stage the polymerization was carried out with the use of a 14.7% monomer for various reaction times, and then, after the addition of a residual monomer, polymerization (the second stage) was continued for one hour. The experimental results are given in Table 4. The polymer yield in the second stage is plotted in Fig. 7 against the reaction time in the first stage. The polymer yield increased with the time until about three hours, but it decreased thereafter.

TABLE 4. RESULTS OF TWO-STAGE POLYMERIZATION BY THE ADDITION OF MONOMER[a)]

a) Reaction conditions: $T = 0°C$; $[K_2S_2O_8]_0 = [AgNO_3]_0 = 31.5$ mmol/l; monomer concentration added in the first-stage, $[M_1]_0 = 0.462$: in the second-stage, $[M_2]_0 = 2.675$ mol/l; reaction time in the lst -stage: variable, the 2nd-stage: 1 hr.

b) P_2, the total polymer yield in the second-stage, was obtained by subtracting P_1 from P_T.

c) $[M_p]_2$, the polymer yield in the second-stage, was corrected as follows by eliminating the small amount of polymer formed during the second-stage with $[M_1]_0$.

$$[M_p]_2 = P_2 \times [M_2]_0 / ([M_1]_0 + [M_2]_0 - P_1)$$

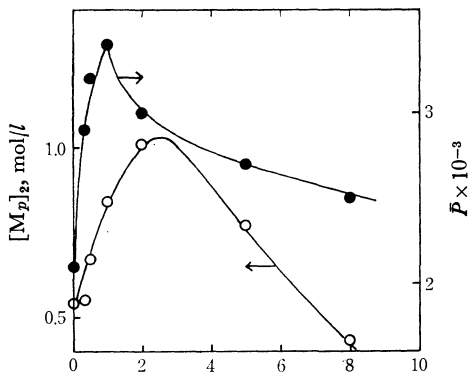

Fig. 7. Polymer yield in the second-stage and the degree of polymerization of the total polymer *vs.* reaction time in the first-stage. Reaction conditions are shown in Table 4.

This indicates that the propagating species accumulate until about three hours have passed, while, after three hours, the number of moles of the propagating species decreases with the reaction time because of the increase in the termination reaction and in the consumption of the catalyst.

It may be concluded from these facts that this redox polymerization is a non-stationary state accompanied by the accumulation of the propagating species in the early stage, and by the consumption of the propagating species in the later stage. The fact that the propagating species increase for three hours leads to the consideration that, in both the early and later stages, this system has a polymerization with a slow initiation.

The polymerization rate and the molecular weight of the polymer, as has been described before, increase continuously with the reaction time in

Reaction temperature=0°C, $[K_2S_2O_8]_0 = [AgNO_3]_0 = 31.5$ mmol/l

a) Number of moles of polymer chains was calculated from the ratio of the amount of polymerized monomer to the number-average degree of polymerization.

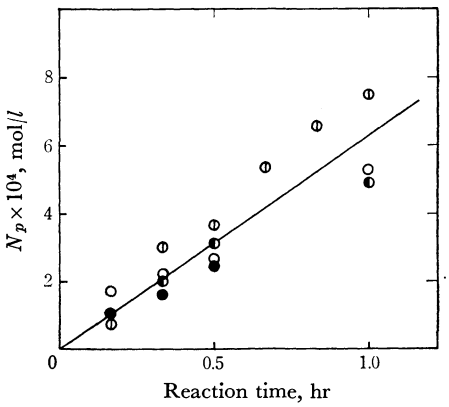

Fig. 8. Number of moles of polymer chains (N_p) *vs.* reaction time at various monomer concentration. $T = 0°C$; $[K_2S_2O_8]_0 = [AgNO_3]_0 = 31.5$ mmol/l; $[M]_0 = 1.65$ (◑), 2.12 (◐), 2.62 (●), 2.68 mol/l (○)

the early stage. This fact suggests that, in the early stage, neither the chain transfer nor the termination reaction is very remarkable, and that the initiation and the propagation reaction are the main elementary reactions. The effect of the monomer concentration on the number of moles of polymer chains is summarized in Table 5. From the experimental data, the number of moles of polymer chains is plotted against the reaction time in Fig. 8. The fact that an almost linear relation was found between them suggests that these redox systems have polymerizations with slow initiations. Since the number of moles of polymer chains was independent of the monomer concentration, the rate-determining step of the initiation reaction may be considered to be the decomposition reaction of the catalyst.

A more quantitative discussion of this polymerization will be given in a subsequent paper.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 2583—2588 (1969)

Graphical Evaluation of the Rate Constants of the Elementary Reactions in the Acrolein Polymerization with the Potassium Persulfate - Silver Nitrate Redox System

Tsutomu KAGIYA, Shigeru MORITA and Kenichi FUKUI

Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received November 4, 1968)

A quantitative study was made of the redox-polymerization of acrolein initiated by the potassium persulfate - silver nitrate system. The reaction mechanism of this polymerization was proposed on the basis of the results of the time-conversion, time-molecular weight curves, and also on the basis of the characteristic features of this polymerization, reported in a previous paper. The rate constants of the elementary reactions in this polymerization were estimated by a graphical method. In the early stage, neither the termination nor the transfer reaction is very remarkable as the initiation reaction, but in the later stage the termination reaction by a recombination of the polymer radical and the transfer reaction increase with the reaction time, as does the initiation reaction also.

In a previous paper[1] on the acrolein polymerization with the potassium persulfate - silver nitrate system, it was reported that the polymerization may be classified as a non-stationary state with a slow initiation in both the early and later stages. This paper will attempt to evaluate the rate constants of elementary reactions on the basis of quantitative kinetic measurements and to discuss the mechanism of this polymerization.

Results and Discussion

The Reaction Mechanism. In the previous paper[1], the redox-polymerization of acrolein with a potassium persulfate - silver nitrate catalyst was classified from a kinetic point of view. This polymerization has the non-stationary state showing an accumulation of the propagating species in the early stage (until 0.5～1.0 hr), and a consumption of the propagating species in the later stage. Moreover, this system is a polymerization with a slow initiation in both the early and later stages. Further, this system was found to show successive polymerization in the early stage, and chain polymerization in the later stage.

The following elementary reactions may, therefore, be assumed for the redox polymerization of acrolein on the basis of the experimental results reported in the previous paper[1] and the results of catalyst decomposition obtained by Bawn *et al.*[2] The respective rate expressions are also shown at the right.

1. Decomposition:

$$\underset{(C)}{Ag^+ + S_2O_8^{2-} + OH^-} \xrightarrow{k_d} SO_4^{2-} + \underset{(C^*)}{SO_4^-\cdot} + \underset{(C^*)}{HO\cdot} + Ag^+$$

$$R_d = k_d[C] \qquad (1)$$

1) T. Kagiya, S. Morita and K. Fukui, This Bulletin, **42**, 2578 (1969).

2) C. E. H. Bawn and D. Margerison, *Trans. Faraday Soc.*, **51**, 925 (1955).

2. Initiation:

$$C^* + M \xrightarrow{k_i} \underset{(P_1^*)}{CM\cdot} \qquad R_i = k_i[C^*][M] \tag{2}$$

3. Propagation:

$$P_n^* + M \xrightarrow{k_p} P_{n+1}^* \qquad R_p = k_p[P^*][M] \tag{3}$$

4. Termination:

$$P_m^* + P_n^* \xrightarrow{k_t} P_{m+n},\ P_m + P_n \qquad R_t = k_t[P^*]^2 \tag{4}$$

5. Transfer:

$$P_n^* + XY \xrightarrow{k_{tr}} P_nX + Y^* \qquad R_{tr} = k_{tr}[P^*][XY] \tag{5}$$

where C represents the potassium persulfate; C*, an anion radical, $SO_4^{-}\cdot$, and an HO· radical; M, the acrolein monomer; P_n^*, an active polymer chain composed of n monomers; [P*], the total concentration of all the active polymer chains, irrespective of size ($\sum_{n=1}^{\infty}[P_n^*]$); P_n, a dead polymer composed of n monomers; XY, the substance to which the activity of P_n^* is transferred; R_d, R_i, R_p, R_t, and R_{tr} the rates of decomposition, initiation, propagation, termination and transfer, and k_d, k_i, k_p, k_t and k_{tr}, the rate constants of these reactions.

It was reported by Bawn *et al.* that the catalyzed decomposition of potassium persulfate in an aqueous solution by the Ag^+ ion occurs according to:

$$Ag^+ + S_2O_8^{2-} \rightarrow Ag^{2+} + SO_4^{-}\cdot + SO_4^{2-}$$
$$Ag^{2+} + OH^- \rightarrow Ag^+ + HO\cdot$$

the second step is very fast compared with the first step, which is the rate-determining step, so that the silver ion (Ag^+) concentration remains constant during the reaction. The rate constant of the decomposition reaction at 0°C was obtained as k_d=0.15 *l*/hr.

The following equations are derived from the elementary reactions described above, when the $SO_4^{-}\cdot$ and HO· have the same reactivity for initiation:

$$-\mathrm{d[C]}/\mathrm{d}t = k_d[C] \tag{6}$$
$$\mathrm{d[C^*]}/\mathrm{d}t = 2R_d - R_i = 2k_d[C] - k_i[C^*][M] \tag{7}$$
$$\mathrm{d[P^*]}/\mathrm{d}t = R_i - 2R_t = k_i[C^*][M] - 2k_t[P^*]^2 \tag{8}$$

Since the polymer formed has a high molecular weight, the overall rate of polymerization is approximately equal to the rate of propagation:

$$R = \mathrm{d[M}_p\mathrm{]}/\mathrm{d}t \fallingdotseq R_p = k_p[P^*][M] \tag{9}$$

were R represents the overall polymerization rate, and [M_p], the amount of monomer polymerized. By integrating Eq. (6), the concentration of potassium persulfate is expressed as a function of the reaction time:

$$[C] = [C]_0 e^{-k_d t} \tag{10}$$

were $[C]_0$ represents the concentration of potassium persulfate at a definite reaction time, 0. The rate-determining step of the initiation reaction is the decomposition reaction of the catalyst, as was pointed out in the previous paper[1]; accordingly, Eq. (7) becomes:

$$\mathrm{d[C^*]}/\mathrm{d}t = 2R_d - R_i = 0 \tag{11}$$

By integrating Eq. (11), and by considering Eq. (10), the sum of polymer chains produced by initiation, $\int R_i \mathrm{d}t$, can be expressed by the following equation:

$$\int R_i \mathrm{d}t = 2\alpha[C]_0(1 - e^{-k_d t}) \tag{12}$$

where α is an efficiency factor of the catalyst.

The Evaluation of the Rate of Elementary Reactions in the Early Stage. The rate constant of the elementary reaction proposed above was determined by means of a graphical method in the non-stationary polymerization.[3] [P*] is given by Eq. (8):

$$[P^*] = \int R_i \mathrm{d}t - 2\int R_t \mathrm{d}t \tag{13}$$

From the facts that the polymerization rate and the molecular weight of the polymer increase with the reaction time, the termination rate may be considered to be smaller than the initiation rate.

When R_t is zero, Eq. (13) becomes:

$$[P^*] = \int R_i \mathrm{d}t = 2\alpha[C]_0(1 - e^{-k_d t}) \tag{14}$$

By a combination of Eqs. (9) and (14), the rate of polymerization is given as:

$$R_p = 2\alpha k_p[C]_0[M](1 - e^{-k_d t}) \tag{15}$$

In general, the number-average degree of polymerization at a given reaction time is defined by the following:

$$\bar{P} = \int R_p \mathrm{d}t \Big/ \left(\int R_i \mathrm{d}t + \int R_{tr} \mathrm{d}t - \int R_t \mathrm{d}t\right) \tag{16}$$

where $\bar{P}$ represents the number-average degree of polymerization. Since, in the early stage, the consumption of the monomer is very small and the value of $k_d t$ is smaller than unity, $\int R_p \mathrm{d}t$ without termination and $\int R_i \mathrm{d}t$ are given as follows by Eqs. (15) and (12) respectively:

$$\int R_p \mathrm{d}t = [M_p] = \alpha k_d k_p [C]_0 [M]_0 t^2 \tag{17}$$
$$\int R_i \mathrm{d}t = 2\alpha k_d [C]_0 t \tag{18}$$

If the transfer reaction to the monomer occurs, Eq. (19) is obtained:

$$\int R_{tr} \mathrm{d}t = \int k_{tr}[P^*][M]\mathrm{d}t = (k_{tr}/k_p)\int R_p \mathrm{d}t \tag{19}$$

From a combination of Eqs. (16), (17), (18) and

3) T. Kagiya, M. Izu, S. Machi and K. Fukui, This Bulletin, **40**, 1049 (1967).

(19), Eq. (16) becomes:

$$1/\bar{P} = 2/(k_p[M]_0 t) + k_{tr}/k_p \qquad (20)$$

The following evaluation of the rate constants of elementary reactions was made in the polymerization which was carried out under a monomer concentration of 2.68 mol/l and under a redox-pair concentration of 31.5 mmol/l (mol ratio 1 : 1). According to Eq. (20), $1/\bar{P}$ is plotted in Fig. 1 against

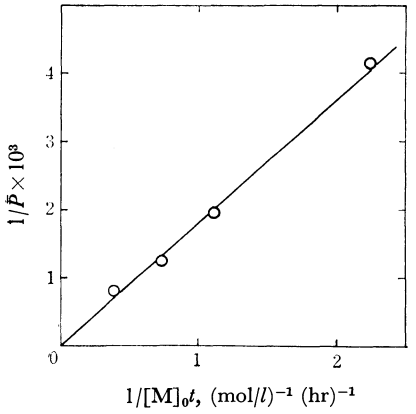

Fig. 1. Reciprocal of degree of polymerization *vs.* $1/[M]_0 t$
T=0°C; $[K_2S_2O_8]_0=[AgNO_3]_0=31.5$ mmol/l; initial monomer concentration, 2.675 mol/l

$1/[M]_0 t$ to give a straight line through the point of origin. This indicates either that the transfer and the termination reaction do not take place or that these reactions compensate each other in Eq. (16). In both cases, k_p was determined from the slope of the straight line in Fig. 1:

$$k_p = 1.1 \times 10^3 \ l/\text{mol}\cdot\text{hr}.$$

As was reported in the previous paper,[1] it was found, from the results obtained using a two-stage polymerization method, that termination reactions occur both in the early and later stages. It may be concluded, therefore, that the termination reaction compensates the transfer reaction in the early stage.

Equation (21) is derived from Eq. (15):

$$R_p/[M] = 2\alpha k_p[C]_0(1 - e^{-0.15t}) \qquad (21)$$

The plot of the $R_p/[M]$ term against the value of $2[C]_0(1-e^{-0.15t})$ gives a straight line through the point of origin, as is shown in Fig. 2. From the slope of the line, $\alpha k_p = 67.5$ l/mol·hr. Since the value of k_p was 1.1×10^3 l/mol·hr according to Eq. (20), as has been mentioned above, the efficiency factor of the catalyst is:

$$\alpha = 6.14 \times 10^{-2}$$

The value of $\int R_i dt$ is thus given by the following equation instead of by Eq. (12):

$$\int R_i dt = 12.28 \times 10^{-2}[C]_0(1 - e^{-0.15t}) \qquad (22)$$

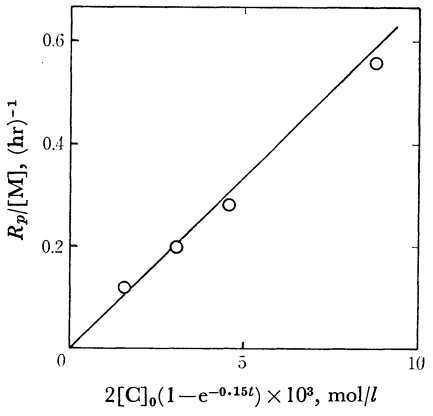

Fig. 2. $R_p/[M]$ *vs.* $2[C]_0(1-e^{-0.15t})$
Reaction conditions are the same as shown in Fig. 1.

The Evaluation of the Rate of Elementary Reactions in the Later Stage. The quantitative evaluation of the rate of elementary reactions in the later stage was continued as follows.

As has been described before, both the transfer and termination reactions take place in this polymerization and compensate each other. When the second-order termination by the polymer radical takes place, the following equation can be derived by integrating Eq. (4):

$$\int R_t dt = \int k_t[P^*]^2 dt = (k_t/k_p^2)\int (R_p^2/[M]^2)dt \qquad (23)$$

By combining Eqs. (9), (13), (22) and (23), Eq. (24) is derived:

$$\frac{R_p}{[M]\int \frac{R_p^2}{[M]^2}dt} = \frac{4.25(1-e^{-0.15t})}{\int \frac{R_p^2}{[M]^2}dt} - \frac{2k_t}{1.1\times 10^3} \qquad (24)$$

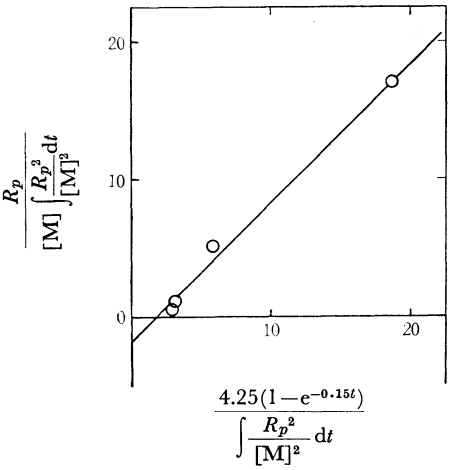

Fig. 3. $\frac{R_p}{[M]\int \frac{R_p^2}{[M]^2}dt}$ *vs.* $\frac{4.25\,(1-e^{-0.15t})}{\int \frac{R_p^2}{[M]^2}dt}$
Reaction conditions are the same as shown in Fig. 1.

By plotting the value of the left side against the first term on the right side in Eq. (24), a straight line with a slope of unity was obtained, as is shown in Fig. 3. From the value of the intercept of the ordinate axis, k_t was found to be 9.9×10^2 l/mol·hr.

Since the ratio of the consumption of the catalyst is 36% in a reaction period of three hours, it can be assumed that the concentration of the catalyst (potassium persulfate) remains almost constant for about three hours after the start of the polymerization. Eq. (25) can then be derived by combining Eqs. (7), (8) and (11);

$$d[P^*]/dt = 2\alpha k_d[C]_0 - 2k_t[P^*]^2 \quad (25)$$

The following equation is obtained by resolving the differential equation[4]:

$$[P^*] = (\alpha k_d[C]_0/k_t)^{1/2} \tanh\left[(4\alpha k_d k_t[C]_0)^{1/2}t\right] \quad (26)$$

By substituting the values of k_d, k_t, $[C]_0$ and α obtained above into Eq. (26), [P*] can be plotted against the reaction time as is shown in Fig. 4.

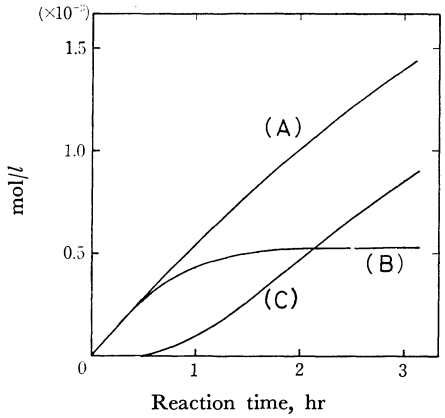

Fig. 4. $\int R_i dt$, [P*] and $2\int R_t dt$ *vs.* reaction time.
(A), $\int R_i dt$; (B), [P*]; (C), $2\int R_t dt$
Reaction conditions are the same as shown in Fig. 1.

$\int R_i dt$ [Eq. (22)] and $2\int R_t dt$ $(=\int R_i dt - [P^*])$ are also plotted in the same figure, Fig. 4. When the consumption of the catalyst is negligible, it is found that [P*] increases with the reaction time, therefore, the termination reaction becomes remarkable after thirty minutes. Since [P*] decreases, however, with the reaction time after about three hours from the start of the polymerization, as was shown in the previous paper,[1] it must be considered in practice that the consumption of the catalyst is not negligible in the later period.

When the recombination between propagating species prevails in the termination, Eq.(27) is derived from Eq.(16):

$$1/\bar{P} = \left(\int R_i dt - \int R_t dt\right)\Big/\int R_p dt + \int R_{tr} dt \Big/ \int R_p dt \quad (27)$$

In Eq.(27), when:

$$h(t) \equiv \int R_i dt - \int R_t dt \quad (28)$$

the value of $h(t)$ can be calculated from Fig. 4, assuming that the termination reaction occurs by means of a recombination between propagating species. When a chain transfer to XY (chain-transfer reagent) takes place with a constant concentration,

$$\int R_{tr} dt = k_{tr}[XY]\int [P^*]dt = (k_{tr}[XY]/k_p)\int \frac{R_p}{[M]}\,dt \quad (29)$$

By a combination of Eqs. (27), (28) and (29), the following equation is derived:

$$\frac{[M_p]}{\bar{P}\int \frac{R_p}{[M]}dt} = \frac{h(t)}{\int \frac{R_p}{[M]}dt} + \frac{k_{tr}[XY]}{k_p} \quad (30)$$

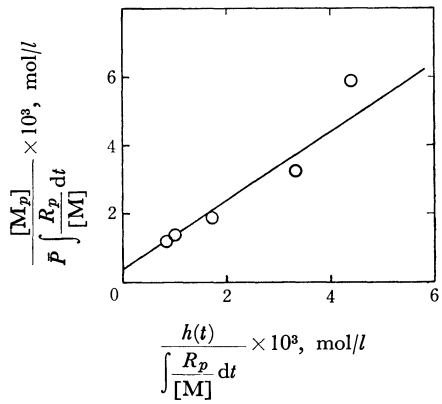

Fig. 5. $\dfrac{[M_p]}{\bar{P}\int \frac{R_p}{[M]}dt}$ *vs.* $\dfrac{h(t)}{\int \frac{R_p}{[M]}dt}$
Reaction conditions are the same as shown in Fig. 1.

The left side is plotted in Fig. 5 against the first term on the right side to give a straight line with the slope of unity. From the intercept on the ordinate axis, $k_{tr}[XY]/k_p$ can be obtained. By substituting the k_p value obtained before into $k_{tr}[XY]/k_p$, $k_{tr}[XY]$ is obtained as 0.44 $(hr)^{-1}$.

The rate equations and the rate constants of the elementary reactions obtained above are summarized in Table 1.

Comparison of Experimental Results with Theoretical Results. The experimental results on both the polymer yield and the degree of polymerization were compared with the equations which had been theoretically derived from the proposed elementary reactions.

The following relationship on the polymer yield is derived from combining Eqs.(9) and (26):

4) M. Magat, *J. Polymer Sci.*, **16**, 491 (1955).

TABLE I. THE RATE EQUATIONS AND THE RATE CONSTANTS OF THE ELEMENTARY REACTIONS

Elementary reaction		Rate equation	Rate constant
Decomposition	$Ag^+ + S_2O_3^{2-} + OH^- \rightarrow SO_4^{2-} + SO_4^{-}\cdot + HO\cdot + Ag^+$	$R_d = k_d[C]$	$k_d = 0.15$ (1/hr)
Initiation	$C^* + M \rightarrow P_1^*$	$R_i = k_i[C^*][M]$	$\int R_i dt = 2\alpha[C]_0(1-e^{-k_d t})$ (mol/l)
Propagation	$P_n^* + M \rightarrow P_{n+1}^*$	$R_p = k_p[P^*][M]$	$k_p = 1.1\times10^3$ (l/mol·hr)
Transfer	$P_n^* + XY \rightarrow P_nX + Y^*$	$R_{tr} = k_{tr}[P^*][XY]$	$k_{tr}[XY] = 0.44$ (l/mol·hr)
Termination	$P_m^* + P_n^* \rightarrow P_{m+n}$	$R_t = k_t[P^*]^2$	$k_t = 9.9\times10^2$ (l/mol·hr)

$$[M_p] = \int k_p(\alpha k_d[C]_0/k_t)^{1/2} \tanh [(4\alpha k_d k_t[C]_0)^{1/2}t][M]dt \quad (31)$$

By substituting various constants, and by graphically integrating with the reaction time, the theoretical value of $[M_p]$ is plotted against the time, and compared with the empirical data, in Fig. 6. A good agreement between observation and theory is observed.

On the other hand, when termination takes place by a recombination of polymer radicals, the following equation can be derived:

$$\bar{P} = \int R_p dt \Big/ \left(\int R_i dt + \int R_{tr} dt - \int R_t dt\right) \quad (16)$$

By substituting Eqs. (31), (12), (29) and (23) into Eq. (16) and by assuming that the [XY] is constant, the following equation is obtained.

The values of each term at various reaction times in Eqs. (32) and (33) are listed in Table 2. Table 2 shows that, in the early stage, both the termination

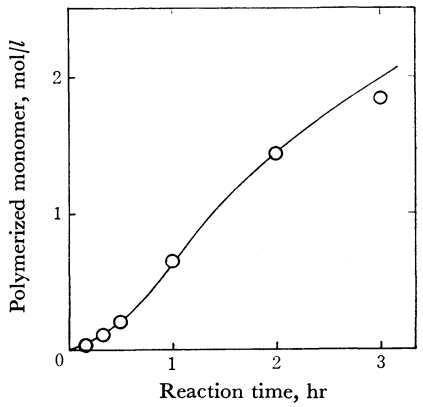

Fig. 6. The amount of polymerized monomer *vs.* reaction time.

(—), theoretical curve
Reaction conditions are the same as shown in Fig. 1.

$$\bar{P} = \frac{\int k_p[P^*][M]dt}{2\alpha[C]_0(1-e^{-k_d t}) + k_{tr}[XY]\int [P^*]dt - k_t\int [P^*]^2 dt}$$

$$= \frac{(\alpha k_d k_p^2[C]_0/k_t)^{1/2}\int \tanh [(4\alpha k_d k_t[C]_0)^{1/2}t][M]dt}{2\alpha[C]_0(1-e^{-k_d t}) + (k_{tr}[XY]/2k_t)\ln\cosh[(4\alpha k_d k_t[C]_0)^{1/2}t] - \alpha k_d[C]_0 t + (\alpha k_d[C]_0/4k_t)^{1/2}\tanh[(4\alpha k_d k_t[C]_0)^{1/2}t]}$$

$$= \frac{595\int \tanh(1.07t)[M]dt}{38.7(1-e^{-0.15t}) + 5.13\log\cosh(1.07t) - 2.9t + 2.71\tanh(1.07t)} \quad (32)$$

$$= \frac{[M_p]\times10^4}{38.7(1-e^{-0.15t}) + 5.13\log\cosh(1.07t) - 2.9t + 2.71\tanh(1.07t)} \quad (33)$$

TABLE 2. VARIATION OF $\int R_i dt$, $\int R_{tr} dt$, $\int R_t dt$ AND THE POLYMER YIELD WITH THE REACTION TIME

Reaction time hr	Initiation reaction $\int R_i dt\times10^4$ mol/l $38.7(1-e^{-0.15t})$	Transfer reaction $\int R_{tr} dt\times10^4$ mol/l $5.13\log\cosh(1.07t)$	Termination reaction $\int R_t dt\times10^4$ mol/l $2.9t-2.71\tanh(1.07t)$	Polymer yield mol/l $[M_p]$	$0.595\int\tanh(1.07t)[M]dt$
0.167	0.953	0.035	0.006	0.040	0.022
0.333	1.88	0.139	0.041	0.111	0.086
0.50	2.79	0.304	0.127	0.212	0.193
1.0	5.38	1.09	0.765	0.66	0.625
2.0	10.0	3.25	3.17	1.44	1.46
3.0	14.0	5.60	6.00	1.84	2.06

Reaction conditions are the same as Fig. 1.

and transfer reactions are very small compared with the initiation reaction and that they compensate each other in both the early and later stages. Therefore, in order to evaluate the propagation rate, it is adequate to adopt the method described above, using $R_t=R_{tr}=0$.

The empirical data is shown in Fig. 7 to agree

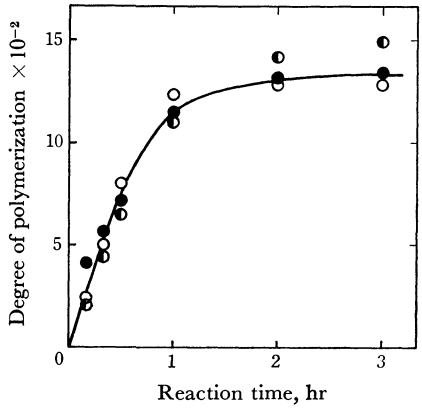

Fig. 7. Degree of polymerization *vs.* reaction time.
(○), experimental data
(◐), theoretical value obtained from Eq. (32)
(●), theoretical value obtained from Eq. (33)
Reaction conditions are the same as shown in Fig. 1.

with the theoretically-derived value. The deviation of the theoretical value in Eq.(32) from the experimental data in the later period is due to the consumption of the catalyst.

The values of k_{tr}[XY] in the polymerization at various monomer and catalyst concentrations are summarized in Table 3. The value of k_{tr}[XY] decreases with the initial monomer concentration, independently of the potassium persulfate concentration. The mechanism of the chain-transfer reaction is not clear, but it may be ascribed to impurities in water. The fact that the value of k_{tr}[XY] decreases remarkably with the initial monomer concentration suggests that the activity of XY is markedly decreased by the formation of the polymer.

TABLE 3. THE VALUE OF k_{tr}[XY]

Initial monomer concentration (mol/l)	k_{tr}[XY] $(hr)^{-1}$
0.449	7.7
1.230[a)]	3.0
1.486	2.0
2.272	0.5

Reaction condition: T=0°C,
$[AgNO_3]_0=[K_2S_2O_8]_0=31.5$ mmol/l
a) $[K_2S_2O_8]_0=15.75$ mmol/l

In the view of the fact that the experimental results on both the polymer yield and the degree of polymerization under several reaction conditions coincide with the equation theoretically derived, the proposed elementary reactions and the rate constants evaluated in the non-stationary-state polymerization may be accepted.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 2589—2592 (1969)

Synthetic Studies of the Derivatives of Acetylene. I. Reactions of 5-Bromopent-3-en-1-yne[1]

Kikumasa SATO and Masao HIRAYAMA

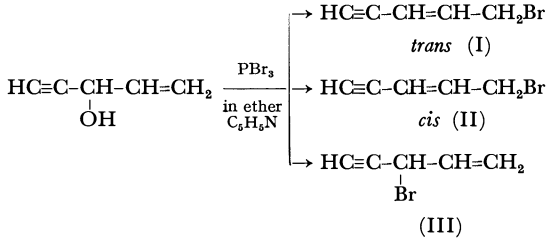
Department of Applied Chemistry, Faculty of Engineering, Yokohama National University, Minami-ku, Yokohama

(Received November 28, 1968)

The preparation of pent-2-en-4-ynylamine and pent-2-en-4-ynylthiol and their derivatives from 5-bromopent-3-en-1-yne was studied. Moreover, in connection with the preparation of the bromide, the rearrangement-bromination of vinylethynylcarbinol was found to give three isomeric bromides, 5-bromopent-*trans*-3-en-1-yne, 5-bromopent-*cis*-3-en-1-yne, and 3-bromopent-1-en-4-yne. Pent-2-en-4-ynylamine was obtained from 5-bromopent-3-en-1-yne by two methods, by the hydrolysis of the hexaminium salt and by the cleavage of *N*-(pent-2-en-4-ynyl)phthalimide. The reaction of 5-bromopent-3-en-1-yne with potassium hydrosulfide and the decomposition of ethyl pent-2-en-4-ynylxanthate by alcoholic ammonia gave pent-2-en-4-ynylthiol.

In previous papers, it was reported that propargyl bromide could be converted to propargylamine and propargyl mercaptan and their derivatives.[2a-c] These studies have now been extended to such a vinylogous bromide as 5-bromopent-3-en-1-yne (I). Compound I may be expected to be useful for some synthetic reactions because it has two different functional groups. It is well known that the bromine atom has so enhanced a reactivity that it undergoes Reformatskii reaction with carbonyl compounds,[3] but there have been only a few other studies, such as those of the reactions with potassium acetate,[4] ethyl acetoacetate,[5] potassium cyanide,[6] and diethylamine.[7] In the present study we examined various substitution reactions of I in order not only to synthesize the conjugated vinylacetylenic amine, thiol, and their derivatives, but also to investigate the difference in the reactivity of the bromine atom between I and propargyl bomide. Almost all of the reaction products prepared were new substances.

The common methods of preparing the bromide involve the rearrangement-bromination of vinylethynylcarbinol[6] and the direct bromination of the corresponding alcohol, pent-2-en-4-yn-1-ol.[3] According to the study of Bohlmann and Viehe,[6] the former method gave a mixture of two isomers, unrearranged bromide and rearranged bromide, judging from the ultraviolet spectrum of the mixture. When we re-examined the rearrangement-bromination reaction, we found that a mixture of three isomeric bromides, rearranged *trans*-5-bromopent-3-en-1-yne (I), *cis*-5-bromopent-3-en-1-yne (II), and unrearranged bromide (III), was obtained in a 49.2% yield. The ratio of I : II : III was



found to be about 2 : 1 : 1 by gas chromatography. The structures of these three isomers were confirmed by their infrared, ultraviolet, and NMR spectra, and by microanalyses of their hexaminium salts. Compound III was identified by its ultraviolet spectrum, which showed no absorption maximum. However, the final confirmation of *cis*- and *trans*-isomers depended on their NMR and ultraviolet spectra. The coupling constants of the olefinic protons of the two isomers are 10.5 and 17.0 Hz values which are characteristic of *cis*- and *trans*-olefinic protons respectively. Moreover, the absorption peaks of the ultraviolet spectra are

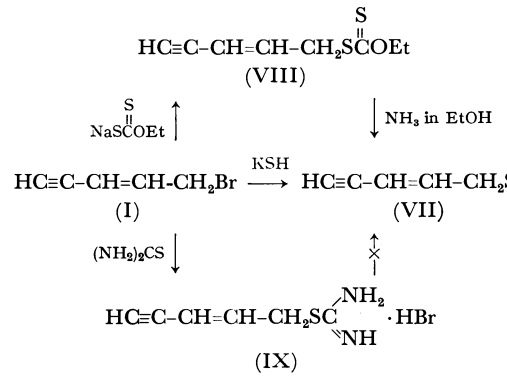
238.5 mμ ($\varepsilon=11400$) and 238 mμ ($\varepsilon=14400$); these values are also complete agreement with the *cis*- and *trans*-structures of the conjugated vinylacetylenic system.[8] Although vinylethynylcarbinol was obtained in a good yield, it is very troublesome to separate the three isomers formed in the following rearrangement-bromination reaction, as will be described in the Experimental section. Therefore, we were obliged to prepare the bromide I by the other direct bromination method[3] of pent-2-en-4-yn-1-ol, which had been obtained in the pure *trans*-form from sodium acetylide and epichlorohydrin.[4]

Allylamine and propargylamine derivatives were prepared from the corresponding halides by Delépine and Gabriel reactions but conjugated vinylacetylenic amines such as V have not been prepared. 5-Bromopent-3-en-1-yne reacted with hexamine in methanol to give the hexaminium salt (IV), which was warmed with concentrated hydrochloric acid to give brown crystals. When the crystals were treated with aqueous potassium hydroxide, pent-2-en-4-ynylamine (V) was obtained as a colorless liquid. On the other hand, the reaction of I with potassium phthalimide gave *N*-(pent-2-en-4-ynyl)phthalimide (VI) in a 92% yield. This result is interesting, for it contrasts with the fact that *N*-propargylphthalimide was obtained in only a 10% yield in a similar reaction.[2a] Compound VI was refluxed with hydrazine hydrate in ethanol and then treated with hydrochloric acid to yield pale brown crystals. The treatment of the crystals with aqueous potassium hydroxide gave the corresponding amine, V, in a 32% yield. Compound V was identified from its infrared and ultraviolet spectra and by the microanalyses of its derivatives. Especially, the location of the absorption maximum in the ultraviolet spectrum indicated that V had the expected conjugated vinylacetylenic structure. Compound V reacted normally with benzoyl chloride, sodium cyanate, phenyl isocyanate, and carbon disulfide to give the corresponding derivatives.

No report has also been found concerning the preparation of such vinylacetylenic thiols as VII. We found that VII could be obtained by two methods, the reaction of I with potassium hydrosulfide and the decomposition of the ethyl xanthate, though VII was not obtained by the hydrolysis of the isothiuronium bromide (IX). Compound I reacted with potassium hydrosulfide in acetone-water to give VII in a 47% yield, and ethyl pent-2-en-4-ynylxanthate (VIII), prepared in a 59.7% yield by the reaction of I with sodium xanthate, was decomposed by alcoholic ammonia also to yield VII in a 55% yield. However, VII could not be obtained by the hydrolysis of *S*-(pent-2-en-4-ynyl)isothiuronium bromide (IX) (itself obtained in a high yield by the reaction of I with thiourea) by aqueous sodium hydroxide because of the resinification of the reaction mixture upon distillation. *p*-Tolyl



pent-2-en-4-ynyl sulfide (X) and pent-2-en-4-ynylthioacetic acid (XI) were prepared by the reaction of I with *p*-thiocresol and thioglycolic acid respectively.

From these results, the present authors conclude that compound I behaves almost like allyl bromide in the substitution reactions presented above, while I also shows a characteristic property with propargyl bromide in such reactions with carbonyl compounds as the Reformatskii reaction.

Experimental[9]

Materials. Vinylethynylcarbinol was obtained by the method of Bohlmann and Viehe.[6] 5-Bromopent-3-en-1-yne was prepared by the bromination of pent-2-en-4-yn-1-ol,[3] which had itself been obtained from sodium acetylide and epichlorohydrin.[4] The other materials were obtained from commercial sources.

Bromination of Vinylethynylcarbinol. The bromination was carried out by a slight modification of the method of Bohlmann and Viehe.[6] A solution of phosphorus tribromide (35.0 g) (0.13 mol) in 50 m*l* of dry ether was stirred, drop by drop and at 10±2°C, into a mixture of vinylethynylcarbinol (24.6 g) (0.3 mol) in 100 m*l* of dry ether containing 2.5 g of pyridine. After the mixture had been heated for 2.5 hr under reflux, the resulting mixture was chilled, poured over ice water, and extracted with ether. The ether was washed with water and saturated aqueous sodium bicarbonate, dried over sodium sulfate, and evaporated. The residue was distilled, giving mixed isomers (21.4 g) (49.2%) of a pale yellow liquid, bp 66—76°C/84 mmHg. The gas chromatography showed three peaks, and the ratio of I : II : III was 0.48 : 0.25 : 0.26. This mixture was distilled into three fractions through a 30 cm column.

Fraction 1 was 3-bromopent-1-en-4-yne (III) (6.3 g) (14.5%); bp 70—74°C/124 mmHg, n_D^{20} 1.5102; ν_{max}^{film} 3270, 2100, 1632, and 890 cm^{-1} (C=CH$_2$); and NMR peaks at δ 2.74 (the acetylenic proton), 4.98 (–CHBr–), 5.18 and 5.49 (terminal olefinic protons *cis* and *trans* to the vicinal olefinic proton respectively), and 6.09 ppm (the last olefinic proton). The ultraviolet spectrum had no absorption peak.

Fraction 2 was 5-bromopent-*cis*-3-en-1-yne (II) (3.5 g) (8.1%); bp 83—84°C/124 mmHg, n_D^{20} 1.5319; ν_{max}^{film} 3280, 2100, 1610, and 765 cm^{-1} (*cis* CH=CH); λ_{max}^{EtOH} 238.5 mμ (ε=11400); NMR peaks at δ 3.23 (the acetylenic proton), 4.11 (bromomethyl protons), 5.51 (the olefinic proton adjacent to the triple bond), and 6.19 ppm (the last olefinic proton); $J_{CH=CH}$=10.5 Hz. Moreover, it was identified as hexaminium bromide; mp 176—177.5°C (Found: N, 19.83%. Calcd for $C_{11}H_{17}N_4Br$: N, 19.64%).

Fraction 3 was 5-bromopent-*trans*-3-en-1-yne (I) (5.6 g) (12.9%); bp 85—87°C/124 mmHg, n_D^{20} 1.5422 (lit.[3] n_D^{17} 1.5430); ν_{max}^{film} 3300, 2080, 1620, and 955 cm^{-1} (*trans* CH=CH); λ_{max}^{EtOH} 238 mμ (ε=14400); NMR peaks at δ 2.90 (the acetylenic proton), 3.93 (bromomethyl protons), 5.65 (the olefinic proton adjacent to the triple bond), and 6.31 ppm (the last olefinic proton); $J_{CH=CH}$=17.0 Hz. These characteristic absorption peaks were in complete accord with those of *trans* authentic bromide prepared according to the method of Henbest and his co-workers.[3]

5-Bromopent-3-en-1-yne-hexamethylenetetramine (IV). A solution of 5-bromopent-3-en-1-yne (36.1 g) (0.25 mol) in 110 m*l* of ether was added, portion by portion, to a hot solution of hexamine (35.2 g) (0.25 mol) in 350 m*l* of methanol. After the solution had been refluxed for 10 min and then left to stand overnight, pale yellow crystals precipitated (54.7 g, mp 183—184°C (dec.)); from the filtrate, after the removal of the solvent, 6.4 more grams of crystal were obtained, mp 179—181°C (dec.). The yield was 86.0%. Recrystallization from methanol gave the pure IV; mp 184—185°C (dec.), ν_{max}^{KBr} 3180, 2080, 1630, and 945 cm^{-1}; λ_{max}^{EtOH} 219 (ε=12000), 228 (ε=15400), and 237 mμ (ε=12000). Found: C, 46.03; H, 6.28%. Calcd for $C_{11}H_{17}N_4Br$: C, 46.33; H, 6.01%.

***N*-(Pent-2-en-4-ynyl)phthalimide (VI).** A mixture of 5-bromopent-3-en-1-yne (4.4 g) (0.03 mol), potassium phthalimide (5.6 g) (0.03 mol), and 30 m*l* of ethanol was stirred for 12 hr under reflux. The removal of ethanol, followed by treatment with dilute aqueous potassium hydroxide, gave white crystals (5.8 g) (92.1%), mp 119—120.5°C. Recrystallization from ethanol provided the pure VI, mp 125—126°C; ν_{max}^{KBr} 3250, 2070, 1770, 955, 800, and 720 cm^{-1}. Found: C, 73.93; H, 4.62%. Calcd for $C_{13}H_9O_2N$: C, 73.92; H, 4.30%.

Pent-2-en-4-ynylamine (V). *A) From 5-Bromopent-3-en-1-yne-hexamethylenetetramine.* To a hot solution of 5-bromopent-3-en-1-yne-hexamethylenetetramine (28.5 g) (0.1 mol) in 330 m*l* of methanol, a 50 m*l* portion of concentrated hydrochloric acid was added, portion by portion, the mixture was then heated for 20 min under reflux. After the mixture had stood overnight, the precipitated ammonium chloride was filtered out; the removal of the solvent from the resulting filtrate gave brown crystals. Recrystallization from methanol gave 14.5 g of pale brown crystals, mp above 250°C; ν_{max}^{KBr} 3220, 3100—2900, 2070, 1600, 1565, 1490, and 955 cm^{-1}.

To a solution of the crystals (8.0 g) in 10 m*l* of water, a solution of potassium hydroxide (4.5 g) in 20 m*l* of water was added at 0—5°C; the resulting solution was extracted with ether. After drying over potassium hydroxide and evaporating, the distillation of the residue gave 1.8 g (40.3% based on hexaminium salt) of a liquid, bp 51°C/20 mmHg, n_D^{20} 1.5078; ν_{max}^{film} 3400—3150, 3300, 2080, 1590, 955, and 850 cm^{-1}; λ_{max}^{EtOH} 226 mμ (ε=14500).

B) From N-(Pent-2-en-4-ynyl)phthalimide. *N*-(Pent-2-en-4-ynyl)phthalimide (4.2 g) (0.02 mol) was treated for 1.5 hr with 80% aqueous hydrazine (1.4 g) (0.02 mol) in 60 m*l* of boiling 95% ethanol. Concentrated hydrochloric acid (3.5 m*l*) was added to the resulting mixture, which was then heated for 20 min under reflux. After the reaction mixture had then cooled and been filtered, the concentration of the filtrate gave 2.1 g (89.2%) of pale brown crystals, mp above 250°C. The infrared spectrum of this crystal was in complete accord with that of the hydrochloride salt obtained by passing hydrogen chloride into an ethereal solution of pent-2-en-4-ynylamine.

These crystals (5.9 g) (0.05 mol) were treated with aqueous potassium hydroxide such as in method A to yield 1.3 g (32.2%) of V, bp 55—56°C/28 mmHg.

This amine gave the following derivatives. Reaction with benzoyl chloride gave *N*-benzoylpent-2-en-4-ynylamine, mp 107—107.5°C (dil. MeOH); Found: C, 77.74; H, 6.05%. Calcd for $C_{12}H_{11}ON$: C, 77.81;

9) All melting points and boiling points are uncorrected and all distillations were carried out in a nitrogen atmosphere. Infrared and ultraviolet spectra were recorded on a Hitachi Model EPI-S2 spectrometer and Hitachi Model EPS-3T spectrometer, respectively. Gas chromatographic analyses were carried out on a Shimadzu Model GC-1C chromatograph and NMR spectra were taken on a JEOL C-60H instrument with tetramethylsilane as an internal reference.

H, 5.99%. Treatment with sodium cyanate and phenyl isocyanate afforded *N*-pent-2-en-4-ynylurea, mp 103—104°C (EtOH); Found: C, 57.49; H, 6.64%. Calcd for $C_6H_8ON_2$: C, 58.05; H, 6.50%, and *N*-phenyl-*N'*-pent-2-en-4-ynylurea, mp 137—137.5°C (EtOH); Found: C, 71.81; H, 6.33%. Calcd for $C_{12}H_{12}ON_2$: C, 71.98; H, 6.04%, respectively. Reaction with carbon disulfide gave pent-2-en-4-ynylammonium pent-2-en-4-ynyldithiocarbamate, mp 89—90°C; Found: C, 55.19; H, 6.21%. Calcd for $C_{11}H_{14}N_2S_2$: C, 55.43; H, 5.92%.

Ethyl Pent-2-en-4-ynylxanthate (VIII). 5-Bromopent-3-en-1-yne (14.5 g) (0.1 mol) was added at 5—8°C to a solution of sodium ethylxanthate in 60 m*l* of ethanol. After the mixture had been stirred for 1.5 hr at room temperature, sodium chloride was filtered out and the filtrate was concentrated *in vacuo*. The residue was distilled to give 11.1 g (59.7%) of a pale yellow liquid, bp 82—84°C/0.3 mmHg, n_D^{20} 1.5880; ν_{max}^{film} 3260, 2100, 1625, 1050 (–S–C(=S)–O–),[10] and 950 cm^{-1}; λ_{max}^{EtOH} 227.5 (ε=21500) and 282.5 mμ (ε=12800).[10] Found: C, 50.78; H, 5.71%. Calcd for $C_8H_{10}OS_2$: C, 51.58; H, 5.41%.

***S*-Pent-2-en-4-ynylisothiuronium Bromide (IX).** 5-Bromopent-3-en-1-yne (14.5 g) (0.1 mol) was added, portion by portion, to a hot solution of thiourea (7.6 g) (0.1 mol) in 180 m*l* of ethanol. After the mixture had been warmed for 3 hr at 50°C, the ethanol was evaporated to give white crystals (25.7 g) (97.0%), mp 142—144°C. Recrystallization from ethanol-isopropyl ether gave the pure IX, mp 146.5—147°C; ν_{max}^{KBr} 3300, 3100, 2100, and 958 cm^{-1}; λ_{max}^{EtOH} 229 mμ (ε=21600). Found: C, 32.63; H, 4.35%. Calcd for $C_6H_9N_2OBr$: C, 32.59; H, 4.10%.

Pent-2-en-4-ynylthiol (VII). *A) Reaction of 5-Bromopent-3-en-1-yne with Potassium Hydrosulfide.* A solution of 5-bromopent-3-en-1-yne (7.5 g) (0.05 mol) in 5 m*l* of acetone was added at room temperature for 30 min to aqueous potassium hydrosulfide prepared by the passage of hydrogen sulfide into a solution of potassium hydroxide (2.8 g) (0.05 mol) in 10 m*l* of water. After the mixture had been stirred for an additional hour, the resulting mixture was extracted with ether. The ether was dried over anhydrous sodium sulfate; the concentrate was distilled *in vacuo* to give 2.3 g (47.0%) of a colorless liquid, bp 46—47°C/15 mmHg, n_D^{20} 1.5580; ν_{max}^{film} 3300, 2550, 2050 ,1625, and 955 cm^{-1}; λ_{max}^{EtOH} 229 mμ (ε=9700).

Reaction with 2,4-dinitrochlorobenzene gave the 2,4-dinitrophenyl sulfide, mp 106.5—107.5°C (EtOH). Found: C, 49.68; H, 3.42%. Calcd for $C_{11}H_8O_4N_2S$: C, 50.00; H, 3.30%.

B) From Ethyl Pent-2-en-4-ynylxanthate. A saturated ammonia solution in 16 g of ethanol was stirred, drop by drop, into pent-2-en-4-ynylxanthate (4.2 g) (0.02 mol) at 55—60°C, then the mixture was stirred for 1.5 hr. The residue obtained after evaporating the solvent was distilled to give 1.1 g (55.0%) of a colorless liquid, bp 48—49°C/16 mmHg. The infrared spectrum of the product was in complete accord with that of the VII prepared by method A.

p-Tolyl Pent-2-en-4-ynyl Sulfide (X). 5-Bromopent-3-en-1-yne (7.1 g) (0.05 mol) was added at room temperature to a solution of *p*-thiocresol (6.2 g) (0.05 mol) and sodium ethoxide, prepared from sodium (1.2 g) (0.05 mol) and 35 m*l* of ethanol. After the mixture had been warmed for 1 hr, the precipitated sodium bromide was filtered; after the ethanol had been evaporated, the filtrate was extracted with ether. The ether extract was dried over anhydrous sodium sulfate and evaporated. The residue was distilled, giving 7.3 g (77.7%) of a liquid, bp 91—93°C/0.3 mmHg, n_D^{20} 1.5944; ν_{max}^{film} 3300, 2050, 1625, 1600, 1495, 955, and 800 cm^{-1}; λ_{max}^{EtOH} 227 mμ (ε=20700). Found: C, 75.92; H, 6.65%. Calcd for $C_{12}H_{12}S$: C, 76.55; H, 6.42%.

Pent-2-en-4-ynylthioacetic Acid (XI). 5-Bromopent-3-en-1-yne (15.2 g) (0.11 mol) was added at room temperature to a solution of sodium hydroxide (8.0 g) (0.2 mol) and thioglycolic acid (9.2 g) (0.1 mol) in 200 m*l* of water, after which the mixture was stirred for 20 hr at room temperature. The reaction mixture extracted with ether to remove the unreacted bromide. The water layer was acidified with 20% dilute sulfuric acid and extracted with ether. The ethereal extract, after being washed with water, dried over calcium chloride, and evaporated, was distilled to give 5.3 g (34.0%) of pale yellow liquid, bp 111—113°C/0.3 mmHg, n_D^{20} 1.5537; ν_{max}^{film} 3250, 3100—2900, 2070, 1710, and 955 cm^{-1}; λ_{max}^{EtOH} 229 mμ (ε=12200). Mol; Found by alkali titration: 157.1. Calcd for $C_7H_8O_2S$: 156.2.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 2593—2595 (1969)

The Absolute Configuration of Isopropylidenecamphor Oxide

Jun KATSUHARA

Sun Star Dentifrice Company, Research Laboratory, Takatsuki, Osaka,

(Received December 5, 1968)

The conversion of (+)-isopropylidenecamphor derived from (+)-camphor into (1R:2S:4S)-isopropylideneborneol and (1R:2R:4S)-isopropylideneisoborneol was described. In light of this configurational correlation, it was concluded that (+)-isopropylidenecamphor oxide derived from isopropylideneborneol has (1R:3R:4S)-, and (−)-isopropylidenecamphor oxide derived from isopropylideneisoborneol, (1R:3S:4S)-configurations.

Djerassi and coworkers[1] have shown that the reversed octant rule is applicable to the Cotton effect at n-π^* transition of transoid cyclopropyl- and epoxy-ketones. To date, however, the optical rotatory dispersion curves of cisoid epoxy-ketones have been reported only with scanty examples and it has not yet been known whether or not the reversed octant rule is applicable to cisoid epoxy-ketones. With a view to formulating the relationship between the Cotton effect and the absolute configuration of cisoid epoxy-ketones, the author has recently reported the assignment of absolute configuration of *trans*- and *cis*-pulegone oxides,[2] *trans*- and *cis*-pinocarvone oxides[3] and discussed the ORD data obtained with these epoxides.

We wish, to describe the determination of absolute configurations of *trans*- and *cis*-isopropylidenecamphor oxides and to report the ORD and CD spectra thereof.

(+)-α-Bromocamphor (**2**), obtained by the bromination of (+)-camphor in the presence of anhydrous aluminum chloride, was grignardized and condensed with acetone in tetrahydrofuran to give a mixture of (+)-camphor (**1**), (+)-α-bromocamphor (**2**), 3-α-hydroxyisopropylcamphor (**3**) and (+)-isopropylidenecamphor (**4**) in the ratio of 44 : 16 : 16 : 24 as determined by VPC analysis. (+)-Isopropylidenecamphor (**4**) was obtained pure from the mixture and was then oxidized with 30% hydrogen peroxide in methanolic 30% sodium hydroxide solution to afford a mixture of *trans*- and *cis*-isopropylidenecamphor oxides. Separation of the mixed isomers was achieved by preparative VPC which afforded chemically pure (+)-**5** (oily) and (−)-**6** (mp 42°C) in an isomer ratio of 33:67.

(+)-Isopropylidenecamphor (**4**) was reduced with lithium aluminum hydride to yield the corresponding alcohol mixture consisting of the crystalline **7** (mp 88°C) in 9 parts and the liquid diastereomeric alcohol **8** in 91 parts.

Beckmann[4] reported that the lithium aluminum hydride reduction of camphor gave isoborneol (exo alcohol) which resulted from the attack of the hydride reagent to the less hindered side of camphor, *i. e.* opposite the geminal dimethyl group. Accordingly, judging from the product ratio found for the present reduction, it may be deduced that the major product **8** is (1R:2R:4S)-isopropylideneisoborneol and the minor diastereomer **7** is (1R:2S:4S)-isopropylideneborneol.

This assignment is supported also by the NMR analysis[5] of these diastereomeric alcohols **7** and **8**. The Δ value, 17.4 Hz, found for chemical shift of C-8 methyl group in **8** reasonably supported the *cis*-configuration of hydroxyl group relative to the methyl group. (See Table 1)

TABLE 1. CHEMICAL SHIFT (τ) OF METHYL GROUP

	7 (endo)			8 (exo)

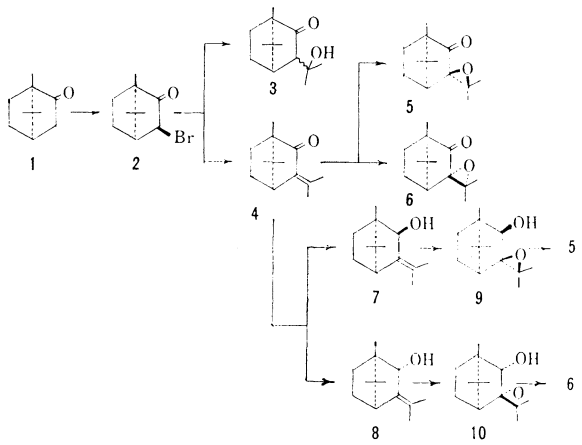


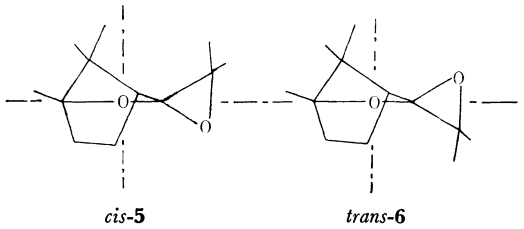
Scheme I.

Epoxidation with perbenzoic acid of **7** and **8** in chloroform afforded the *β*-epoxide (**9**)[6] of the (1R:2R:3R:4S)-configuration and the *α*-epoxide (**10**) having the (1R:2S:3S:4S)-configuration, respectively. These diastereomeric epoxides **9** and **10** were then oxidized with chromic acid in acetone, when (+)-*cis*-(1R:3R:4S)-isopropylidenecamphor oxide (**5**) was obtained from **9** and (−)-*trans*-(1R:3S:4S)-isopropylidenecamphor oxide (**6**) from **10**, the absolute configurations naturally having followed from the respective parent compounds. Compounds **5** and **6**, which were derived *via* an alternative route of transformation from the same parent ketone (**4**), were identified by means of IR- and VPC-comparison with (+)-*cis*-**5** and (−)-*trans*-**6** (See Scheme 1.).

Based on the ORD-studies of various bicyclo-[2.2.1]heptanone systems, Klyne[7] suggested that the octant rule is applicable to bicycloheptanone systems and accounted for the contribution of substituents to the overall ORD of the systems. For example, the ORD contributions of C-8 ,C-9 and C-10 in camphor was estimated as $a=+96$, by comparing the molar amplitude (+71) found for camphor[8] with that (−25) for camphenilone.

When this empirical generalization is applied to the systems **5** and **6**, whose octant projection diagrams are shown in Scheme II, the contribution of oxirane ring to the overall ORD of the respective diastereomeric isopropylidenecamphor oxides may be calculated in the same way: the *β*-oxirane group in **5** has a positive contribution (in ORD), $a=72-71=+1$ whereas the *α*-oxirane in **6** has a negative one, $a=41-71=-30$.

The magnitude of the amplitude contribution by the substituents in the ORD curve of the present



cis-**5** *trans*-**6**

Scheme II.

cisoid epoxy-ketone is too small to draw any definite conclusion on the validity of the reversed octant rule being applied to transoid epoxy-ketones in general.

Experimental[9]

Bromination of Camphor (1). Bromine (121 g) was added dropwise with stirring during 2 hr into a mixture of camphor (mp 178°C, $[\alpha]_D^{25}$ +44.18° (*c* 0.94, ethanol): 100 g, 0.66 mol) and anhydrous aluminum trichloride in 200 m*l* of dried carbon tetrachloride and the reaction mixture was stirred for further 6 hr at 60°C. After removal of solvent *in vacuo*, the crude product was washed with chilled *n*-hexane to give (+)-*α*-bromocamphor (**2**), mp 77°C, $[\alpha]_D^{20}$ +136.0±0.4° (*c* 0.89, ethanol), UV λ_{max}^{MeOH} m*μ* (*ε*), 306 (97): CD m*μ* ([*θ*]) in methanol, 350 (0), 315 (+5645), 265 (0), 220 (−1392), 212 (0), 205 (+5721), 34% yield.

Preparation of Isopropylidenecamphor (4). *α*-Bromocamphor (**2**) (35 g, 0.15 mol) in 280 m*l* of tetra-

9) Infrared spectra were recorded on a Shimadzu Model 27-G spectrophotometer. Optical rotatory dispersion and circular dichroism measurements were made on a Nippon Bunko Spectropolarimeter Model ORD/UV-5. Optical rotation measurements were recorded on a Perkin-Elmer Model 141 with a 10 cm-cell. Gas-liquid partition chromatography analyses were carried out using a Shimadzu 2-C gas chromatograph. A 3 mm×2.25 m column of 20% Hyporose-80 on Celite-545 served for VPC analyses. Nuclear magnetic resonance spectra were recorded with a Varian A-60 spectrometer.

hydrofuran was added to 3.5 g (0.14 g atom) of magnesium in 20 m*l* of THF under a nitrogen atmosphere during 1 hr. After 3 hr stirring, acetone (41 m*l*, 0.64 mol) was added to the reaction mixture and was reacted for 4 hr. The reaction mixture was poured onto ice-water and the organic layer was extracted with ether after ammonium chloride solution was added. Ethereal extracts were combined, washed and dried. Removal of solvent under reduced pressure yielded a crude product (27.9 g, 99%), which was analyzed by VPC. The product consisted of 44% **1**, 16% **2**, 16% 3-α-hydroxyisopropylcamphor (**3**),[10] mp 88°C, Found: C, 74.58; H, 10.61%. Calcd for $C_{13}H_{22}O_2$: C, 74.22; H, 10.56%, and 24% (+)-isopropylidenecamphor (**4**), liquid, $[\alpha]_D^{22}$ +201.1±6.6° (*c* 0.36, methanol), UV λ_{max}^{MeOH} mμ (ε), 248 (9110), 332 (70): CD mμ ([θ]) in methanol, 377 (0), 335 (+980), 305 (+1076), 250 (+21573), 210 (0).

Preparation of Mixture of Isopropylidenecamphor Oxides. A mixture of (+)-**4** (5 g, 0.038 mol) in methanol (50 m*l*) and 50 m*l* of 30% hydrogen peroxide in 50 m*l* of water was kept at 60°C, and to this was added dropwise a 30% aqueous solution (50 m*l*) of sodium hydroxide over a 30 min period. Stirring was continued for 7 hr, the temperature being maintained at 60°C. The reaction mixture was poured into 100 m*l* portion of ether, and the organic layer was separated and worked up as usual to give a crude product (4.5 g). The VPC analysis indicated that the crude product contained 33% of **5** and 67% of **6**.

Isolation and Properties of Pure Isopropylidenecamphor Oxides (5) and (6). Isolation of each diastereomer from the mixture was effected by preparative VPC. Further purification of the fraction on a silica gel column gave pure **5**: the IR-spectrum exhibited the following peaks ν_{max} 1760, 1380, 910 cm^{-1}: $[\alpha]_D^{28}$ +176.3±2.4° (*c* 0.9, methanol): ORD mμ ([φ]) in methanol, 400 (+1300), 333 (+5312), 295 (−1887), 228 (+7316), 210 (−7712): CD mμ ([θ]) in methanol, 350 (0), 316 (+5536), 255 (+184), 215 (+12263), 208 (+9073): UV λ_{max}^{MeOH} mμ (ε), 310 (50), Found: C, 74.37; H, 9.71%. Calcd for $C_{13}H_{20}O_2$: C, 74.94; H, 9.70%, and **6**: the IR-spectrum main bands ν_{max} 1750, 1380, 1015, 960, 930, 920, 830, 770 cm^{-1}; $[\alpha]_D^{28}$ −21.7±0.7° (*c* 0.9, methanol): ORD mμ ([φ]) in methanol, 400 (+343), 334 (+1532), 298 (−2475), 294 (−2541), 276 (−2312), 226 (−7728), 206 (+8608): CD mμ ([θ]) in methanol, 347 (0), 318.5 (+2477), 265 (0), 213 (−9554), 207 (−6176): UV λ_{max}^{MeOH} mμ (ε), 310 (49), mp 42°C, Found: C, 74.70; H, 9.70%. Calcd for $C_{13}H_{20}O_2$: C, 74.94; H, 9.70%.

Lithium Aluminum Hydride Reduction of Isopropylidenecamphor (4). Isopropylidenecamphor (5 g, 0.038 mol) dissolved in absolute ether (30 m*l*) was added dropwise with stirring to a chilled (−10°C) slurry of lithium aluminum hydride (3 g, 0.079 mol) in ether. Upon completion of addition, the reaction mixture was stirred at 0°C for an additional hr and then at 15—20°C for 10 hr, and finally, refluxed for 2 hr. Excess hydride was then decomposed by addition of moistened ether under effective cooling. The organic layer was separated, filtered and dried. Removal of ether gave a mixture of **7** and **8** (yield 4.5 g, 89%). The alcohols **7** and **8** were obtained pure by means of silica gel chromatography: **7**, 9 parts, mp 88°C, Found: C, 80.27; H, 11.39%. Calcd for $C_{13}H_{22}O$: C, 80.35; H, 11.41%, and its NMR spectrum indicated in $CDCl_3$ three three-hydrogen singlets (τ 9.23, 9.12, 9.00) for methyl at C-9, C-8, C-10, a three-hydrogen doublet (τ 8.36, *J*=1.5 Hz) for methyl at C-12, a three-hydrogen singlet (τ 8.25) for methyl at C-11, one-hydrogen doublet (τ 7.69, *J*=4.0 Hz) at C-4, and one-hydrogen singlet (τ 5.77) for the hydrogen on the carbon bearing the hydroxyl group; in pyridine three three-hydrogen singlets (τ 9.15, 9.10, 8.97) for methyl at C-9, C-8, C-10, a three-hydrogen doublet (τ 8.30, *J*=1.5 Hz) for methyl at C-12, a three-hydrogen singlet (τ 8.05) for methyl at C-11, one-hydrogen doublet (τ 7.60, *J*=4.0 Hz) at C-4, and one-hydrogen singlet (τ 5.55) for the hydrogen on the carbon bearing the hydroxyl group; **8**, 91 parts, liquid, $[\alpha]_D^{20}$ +127.7±0.8° (*c* 0.4 ethanol), and its NMR spectrum indicated in $CDCl_3$ three three-hydrogen singlets (τ 9.17 9.05, 9.02) for methyl at C-9, C-10, C-8, a three-hydrogen doublet (τ 8.32, *J*=1.0 Hz) for methyl at C-12, a three-hydrogen singlet (τ 8.18) for methyl at C-11, one-hydrogen doublet (τ 7.59, *J*=4.0 Hz) at C-4, and one-hydrogen singlet (τ 6.12) for the hydrogen on the carbon bearing the hydroxyl group; in pyridine three three-hydrogen singlets (τ 9.12, 8.90, 8.73) for methyl at C-9, C-10, C-8, a three-hydrogen doublet (τ 8.27, *J*=1.0 Hz) for methyl at C-12, a three-hydrogen singlet (τ 8.03) for methyl at C-11, one-hydrogen doublet (τ 7.53, *J*=4.0 Hz) at C-4, and one-hydrogen singlet (τ 5.87) for the hydrogen on the carbon bearing the hydroxyl group.

Preparation of *cis*- (5) and *trans*-Isopropylidenecamphor Oxide (6). To an ice-cold solution of perbenzoic acid in chloroform was added 0.26 g of **7** in 5 m*l* of chloroform. The reaction mixture was kept at 0°C for 16 hr. The reaction mixture was then washed with 5% sodium carbonate solution and dried over anhydrous sodium sulfate. Removal of solvent under reduced pressure gave an oily residue, which upon purification on an alumina column, afforded the epoxide **9** (0.13 g). A solution of **9** (100 mg) in acetone (1 m*l*) was added to a solution of chromic acid (55 mg) in water (1 m*l*) containing sulfuric acid (0.2 m*l*) with stirring at 0°C for 1 hr. Water (5 m*l*) was added and the reaction mixture was extracted with ether. The combined ether extract was washed with a 3% sodium hydrogencarbonate solution, water, and then dried over anhydrous sodium sulfate. Removal of solvent yielded a crude product (82 mg), which was then purified by silica gel column chromatography to give pure **5**. In exactly the same manner as described above, epoxidation of **8** (0.64 g) with perbenzoic acid furnished an oily epoxide (**10**) (0.42 g), which in turn, was further oxidized with chromic anhydride to give **6** (0.31 g).

The author wishes to thank Professor T. Matsuura of Hiroshima University, Professor Y. Inouye of Kyoto University, Dr. H. Minato, Dr. K. Kuriyama and Dr. K. Tori of Shionogi Research Laboratory, Dr. M. Kobayashi, Mr. M. Yasufuku, Mr. K. Hashimoto and Mr. H. BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 2596—2599 (1969)

The Cobalt Carbonyl-catalyzed Hydroesterification of 3-(β-Cyanoethoxy)propene with Carbon Monoxide and Methanol

Akio MATSUDA

Government Chemical Industrial Research Institute, Tokyo, Mita, Meguro-ku, Tokyo

(Received December 20, 1968)

The cobalt carbonyl-catalyzed hydroesterification of 3-(β-cyanoethoxy)propene with carbon monoxide and methanol occurred in the presence of a small amount of hydrogen at a moderate temperature, methyl 4-(β-cyanoethoxy)butyrate being produced in a much larger amount than methyl 2-methyl-3-(β-cyanoethoxy)propionate. The double-bond isomerization leading to the formation of propionaldehyde dimethylacetal and ethylene cyanohydrin occurred simultaneously. The selectivity to the double-bond isomerization was very large at a low pressure; it decreased as the pressure was increased, with a corresponding increase in selectivity to the hydroesterification. The reaction rate was not increased by the addition of pyridine, but it was increased about tenfold by the addition of palladium chloride. Thus, the reaction could be carried out at a lower temperature in the presence of palladium chloride. The selectivity to the hydroesterification, however, did not increase upon the addition of palladium chloride, as the double-bond isomerization was also accelerated by its addition.

In a preceding paper on the intramolecular hydroesterification of allyl alcohol with carbon monoxide,[1] it was reported that the selectivity to the hydroesterification product, γ-butyrolactone, could not exceed 60% because of the simultaneous isomerization of allyl alcohol into propionaldehyde.

In the present study, in this connection, the hydroesterification of 3-(β-cyanoethoxy)propene, an etheric derivative of allyl alcohol, is studied with the intention of obtaining methyl 4-(β-cyanoethoxy)-butyrate in a good yield. The reaction proceeds in the presence of a small amount of hydrogen at a moderate temperature; methyl 4-(β-cyanoethoxy)-butyrate and methyl 2-methyl-3-(β-cyanoethoxy)-propionate are produced as the hydroesterification products, there being much more of the former than of the latter. However, an unexpected side-reaction leading to the formation of propional-dehyde dimethylacetal and ethylene cyanohydrin occurs to a considerable extent.

Experimental

The 3-(β-cyanoethoxy)propene was prepared by the cyanoethylation of allyl alcohol with acrylonitrile in the presence of sodium methoxide, and then distilled (73°C/3 mmHg). The propoxypropionitrile and methoxypropionitrile were also prepared by the cyanoethylation of propanol and methanol with acrylonitrile. The propionaldehyde dimethylacetal and isobutyraldehyde dimethylacetal were prepared by the reaction of methanol with propionaldehyde and isobutyraldehyde. The carbon monoxide and dicobalt octacarbonyl were prepared by a procedure described previously.[2] The palladium chloride and the other reagents were obtained commercially. The methanol and pyridine were rectified before use.

The reactions were carried out in the same 300-cc stainless-steel autoclave and with the same technique as was described previously;[2,3] the reaction was started at a desired temperature by dropping in dicobalt octacarbonyl, packed in a stainless-steel saucer, from a wing of the stirrer. The total pressure was kept constant during the reaction by supplying carbon monoxide from a pressure-storage vessel through a pressure regulator; the reaction temperature was controlled within ±1°C. The product composition was quantitatively determined by the gas-chromatographical method in a manner similar to that already described.[1]

Product Identification. The NMR spectra were measured at 100 Mc in carbon tetrachloride, with tetramethylsilane as the internal standard.

Methyl 4-(β-cyanoethoxy)butyrate: bp *ca.* 100°C/10^{-2} mmHg. IR spectrum: C=O (ester) 1735 cm^{-1}, C≡N 2240 cm^{-1}. Results and Discussion

The Effect of Bases. In connection with the previous finding that the rate of the hydroesterification in the presence of a small amount of hydrogen is selectively increased by the addition of pyridine(Py),[1-4] the effects of such bases as Py and sodium methoxide on the present reaction were first examined.

The results are shown in Table 1. The first-order rate constant, k, was calculated according to the half-time method by means of this equation: $k=\ln 2\,/t_{1/2}$. The half-time, $t_{1/2}$, was estimated from the gas-supplying curve during the reaction and the final conversion, on the assumption that the amount of gas supplied was proportional to the amount of the reacted olefin. The ratio of methyl 4-(β-cyanoethoxy)butyrate to methyl 2-methyl-3-(β-cyanoethoxy)propionate was very large (30—40), indicating that the terminal methoxycarbonylation predominated in this case; this trend is the same as that observed in the hydroesterification of propylene and methyl acrylate.[2,4] The selectivity to β-propoxypropionitrile resulting from the hydrogenation of 3-(β-cyanoethoxy)propene was less than 1%. Propionaldehyde dimethylacetal and ethylene cyanohydrin were produced in equimolar amounts. Propionaldehyde dimethylacetal may result from the double-bond isomerization of 3-(β-cyanoethoxy)-propene, followed by the reaction with methanol. The other possible route involving the formation of allyl alcohol as an intermediate is not important, since, if such a route were important, γ-butyro-

lactone would result from the intramolecular hydroesterification of the intermediate allyl alcohol in a yield comparable with that of propionaldehyde dimethylacetal,[1] whereas the amount of γ-butyrolatone in the product was very small compared with the amount of propionaldehyde dimethylacetal.

The results of experiments carried out at various pressures, keeping the other conditions equal to those in Expt. No. 2, are shown in Fig. 1. The double-bond isomerization is presumed to be catalyzed by cobalt hydrotricarbonyl, since the selectivity to propionaldehyde dimethylacetal was very large at a low pressure, as had been observed in the previous study.[1]

$$\begin{array}{l} CH_2CH{=}CH_2 \\ \quad | \\ OCH_2CH_2CN \end{array} \xrightarrow{HCo(CO)_3} \begin{array}{l} CH{=}CHCH_3 \\ \quad | \\ OCH_2CH_2CN \end{array} \xrightarrow[-HOC_2H_4CN]{+2CH_3OH} CH_3CH_2CH(OCH_3)_2 \qquad (1)$$

As the pressure increased from 50 to 300 kg/cm^2, the selectivity to propionaldehyde dimethylacetal decreased and the selectivity to the hydroesterification products increased. The rate constant, k, showed a peak at 100 kg/cm^2; it began to decline as the pressure increased from 100 to 300 kg/cm^2. These effects of the total pressure are clearly due to the carbon monoxide partial pressure, since the rate constant, k, decreases by decreasing the hydrogen partial pressure, while the selectivity to propionaldehyde dimethylacetal remains unchanged (compare Expt. No. 6 with No. 2).

The addition of such bases as Py and sodium methoxide did not affect the reaction rate, but it increased the selectivity to the hydroesterification products. This increase in the selectivity seems to be the direct consequence of the fact that the residue is remarkably reduced by the addition of these bases. The residue is a mixture of unidentified polymers, probably resulting from the hydroformylation of 3-(β-cyanoethoxy)propene, followed by the polymerization of the resulting aldehydes; this is in accordance with the fact that the residue is considerably reduced by decreasing the hydrogen content of the gas used (Expt. No. 6), since the selectivity to the hydroformylation decreases upon a decrease in the hydrogen partial pressure.[2] The residue also decreases upon a decrease in the reaction temperature, resulting in an increased selectivity to the hydroesterification products.

In a preceding study of the hydoesterification of acrylonitrile, it was found that the addition of Py is effective in increasing the rate of the hydroesterification because it accelerates the formation of an acylcobalt carbonyl-intermediate, and that the methanolysis of this intermediate is very fast.[3] Consequently, the rate-determining step in the present reaction is not the formation of an acylcobalt carbonyl-intermediate, since the reaction rate in this case does not increase with the addition of pyridine. Therefore, the most probable rate-determining step in the present reaction is the formation of an alkylcobalt carbonyl-intermediate from olefin and cobalt hydrocarbonyl. If the formation of an alkylcobalt carbonyl-intermediate from olefin and cobalt hydrocarbonyl is really the rate-determining step, the reaction rate would probably be affected by weakening the olefinic double-bond by coordination.

The Effect of Palladium Chloride. Olefins can be activated by the π complex formation with palladium chloride to undergo reactions with various nucleophiles.[5] It has also been said that a palladium-compex can catalyze the carbonylation of olefins because it can activate the olefinic double-bond by the π complex formation.[6] Therefore, it seems probable that the reaction between an olefin and cobalt hydrocarbonyl can also be catalyzed by palladium chloride.

The results of experiments carried out in the presence of palladium chloride are shown in Table 2. Expectedly, the effect of palladium chloride on the rate was very remarkable. The rate constant, k, increased about tenfold upon the addition of a small amount of palladium chloride. The rate constant, k, in the presence of a small amount of palladium chloride was further increased by the addition of Py equimolar to dicobalt octacarbonyl. Thus, the reaction could be carried out at 90°C in the presence of small amounts of palladium chloride and Py (Expt. No. 9).[7] However, the selectivity to the hydroesterification products decreased upon the addition of palladium chloride, while the selectivity to propionaldehyde dimethylacetal increased; this is because palladium chloride accelerates the double-bond isomerization to a larger extent than it does the hydroesterification. The fairly large amount of γ-butyrolactone which is found in the products of the reactions carried out in the presence of palladium chloride probably results from the decomposition of methyl 4-(β-cyanoethoxy)butyrate, since the formation of allyl alcohol as an intermediate is unlikely, as has been mentioned before. In fact, such a decomposition took place when the products were distilled at a high temperature:

$$\begin{array}{l} CH_2CH_2CH_2COOCH_3 \\ \quad | \\ OCH_2CH_2CN \end{array} \longrightarrow \begin{array}{l} H_2C{-}CH_2 \\ \quad | \quad | \\ H_2C \quad C{=}O \\ \quad \backslash O / \end{array} + (CH_2{=}CHCN)_n + CH_3OH \qquad (2)$$

The residue	17	15	8	12	12

a) *Cf.* Table 1.
b) The selectivity to isobutyraldehyde dimethylacetal in each run was less than 1%.

That the amount of γ-butyrolactone produced was small in the reaction carried out at 90°C (Expt. No. 9) is understandable, since the decomposition of methyl 4-(β-cyanoethoxy)butyrate would be slow at such a low temperature.

Although the reaction rate in the presence of palladium chloride increased upon the addition of Py, this is not because the carbon monoxide-insertion steps are accelerated by Py, for the selectivity to the hydroesterification product is not affected by the addition of Py. The effect of Py on the rate in this case should, therefore, be quite different from those observed in former studies;[1-4] this effect may be attributable to, for example, the activation of palladium chloride by Py.

In conclusion, it can be said to be certain that the formation of an alkylcobalt carbonyl-intermediate can be accelerated by palladium chloride, but not by Py alone; this is consistent with the former assumption that Py was effective in increasing the rate of the hydroesterification because it accelerated the carbon monoxide-insertion step by forming the acylcobalt carbonyl-Py complex:[3]

$$RCo(CO)_4 + Py \rightarrow RCOCo(CO)_3(Py) \xrightarrow[\text{fast}]{+CH_3OH} RCOOCH_3 + HCo(CO)_3 + Py$$

A more extensive study of the effect of palladium chloride is now in progress.

Coumarins. VII. The Acid-catalyzed Reaction of Aromatic Compounds with β-Chlorocarboxylic Acids[1]

Kikumasa SATO,* Yau-Shin LIN* and Takeshi AMAKASU**

* *Department of Applied Chemistry, Faculty of Engineering, Yokohama National University, Ohka-machi, Minami-ku, Yokohama*

** *Chemical Laboratory, Seimi Chemical Co., Ltd., 2645, Chigasaki, Chigasaki-shi, Kanagawa*

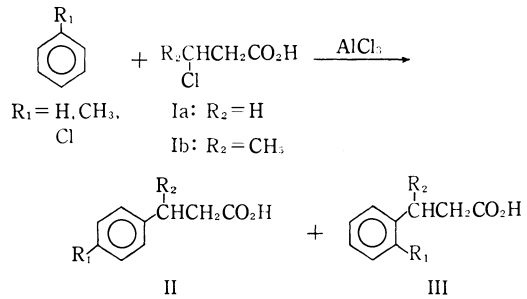
(Received December 31, 1968)

The aluminum chloride-catalyzed reaction of aromatic compounds, such as benzene and phenols, with β-chlorocarboxylic acids was investigated. Although the reactions of benzene, toluene, and chlorobenzene with β-chloropropionic acid were found to give the corresponding dihydrocinnamic acids in high yields, attempts to prepare dihydrocoumarin by a similar reaction of phenol were unsuccessful. Similarly, β-arylbutyric acids were obtained in good yields by means of the aluminum chloride-induced reaction of aromatic hydrocarbons with β-chlorobutyric acid (Ib). In contrast, phenols, such as phenol, *o*- and *m*-cresols, reacted with Ib under similar conditions to provide the corresponding β-(*p*-hydroxyphenyl)butyric acids in 22—60% yields, while a 51% yield of β-(5-hydroxy-2-methylphenyl)butyric acid was obtained upon a similar treatment of *p*-cresol with the acid Ib.

An earlier paper in this series[2] has demonstrated that the aluminum chloride-catalyzed reaction of phenols with crotonic acid gives 4-methydihydrocoumarins or their isomers and that dihydroumbelliferone is obtained by the reaction of resorcinol with acrylic acid in the presence of the ethyl ester of polyphosphoric acid. These studies have been extended to the corresponding β-chlorocarboxylic acids. Whereas the acid-catalyzed reactions of aromatic compounds with α,β-unsaturated acids have been extensively studied, little attention has been given to the similar reaction with β-chlorocarboxylic acids.

It has been shown[3] that the condensation of aromatic compounds, such as benzene, toluene, and chlorobenzene, with β-chlorocarboxylic acids, such as β-chloropropionic acid (Ia) and β-chlorobutyric acid (Ib), in the presence of aluminum chloride gives the corresponding indanones; no yields have been given, however. The aluminum chloride-catalyzed reactions of benzene with Ia[4] and with its ethyl ester[5] have previously been shown to provide dihydrocinnamic acid. Recently Dann and his coworkers[6] have reported that phenols condense with Ia in hydrofluoric acid to afford β-chloro-2-hydroxypropiophenones. No method of preparing dihydrocoumarins by the acid-catalyzed reaction of phenols with I has yet appeared in the literature.

In the present study we have examined the condensation of such aromatic compounds as phenols with Ia and Ib, using anhydrous aluminum chloride or boron trifluoride etherate.



II III

A convenient method of preparing dihydrocinnamic acid (II, $R_1=R_2=H$) was developed by the use of at least two molecular proportions of aluminum chloride for the reaction of benzene with Ia. Similarly, toluene reacted with Ia at 50—55°C for 5 hr to give a high-total yield of the corresponding

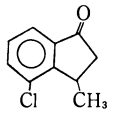
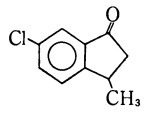
a) The inert solvent used was *sym*-tetrachloroethane (50 m*l*).
b) Attempts to isolate the individual compounds were unsuccessful.

dihydrocinnamic acids, II and III ($R_1=CH_3$, $R_2=H$), in the same ratio as that of II to III ($R_1=$ Cl, $R_2=H$). On the other hand, Ib, when treated with benzene in the presence of 2 equivalents of aluminum chloride at 65—70°C, furnished β-phenylbutyric acid (II, $R_1=H$, $R_2=CH_3$) in a 70% yield. Toluene behaved analogously when treated with Ib, giving the corresponding butyric acids, II and III ($R_1=R_2=CH_3$). While the reaction of chlorobenzene with Ib at 100°C gave the corresponding indanones, IVa (56%) and IVb (16%), under mild conditions a mixture of their precursors, II and III ($R_1=Cl$, $R_2=CH_3$), was obtained in a 33% yield. These results, summarized in Table 1, indicate the predominant alkylation rather than acylation of aromatic compounds with I; they also confirm, along with the infrared spectra and their physical properties, the II and III structures for the β-arylacids.

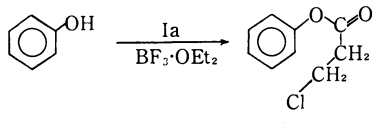


IVa



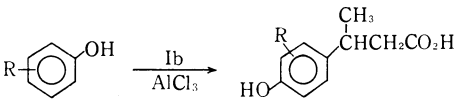
IVb

Although attempts to prepare dihydrocoumarin by extending the above results from Ia to phenol failed, phenyl β-chloropropionate (V) was obtained in a 26% yield when phenol was treated with Ia at 85—95°C for 4 hr in boron trifluoride etherate. The infrared spectrum was identical with that of an authentic sample of V.



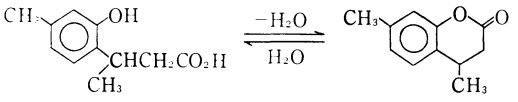
V

In contrast, when phenol was treated with Ib in the presence of 3 equivalents of anhydrous aluminum chloride in *sym*-tetrachloroethane, β-(4-hydroxyphenyl)butyric acid (VIa) was obtained in a 52% yield. The structure follows from the infrared spectrum, which clearly shows hydroxyl and acid C=O bands and an out-of-plane deformation of aromatic C–H at 3100, 1700, and 820 cm^{-1} respectively.



VIa, R=H
b, R=2-CH_3
c, R=3-CH_3

o-Cresol, when treated similarly with Ib, gave the corresponding butyric acid, VIc (22%). The new compound, VIc, was verified by a study of its infrared spectrum and by elemental analysis. With *m*-cresol white crystals, mp 123—124°C, were obtained. The analytical data agreed with the formula $C_{11}H_{14}O_3$, which is in accord with the structure of the *p*-alkylated product, VIb, and the *o*-isomer, VII.



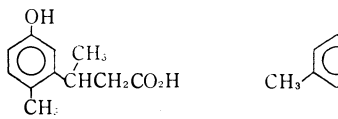
VII VIII

The infrared spectrum exhibited hydroxyl and carbonyl absorptions at 3150 and 1690 cm^{-1} respectively, along with aromatic deformations (860, 820 cm^{-1}). This spectrum does not make it possible to distinguish clearly between VIb and VII. The compound VII, obtained by the hydrolysis of the corresponding dihydrocoumarin, VIII, is known[7] to undergo an intramolecular dehydration cyclization to VIII. Accordingly, attempts to prepare VIII from the product resulted in the recovery of the starting material, VIb. Thus, it may be concluded that the product is β-(4-hydroxy-

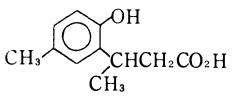
7) T. Nakabayashi, *Yakugaku Zasshi* (*J. Pharm. Soc. Japan*), **74**, 23 (1954).

2-methylphenyl)butyric acid (VIb).

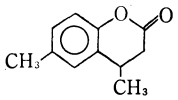
On the other hand, *p*-cresol behaved abnormally when similarly treated with Ib, giving crystals with a melting point of 111—112°C. The product was shown by elemental analysis to have the formula $C_{11}H_{14}O_3$, which is in accord with those of IX and X. The infrared spectrum showed hydroxy and acid C=O absorptions respectively at 3200 and 1710 cm^{-1}, in addition to an out-of-plane deformation of aromatic C–H at 860 and 800 cm^{-1}. The experimental fact that an attempt at cyclization to XI results in the recovery of the starting material may eliminate the possibility of such a structure as the *o*-alkylated product, X. Furthermore, in order to obtain evidence for the structure (IX), conversion to the indanone derivative XII was attempted. Compound IX, upon treatment in polyphosphoric acid (PPA) at 60—70°C for 1 hr, was converted into the corresponding indanone, XII, which gave its semicarbazone. The infrared spectrum of compound XII indicated the presence of a hydroxyl group (3300 cm^{-1}), a ketone carbonyl group (1675 cm^{-1}), and two adjacent hydrogen atoms of substituted benzene (820 cm^{-1}). Thus, the product,



IX

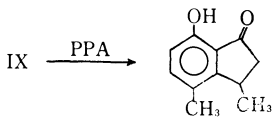


X



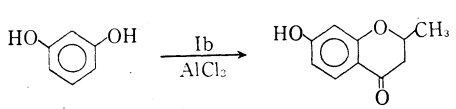
XI

IX, was proved to be *β*-(5-hydroxy-2-methylphenyl)butyric acid.



XII

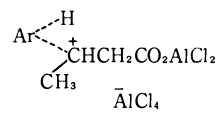
When resorcinol was similarly treated with Ib in the presence of 3.3 equivalents of aluminum chloride at 85—90°C for 5 hr, 7-hydroxy-2-methylchromanone (XIII) was obtained in a 34% yield. The product, XIII, identical in properties with that previously reported, showed an infrared spectrum consistent with the structure of the chromanone derivative.



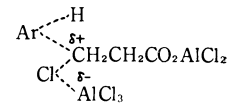
XIII

From the results obtained in this experiment, the following conclusions can be reached. While *β*-chlorocarboxylic acid, Ib, reacts not only with aromatic hydrocarbons and chlorobenzene, but also with phenols (but not resorcinol) to give *β*-arylbutyric acids, the aluminum chloride-catalyzed reaction of Ia takes place only with aromatic compounds, except for the cases of phenols and their ethers. In addition, it should be noted that the formation ratios of II to III are remarkably different between the reaction of Ia and that of Ib (Table 1). These facts suggest that the transition state (*i. e.*, XIV) in the attack of the electrophilic *β*-carbon of Ib on an aromatic nucleus might differ from that of Ia (*i. e.*, XV).

Anhydrous aluminum chloride is believed, of course, to coordinate with a chloro group and not only with a carboxylic group[2,8] but also with the hydroxyl group[9] of a phenol. The observation that the use of at least two and three molecular proportions of aluminum chloride in the reaction of



XIV



XV

aromatic hydrocarbons and of phenols respectively are necessary in order to obtain good yields of the products (II, III and VI, IX) supports this suggestion. In addition, the liberation of hydrogen chloride observed on the cold treatment of I acids with aluminum chloride results from the first step, in which the aluminum salt of I may be formed.

Experimental

All the melting points, determined on a Shimadzu Type MM-2 micro hot stage, and all the boiling points are uncorrected. The infrared spectra were recorded on a Hitachi Model EPI-S2 spectrophotometer, while gas chromatographic analysis were carried out on a Shimadzu Model GC-1C chromatograph.

Materials. *β*-Chloropropionic acid (Ia) (72.5%) was prepared by the addition of dry hydrogen chloride to acrylic acid at 10—20°C[10]; bp 101—103°C/12 mmHg; mp 38.5—40°C (from ligroin) (lit[10] mp 40.5°C). *β*-Chlorobutyric acid (Ib) was obtained in a quantitative yield by the similar treatment of the dry gas with crotonic acid in ether at 0°C for three days; bp 111—112°C/20 mmHg (lit[11] bp 98.5—99.5°C/12 mmHg). The other materials were obtained from commercial sources.

Dihydrocinnamic Acid (II, R_1=R_2=H). *Typical Procedure A.* Fine-powdered anhydrous aluminum chlo-

ride (56.1 g, 0.42 mol) was added slowly to a solution of Ia (21.7 g, 0.2 mol) in 120 ml of benzene, after which stirring was vigorously continued. The mixture was gradually heated on an oil bath and kept under the conditions shown in Table 1. The resulting mixture was chilled and poured over water containing crushed ice and concentrated hydrochloric acid. The organic layer was separated from the aqueous layer, which was then shaken with benzene. The extract was combined with the separated organic material, and then washed with water. After the extract had been dried over anhydrous magnesium sulfate and the solvent had been removed, the residue was distilled under reduced pressure to afford 50.8 g (84%) of a colorless oil; bp 153—155°C/12 mmHg (lit[4] bp 125—126°C/4 mmHg). It solidified after standing for some time. Recrystallization from ligroin gave the pure product; mp 48°C (lit[4] mp 48—49°C): ν_{max}^{KBr} 1700 (C=O), 750, 700 cm^{-1} (mono-substituted).

The product (23 g) was heated in PPA (280 g) at 70°C for 1 hr. The subsequent treatment of the mixture according to the usual manner provided indanone (14.6 g, 70%); mp 38.5°C (from ligroin) (lit[12] mp 40°C).

***p*- and *o*-Methyldihydrocinnamic Acids (II and III; $R_1=CH_3$, $R_2=H$).** The Procedure A shown above was followed, using the molar ratios of the reagents and the conditions listed in Table 1. The fractional recrystallization of the crude products (bp 140—143°C/3 mmHg, mp 50—80°C) from aqueous acetic acid (1 : 1.5, vol) and ligroin furnished II ($R_1=CH_3$, $R_2=H$); mp 115—116°C (lit[13] mp 117°C); ν_{max}^{KBr} 1700 (C=O), 810 cm^{-1} (aromatic C-H).

The recrystallization-mother liquor was extracted with ether and dried. The removal of the ether, followed by fractional distillation, gave 59.2 g of III ($R_1=CH_3$, $R_2=H$), which was then recrystallized from 95% ethanol to afford the pure product; mp 100—102°C (lit[14] mp 102°C); ν_{max}^{KBr} 1700 (C=O), 780 cm^{-1} (ortho-disubstituted).

***p*- and *o*-Chlorodihydrocinnamic Acids (II and III; $R_1=Cl$, $R_2=H$).** These compounds were prepared by means of Procedure A. The reaction was carried out under the conditions presented in Table 1. The resulting organic material, like that described above, was washed with diluted sodium hydroxide (50 ml × 3). Acidification, followed by filtration, gave 8 g of the crude product, II. Recrystallization from water provided colorless crystals; mp 94—96°C (lit[15] mp 91—93°C).

The filtrate was extracted with ether. Drying and the removal of the solvent afford 12 g of the crude compound, III, which was then recrystallized from aqueous ethanol to provide colorless crystals; mp 118—120°C (lit[16] mp 123°C).

Found: C, 58.80; H, 5.19%. Calcd for C_9H_9ClO: C, 58.55; H, 4.91%.

Phenyl β-Chloropropionate (V). To a mixture of 9.4 g (0.1 mol) of phenol and 10.8 g (0.1 mol) of Ia, boron trifluoride etherate (21.3 g, 0.15 mol) was added, drop by drop. The mixture was stirred and heated on an oil bath at 85—95°C for 4 hr. The resulting mixture was poured onto an ice-water slurry. The organic layer was separated from the aqueous layer, which was shaken with ether. The extract was washed with water and with saturated sodium bicarbonate, and then dried over magnesium sulfate. The removal of the ether, followed by distillation, gave V (3.9 g, 26%) as a colorless oil; bp 94—95°C/2 mmHg (lit[17] bp 132—135°C/12 mmHg); ν_{max}^{film} 1750 (ester, C=O), 750, 690 cm^{-1} (monosubstituted).

Found: C, 58.43; H, 5.10%. Calcd for $C_9H_9ClO_2$: C, 58.55; H, 4.91%.

β-Phenylbutyric Acid (II, $R_1=H$, $R_2=CH_3$). This compound was prepared according to Procedure A using the conditions shown in Table 1. The resulting extract was shaken with diluted sodium hydroxide, and the alkaline layer was acidified with hydrochloric acid. Extraction with ether, drying, and the subsequent removal of the solvent gave a crude oil, which was fractionated to yield the pure product (11.5 g, 70%); bp 145—148°C/5 mmHg (lit[18] bp 168°C/17 mmHg). It solidified and was recrystallized from ligroin, providing the pure compound as colorless crystals; mp 35—36°C (lit[18] mp 36—38.5°C); ν_{max}^{film} 1700 (C=O), 750, 690 cm^{-1} (aromatic C-H).

β-(*p*-Tolyl)butyric Acid (II, $R_1=R_2=CH_3$) and Its *o*-Isomer (III, $R_1=R_2=CH_3$). Procedure A was followed, using the molar ratios of the reagents and the conditions listed in Table 1. A mixture (7.3 g, 41%) of the compounds II and III was obtained, through such a workup as has been described above, from the resulting reaction mixture; bp 165—167°C/15 mmHg. It solidified after standing in an ice-box. Filtration gave the *p*-isomer (2.3 g), which was recrystallized from petroleum ether to afford the pure compound; mp 88—89°C (lit[19] mp 91°C); ν_{max}^{KBr} 1700 (C=O), 810 cm^{-1} (*p*-substituted).

The filtrate was fractionated to give the *o*-isomer (5 g); bp 168—169°C/13 mmHg (lit[20] bp 166—167.5°C/12 mmHg); ν_{max}^{film} 1700 (C=O), 780 cm^{-1} (*o*-substituted).

4-Chloro-3-methylindanone (IVa) and Its Isomer (IVb). These compounds were prepared according to Procedure A, using 40 ml of chlorobenzene, 12 g (0.1 mol) of Ib, and 33 g (0.25 mol) of aluminum chloride. The reaction was carried out at 100°C for 5 hr. The resulting mixture was treated such as has already been described, giving an organic material which was then shaken with an aqueous alkaline solution. After drying and the removal of the solvent, the residual oil was distilled to afford a mixture of IVa and IVb (13 g, 72%); bp 134—135°C/18 mmHg. A part of it solidified after standing at 0°C for a while. Filtration gave IVa (4.5 g), which was recrystallized from petroleum ether, providing the pure compound; mp 45—46°C (lit[3] mp 47°C); ν_{max}^{KBr} 1705 (ketone C=O), 840, 790, 780 cm^{-1} (1,2,3-trisubstituted).

The product gave the semicarbazone; mp 220—223°C.

Attempts to isolate the analytical sample, IVb, from the filtrate by repeated distillations failed; bp 136—140°C. Gas-chromatographic analysis showed the distillate (8.5 g) to consist of IVa (60%) and IVb (40%). The formation ratio of IVa to IVb is, accordingly, 0.78/0.22.

β-(*p*-Chlorophenyl)butyric Acid (II, R_1=Cl, R_2=CH_3) and Its *o*-Isomer III (R_1=Cl, R_2=CH_3). The procedure involves the use of an inert solvent such as *sym*-tetrachloroethane. Procedure A was followed, except for the use of such a solvent, using the molar ratio of the reagents and the conditions presented in Table 1. Fractional distillation gave a colorless oil (6.5 g, 33%), which was shown by means of gas-chromatographic analysis to be a mixture of the corresponding II and III. Attempts to isolate the individual compounds by a variety of means such as gas chromatography were unsuccessful; bp 170—173°C.

Found: C, 60.39; H, 5.81%. Calcd for $C_{10}H_{11}ClO_2$: C, 60.46; H, 5.53%.

β-(*p*-Hydroxyphenyl)butyric Acid (VIa). *Typical Procedure B.* A solution of phenol (9.4 g) and Ib (12 g, 0.1 mol) in *sym*-tetrachloroethane (25 m*l*) was added, drop by drop, to a stirred suspension of anhydrous aluminum chloride (40 g, 0.3 mol) in the solvent (25 m*l*) at 0—5°C for 1 hr, after this period stirring was vigorously continued until the evolution of hydrogen chloride subsided. The mixture was then gradually heated on an oil bath and kept at 70—75°C for 6 hr; the resulting mixture was chilled and poured over an ice-water slurry (300 m*l*) containing concentrated hydrochloric acid (100 m*l*). The organic layer was separated from the aqueous layer, which was then shaken with three 100 m*l* portions of ether. The extract was combined with the separated organic material and then washed with a saturated sodium bicarbonate solution and water. After it had been acidified with hydrochloric acid and extracted with ether, the extract was dried over anhydrous magnesium sulfate. The removal of the solvent gave a viscous oil contaminated with the starting Ib, which could be removed by means of high-vacuum distillation. It solidified after standing in an ice-box for some time. Filtration, followed by recrystallization from benzene, provided VIa (9.4 g, 52%): mp 136—138°C (lit[21] mp 136°C); ν_{max}^{KBr} 3100 (OH), 1700 (C=O) and 820 cm^{-1} (*p*-disubstituted).

Found: C, 66.59; H, 6.94%. Calcd for $C_{10}H_{12}O_3$: C, 66.65; H, 6.71%.

β-(4-Hydroxy-3-methylphenyl)butyric Acid (VIb). Procedure B for the preparation of VIa was followed, using 10.8 g (0.1 mol) of *o*-cresol, 12 g (0.1 mol) of Ib, 40 g (0.3 mol) of anhydrous aluminum chloride, and 50 m*l* of the solvent. The reaction was carried out at 70—75°C for 7 hr. VIb (4.2 g, 22%) was obtained as the product, through a work-up such as that shown above; mp 107—108°C (from benzene); ν_{max}^{KBr} 3400 (OH), 1680 (C=O) and 850, 800 cm^{-1} (1,3,4-trisubstituted).

Found: C, 67.71; H, 7.36%. Calcd for $C_{11}H_{14}O_3$: C, 68.02; H, 7.27%.

β-(4-Hydroxy-2-methylphenyl)butyric Acid (VIc). Compound VIc was prepared by means of Procedure B. The reaction was carried out under the same conditions as were shown in the preparation of VIb, using 5.4 g (0.05 mol) of *m*-cresol, 6 g (0.05 mol) of Ib, 20 g (0.15 mol) of aluminum chloride, and 25 m*l* of the solvent. When a viscous oil, obtained from the reaction mixture through the same work-up, was allowed to stand in an ice-box for two weeks, it solidified. Recrystallization from benzene afforded VIc (11 g, 60%): mp 123—124°C; ν_{max}^{KBr} 3150 (OH), 1690 (C=O), and 860, 820 cm^{-1} (1,2,4-trisubstituted).

Found: C, 67.80; H, 7.33%. Calcd for $C_{11}H_{14}O_3$: C, 68.02; H, 7.27%.

β-(5-Hydroxy-2-methylphenyl)butyric Acid (IX). This compound was prepared according to Procedure B, using 21.6 g (0.2 mol) of *p*-cresol, 24 g (0.2 mol) of Ib, 80 g (0.6 mol) of aluminum chloride, and 100 m*l* of the solvent. The reaction was carried out at 70—85°C for 7 hr. Recrystallization from benzene gave IX (19.8 g, 51%); mp 111—112°C; ν_{max}^{KBr} 3200 (OH), 1710 (C=O), 860, 800 cm^{-1} (1,2,5-trisubstituted).

Found: C, 67.77; H, 7.38%. Calcd for $C_{11}H_{14}O_3$: C, 68.02; H, 7.27%.

7-Hydroxy-3,4-dimethylindan-1-one (XII) A mixture of IX (3 g) and PPA (40 g) was stirred at 60—70°C for 1 hr, poured over cold water, and then extracted with ether. After it had been washed with a saturated sodium bicarbonate solution and with water, and dried over anhydrous magnesium sulfate, the solvent was removed to give a crude product; mp 35°C (lit[22] mp 53—54°C); ν_{max}^{KBr} 3300 (OH), 1675 (C=O) and 820 cm^{-1} (1,2,3,4-tetrasubstituted). The compound gave the semicarbazone; mp 203—205°C (from water) (lit[22] mp 217°C).

Found: C, 61.94; H, 6.67%. Calcd for $C_{12}H_{15}N_3O_2$: C, 61.78; H, 6.48%.

7-Hydroxy-2-methylchromanone (XIII). Procedure B was followed, using 11 g (0.1 mol) of resorcinol, 12 g (0.1 mol) of Ib, 45 g (0.33 mol) of aluminum chloride, and 50 m*l* of the solvent. The reaction was carried out at 85—90°C for 5 hr. The extract, obtained in the usual manner, was washed with a sodium hydroxide solution, and the alkaline layer was acidified with hydrochloric acid. Filtration, followed by recrystallization from water, afforded XIII (6 g, 34%); mp 174—176°C (lit[6] mp 175—176°C); ν_{max}^{KBr} 3100 (OH), 1600 (C=O), 850, 780 cm^{-1} (aromatic C–H). The compound gave the semicarbazone; mp 205—207°C (from aqueous ethanol).

Found: C, 66.90; H, 5.89%. Calcd for $C_{10}H_{10}O_3$: C, 67.40; H, 5.50%.

Argentation Constants of Styrene Derivatives*1

Yoshiaki INAKI, Shun-ichi NOZAKURA and Shunsuke MURAHASHI

Department of Polymer Science, Faculty of Science, Osaka University, Toyonaka, Osaka

(Received January 22, 1969)

Equilibrium constants for the formation of silver ion complexes (argentation constants) of styrene derivatives in water were measured at 0 and 25°C by Andrews and Keefer's solubility method. The argentation constants for the 1 : 1 complex (K_1) decreased in this order: *cis*-β-alkylstyrene>α-alkylstyrene>*trans*-β-alkylstyrene, for a given alkyl group. This order was related to differences in the resonance stabilization of the double bond. The K_1 values of the α- and β-alkylstyrene series did not seem to correlate with Taft's steric substituent constant, E_s, within the respective series. However, when the hyperconjugation effect of alkyl substituents was considered, a good linearity between log K_1 and Hancock's parameter, E_s^c, was obtained. Thus, the steric effect was separated from the hyperconjugation effect, and it was found that the steric effects for the three series are nearly identical. Thermodynamic data indicated that an isokinetic relationship holds between ΔH and ΔS and that the argentation equilibrium is controlled mainly by the entropy factor. The degree of methyl substitution at the double bond of styrene slightly influenced the K_1 values, although 1,2-dihydronaphthalene had an abnormally large K_1 value.

The argentation (silver ion complexation) equilibria of unsaturated compounds have been investigated by several groups of workers.[1-6] The stabilities of the complexes of the silver ion with unsaturated compounds may be interpreted as the sum of the independent contributions of polar, resonance, and steric effects of substituents. The polar effects were discussed in terms of the Hammett ρ–σ relation for benzene derivatives by Andrews and Keefer[1] and for ring-substituted styrenes and other olefins by Fueno and his co-workers.[2-4] For the resonance effect, it has already been established that the argentation equilibria are affected by the conjugation of substituents with the reaction center.[5] Although the literature contains references to the steric effect of substituents on the argentation equilibria, the investigations have not been extended beyond qualitative discussions. Both Winstein and Lucas[5] and Fueno *et al.*[2] suggested that the reason for the reluctance of β-methylstyrene to argentate is the steric effect of the substituent. Muhs and Weiss[6] measured the argentation constants of many unsaturated compounds by the gas chromatographic method and discussed the steric effects of substituents qualitatively.

The present investigation was undertaken to obtain information concerning the steric effects in the argentation of styrene derivatives. In separate reports,[7,8] we have previously reported on our observations of the steric effects in the radical copolymerizations of α- and β-alkylstyrenes with acrylonitrile. From the difference in the steric effects of α- and β-alkylstyrenes in the radical copolymerizations, it was deduced that the transition state of the radical polymerization is not of the π-complex type but of the σ-complex type. Since it is known that the silver ion forms a π-complex with an unsaturated compound, the steric effect in the argentation of styrene derivatives may also give information concerning the transition state of the radical polymerizaion.

In the present investigation, the argentation constants of α- and β-alkylstyrenes in water were measured by Andrews and Keefer's solubility method.[1] Also, the argentation constants of *cis*- and *trans*-α,β-dimethylstyrenes, β,β-dimethylstyrene, 1,2-dihydronaphthalene, and indene were determined and compared with the values of the above styrenes.

Experimental

Materials. The styrene and α-methylstyrene were obtained commercially. The other α-alkylstyrenes were synthesized by the Wittig reaction of alkyl phenyl ketones, much as in a previous paper.[8] By the Wittig reaction of the corresponding aldehydes, β-alkylstyrenes were prepared.[7] The *cis*- and *trans*-isomers of these styrenes were fractionated by distillation under reduced pressure, using a stainless-steel helipack column of about 30 theoretical plates. Also, the *cis*-and *trans*-α,β-dimethylstyrenes, and β,β-dimethylstyrene were obtained by the Wittig reaction. The 1,2-dihydronaphthalene was synthesized according to the literature.[9] The indene was obtained commercially. These olefines were purified by rectifications under reduced pressure and, immediately before use, were treated with lithium aluminum hydride overnight and redistilled under a high vacuum. The silver nitrate and potassium nitrate were of an analytical grade and used without further purification. The solvent for extraction, *n*-hexane, was purified in the usual way.

Measurements of the Solubility. All the experiments were carried out in the dark.

Samples of styrene derivatives (0.1—1.0 g) were added to 20 m*l* of aqueous silver nitrate solutions of varying silver ion concentrations, all the solutions containing enough potassium nitrate to maintain an ionic strength of unity. The mixtures were shaken vigorously in 50 m*l* glass-stoppered Erlenmeyer flasks for 3 hr in a constant-temperature bath at 0.00±0.05°C and 25.00±0.05°C in order to saturate the aqueous phase with styrenes. It was confirmed that one hour of shaking was sufficient for the argentation equilibrium to be reached.

9) J. von Brawn and G. Kirchbaum, *Ber.*, **54**, 604 (1921).

After the two phases had been fully separated by being kept standing (5 hr), measured volumes of the saturated aqueous phase were pipetted out and extracted with 5—10 m*l* portions of hexane by shaking in glass-stoppered flasks for one hour. The optical density of the hexane phase was measured against a hexane blank on a Hitachi Spectrophotometer (EPS-3T) at a wavelength appropriate for each styrene, the molecular extinction coefficients having been previously determined. The spectra were scanned from 210 mμ through 360 mμ to check the impurity in the solutions. It was also checked whether one extraction for one hour is sufficient for the removal of all of the styrenes, both free and complexed, from the aqueous phase. The volume of the hexane phase was adjusted to obtain the optical density readings between 0.200 and 0.800.

The total styrene concentrations of the saturated aqueous solutions were calculated from the optical density of the hexane solutions. The wavelengths (λ) and the corresponding values of the molecular extinction coefficients (ε) are given in Table 1.

Results

Argentation Constants. According to Andrews and Keefer,[1] the equilibrium reactions of styrenes (St) with the silver ion in the aqueous phase can be explained in terms of these equilibria:

$$Ag^+ + St = Ag\text{–}St^+$$
$$K_1 = [Ag\text{–}St^+]/[Ag^+][St] \quad (1)$$
$$Ag^+ + Ag\text{–}St^+ = Ag_2\text{–}St^{2+}$$
$$K_2 = [Ag_2\text{–}St^{2+}]/[Ag^+][Ag\text{–}St^+] \quad (2)$$

here, K_1 and K_2 are the equilibrium constants for the formation of the Ag-St$^+$ and Ag$_2$-St^{2+} complexes respectively.

An additional constant, K, introduced to facilitate the calculations of K_1 and K_2, is defined as:

$$K = \frac{[St]_t - [St]}{[Ag^+][St]} = K_1 + K_1K_2[Ag^+] \quad (3)$$

where $[St]_t$ and $[St]$ are the molar concentrations of all the styrene-containing species and of free styrene respectively, and where $[Ag^+]$ is the molar concentration of the free silver ion.

The solubilities were measured for styrene derivatives at 25°C, and the values of K were calculated from Eq. (3). If the equilibria (1) and (2) account for all the complexes formed, and if additional reactions do not contribute appreciably to the complex formation, the plots of K against $[Ag^+]$ should give a straight line. This was found to be the case, with reasonable accuracy, for all the styrene derivatives investigated. Figure 1 shows examples of these plots for *cis*-β-alkylstyrenes at 25°C. In such plots the ordinate intercept is K_1 and the slope is K_1K_2. The values of K_1 and K_2 thus obtained are given in Table 2. These values were determined by the method of least-squares with an error of about one percent.

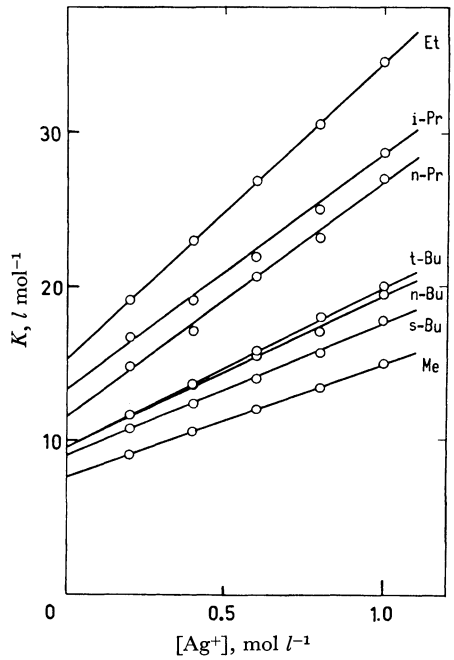

Fig. 1. Plots of K vs. [Ag+] for *cis*-β-R-styrene at 25°C.

It may be noticed that the values of K_2 are appreciably smaller than the K_1 values and are insensitive to the variation in the structure of styrenes. The values of K_1 which are a measure of the stabilities of the complexes, decrease in this order for a given alkyl:

cis-β-alkylstyrene>α-alkylstyrene>*trans*-β-alkylstyrene

The K_1 value obtained for styrene in our work is in reasonable agreement with the value obtained by Andrews and Keefer.[10] However, the K_1 values for β-methylstyrenes are larger than those given in the literature.[2,5] When rectificated samples of β-alkylstyrenes without further purification were used, abnormal peaks of benzaldehyde were found in the ultraviolet spectra of the extracted hexane solutions. Since the solubility of benzaldehyde in the aqueous phase is high, while the equilibrium constant is small, the K_1 values obtained were as small as the values in the literature. Samples which were treated with lithium aluminum hydride in order to remove the benzaldehyde gave smaller solubilities in the aqueous phase and larger K_1 values.

Temperature-dependence. The argentation constants were measured at 0 and 25°C for α- and β-alkylstyrenes. At temperatures higher than 30°C the solutions became turbid and silver metal precipitated during the equilibration, thus precluding measurements.

Listed in Table 3 are the values of K_1 and K_2 obtained at 0°C from the plots described above. The values of K_1 at 0°C are greater than those at

25°C. These results indicate that the silver ion complexes are stable at lower temperatures.

From the K_1 values at 0 and 25°C, the thermodynamic data for the argentation in water were obtained. Table 4 gives the entropy and enthalpy changes in the argentation for α- and β-alkylstyrenes in water.

Discussion

Alkyl Substituent Effect. It has been established that, in the styrene molecule and in most styrene derivatives, the vinyl group is the center for the coordination of the silver ion.[2,10] On the basis of this consideration, it appears very likely that the K_1 values are related to the nature of the substituent about the double bond of styrenes. The effects of substituents on argentation constants may be divided into the independent contributions of the polar, resonance, and steric effects of the substituents. Thus, Taft's equation can be applied:

$$\log (K/K_0) = \rho^*\sigma^* + \delta E_s + \gamma E_\psi \qquad (4)$$

where σ^*, E_s, and E_ψ are the polar, steric, and resonance substituent constants and where ρ^*, δ, and γ are the corresponding reaction parameters. K_0 is the equilibrium constant of a standard reaction (methyl substituent). In Fig. 2, the K_1 values for

α- and β-alkylstyrenes at 25°C are plotted against the alkyl substituents, which are arranged in the increasing order of E_s. The plots shows zigzag curves, although they show similar patterns for the respective series. A similar tendency is shown by the results of Muhs and Weiss[6] for alkyl-substituted ethylenes.

of α- and β-alkylstyrenes. It indicates that, for *cis*- and *trans*-β-alkylstyrenes, the extent of conjugation does not change appreciably within each series except for *cis*-β-*t*-butylstyrene. This means that the resonance factor varies little within each series. However, in the case of α-alkylstyrenes, the wavelengths of maximum absorption shift lower with an increase in the bulkiness of the alkyl substituents. It is generally known that an increase in the extent of conjugation causes a reduction in K_1 values. It appears, then, that the bulky alkyl groups of α-alkylstyrenes cause an increase in K_1 value as a result of the steric inhibition of conjugation. Table 5 also indicates that the resonance effect of styrene is different from those of alkylstyrenes.

Another important factor affecting the complex formation is the steric effect of the substituents neighboring the double bond. As has previously been mentioned, no correlation between K_1 and E_s can be found in Fig. 2. From Fig. 2 it appears that the K_1 values in each series can be classified into three groups according to the number of α-hydrogen atoms in the alkyl substituent. This classification suggests the effect on argentation of the hyperconjugation of the alkyl group. Therefore, we tried to separate the effects of substituents into the independent contributions of the steric substituents and the hyperconjugation effects of alkyl substituents, as represented by the equation:

$$\log (K/K_0) = \delta E_s^c + h(n - 3) \qquad (5)$$

where n is the number of α-hydrogen atoms in alkyl groups and where h is an adjustable parameter representing a measure of the hyperconjugation effect. We here used Hancock's E_s^c values[11] rather than Taft's E_s values, becuase the E_s^c values are based upon the quantitative separation of the hyperconjugation effect from Taft's steric

11) C. K. Hancock, E. A. Meyers and B. J. Yager, *J. Am. Chem. Soc.*, **83**, 4211 (1961).

substituent constants. The correlation of $\log K_1$ by Eq. (5) gave a good linearity, as is shown in Fig. 3. The h parameter was determined by trial

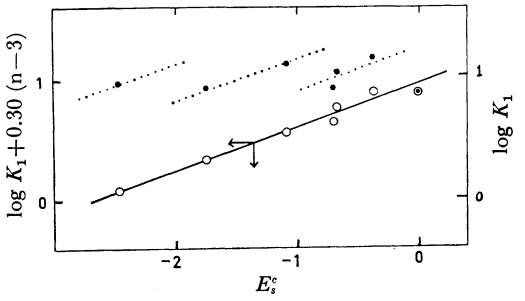

Fig. 3. Relationship between argentation constants of *cis*-β-R-styrene and E_s^c.

and error. The negative value of h in Fig. 3 indicates that the hyperconjugation effect serves to reduce the K_1 value. This is consistent with qualitative recognition that, as has already been mentioned, the conjugation between a substituent and the reaction center causes a reduction in the K_1 value.

The polar effect of substituents on the argentation of benzene derivatives was discussed by Andrews and Keefer[1] in the Hammett ρ–σ relation; they reported a reaction constant $\rho=-1.6$ for σ_m. Also, the two reaction constants $\rho=-0.766$[2] and $\rho=-5.07$[3] were reported by Fueno *et al.* for ring-substituted styrenes and vinyl compounds respectively. In our case, it is appropriate to discuss the polar effect using the reaction constant of vinyl compounds, $\rho=-5.07$, in the Hammett ρ–σ_m relation. Table 6 shows only a small difference in

the polar substituent effects $\rho\sigma_m$ of alkyl groups; therefore, the polar effect of substituents can be neglected.

It was found that Eq. (5) holds in the case of the argentation of alkenes in ethylene glycol, which has been studied by Muhs and Weiss using gas

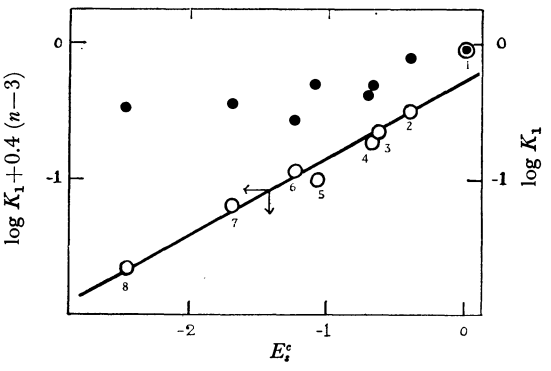

Fig. 4. Relationship between argentation constants of 1-alkene and E_s^c at 40°C.

chromatography (Fig. 4).[6] The substituent effect of alkenyl alkyl ethers on the argentation, which was investigated by Fueno *et al.*,[4] may be interpreted in a similar manner.

The same treatment as in Fig. 3 was also applied to α- and β-alkylstyrenes; all the results are given in Fig. 5. The slope of these straight lines corre-

sponds to the δ parameter, the steric reaction constant. Figure 5 indicates that the δ parameters of *cis*-β- and *trans*-β-alkylstyrenes are practically the same. Figure 5 also indicates that the δ parameter of the α-alkyl series is nearly equal to that of the β-alkyl series. However, since the α-alkyl groups exhibit a steric inhibition of resonance, as has been shown above, the real steric effect of the α-alkylstyrene series must be larger than the apparent value.

As has already been mentioned, Table 2 (or Fig. 5) shows a reasonable difference in the K_1 values of α-, *cis*-β-, and *trans*-β-alkylstyrenes for a given alkyl. In the previous discussion using Eq. (4), the resonance factor was assumed to be

constant within each series except the α-alkylstyrene series. When we compare the α-series, the *cis*-β-series, and the *trans*-β-series using the same equation, however, the difference in the resonance factor should be considered. The difference in the resonance factor between the three series corresponds to the large distance between the experimental lines of the α-, the *cis*-β-, and the *trans*-β-series in Fig. 5.

In order to obtain further information regarding the nature of the complexation of styrene derivatives, the thermodynamic data, ΔH and ΔS, for complexation were evaluated from the K_1 values at 0 and 25°C. No simple relation between the ΔH (or ΔS) and E_s^c values of the substituent groups was found. However, as is shown in Fig. 6, a linear correlation was found to exist between ΔH and ΔS (isokinetic relationship); the plots for α-, *cis*-β- and *trans*-β-series fell on the same line, in contrast with the case of alkenyl alkyl ethers.[4] The isokinetic temperature, 250°K, was obtained from the slope of the straight line. Since the measurements of the argentation constants were carried out above the isokinetic temperature, the entropy factor is considered to be more important than the enthalpy in this equilibrium.

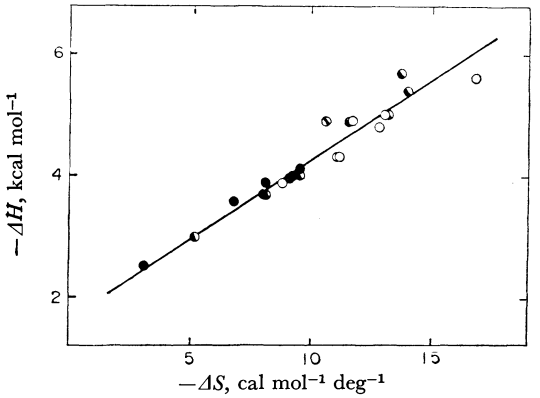

Fig. 6. Plots of ΔH *vs.* ΔS.
⊘ Styrene ◔ α-R–Styrene ● *cis*-β-R–Styrene
○ *trans*-β-R–Styrnene

Argentation Constants of the Other Styrene Derivatives. Further substitution of methyl groups at the double bond slightly influenced the K_1 values. Table 2 indicates that the K_1 values for *cis*-α,β-dimethylstyrene, and β,β-dimethylstyrene are nearly equal to the K_1 value of *trans*-β-methylstyrene, although smaller than those of α- and *cis*-β-methylstyrenes. This is considered to be due to the fact that the inhibition of conjugation between the benzene ring and the double bond is more important than the steric effect in the complex formation of those styrenes.

Considering the structure and the strain of the olefin, the K_1 value of indene is reasonable. However, the very large K_1 value of 1,2-dihydronaphthalene was unexpected from the structure of this molecule.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 2610—2614 (1969)

Synthetic Reactions by Complex Catalysts. XIII. Carbonylation of Amines by Group IB and IIB Metal Compound Catalysts*1

Takeo SAEGUSA, Shiro KOBAYASHI, Kiwami HIROTA and Yoshihiko ITO

Department of Synthetic Chemistry, Kyoto University, Sakyo-ku, Kyoto

(Received January 29, 1969)

The present investigation was undertaken in order to examine the catalytic activities of Group IB and IIB metal compounds in the carbonylation of aliphatic and aromatic amines with carbon monoxide, and in order to compare the catalyst activities with those of other metal compounds. It was found that: i) copper compounds are excellent catalysts for the carbonylation of aliphatic amines to produce the corresponding formamides; ii) the catalytic activities of copper compounds are enhanced by the addition of water; and iii) chloroauric acid catalyzes the carbonylation of aromatic amine, whereas copper compounds do not. The temperature effects on the carbonylation of morpholine were also examined.

We have preliminarily reported the copper-catalyzed carbonylation of amines; in this process primary and secondary amines are smoothly converted by carbon monoxide into the corresponding

*1 Presented in part at the 20th Annual Meeting of the Chemical Society of Japan, Tokyo, April, 1967.

formamides.[1] Now, we wish to report more detailed and more comprehensive studies of the catalytic activities of Group IB and IIB metal compounds in the carbonylation of amines.

Various catalysts have hitherto been reported for the amine-carbon monoxide reaction. Transition metals of Groups IV to VIII,[2,3] their salts,[3-6] their metal carbonyls,[7-9] and the corresponding organometallic compounds[10] catalyze this reaction to produce a mixture of formamide, urea, isocyanate, and oxamide. The alkali metal alcoholate catalyzes the carbonylation of amine to produce the corresponding formamide.[11] In addition, one patent has claimed the production of *N*-methylformamide and *N,N*-dimethylformamide from methylamine and dimethylamine respectively by a catalyst selected from the group consisting of cuprous and cupric chlorides, ammonium chloride, potassium acetate, and boron fluoride.[12]

The purpose of the present investigation is to examine the catalytic activities of Group IB and IIB metal compounds in the carbonylation of aliphatic and aromatic amines with carbon monoxide. We have found that: i) copper compounds are excellent catalysts for the carbonylation of aliphatic amines to produce the corresponding formamides; ii) the catalytic activities of copper compounds are enhanced by the addition of water, and iii) chloroauric acid catalyzes the carbonylation of aromatic amine, but copper compounds do not.

Experimental*2

Materials. All the amines were distilled before use. The copper compounds and other metal salts were commercial reagents which were used as received. The carbon monoxide was reagent-grade.

Reaction Procedures. Method A. An amine and a catalyst were placed in a 200 m*l* stainless-steel autoclave equipped with a magnetic stirrer; the autoclave was then charged with carbon monoxide up to a pressure of 60—80 kg/cm^2 at room temperature. The autoclave was closed and heated at a given temperature for a given time. Then, any catalyst precipitated was separated by filtration, and the reaction mixture was distilled or analyzed directly by glpc.

Method B. The reaction was carried out in a 50 m*l* stainless-steel pressure tube without stirring. The after-treatment of the reaction mixture was carried out by the same procedure as in Method A.

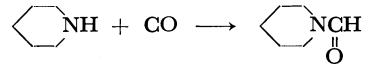
Identification and Analyses of the Prod cts. The reaction products were identified by comparing their NMR and infrared spectra and the glpc retention times with those of the respective authentic samples. The columns of glpc were PEG 6000 and Silicone DC 550. The yields of the products were determined by glpc analyses and, in some cases, by fractional distillation.

Preparations of Authentic Samples. The authentic formamide derivatives were prepared by treating the respective amines with ethyl formate. The boiling points of these authentic samples were as follows: *N*-formylpiperidine: 90—92°C/9 mmHg; *N,N*-diethylformamide: 177—178°C; *N*-formylpyrrolidine: 97—98°C/15 mmHg; *N*-2-hydroxyethylformamide: 134—136°C/0.4 mmHg; *N*-*n*-butylformamide: 142—144°C/45 mmHg; *N*-allylformamide: 120—122°C/48 mmHg; *N*-ethylformamide: 109°C/30 mmHg; *N*-formylmorpholine: 121—124°C/15 mmHg; formanilide: 90—91°C/12 mmHg, (mp 47°C), and *N*-methylformanilide: 131—133°C/25 mmHg.

The authentic samples of 1,1′-carbonyldipiperidine and 4,4′-carbonyldimorpholine were prepared by the reaction of piperidine and morpholine with phosgene; the melting points were 42°C (lit.,[13] mp 42—43°C) and and 141—142°C (lit.,[13] mp 143°C) respectively.

Results and Discussion

Carbonylation of Piperidine. The Group IB and IIB metal compounds were examined for catalyst activity in the carbonylation of piperidine. Their catalytic activities were also compared with



those of other metal compounds. The Group IB and IIB metal compounds, especially copper compounds, are quite active. The typical transition metal salts of the Group VIII elements, *e.g.*, Fe, Co, Ni and Pd, are less active than copper catalysts. Aluminum chloride, a strong Lewis acid, is a poor catalyst.

The catalytic behavior of the copper compounds in the amine-carbon monoxide reaction is distinguished from that of typical transition metal catalysts by the highly selective production of formamide. In the copper-catalyzed reaction, a small amount (usually only a few percent) of a *N,N′*-dialkyl derivative of urea was formed as the sole by-product.[1]

The amount of the by-product is much smaller than that in the reaction with palladium[6] and

manganese[9] catalysts. The piperidine-carbon monoxide reaction with catalysts of Ag, Au, Zn, Cd, and Hg salts also produces a trace amount of 1,1′-carbonyldipiperidine (only a few percent) as a by-product.

The coordination of carbon monoxide with cuprous salts in the presence of amine is well known.[15] It is not unreasonable to assume that carbon monoxide coordination plays an important role in the catalysis. When cupric salts are used as catalysts, they may be reduced by carbon monoxide into cuprous species which are possibly the real active species of the catalyst.

Copper compounds also catalyze the α,α-addition of the nitrogen-hydrogen bond of aliphatic amine to isocyanide.[16] It is interesting to note that the reaction with the aliphatic amine-isocyanide is similar to the reaction of the present studies, since isocyanide and carbon monoxide are isoelectronic. These two reactions caused by copper catalysts may be formulated in an analogous manner:

$$R_2NH + :C \leqq O \longrightarrow R_2NCH \overset{\|}{O}$$

$$R_2NH + :C \leqq N\text{-}R^1 \longrightarrow R_2NCH \overset{\|}{N}\text{-}R'$$

Carbonylation of Dimethylamine. Copper compounds also catalyze the dimethylamine (DMA)-carbon monoxide reaction to produce *N,N*-dimethylformamide (DMF) (Table 2). The by-product is *N,N,N′,N′*-tetramethylurea, produced only in small amounts. It is quite interesting to observe that the catalytic activity of the copper catalyst is enhanced by the addition of water. The accelerating effect of water may be closely related to the fact that CuCl-CO complexization

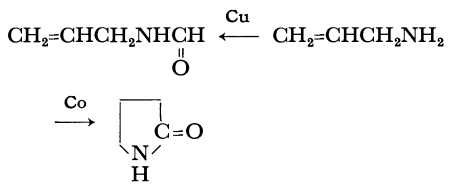
is favored by water.[15]

The effect of a small amount of water is clearly demonstrated in the last two runs of Table 2, where the carbonylation by the CuCN catalyst was carried out both in the absence (Exp. No. 22) and in the presence of water (Exp. No. 23). The addition of 10 mol% of water increases the rate and the conversion four or five fold. Furthermore, DMA carbonylation is efficiently carried out in an aqueous system (Exp. No. 19 to No. 21, Table 2). There are two possible explanations of the effect of water. First, the water molecule is incorporated into the copper-DMA complex as a ligand, thus possibly modifying (increasing) the catalyst activity. Second, the water converts carbon monoxide to formic acid, which may then be responsible for the carbonylation reaction. In fact, it has been established that the addition of water to a reaction system without a metallic catalyst increases the rate of carbonylation, although the actual rate is quite low.[11]

Carbonylations of Miscellaneous Amines. Other aliphatic amines can also be carbonylated by means of copper-compound catalysts (Table 3). The carbonylation of secondary amines appears to be easier than that of primary amines.

The carbonylation of allylamine differentiates the copper catalyst from the cobalt carbonyl catalyst. The copper-catalyzed carbonylation of allylamine yields only *N*-allylformamide, whereas the cobalt carbonyl-catalyzed reaction gives the cyclization product, 2-pyrrolidinone.



Temperature Effects on the Carbonylation of Morpholine. The rate of the carbonylation of morpholine is increased by raising the reaction temperature (Table 4). A small amount of 4,4′-carbonyldimorpholine by-product was formed at a higher reaction temperature (Exp. No. 33). The

urea may be produced by the copper-catalyzed oxidation of morpholine with oxygen,[13] which is possibly present as a contaminant in the reaction system.

Carbonylation of Aromatic Amines. Copper compounds are inactive in the reaction of aromatic amines with carbon monoxide. On the other hand, chloroauric acid is active (Table 5).

From the isoelectronic relationship between carbon monoxide and isocyanide, it is also of interest to note that copper compounds do not work as effectively in the aromatic amine-isocyanide reaction as does chloroauric acid.[17]

Intramolecular Hydrogen Bonding in α-Keto- and α-Alkoxy-carboxylic Acids. VII. Ultraviolet Spectra of Phenylglyoxylic Acid in Various Solvents

Minoru HIROTA and Fumiaki SHINOZAKI*1

Department of Applied Chemistry, Faculty of Engineering, Yokohama National University, Minami-Ku, Yokohama

(Received February 7, 1969)

The ultraviolet spectra of phenylglyoxylic acid were determined in various solvents as well as in the mixtures of solvents. A very remarkable hypsochromic shift with increase in intensity was observed when the solvent participates in the formation of hydrogen bond as a hydrogen acceptor. The measurement of the spectra in binary mixtures of the solvents shows that the hypsochromic shift is due to the formation of a 1 : 1 complex of $C_6H_5COCOOH\cdots$solvent type. This hypsochromic shift is interpreted by the destruction of the chelate ring formed by the intramolecular hydrogen bond which enforces the acid molecule to the planar conformation. This view is supported by the simple LCAO-MO calculation on this molecule.

It has been shown that the intramolecular hydrogen bonding between the carboxylic hydroxyl group and the α-oxygen containing functional groups plays an important role in the appearance of the *trans*-conformation*2 of the carboxyl group.[2-5] Thus, the α-alkoxy and α-oxo-carboxylic acids can exist as *trans*-conformers while the usual carboxylic acids take the *cis*-conformation exclusively. Phenylglyoxylic acid is an α-oxo-carboxylic acid which is capable of forming an intramolecular hydrogen bond as exemplified by Ib. We have studied it by means of infrared spectroscopy.[2] It has been also studied more extensively by Oehme *et al.*[6]

It seems certain that the acid takes a nearly planar conformation when it exists as an intramolecularly hydrogen bonded *trans*-conformer (Ib), in which both carbonyl groups are kept at a *trans* position to each other by hydrogen bond formation. The *cis* conformation of the usual carboxyl group is assumed to be about 2 kcal/mol more stable than the *trans* one,[7] but the *trans*-conformer of phenylglyoxylic acid is predominant in inert solvents because the O-H···O=C hydrogen bond energy (estimated to be about 4—5 kcal/mol) overcomes the stabilization energy of the *cis*-conformer.[8] From the measurement on the temperature dependence of the intensities of the O-H stretching absorption bands assigned to both conformations, the *trans*-conformer is shown to be more stable, and

*1 The present address: Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo.

*2 The *cis* or *trans* implies that the oxo(O=)-group and the hydrogen of the carboxyl group are *cis* or *trans*, respectively, with respect to the C-O bond.[1]

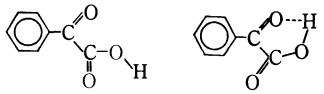
the enthalpy of the conversion was determined to be 1.78 kcal/mol.

In polar solvents, the intramolecular hydrogen bond may be weakened or destroyed both by the usual polar effect and by the intermolecular association. We found a remarkable solvent effect on the ultraviolet spectrum of this acid. The acid has an absorption band at 277.8 mμ (ε, *ca.* 6000) in *n*-hexane, while the absorption in ethanol is at 252.5 mμ (ε, 12100).[9]

In order to interpret this drastic change of absorption spectra in both solvents, the spectra of phenylglyoxylic acid were measured in various solvents and also in binary mixtures of these solvents. The acid is shown to form a 1 : 1 complex with the hydrogen accepting solvent.



Ia Ib

Experimental

Materials. Phenylglyoxylic acid was prepared from benzoyl chloride and cuprous cyanide by the usual method.[10] Commercial spectro-grade *n*-hexane, methylene chloride and chloroform were used as solvent without further purification. Diethyl ether, ethanol and acetonitrile of commercial special grade were purified by the usual procedures.

Measurement of the Spectra. The ultraviolet spectra were measured by a Hitachi EPS-3T recording spectrophotometer. The molecular orbital calculation of the compound was carried out by a NEAC-2230 digital computer.

Results and Discussion

The ultraviolet spectra of phenylglyoxylic acid were determined in six solvents, the results of which are shown Fig. 1. Characteristic data on the absorption maxima are listed in Table 1. As shown in Table 1, the acid has an intense absorption band at about 250 mμ in ethanol, ether and acetonitrile, while it has a weaker absorption band at a longer wavelength in hexane, methylene chloride and chloroform.

The absorption bands at 250 mμ and at 280 mμ can be assigned to the solvated *cis*-conformation (Ia) and intramolecularly hydrogen bonded *trans*-conformation (Ib) of phenylglyoxylic acid, respectively. From the measurement of the O–H stretching and the C=O stretching absorption bands in the infrared region, it was concluded that the acid should take the hydrogen bonded *trans*-conformation in inert solvents which cannot participate in the formation of intermolecular hydrogen bonds to the acid. The similarity of the absorption spectra suggests a similar conformation in chloroform and methylene chloride with that in *n*-hexane. In other words, the intramolecular hydrogen bonding of the acid persists in the solvents of considerable hydrogen donating property. The absorption at about 250 mμ (ε: 12000) in hydrogen accepting solvents may be attributable to the benzoyl chromophore, because it is similar both in the location of the absorption maximum and in intensity. For example, benzaldehyde[11] has an intense absorption maximum at 242 mμ with a shoulder at 248 mμ, their intensities being 14000 and 12500, respectively. This means that the conjugation of the whole molecule is interrupted and the absorption caused by the benzoyl partial chromophore is observed in ethanol, diethyl ether and acetonitrile. These solvents are more or less basic and have hydrogen accepting ability. In these solvents, the intramolecular hydrogen bond of the acid might be destroyed and the intermolecular hydrogen

bond between the acidic O–H groups and the solvents might be formed instead. The acid is enforced to take an otherwise unfavorable *trans*-conformation by the intramolecular hydrogen bond, but it can form intermolecular hydrogen bond in the favorable *cis*-conformation. As there is no interaction between the acidic O–H and the ketonic carbonyl groups in the *cis*-form, the carboxyl group is not fixed on the plane of the benzoyl group and the rotation around the C–C bond between the carbonyl and the carboxyl carbons may occur rather freely. This may hinder the conjugation of the whole molecule and results in the appearance of the absorption band of the benzoyl chromophore in ethanol and other hydrogen accepting solvents.

It is doubtful whether the remarkable solvent dependence of the absorption spectrum is due to the electronic interaction through the hydrogen bond, and the molecule was studied from a molecular orbital theoretical point of view. The HMO calculation was carried out with phenylglyoxylic acid employing the parameters $h_{\dot{O}}=1.0$, $h_{\ddot{O}}=2.0$,

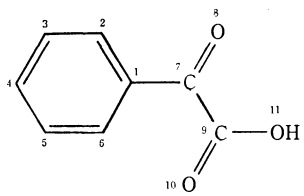

Fig. 2 (1)

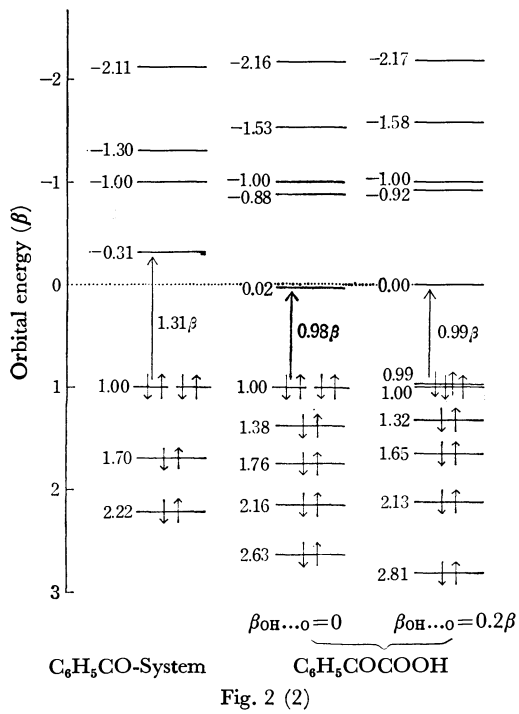

Fig. 2 (2)

Fig. 2. Simple LCAO-MO energy diagrams for phenylglyoxylic acid.

$k_{C-O}=0.8$ and $k_{C=O}=1.0$.[12] The π-electronic interaction through the hydrogen bond was considered by assuming the non-zero resonance integral ($\beta_{OH\cdots O}=0.2\beta$) between the oxygen atoms participating in the formation of hydrogen bond, but the lowest $\pi\rightarrow\pi^*$ transition energy does not change remarkably from the result obtained by neglecting the hydrogen bond effect ($\beta_{OH\cdots O}=0$).

On the other hand, the $\pi\rightarrow\pi^*$ transition energy of the benzoyl system was higher than that of phenylglyoxylic acid, so the solvent effect on its absorption spectrum is explained that the conjugate system is non-planar when the intramolecular hydrogen bond is absent. A very low double bond character of C_7–C_9 bond (bond order $p_{7,9}=0.333$) probably allows to rotate rather freely around this C–C bond. Further study on this problem is in progress, and above interpretation on the absorption spectrum agrees with the result of the Pariser-Parr-Pople MO calculation, details of which will be reported elsewhere.

In short, phenylglyoxylic acid associates with solvents which act as hydrogen acceptors in forming hydrogen bond, while it holds an intramolecularly hydrogen bonded form in the solvent with hydrogen donating ability.

In order to investigate the nature of the interaction between the acid and the solvents, the absorption spectra were measured in a binary mixture of solvents, such as methylene chloride-ethanol, *n*-hexane-diethyl ether, *etc.* The absorption spectra in binary mixture of the solvents are shown in Fig. 3. The isosbestic points were observed in all solvent systems investigated at the concentrations, at most, below 10%, and suggest the formation of only one kind of complexed species of definite composition in these concentration ranges. In order to determine the composition of the complexes, the absorption spectra of the acid in the mixture of the solvents in varying proportions were analysed by a method similar to that reported by Brealey and Kasha.[13] It was assumed that the equilibrium given by Eq. (1) exists between the solvent and solute, where r is constant throughout the range in which the isosbestic point is observed in the spectra.

$$C_6H_5COCOOH + r\cdot Solvent \rightleftarrows C_6H_5COCOOH\,(Solvent)_r \qquad (1)$$

The stability constant K and the number of solvated molecule r were calculated from the plots of $\log_{10}\{[Complex]/[C_6H_5COCOOH]\}$ against $\log_{10}$-[Solvent] shown by Fig. 3. From the definition of the formation constant expressed by Eq. (2),

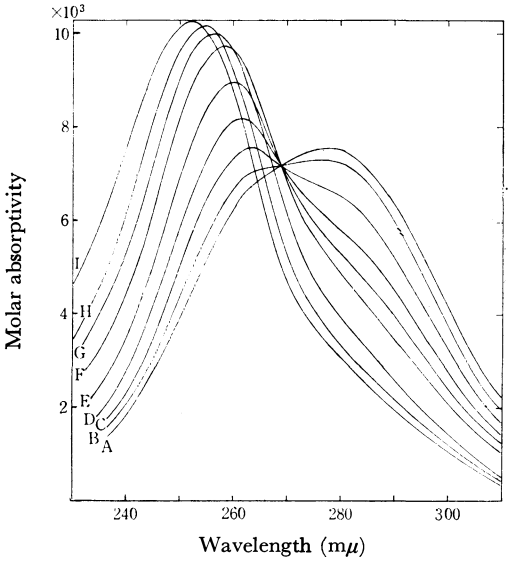

Fig. 3 (a)

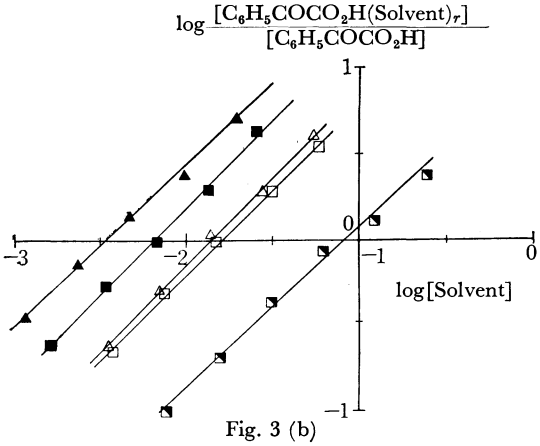

Fig. 3 (b)

Fig. 3. The ultraviolet spectra of phenylglyoxylic acid in the binary mixtures of the solvents.
(a) An example of the spectra in the binary mixtures of the hydrogen accepting solvent (ethanol) and the inert solvent (methylene chloride).
A: pure CH_2Cl_2, B: 0.4% ethanol, C: 1.6% ethanol, D: 3.2% ethanol, E: 6.4% ethanol, F: 12.8% ethanol, G: 50% ethanol, H; 80% ethanol and I: pure ethanol.
(b) Logarithm of the concentration of the hydrogen accepting solvent *versus* log $\{[C_6H_5COCOOH\cdot(Solvent)_r]/[C_6H_5COCOOH]\}$.

Eq. (3) is easily derived by taking logarithm.

$$K = [C_6H_5COCOOH\cdot(Solvent)_r]/[C_6H_5COCOOH][Solvent]^r \quad (2)$$

$$\log K = \log\{[Complex]/[C_6H_5COCOOH]\} - r\cdot\log[Solvent] \quad (3)$$

This indicates that the tangent of the log{[Complex]/[$C_6H_5COCOOH$]} *vs.* log[Solvent] plot will give the r-value and the intercept of the log[Solvent] axis will give the log$K$ value multiplied by r. The formation constants and the number of associated solvent molecule of some hydrogen bond complexes of phenylglyoxylic acid are tabulated in Table 2.

Table 2. The association constants K and the mole ratios r of the phenylglyoxylic acid-solvent complexes

Solvent system	K	r
C_6H_{14}–C_2H_5OH	219	0.95
C_6H_{14}–$(C_2H_5)_2O$	77.6	1.02
CH_2Cl_2–C_2H_5OH	178	1.03
CH_2Cl_2–$(C_2H_5)_2O$	61.7	0.98
CH_2Cl_2–CH_3CN	9.73	0.92

Formation of the 1 : 1 complex of phenylglyoxylic acid with ethanol as well as with ether and with acetonitrile, was thus confirmed from the r-values presented in the table. On the other hand, the acid does not form hydrogen bond with chloroform or methylene chloride, which can act as hydrogen donor in hydrogen bond formation. The results are in accordance with the fact that the carboxyl group is acidic and has a tendency to donate hydrogen to other molecules, while the basicity of the acid is rather low in comparison with other carbonyl compounds. The stronger hydrogen bond complex is formed when the hydrogen acceptor(solvent) has a stronger hydrogen accepting power and when the inert solvent is less polar.

In summary, the remarkable solvent shift observed in the ultraviolet spectrum of the acid is due to the 1 : 1 complex formation with hydrogen accepting solvents, which destroys the intramolecular hydrogen bonding present in inert solvents and allows the non-planar conformation of the acid.

The authors are grateful to Professor M. Ōki of the University of Tokyo and Professor H. Kakiuchi of Yokohama National University for their valuable advice throughout this investigation. The present investigation was partly supported by a Scientific Research Grant from the Ministry of Education for which the authors are grateful.

Structure Proof of Diarylmethanes Formed in the Jacobsen Reaction of Monochlorotetramethylbenzenes[1]

Hitomi Suzuki

Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto

(Received February 7, 1969)

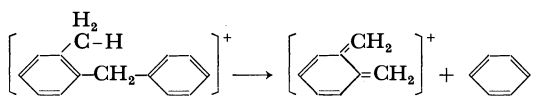
The Jacobsen reaction of monochlorotetramethylbenzenes was found to yield dichloroheptamethyldiphenylmethanes as by-product. Their indefinite structure proof was made on spectroscopy and synthesis. ^{1}H NMR spectra for a variety of polymethyldiphenylmethanes and their chlorine derivatives were determined.

In contact with concentrated sulphuric acid, monochlorotetramethylbenzenes (CTB) undergo disproportionation to give chloropentamethylbenzene (I) and 3-chloropseudocumene-5-sulphonic acid (II).[2,3] This is another phase of the Jacobsen reaction, which has long been recognized for its unique feature to orient the ring alkyl groups to vicinal positions.[4] Under suitable conditions, however, the reaction was found to yield as by-product an appreciable amount of dichloroheptamethyldiphenylmethanes.[5] When considered in connection with the recent proposal of diphenylalkane intermediate for the disproportionation of primary alkyl groups in the Friedel-Crafts reaction,[6] this result seems to provide a clue to elucidate the mode of intermolecular methyl transfer in the Jacobsen reaction. In the present work, the structures of these by-products have been definitely established.

New by-product from the Jacobsen reaction of CTB was high-melting, colourless prisms, poorly soluble in ordinary solvents. The analysis fitted the formula $C_{20}H_{24}Cl_2$ and the molecular weight determined from mass spectrum corresponded to 334 (Calcd 335). ^{1}H NMR spectrum showed the presence of one aromatic proton, two methylene protons, and twenty-one methyl protons. This composition was compatible only with dichloroheptamethyldiphenylmethane (DHD), and ruled out the other possibilities of dichloro-octamethyldiphenyl or dichlorohexamethyldiphenylethane.

Chlorodurene (IV) and chloroprehnitene (VI) mainly gave a single DHD (mp 213—215°C and mp 226—227°C, respectively), and the presence of other isomeric impurities was not so important. However, chloroisodurene (V) yielded an intimate mixture of two isomeric DHD (mp 215—216°C)[7] in the approximate ratio of 3 : 1, and several attempts for fractional crystallization proved to be fruitless, presumably due to the slight difference in their solubility in organic solvents used.

The mass spectra of these DHD showed intense fragment ion peaks at 166 ($C_{10}H_{11}Cl^+$) or 180 ($C_{11}H_{13}Cl^+$), characteristic for *o*-methyldiphenylmethanes, which arose from the ionic unimolecular rearrangement-dissociation reactions represented as below:[8]



Examination of ^{1}H NMR spectra of a variety of polymethyldiphenylmethanes and their chloro derivatives (Table 2) has revealed the following correlations useful for structural assignment: 1) Aromatic protons ortho to the methylene group absorb fairly high field (3.5—4.0 τ) from meta or para protons (3.1—3.3 τ). 2) The replacement of meta or para methyl group by chlorine atom usually gives little effect to the methylene protons. However, an ortho chlorine atom deshields these protons by

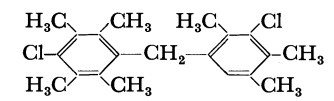
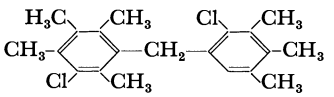
0.20—0.25 τ and the effect is additive. 3) A large downfield shift (0.25—0.30 τ) of the methylene protons is seen when the fourth ortho substituent group is introduced into the ring. Since the third ortho substituent gives little effect, such extra downfield shift is probably to be attributed to a combination of the steric and electronic influence enhanced by the restricted rotation of the benzene rings.

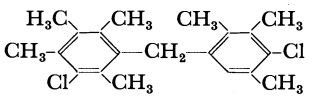
All the DHD showed a peak for ortho hydrogen atom at 3.73—3.77 τ. No chlorine atom is adjacent to the aromatic proton, otherwise the absorption will occur further downfield. The methylene protons of DHD derived from IV, V and VI absorbed at 6.08, 5.93, and 5.74 τ, respectively, indicating the presence of zero, one, and two ortho chlorine atoms. The minor component of the DHD mixture from V and the DHD from IV are supposed to possess a similar constitution in the vicinity of the methylene bridge, since both products showed the same τ - values for the aromatic and methylene protons. With these in mind and assuming no crucial rearrangement of the original hydrocarbon skeleton during the reaction, the tentative structures can readily be formulated as XVI—XIX:



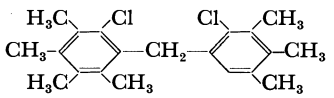
(XVI from IV)



(XVII from V, major product)

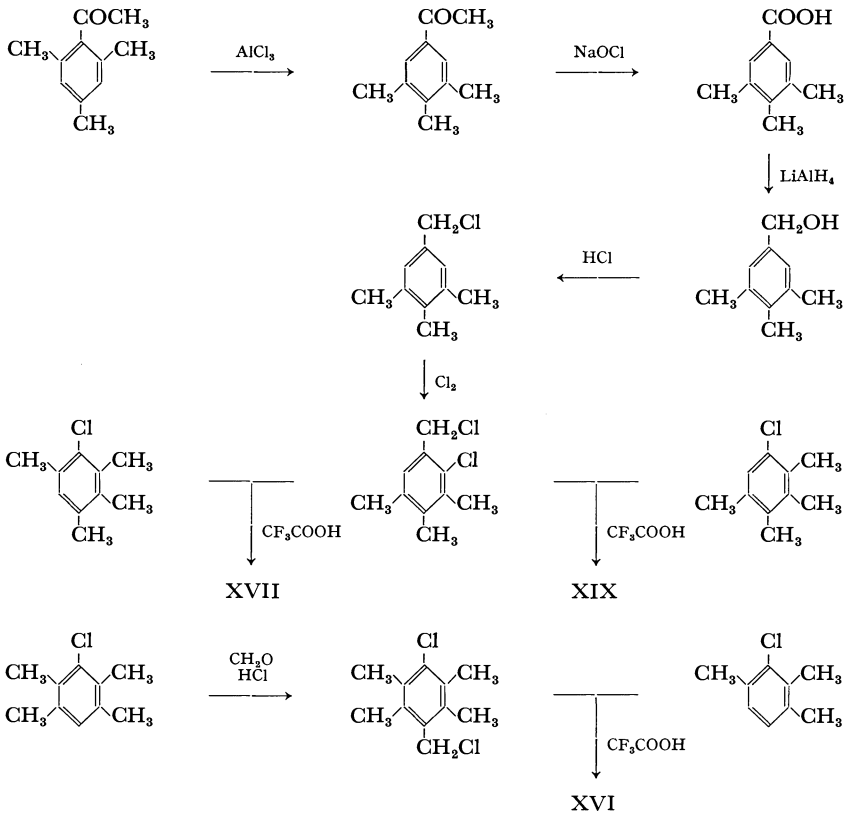


(XVIII from V, minor product)



(XIX from VI)

The structural formulae proposed above were finally confirmed through unequivocal synthesis. Authentic specimens were prepared, with the exception of XVIII, according to the sequence outlined in Scheme 1 and their identity with the products was confirmed by the complete coincidence of the infrared spectra. XVIII was not accessible by the reaction of 3-chloropseudocumene with 5-chloro-2,3,4,6-tetramethylbenzyl chloride, instead 3′,5-dichloro-2,2′,3,4,4′,5′,6-heptamethyldi-



Scheme 1

phenylmethane was formed. An attempt to prepare 5,4′-dichloro-6′-iodo-2,2′,3,3′,4,5′,6-heptamethyldiphenylmethane by blocking the reactive 5-position of VII with iodine atom, and to convert this into XVIII by reductive removal of the blocking group was unsuccessful because of the failure to obtain the expected condensation. The reaction proceeded very slowly with the replacement of iodine atom by the benzyl group.

The formation of XIX from VI is rather unusual since the original prehnitene skeleton has been partly modified in the product. This anomaly may be explained by the rearrangement of the initially formed 5′,6-dichloro-2,2′,3,3′,4,4′,5-heptamethyldiphenylmethane through the 1,2-shift of the benzyl group, and may also be responsible for the partial isomerization of VI to V observed during the disproportionation.

Experimental

IR spectra were determined for KBr disc on a Jasco DS-402G spectrophotometer. ^{1}H NMR spectra were measured in carbon tetrachloride unless otherwise stated, using TMS as internal standard, on a JNM-3H spectrometer. Mass spectra were measured on an AEI MS-9 mass spectrometer at source temperature of 200°C. All mp's were determined on a hot-stage and are uncorrected.

Materials. Chlorohemimellithene (III, bp 116—117°C/33 mmHg), chlorodurene (IV, mp 47—48°C, bp 119—121°C/20 mmHg), chloroisodurene (V, bp 113—115°C/20 mmHg) and chloroprehnitene (VI, bp 126—127°C/20 mmHg) were prepared from the corresponding hydrocarbons by chlorination in chloroform.[3] 3-Chloropseudocumene (VII, bp 108—110°C/30 mmHg) was prepared from a mixture of monochloropseudocumenes as described in literature.[9]

3,4,5-Trimethylbenzoic Acid (VIII). 3,4,5-Trimethylacetophenone (58 g)[10] was added dropwise to the 10% sodium hypochlorite solution (600 ml) so as to maintain the reaction temperature at 55—60°C. The solution was then treated with a little decolourizing carbon and made acidic with dilute hydrochloric acid. White precipitate was filtered off, washed with cold water, and crystallized from 95% ethanol. Large colourless prisms, mp 220—222°C (lit.[10] 220.5—221.5°C). Yield, 39.3 g (68%).

3,4,5-Trimethylbenzyl Alcohol (IX). To a solution of lithium aluminium hydride (5 g) in dry THF (100 ml), a warm, saturated THF solution of VIII (20 g) was added with stirring. The mixture was gently refluxed for 1 hr and then concentrated to one third of the total volume. Upon pouring into excess water, the mixture separated an oil, which soon solidified to

10) D. E. Pearson and J. D. Bruton, *J. Org. Chem.*, **19**, 957 (1954).

crystalline mass and was recrystallized from light petroleum as silky fine, long needles, mp 72—74°C (lit.[11] mp 78°C). Yield, 15.5 g (85%).

3,4,5-Trimethylbenzyl Chloride (X). A solution of IX in ligroin was stirred with concentrated hydrochloric acid, and hydrogen chloride was passed to saturation. Removal of the solvent under reduced pressure, followed by several recrystallization of the residue from light petroleum gave colourless needles, mp 36—37°C. Readily soluble in ordinary solvents.

Found: C, 71.28; H, 7.91%. Calcd for $C_{10}H_{13}Cl$: C, 71.21; H, 7.77%.

2-Chloro-3,4,5-trimethylbenzyl Chloride (XI). A crystal of iodine was added to a solution of X in carbon tetrachloride, and gaseous chlorine was passed at 0°C, controlling the extent of chlorination with gas chromatograph. The solvent was removed under reduced pressure, and the residue was crystallized from light petroleum in the form of colourless needles, mp 57—58°C.

Found: C, 59.20; H, 5.85%. Calcd for $C_{10}H_{12}Cl_2$: C, 59.13; H, 5.96%.

This compound was also obtained by stirring a mixture of III (15.5 g), 36% formalin (10%) and concentrated hydrochloric acid (40 m*l*) at 80—90°C for 24 hr under the gentle introduction of hydrogen chloride. Ordinary working-up, followed by fractional distillation gave the starting material (bp 112—113°C/27 mmHg, 7.5 g) and the chloromethylated product (bp 167—168°C/27 mmHg, 8.0 g). Recrystallization of the latter from light petroleum gave white needles, mp 47—49°C, which were identified as XI by comparison with infrared spectra. Some isomeric impurities accompanying the product were difficult to remove.

5-Chloro-2,3,4,6-tetramethylbenzyl Chloride (XII). A mixture of V (13.2 g), 37% formalin (60 m*l*) and hydrochloric acid (60 m*l*) was heated at 80—90°C, and hydrogen chloride was passed with stirring for 8 hr. After cooling, the solid product was filtered off, washed with water, and pressed to remove some oily part. Repeated recrystallization from ethyl acetate gave XII as white needles, mp 111—112°C. Yield of pure product, 8.7 g (48%).

Found: C, 61.09; H, 6.52%. Calcd for $C_{11}H_{14}Cl_2$: C, 60.84; H, 6.50%.

IV and VI similarly gave *4-chloro-2,3,5,6-tetramethylbenzyl chloride (XIII)* as large plates, mp 92—93°C, and *6-chloro-2,3,4,5-tetramethylbenzyl chloride (XIV)* as needles, mp 100—101°C, respectively.

XIII: Found: C, 60.94; H, 6.67%.

XIV: Found: C, 61.00; H, 6.66%.

Calcd for $C_{11}H_{14}Cl_2$: C, 60.83; H, 6.50%.

3-Chloro-5-iodo-1,2,4-trimethylbenzene (XV). VII (15.5 g) was iodinated at 70°C by stirring with iodine (10.2 g), periodic acid dihydrate (4.56 g), and 83% acetic acid (120 m*l*) containing small amounts of sulphuric acid as catalyst.[12] The heavy oily product was distilled under 22 mmHg. The main fraction came over at 167—168°C and weighed 20.7 g (74%).

Found: C, 38.63; H, 3.45%. Calcd for $C_9H_{10}ClI$: C, 38.53; H, 3.59%.

Disproportionation of Monochlorotetramethylbenzene (CTB). A mixture of CTB (16.9 g) and sulphuric acid (98 g) was stirred vigorously in an Erlenmeyer flask fitted with a side-arm for gas exit. The content soon turned dark brown, and sulphur dioxide, accompanied by some hydrogen chloride, was slowly liberated. After 50—55 hr, the reaction was quenched by pouring the mixture onto crushed ice, and any solid products formed were filtered off, washed thoroughly with water and chromatographed on alumina using light petroleum as eluant. Some unchanged CTB and I (5.4—6.3 g) came first, and diarylmethanes (0.8—1.4 g) followed over a wide range of eluates. These diarylmethanes were best crystallized from hot ligroin. Their physical properties are given in Table 1.

Preparation of Chlorinated Polymethyldiphenylmethanes. Chlorinated polymethyldiphenylmethanes were prepared by the following three procedures: 1) Condensation of chloro-hydrocarbons with formaldehyde in hot formic acid. 2) Reaction of a benzyl chloride with hydrocarbons in trifluoroacetic acid. 3) Chlorination of polymethyldiphenylmethanes. The last method had only limited use, because the products usually contained several diarylmethanes as well as some unidentified substances, and their separation was very difficult. In some cases, extensive transbenzylation occurred during the condensation; *e. g.* an attempt to prepare 6′-chloro-2,2′,3,3′,4,4′,5,5′,6-nonamethyldiphenylmethane by condensing VI with 2,3,4,5,6-pentamethylbenzyl chloride in trifluoroacetic acid gave a mixture of three diarylmethanes.

Catalytic Activities of Salicylaldehyde Derivatives. I. Catalytic Effects of 4-Formyl-3-hydroxyphenyltrimethylammonium Bromide on the Racemization of L-Amino Acid

Makoto ANDO and Sakae EMOTO

The Institute of Physical and Chemical Research, Yamato-machi, Kitaadachi-gun, Saitama

(Received February 14, 1969)

The pyridoxal-like catalytic effects of salicylaldehyde derivatives on the racemization of amino acid in the presence of a metal ion is known to be promoted by the substitution of an electron-attracting group in the benzene ring. Of the salicylaldehyde derivatives tested thus far, 4-formyl-3-hydroxyphenyltrimethylammonium bromide shows the most effective catalytic activity of racemization at pH 10 and at 80°C; the rate constant was 11.0×10^{-3} min^{-1}. The catalytic activity of this compound was studied under various conditions; the activation energy of the racemization of L-glutamic acid at pH 10 was 14.3 kcal/mol.

In the presence of a metal ion, pyridoxal has such a catalytic effects on amino acid as racemization and transamination. The benzene analogues were studied by Snell *et al.*,[1,2] who found that 4- and 6-nitrosalicylaldehydes had catalytic effects similar to those of pyridoxal on L-amino acid.[2] Thereafter, in the studies of the racemization of amino acid, it was recognized that even salicylaldehyde showed catalytic activity in the presence of a metal ion.[3,4] Recently, Yoshikawa *et al.* found that nitro-, sulfo-, and sulfonamide-derivatives of salicylaldehyde had also catalytic effects on the racemization of L-glutamic acid in the presence of a metal ion, and observed that an electron-attracting substituent on the salicylaldehyde ring promoted the catalytic activities, among which *p*-substitution was the most effective.[5] Since, as is well known, the tetrasubstituted ammonium group is a strong electron-attracting group, the *p*-trimethylammonium derivating of salicylaldehyde may be expected to be a stronger catalyst in racemization than all others known. This paper will deal with the synthesis of 4-formyl-3-hydroxyphenyltrimethylammonium bromide and with the measurement of its catalytic effect on the racemization of L-glutamic acid in the presence of a metal ion.

Experimental

Synthesis of 4-Formyl-3-hydroxyphenyltrimethylammonium Bromide (I). To a solution of sodium hydroxide (5 g) in methyl aclohol (200 m*l*), *p*-*N*,*N*-dimethylaminosalicylaldehyde[6,7] (15 g) and methyl iodide (50 g) were added successively, and then the solution was boiled for 24 hr. After the solution had been evaporated to syrup *in vacuo*, the syrup was extracted with an equivolume mixture of water and ethyl acetate (the aqueous layer was acidic); the aqueous solution was then evaporated under diminished pressure and treated with acetone. The precipitate, a mixture of *N*-methylated and *N*,*O*-dimethylated compound, was collected on a filter paper. It was very difficult to control the reaction to give the *N*-methylated compound alone, or to separate the *N*-methylated compound from the *N*,*O*-dimethylated product. Therefore, the mixture was boiled for 1 hr with 48% hydrobromic acid (50 m*l*), and then, after the solution had been cooled and diluted with water (100 m*l*), the resinous material was filtered off with charcoal. The filtrate was concentrated to a syrup under reduced pressure and digested with methanol to crystallize it. After recrystallization from methyl alcohol, the crystalline product was shown by a study of the analytical data to be a mixture of I and a small amount of the corresponding iodide. In order to convert the iodide into I, the mixture was dissolved in water (20 m*l*) and stirred with freshly-precipitated silver bromide (prepared from silver nitrate (5 g)) at room temperature for 3 hr. The silver halide was then filtered off and the filtrate was concentrated at diminished pressure. After recrystallization from methanol, 5.3 g of I were obtained. mp 197°C dec. (uncorrected). Found: C, 46.12; H, 5.11; N, 5.61; Br, 30.79%. Calcd

Preparation of Solution. *Solution of Amino Acid.* A solution of amino acid (0.1 mol) and cupric sulfate (2 mmol) in a small amount of water was adjusted to the required pH value with 2N sodium hydroxide, and then diluted with water to make a final volume of 100 ml.

Solution of Catalyst. The catalyst (2 mmol) was dissolved in 100 ml of the required Sörensen 0.05M borate buffer solution and the pH was corrected with a slight amount of 2N sodium hydroxide.

Procedure of Racemization. Unless otherwise stated, the reactions were carried out using the solutions described above. A mixed solution of amino acid (2 ml) and a catalyst (2 ml) was reacted in a tightly-stoppered test tube on a temperature-regulating water bath. When the required temperature was below room temperature, each solution was cooled for 1 hr at that temperature before mixing. After the required reaction time, the mixture was cooled under a trap and 6N hydrochloric acid (5 ml) was added immediately in order to stop the reaction. The optical rotation of the solution $[\alpha_t]$ was measured in a 10 cm tube by a Perkin-Elmer model 141 polarimeter (direct reading 0.001°) at 589 mμ. The racemization yield was calculated as follows:

$$100([\alpha_0] - [\alpha_t])/[\alpha_0]$$

Analysis of Amino Acid. After the reaction had been stopped with hydrochloric acid, the solution was diluted with water (250 fold). The amino acid content in the dilute solution (0.5 ml) was analyzed by a Mitamura Riken model II auto amino-acid analyzer.

Results and Discussion

Effect of Kind of Metal Ion Present. The effect of the kind of metal ion on the racemization was examined at 80°C at pH 10 for 3 hr. Some metal salts were not dissolved in the pH-adjusted 1M glutamic acid solution, so every metal salt was added in the solid state and reacted as it was. During the reaction, cuprous or ferrous ions might be partly turned to cupric and ferric ions respectively, but their effect was not detectable. The results are listed in Table 1. Since, of the metal ions tested, cupric, cuprous, ferric, ferrous, and aluminum ions were most effective, and since the cupric ion was the best of all, racemization was thereafter carried out in the presence of the cupric ion.

TABLE 1. COMPARISON OF METAL IONS IN RACEMIZATION OF L-GLUTAMIC ACID

Metal ion	Racemi. yield	Metal ion	Racemi. yield	Metal ion	Racemi. yield
Cu^{2+}	84.2%	Sn^{2+}	34.7%	Zn^{2+}	15.0%
Cu^{+}	81.7	Hg^{2+}	17.6	Pb^{2+}	14.3
Fe^{3+}	76.6	none	17.4	Co^{2+}	12.3
Fe^{2+}	75.0	Ba^{2+}	17.1	Ni^{2+}	10.4
Al^{3+}	71.2	Ca^{2+}	16.4	Mg^{2+}	9.8

Metal ion (0.04 mmol), catalyst (0.04 mmol), and L-glutamic acid (2 mmol) were used and reacted at 80°C for 3 hr at pH 10.

Effect of the Amounts of the Catalyst and the Cupric Ion. Racemization was carried out at pH 10 by altering the amounts of the catalyst and of the cupric ion (0—0.08 mmol) with 2 mmol of L-glutamic acid at 80°C for 1 hr. The results are shown in Fig. 1. As is shown in Fig. 1, the racemization was hastened when accompanied by an increase in the concentrations of the catalyst and of the cupric ion. However, its speed was gradually slowed when their concentrations became more than 0.04 mmol. Most reactions were undertaken in the presence of 0.04 mmol portions of the catalyst and the cupric ion. Of course, it is possible to enrich the catalyst more and more, because of its very high solubility in the reaction system.

○ Amounts of both catalyst and cupric ion were altered.
□ Amount of cupric ion was altered and that of catalyst was constant (0.04 mmol).
△ Amount of catalyst was altered and that of cupric ion was constant (0.04 mmol).

Effect of the Kind of Buffer Solution. Snell and Longenecker[8] have reported that in the catalytic α,β-elimination reaction of serine derivatives in the presence of pyridoxal and a metal ion, they observed the effect of the kind of buffer solution used. In order ourselves to study the effect of the kind of buffer solution, we dissolved 4-formyl-3-hydroxy-

8) J. B. Longenecker and E. E. Snell, *J. Biol. Chem.*, **225**, 409 (1957).

phenyltrimethylammonium bromide in borate, carbonate, and Britton-Robinson buffer solution (a mixture of phosphoric acid, acetic acid, boric acid, and sodium hydroxide solutions), all at pH 10. Because, at high temperatures, there was some uncertainty of this pH value being kept, the reaction was carried out at 25°C for 1 day and also for 7 days. The results are given in Table 2, which

Table 2. Comparison of kinds of buffer solutions in racemization reaction

shows no serious effect of the kind of buffer solution on the racemization.

Effect of pH-Value. The effect of the pH-value on the catalytic racemization of glutamic acid was examined with or without cupric ions in a 0.05M borate buffer solution (pH 8—12) at 80°C for 1 hr; we also examined the effect on the racemization of L-alanine at pH 0—14 for 3 hr in a 0.04M Britton-Robinson buffer solution. The results are given in Fig. 2. As this figure shows, no actual racemization was observed below pH 8, and, in contrast with the case of pyridoxal,[9] no optimum pH value was observed, just as with 5-nitro- and 4-sulfo-salicylaldehydes;[5] namely, in the more alkaline solution, the faster racemization occurred in our experimental pH region. Because the racemization yields were reasonable compared with those of 5-nitro- and 4-sulfo-salicylaldehydes,[5] we can say that the zwitter ion is not formed between the ammonium group and the phenol group.

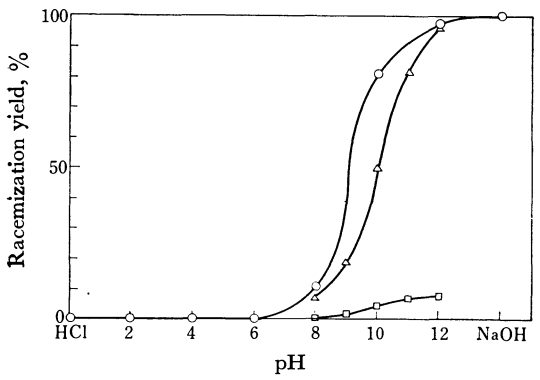

Fig. 2. Effect of pH value on racemization yield at 80°C.
△ Racemization of L-glutamic acid for 1 hr in the presence of cupric ion.
□ Racemization of L-glutamic acid for 1 hr without cupric ion.
○ Racemization of L-alanine for 3 hr in the presence of cupric ion.
HCl and NaOH mean that alanine salt is dissolved in 1N hydrochloric acid and 1N sodium hydroxide, respectively.

Effect of pH on the Rate Constant of the Racemization of L-Glutamic Acid. The racemization yield of L-glutamic acid in the presence of cupric ions at 80°C and at pH 8—12 for various periods of time was determined. The racemization should theoretically be a first-order reaction, and the relation between the rate constant, k, the time, t, and the observed rotation, $[\alpha_t]$, at t can be written as follows:

$$kt = 2.30 \times (\log[\alpha_0] - \log[\alpha_t])$$

At pH 10, in contrast with the case of pyridoxal, the activity of which decreased during the reaction,[5] 4-formyl-3-hydroxyphenyltrimethylammonium bromide indicated a first-order reaction, except at pHs 11 and 12. The plots which obeyed the first-order rate are shown in Fig. 3; the rate constants at pH 8, 9, and 10 were 1.2×10^{-3} min^{-1}, 3.3×10^{-3} min^{-1}, and 11.0×10^{-3} min^{-1} respectively. Of the salicylaldehyde derivatives tested to date, this compound was found to have the most effective activity.

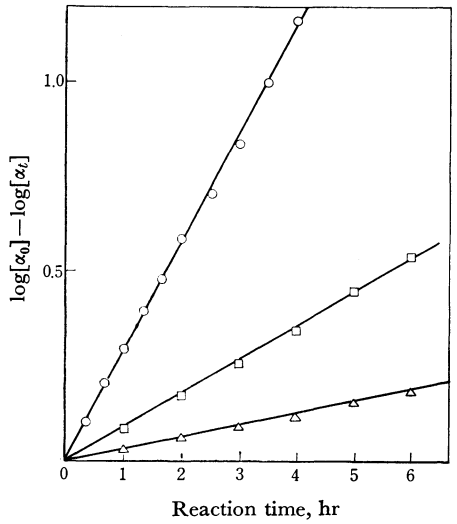

Fig. 3. Catalytic activities at pH 8, 9 and 10 in the presence of cupric ion at 80°C.
△ pH 8 □ pH 9 ○ pH 10

Table 3. The rate constant k at various temperatures

Temp.	k
100°	28.9×10^{-3} min^{-1}
90	18.2
80	11.0
70	6.20
60	3.35
50	1.69
40	0.801
20	0.155

L-Glutamic acid (2 mmol), cupric sulfate (0.04 mmol), and catalyst (0.04 mmol) were used, and reacted at pH 10.

Activation Energy of the Racemization of L-Glutamic Acid. The effect of the temperature on the rate constant of the racemization of L-glutamic acid at pH 10 was also studied. The rate constants, k, at various temperatures are listed in Table 3. A linear relation between $\log k$ and $1/T$ was observed, as is shown in Fig. 4, and the activation energy was found to be 14.3 kcal/mol.

Determination of the Amount of Glutamic Acid. After the racemization reaction had been carried out at 80°C and at pH 10 for 3 hr or 6 hr, the amount of glutamic acid was changed within the limits of experimental error; although the amount of ammonia increased considerably, it was still an unmeasurable amount.

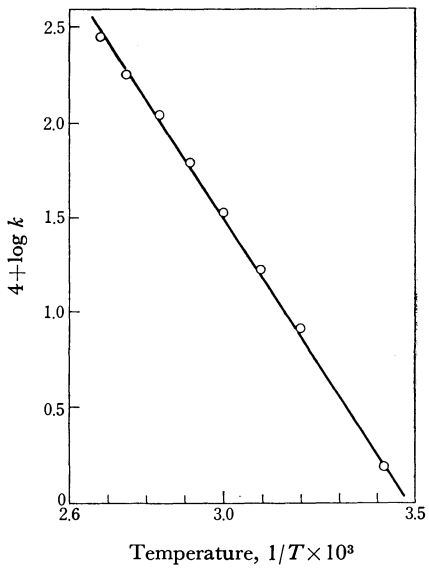

Fig. 4. Effect of temperature on rate constant at pH 10 in the presence of cupric ion.

It is easy to recover racemized free glutamic acid from the concentrated solution of a low pH, because the catalyst is very soluble in the solution.

The authors wish to express their sincere thanks to Dr. H. Homma and his co-workers of this institute for elemental analyses.

Catalytic Activities of Salicylaldehyde Derivatives. II. Kinetic Studies of the Racemization of Amino Acid

Makoto Ando and Sakae Emoto

The Institute of Physical and Chemical Research, Yamato-machi, Kitaadachi-gun, Saitama

(Received February 14, 1969)

In the racemization reaction of L-glutamic acid, catalyzed by salicylaldehyde derivatives and cupric ions, the rate constants, k, of 3-bromo-, 3-methoxy-, 3-methyl-, 3-nitro-, 4-methyl-, 5-bromo-, 5-methoxy-, 5-methyl-, and 5-nitro-salicylaldehydes and of salicylaldehyde were measured and the kinetic relation between the rate constant, k, of the salicylaldehyde derivatives and the corresponding Hammett's constant, σ, was studied. A linear relation between log k and the σ of 4- or 5-substituted salicylaldehydes and another linear relation between log k and the σ of 3-substituted salicylaldehydes were found. The activation energies of the racemizations catalyzed by pyridoxal, 3-nitro-, and 5-nitro-salicylaldehydes and by salicylaldehyde were determined, but no distinct difference between 3-nitrosalicylaldehyde and 5-nitrosalicylaldehyde was observed.

It has been reported that, in the racemization of sodium L-glutamate at pH 10 and at 80°C, 4-formyl-3-hydroxyphenyltrimethylammonium bromide, which is a salicylaldehyde derivative substituted by one of the strongest electron-attracting groups, has the most effective catalytic activity.[1] Yoshikawa *et al.*[2] have stated that the order of the racemization yield of L-glutamic acid catalyzed by nitro-, sulfo-, and sulfonamide-derivatives of salicylaldehyde agreed with the order of Hammett's constant, σ. The *p*-trimethylammonium group has a larger value based on the ionization of substituted benzoic acids than those of the corresponding nitro-, sulfo-, and sulfonamide groups.[3] This paper will deal with the kinetic relation between the catalytic activity of various salicylaldehyde derivatives and Hammett's constant, σ, of the corresponding substituents.

The activation energy of racemization catalyzed by 3-nitro- and 5-nitro-salicylaldehydes, salicylaldehyde, and pyridoxal was also studied.

Experimental

Preparation of Catalysts. 3-Bromo-,[4] 5-bromo-,[5] 4-dimethylamino-,[6] 3-methyl-,[7] 4-methyl-,[8] 5-methyl-,[9] 5-methoxy-,[10] 3-nitro-,[11] and 5-nitro-salicylaldehydes,[11] 4-formylphenyltrimethylammonium iodide,[12] 4-formyl-3-hydroxyphenyltrimethylammonium bromide,[1] and pyridoxal[13] were prepared by the method described in the literature.

Procedure of Racemization. Racemization was carried out as has been described before.[1] All the reactions were performed at pH 10 according to precedent. To 2 m*l* of a solution in a tightly-stoppered test tube containing sodium L-glutamate (2 mmol) and cupric sulfate (0.04 mmol) (pH 10), 2 m*l* of a borate buffer solution (pH 10) of a catalyst (0.04 mmol) were added; the mixture was reacted at the mentioned temperature for the mentioned time. When the required temperature was below room temperature, each solution was cooled for 1 hr at that temperature before mixing. After the required reaction time, 5 m*l* of 6N hydrochloric acid were added and the optical rotation of the solution $[\alpha_t]$ was measured by a Perkin-Elmer model 141 polarimeter (direct reading, 0.001°). The racemization yield was calculated as follows:

$$100([\alpha_0] - [\alpha_t])/[\alpha_0]$$

Results and Discussion

Effect of the Kind of Substituent of Benzaldehyde. The *o*-hydroxyl group in benzaldehydes must play a crucial role in the catalytic activity of racemization, and an electron-attracting substituent on the benzene ring promotes the activity.[2] In order to verify the effects of various kinds of substituents on racemization, several salicylaldehydes and benzaldehydes were carefully examined. The results are listed in Table 1, which shows

Aldehyde (0.04 mmol), cupric sulfate (0.04 mmol), and L-glutamic acid (2 mmol) were used and reacted at 80°C for 3 hr.

that no benzaldehyde derivatives except *o*-methoxybenzaldehyde showed any activity of racemization. The activity of salicylaldehyde derivatives which were substituted by electron-releasing groups was weaker than that of derivatives substituted by electron-attracting groups and that of salicylaldehyde itself. Moreover, the racemization yield of 3-substituted salicylaldehyde was lower than that of the corresponding 5-isomer.

Relation between the Rate Constant, k, and Hammett's Constant, σ. The rate constant of the racemization of sodium L-glutamate in the presence of cupric ions and catalyzed by salicylaldehyde derivatives was studied. The rate constant was calculated as follows:

$$kt = 2.30 \times (\log [\alpha_0] - \log [\alpha_t])$$

where k is the rate constant, t is the time, and $[\alpha_t]$ is the observed rotation at t. The rate constant of racemization catalyzed by 4-formyl-3-hydroxyphenyltrimethylammonium bromide at 80°C has been described previously.[1] The activities of 3-bromo-, 5-bromo-, 3-methoxy-, 5-methoxy-, 3-methyl-, 4-methyl-, 5-methyl-, 3-nitro-, and 5-nitrosalicylaldehydes and salicylaldehyde were also measured at 80°C. However, within 2 or 3 hr the catalytic activity of 3-bromo-, 5-bromo-, and 3-nitro-salicylaldehydes was gradually lowered, probably because of the decomposition of these catalysts. The plots indicating the first-order reaction are shown in Fig. 1, from which rate con-

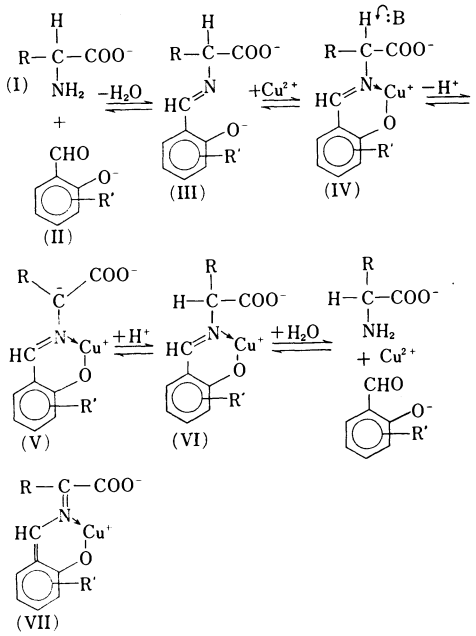
□ 3-Substituted salicylaldehydes.

stants, k, were calculated. In Fig. 2 log k is plotted against Hammett's constant, σ.[3] As Fig. 2 shows, the rate constants of 5-substituted salicylaldehydes were larger than those of the corresponding 3-isomers, probably because of some ortho steric effect in the formation of the chelate ring (IV), though the structure of the chelate complex around the copper has not yet been satisfactorily clarified.

A linear relation between log k and Hammett's constant, σ, of 4- or 5-substituted salicylaldehydes, and an another linear relation between log k and the σ of 3-substituted salicylaldehydes, were observed; the reaction constants were 0.76 and 0.91 respectively.



Snell[14] reported that, in a Schiff's base (III) of pyridoxal and amino acid, the α-carbon atom of amino acid was conjugated with the nitrogen atom of the pyridine ring and that consequently the α-proton of amino acid was eliminated easily and a racemization reaction occurred. However, Pullman[15] pointed that the conjugated system was only extended to the nitrogen atom of amino acid; before the transition state the α-carbon atom did not belong to the conjugated system. Yoshikawa[2] discussed how the electron-withdrawing power of the nitrogen atom of amino acid was activated by the inductive effect of the substituted benzene ring.

Since our results showed that the rate constant of the catalytic racemization by substituted salicylaldehydes obeyed Hammett's rule, the rapid formation of aldimine (III, IV) and the decrease in electron density around the nitrogen atom of the stabilized aldimine-chelate system should be caused mainly by inductive and mesomeric effects. Thus, the α-carbon of amino acid, affected by partial positively-charged aldimine nitrogen, would be readily converted to carbanion (V) by basic catalysis.

The negligible transamination together with the racemization of the glutamic acid catalyzed by 4-formyl-3-hydroxyphenyltrimethylammonium bromide[1] suggest that the p-trimethylammonium group should be unfavorable to the formation of a conjugated system with ketimine (VII)[2] from carbanion (V).

Activation Energy of Racemization, Catalyzed by 3-Nitro-, 5-Nitro-salicylaldehydes, Salicylaldehyde, and Pyridoxal Hydrochloride. Because the rate constant of 5-nitrosalicylaldehyde was larger than that of 3-nitrosalicylaldehyde, the

activation energies might differ from each other as a result of the ortho steric effect on the hydroxyl group. The rate constants of 3-nitro-, 5-nitrosalicylaldehydes, salicylaldehyde, and pyridoxal hydrochloride were measured at various temperatures. At 80°C pyridoxal did not satisfy the first-order reaction, as has previously been described,[1] but below 50°C our results followed the first-order reaction equation at first. At temperatures higher than 90°C, as compared with the catalytic activity of 5-nitrosalicylaldehyde, that of 3-nitrosalicylaldehyde was lowered very much as time passed, probably because of its decomposition, but the rate constant was measured only below 80°C. The rate constants are summarized in Table 2. The linear relations observed between log k and $1/T$ are shown in Fig. 3. Because the line of 3-nitrosalicylaldehyde almost overlapped with that of the 5-isomer, so that they could not be distinguished from each other, the line of the 3-isomer was omitted from Fig. 3. The activation energies of pyridoxal, 5-nitrosalicylaldehyde, 3-nitrosalicylaldehyde, and salicylaldehyde were 13.0 kcal/mol, 14.3 kcal/mol, 14.4 kcal/mol, and 16.0 kcal/mol respectively. The activation energy of 4-formyl-3-hydoxyphenyltrimethylammonium bromide was 14.3 kcal/mol.[1] Pyridoxal has the least activation energy and the largest rate constant, and it was the best catalyst for racemization, but, as has been established before, at high temperatures the catalytic activity was lowered as time passed. No distinct difference in activation energy was observed between 5-nitrosalicylaldehyde and 3-nitrosalicylaldehyde.

Sulfilimine. I. Synthesis and Formation Mechanism

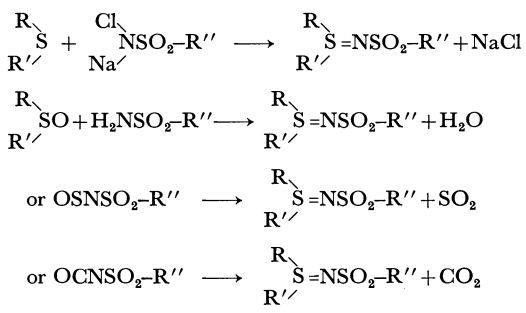
Kenji TSUJIHARA, Naomichi FURUKAWA, Keiko OAE and Shigeru OAE

Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sugimoto-cho, Sumiyoshi-ku, Osaka

(Received February 18, 1969)

The kinetics of the reaction of sulfide and chloramine T was investigated. The reaction was very much affected by pH, and the rate reached the maximum at pH 5.5. The reaction was found to be facilitated by the substitution of an electron-releasing group in phenyl rings of aryl methyl sulfides. From these observations the rate-determining step appears to involve the formation of the sulfonium cation intermediate. From the mechanistic study of this reaction, an effective procedure for the synthesis of sulfilimine was devised.

N-Sulfonylsulfilimines have been known to be prepared either by treating the corresponding sulfides with *N*-sulfonyl-haloamide,[1] or by the reaction of the sulfoxides with sulfonamide[2] or sulfinylsulfonamide[3] or sulfonylisocyanate.[4] Among these, the first method is most commonly used.



However, it is difficult to synthesize diarylsulfilimines by these methods, especially those bearing strong electron-withdrawing substituents such as halo or nitro groups. This may suggest that the formation of sulfilimine from sulfide and haloamide involves the initial slow step of halogenation of sulfide with active halogen, since the electron-withdrawing groups or substituents would hinder the formation of such a halogenated complex.

On the other hand, the similar reaction to synthesize sulfoxides from the sulfides and active halogen complex in aqueous media suggests that the initial halogenation is quite rapid and the subsequent nucleophilic attack of either acylate ion

or water is the slow step of the reaction.[5]

Although there have been a few works[6] which deal with mechanisms of the reaction between sulfides and chloramine T, these data are not sufficient for considering the mechanism of the reaction in detail, since the reaction systems are too complicated and hence no well-defined kinetic study has been performed.

We have carried out an extensive kinetic investigation which includes the effect of pH and the substituent effect and found out that the reaction is very much dependent on the change of pH. Thus, when a condition is set at the pH giving the largest rate of this reaction, even diarysulfilimines bearing electron-withdrawing substituents can be readily prepared. This paper will describe a detailed account of the kinetic study and the application of the results to a useful synthetic procedure.

Results and Discussion

The Mechanism of the Reaction of Aryl Methyl Sulfides with Chloramine T. Aryl methyl sulfides and chloramine T were used for the kinetic experiments. The reaction was carried out in 60% aqueous methanol solution at a constant temperature and pH. The kinetic measurements for this reaction were carried out by following the increase of the absorbance due to I_3^- at 353 mμ in the spectrum, since it is reflected in the decrease of chloramine T which can oxidize potassium iodide to give free iodine in an acidic solution. In this case, a suitable acid to acidify the solution was acetic acid and not sulfuric acid or other strong mineral acids.

The reaction was found to follow the usual second order kinetic relationship nicely over the range of 0—80% reaction (Fig. 1).

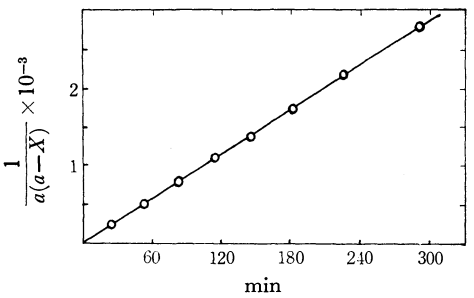

Fig. 1. Example of second order kinetics
a: the same initial concentration of methyl phenyl sulfide and chloramine T
x: a concentration of sulfilimine produced
reaction was carried out at 30°C and pH 8.61

The effect of pH on the apparent second-order rate constant K_{obs} was examined and the results are shown in Fig. 2. A plot of log K_{obs} *vs.* pH

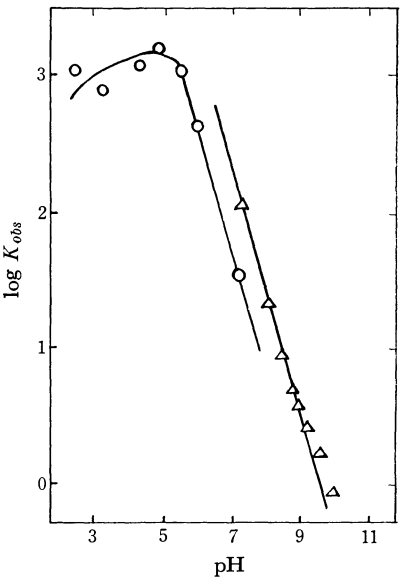

Fig. 2. The effect of pH on K_{obs}
○: at 15°C △: at 30°C

gives a straight line with a slope of −1.0 in the region between about pH 5.5 to pH 9, where the decrease of one pH unit results in the 10 fold increase of K_{obs} value.

The effects of the *p*-substituents in the phenyl ring of the sulfides upon K_{obs} are shown in Fig. 3.

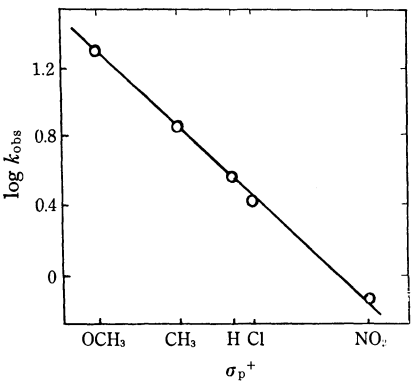

Fig. 3. The effects of the *p*-substituents in the aryl methyl sulfides on K_{obs}
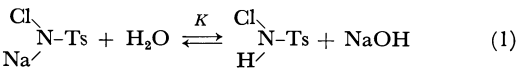
temperature 30.0°C pH 9.07

A plot of log K_{obs} *vs.* σ_p^+ gives a straight line with a slope of −0.94 ($\rho = -0.94$). This seems to indicate that the formation of the chloro-sulfonium cation takes part in the rate-determining step of this reaction.

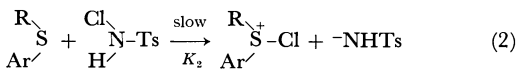
5) T. Higuchi and K.-H. Gensch, *J. Am. Chem. Soc.*, **88**, 5486 (1966); W. Tagaki, M. Ochiai and S. Oae, *Tetrahedron Letters*, **58**, 6131 (1968).

6) J. Benes, *Collection Czech. Chem. Commun.*, **28**, 1171 (1963); A. Kucsman, I. Kapovits and M. Balla, *Tetrahedron*, **18**, 75 (1962).

Based on these observations, the following mechanism may be formulated for the reaction of sulfide with chloramine T.

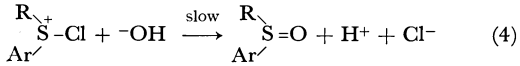


(1)



(2)

(3)



(4)

Chloramine T (I) is presumed to be in the equilibrium with its free state (II) and sulfides are considered not to react with I but with II, since the rate of this reaction is very much facilitated by the addition of a weak acid, while I is not capable to liberate free iodine from potassium iodide in alkaline solution.

Meanwhile, in the reaction shown by Eq. (2), the sulfides that possess electron-richer S atoms would react more readily with (II), namely giving minus ρ value with substituted phenyl methyl sulfides, whereas, Eq. (3) involves the chlorosulfonium cation and requires an entirely opposite electronic effect for a facile formation of sulfilimines.

The small negative ρ values (-0.94) obtained from the overall rate constants appears to suggest that the rate determining step is the second step shown by Eq. 2.

Thus, the following rate equation may be formulated.

$$d[\text{Sulfilimine}]/dt = K_2[\text{II}][\text{Sulfide}]$$

$$\text{From Eq. (1), } [\text{II}] = \frac{K[\text{I}]}{[\text{OH}^-]} = K \times 10^{14-\text{pH}}[\text{I}]$$

$$d[\text{Sulfilimine}]/dt = K_2[\text{II}][\text{Sulfide}]$$
$$= K_2 \cdot K \cdot 10^{14-\text{pH}}[\text{I}][\text{Sulfide}]$$
$$= K_{\text{obs}}[\text{I}][\text{Sulfide}]$$

The use of aqueous media for a solvent of this reaction could lead to the formation of the by-product, sulfoxide, according to Eq. (4) and hence the addition of a larger amount of water into the system could give rise to the higher ratio of sulfoxide among the products.[6]

This was not the case, however, when the reaction was conducted in the presence of a small quantity of added acid; the time required for the reaction became very short and sulfilimines were formed nearly in quantitative yields. In the conventional procedure in which no weak acid is added, a considerable portion of sulfoxide is formed in the products. This is considered to be formed by the hydrolysis of sulfilimine once formed, since the formation of sulfilimine is quite slow and sulfilimine formed would be hydrolyzed slowly under the reaction conditions. These results show that the reaction shown by Eq. (3) is considerably faster than that of sulfoxide formation (Eq. (4)).

In Fig. 2, the plateau of the curve below about pH 5 is assumed to be due to the sudden change of the rate determining step of the reaction.

p-Toluenesulfonamide anion, $^-$NHTs, formed according to Eq. (2) begins to be protonated to form the corresponding sulfonamide in a low pH region and the chlorosulfonium cation formed would react not only with the sulfonamide, but also with the aqueous solvent media. As the corollary, the sole reaction product quantitatively obtained is sulfilimine at pH 6, but at pH 2 the yield of sulfilimine became 50% while sulfoxide is formed in the same 50% yield.

The rate of sulfoxide formation (Eq. (4)) is considered to be nearly equal to, or a little smaller than that of the halosulfonium cation formation in the reaction of sulfide with halogen in aqueous media, since it is known that the rate determining step of sulfoxide formation is the reaction of the halosulfonium cation with hydroxylic species.[5]

Synthetic Application. Since it has become clear that the formation of sulfilimine becomes very facile at around pH 5, we have devised a better reaction condition for facile syntheses of sulfilimines by the addition of a small amount of a weak acid, such as acetic acid.

Sulfilimine has been prepared usually by treating sulfide with an *N*-haloamide such as chloramine T in aqueous media with either methanol, acetone or some other water miscible solvents. However, the use of water often leads to the formation of a by-product sulfoxide, and sometimes makes it difficult to dissolve the sulfides such as methyl aryl sulfides and reduces the yields of products.

In order to overcome these difficulties, we used commercial methanol as the only solvent and increased the yield of *N*-sulfonyl-sulfilimines.

In general, dialkyl and alkyl aryl sulfides readily react with chloramine T. However, diaryl sulfides do not react with chloramine T under the same reaction condition. Moreover, when an electron-withdrawing group is introduced into either one of phenyl rings of the sulfides, the reaction does not proceed. However, when the reaction was carried out by adding a small amount of a weak acid such as acetic acid, even the diarylsulfilimines having nitro and halo groups were successfully obtained in high yields.

This method is quite effective, since the acid is acting on chloramine T to liberate the free chloramine T, which supplies an active chlorine to react readily with the lone electron pair of sulfides.

The yields and mps of sulfilimines are shown in Table 1.

a) The product was separated by using chromatographic technique over silica-gel.

Experimental

Kinetic Procedure of the Mechanism of the Reaction of Aryl Methyl Sulfides with Chloramine T. The kinetic experiments were carried out while maintaining both the temperature (15±0.06, 30±0.08°C) and the pH constant using the following buffer solutions in 60% aqueous methanol media. After the reaction the pH of the solution was measured. Buffer solutions:

Potassium biphthalate-HCl (below pH 4), CH_3COOH-CH_3COONa (pH 4—6.5), KH_2PO_4-Na_2HPO_4 (pH 6.5—8.5), H_3BO_3, KCl-Na_2CO_3 (pH 8.5—10.5)

Both the sulfide and the chloramine T solutions preheated to the prescribed temperature were mixed quickly and the mixture was kept at a constant temperature during the kinetic experiments. An aliquot portion (1—2 m*l*) of the reaction mixture was taken up from time to time for 5—10 times and was quenched with 2 m*l* 1N KI. Then 5 m*l* 3N AcOH aqueous solution and the water was added to the prescribed volume.

Free iodine liberated from potassium iodide by the reaction with unchanged chloramine T is in the equilibrium with triiodide ion I_3^- with absorbance at 353 mμ was followed.

The concentrations of unreacted chloramine T were obtained by the following equation.

$$\text{Chloramine T} = \frac{A}{\varepsilon}$$

A: the absorbance at 353 mμ

ε: the molar extinction coefficient which was determined for using a known amount of chloramine T under the same condition.

Syntheses. The sulfides used were prepared by the general methods and purified either by distillation or recrystallization. The bps and mps of used sulfides are following:

di-methyl bp 37—38°C di-*i*-propyl bp 119—120°C, di-*n*-butyl bp 163—164°C, tetramethylene bp 119—120°C pentamethylene bp 140—141°C, methyl phenyl bp 84—85°C/15 mmHg methyl *p*-tolyl bp 81.5—82°C/7 mmHg, methyl *p*-methoxyphenyl bp 99°C/3 mmHg, methyl *p*-chlorophenyl bp 103—104°C/12 mmHg, methyl *p*-nitrophenyl mp 67—68°C, ethyl phenyl bp 85—86°C/

12 mmHg, iso-propyl phenyl bp 92—93°C/3 mmHg, *t*-butyl phenyl bp 96—97°C/15 mmHg, di-benzyl mp 49—50°C, benzyl phenyl mp 41—42°C, 2-phenylethyl phenyl bp 189—190°C/15 mmHg, di-phenyl bp 117—118°C/2 mmHg, phenyl *p*-tolyl bp 159—160°C/8 mmHg phenyl *p*-chlorophenyl bp 167—168°C/10 mmHg, phenyl *p*-nitrophenyl mp 55—56°C, di-*p*-methoxyphenyl mp 45—46°C. Sulfilimines were prepared from the corresponding sulfides and chloramine T by the following general methods (A) and (B).

(A): To 0.01 mol of sulfide in 20 m*l* of commercial methanol was added 0.011 mol of chloramine T in 20 m*l* of methanol at room temperature. The mixture was permitted to stand at 50°C for 1—5 hr and poured into a cold dilute sodium hydroxide solution. The precipitate was filtered, washed with water and recrystallized from methanol-water or acetone-hexane mixture.

(B): In 30 m*l* of methanol were dissolved 0.01 mol of sulfide and 0.011 mol of chloramine-T. To this solution was added dropwise 1.0 m*l* of acetic acid in 5 m*l* of methanol at room temperature. The mixture was allowed to stand at 50°C for 0.2—3 hr and poured into a cold dilute sodium hydroxide solution and a precipitate formed was filtered, then washed with water, Sometimes an oily product was extracted with two 30 m*l* portions of chloroform and the chloroform layer was washed with water, dried and the solvent removed. The residue was then washed with ether. Crude products were recrystallized from either acetone-hexane or methanol-water mixture.

The Reaction at a Low pH. Into a solution of methyl phenyl sulfide (0.001 mol) dissolved in 50 m*l* of methanol and 10 m*l* of 0.5N H_2SO_4 aq. chloramine T (0.0011 mol) dissolved in 10 m*l* of methanol was added and the reaction mixture (pH was about 2) was allowed to stand for 0.5 hr at room temperature, then poured into a dil-NaOH aq. solution. The products were extracted twice with each 30 m*l* portions of chloroform and the chloroform layer was washed with water, dried and the solvent removed. The composition of the products was calculated from the NMR spectra in which CH_3 on S atom of the sulfilimine and the sulfoxide and CH_3 in *p*-tolyl group give the chemical shifts of 2.84, 2.71 and 2.35 ppm respectively. The composition was found to be 50% sulfilimine and 50% sulfoxide.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 2635—2647 (1969)

Conformational Studies of Acetonated α-L-Sorbo- and β-D-Fructopyranoses by Means of Proton Magnetic Resonance Spectroscopy[1]

Takashi MAEDA, Kazuo TORI, Shiroh SATOH and Kanji TOKUYAMA

Shionogi Research Laboratory, Shionogi & Co., Ltd., Fukushima-ku, Osaka

(Received February 19, 1969)

The favored conformations of the pyranose rings of several acetonated α-L-sorbo- and β-D-fructopyranoses have been revealed by proton magnetic resonance spectroscopy. The conformations of the rings of the pyranoses are unchanged by the introduction of 1,2-*O*- or 1,3-*O*-isopropylidene groups in α-orientation of L-sorbose, but they are affected by the introduction of the 2,3-*O*-isopropylidene group. These findings support the fact that 2,3-*O*-isopropylidene-α-L-sorbopyranose was not obtained by the acetonation of L-sorbose. The rings of diacetonated D-fructopyranoses with a *cis*-fused acetal ring adopt a distorted conformation; however, those of diacetonated L-sorbopyranoses with a *trans*-fused acetal ring are only slightly distorted from the stable 1C conformation. Angyal's anticipation of the difficult acetalation of the *trans*-glycol of a pyranose has been further experimentally supported.

Our previous studies[3] of the conformations of acetonated L-sorbofuranose rings in solutions by proton magnetic resonance (PMR) spectroscopy showed that their conformations, restricted by the ring strain of the isopropylidene ring, play an important role in the acetonation of L-sorbose. As a part of a program of research into the reaction mechanism of the acetonation,[3,4] we have investigated the conformations of the acetonated L-sorbopyranoses, which were obtained at an initial

stage of acetonation.[4-6] In general, there are five possible monoacetonated L-sorbopyranoses; 1,2-*O*-isopropylidene-α- (type A), 1,2-*O*-isopropylidene-β- (type B), 1,3-*O*-isopropylidene-α- (type C), 1,3-*O*-isopropylidene-β- (type D), and 2,3-*O*-isopropylidene-α-L-sorbopyranoses (type E). The benzylidenation[2,7,8] and the ethylidenation[7,9] reactions yielded compounds of the types A and C, while the acetonation produced a type A compound. No compounds of the types B, D and E have yet been isolated; no formation of a type E compound is especially attractive since a derivative of this type can be formed more easily by the acetonation of D-fructose.[10]

Several workers have shown, on the basis of PMR studies, that the pyranose rings of compounds of the type E, such as 1,2-*O*-alkylidene-α-D-glucopyranose[11-14] and 1,2 : 3,4-di-*O*-isopropylidene-α-D-galacto- and β-L-arabinopyranoses (XXIII),[15] adopt distorted chair or skew conformations. In particular, 1,2-*O*-cyanoethylidene-α-D-glucopyranose has been reported to adopt a skew conformation.[11] On the other hand, Trotter and Fawcett[13] pointed out, by X-ray crystal analysis, that this compound is in a distorted, flattened Cl conformation and proposed that the PMR spectra are compatible with the conformation determined in the solid state.

This paper will deal with conformations of the pyranose rings in twelve acetonated derivatives of α-L-sorbo- and β-D-fructopyranoses by means of PMR spectroscopy. The conformations of these compounds were determined on the basis of the magnitude of their vicinal coupling constants, obtained with reference to those of 1,2,3,4,5-penta- (I), and 1,3,4,5-tetra-*O*-acetyl-α-L-sorbopyranoses (II), 1,2,3,4,5-penta- (III) and 1,3,4,5-tetra-*O*-acetyl-β-D-fructopyranoses (IV), all of which have the 1C conformation, as has previously been reported.[16]

Experimental

Measurements. All the PMR spectra were taken with a Varian HA-100 spectrometer operating at 100 MHz at an ordinary probe temperature by using about 5% (w/v) solutions in chloroform-d ($CDCl_3$), benzene-d_6(C_6D_6), pyridine-d_5(C_5D_5N), dimethylformamide-d_7 (DMF-d_7) and/or dimethyl sulfoxide-d_6 (DMSO-d_6). The charts were calibrated with direct readings of resonance frequencies using a Hewlett-Packard HP-5212 electronic counter with accuracies to within ±0.2 Hz or less. The spin-decoupling experiments were performed on the spectrometer in the frequency-swept and TMS-locked modes by using two Hewlett-Packard HP-200 ABR audio-oscillators and the HP-5212 A counter. The accuracies of the magnitudes of the chemical shifts, τ, and the coupling constants, J, are within about τ 0.02 and 0.2 Hz respectively.

The infrared (IR) spectrum of XXII was measured with a Nippon Bunko DS 402 G infrared spectrometer by using a 4.2 mg/8 m*l* (in 20 mm-cell) solution in carbon tetrachloride.

The melting points were recorded on a Kofler microstage apparatus and have been corrected. The optical rotations were measured with a Perkin-Elmer model-141 polarimeter. The concentrations were recorded in percentages.

Analysis of PMR Spectra. In the compounds reported here, the pyranose-ring protons, H_6, $H_{6'}$, H_3, H_4, and H_5, can be classified as composing an ABXYZ spin system. Therefore, it is quite certain that their signals show second-order patterns depending on the $\Delta\nu_{ij}/J_{ij}$ values, where $\Delta\nu_{ij}$ is the value of the difference in chemical shifts between H_i and H_j expressed in frequency unit. The signals of the protons H_1 and H_1' appear, in general, as an AB-type quartet. In order to determine the J values from the signal pattern with accuracies to less than 0.2 Hz, their spectra were analyzed by using the proton double resonance (PMDR) technique and by applying the solvent effects of benzene and pyridine. Since all the compounds examined here contain one or two 1,3-dioxolane rings besides hydroxyl or acetoxy groups, an alteration in the solvent from $CDCl_3$ to C_6D_6 or C_5D_5N can be expected to change their PMR spectral patterns considerably.[17] The altera-

tion in the solvent frequently changed their signal patterns into those which can be analyzed by the first-order approximation. However, in some cases the signal patterns can be analyzed by the usual procedure.[18] The chemical shifts and J values obtained are summarized in Tables 1 and 2.

Materials. 1,2-*O*-Isopropylidene-3-*O*-methyl-4,5-di-*O*-acetyl-β-D-fructopyranose (VII). A solution of 1,2 : 4,5-di-*O*-isopropylidene-3-*O*-methyl-β-D-fructopyranose[19] (2.0 g) in 60% aq. acetic acid (10 ml) was warmed at 45°C for 4 hr. The complete removal of the solvent under reduced pressure gave a syrup; the syrup was immediately acetylated with acetic anhydride (20 ml) and pyridine (20 ml) at room temperature for 3 hr. The mixture was then poured onto crushed ice and neutralized with an excess of sodium hydrogencarbonate. The solution was extracted with chloroform; the chloroform solution was washed with water, 2N HCl, and water, and dried with anhydrous magnesium sulfate, after which the solvent was removed. The recrystallization of a residue from water and methanol gave VII in a good yield. It had a mp of 101—102°C, $[\alpha]_D^{21}$ −130.8 (*c* 1.027, acetone). Found: C, 52.96; H, 6.97%. Cacld for $C_{14}H_{22}O_8$: C, 52.82; H, 6.97%.

Ethyl 1,3-*O*-Isopropylidene-4,5-di-*O*-acetyl-α-L-sorbopyranoside (X). A mixture of ethyl α-L-sorbopyranoside[20] (0.8 g), acetone dimethylketal (15 ml) and *p*-toluenesulfonic acid (70 mg) was stirred vigorously at room temperature. A clear solution was soon obtained. After 15 min, the fine crystals which precipitated were collected by filtration. The crystals were recrystallized from ethyl acetate and then acetone. Ethyl 1,3-*O*-isopropylidene-α-L-sorbopyranoside was obtained as needles (0.46 g), mp 178—179°C, $[\alpha]_D^{22}$ −60.4 (*c* 0.998, acetone). Found: C, 53.11; H, 7.98%; mol wt, 247. Calcd for $C_{11}H_{20}O_6$: C, 53.21; H, 8.26%; mol wt, 248. The needles (1.09 g) were acetylated with acetic anhydride (1 ml) and pyridine (1 ml) for 18 hr in a refrigerator. The mixture was then poured into ice water (10 g) and made alkaline with sodium bicarbonate. The solution was extracted with chloroform, and the chloroform was washed with a 2N hydrochloric acid solution. The dried extract was evaporated to give X as a syrup (130 mg); $[\alpha]_D^{23}$ −48.6 (*c* 0.970, acetone). Found: C, 54.48; H, 7.44%. Calcd for $C_{15}H_{24}O_8$: C, 54.21; H, 7.28%.

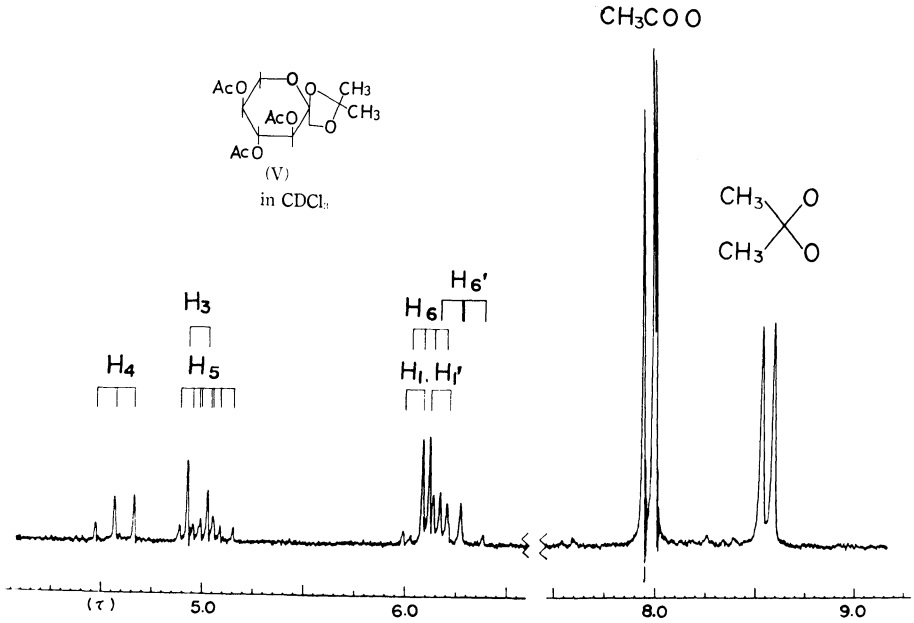

Fig. 1. PMR spectrum of V in $CDCl_3$ at 100 MHz.

dene 3,4,5-tri-*O*-acetyl-α-L-sorbopyranose (V)[4c] in $CDCl_3$ at 100 MHz. Two singlets in the high field (τ 8.52 and 8.58) are due to the isopropylidene methyls; they appear somewhat broad compared with those due to the acetoxyl methyls at τ 7.93, 7.98 and 7.99, because of the long-range coupling over 4 σ bonds.[21] The signals of H_6 and $H_{6'}$ appear as a quartet at τ 6.13 (J=(−)11.2 and 6.1 Hz) and a quartet at τ 6.23 (J=(−)11.2 and 10.2 Hz) respectively. An AB-type quartet at τ 6.04 and 6.12 (J=(−)11.8 Hz) can be assigned to H_1 and $H_{1'}$. Among the three signals arising from H_3, H_4 and H_5 at low fields, the doublet at τ 4.98 (J=9.8 Hz) should be assigned to H_3; the doublet at τ 4.57 (J=9.8 and 9.4 Hz), to H_4, and the octet at τ 5.02 (J=9.4, 6.1 and 10.2 Hz), to H_5. A similar analysis of the spectrum of V in C_6D_6 gave the results shown in Tables 1 and 2. The J values determined from the two spectra agreed well with each other. A comparison of the J values obtained with those of I and II (see Table 2) confirmed that the pyranose ring of V has the 1C conformation, in which all the secondary acetoxyl groups are equatorial. 1,2-*O*-Benzylidene- (VIII)[8] and 1,2-*O*-ethylidene-3,4,5-tri-*O*-acetyl-α-L-sorbopyranoses (IX)[9] were also believed to be in the conformation (see Table 2).

The spectrum of an analogous derivative of D-fructose, 1,2-*O*-isopropylidene-3,4,5-tri-*O*-acetyl-β-D-fructopyranose (VI),[22] whose C_5-acetoxyl group is expected to be axial, was examined in $CDCl_3$; two quartets due to H_6 and $H_{6'}$ appeared at τ 5.92 (J=(−)13.2 and 1.3 Hz) and 6.22 (J=(−)13.2 and 1.9 Hz) respectively. The signals of H_1 and $H_{1'}$ coincide as a singlet as τ 6.06. The signals due to other ring protons are too complicated to be analyzed. The spectrum in C_6D_6 shows somewhat separated signals (Fig. 2). Double irradiation at the resonance center of H_6 and $H_{6'}$ at τ 6.53 and 6.22 caused a multiplet at τ 4.58 to collapse into a doublet (J=3.2 Hz). The multiplet is clearly assignable to H_5 (Fig. 2b). The remaining doublet and quartet, at τ 4.31 (J=10.4 Hz) and τ 4.46 (J=10.4 and 3.2 Hz), should be assigned to H_3 and H_4 respectively.

To confirm the assignment of the spectra of of VI, 1,2-*O*-isopropylidene-3-*O*-methyl-4,5-di-*O*-acetyl-β-D-fructopyranose (VII) was also studied. VII was prepared from 1,2:4,5-di-*O*-isopropylidene-3-*O*-methyl-β-D-fructopyranose[19] by hydrolysis with 60% acetic acid, followed by acetylation. The spectra of VII in $CDCl_3$ and in C_6D_6 are readily analyzed. Doublets at τ 6.45 in $CDCl_3$ and at τ 6.43 in C_6D_6 (J=10.0 Hz) due to H_3; the quartets at τ 4.79 in $CDCl_3$ and τ 4.41 in C_6D_6 (J=10.0 and 3.4 Hz) due to H_4, and the octets at τ 4.70 in $CDCl_3$ and τ 4.52 in C_6D_6 to H_5 are quite distinct. The J values obtained ($J_{3,4}$=10.0—10.4 and $J_{4,5}$=3.2—3.4 Hz) from VI and VII agreed well with those obtained from III and IV, which have been established to adopt the 1C conformation.[16] The lower-field part of C_6-methylene proton signals [VI, 5.92 ($CDCl_3$) and 6.22 (C_6D_6); VII, 5.95 ($CDCl_3$) and 6.25 (C_6D_6)]

(a) Normal spectrum (b) PMDR spectrum

can be assigned to the axial protons ($H_{6'}$) although the assignment does not obey the general rule[23] that the signal of an axial proton of a pyranose ring appears at a higher field than does that of an equatorial proton. The fact is accounted for by the long-range shielding effects of the acetoxyl group at C_5 in the *trans*-diaxial relation to $H_{6'}$.

The above-mentioned facts, that the pyranose rings of the compounds V—VII adopt 1C conformations, show that the introduction of a 1,2-*O*-isopropylidene ring causes no changes in the stable 1C conformation of the parent pyranose ring.[24] It is noteworthy that no such type B compounds such as β-anomer of V, are formed. This can be attributed to the fact that the 1,2-*O*-isopropylidene ring orients the pyranose ring in the same direction as does the influence of the anomeric effect of a methoxyl group as has been reported in the case of L-sorbofuranose.[3] The type B compounds, if they are formed, might exist in an unstable Cl chair or as a mixture of 1C and Cl forms similar to the case of methyl 1,3,4,5-tetra-*O*-acetyl-β-L-sorbopyranoside.[16]

ii) 1,3-O-Isopropylidene Compounds (Types C and D). Ethyl 1,3-*O*-isopropylidene-4,5-di-*O*-acetyl-α-L-sorbopyranoside (X) was prepared from the acetonation of ethyl α-L-sorbopyranoside,[21] followed by acetylation. The spectrum of X in $CDCl_3$ is somewhat complicated as a result of the overlapping of the signals. The signals of the methylene protons of the *O*-ethyl group constitute the A_2 part of an A_2X_3 system,[25] which partially overlaps with the higher field part of the C_1-methylene proton signals, H_3, H_6, and $H_{6'}$. The ring protons display a well resolved pattern and could be easily analyzed (Fig. 3). The J values obtained from the ring proton signals similar to those of I, II, and V show that the pyranose ring of X should have the 1C chair form. Therefore, X was confirmed to exist as a stable conformation of a *trans*-decalin type. The analogous compounds, methyl 1,3-*O*-benzylidene-(XI)[8] and 1,3-*O*-ethylidene-α-L-sorbopyranosides[9] (XII) also have conformation similar to that of X, judging from their J values. Therefore, the easy formation of 1,3-*O*-benzylidene- or 1,3-ethylidene-α-L-sorbopyranose from the acetalation of L-sorbose is reasonable. It is exceptionsl that no 1,3-*O*-isopropylidene-α-L-sorbopyranose is detected from the acetonation; its absence is probably responsible for the high instability of an axial methyl

XIV
Chart 3

group at the 2-position of 1,3-dioxane.[26] This is known as the Brown-Brewster-Schechter rule.[27]

The type D compounds, the β-anomers of X—XII, have not been detected from the acetalations.[2,4,7-9] Their absence results from their stereochemical instabilities. For instance, an examination of the Dreiding models indicates that they must be in an unstable conformation of a *cis*-decalin type and of the Cl chair form. Our recent studies[2] have supported this suggestion: the pyranose ring of 1,3-*O*-benzylidene-2,4,5-tri-*O*-acetyl-β-L-sorbopyranose (XIII) has been concluded to have the conformation indicated by the models.

iii) 2,3-O-Isopropylidene Compound (Type E). The spectrum of 2,3-*O*-isopropylidene-1,4,5-tri-*O*-acetyl-β-D-fructopyranose (XIV) in $CDCl_3$ exhibits well-separated patterns; the signals were readily assigned as is shown in Fig. 4. Double irradiation at the resonance center of H_4 at τ 4.42 caused the collapse of the doublet assignable to H_3 at τ 5.88 (J=3.8 Hz) into a singlet, and that of the quartet due to H_6 at τ 6.03 (J=0.5, 5.3 and 12.3 Hz) into a sharp quartet (J=5.3 and 12.3 Hz) (Fig. 4b). Therefore, the presence of a long-range coupling between H_4 and H_6 was established.

Rees *et al.*[12] pointed out that 1,2-*O*-isopropylidene-3,4,6-tri-*O*-acetyl-α-D-glucopyranose (XV), the corresponding aldose derivative, has a distorted, flattened Cl chair conformation. Its reported J values are recorded in Table 2. The $J_{3,4}$ and $J_{4,5}$ values in XIV are not greatly different from corresponding values, $J_{2,3}$ and $J_{3,4}$, of XV.[13] Therefore, the pyranose ring of XIV seems to have a distorted, flattened 1C form. The values of the coupling constants, $J_{5,6}$ and $J_{5,6'}$, in the 1C

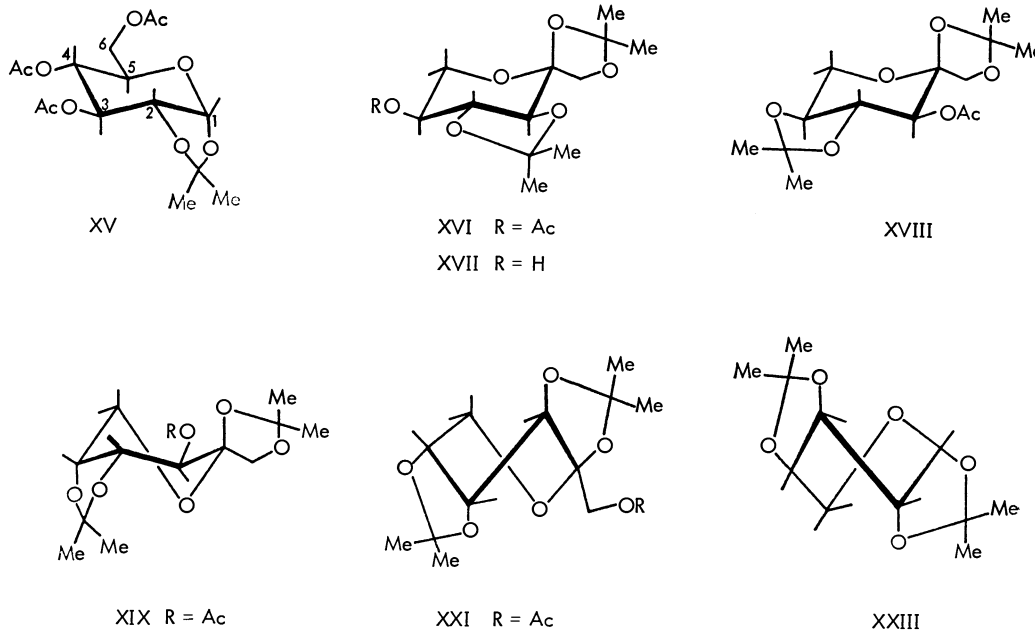

Chart 4

conformation can be expected to be about 2 Hz from the Karplus correlation,[28] since the H_5 is inevitably situated in the bisectional conformation between H_6 and $H_{6'}$. However, the values of $J_{5,6}$ (5.3 Hz) and $J_{5,6'}$ (6.8 Hz) deviate from the correlation in even a qualitative sense. Other possible skew conformations, among which one depicted in Chart 2 is the most probable, appear highly unlikely judging from the comparison of J values in 2,3 : 4,5-di-*O*-isopropylidene-β-D-fructopyranose (XXII),[10] which adopts a skew conformation, as will be described below. Therefore, the distorted Cl conformation is most likely for the pyranose ring of XIV. The presence of the long-range coupling between H_4 and H_6 also sup-

28) M. Karplus, *J. Chem. Phys.*, **30**, 11 (1959); *J. Am. Chem. Soc.*, **85**, 2870 (1963).

ported this conclusion, because it seems that H_4 and H_6 should have an equatorial conformation if we apply the "W-letter" rule.[21] As the $J_{5,6}$ value is smaller than the normal $J_{a,a}$ value, and since $J_{5,6'}$ is larger than $J_{a,e}$, the pyranose ring must be flattened. This conformation of XIV is fixed in a temperature range from 37 to 150°C in DMF-d_7 because the J values are unchanged in this temperature range.

The results show that the fused 2,3-*O*-isopropylidene group locked the pyranose ring in an unexpected direction. This is the reason why 2,3-*O*-isopropylidene-α-L-sorbopyranose is not detected in the acetonation of L-sorbose. If this compound were formed, it should adopt an unstable Cl conformation because of the ring strain of the 2,3-*O*-acetal. This unfavorable steric requirement must inhibit its formation.

Diacetonated Derivatives. It has been pointed out[29] that, in order to form the *O*-isopropylidene derivative of a vicinal glycol group of a pyranose a decrease in the projected angle in the chair form imposes little strain on the *cis*-configuration, whereas the acetonation of *trans*-glycol with acetone is impossible since a decrease in the projected angle of *trans*-one would cause severe distortion. Thus, a *trans*-fused 1,3-dioxolane formed from the acetonation with acetone dimethylketal is expected to be formed without such a distortion, that is, it should deform the pyranose ring to which it attached only slightly. We investigated 1,2 : 3,4-di-*O*-isopropylidene-α-L-sorbopyranose (XVII),[4c] its acetate (XVI),[4c] and 1,2 : 4,5-di-*O*-isopropylidene-3-*O*-acetyl-α-L-sorbopyranose (XVIII).[4c]

The spectrum of XVI in $CDCl_3$, shown in Fig. 5 exhibits well-separated signals, which were easily assigned. The assignment was further confirmed by the aid of solvent shifts in C_6D_6 and by comparison with the spectra of XVII in $CDCl_3$ and in C_6D_6. In the case of XVIII, the spectrum in $CDCl_3$ shown in Fig. 6 was rather complicated. Double irradiation at the resonance center of a doublet at τ 4.84 (J=10.4 Hz) due to H_3 caused the collapse of a quartet at τ 6.13 (J=10.4 and 8.8 Hz) assignable to H_4 into the doublet (J=8.8 Hz) (Fig. 6b). The assignment of the remaining signals are quite obvious, as is shown. The J values of XVI—XVIII for ring protons ($J_{3,4}$=9.5—10.4, $J_{4,5}$=8.8—10.0, $J_{5,6}$=5.3—5.5 and $J_{5,6'}$=9.7—10.0 Hz) indicate that their ring conformations are slightly distorted 1C forms compared with those of I, II, and V. In these conformations, and 1,3-dioxolane at the 3,4- and 4,5-positions must adopt half-chair conformations.

The conformation of a pyranose ring is not very much distorted by the introduction of a *trans*-acetal group, but it is much influenced by a *cis*-acetal group, as is confirmed below. In the spectrum of 3-*O*-acetyl-1,2:4,5-di-*O*-isopropylidene-β-D-fructopyranose (XIX)[23] in $CDCl_3$, an AB-type quartet

(a) Normal spectrum (b) PMDR spectrum

assignable to H_1 and $H_{1'}$ appears at τ 6.07 and 6.17 (J=9.1 Hz). The signal due to H_3 is observed at τ 4.90 as a doublet (J=7.8 Hz). The signals of other ring protons are too close to each other to analyze in a simple way. In C_6D_6 and in C_5D_5N, the signals of the ring protons were more separated, although some of them appear as second-order patterns. The spectrum in the last solvent was assigned as is shown in Fig. 7a. Double irradiation at the resonance center of the double at τ 4.56 (J=7.8 Hz) due to H_3 causes the collapse of the multiplet assignable to H_4 around τ 5.52 into a doublet (J=5.0 Hz) (Fig. 7b). Even in these solvents, the signals due to H_5, H_6, and $H_{6'}$ are too close to each other to analyze. The analysis of the spectrum of the deacetyl derivative of XIX (XX)[10a,30] gave similar results. Judging from the J values ($J_{3,4}$=7.8 and $J_{4,5}$=5.0 Hz), the projected angles of $\phi_{3,4}$ seems to decrease, and those of $\phi_{4,5}$ to increase, as compared to the case of VI. Therefore, the conformation of the pyranose ring is more distorted by a *cis*-fused dioxolane than by a *trans*-fused one, as is to be expected.

Finally, we investigated the conformation of 2,3 : 4,5-di-*O*-isopropylidene-β-D-fructopyranose (XXII)[10] and its acetate (XXI).[10] Cone *et al.*[15]

reported that 1,2:3,4-di-*O*-isopropylidene-α-D-galacto- and β-L-arabinopyranose (XXIII) adopt a skew conformation. Our finding that XIV, the partially deacetonated derivative of XXII, adopts the Cl conformation reasonably led us to anticipate that the pyranose rings of XXI and XXII might adopt a skew conformation, much as the acetonated aldoses have the same arabino-configuration as XXI and XXII. The signals due to the ring protons of XXII are well-separated and are assigned as is shown in Fig. 8a, where the signals due to the $C\underline{H}_2O\underline{H}$ group appear as an ABX-type signal, but the addition of deuterium oxide to the solution examined changed the signal into an AB type quartet (J=12.0 Hz) (Fig. 8b). From the ABX pattern,[18] $J_{1,1'}$, $J_{1,OH}$, and $J_{1',OH}$ were calculated to be 12.0, 3.8, and 9.2 Hz respectively.

The infrared spectrum of XXII in a dilute solution of carbon tetrachloride shows the presence of two OH bands at 3518 and 3640 cm^{-1}; the

distances between OH–O have been calculated[31] to be about 1.5 and 2.34 Å respectively. The close proximity between OH–O (1.5 Å) gave valuable information concerning the conformation; an examination of the Dreiding models indicates that the intramolecular hydrogen-bonding of this OH toward C_4–O in the skew conformation depicted in Chart 2, and in other conformations, it is difficult to form the hydrogen-bonding. The latter hydrogen-bonding may exist between C_1–OH and ring-O or C_2–O in that conformation.

The spectrum of XXI in $CDCl_3$ exhibits well-separated signals and was easily analyzed; the results are shown in Fig. 9. The coupling constants obtained from the spectra of both XXI and XXII are in good agreement with those reported for those of XXIII[15] (see Table 2). Thus, the IR spectrum of XXII and the PMR spectra of XXI and XXII are uniquely compatible with the skew conformation.

In conclusion, the compounds of the types A and C have the same 1C conformation as α-L-sorbopyranose. On the other hand, the compounds of the types B, D, and E compounds have distorted conformations. Therefore, the formation of the type A and C compounds at the initial stages of the acetalations of L-sorbose[2,4,5,7–9] is reasonable. We have also established that the conformation of a pyranose is much more influenced by the introduction of a *cis*-fused acetal ring than by that of a *trans*-fused one. This fact experimentally supported Angyal's anticipation[29] of the difficult acetalation of the *trans*-glycol of a pyranose. The easy formation of the type E compound XXII from the acetalation of D-fructose[10] is very interesting, although the reasonable type A compound XX[30] appeared as the initial product. This fact can be explained in the light of the present finding in terms of the distortion of XX, which causes C_3–OH to be so close to C_2–O as to enable them to form the 1,3-dioxolane at the 2,3-position, unlike as in the parent D-fructopyranose.

The authors are deeply grateful to Professor Toshihiko Okamoto, the University of Tokyo, and Dr. Ken'ichi Takeda, Director of this laboratory, for their encouragement.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 2648—2655 (1969)

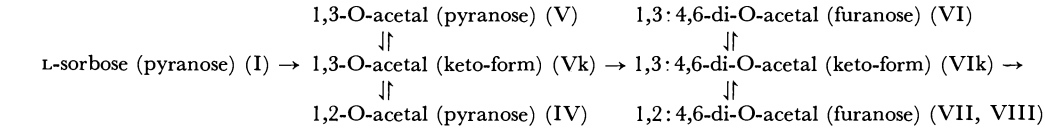
The Acetalation Mechanism of L-Sorbose[1-3]

Takashi MAEDA, Yoshiyuki MIICHI and Kanji TOKUYAMA

Shionogi Research Laboratory, Shionogi & Co., Ltd., Fukushima-ku, Osaka

(Received February 19, 1969)

The following reaction mechanism of the acetonation of L-sorbose is proposed:



2,3:4,6-di-*O*-acetal (furanose) (II). The pyranose-to-furanose ring conversion (I→II) proceeds *via* the keto-form intermediates Vk and VIk; VIk is formed by the preferable attack of acetonating reagents on the primary hydroxyl group at the C_6 of Vk followed by cyclization with the hydroxyl group at C_4. The isolation of such keto-form intermediates as were successfully obtained from the acetalations of 1-*O*-methyl- (X) and 1,6-di-*O*-methyl-L-sorboses (XVIII) gave strong support to the above mechanism. This acetonation mechanism can also be used in the other acetalations of I; however, in the case of the benzylidenation there is a possibility that the reaction might be *via* the pathway of 1,3-*O*-acetal (pyranose)⇄1,3-*O*-acetal (furanose) (Vb)→1,3:4,6-di-*O*-acetal (furanose).

The acetonation of L-sorbose (I) is used to prepare a synthetic intermediate, 2,3:4,6-di-*O*-isopropylidene-α-L-sorbofuranose (II), for L-ascorbic acid production.[4] However, this process has not yet been subjected to systematic studies despite its relatively lower yield and longer reaction period compared with other process of L-ascorbic acid production. Without any detailed evidence, it has long been believed that the mechanism of the acetonation is that I exists as α-L-sorbofuranose, which is converted into II *via* 2,3-*O*-isopropylidene-α-L-sorbofuranose (III) (mechanism 1).[5] Recently, however, I was confirmed to exist as α-L-sorbopyranose in the 1C conformation by the analyses of the PMR spectra[6] and of the optical rotatory dispersion.[7] The pyranose-to-furanose equilibrium of I was concluded to shift far to the left, as in D-glucose and D-xylose, becuase of its xylo-configuration.[8] Accordingly, the mechanism 1 is unlikely.

A correct mechanism was necessary to improve the reaction conditions of the acetonation. We have proposed previously that the process of the acetonation with acetone in the presence of sulfuric acid should be *via* the pathway of I→1,2-*O*-isopropylidene-α-L-sorbopyranose (IV)→$(IV)_2$→II⇆III (mechanism 2).[9]

Our recent works[10,11] have shown that the acetonation with acetals of acetone affords many kinds of acetonated compounds including the above-described derivatives under controlled conditions. These compounds were 1,3:4,6-di-*O*-isopropylidene-β-L-sorbofuranose (VI) and 1,2:4,6-di-*O*-isopropylidene-α- (VII) and β-L-sorbofuranoses (VIII). Besides these types of compounds, 1,3-*O*-ethylidene-α-L-sorbopyranose (Ve)[12] and 1,3-*O*-benzylidene-

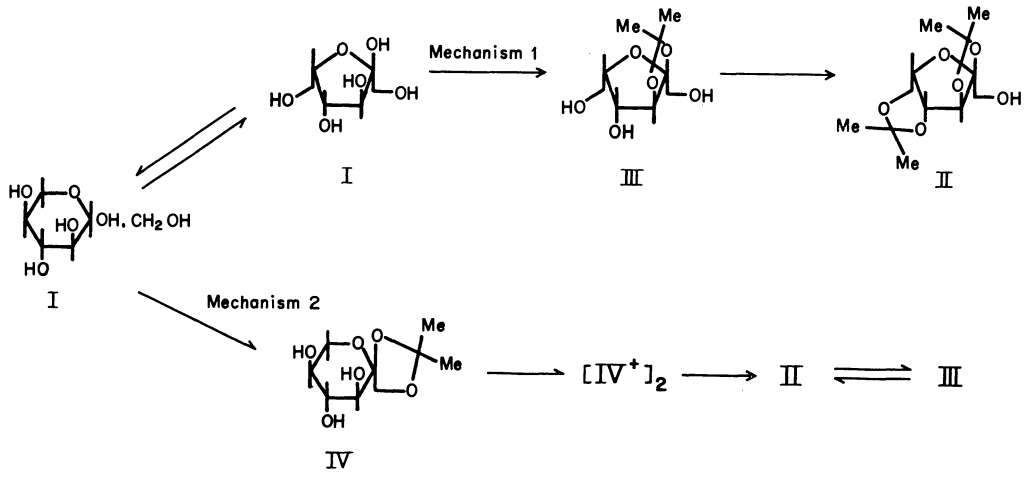

Chart 1

α-L-sorbopyranose (Vb)[13] were obtained from the ethylidenation and the benzylidenation reactions respectively.[14] Ohle[15] reported an unknown diacetonated compound; we identified it as VI by acetonating I with acetone in the presence of cupric sulfate. Patil and Bose[16] reinvestigated his reaction and isolated this unknown product. They also reported the formation of III, VII and 1,2-*O*-isopropylidene-α-L-sorbofuranose (IX).

The mechanism 2 could not explain the formation of the above-described reaction products. It was, then, found necessary to alter it, although the initial formation of IV has been unequivocally established.[9] The present paper presents a novel reaction mechanism of the acetonation, generally the acetalation, of I, a mechanism which accounts for the yielding of new intermediate products.

Results and Discussion

When slightly acidic conditions were used, the acetonation of I afforded II, VI, VII, and VIII.[10,11] On the other hand, mostly II was obtained under highly acidic conditions.[4,9] The acidic treatment of VI in the absence of acetonating reagents easily gave II as the major product and VII and VIII as the minor products, while such a treatment of VII or VIII gave II to only a limited extent. Therefore, the acetonation process must be *via* the pathway of I→(IV⇄1,3-*O*-isopropylidene-α-L-sorbopyranose (V))→VI→II⇄III. This pathway agreed well with the results of the ethylidenation[12] and the benzylidenation.[13] Although V was not obtained, the formation of Ve and Vb from other acetalations suggested its possible presence.

Formation of Monoacetonated Pyranoses (IV and V). In a preceding paper,[3] we confirmed the conformational role in the stability of the acetonated sorbopyranoses. The results can be summarized as follows: (i) the formation of β-anomers of IV and V is inhibited by their unfavorable steric factors, and (ii) that of 2,3-*O*-isopropylidene-α-L-sorbopyranose can be ruled out because of the strain of the 2,3-*O*-isopropylidene ring, which causes the pyranose ring conformation to be changed from the stable 1C chair to the unfavorable C1 form. Therefore, only IV and V can be formed.

The alcohol structure has a remarkable influence upon the acetal formation in the markedly decreasing order of primary→secondary→tertiary.[17] Among the five hydroxyl groups of the α-pyranose form of I in the 1C conformation, the axial hydroxyl group at C_2 is tertiary and is sterically hindered with axial hydrogens at C_4 and C_6; the three equatorial hydroxyl groups at C_3, C_4 and C_5 are considered to be hindered because of the steric over-crowding. The primary hydroxyl at C_1, which is sterically least hindered, is the most reactive in acetal formation. The conjugate acid of acetone or acetals of acetone reacts with the primary hydroxyl to afford a protonated form, XXI, as an intermediate; this may then be converted into stable

IV and V by two possible cyclic acetal formations with hydroxyl groups at C_2 and C_3 respectively. Therefore, the formation of IV and V at the initial stages is quite reasonable. Two compounds of the type V, Ve and Vb, were easily obtained from the ethylidenation[12] and the benzylidenation,[13] however, V itself could not be isolated. This must result from the instability of the axial methyl group at the 2-position of 1,3-dioxane of V, since one of two methyl groups is inevitably axial in the chair conformation of the six-membered *O*-isopropylidene group.[18,19] Of course, the 1,3-*O*-isopropylidene derivative was easily prepared when the hydroxyl at C_2 was blocked.[3] The predominant attack of acetalating agents on the primary hydroxyl groups sterically least hindered accords well with the results of the acetalations of D-glucose and D-galactose,[20-22] which yield 4,6-*O*-acetalated compounds as the initial products. In both acetalations, the primary hydroxyl groups at C_6 are initially attacked by aldehydes or their conjugate acids.

Ring Conversion of Monoacetonated Pyranoses to Diacetonated Furanoses. The ring conversion of the pyranoses (IV and V) to the furanose (VI) is the most important step in the acetonation. We can assume the presence of a keto-form intermediate, Vk, which is an equilibrium intermediate between IV and V. The primary hydroxyl group at C_6 of Vk must be most reactive for the same reason as in the case of the α-pyranose form of I. The keto-form intermediate, Vk, reacts with acetonating reagents to afford XXII, which is then converted into VIk, the keto-form of VI, by 1,3-dioxane ring formation at the 4,6-position. Thus-formed VIk is isolated as the furanose form, VI. In this step, another intermediate, XXIII, with 1,3-dioxolane might exist, since it is well known, in the acid-catalyzed acetalations of glycerol, that the 1,3-dioxolanes form rapidly in the initial kinetic phase and that the 1,3-dioxanes are predominant at equilibrium.[23]

This idea that the pyranose-to-furanose conversion can occur through keto-form intermediates was supported by the following evidence. 1-*O*-Methyl-L-sorbose (X)[24] was prepared from 1-*O*-methyl-2,3 : 4,6-di-*O*-isopropylidene-α-L-sorbofuranose (XI)[25] by partial deacetonation with 60% acetic acid to give 1-*O*-methyl-2,3-*O*-isopropylidene-α-L-sorbofuranose (XII),[25] followed by further deacetonation with 1N hydrochloric acid at room temperature. As the acetylation of X gave 1-*O*-methyl-3,4,5-tri-*O*-acetyl-α-L-sorbopyranose (XIII) exclusively, X adopts to a pyranose form. The acetonation of X gave 1-*O*-methyl-3,4: 5,6-di-*O*-isopropylidene-L-sorbose (XIV). The IR spectrum (liquid film) of XIV showed an absorption band at 1738 cm^{-1} due to a carbonyl group. The reduction with lithium aluminum hydride in ether yielded an alcohol, which was isolated as a benzoate (XV). The structure of XV was identified as 5-*O*-benzoyl-6-*O*-methyl-1,2:3,4-di-*O*-isopropylidene-D-glucitol; it was synthesized from 6-*O*-benzoyl-1,2:3,4-di-*O*-isopropylidene-D-glucitol (XVI)[26] by the scheme as shown in Chart 2. Therefore, the structure of XIV was established. The further acetonation of X gave XI at the expense of XIV. The pyranose-to-furanose conversion (X→XI) apparently occurred through the keto-form intermediate (XIV). This result unequivocally supported the idea that the pyranose-to-furanose conversion (IV, V→VI) in the acetonation of I can occur through the keto-form intermediates.

1,6-Di-*O*-methyl-L-sorbose (XVIII) was prepared from XII *via* 1,6-di-*O*-methyl-2,3-*O*-isopropylidene-α-L-sorbofuranose (XVII) by partial methylation with methyl iodide in the presence of silver oxide, followed by the deacetonation of the 2,3-*O*-isopropylidene group with 1N hydrochloric acid at room temperature. The acetalation of XVIII was expected to afford the derivative of a furanose form, since XVIII can not adopt a pyranose form. The benzylidenation of XVIII with benzaldehyde unexpectedly gave 1,6-di-*O*-methyl-3,5-*O*-benzylidene-L-sorbose (XIX), accompanied by other two monobenzylidenated derivatives.[27] The IR spectrum (Nujol mull) of XIX showed the existence of a band due to carbonyl at 1720 cm^{-1}. The PMR spectra of the acetate of XIX (XX) in $CDCl_3$ and in C_6D_6 showed a triplet at τ 4.55 ($J_{3,4}=J_{4,5}=1.8$ Hz) assignable to the signal of the proton at C_4 bearing acetoxyl group. These spectral data supported the proposed structure. The formation of XIX suggested that even XVIII reacted as a keto-form in the acetalation, and supported the above-described idea.

Formation of the Final Product, II. Thus-formed VIk can be converted into four furanoses, VI, VII, VIII, and II. It is quite natural to assume

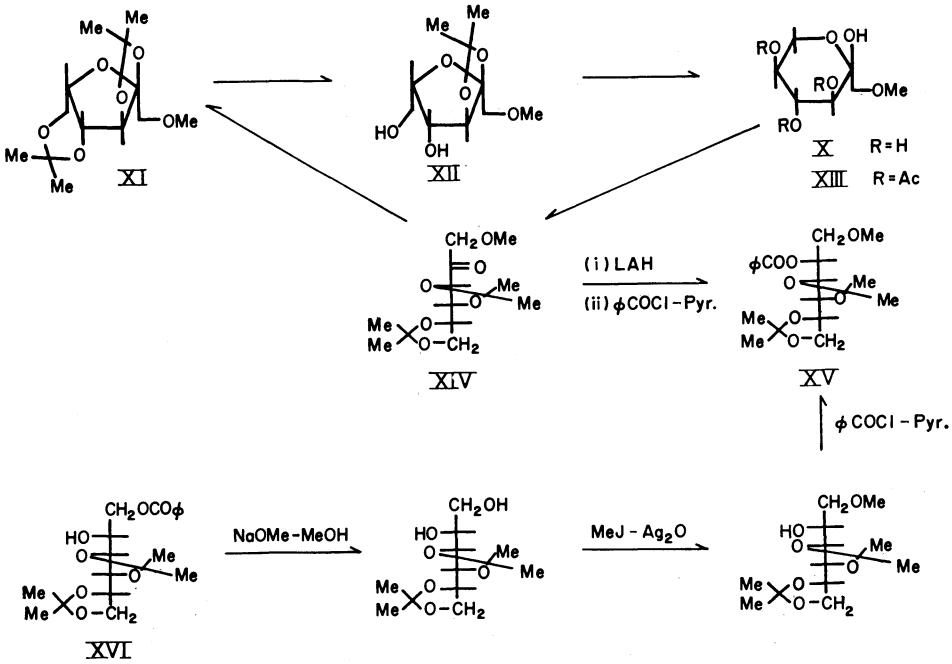

Chart 2

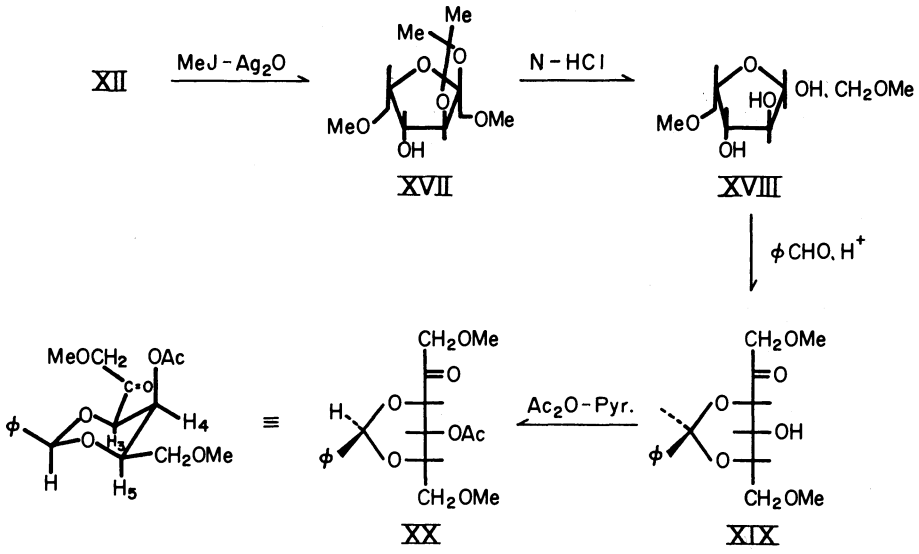

Chart 3

the existence of an equilibrium of furanoses, VII, VIII⇄VIk⇄VI, corresponding to that of pyranoses, IV⇄Vk⇄V. The stabilities of these diacetonated furanoses have been previously reported.[28] All these furanoses have a 4,6-*O*-isopropylidene group, which locks their furanose ring to the half-chair conformation of the C_3-*exo*-C_4-*endo* type. The 2,3-*O*-isopropylidene group of II and the 1,3-*O*-isopropylidene group of VI also lock the furanose ring in the same direction. Therefore, II and VI are more stable than the others. As Brown, Brewster, and Schechter pointed out,[18] a five-membered isopropylidene ring is more stable than a six-membered one. II is the most stable form among the diacetonated furanoses. Thus, VIk can be converted into II preferably.

As has been described above, it may be concluded

28) T. Maeda, K. Tori, S. Satoh and K. Tokuyama, This Bulletin, **41**, 2495 (1968).

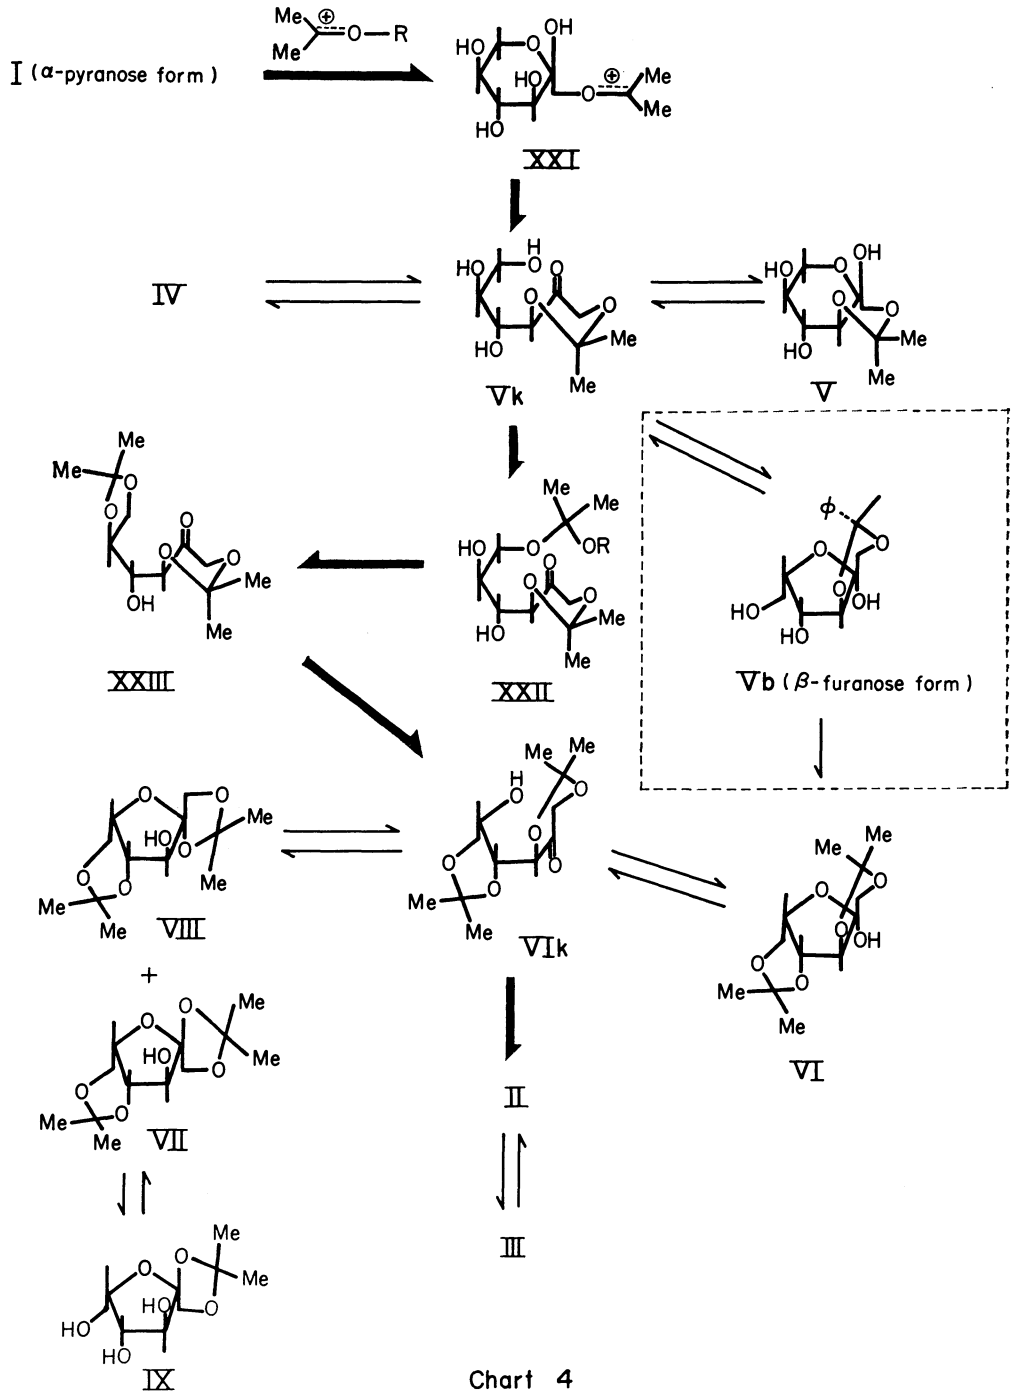

Chart 4

that the acetonation occurs *via* keto-form intermediates. The process of the acetonation proceeds *via* the pathway of

$$\begin{array}{cccc} & \text{IV} & & \text{VI} \\ & \downarrow\uparrow & & \downarrow\uparrow \\ \text{I} \rightarrow & \text{Vk} & \rightarrow \text{VIk} & \rightarrow \text{II}. \\ & \downarrow\uparrow & & \downarrow\uparrow \\ & \text{IV} & & \text{VII,VIII} \end{array}$$

The pathway is shown in detail in Chart 4, which includes minor pathways. The benzylidenation and the ethylidenation gave similar products under acidic conditions similar to those of the acetonation. Therefore, it may reasonably be concluded that the proposed mechanism for the acetonation can be generally applied to acetalations.

In the case of the benzylidenation,[13] the β-

furanose form of 1,3-*O*-benzylidene-L-sorbose (Vb) was found; the analyses of the PMR spectra and of the acetylation products of Vb clearly showed the existence of an equilibrium between the α-pyranose and the β-furanose forms.[13] The compound exists as the β-furanose form in a crystalline state and as an equilibrium mixture of the α-pyranose form, the keto-form and the β-furanose form in a solution. It is difficult to explain the preference of the β-furanose form of Vb only in the benzylidene derivative on the basis of the steric effect. Some additional polar factor of the 1,3-*O*-benzylidene ring must possibly be assumed,[13] since the acetate of the unstable β-pyranose form is abnormally obtained from the acetylation of Vb in the same proportion as that of the α-pyranose form. The existence of the β-furanose form of Vb suggests the possibility that the benzylidenation, proceeds exceptionally, *via* the β-furanose form of Vb.

We have shown that the process of the acetonation with acetone should be *via* the pathway of I→IV→$(IV)_2$→II⇄III because of the second-order reaction at the step from IV to II.[9] The intermediate IV was concluded to be acetonated with another molecule of IV, but not with acetone. The present kinetic study shows that the addition of a large amount of acetone dimethylketal to a solution of IV in acetone containing sulfuric acid changed the reaction order from the second-order to the first-order. This means that the acetals of acetone attack more easily than acetone does; the dimeric intermediate $(IV)_2$ should thus be XXII, in which the "OR" group is L-sorbose moiety. The preferable attack of the acetals must be caused by the stabilities of the intermediates XXII; the reaction with acetone gave XXII of the hemiacetal type (R=H), which should naturally be less stable than XXII of the acetal type (R=alkyl or sorbose) formed from the reaction with acetals of acetone.

It is very interesting that the reaction also proceeds when such a non-acidic catalyst as cupric sulfate was used; even in this case, however, the medium became slightly acidic because the formation of the complex of I with cupric ion freed the sulfuric acid. Therefore, it can be said that this reaction is also a kind of acid-catalyzed acetonation. Thin-layer chromatographic analyses showing the presence of the common intermediates IV—VIII supported this conclusion. Patil and Bose[16b] suggested a pathway of IV→IX→VII, which is similar to mechanism 1. Their suggestion is unlikely for the same reason that the mechanism 1 is. Further, there is no driving force to transform the pyranose IV into the furanose IX. The formation of IX might be due to the equilibrium with VII, as III is formed from II.

Experimental

All the melting points were recorded on a Kofler micro-stage apparatus and have been corrected.

The optical rotations were determined in an acetone solution unless otherwise stated, and the concentrations were recorded in percentages.

The PMR spectra were measured on a Varian A-60A spectrometer using 5% solutions of the samples in either chloroform-d ($CDCl_3$) or benzene-d_6 (C_6D_6), with TMS as the internal standard. The range of chemical shifts shown means merely that the signals occurred somewhere in the range.

Thin-layer chromatography was carried out on a silica gel plate using either acetone-chloroform (1 : 9 v/v, solvent A) or *n*-hexane-ether (2 : 1 v/v, solvent B) for both detection and preparation. The R_f values of the products were reported for II—VIII. The separated materials were located with iodine vapor of 0.2% resorcin in 10% ethanolic phosphoric acid (Seliwanoff test),[29] followed by heating on an oven. The separations of the reaction products were carried out by preparative thin-layer chromatography (PTC) unless otherwise noted. In some cases, the developed zones were extracted with acetone. The evaporation of the acetone *in vacuo* gave materials. The solvents used were removed under reduced pressure at below 40°C.

Transformation of 1,3:4,6-Di-*O*-isopropylidene-β-L-sorbofuranose (VI). i) A mixture of VI[11] (1.0 g), acetone dimethylketal (5 m*l*), chloroform (5 m*l*), and *p*-toluenesulfonic acid (TsOH) (50 mg) was stirred at room temperature for 4 hr. The solution was neutralized with methanolic sodium methoxide and then concentrated. The chloroform solution of the residue was washed, dried, and evaporated to a crystalline syrup (1.05 g). The recrystallization of the syrup from benzene gave the starting material, VI (170 mg). From the mother liquor, VI[11] (41 mg), 1,2:4,6-di-*O*-isopropylidene-α- (VII)[10,11] (71 mg) and β-L-sorbofuranoses (VIII)[11] (13 mg) were isolated.

ii) A solution of VI (1.0 g), chloroform (5 m*l*), ether (10 m*l*), and TsOH (55 mg) was stirred at 45—48°C for 3 hr and then worked up in a way similar to that described above. A syrup (1.0 g) was obtained, and from the syrup 2,3:4,6-di-*O*-isopropylidene-α-L-sorbofuranose (II)[4] (27 mg), VII (94 mg), VIII (30 mg), and VI (88 mg) were isolated.

Transformation of VII and VIII. A mixture of VII (500 mg), chloroform (3 m*l*), ether (5 m*l*), and TsOH (28 mg) was stirred at 40—45°C for 3 hr and then worked up in a way similar to that described above. A crystalline syrup was obtained. The recrystallization of the syrup gave the starting material (VII) (230 mg). From the mother liquor, a syrup (41 mg) was obtained; the thin-layer chromatogram of the syrup showed the starting material (VII) as a major spot and II and VI as minor spots. Similar results were obtained from the reaction of VIII under the same conditions.

1-*O*-Methyl-L-sorbose (X). A solution of 1-*O*-methyl-2,3:4,6-di-*O*-isopropylidene-α-L-sorbofuranose (XI) (30.5 g) in 60% aq. acetic acid (110 m*l*) was warmed at 40°C. After 3 hr, the solution was evaporated completely. The distillation of the residue gave 1-*O*-methyl-2,3-*O*-isopropylidene-α-L-sorbofuranose (XII) (26.7 g), bp 148—150°C/2 mmHg. XII (10 g) was

29) A. Anno and N. Seno, "Jikken Kagaku Kōza," Bd. 23, ed. by Chem. Soc. Japan, Maruzen, Tokyo (1957), p. 374.

hydrolyzed with 1N hydrochloric acid (100 ml) at room temperature. After 2 days, the reaction mixture was neutralized with a slight excess of Amberlite IR-45 and then evaporated to give X as a syrup (7.8 g), $[\alpha]_D^{24}$ −32.9 (*c* 0.471, water). Found: C, 43.29; H, 7.38%. Calcd for $C_7H_{14}O_6$: C, 43.29; H, 7.27%.

Acetylation of X. A mixture of X (2.0 g), acetic anhydride (10 ml), and pyridine (10 ml) was reacted in a refrigerator. After 16 hr, the solution was poured onto crushed ice and made alkaline with sodium bicarbonate. The chloroform extract was washed with 1N hydrochloric acid, and water, and then dried. The evaporation of the solvent gave crude crystals (1.8 g). The recrystallization of the crystals from ether gave 1-*O*-methyl-3,4,5-tri-*O*-acetyl-α-L-sorbopyranose (XIII) (0.98 g) as needles. It had mp 115.5—117°C, $[\alpha]_D^{24}$ −16.4 (*c* 1.026). Found: C, 49.01; H, 6.37%. Calcd for $C_{13}H_{20}O_9$: C, 48.75; H, 6.29%. PMR ($CDCl_3$)[30] τ: 7.92, 7.97 and 7.99 (OAc), 6.57 (OCH_3), 6.08 (OH), 6.6—6.7 (C_1-protons), 5.07 (H_3, doublet, $J_{3,4}$=9.5 Hz), 4.47 (H_4, doublet-doublet, $J_{4,5}$=9.5 Hz), 5.05 (H_5, multiplet), 6.1—6.3 (C_6-protons).

Acetonation of X. A mixture of X (8.7 g), acetone dimethylketal (150 ml), TsOH (260 mg), and dried chloroform (80 ml) was stirred at room temperature. After 3.5 hr, the reaction mixture was made alkaline with sodium bicarbonate and then extracted with chloroform. The dried chloroform was evaporated to give a syrup (10.3 g), which was then used; (i) for the isolation of 1-*O*-methyl-3,4:5,6-di-*O*-isopropylidene-L-sorbose (XIV), and (ii) for further acetonation. (i) The syrup (1.5 g) was separated into XIV (195 mg, R_f=0.3) and XI (240 mg, R_f=0.5) by PTC with ether-*n*-hexane (2 : 3 v/v). XIV: syrup, $[\alpha]_D^{24}$ +10.5 (*c* 1.861). Found: C, 56.63; H, 8.07%. Calcd for $C_{13}H_{22}O_6$: C, 56.92; H, 8.08%. (ii) The syrup (1.0 g) was further treated with acetone dimethylketal (15 ml) and TsOH (500 mg) at 41—42°C. No XIV was detected in the TLC. After 5.5 hr, the solution was worked up by the above-described procedure. XI (590 mg) was thus obtained.

Reduction of XIV with Lithium Aluminum Hydride. A mixture of XIV (866 mg), lithium aluminum hydride (0.45 g) and ether (30 ml) was stirred at room temperature. After 7 hr, excess lithium aluminum hydride was deactivated with ether saturated with water. The precipitates were filtered off, and then the filtrate was evaporated. The resulting syrup, dissolved in chloroform, was washed with water and dried. The evaporation of the solvent gave a syrup (726 mg), which was immediately benzoylated with benzoyl chloride (1 ml) and pyridine (15 ml), without further purification. 5-*O*-Benzoyl-6-*O*-methyl-3,4:5,6-di-*O*-isopropylidene-D-glucitol (XV) (422 mg, R_f=0.65) was isolated by PTC with benzene-ether (4 : 1 v/v) from the crude product (1.15 g). XV: syrup, $[\alpha]_D^{24}$ +13.1 (*c* 0.566). Found: C, 63.19; H, 7.48%. Calcd for $C_{20}H_{28}O_7$: C, 63.14; H, 7.42%.

Preparation of XV from 6-*O*-Benzoyl-1,2:3,4-di-*O*-isopropylidene-D-glucitol (XVI). XVI (1.0 g) was debenzoylated with methanolic sodium methoxide by the procedure of Mizoiri *et al.*[26] to give 1,2:3,4-di-*O*-isopropylidene-D-glucitol, which was methylated with methyl iodide (20 g) in the presence of silver oxide (1.0 g) under refluxing for 10 hr. The resulting 6-*O*-methyl-1,2:3,4-di-*O*-isopropylidene-D-glucitol (150 mg) was isolated as a syrup in the pure state from the reaction product (0.93 g) by PTC using the solvent A (R_f=0.50). The treatment of the syrup with bezoyl chloride and pyridine, followed by purification by PTC, gave a benzoate (88 mg) which was identified with XV by a study of its TLC and IR spectrum.

1,6-Di-*O*-methyl-L-sorbose (XVIII). A mixture of XII (10 g), methyl iodide (250 g) and silver oxide (30 g) was refluxed for 1.5 hr. Precipitates were then filtered off, and the filtrate was evaporated completely. The resulting syrup was dissolved in *n*-hexane (100 ml) and washed with water (50 ml×10). The aqueous layer was extracted with chloroform (100 ml×3), dried, and evaporated to give 1,6-di-*O*-methyl-2,3-*O*-isopropylidene-α-L-sorbofuranose (XVII) (9.5 g). XVII was hydrolyzed with 1N hydrochloric acid (110 ml) at room temperature. After 3 days, the solution was neutralized with Amberlite IR-45, washed with benzene, and then evaporated to give a syrup (5.5 g) which solidified after standing several days in a desiccator. The recrystallization from ethyl acetate gave XVIII as prisms (4.0 g), mp 78—80°C, $[\alpha]_D^{24}$ −5.3 (*c* 0.997, chloroform). Found: C, 46.15; H, 7.71%. Calcd for $C_8H_{16}O_6$: C, 46.15; H, 7.75%.

Benzylidenation of XVIII. A mixture XVIII (8.7 g), benzaldehyde (27 ml), and TsOH (47 mg) was stirred at room temperature. After 1 hr the reaction mixture was neutralized with sodium bicarbonate. The dried chloroform extract was evaporated to give a syrup (5.8 g) in which three major compounds were detected by TLC with solvent A; their R_f values were 0.50, 0.44, and 0.23 respectively. PTC with the same solvent gave needles (0.31 g, R_f 0.23) and a syrup mixture of two unknown compounds (2.28 g) (R_f 0.50 and 0.44). The recrystallization of the needles from ether gave 1,6-di-*O*-methyl-3,5-*O*-benzylidene-L-sorbose (XIX) (89 mg), mp 89—93°C, $[\alpha]_D^{20}$ −6.0 (*c* 0.329). Found: C, 60.92; H, 6.83%; mol wt 300. Calcd for $C_{15}H_{20}O_6$: C, 60.80; H, 6.80%; mol wt, 296. Unknown compounds with higher mobilities[27] were isolated by repeated PTC; a compound of R_f 0.50: syrup, 45 mg, $[\alpha]_D^{22}$ −6.9 (*c* 1.011). Found: C, 61.09; H, 6.92%; mol wt, 329. Calcd for $C_{15}H_{20}O_6$: C, 60.80; H, 6.80%; mol wt, 296; a compound of R_f 0.44: syrup, 100 mg, $[\alpha]_D^{22}$ −1.9 (*c* 0.627). Found: C, 60.78; H, 7.04%; mol wt, 305. Calcd for $C_{15}H_{20}O_6$: C, 60.80; H, 6.80%; mol wt, 296.

Acetylation of XIX. XIX (78 mg) was acetylated with acetic anhydride (1 ml) and pyridine (1 ml). The same work-up as in the acetylation of X produced a crude acetate (91 mg). The recrystallization from ether gave 1,6-di-*O*-methyl-4-*O*-acetyl-3,5-*O*-benzylidene-L-sorbose (XX) (54 mg) as needles, mp 98—99.8°C, $[\alpha]_D^{24}$ −46.9 (*c* 0.384). Found: C, 60.24; H, 6.54%. Calcd for $C_{17}H_{22}O_7$: C, 60.34; H, 6.55%. PMR ($CDCl_3$) τ: 7.93 (OAc), 6.58 and 6.64 (OCH_3), 4.32 (benzylic proton), ~6.6 (methylene protons at C_1), 5.33 (H_3, doublet, $J_{3,4}$=1.8 Hz), 4.55 (H_4, doublet-doublet, $J_{4,5}$=1.8 Hz), 5.88 (H_5, multiplet) and 6.4—6.6 (methylene protons at C_6); PMR (C_6D_6) τ: 8.35 (OAc), 6.82 and 6.88 (OCH_3), 4.72 (benzylic proton), 5.72 and 5.84 (methylene protons at C_1, $J_{1,1}$=18.3 Hz), 5.92 (H_3, doublet, $J_{3,4}$=1.8 Hz), 4.55 (H_4, doublet-doublet,

30) The *J* values supported the pyranose structure of XIII.[3]

$J_{4,5}$=1.8 Hz), 6.13 (H_5, multiplet) and 6.5—6.6 (methylene protons at C_6).

Kinetic Measurements of the Reaction of IV with Acetone Dimethylketal. Kinetic measurements were made polarimetrically[31] at 15, 25, and 35°C. A Yanagimoto Automatic Recording Polarimeter, model OR-1, was used. Acetone (5 m*l*) containing conc. sulfuric acid (45 mg) was added to a 10 m*l* solution of IV (300 mg) and acetone dimethylketal (3.00 g) in acetone at the appropriate temperature. The solution was transformed into 10 cm polarimeter cell for optical rotation determination. The data are shown in Fig. 1 and Table 1.

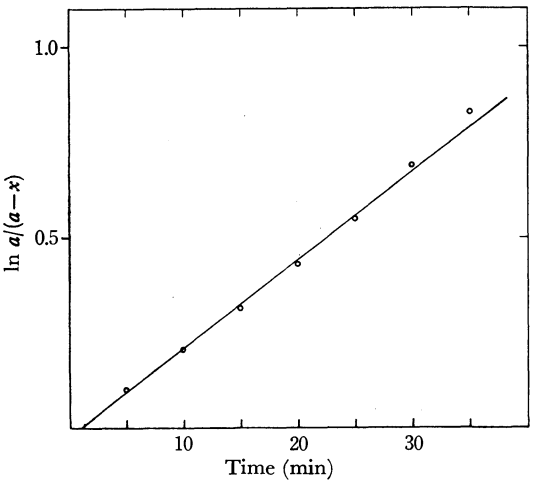

Fig. 1. Values of concentration function *vs.* time at 25°C.

Table 1. The rate constants

Reaction temp.	Rate constants $\times 10^{-4}$ (sec^{-1})
15	1.52
25	3.80
35	8.62

Acetonation of I in Acetone. A mixture of I (5.0 g), acetone (500 m*l*), and sulfuric acid (121 mg) was stirred at 30°C for 5 hr. The solution was then neutralized by a few drops of a sodium hydroxide solution. The unreacted I was filtered and washed with acetone. The combined filtrate was evaporated to give a syrup; this syrup was then dissolved in chloroform, washed with water, and dried, and the chloroform was evaporated. The recrystallization of the residual syrup (750 mg) from *n*-hexane gave VI (59.5 mg). From the mother liquor, II (53.6 mg), VII (89.4 mg), VIII (62.0 mg), and VI (42.7 mg) were isolated by repeated PTC (solvent A).

Acetonation of I in the Presence of Cupric Sulfate. A mixture of I (5.0 g), acetone (500 m*l*), and anhydrous cupric sulfate (50 g) was stirred for 8 hr at room temperature. After the cupric sulfate and the unreacted I had been removed by filtration, the neutralized solution with a few drops of a 2N sodium hydroxide solution was worked up in a way similar to the acetonation of I in acetone. II (140 mg), VII (273 mg), VIII (114 mg), and VI (114 mg) were obtained.

The authors wish to express their deep gratitude to Professor Toshihiko Okamoto, the University of Tokyo, and Dr. Ken'ichi Takeda, Director of this Laboratory, for their encouragement.

31) Under the reaction conditions employed, II as the major product and traces of 1-*O*-methoxyisopropyl-2,3:4,6-*O*-isopropylidene-α-L-sorbofuranose[11] were detected as products in the thin-layer chromatograms. The further acetonation of II under these conditions fortunately did not affect the kinetic measurements.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 2656—2662 (1969)

A Destructive Ethylation Reaction of Benzene with 3-Methylpentane-1-^{14}C

Yukio SUGAHARA,*1 Jun-ichi HAYAMI, Akira SERA and Ryozo GOTŌ

Department of Chemistry, Faculty of Science, Kyoto University, Kyoto

(Received March 10, 1969)

The destructive alkylation reaction of benzene with 3-methylpentane to give ethylbenzene in the presence of aluminum chloride was investigated. When 3-methylpentane-1-^{14}C was employed, radioactive ethylbenzene was obtained. A radioassay of radioactive ethylbenzene showed that: a) the specific radioactivity of the ethylbenzene was about one-third that of the starting 3-methylpentane-1-^{14}C, and b) more than 90% of the radioactivity of the ethylbenzene was present on the β-carbon atom of the ethyl group. These findings suggested a preceding equilibrium between 3-methylpentane and 2-methylpentane, which resulted in an equivalent localization of the radioactive label on three methyl groups of these C_6-hydrocarbons. A carbonium-ion mechanism including an intermediate ethyl cation was discussed in detail.

In 1935, Ipatieff and his co-workers[1-3] reported that the treatment of benzene with 2,2,4-trimethylpentane in the presence of an aluminum chloride-hydrogen chloride catalyst yielded *t*-butylbenzene and p-di-*t*-butylbenzene as well as isobutane. This method of preparing alkylbenzenes from arenes and alkanes was found to be affected by many kinds of Friedel-Crafts catalysts.

These reactions, examples of what Ipatieff originally termed "Destructive Alkylation,"[4] probably proceed through a carbonium-ion process. A scheme for the *t*-butylbenzene formation may be represented as is shown. The scheme involves: 1) hydride abstraction from 2,2,4-trimethylpentane by an appropriate catalytic species to give a tertiary cation, 2) which then affords a *t*-butyl cation and an isobutene molecule by β-cleavage reaction. 3) The *t*-butyl cation formed by the β-cleavage and/or formed from isobutene by the addition of a proton, alkylates benzene to give *t*-butylbenzene. 4) The *t*-butyl cation can abstract the hydride ion from 2,2,4-trimethylpentane to give isobutane and the tertiary cation.

In the destructive alkylation of the C_6-alkanes-benzene system, ethylbenzene has been reported to be the main product. Actually, in the presence of an aluminum chloride-hydrogen chloride catalyst, the destructive alkylation of benzene with 3-methylpentane afforded ethylbenzene and a small amount of an alkylbenzene mixture.[5] Most probably, the attacking species in the formation of ethylbenzene is either ethylene or ethyl cation; however, the mode of the cleavage of 3-methylpentane remains to be examined.

In the present paper, the authors wish to present some experimental results which may shed light on the mechanism of the formation of ethylbenzene in a "destructive alkylation" reaction. A tracer experiment was performed using 3-methylpentane-1-^{14}C.

Results

Synthesis and Degradation of 3-Methylpentane-1-^{14}C. Carbon-14-labeled 3-methylpentane was prepared in the following way:

$$^{14}CH_3I + Ph_3P \rightarrow {}^{14}CH_3\overset{\oplus}{P}\cdot Ph_3\cdot I^{\ominus} \rightarrow$$

$$^{14}CH_3\overset{\oplus}{P}\cdot Ph_3\cdot Br^{\ominus} \rightarrow {}^{14}CH_2{=}P\cdot Ph_3$$

$$CH_3{-}CH_2{-}\underset{|}{\overset{CH_3}{\overset{|}{C}}}H{-}CHO + {}^{14}CH_2{=}P\cdot Ph_3 \rightarrow$$

$$CH_3{-}CH_2{-}\underset{|}{\overset{CH_3}{\overset{|}{C}}}H{-}CH{=}{}^{14}CH_2 \rightarrow$$

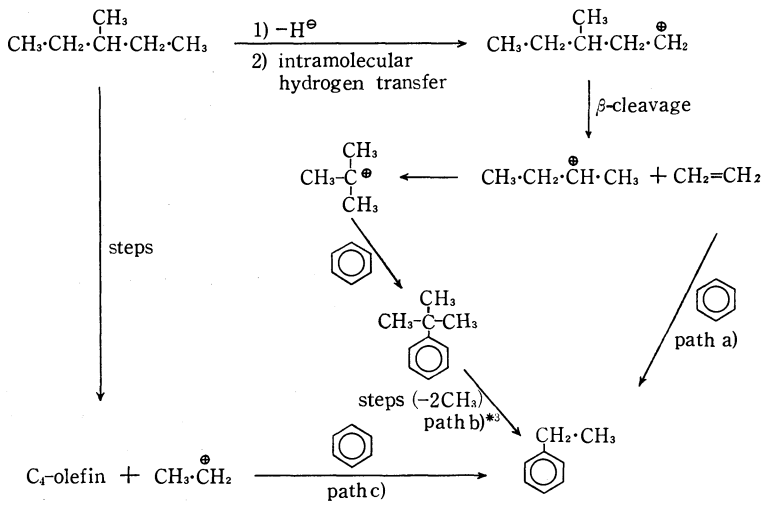
$$CH_3{-}CH_2{-}\underset{|}{\overset{CH_3}{\overset{|}{C}}}H{-}CH_2{-}{}^{14}CH_3$$

The Wittig reaction of 2-methylbutanal with methyltriphenylphosphonium bromide-methyl-^{14}C, followed by a catalytic hydrogenation, gave 3-methylpentane-1-^{14}C (5.28 μCi/mol).*2 A carrier was used where necessary. The systematic degradation of this labeled hydrocarbon was carried out as follows:

$$\underset{①}{CH_3}{-}\underset{②}{CH_2}{-}\underset{③}{\overset{④CH_3}{\overset{|}{C}}}H{-}\underset{②}{CH_2}{-}\underset{①}{CH_3} \xrightarrow[h\nu]{Br_2} CH_3{-}CH_2{-}\underset{|}{\overset{CH_3}{\overset{|}{C}}}{-}CH_2{-}CH_3$$
$$\qquad\qquad\qquad

show the important features of the "destructive ethylation" reaction. The oxidation of radioactive ethylbenzene to benzoic acid reveals that more than 90% of the radioactivity was present on the β-carbon atom of ethylbenzene. Although the origin of the radioactivity on the α-carbon atom (less than 10%) remains uncertain, this result clearly shows that no symmetric C_2-compound could be an intermediate of the reaction. Mention should be made of the specific activity of the product, ethylbenzene. The observed figure (1.53 μCi/mol) was very close to one-third of the activity of the starting material, 3-methylpentane (5.14 μCi/mol). Any mechanism that can be applicable in the present investigation should be able to give a rational explanation of the above findings.

Three pathways can be postulated for the formation of ethylbenzene in the destructive alkylation. They are: a) the reaction of ethylene with benzene; b) the formation of *t*-butylbenzene or higher alkylbenzenes by the reaction of *t*-butyl or other higher alkyl cations with benzene, followed by a sidechain demethylation to give ethylbenzene, and c) the reaction of the ethyl cation with benzene. These are summarized in the following scheme:



The results of the tracer experiment eliminate path a), the intervention of ethylene or other symmetric C_2-species as a direct precursor of ethylbenzene. Symmetrical intermediate(s) should incorporate an equal amount of radioactivity on both the α- and β-carbon atoms of ethylbenzene; however, this was found not to be the case.

Path b) can be ruled out by examining the fate of *t*-butylbenzene under the destructive alkylation conditions. The treatment of *t*-butylbenzene in benzene with aluminum chloride at an elevated temperature afforded not only ethylbenzene, but in addition, cumene, toluene, and *n*-propylbenzene. These four products were found to be produced in comparable amounts. One of the important features is that an appreciable amount of *t*-butylbenzene survived even after a considerable amount of alkylbenzenes had been formed. In the present instance of a destructive ethylation reaction, the ethylbenzene formed was accompanied by only small amounts of cumene and *n*-propylbenzene and by only a trace of *t*-butylbenzene. These findings suggest that the *t*-butylbenzene route (or path b) can not constitute a major part of the ethylbenzene formation under the conditions used.

Path c) remains to be examined. The intervention of the ethyl cation in the Friedel-Crafts reaction with ethyl halides is a well-known phenomenon. Roberts, Ropp, and Neville[6] reported that the reaction of ethyl-β-^{14}C chloride with benzene in the presence of aluminum chloride gave ethyl-β-^{14}C-benzene. They also found that ethyl-β-^{14}C-benzene showed little or no tendency to randomize its radioactivity even under vigorous Friedel-Crafts conditions. The results in Table 2 strongly suggest that the attacking species is the ethyl cation;*4 that is, path c) might be followed.

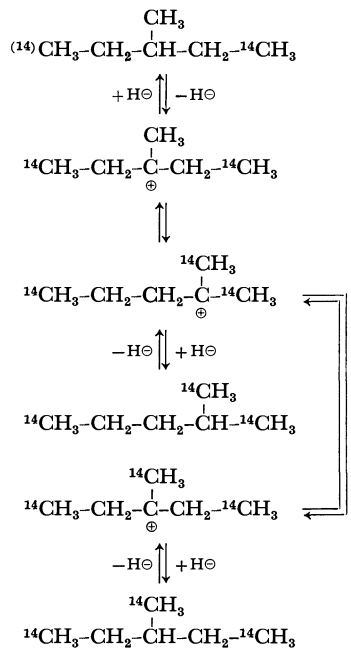
A reasonable explanation of the specific radioactivity of ethylbenzene may be given in terms of a

*3 Or *via* higher alkylated benzene(s).

6) R. M. Roberts, G. A. Ropp and O. K. Neville, *J. Am. Chem. Soc.*, **77**, 1764 (1955).

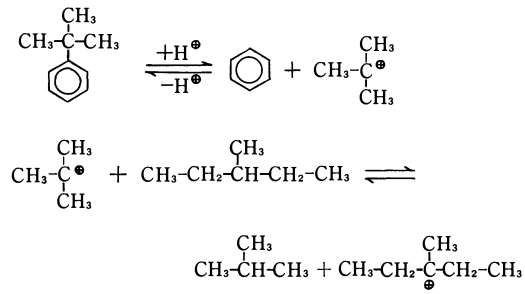
*4 The ethyl cation may be in a form of an aluminum chloride complex or in a tight ion pair. Interventions of the carbonium ion intermediates are thoroughly discussed in the leading references. For a detailed discussions, *cf.* G. A. Olah and M. W. Meyer, "Friedel-Crafts and Related Reactions," edited by G. A. Olah, Vol. I, Interscience Publishers, New York (1963), p. 623.

rapid equilibrium between 3-methylpentane and 2-methylpentane in the presence of aluminum chloride. Schneider and Kennedy[7] have reported an isomerization of 3-methylpentane to 2-methylpentane, and *vice versa*, catalysed by Friedel-Crafts catalysts. Evering and Waugh[8] have presented the rate constants of an aluminum chloride-catalyzed isomerization reaction. The rate constants in *n*-hexane at 100°C were 150 hr^{-1} and 65 hr^{-1} for the isomerization of 3-methylpentane to 2-methylpentane, and for the reverse reaction, respectively. In addition, Karabatsos *et al.*[9] proved that there was no mixing between terminal carbon atoms and internal carbon atoms during the isomerizations of saturated hydrocarbons under the influence of the Friedel-Crafts catalysts. A rapid interconversion of this sort gives rise to radioactive randomization; hence, the three terminal methyl groups in 2- and 3-methylpentanes become equally labeled by radioactive carbon atoms, as is shown in the following scheme:



These equilibria indicate the presence of the 1,1-dimethylbutyl cation (and its conjugate acid, 2-methylpentane) in the reaction mixture. From the well-known β-cleavage rule, the precursor of the ethyl cation should be the 1,1-dimethylbutyl cation rather than the 1-methyl-1-ethylpropyl cation. The β-cleavage process now gives rise to the ethyl cation and isobutene. The presence of isobutane as the main product in the destructive alkylation of 3-methylpentane instead of isobutene shows another feature of the reaction. Isobutene can be converted into *t*-butylbenzene in the presence of benzene under Friedel-Crafts alkylation conditions. Surprisingly, in the present investigation, essentially no *t*-butylbenzene was isolated from the reaction mixture. It seemed of interest to determine the fate of *t*-butylbenzene.

In a destructive alkylation in the presence of added *t*-butylbenzene, g. l. c. analysis showed the rapid disappearance of *t*-butylbenzene, and the formation of a large amount of isobutane. The amount of ethylbenzene produced was not substantially affected by the addition of *t*-butylbenzene. From these observations, the following scheme may be suggested for the fate of *t*-butylbenzene under the present conditions:



From the experimental results and from the considerations cited above, one can postulate the following reaction scheme for the destructive ethylation of benzene with 3-methylpentane in the presence of aluminum chloride at an elevated temperature. The first stage of the reaction is the initiation of the reaction by an abstraction of hydride from 3-methylpentane with a polarized catalyst complex to give the tertiary cation. The cation produced is involved in a rapid equilibrium with a tertiary cation from 2-methylpentane, which is subjected to the β-cleavage reaction to yield an ethyl cation and isobutene. The ethyl cation thus formed alkylates benzene to give ethylbenzene, and isobutene is protonated to give the *t*-butyl cation. The role of the *t*-butyl cation is either to alkylate benzene to give *t*-butylbenzene, or to abstract hydride from 3-methylpentane (or 2-methylpentane as well) to give the carbonium ion. The last sequence of the reaction would maintain the reaction cycle.

Experimental

All the melting and boiling points are uncorrected. Glc analyses were carried out by means of a Yanagimoto Gas Chromatograph G.C.G.-5DH with 5% TG-3000 on a Celite 545 (40—60 mesh) 2.25-m column, and preparative glc was achieved using Yanagimoto G.C.G.-2 with a silicon-grease DC-703 2-m column.

Radioactivity Assay. The radioactivity was measured by means of a Nuclear Chicago Liquid Scintillation Spectrometer 6801, using dioxane-base organic phosphor (1,4-dioxane : naphthalene : POP : POPOP=1 *l* : 120g: 7g : 0.05 g). Correction was made for the quenching using 3-methylpentane-^{14}C as the internal standard. Methyl ethyl ketone 2,4-dinitrophenylhydrazone and iodoform were converted into carbon dioxide in a Barker-type wet-combustion apparatus; carbon dioxide fixed with ethanolamine was served for assay.

Preparation of Methyltriphenylphosphonium Bromide-methyl-^{14}C. In a vacum manifold, methyl iodide-^{14}C (100 μCi, from the Radiochemical Center, Amersham) was transferred on 10-fold equivalents of triphenylphosphine by the aid of liquid nitrogen. The mixture was then warmed to 30°C and chilled again. This procedure was repeated several times, and the total system was flushed with non-radioactive methyl iodide. The methyl iodide washing was condensed on triphenylphosphine to give essentially quantitative yield of methyltriphenylphosphonium iodide-methyl-^{14}C. The crude iodide was dissolved in aqueous ethanol and was treated with freshly-prepared silver oxide. The mixture was filtered, and the precipitate was treated with non-active methyltriphenylphosphonium iodide several times. The combined filtrate and washings was acidified with hydrobromic acid, and the solution was concentrated to dryness. The residue was recrystallized from ethanol-ether to give pure methyltriphenylphosphonium bromide-methyl-^{14}C in a radioactive yield of over 90%.

Preparation of 3-Methylpentane-1-^{14}C. In a 15-m*l* centrifugal tube stoppered with a serum cap, was placed 0.26 g of sodium hydride (53% mineral oil dispersion). Two milliliters of dry light petroleum (bp 30—35°C) was then introduced into the tube through a hypodermic needle, and the suspension was centrifuged. The supernatant was drawn off and the washing was repeated with other two 2-m*l* portions of dry light petroleum. The tube was evacuated to remove the remaining light petroleum and was then flushed with dry nitrogen through hypodermic needles. Two and a half mililiters of dry dimethylsulfoxide was added through a needle, and the mixture was warmed at 70—75°C for 45 min. After the mixture had been cooled to room temperature, to this a solution of 1.79 g of methyltriphenylphosphonium bromide-methyl-^{14}C (5.0 mmol) in dry dimethylsulfoxide was added through a needle. After 10 min, 0.47 g of 2-methylbutanal*[5] (5.5 mmol) was introduced to the solution through a needle, the mixture was then allowed to react for 2 hr at room temperature. The reaction mixture was transferred into a distillation apparatus, and the reaction vessel was washed with non-radioactive 3-methylpentane (0.5 m*l*); the washings were also transferred into the distillation apparatus. Destillation was carried out to collect all of the low-boiling materials in a Dry Ice-acetone-cooled trap. The distillate was treated with a mercuric chloride-mercuric oxide mixture*[6] in ethanol for 2 hr; subsequent distillation afforded a mixture of 3-methylpent-1-ene-^{14}C, 3-methylpentane, and ethanol.

This mixture was hydrogenated using a pre-hydrogenated Adams' platinum oxide catalyst under ordinary pressure at room temperature for 24 hr. The catalyst was then filtered off and washed with non-radioactive 3-methylpentane (0.5 m*l*). To the combined filtrate and washings, a drop of cold conc. sulfuric acid was added and the mixture was stirred at ice-bath temperature. The organic layer was separated, washed with cold aqueous sodium hydrogen carbonate and water, dried over Drierite, and distilled to afford 3-methylpentane boiling at 62—63°C. The overall radioactive

*[5] Prepared from *s*-butyl magnesium bromide and ethyl orthoformate.

*[6] Mercuric chloride, made alkaline with several drops of sodium hydroxide.

yield was 30.1%.

Preparation of 3-Methyl-pentane-3-methyl-^{14}C. The Wittig reaction of pentanone-3 with methyltriphenylphosphonium bromide-methyl-^{14}C under similar conditions, followed by catalytic hydrogenation, gave the labeled hydrocarbon with a radioactive yield of better than 60%.

Degradation of 3-Methylpentane-1-^{14}C. *i) 3-Bromo-3-methylpentane-1-^{14}C.* The photochemical bromination of a 10.2 g portion of 3-methylpentane-1-^{14}C was carried out using the halogenation apparatus described by Roberts and Mazur[10] with a slight modification. Bromine was introduced into a reaction zone by means of a dry-nitrogen stream bubbling through a bottle containing bromine at room temperature. Irradiation was achieved by a high-pressure mercury lamp (HQ-400Q, Nihon Denchi). After the evolution of hydrogen bromide had ceased, a small portion of solid potassium carbonate was added. The subsequent distillation of the bromination product gave 3-bromo-3-methylpentane-1-^{14}C which boiled at 61.5—62.5°C/59 mmHg (5.63 g). No isomeric monobromides were detected.

ii) 3-Methylpent-2-ene-1-^{14}C. A mixture of 3-bromo-3-methylpentane-1-^{14}C (5.63 g) and water (25 m*l*) in a 50-m*l* flask was refluxed for 10 hr. The organic layer was separated from a cooled reaction mixture, and the aqueous layer was extracted with isooctane. The combined organic layer was dried over potassium carbonate, and distilled to give 3-methylpent-2-ene-1-^{14}C (2.34 g); bp 70.5—73.5°C.

iii) 3-Methylpentane-2,3-diol-1-^{14}C. In a three-necked 100-m*l* flask equipped with a Dimroth condenser, a thermometer, and a serum cap, were placed 18 g of 90% formic acid (0.35 mol) and 4.4 g of 30% hydrogen peroxide (0.04 mol); the mixture was stirred magnetically. A 2.1-g portion of 3-methylpent-2-ene-1-^{14}C (0.025 mol) was added, drop by drop, through a hypodermic needle while the temperature was kept below 45°C. After having been stirred for 1 hr at this temperature, the mixture was allowed to stand overnight at room temperature. Formic acid and water were distilled off under reduced pressure from the reaction flask, and to the residual viscous liquid there was added 20-g portion of sodium hydroxide in 40 m*l* of water under cooling. After stirring for 1 hr, the solution was extracted with six 10-m*l* protions of ether, and the ethereal layer was dried over magnesium sulfate. Ether was then distilled off; the subsequent distillation of the residue gave 3-methylpentane-2,3-diol-1-^{14}C (0.59 g) which boiled at 93°C/16 mmHg.

iv) Degradation of 3-Methylpentane-2,3-diol-1-^{14}C. In a 200-m*l* flask, 0.59 g of 3-methylpentane-2,3-diol-1-^{14}C (5.0 mmol) was oxidized overnight with 1.12 g of sodium metaperiodate (5.25 mmol) in 50 ml of water at room temperature. The reaction mixture was then distilled under reduced pressure, and the distillate was collected in a Dry Ice-acetone-cooled trap to give solution A. A 2-m*l* portion of the solution A was added to a solution of 50 mg of dimedone in 13 m*l* of water. A slight warming was applied, and then the solution was allowed to stand overnight at room temperature. Crystalline precitates were collected and recrystallized from aqueous methanol to afford pure acetaldehyde dimedone, mp 142—142.5°C.

To the remaining portion of the solution A, a slight excess of an aqueous potassium permanganate solution was added. After the reaction had been completed, excess permanganate was decomposed with a few drops of a sodium hydrogen sulfite solution and manganese dioxide formed was filtered off to give filtrate B. To a 10-m*l* portion of the cold filtrate B, 2 g of sodium hydroxide and an iodine-iodide solution containing 1.2 g of iodine and 2.4 g of potassium iodide were added successively. Iodoform was collected by filtration.

To the remaining portion of filtrate B, 0.53 g of 2,4-dinitrophenylhydrazine in 20 m*l* sulfuric acid-aqueous ethanol solution was added, and the precipitates were collected by filtration. Recrystallizations from ethanol afforded methyl ethyl ketone 2,4-dinitrophenylhydrazone, mp 115°C.

The above acidic filtrate was then steam distilled, and the initial 200-m*l* portion of the distillate was collected. Barium carbonate was added to this distillate, and the mixture heated for 24 hr. After cooling, excess barium carbonate was filtered off and the filtrate was evaporated to dryness. After recrystallizations from aqueous ethanol, barium acetate was dried at 120°C under reduced pressure over phosphorus pentoxide.

v) Degradation of Radioactive Barium Acetate. Barium acetate was degraded to carbon dioxide using the apparatus described by Phares.[11] Some modifications were made, however. In the present experiment, two 1N sodium hydroxide traps were used in order to absorb carbon dioxide. A stream of carbon dioxide-free nitrogen was used to convey the gas evolved. Furthermore, barium carbonate obtained was treated with perchloric acid in an evacuated Barker-type apparatus to regenerate carbon dioxide which was then again fixed with ethanolamine, and the solution was subjected to radioassay.

Destructive Alkylation. A typical experimental procedure of the destructive alkylation will be described. A mixture containing 6.15 g of 3-methylpentane (0.071 mol), 11.2 g of benzene (0.143 mol), 0.95 g of freshly-prepared anhydrous aluminum chloride (0.007 mol), and 0.064 g of water (0.0035 mol) was heated at 100°C in a glass autoclave and agitated. After an appropriate reaction period, the reaction mixture was poured into ice-water and 1 m*l* of conc. hydrochloric acid was added. The organic layer was separated, washed with cold saturated aqueous sodium hydrogen carbonate and then with cold water, and dried over anhydrous magnesium sulfate. In some experiments, *t*-butylbenzene was added in the initial reaction mixture. In this case, *t*-butylbenzene was added to the initial reaction mixture in an amount equal to that expected to be present in a destructive ethylation mixture without any added *t*-butylbenzene (here, 0.265 g).

Analysis of the reaction products by glc indicated the presence of isobutane (a large amount), 2- and 3-methylpentanes, benzene, toluene (small amounts), ethylbenzene (the main product), xylenes (small amounts), and a trace of higher alkylbenzenes. Toluene and xylenes were found to appear when reactions were carried out for 12 hr or longer, although ethylbenzene began to be produced within one hour. In the presence

11) E. F. Phares, *Arch. Biochem. Biophys.*, **33**, 173 (1951).

of added *t*-butylbenzene, an increased amount of isobutane was detected by glc; however, no *t*-butylbenzene was present in the product.

Degradation of Radioactive Ethylbenzene. Ethylbenzene was collected by a preparative glc. Oxidation of 0.424 g of radioactive ethylbenzene (4 mmol) with 4.11 g of potassium permanganate (26 mmol) in water (20 m*l*) was performed by heating the mixture for 3 hr. Manganese dioxide was filtered out, and the filtrate and aqueous washings (3 m*l*) were combined. The solution was acidified with conc. hydrochloric acid and extracted with three 10-m*l* portions of ether. Evaporation of ether gave a residue which was recrystallized from water to afford 0.372 g of pure benzoic acid.

The authors are grateful to the staff of the Radioisotope Research Laboratory, Kyoto University, who generously allowed the authors to use the facilities for the tracer experiments.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 2662—2665 (1969)

Synthesis of 2-Amino-4-hydroxy-6-acetyl-7-methyl-7,8-dihydropteridine

Katsura SUGIURA and Miki GOTO

Department of Chemistry, Gakushuin University, Toshima-ku, Tokyo

(Received March 10, 1969)

2-Amino-4-hydroxy-6-acetyl-7-methylpteridine was synthesized by condensation of 2,4,5-triamino-6-hydroxypyrimidine and triketopentane. Reduction of this compound with sodium amalgam yielded a coloring matter, whose UV-spectra and chemical reactions strictly correspond to those of sepiapterin or isosepiapterin. On the basis of NMR spectra, the coloring matter was proved to be 7,8-dihydro-2-amino-4-hydroxy-6-acetyl-7-methylpteridine. Hence, it can be concluded that sepiapterin has the 7,8-dihydro structure as proposed by Nawa.

Sepiapterin is the main pteridine from the mutant *sepia* of the flies, *Drosophila melanogaster* and from the mutant *lemon* of the silkworms, *Bombyx mori*. This compound was proved to be 2-amino-4-hydroxy-6-lactyl-7,8-dihydropteridine by Nawa; evidence to support the 7,8-dihydro structure was obtained by demonstrating the production of dihydroxanthopterin from sepiapterin on treatment with borax solution.[1] Some additional evidences suggested also the 7,8-dihydro structure.[2-5]

The present work was undertaken in order to prove the dihydro structure more definitely by synthesizing a model compound and measuring the NMR spectrum. We have synthesized 2-amino-4-hydroxy-6-acetyl-7-methylpteridine (I) by condensation of 2,4,5-triamino-6-hydroxypyrimidine and triketopentane. Dihydro-2-amino-4-hydroxy-6-acetyl-7-methylpteridine was obtained by reduction of the compound with sodium amalgam. The UV-spectra of the dihydro compound corresponded strictly to those of sepiapterin, and the chemical reactions were similar to those reported for sepiapterin and isosepiapterin.[6,7] On the basis of NMR spectra and UV-spectral change on reduction with sodium borohydride, it was clearly demonstrated that the dihydro compound has the structure *7,8-dihydro*-2-amino-4-hydroxy-6-acetyl-7-methylpteridine. Hence, it can be now definitely concluded that sepiapterin has the 7,8-dihydro structure, as suggested by Nawa.[1]

Experimental

The NMR spectra were obtained with a Varian A-60 instrument with tetramethylsilane or sodium (ω-trimethylsilyl)trimethylenesulfonate as an internal reference. Each sample was dissolved in deuteriodimethylsulfoxide or 1N NaOD at a 10% concentration just before use. The UV-spectra were obtained using a Hitachi EPS-3 spectrophotometer.

2-Amino-4-hydroxy-6-acetyl-7-methylpteridine (I). 2,4,5-Triamino-6-hydroxypyrimidine sulfate mono-

hydrate (2.8 g) was dissolved in 60 m*l* of 1N hydrochloric acid at 70—90°C. Triketopentane (1.3 g) was added drop by drop and the mixture was heated for 15 min at 100°C. The solution was neutralized with 10N sodium hydroxide and left standing at room temperature. The precipitate was dissolved in 20 m*l* of 1N sodium hydroxide and filtered. Addition of a few drops of 10N sodium hydroxide gave yellow needles of the sodium salt of I, yield, 1.2 g. The salt (200 mg) was dissolved in 10 m*l* of water, acidified with acetic acid, and the resulting precipitate was filtered and washed with water, ethanol and ether. The pale yellow material was dried *in vacuo* over P_2O_5 at 120°C, yield, 160 mg, mp>250°C. NMR (1N NaOD, 40°C): τ 7.45 (3H, singlet, $-COCH_3$); UV: $\lambda_{max}^{0.1NNaOH}$ mμ (ε), 273 (1.78×10^4), 310 (7.0×10^3), 366 (1.45×10^4); $\lambda_{min}^{0.1NNaOH}$ mμ (ε), 239 (5.5×10^3), 302 (6.9×10^3), 324 (6.6×10^3); $\lambda_{max}^{0.1NHCl}$ mμ (ε), 269 (9.8×10^3), 321 (1.37×10^4), 380 (*infl.*, 1.2×10^3); $\lambda_{min}^{0.1NHCl}$ mμ (ε), 249 (6.5×10^3), 290 (5.8×10^3). Found: C, 49.02; H, 4.14; N, 31.11%. Calcd for $C_9H_9N_5O_2$: C, 49.31; H, 4.40; N, 31.95%.

2-Amino-4-hydroxy-6-(1-hydroxyethyl-7-methylpteridine (II). The sodium salt of I (482 mg) in 25 m*l* of water was added with 740 mg of sodium borohydride in 20 m*l* of 0.01N sodium hydroxide. The mixture was stirred for 6 hr at room temperature and acidified slightly with 6N hydrochloric acid. The pale brown precipitate thus obtained was crystallized from dimethylformamide and the material further purified by dissolving in 1/25N sodium hydroxide and precipitating with acetic acid. The faint yellow product (300 mg) was dried at 120°C over P_2O_5 for 6 hr, mp> 250°C. NMR (1N NaOD, 40°C): τ 8.45 (3H, doublet, J=7 cps, CH_3), 7.44 (3H, singlet, CH_3), 4.80 (1H, quartet, J=7 cps, CHOH). UV: $\lambda_{max}^{0.1NNaOH}$ mμ (ε), 253 (2.42×10^4), 358 (9.0×10^3); $\lambda_{min}^{0.1NNaOH}$ mμ (ε), 220 (9.2×10^3), 297 (1.4×10^3); $\lambda_{max}^{0.1NHCl}$ mμ (ε), 216 (2.18×10^4), 253 (1.04×10^4), 322 (1.03×10^4); $\lambda_{min}^{0.1NHCl}$ mμ (ε), 240 (8.7×10^3), 276 (2.4×10^3). Found: C, 46.88; H, 5.20; N, 30.51%. Calcd for $C_9H_{11}N_5O_2\cdot\frac{1}{2}H_2O$: C, 46.96; H, 4.81; N, 30.43%. II was also obtained by reduction of I with zinc powder in 0.5N sodium hydroxide at 40°C or by hydrogenation in 0.1N sodium hydroxide over PtO_2 (1 mole of hydrogen was absorbed per mole of I). Hydrogenation over palladised black in 0.1N sodium hydroxide did not give II.

2-Amino-4-hydroxy-6-(1-hydroxyethyl)-7-methyl-5,6,7,8-tetrahydropteridine (III). II (90 mg) was dissolved in 11 m*l* of 6N hydrochloric acid and hydrogenated over Adams' catalyst (60 mg). Hydrogenation was stopped, when 2.3 mol of hydrogen was absorbed per mole of II. The catalyst was filtered off and the solution was concentrated to dryness *in vacuo* at 40°C. Recrystallization of the product from a mixture of water, ethanol and ether (3 : 5 : 1) gave faint orange needles (hygroscopic), yield, 58 mg, mp>250°C. For analyses the material was dried *in vacuo* for 6 hr over P_2O_5 at 100°C. UV: $\lambda_{max}^{0.1NNaOH}$ mμ (ε), 255 (*infl.*, 6.3×10^3), 288 (8.5×10^3); $\lambda_{min}^{0.1NNaOH}$ mμ (ε), 235 (4.3×10^3); $\lambda_{max}^{0.1NHCl}$ mμ (ε), 218 (*infl.*, 1.20×10^4), 265.5 (1.79×10^4); $\lambda_{min}^{0.1NHCl}$ mμ (ε), 237 (5.4×10^3). Found: C, 39.98; H, 6.44; N, 26.71%. Calcd for $C_9H_{15}N_5O_2\cdot HCl\cdot\frac{1}{2}H_2O$: C, 39.93: H, 6.28; N, 25.87%.

2-Amino-4-hydroxy-6-acetyl-7-methyl-7,8-dihydropteridine (IV). The sodium salt of I (600 mg) was dissolved in 200 m*l* of 0.03N sodium hydroxide, 33 g of 4% sodium amalgam was added and the mixture was stirred for 2 hr. Mercury was removed and the mixture stirred for 2 hr at room temperature. The solution was neutralized with 6N hydrochloric acid and concentrated *in vacuo* at below 40°C. The concentrate was placed on a 7.0×24.0-cm column of Avicel (microcrystalline cellulose, FMC Corp.) and the column was eluted with 2-propanol, 1% ammonia (2 : 1). A yellow band was eluted and the eluate was acidified with acetic acid. The solution was placed on a 4.0×15.0 cm column of Florisil (100—200 mesh); the yellow compound was adsorbed at the top of the column. The column was washed well with water and then the compound was eluted with 20% aqueous acetone. The eluate was concentrated to dryness *in vacuo*, and the residue was recrystallized from water to give yellow needles (hygroscopic), yield, 102 mg, mp 200—201°C. UV- and NMR-spectra are given in Figs. 1 and 4. For analyses the sample was dried *in vacuo* over P_2O_5 at 100°C. Found: N, 29.51%. Calcd for $C_9H_{11}N_5O_2\cdot H_2O$: N, 29.28%.

Results and Discussion

The product obtained by condensation of 2,4,5-triamino-6-hydroxypyrimidine and triketopentane in acidic media was reduced with 4% sodium amalgam to give a coloring matter with a yellow fluorescence (λ_{max} 513 mμ; exciting wave length: 365 mμ). The UV-spectra of this compound is shown in Fig. 1.

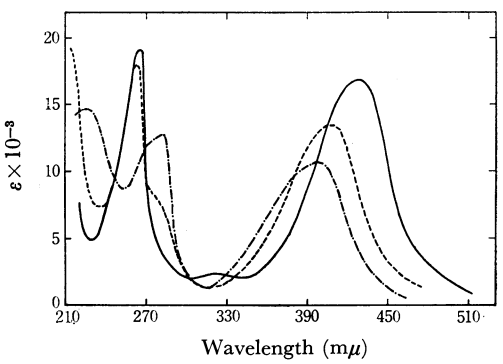

Fig. 1. UV-Absorption spectra of the coloring matter, 2-amino-4-hydroxy-6-acetyl-7-methyl-7,8-dihydropteridine.
—— in 0.1N sodium hydroxide
------ in M/30 KH_2PO_4-Na_2HPO_4 (pH 7.0)
—·— in 0.1N hydrochloric acid

The reduced product gave the following reactions:[6]

1) Oxidation with alkaline permanganate solution gave 2-amino-4-hydroxy-7-methylpteridine-6-carboxylic acid (V).[8]

2) Oxidation with hydrogen peroxide in 0.1N sodium hydroxide gave 2-amino-4,6-dihydroxy-7-

8) F. Weygand, H. Simon, K. D. Keil and H. Millauer, *Chem. Ber.*, **97**, 1002 (1964).

methylpteridine (VI).[9]

3) Treatment with excess sodium borohydride in 0.1N sodium hydroxide gave quantitatively

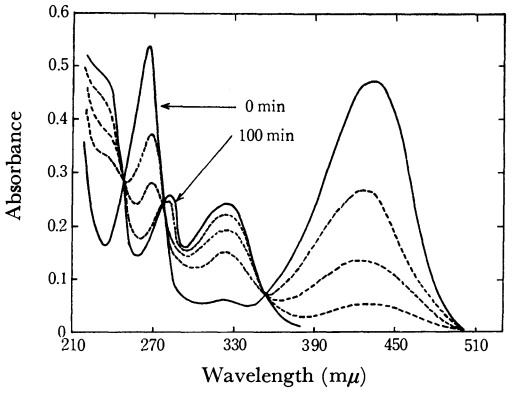

Fig. 2. UV-Spectral change of the coloring matter IV on reduction with sodium borohydride.
The compound (17 μg) was dissolved in 2.5 ml of 0.1N sodium hydroxide and 5 mg of sodium borohydride added (22°C). The UV-absorption spectra were determined before (——) and after 20, 40, 60 (------) and 100 min reduction. The spectrum at 100 min (——) remained unchanged even after 150 min.

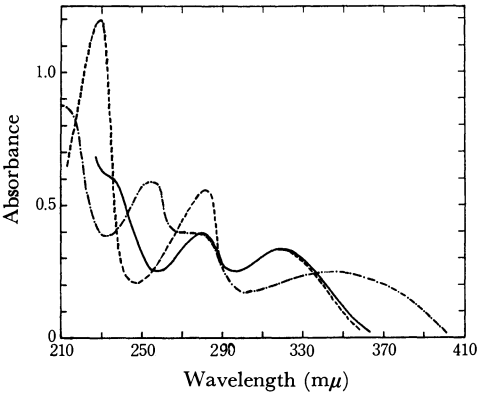

Fig. 3. UV-Spectra of the reduction ($NaBH_4$)product of the coloring matter IV.
The yellow compound IV in 0.1N sodium hydroxide was treated with excess sodium borohydride; the yellow solution became colorless. Excess sodium borohydride was destroyed with acetone. The solution was neutralized and the compound purified using a Sephadex G-25 fine column (developer: water) and an Avicel column (developer: 2-propanol, 1% ammonia=2:1). The UV-spectra of the product are quite in agreement with those of 2-amino-4-hydroxy-6-methyl-7,8-dihydropteridine.

2-amino-4-hydroxy-6-(1-hydroxyethyl)-7-methyl-7,8-dihydropteridine (VII), whose UV-spectra (Fig. 3) are superimposable on those of 2-amino-4-hydroxy-6-methyl-7,8-dihydropteridine;[10] UV-spectral change on reduction is given in Fig. 2. VII on heating in dilute acetic acid gave the original coloring matter (IV) and 2-amino-4-hydroxy-6-(1-hydroxyethyl)-7-methylpteridine (II).

4) Treatment with bromine in water or in 0.1N hydrochloric acid gave the original compound, 2-amino-4-hydroxy-6-acetyl-7-methylpteridine (I).

5) Reduction with sodium borohydride at pH 7.0 gave 2-amino-4-hydroxy-6-(1-hydroxyethyl)-7-methyl-5,6,7,8-tetrahydropteridine (III).

6) Action of iodine in 0.1N sodium hydroxide gave 2-amino-4-hydroxy-7-methylpteridine-6-carboxylic acid.[8]

Identification of the products described above was carried out by paper chromatographic and UV-spectral comparison with authentic materials. R_f-values of pteridines are given in Table 1.

Table 1. R_f-Values of pteridines

Compound	R_f-values

	0.67	0.67	0.64	0.46

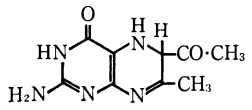
* Solvent: A, 2-propanol, 1% ammonia (2:1)
B, 2-propanol, 2% ammonium acetate (1:1)
C, 1-butanol, acetic acid, water (4:1:1)
D, 3% aqueous ammonium chloride

These results are in accordance with the observation for sepiapterin[1] and isosepiapterin[6] and suggest that the yellow coloring matter is a dihydropteridine with an acetyl group at the 6-position and a methyl group at the 7-position and not its isomer. Moreover, the absorption spectra of the dihydropteridine in acidit, neutral and alkaline media were superimposable on the corresponding spectra of sepiapterin and isosepiapterin; this evidence suggests that the dihydropteri-

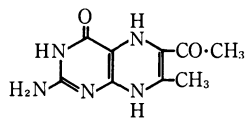
10) W. Pfleiderer and H. Zondler, *Chem. Ber.* **99**, 3008 (1966).

dine has the same chromophore as in sepiapterin and isosepiapterin. Proof of the dihydro structure of the colored reduction product of the ketone was obtained from a study of the nuclear magnetic resonance spectrum of the coloring matter.

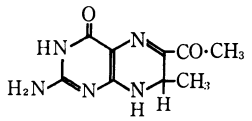
The following three dihydro structures come into consideration for dihydro-2-amino-4-hydroxy-6-acetyl-7-methylpteridine:



(VIII)



(IX)



(X)

The NMR spectrum of dihydro-2-amino-4-hydroxy-6-acetyl-7-methylpteridine (Fig. 4) has a singlet at $\tau=7.66$, a doublet at $\tau=9.03$, a quartet at $\tau=5.37$ and broad singlets at $\tau=3.22$, 2.25 and -0.28; the proton ratio of each signal is 3 : 3 : 1 : 2 : 1 : 1. In comparison with NMR signals of guanosine in deuteriodimethylsulfoxide,[11] the signals $\tau=3.22$, 2.25 and -0.28 can be assigned to the amino protons at the position 2, the imino protons at the positions 8 and 3, respectively. The signal at $\tau=7.66$ is assigned to the acetyl protons at the position 6 and the doublet signal at $\tau=9.03$ to the methyl protons at the position 7. The quartet signal at $\tau=5.37$ is assigned to the proton at the position 7; this is coupling with the signal ($\tau=9.03$) of the neighboring methyl protons ($J=7$ cps) and *vice versa* ($J=7$ cps). This evidence supports the structure X for the dihydro coloring matter and the 5,6- and 5,8-dihydro structures (VIII and IX) are ruled out. It can be now definitely concluded that the dihydro-2-amino-4-hydroxy-6-acetyl-7-methylpteridine, and also, by analogy, sepiapterin has the 7,8-dihydro structure.

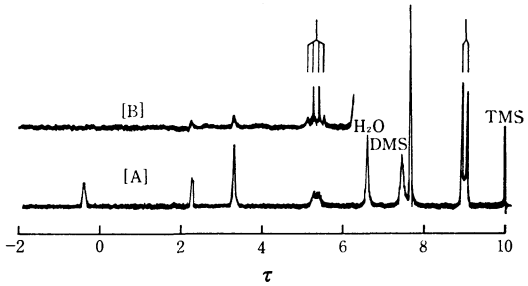


Fig. 4. NMR spectra of the yellow coloring matter IV.

The spectra were obtained with tetramethylsilane as an internal reference (60 Mc, 40°C). After spectrum A was measured in deuteriodimethylsulfoxide, a small amount of D_2O was added to exclude the interaction between the ring protons at the positions 7 and 8, and spectrum B was taken again.

The authors wish to express their thanks to Dr. M. Kondo and Mr. K. Ono, Sankyo Co., Ltd., for measuring NMR spectra and for carrying out microanalyses.

Amine Derivatives of 1-(1′-Phenyl-2′-bromoethyl)-5-methyltetrazole

Akira TERADA* and Alfred HASSNER**

* *Department of Chemistry, Kyushu Institute of Technology, Tobata-ku, Kitakyushu*
** *Department of Chemistry, University of Colorado, Boulder, Colorado, U.S.A.*

(Received March 10, 1969)

As part of search for a potential new type of antimalarial, several 1-(1′-phenyl-2′-aminoethyl)-5-methyltetrazoles were prepared by the amination of 1-(1′-phenyl-2′-bromoethyl)-5-methyltetrazole using various amines, such as mono- and diamines of aliphatic and alicyclic. The reaction in the presence of a large excess of amine occurred smoothly on heating at 100—130°C, and it gave the title product without any significant by-product such as the bistetrazole compound, even though a primary amine was used.

The addition of halogens to olefins in a nitrile solvent in the presence of silver perchlorate has been shown by Hassner and his co-workers[1] to lead to nitrilium-ion intermediates. The latter reacts with azide ions, thus providing a useful method of synthesizing tetrazoles containing an additional halogen function, which can be converted to other functional groups by nucleophilic substitution. Thus, styrene reacts with bromine and silver perchlorate in acetonitrile in the presence of sodium azide to yield, in one step, 1-(1′-phenyl-2′-bromoethyl)-5-methyltetrazole (I).

A number of tetrazole derivatives have been of interest as synthetic drugs; among them, pentamethylene-tetrazole, 5-(2-dimethylaminoethoxymethyl)-1-phenyltetrazole, 4-phenyl-1-[2-(5-tetrazolyl)ethyl]piperazine, and 1-(*p*-chlorobenzyl)-5-imino-4-octyltetrazoline are especially well known.[2] An examination of the compounds that exhibit a significant therapeutic effect against malaria,[3–6] including quinine, reveals that many of them are structurally composed of a molecule forming a rigid portion, which has a high electron density and which often contains one or more N-atoms, and of a less rigid side chain, which is often an amino alkanol or a dialkylamino alkylamine.

The stability of tetrazole nuclei, the availability of such bifunctional tetrazoles as I, and the interest by one of the present authors[7] in the chemistry of styrene derivatives have led us to study amine and diamine derivatives of I as potential antimalarials. An added advantage of the members of the tetrazole system is their relatively low toxicity, as indicated by an MTD of over 0.20 mg/g in chicks.[4] Although the few tetazoles studied in the past have lacked antimalarial activity, too few were examined and none of them contained aminoalkyl or similar substituents.

The starting material, I, was prepared according to the directions previously reported.[1] Although there was no precipitation when bromine was added to an acetonitrile solution of silver perchlorate, silver bromide precipitation was rapid upon the addition of styrene to this system. This can be attributed to the formation of a three-membered-ring bromonium ion and to the concurrent trapping of the bromide ion by silver perchlorate, thus prohibiting the formation of styrene dibromide and enhancing attack by acetonitrile, all leading to the formation of a nitrilium-ion intermediate. The tetrazole I was obtained in a 48% yield[8] after the extraction of the reaction products with hot petroleum benzine. From the mother liquors of the extraction, styrene dibromide was obtained in an 11% yield. The residue of the above extraction was a crude 2-methyl-4-phenyl-2-oxazoline hydro-

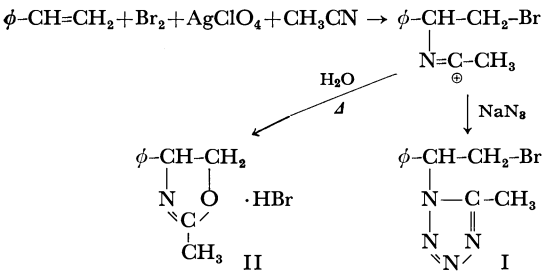
8) Ref. 1 had reported a 35% yield.

bromide (II).[9] This oxazoline salt is formed even after the reaction products have been washed with a small amount of 20% sodium hydroxide; it must, therefore, result from the cyclization of 1-acetoamido-2-bromoethylbenzene. The latter presumably results from the reaction of some remaining nitrilium ion with water during the work-up. The instability of *N*-(2-haloethyl)-amides and the facility with which they cyclize to oxazoline salts has been recognized by Lusskin and Ritter.[10] It may, therefore, be concluded that heating during the petroleum benzine extraction results in the formation of the oxazoline salt.



The formation of 1-(1′-phenyl-2′-aminoethyl)-5-methyltetrazoles (III) was accomplished smoothly by heating I with a large excess of amine or diamine at 100—130°C for 24 hr.

No bistetrazole formation of the type IV was observed when the amine was primary, because at least a ten-fold excess of amine was employed. The amines used in this study were dimethylamine, morpholine, piperidine, pyrrolidine, γ-acetoxypropylamine, δ-(pyrrolidino)butylamine, 2-diethylaminoethylamine, 2-amino-5-diethylaminopentane, and 1-amino-3-diethylamino-2-propanol. The δ-(pyrrolidino)butylamine was prepared by the lithium aluminum hydride reduction of γ-(pyrrolidino)-butyronitrile. The tetrazole derivatives obtained (IIIa—i) are shown above. No significant antimalarial activity was found for these compounds in screening tests on mosquitoes A. Aegypti.[11]

Experimental

Materials. All the amines, γ-acetoxypropylamine, dimethylamine, morpholine, piperidine, and pyrrolidine were available commercially as reagent-grade substances and were used without exceptional purification. The γ-(pyrrolidino) butyronitrile was also obtained commercialy. The 2-amino-5-diethylaminopentane (bp 74°C/20 mmHg), 2-diethylaminoethylamine (bp 55—56° C/30 mmHg), and 1-amino-3-diethylamino-2-propanol were furnished by the U.S. Army, Water Reed Medical Center, and were purified by vacuum distillation.

1-(1′-Phenyl-2′-bromoethyl)-5-methyltetrazole (I). According to the directions of Gault,[9] I was prepared using acetonitrile as the only solvent of the system, while Gault used ether as the solvent in his styrene additions. A brown oil (3.612 g) was obtained from 1.17 g of styrene (0.012 mol) after the usual work-up. The repeated extraction of the oil with boiling petroleum benzine gave 1.444 g (48.3%) of I, mp 109—110°C (lit,[1] mp 109—111°C, 35% yield).

From the mother liquor, 319 mg (10.8%) of styrene dibromide were recovered, mp 69—70.5°C (lit,[12] mp 73°C). Its identity was proved by a mixed-melting-point test with an authentic sample.

The residue of the above hot-petroleum-benzine extraction was 1.758 g, which solidified on standing. Recrystallization from benzene gave white crystals of 2-methyl-4-phenyl-2-oxazoline hydrobromide; mp 163—165°C (lit,[9] 165°C, 169—170°C).

1-(1′-Phenyl-2′-dimethylaminoethyl)-5-methyl tetrazole (IIIa). A mixture of 267 mg (1 mmol) of 1-(1′-phenyl-2′-bromoethyl)-5-methyltetrazole (I) and 10 m*l* of diethylamine (25% aq. solution) was heated in a sealed glass tube in a steam bath for 24 hr. After concentration to dryness under a vacuum, the residue was dissolved in dilute hydrochloric acid and filtered. Concentration and alkalization with potassium hydroxide gave 186 mg (80.5%) of needles; mp 86—87°C. Recrystallization from benzene-petroleum benzine gave an analytical sample. This product was easily soluble in water.

Found: C, 62.41; H, 7.39%. Calcd for $C_{12}H_{17}N_5$:

1-(1′-Phenyl-2′-morpholinoethyl)-5-methyltetrazole (IIIb). A mixture of 267 mg (1 mmol) of I in 20 m*l* of mopholine was refluxed for 17 hr. Working-up as usual gave 234 mg (85%) of the product; mp 156—157°C. Recrystallization from ethanol-water raised the melting pount to 158—160°C.

Found: C, 61.34; H, 7.11%. Calcd for $C_{14}H_{19}N_5O$: C, 61.52: H, 7.01%.

ν_{max}^{KBr}: 2967, 2941, 2865 (CH_3, CH_2); 2809, 1114 (morpholino); 1520 (tetrazole ring); 1493, 1460, 1443, 1403, 1379, 1127, 1068, 1033, 1008, 913, 873, 793; 728, 701 cm^{-1} (monosubstituted benzene).

1-(1′-Phenyl-2′-piperidinoethyl)-5-methyltetrazole (IIIc). The usual procedure gave an 86% yield of the product; mp 130—130.5°C. Recrystallization from ethanol-water raised the melting point to 132—133°C.

Found: C, 66.20; H, 7.79%. Calcd for $C_{15}H_{21}N_5$: C, 66.39; H, 7.80%.

ν_{max}^{KBr}: 3049 (phenyl); 2950, 2865 (CH_3, CH_2); 2793, 2770 (piperidino); 1529 (tetrazole ring); 1497; 1453, 1445, 1403, 1381, 1309, 1279, 1167, 1124, 1111, 1098, 1044, 870, 782; 730, 701 cm^{-1} (monosubstituted benzene).

Reaction of I and γ-Acetoxypropylamine. A mixture of 267 mg (1 mmol) of I and 3 m*l* of γ-acetoxypropylamine was heated on a steam bath for 24 hr. Evaporation under reduced pressure, extraction with dil. hydrochloric acid, alkalization of the extract with sodium hydroxide, and extraction again with benzene as usual finally gave 158 mg (60.5%) of the product, a white viscous oil. The infrared spectrum showed no carbonyl peaks of acetoxyl, but there were peaks of hydroxyl; this oil was, therefore, concluded to be 1-[1′-phenyl-2′-(γ-hydroxypropylamino)ethyl]-5-methyltetrazole (IIId).

ν_{max}^{Liquid}: 3367 (NH, OH); 3058 (phenyl); 2985, 2882; 2717; 1531 (tetrazole ring); 1504, 1408, 1383; 1111 (alcohol); 749, 701 cm^{-1} (monosubstituted benzene).

All attempts to form a crystalline salt by the use of hydrobromic, hydrochloric, fumaric, sorbic, and tartaric acids were unsuccessful.

The Picrate. This was obtained as usual. Recrystallization from benzene gave yellow crystals, mp 149.5°C.

Found: C, 48.75; H, 5.66%. Calcd for $C_{19}H_{22}N_8O_8$: C, 48.50; H, 6.43%.

δ-(Pyrrolidino)butylamine. Into a solution of 4.20 g (0.1 mol as 90% purity) of lithium aluminum hydride in 200 m*l* of absolute ether under ice-cooling, 13.8 g (0.1 mol) of γ-(pyrrolidino)butylonitrile in 20 m*l* of absolute ether were stirred over a 40-min period. The reaction system was then allowed to stand overnight at room temperature. Four m*l* of water were vigorously stirred in, drop by drop, under deep cooling, and then 3 m*l* of 20% sodium hydroxide and 14 m*l* of water were added. The ether layer was separated by decantation, and the residue was washed twice with much ether. The combined ether solution was dried over potassium hydroxide pellets. On the removal of the solvent, 13.87 g of a yellow oil were obtained. This was shown to be an almost pure δ-(pyrrolidino)butylamine by the infrared spectrum determination. The yield was almost theoretical.

ν_{max}^{Liquid}: 3413, 3322, 3226, 1639 (NH_2); 2817 (*N*-alkylpyrrolidine); 1149 (tertiary amine); 1099 (primary amine); 880 cm^{-1} (amine., liquid).

Purification by vacuum distillation gave 11.35 g of a water-white liquid, bp 83—85°C/7 mmHg, whose infrared spectrum was completely identical with that of the original sample.

The Dihydrobromide. The usual method of preparation gave crystals. Recrystallization from ethanol gave an analytical sample; mp 126—127°C.

Found: C, 31.58; H, 6.74%. Calcd for $C_8H_{18}N_2 \cdot 2HBr$: C, 31.60; H, 6.63%.

1-[1′-Phenyl-2′-(δ-pyrrolidinobutylamino)ethyl]-5-methyltetrazole (IIIe). One mmol (267 mg) of I in 969 mg of the diamine obtained above was heated on a steam bath for 24 hr. After the excess amine had been removed by vacuum distillation and usual work-up, 228 mg of a yellow oil were obtained. The Beilstein reaction was negative.

ν_{max}^{Liquid}: 3356 (NH); 3058, 1499, 729, 701 (phenyl); 2809 (pyrrolidinoalkyl); 1527 (tetrazole ring); 1143, 1121 cm^{-1} (tertiary amine).

The usual salt formation with hydrochloric acid and crystallization from a solvent, an acetone-benzene-ethanol mixture, gave 318 mg (79%) of the analytical sample, dihydrochloride; mp 193—195°C.

Found: C, 53.73; H, 7.56%. Calcd for $C_{18}H_{28}N_6 \cdot 2HCl$: C, 53.86; H, 7.53%.

1-(1′-Phenyl-2′-pyrrolidinoethyl)-5-methyltetrazole (IIIf). A mixture of 167 mg (0.625 mmol) of I and 2 m*l* of pyrrolidine was refluxed for 24 hr. After work-up as usual, alkalization with conc. ammonia gave 132 mg (82%) of the product; mp 122—123°C.

Found: C, 65.44; H, 7.48%. Calcd for $C_{14}H_{19}N_5$: C, 65.34; H, 7.44%.

ν_{max}^{KBr}: 3049 (phenyl); 2994, 2959, 2841; 2778 (pyrrolidinoalkyl); 1520 (tetrazole ring); 731, 703 (monosubstituted benzene); and other spectral peaks, 1495, 1456, 1437, 1404, 1383, 1355, 1325, 1297, 1261, 1236, 1205, 1156, 1147, 1111, 1092, 1053, 1031, 952, 880, 777 cm^{-1}.

1-[1′-Phenyl-2′-(β-diethylaminoethylamino)ethyl]-5-methyltetrazole (IIIg). A sample of 534 mg (2 mmol) of I in 10 m*l* of β-diethylaminoethylamine was heated under reflux for 24 hr. After work-up as usual, 409 mg (45%) of the dihydrobromide were obtained. Recrystallization from an acetone-benzene-*n*-butanol mixture gave an analytical sample; mp 157—159°C (decomp).

Found: C, 41.70; H, 6.21%. Calcd for $C_{16}H_{26}N_6 \cdot 2HBr$: C, 41.39; H, 6.08%.

ν_{max}^{KBr}: 3521, 3436 (NH); 3030 (phenyl); 2778, 2632, 2445 (amine hydrobromide, broad); 1520 (tetrazolering); 1453, 1433, 1403, 1017; 740, 698 cm^{-1} (monosubstituted benzene).

1-[1′-Phenyl-2′-(δ-diethylamino-α-methylbutylamino)ethyl]-5-methyltetrazole (IIIh). A mixture of 534 mg (2 mmol) of I and 10 m*l* of 2-amino-5-diethylaminopentane was heated under reflux for 24 hr. After work-up as usual, the hydrobromide amorphous was obtained. This was very hygroscopic and gave a negative result on attempted crystallization. The dried sample was submitted to elemental analysis and showed the following results:

Found: C ,44.76; H, 7.53; N, 12.21%. Calcd for $C_{19}H_{32}N_6 \cdot 2HBr$: C, 45.08; H, 6.77; N, 16.60%.

ν_{max}^{KBr}: 3413 (NH); 2950, 2874 (CH_3, CH_2); 2688

(amine hydrobromide, broad); 1524 (tetrazole ring); 741 (weak), 701 (monosubstituted benzene), and other peaks, 1453, 1395, 1072, 1042, 1031 cm^{-1}.

1-[1′-Phenyl-2′-(γ-diethylamino-β-hydroxypropylamino)ethyl]-5-methyltetrazole (IIIi). A mixture of 534 mg (2 mmol) of I and 10 m*l* of 1-amino-3-diethylamino-2-propanol was refluxed for 24 hr. After work-up as usual and after the removal of the excess amine by vacuum distillation, 349m g of an oil, a free amino product, was obtained. The usual hydrobromide formation and the trituration of the oily product in acetone gave a brown powder. This decomposed at 160—163°C and was also very hygroscopic.

Found: C, 37.31; H, 6.67; N, 9.38%. Calcd for $C_{17}H_{28}N_6O \cdot 2HBr$: C, 42.69; H, 6.32; N, 17.57%.

Disagreements in these analytical results can be explained to some extent if we assume that some 1-amino-3-diethylamino-2-propanol dihydrobromide(Calcd for $C_8H_{18}N_2O \cdot 2HBr$: C, 27.27; H, 6.54; N, 9.09%) might contaminate the analytical sample. However, the excess amine had been completely removed by vacuum distillation after the reaction. The following infrared spectrum determination shows that the product was mainly an amine derivative of tetrazoe (this sample was submitted to the screening test previously described).

ν_{max}^{KBr}: 3413 (OH, NH); 2778—2353 (amine hydrobromide, broad); 1538 (tetrazole ring); 765, 703 (monosubstituted benzene), and other peaks, 1558, 1453, 1395, 1099, 1028, 826, 800 cm^{-1}.

Attempts to purify the crude products of IIIh and IIIi further by recrystallization were unsuccesful because of their high hygroscopicities and low crystallinities.

This investigation was supported by Contract DADA 17-67-C-7091 from the U.S. Army Medical Research and Development Command (Contribution No. 531 from the Army Research Program on Malaria).

Partial Asymmetric Synthesis in the Simmons-Smith Reaction. III. A Modification of the Reaction[1]

Seiji SAWADA and Yuzo INOUYE

Institute for Chemical Research, Kyoto University, Uji, Kyoto

(Received March 14, 1969)

A modification of the Simmons-Smith reaction, which involves a prior reaction of ethyl iodide with zinc copper couple followed by addition of methylene iodide and olefins, was proposed. The improved yields of cyclopropane products were obtained with various olefin substrates. It is likely that the operating species in the present modification is ethyliodomethylzinc.

Simmons and Simth[2,3] have developed a stereospecific synthesis of cyclopropanes which involves the treatment of olefins with methylene iodide and zinc copper couple. The active organozinc intermediate was generated also by Wittig[4] through the addition of diazomethane solution to zinc iodide in ether. The operating species in this reaction has been looked upon as being iodomethylzinc iodide[2,4,5] (III) or its dimer, bis-iodomethylzinc (II), although unequivocal evidence for this has not yet been presented.

Recently, Furukawa and his coworkers[6] have modified this reaction by replacing zinc copper couple with commercial diethylzinc and claimed remarkable improvement in the yield of cyclopropane compounds from olefins. This modification was featured in particular by its excellent performance even with cation-sensitive olefins such as vinyl ethers, in which with the conventional reagent, the competitive polymerization of olefins caused by the Lewis acid catalysis of zinc iodide in the medium outweighed the formation of desired cyclopropanes.

The following two organomagnesium compounds are relevant to this problem: methylene dimagnesium diiodide[7] which was prepared by the treatment

of magnesium with methylene iodide, and α-halomethyl Grignard reagent[8] obtained by substitution of isopropylmagnesium chloride with methylene dihalide at dry-ice temperature. Although both organomagnesium compounds were inactive for methylene-transfer to olefins under the corresponding conditions, iodomethylmagnesium iodide reacted at −70°C with cyclohexene to give norcarane in the presence of equimolar zinc iodide or cadmium iodide (8 or 5% yield respectively).

Wittig[9] described recently that bis-benzoxymethylzinc, which was obtained by the exchange of iodomethyl ligands in the dimeric form of the Simmons-Smith reagent with benzoxymethyl groups having a similar nucleophilicity, successfully transferred methylene to cyclohexene to give norcarane in good yields, and this was achieved only in the presence of zinc iodide.

In connection with the above-mentioned reactions and also with our asymmetric syntheses[1] in this type of reaction, we wish to report a further modification of the Simmons-Smith reaction. The present procedure consists of the reaction of ethyl iodide with zinc copper couple which gives ethylzinc iodide probably in an equilibrium with diethylzinc plus zinc iodide,[10] and subsequent introduction of methylene iodide and olefin substrates. A mild reaction took place upon the addition of methylene iodide and olefin under stirring at room temperature and after a period of 0.5—5.0 hr, the reaction mixture was treated in the usual way[1-3] to give the corresponding cyclopropane products. In Tables 1 and 2 are summarized the yields of cyclopropane products obtained by the present procedure in comparison with those by the Simmons-Smith reagent and by the Furukawa modification.[6] The present modification offers the advantage of enabling one to eliminate explosion hazards which are so frequently encountered on handling diethylzinc and even to ensure much improved yields of cyclopropanes.

An equilibrium as schemed below is conceivable for the present system and the operating species responsible for methylene-transfer may be either ethyliodomethylzinc (I), bis-iodomethylzinc (II) or iodomethylzinc iodide (III).

$$EtZnI \rightleftarrows Et_2Zn + ZnI_2 \xrightarrow{CH_2I_2} \underset{(I)}{EtZnCH_2I} + ZnI_2 + EtI$$

$$2\,EtZnCH_2I \rightleftarrows \underset{(I)}{Et_2Zn} + \underset{(II)}{Zn(CH_2I)_2} \rightleftarrows Et_2Zn + 2\,ICH_2ZnI \quad (III)$$

Both the reactivity and reaction yield in the present modification surpassed those in the conventional Simmons-Smith reaction, and compared well with those in the Furukawa modification except that the

present modification was accompanied by the undesirable olefin polymerization as was also the case with the conventional procedure (runs 2, 9, 11 and 12). Accordingly, active intermediate may reasonably be looked upon as being ethyliodomethylzinc (I), and thus the reaction mechanism may be essentially the same as that in the Furukawa modification.

The behavior of the present organozinc reagent toward olefinic alcohols is worthy of note. When crotyl alcohol was allowed to react with equimolar iodomethylzinc iodide (III), 1-methyl-2-hydroxymethylcyclopropane was just sparingly produced (8%, run 13), whereas with the use of an excess of the reagent (2.5 mol equivalent, run 14) a much higher yield (65%) of the cyclopropane alcohol was obtained. A similar trend was observed in run 15 where sodium crotylate was employed instead of the free alcohol. This observation suggests that crotyl alcohol coordinates primarily with zinc atom in the reagent to form a zincate complex which in turn dissociates predominantly with elimination of methyl iodide so far as alcoholic hydrogen is available. It seems likely that crotoxyzinc iodide thus formed (or sodium crotylate in run 15) undergoes spontaneous substitution with surplus methylene-transfer reagent to form another zincate (IV), iodomethylzinc crotylate, which decomposes eventually to afford cyclopropane product. Runs 16 and 17 stand for this mechanism proposed.

The treatment of enamine (run 11) with the present organozinc reagent in ether-tetrahydrofuran (1 : 1) resulted in the formation of 1-piperidinobicyclo[4,1,0]heptane without any separation of gelatinous precipitate.[11] (−)-Menthyl crotonate and cinnamate failed to afford the corresponding cyclopropane acids when subjected to the present reaction procedure under the standard conditions.

11) E. P. Blanchard, H. E. Simmons and J. S. Taylor, *J. Org. Chem.*, **30**, 4321 (1965).

Experimental

The cyclopropane product in each run was identified by glpc, IR- and NMR-spectral comparisons with the respective authentic specimen. The yields were estimated by glpc-analysis except in runs 2, 9, 11, 12 and 14 where the products were actually isolated.

Stock Solution of Ethylzinc Iodide. Ethyl iodide (156 g, 1 mol) was allowed to react with zinc copper couple (70 g, 1 atom) in absolute ether (900 m*l*), and the mixture was stirred at room temperature overnight. The supernatant liquid was withdrawn free from sludge and stored in a stoppered flask carrying a drying tube. After storage at room temperature for a week, no precipitate was formed and the activity of the solution remained unchanged.

The cyclopropane synthesis in the present modification is exemplified by the typical run with cyclohexene to give norcarane (run 1) and essentially the same procedure except in runs 11 and 12, was followed for other runs in the mol ratio of olefin: $EtZnCH_2I = 1 : 1$.

Synthesis of Norcarane (Run 1). Methylene iodide (15 g, 0.055 mol) was added to an aliquot of the stock solution (100 m*l*) containing 2 mol equivalent of active ethylzinc iodide and the reaction mixture was stirred at 30—35°C for 1 hr. To the chilled solution, cyclohexene (4.1 g, 0.05 mol) was added and the mixture was gently refluxed under stirring and after 2 hr, *ca.* 50 m*l* of ether was distilled off. The resulting pale yellow mixture was decomposed with water and dil. HCl, and the organic layer was separated, washed with water, sodium thiosulfate solution and again with water, and dried over anhydrous $MgSO_4$. The solution which contained norcarane in a 92% yield as determined by glpc-analysis was ozonized to remove unreacted cyclohexene and washed with NaOH solution. After drying over anhydrous $MgSO_4$, the solution was distilled to give norcarane boiling at 115—117°C, n_D^{25} 1.4540. The IR- and NMR-spectra were identical with those of the authentic specimen. Yield 2.8 g. Additional amount of norcarane (1 g) was recovered by the rectification of the forerun (bp 70—115°C), totalizing the yield as 3.8 g (88%).

Synthesis of 1-(1-Piperidino)bicyclo[4.1.0]hep-

tane (Run 12). Methylene iodide (6 g, 0.02 mol) was allowed to react with ethylzinc iodide (40 m*l* of the stock solution, 0.04 mol) and 40 m*l* of absolute tetrahydrofuran was added to the solution. After 1 hr's stirring, 1-(1-piperidino)cyclohexene (bp 120°C/17 mmHg, n_D^{20} 1.5120[11]; 3 g, 0.018 mol) in 10 m*l* of THF was introduced at 30—40°C and the mixture was refluxed for an additional hr. The reaction mixture was hydrolyzed with dil. HCl and then was made alkaline with sodium carbonate. The organic layer, which exhibited a single peak of the product on glpc-analysis and indicated the absence of the parent enamine, was washed with saturated sodium chloride solution and dried over anhydrous magnesium sulfate. After removal of the solvent, the residual oil was distilled to give 1-(1-piperidino)bicyclo-[4.1.0]heptane, bp 115°C/17 mmHg, n_D^{25} 1.4889. Found: C, 80.10; H, 11.93; N, 7.66%: Calcd for $C_{12}H_{21}N$: C, 80.38; H, 11.81; N, 7.81%. Yield 0.9 g (28%).

Aminocyclitols. XX. Bromination of DL-*epi*-Inositol

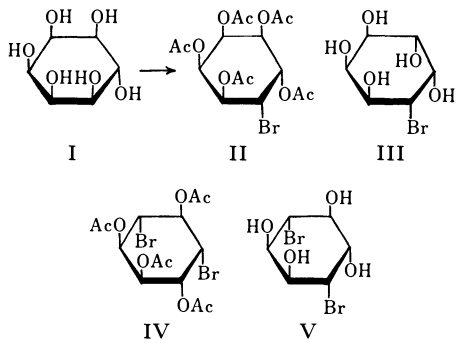
Tetsuo SUAMI, Akira SUZUKI,* Masaru UCHIDA and Shin-ichi YANAGIDA

Department of Applied Chemistry, Faculty of Engineering, Keio University, Koganei-shi, Tokyo
** Central Research Laboratory, Kanto Denka Co., Ltd., Shibukawa, Gunma*

(Received March 19, 1969)

Bromination of DL-*epi*-inositol yielded two hitherto unknown dibromo-dideoxyinositols, along with two known bromo-deoxyinositols (DL-5-bromo-5-deoxy-*allo*-inositol and DL-1-bromo-1-deoxy-*neo*-inositol). The proton magnetic resonance spectroscopic studies of the dibromo-dideoxyinositols with the aid of spin decoupling technique established their configurations to be DL-2,4-dibromo-2,4-didoxy-*chiro*-inositol and DL-1,4-dibromo-1,4-dideoxy-*chiro*-inositol.

As a continuation of the previous paper of this series,[1] configurational studies of two hitherto unknown dibromo-dideoxyinositols which were obtained from DL-*epi*-inositol by a drastic bromination will be described in the present article.



Scheme 1

When DL-*epi*-inositol (I)[2] was heated in a mixture of acetyl bromide and acetic anhydride in a sealed tube at 130—140°C for 8 hr, two new dibromo-dideoxyinositols (IV and V) were obtained, along with two known bromo-deoxyinositols (II and III).[3-5] One of the two reported bromo-deoxyinositols was DL-1,2,3,4,6-penta-*O*-acetyl-5-bromo-5-deoxy-*allo*-inositol (II) which had been described by McCasland and his co-workers in this bromination.[3] Another bromo-deoxyinositol was found to be identical with DL-1-bromo-1-deoxy-*neo*-inositol (III), which had been prepared by McCasland *et al.*[4] and Nakajima and Kurihara[5] in other preparations.

From the bromination mixture of I, II was first isolated in a yield of 25.5%, as was described by McCasland *et al.*[3] Then the tetra-*O*-acetyl-dibromo-dideoxy-inositol of mp 180—182°C (IV) was obtained in a yield of 4.2% from the mother liquor of II after a long storage in a refrigerator,

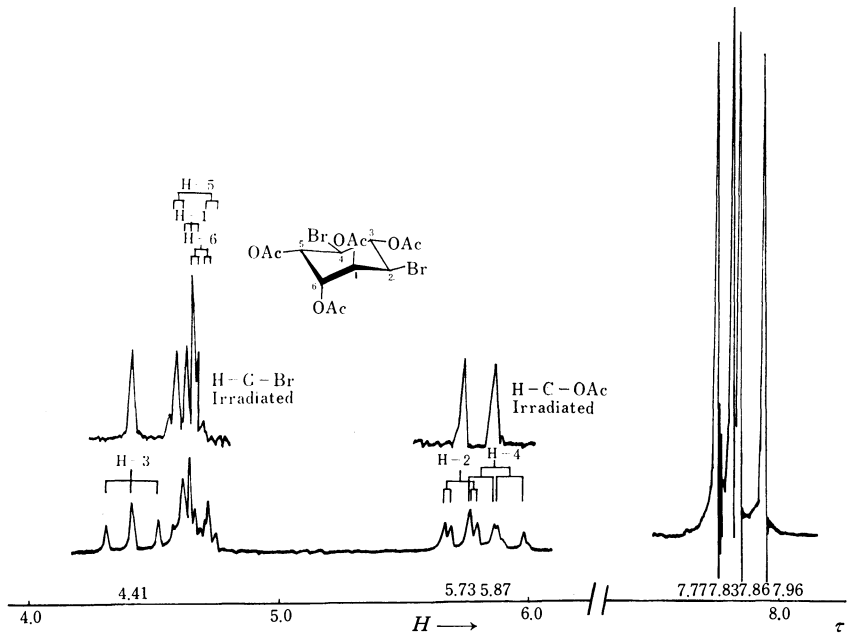

Fig. 1

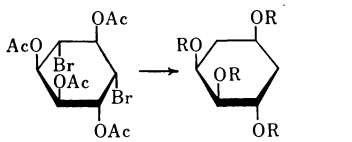
and its structure was assigned to be DL-1,3,5,6-tetra-*O*-acetyl-2,4-dibromo-2,4-diedoxy-*chiro*-inositol by pmr spectroscopic studies, as will be described below.

Another dibromo-dideoxyinositol of mp 220—222°C (dec.) (V) was recovered in a 9.6% yield from the mother solution of IV after it had been hydrolyzed, and V was assigned to be DL-1,4-dibromo-1,4-dideoxy-*chiro*-inositol by pmr spectroscopic and chemical evidences.

Finally, III was obtained in a yield of 5.2% by adding ethanol to the mother liquor of V.



IV VII

R=CO·C$_6$H$_4$·NO$_2$

Scheme 2

In order to establish the configuration of IV, a catalytic debromination was carried out to give an oily product of tetra-*O*-acetyl-dideoxyinositol which failed to crystallize. Hydrolysis of this oily product afforded cyclohexanetetrol as a syrup, which was converted to a crystalline tetra-*O*-*p*-nitrobenzoyl-cyclohexane-tetrol (VII).

The proton magnetic resonance spectrum of IV was determined in deuteriochloroform at 100 Mc and was shown in Fig. 1 which enabled us to establish its conformation for the following reasons: 1) The four protons (H–C–OAc) showed a signal pattern at τ 4.31—4.75. In the lowest field, there was a triplet centered at τ 4.41 with a coupling constant of 10.5 Hz which revealed an axial-axial-axial arrangement of three neighboring protons. 2) The two protons (H–C–Br) exhibited the signal at τ 5.66—6.00. When these protons were irradiated, the above mentioned triplet collapsed to a singlet (Fig. 1). This fact proved that there were two bromo groups adjacent to the proton which had shown the triplet. 3) When the four protons (H–C–OAc) were irradiated simultaneously, the complex signals of the two protons (H–C–Br) collapsed to a doublet with an equal intensity (Fig. 1). This phenomenon showed that these two protons (H–C–Br) were geometrically not equivalent in their environments. Therefore, if an acetoxy group on C-1 was in an axial position, an acetoxy group on C-5 had to be in an equatorial position. 4) This arrangement of the protons was also confirmed by a coupling constant observed in the spectrum. That is, $J_{1-2}=3$ Hz, $J_{2-3}=10.5$ Hz, $J_{3-4}=10.5$ Hz and $J_{4-5}=12$ Hz, and the observed spectrum at τ 4.59—4.75 was the superposition of the three sets of a quartette. Now, the three of the four acetoxy groups occupied their proper positions, that is, there were two equatorial acetoxy groups and one axial acetoxy group. 5) The methyl protons of the four acetoxy groups showed four sharp signals at τ 7.77 (3H), 7.83 (3H), 7.86 (3H) and 7.96 (3H). The first two signals were attributed to two axial acetoxy groups and the fourth signal was ascribed to an equatorial acetoxy group.[6] Considering the fact that there was

6) F. W. Lichtenthaler and P. Emig, *Carbohyd. Res.*, **7**, 121 (1968).

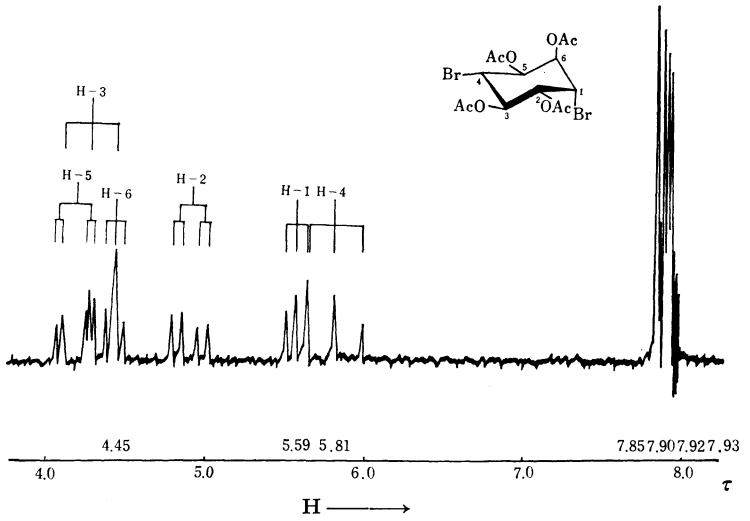


Fig. 2

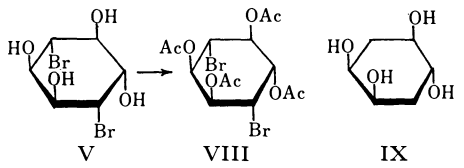
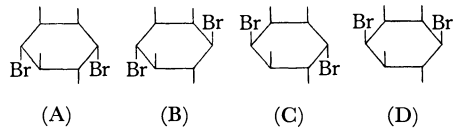
one equatorial acetoxy group between two bromo groups, a signal of this type of an acetoxy group was shifted to a considerably lower field by a deshielding effect of the neighboring bromo groups. An analogous phenomenon had been observed in the pmr spectrum of DL-3-*N*-acetyl-1,5,6-tri-*O*-acetyl-2,4-dibromo-2,4-dideoxy-*chiro*-inosamine-3,[1] where a signal of an equatorial acetamido group on C-3 was shifted to a lower field by an influence of vicinal bromo groups. Therefore, the third signal (τ 7.86) was ascribed to an equatorial acetoxy group located between two bromo groups. Now, the whole conformation of IV was established to be DL-1,3,5,6-tetra-*O*-acetyl-2,4-dibromo-2,4-dideoxy-*chiro*-inositol.

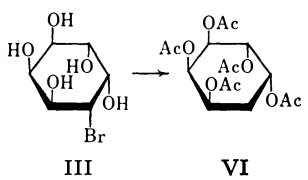


Scheme 3

The configuration of another dibromide (V) of mp 220—222°C (dec.), was studied by a catalytic hydrogenolysis and determination of pmr spectrum. A catalytic hydrogenolysis of V with Raney nickel in the presence of Amberlite IR-4B afforded cyclohexanetetrol of mp 206—208°C (IX). As judged by the melting points of its acyl derivatives, this cyclohexanetetrol was *para*-cyclohexanetetrol of (124/5).[7] Therefore, the possible configuration of V was limited to the following four structures.

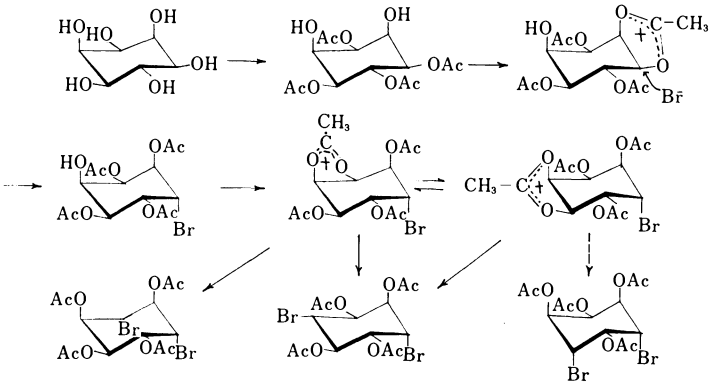


The pmr spectrum of tetra-*O*-acetyl derivative of V (VIII) in deuteriochloroform (Fig. 2) revealed four sharp signals at τ 7.85, 7.90, 7.92 and 7.93 which were attributed to the four acetoxy groups. The signals of the two protons (H–C–Br) produced a quintet (τ 5.50—6.00) which consisted of two triplets. The coupling constant of the triplet centered at τ 5.81 was 10 Hz, suggesting the existence of an axial-axial-axial arrangement of three neighboring protons. Another triplet centered at τ 5.59 had a coupling constant of 3.5 Hz, which revealed equatorial-equatorial-equatorial, an axial-equatorial-axial, an axial-equatorial-equatorial, an equatorial-axial-equatorial or an equatorial-equatorial-axial arrangement of three neighboring protons. These facts were compatible only with the structure of A and all other structures could not produce the above mentioned triplets. Also the complex pattern of the signals produced by the remaining four protons (H–C–OAc) helped to confirm the configuration. Hence VIII was reasonably assigned to be DL-2,3,5,6-tetra-*O*-acetyl-1,4-dibromo-1,4-dideoxy-*chiro*-inositol.



Scheme 4

7) G. E. McCasland, Stanly Furuta, L. F. Johnson and S. N. Shoolery, *J. Org. Chem.*, **28**, 894 (1963); This system for the naming of stereoisomers was proposed by G. E. McCasland: G. E. McCasland, "Advances in Carbohydrate Chemistry," Vol. 20, Academic Press Inc., London (1965), p. 13.



Scheme 5

The configuration of monobromide, III, was assigned to be DL-1-bromo-1-deoxy-*neo*-inositol by the following evidence. The pmr spectrum of III (mp 222—223°C) determined in deuterium oxide at 60 and 100 Mc were identical with the optically active L-1-bromo-1-deoxy-*neo*-inositol prepared by McCasland *et al.*[8] The melting point of this bromide was different from that of bromoquercitol prepared by McCasland *et al.*[8] from 1,2-anhydro-*allo*-inositol. But this could be accounted for by the fact that the present compound was racemic and McCasland's compound was levo-rotatory.

The catalytic hydrogenolysis of III yielded the previously known DL-*talo*-quercitol derivative (VI)[8] and this fact supported the above mentioned configuration of III.

The mechanism of the bromination reaction giving the dibromo-dideoxyinositols (IV and V) is proposed as follows. The monobromination of DL-*epi*-inositol occurs *via* a formation of an intermediary acetoxonium ion[9] which is then opened by a bromide ion in a manner of trans diaxial opening to give II. The second step of the bromination is likely to be a formation of another acetoxonium ion which gives E, F and G by an attack of a bromide ion. E and F are IV and V respectively, which were actually obtained in the present experiment, but G was not obtainable in this work.

Experimental

The melting points reported were determined in a liquid bath and uncorrected. The pmr spectra of the samples were recorded on Varian Associates A-60D and HA-100 spectrometers at the frequency of 60 and 100 Mc in deuteriochloroform, deuteriodimethylsulfoxide or deuterium oxide with tetramethylsilane or sodium trimethylsilylpropanesulfonate as an internal standard. The peak positions are given in τ-values.

DL-1,2,3,4,6-Penta-*O*-acetyl-5-bromo-5-deoxy-*allo*-inositol (II). Ten sealed tubes, containing a mixture of DL-*epi*-inostitol (I) (3.0 g), acetyl bromide (5.0 m*l*) and acetic anhydride (5.0 m*l*), were heated at 135—140°C for 6 hr. Then the mixture was evaporated under reduced pressure. The residue was acetylated with acetyl bromide. The reaction mixture was evaporated under reduced pressure. The oily residue was dissolved in 100 m*l* of ethanol, decolorized with active charcoal and left to settle. The crystals were collected by filtration to give 21.6 g of a crude product of mp 145—149°C. Recrystallization from ethanol afforded 17.9 g of II (25.5% yield), mp 152—153°C. (lit.[3] mp 153°C). (Found: C, 42.37; H, 4.67; Br, 17.63%).

DL-1,3,5,6-Tetra-*O*-acetyl-2,4-dibromo-2,4-dideoxy-*chiro*-inositol (IV). The mother liquor of II was left to settle in a refrigerator for a long period (two months) to give 3.4 g of a crystalline product of mp 176—180°C. The product was recrystallized from ethanol to give 3.0 g (4.2% yield) of an analytically pure sample of IV, mp 180—182°C.

Found: C, 35.79; H, 4.00; Br, 34.06%. Calcd for $C_{14}H_{18}Br_2O_8$: C, 35.44; H, 3.78; Br, 33.75%.

DL-Tetra-*O*-*p*-nitrobenzoyl-cyclohexane-1,2,3,5-tetrol (125/3) (VII). A 560 mg portion of IV was hydrogenated in 50% aqueous ethanol (20 m*l*) with Raney nickel and Amberlite IR-4B under 3.4 kg/cm^2 of hydrogen pressure for 20 hr. After the catalyst and the ion exchange resin were removed by filtration, the filtrate was evaporated giving an oily residue. The residue was heated in a mixture of 2N hydrochloric acid (15 m*l*) and ethanol (15 m*l*) for 20 hr under reflux. The hydrolyzate was evaporated *in vacuo* and an oily residue was acylated with *p*-nitrobenzoyl chloride (30 mg) in pyridine (15 m*l*). After an excess acylating reagent was removed by evaporation, the residue was crystallized from a mixture of acetone and ether to give 33 mg (3.8% yield) of needles melting at 221—223°C.

Found: C, 54.43; H, 3.61; N, 7.09%. Calcd for $C_{32}H_{24}N_4O_{16}$: C, 54.85; H, 3.25; N, 7.52%.

8) G. E. McCasland, S. Furuta, L. F. Johnson and J. N. Shoolery, *J. Am. Chem. Soc.*, **83**, 2335 (1961); G. E. McCasland, S. Furuta and V. Bartuska, *J. Org. Chem.*, **28**, 2096 (1963); The pmr spectrum of III was determined and compared with that of authentic sample of L-1-bromo-1-deoxy-*neo*-inositol by Professor G. E. McCasland.

9) R. Boshan and S. Winstein, *J. Am. Chem. Soc.*, **78**, 4921 (1956).

DL-1,4-Dibromo-1,4-dideoxy-*chiro*-inositol (V). The mother liquor of IV was mixed with 25 m*l* of 2N hydrochloric acid. The mixture was heated under reflux for 20 hr and then evaporated under reduced pressure. The residue was dissolved in 15 m*l* of water and decolorized with active charcoal. The solution was again evaporated to 5 m*l* and left to settle in a refrigerator. Then a crude products (5.1 g) of mp 202—212°C (dec.) was collected by filtration and recrystallized from 10 ml of boiling water to give 4.9 g (9.6% yield) of V, mp 220—222°C (dec.).

Found: C, 24.01; H, 3.33; Br, 58.53%. Calcd for $C_6H_{10}O_4Br_2$: C, 23.53; H, 3.27; Br, 59.29%.

DL-2,3,5,6-Tetra-*O*-acetyl-1,4-dibromo-1,4-dideoxy-*chiro*-inositol (VIII). A 535 mg portion of V was acetylated overnight with acetic anhydride (5 m*l*) in pyridine (5 m*l*) at room temperature. After an excess reagent was removed under reduced pressure, the oily product was dissolved in chloroform. The chloroform solution was washed with cold water, dried over anhydrous sodium sulfate and evaporated. The residue was crystallized from ethanol to give 325 mg of the product. The product was recrystallized from the same solvent giving 303 mg (36.8% yield) of fine crystals, mp 120—123°C.

Found: C, 35.69; H, 3.99; Br, 33.83%. Calcd for $C_{14}H_{18}Br_2O_8$: C, 35.44; H, 4.09; Br, 33.75%.

DL-Cyclohexane-1,2,4,5-tetrol (124/5) (IX). A 2.23 g portion of V was hydrogenated in 50% aqueous ethanol (30 m*l*) with Raney nickel and Amberlite IR-4B under 3.4 kg/cm² of hydrogen pressure for 20 hr. After the catalyst and the ion exchange resin were removed by filtration, the filtrate was evaporated under reduced pressure. The oily residue was crystallized from ethanol to give a crude product (203.5 mg) of mp 202—205°C. The product was recrystallized from ethanol to give 154.1 mg (14.24% yield) of an analytically pure sample, mp 206—208°C (lit.[7] mp 208—209°C). (Found: C, 48.64; H, 8.16%.).

The product was acylated with acetic anhydride in pyridine giving the tetra-*O*-acetyl derivative of mp 89—91°C (lit.[7] mp 91—93°C), and with benzoyl chloride in pyridine to yield the tetra-*O*-benzoyl derivative of mp 169—171°C (lit.[7] mp 172—173°C).

DL-1-Bromo-1-deoxy-*neo*-inositol (III). Ethanol was added to the mother liquor of V until the solution was turbid. Then the solution was left to settle in a refrigerator to give 4.2 g of a crystalline product. The crude product was collected by filtration and recrystallized from 90% ethanol to give 3.1 g (5.2% yield) of III, mp 210—213°C dec. (lit.[5] 214°C dec.). (Found: C, 29.43; H, 4.44; Br, 33.01 %).

DL-Penta-*O*-acetyl-*talo*-quercitol (VI). A 1.0 g portion of III was dissolved in 15 m*l* of water and hydrogenated in 3.4 kg/cm² of hydrogen pressure in the presence of Raney nickel catalyst (2 spatulas) and Amberlite IR-4B for 20 hr. Then the mixture was filtered, and the filtrate was evaporated under reduced pressure. The residue was acetylated by the usual procedure, and the product was recrystallized from ethanol to give 109 mg (7.1% yield) of fine crystals, mp 170—171°C (lit.[5] mp 170°C). (Found: C, 51.08; H, 6.01%).

VI was hydrolyzed in 2N hydrochloric acid and the hydrolyzate was evaporated *in vacuo*. The residue was recrystallized from aqueous ethanol to give DL-*talo*-quercitol, mp 222—225°C (dec.) (lit.[5] mp 225°C dec.). (Found: C, 44.08; H, 7.44%).

The authors wish to thank Professor G. E. McCasland for the comparison of the pmr spectra. Thanks are due also to Professor Sumio Umezawa for his helpful advice. The financial support from the Ministry of Education for this work is gratefully acknowledged.

The Rate of Penetration of Photographic Chemicals into Gelatin Layers. I. Diffusion Rate of Developing Materials

Haruhiko IWANO

Research Laboratories, Ashigara, Fuji Photo Film Co., Ltd., Minami-ashigara, Kanagawa

(Received March 8, 1969)

The rate of diffusion of various kinds of developing materials through coated gelatin layers was determined by using silver halide as a detector. *p*-Phenylenediamines have the biggest diffusion constants among materials tested. They have no pH-dependency nor concentration-dependency. *p*-Aminophenols have slightly lower diffusion constants than the corresponding *p*-phenylenediamines. The constants increase with increase in molecular sizes and also with pH. Hydroquinones have relatively low diffusion constants. They are considerably affected by variation of pH, concentration and ionic strength. These characteristics are discussed in connection with the chemical structures of developing materials.

The penetration of photographic chemicals into gelatin layers is a fundamental problem for rapid development process.

Since the measurement of dye-diffusion by Herzog and Polotzky,[1] many investigations have been reported about the diffusion of dyes and photographic chemicals in gelatin gel. Ostwald and Quast,[2] Pontius and his colaborators[3] and other investigators[4,5] determined the rate of diffusion of various dyes. Blyumberg and Davidkin[6] and Bagdanov and Polyakova[7] measured the diffusion rate of developing materials, halides and alkaline substances. Adair[8] and other investigators[9] adopted a capillary tube method to determine the diffusion rate of bromide ion in gelatin gel.

The diffusion rate in gelatin gel is different from that in a coated gelatin layer. Reckziegel[10] is the first who investigated the diffusion in coated layers.

The author made a series of investigations using gelatin coatings, and this paper deals particularly with the effect of molecular size, pH, ionic strength and temperature on the diffusion rate of various developing materials.

Experimental Procedure

The method of measurement was similar to that by Reckziegel.[10]

Test Samples. Various thickness of gelatin layers (0 to 26 μ) were coated on a silver bromo-iodide emulsion layer applied on a film support with 2.7 μ thickness which acted as a detector layer (Fig. 1).

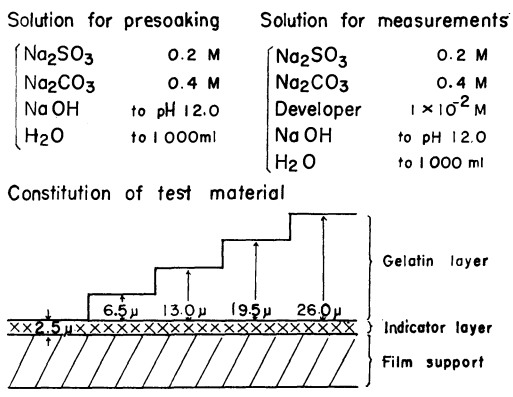

Fig. 1. Explanation of experimental procedure.

Measurement. Pre-swollen samples were dipped into a bromide-free solution containing a developing material. The developing material diffuses through gelatin to the emulsion layer at the bottom and then reduces silver halide instantaneously. The blackening indicates the time required for penetration. The solu-

tion used for pre-soaking to eliminate the effect of swelling had the same composition as the developer solution except that it did not contain the developing material.

Accuracy. The relative errors for measurement of layer thickness fell within ±2% by Tsugami Precision Microcator under 95% confidence limit, and that of diffusion time fell within ±5% under 95% confidence limit.

Theoretical Treatment of Diffusion Process

One dimensional expression of Fick's diffusion law may be applied to the penetration of developing materials through the gelatin layer;

$$\partial c/\partial t = K\partial^2 c/\partial x^2 \quad (1)$$

were c is the concentration of the developing material, t the time required for the developer to diffuse through the layer with thickness x and K the diffusion constant. Following Lederer,[11] Eq. (1) can be solved as follows:

$$C_i = C_a[1-(4/\pi)\cos(\pi l/2x)\exp(-ft) -(4/3\pi)\cos(2\pi l/2x)\exp(-9ft)+\cdots] \quad (2)$$

where $f = \pi^2 K/4x^2$

C_i: Concentration of the developing material at x from surface of gelatin layer.

C_a: Concentration of the developing material in bulk solution.

Supposing that the blackening of the detector layer occurs instantly when the first portion of the developing material (m) has reached through gelatin layer (x) to the detector layer, the following relation can be obtained between m and x by integrating Eq. (2).

$$m = C_a[a-(8/\pi^2)(x+a)\sin\{\pi a/(x+a)\}\exp(-ft)+\cdots] \quad (3)$$

Here, a means a hypothetical diffused length of the developing material into the detector layer to induce the first blackening.

If $h + a \gg 2a$, Eq. (3) can be simplified by approximation.

$$m = C_a a\{1-(4/\pi)\exp(-\pi^2 Kt/4x)\} \quad (4)$$

By considering the condition,

$$\lim_{x\to\infty}\{\log(C_a a/C_a a-m)\} = 0 \quad (5)$$

we can derive from simplification of Eq. (4)

$$t = (4x^2/\pi^2 K)\ln(4/\pi) \quad (6)$$

or

$$x = K't^{1/2} \quad (7)$$

where

$$K' = \pi K^{1/2}/2\{\ln(4/\pi)\}^{1/2}$$

Equation (6) or (7) means that, if penetration of the developing materials proceeds by Fick's diffusion process, the time required to penetrate through the layer will be proportional to the square of layer thickness.

Experimental Results

1. Diffusion of Various Types of Developers. The rate of diffusion was determined by a solution containing 10 mmol/l of the developing material, 0.2 mol/l of Na_2SO_3, 0.4 mol/l of Na_2CO_3 and NaOH or H_2SO_4 to adjust pH. Plots of layer thickness *vs.* square root of penetration time showed linear relation for almost all developers examined (Fig. 2). This means that the diffusion process satisfies Fick's law, so far as the equation is con-

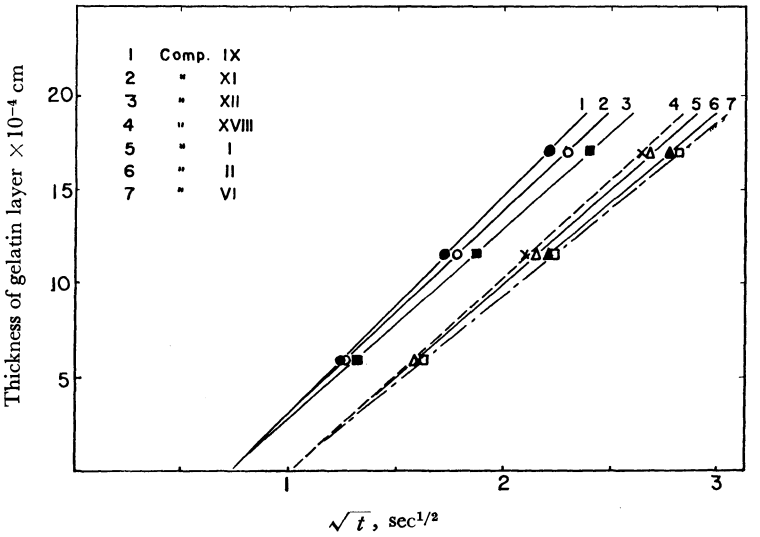

Fig. 2. Distance - time relation during diffusion process.

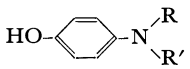
11) E. L. Lederer, *Kolloid Z.*, **44**, 108 (1928).

cerned. Therefore, the diffusion constant can be obtained from the tangent(K) of Fig. 2 by using Eq. (7).

The diffusion constants of various types of developers thus obtained are listed in Tables 1—3. The results showed: (1) In the series of *p*-aminophenols and *p*-phenylenediamines, diffusion constants decreased with the increase in size of substituted groups, but no distinct rule could be observed about hydroquinone derivatives. (2) The diffusion constants of *p*-phenylenediamines were generally greater than those of corresponding *p*-aminophenols and the latter were greater than those of hydroquinones.

Table 1. Diffusion constants of *p*-aminophenols



Comp.	R	R′	$D\times10^{-7}$ cm²/sec
I	-H	-H	1.69
II	-H	$-CH_3$	1.58
III	-H	$-C_2H_5$	1.20
IV	-H	$-s\text{-}C_4H_9$	1.05
V	-H	$-n\text{-}C_4H_9$	1.05
VI	-H		0.923
VII	-H		0.695
VIII	$-C_2H_5$	$-C_2H_5$	0.962

XI	4-Amino-*N*-ethyl-*N*-hydroxyethylaniline	1.77
XII	3-Methyl-4-amino-*N*-ethyl-*N*-hydroxyethylaniline	1.46

Table 3. Diffusion constants of hydroquinones and other developing materials

Hydroquinone and other developing material		$D\times10^{-7}$ cm²/sec
XIII	Hydroquinone	0.695
XIV	Methylhydroquinone	0.324
XV	2,5-Dihydroxyphenylamylketone	0.527
XVI	2,5-Dihydroxyphenylcetylketone	0.057
XVII	Phenylhydroquinone	0.645
XVIII	1-Phenyl-3-pyrazolidone	1.27
XIX	Amidol	1.42
XX	Pyrogallol	0.424

2. Effect of pH. The pH-dependency of the diffusion of three types of developing materials differed from each other.

A typical *p*-phenylenediamine (compound XII) showed no pH-dependency over a pH-range from 9.4 to 12.0, as shown in Fig. 3. On the other hand, *p*-aminophenols had some pH-dependency. This dependency became smaller with increase in pH. In fact, it almost disappeared over pH 10.7 in the case of metol.

In contrast to the results of *p*-aminophenols, the rate of diffusion of hydroquinones decreased with increase in pH.

3. Effect of Temperature. The temperature dependency of three types of developers also showed some difference from one another (Fig. 4).

The plots of rate *vs.* $1/T$ consists of two straight lines in case of hydroquinone. Activation energies

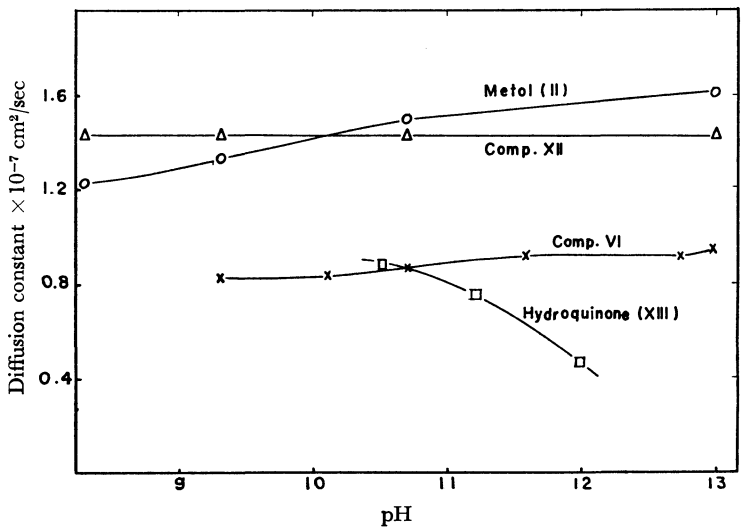

Fig. 3. Effect of pH on diffusion constant.

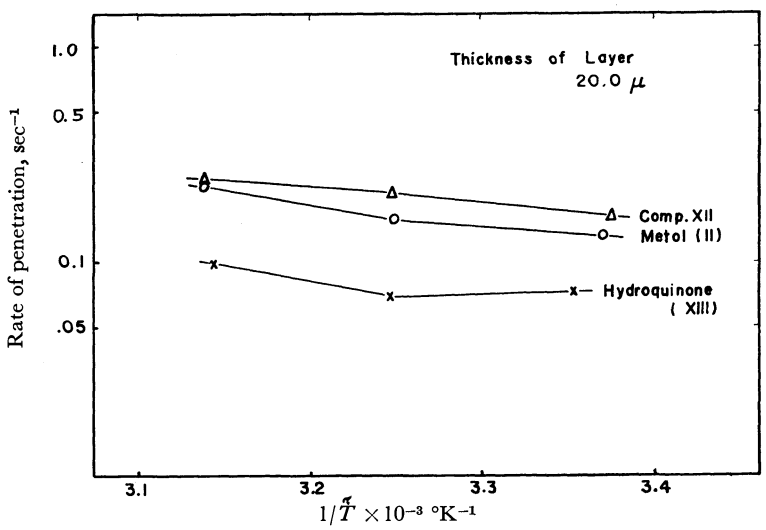

Fig. 4. Effect of temperature on penetration rate.

of diffusion obtained from the slope of the curves for the three types of developing materials are listed in Table 4.

Table 4. Activation energy of diffusion

Compound	Temperature	$E_{act.}$
II	23—35°C	2.9 kcal/mol
	35—45°C	6.5 kcal/mol
XII	23—45°C	3.1 kcal/mol
XIII	35—45°C	7.2 kcal/mol

4. Effect of Concentration of Developing Materials. The diffusion constants of *p*-aminophenols and *p*-phenylenediamines did not show any dependence on concentration except the case of extremely low concentration, but that of hydroquinone showed relatively large dependence up to the concentration of 8×10^{-2} mol/*l* (Fig. 5). The fact that the diffusion constant of metol is independent of concentration means that this process is pure physical diffusion which can be expressed by Fick's law.

5. Penetration of Developing Materials into Unswollen Layer. Measurement of penetration into the gelatin layer which had not been preswollen also gave a linear relation between the depth of penetration and the square root of penetration time (Fig. 6). Therefore, this penetration process can be simulated to diffusion, although it contains many complicated processes such as absorption of water by gelatin, swelling and hydration.

The apparent rate of penetration was independent of the types of developing materials, if the applied

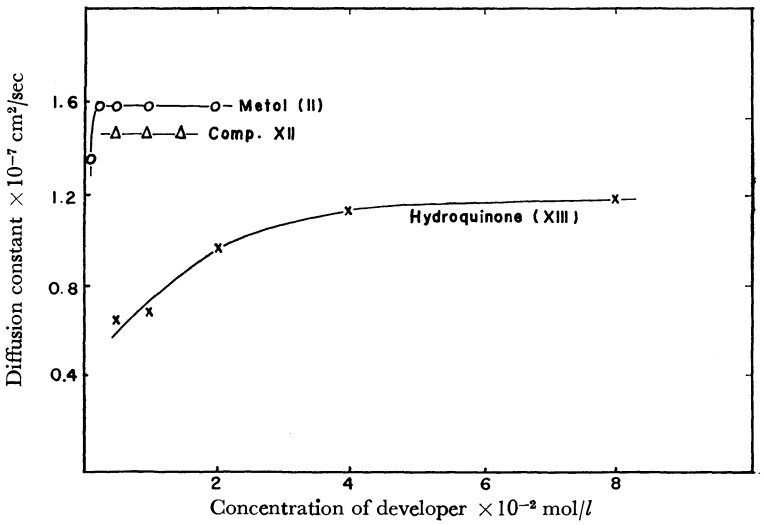

Fig. 5. Effect of developer concentration on diffusion.

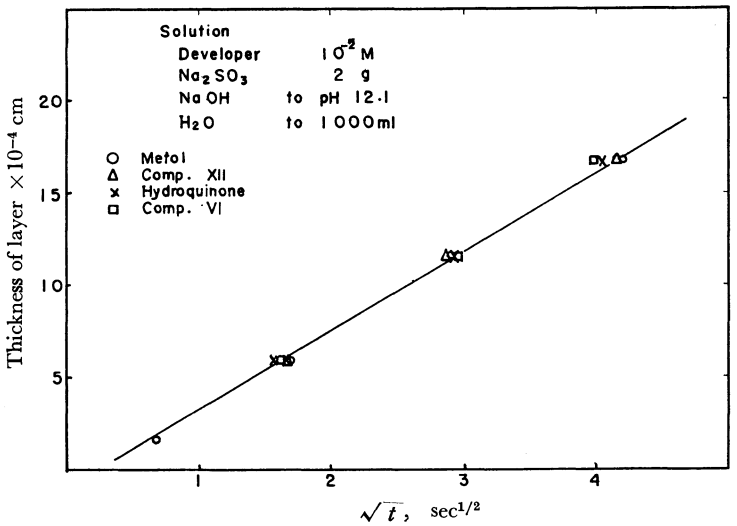

Fig. 6. Penetration of developer into unswollen layer.

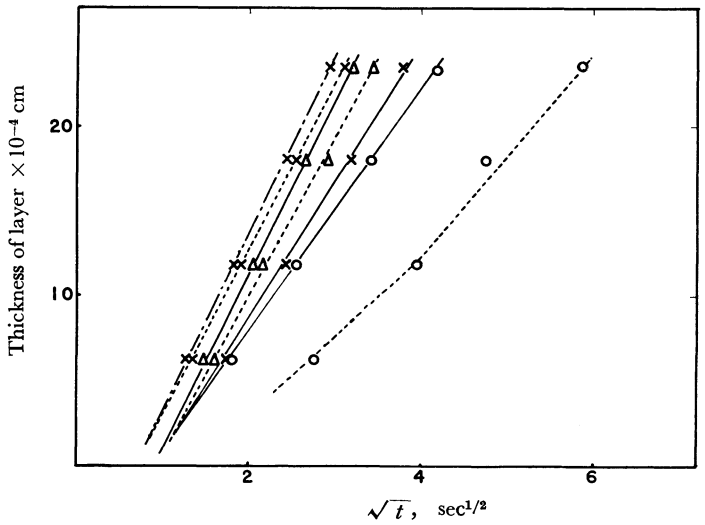

Fig. 7. Effect of salt on penetration.
△ Comp. II, × Comp. XII, ○ Comp. XIII
—— with Na_2SO_4, ----- without Na_2SO_4, —·— Na_2SO_4 soln. was applied only in pre-swelling

solution had low ionic strength or relatively low pH. This result is interpreted from the slow penetration rate of OH^- ion in these solutions which determines the initiation of blackening of detector layer. This explanation is supported by the fact that the initiation of blackening occurred about 1 sec after OH^- ion had reached the bottom layer (detector).

On the other hand, the rate of penetration from solutions of high alkalinity or of high ionic strength depended on the types of developing materials.

6. The Effect of Salt Concentration. The presence of salts such as Na_2SO_4 affected the diffusion rate in different ways according to the types of developing materials, as shown in Fig. 7. The presence of Na_2SO_4 accelerated the diffusion of hydroquinone and metol, but retarded that of a *p*-phenylenediamine derivative (compound XII). The accelerated diffusion of the compound XII, however, could also be observed, in the case Na_2SO_4 was present only in the swelling solution and not in the solution of the developing material.

Discussion

Three types of developing materials showed different characteristics with respect to diffusion.

p-Phenylenediamines have two amino groups and

no hydroxy group. They have the biggest diffusion constants, no pH-dependence or concentration dependence. Their activation energies are constant over 23—45°C. Ionic strength slightly affects the diffusion.

Hydroquinone with two hydroxy groups has just the opposite property. Its diffusion constant is the smallest and had big pH- and concentration-dependence. It varies considerably with the change of ionic strength. The apparent activation energy varies with temperature. *p*-Aminophenols have one amino and one hydroxy group. They have the characteristics intermediate between the two mentioned above.

In alkaline medium, dissociated functional groups of gelatin will interact with charged developing materials, thus affecting the rate of diffusion. Therefore, it seems that hydroquinone which dissociates with $pK_1=9.9$ and $pK_2=11.4$ has relatively large dependency on pH, concentration and ionic strength, and that non-dissociating *p*-phenylenediamines do not have such dependency.

The constancy of diffusion coefficient over a wide range of concentration of a developing material means that (1) the penetration into pre-swollen layers can be treated as pure diffusion and that (2) the condition $C_a \times a \gg m$ is satisfied to calculate K by Eq. (6).

Hydroquinone does not have a constant rate of diffusion under 8×10^{-2} mol/*l*. This means again that it has some interaction with the medium or it has relatively large m value.

The decrease in diffusion constant with increase in molecular size of substituted group in *p*-aminophenol supports the suggestion by Alburger[12] who assumed that the property of duratol having a tendency to develop surface layer selectively is due to its molecular size. But the property is more closely related to the activity of the duratol rather than its poor diffusibility.

This investigation is concerned only with the first step of development processes. Many successive steps might affect the rate of development. The effect of pre-bathing and control of swelling by addendants to the solution or to gelatin are also important in photographic development.

The author wishes to acknowledge the helpful suggestions made by Professor Dr. W. F. Berg of the Swiss Federal Institute of Technology, and the discussions with Mr. Ueda and Mr. Nakajima of this Laboratory. He also wishes to express his sincere thanks to Mr. Koseki, director of the Laboratory, for permission to write this article.

Synthetic Inorganic Ion-exchange Materials. XIII. The Mutual Separation of Alkali Metals with Three Different Antimonic Acids

Mitsuo ABE

Department of Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received June 12, 1968)

The present paper will describe the use in the chromatographic separation of alkali metal ions on columns of the three different antimonic acids;[1] amorphous (S_A), glassy (S_G), and crystalline (S_C). The samples were prepared as was been described in a preceding paper,[2] and then controlled

Exchanger: 0.100 g ,total volume: 25.0 m*l*, 20 ± 0.05°C, immersion; 24 hr.
S_A: amorphous antimonic acid, S_G: glassy antimonic acid, S_C: crystalline antimonic acid.
Distribution coefficient was calculated from the following equation;

$$K_d = \frac{A_0 - A_s}{A_s} \cdot \frac{ml}{g}$$

where A_0 is the concentration of alkali metal in the solution before equilibration (1×10^{-3} mol/*l*), A_s is the concentration in the solution after equilibration, m*l* is total volume of the solution in mililiters, and g is the weight of the sample in grames.

1) M. Abe and T. Ito, This Bulletin, **41**, 333 (1968).
2) M. Abe and T. Ito, *ibid.*, **41**, 2366 (1968).

in a 100—200 mesh size. The column experiments were carried out with a column ($0.8\phi \times 6.0$ cm) containing 3.0, 6.4, and 3.9 g for S_A, S_G, and S_C respectively. The concentration of alkali metals was determined flame-photometrically by using a Hitachi EPU-2A with a flame apparatus, H-2, attached.

Results and Discussion

Affinity Series for Alkali Metal Ions. Table 1 gives the values of the distribution coefficients for alkali metal ions on three different antimonic acids. The K_d values on S_C are higher than those on S_A and S_G except in the case on Li^+ adsorption, and S_A gives values almost identical with those obtained on S_G. The affinity on the S_A and S_G was found to increase in the order: $Li^+ < Na^+ < K^+ < Rb^+ < Cs^+$ in the acid solution, while the order was: $Li^+ < Na^+ \fallingdotseq Cs^+ < K^+ = Rb^+$ in the ammonium nitrate solution. The affinity series on the S_C may be written as $Li^+ < K^+ < Cs^+ < Rb^+ < Na^+$ in the acid solution and $Li^+ < K^+ < Rb^+ < Cs^+ < Na^+$ in the ammonium nitrate solution. The difference in selectivity is very large compared with those obtained for the sulfonic acid resins. In the acid solution, Rb^+ was more strongly adsorbed than Cs^+, with the separation factor of 5.8. Na^+ was more strongly adsorbed than any other alkali metal ions in the solutions of both nitric acid and ammonium nitrate. The separation factor in the pairs of lithium and other alkali metals may be compared favorably with those of other cation exchangers.

According to Lefebvre,[3] the inverse selectivity should prevail for alkali metals: $Na^+ < K^+ < NH_4^+ < Rb^+ < Cs^+$ on the polyantimonic acid.

When a large volume of a 0.1 N soultion of various alkali metal salts was passed through an S_C column, the uptake of alkali metals showed the values of 1.0, 2.8, 2.4, 1.4, and 1.2 meq/g for Li^+, Na^+, K^+, Rb^+, and Cs^+ respectively. In the solutions with a constant ionic strength of 0.1 M ($HNO_3 + MNO_3$), ion-exchange isotherms on the S_C gave ogee-sharp curves,[4] as is the case with rigid inorganic ion-exchangers (*e. g.*, zirconium phosphate, zeolites, and basic cancrinite). These results indicate that the selectivity coefficient varies strongly with the ionic composition and that the reversal of selectivity, which may be due to steric factors, arises from the course of conversion. The crystalline antimonic acid presents a fairly rigid lattice, for the volume change on conversion from the hydrogen form to the alkali forms is very small; accordingly, the lattice constants of various forms gave 10.30, 10.33, 10.37, 10.38, 10.40 and 10.47 Å for Na, Rb, Li, H, Cs, and K forms, without any change in the crystal system. The increased order in the lattice constant conforms to the inverse order in the affinity series for micro amounts of all the alkali metal ions except Li^+.

Separation of Alkali Metal Ions on the Columns of the Three Different Antimonic Acids. Small amounts of various alkali metal ions were adsorbed onto the column and then eluted with different eluants.

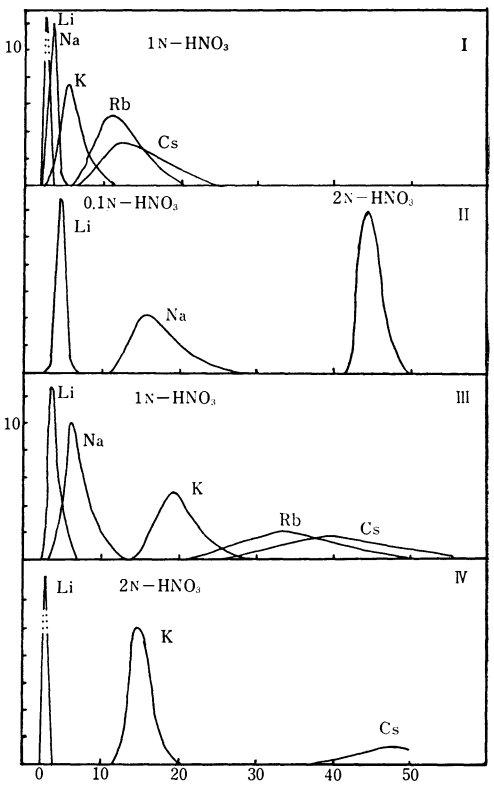

Fig. 1. The elutions of alkali metals with nitric acid of various concentrations on the three different antimonic acids.
Fraction: 5.5 m*l*, alkali metal: each 0.02 mmol, flow rate; 0.3 m*l*/min
I and II: amorphous antimonic acid, III: glassy antimonic acid, IV: crystalline antimonic acid.

Elution with Various Nitric Acid Solutions. On the S_A and S_G, all of the alkali metal ions were more easily eluted with nitric acid of a relatively dilute solution than in the case of S_C, and the elution curves were always somewhat asymmetric. Complete separation were made for Li^+, Na^+, and K^+ with an 0.1 N (S_A) or 0.2 N (S_G) and 2 N nitric acid solution. On S_C, a good separation was obtained for Li^+, K^+, and Cs^+ with a 2 N nitric acid solution, but Na^+ and Rb^+, were not eluted within 70 fractions.

4) M. Abe and T. Ito, Preprints for The 19th Annual Meeting of The Chemical Society of Japan (April, 1966) Vol. II, p. 292.

It has been established that, on the organic ion-exchangers, the mutual separation between Rb^+ and Cs^+ is very difficult. The separation on the S_C can be made completely with a 4N nitric acid solution. The separation factor, α_{Rb}^{Cs}, calculated from the peak volume in the elution curves showed 5.6. Sodium ions were more strongly adsorbed than any other alkali metal ions and could not be eluted by a relatively concentrated nitric acid solution within the column volume shown in Fig. 2-I. Figure 2-II shows that the order of peak

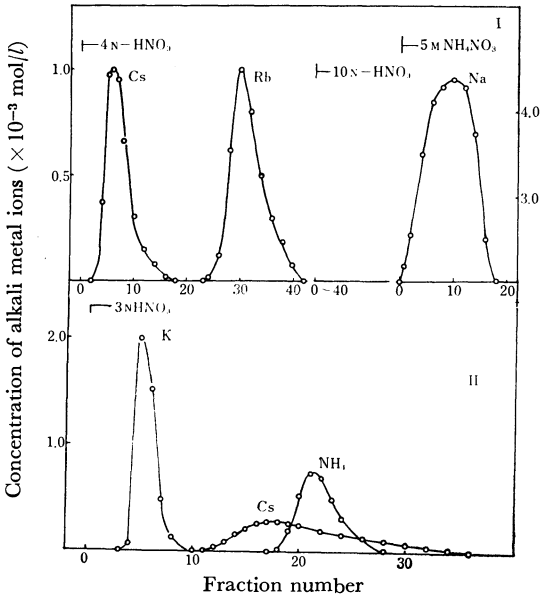

Fig. 2. The elution of alkali metals on crystalline antimonic acid
I: separation of sodium, rubidium and cesium fraction; 5.5 m*l*, Rb and Cs; each 0.04 mmol, Na; 0.1 mmol
II: elution of potassium, cesium and ammonium, ions
fraction; 5.6m*l*, K, Cs and NH_4; each 0.02mmol
Flow rate: 0.3 m*l*/min.

volume in the elution curves was $K^+ < Cs^+ < NH_4^+$ and that S_C was not for selective for ammonium and cesium ions, while there was a broader curve for cesium ions. With eluants of both nitric acid and ammonium nitrate solutions, the time required was relatively short, only about 10 hr being sufficient for a complete separation of a miligram-amount of alkali metals (Fig. 3-I).

Elutions with Various Ammonium Nitrate Solutions. On S_C, pairs of neighbouring alkali metal ions, such as Li-K, K-Rb,and Cs-Na, were

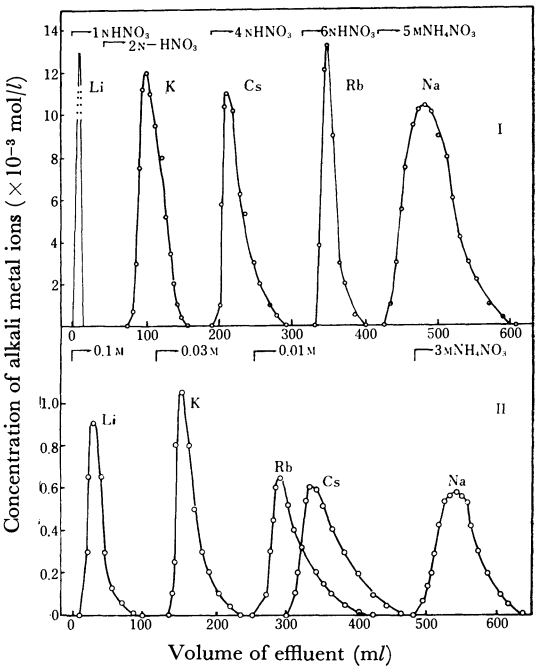

Fig. 3. The separation of alkali metal ions with nitric acid and ammonium nitrate of various concentration on the crystalline antimonic acid S_C.
Flow rate: 0.6 m*l*/min.
I: with the nitric acid and ammonium nitrate solutions, Li; 0.01 mmol, Na; 0.1 mmol, K, Rb, Cs; each 0.04 mmol
II: with the ammonium nitrate solutions, Li; 0.02 mmol, Na, K, Rb, Cs; each 0.04 mmol

easily separated in the same column length, but not the Rb-Cs pair (Fig. 3-II). On S_A and S_G, all the alkali metal ions except Li^+ were removed as a group with a 0.03M ammonium nitrate solution.

These results indicate the presence of antimonic acid of two types, with a different selectivity for alkali metal-ions adsorptions, a difference may be closely related to the disparity in the surface structure.[2] The S_G and S_C were favorable for column work because their lower solubilities and their suitable granular forms. The S_C was especially stable against almost all reagents, including concentrated acid and alkaline solutilons and oxidizing agents. The S_A was unsuitable, since it was relatively soluble in water and was gradually transformed into crystalline antimonic acid in a relatively concentrated acid solution.

The author wishes to express his thanks to Professor Takuji Ito for his valuable advice and discussions throughout this work.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 2686—2688 (1969)

Synthesis of Hypothiaminic Esters[1]

Goro TSUKAMOTO, Toshio WATANABE and Isamu UTSUMI

Pharmaceutical Research Laboratory, Tanabe Seiyaku Co., Ltd., Kashima-cho, Higashiyodogawa-ku, Osaka

(Received September 16, 1968)

In a previous paper we reported that hypothiaminic acids (I, VIII) would undergo disproportionation in methanolic hydrogen chloride to the corresponding thiolsulfonates (VII) on the basis of the formation of product (A), which was positive toward thiochrome reaction after treatment with cysteine and isolation of thiaminic acid (VI).[2]

We have made an attempt to isolate the product (A) and confirm its structure.

A solution of I in methanolic hydrogen chloride gave crystals (A), mp 110—112°C. Analogously, the same treatment in ethanolic hydrogen chloride solution of I afforded crystals (B), mp 118—120°C, which were oxidized with hydrogen peroxide to VI.

The structures of these compounds (A, B) were confirmed to be not thiolsulfonate-type compound (VII) but sulfinic esters (V) by means of NMR spectra.

The preparation of sulfinic ester by the reaction of I with diazomethane and the action of ethyl chloroformate on II in methanol gave also Va.[3]

However, sodium hypothiaminate (IX) was treated with ethyl chloroformate in chloroform to yield colorless prisms (mp 133—135°C). On the basis of spectral and analytical data, the structure of the compound was confirmed to be 1,2-oxathiolane-2-oxide derivatives (XII, hereinafter called sulfinothiamine). So far as we know, there is no report on 5-membered ring sulfinic ester.

Compound VIII was allowed to react with thionyl chloride to give sulfinyl chloride (XI) which upon the action of base cyclized to XII. XI could be prepared simply by treating X or XIV with chlorine. Similarly, the disulfide III was converted to open-chain sulfinic ester Vb by chlorine oxidation.

It was noteworthy that the bridge methylene of XII between the pyrimidine and *N*-formyl moiety showed spectrum of AB system ($J=15$ cps). The magnetic non-equivalence of the methylene seems to be due to a rotational restriction caused by the bonding between the 4-amino group and $^{+}S{=}O^{-}$ group. This might be supported by the fact that no splitting of the methylene was observed in 1,2-oxathiolane XIII, synthesized recently by Nakano and Nishimura.[4] Compound XIII was oxidized with perbenzoic acid to give XII.

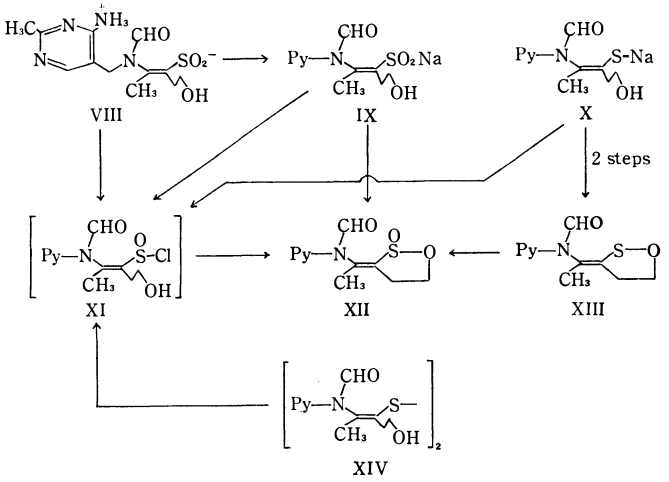

Fig. 2.

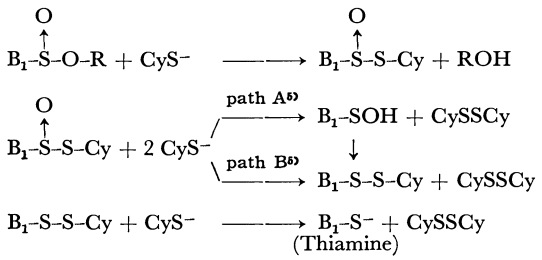
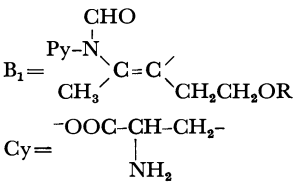
It was found that V was reduced quantitatively to thiamine with 1000 mol of cysteine per mol of Vb at pH 8.6 and 50°C for 2 hr. Accordingly, the following mechanism appears applicable:





Reduction of XII to thiamine proceeds with difficulty in comparison with that of open-chain sulfinic esters (V). This might be unusual in view of the fact that the rates of hydrolysis of sultones[6] or lactones[7] are known to be very fast in comparison with the open-chain analogs. Unfortunately, there has been no data for the properties of cyclic sulfinate, even for the synthesis. A molecular model suggests a close proximity between the 4-amino group and +S=O⁻ group which would cause a strong interaction between the two groups resulting in a hindered rotation around the bridged methylene bonds as discussed for the unusual splitting of methylene protons in the NMR spectrum of XII. The same interaction might be also the cause of the resistance to the reduction, although further work is necessary in order to elucidate this interesting phenomenon.

Experimental

Methyl *O*-Benzoylhypothiaminate (Va). *i) From I.* A solution of I (840 mg) in absolute methanol (20 m*l*) containing 0.1M hydrogen chloride was warmed in a bath kept at 70° for 1 hr. The solution was concentrated *in vacuo*. After the residue dissolved in water was washed with ether, the aqueous solution, which was made alkaline with sodium bicarbonate, was extracted with chloroform. The extract, which was washed with water and dried over sodium sulfate, was concentrated *in vacuo* and to the residue was added ether to give colorless prisms (500 mg), mp 108—110°C. Recrystallization from ethanol - ether gave Va as colorless prisms, mp 110—112°C.

Found: C, 55.76; H, 5.94; N, 12.72; S, 7.16%. Calcd for $C_{20}H_{24}O_5N_4S$: C, 55.55; H, 5.59; N, 12.96; S, 7.42%.

IR ($CHCl_3$) cm^{-1}: 1713 (C=O), 1665 (NCHO), 1115 (S=O), 980 (S–O). NMR (in $CDCl_3$) τ: 5.55 (s C–CH_2–N).

The reaction of I (120 mg) in ethanol with a large quantity of diazomethane afforded Va (100 mg).

ii) From II. To a solution of II (420 mg) in methanol (15 m*l*) was added ethyl chloroformate (110 mg) under cooling with ice water. The mixture was allowed to stand at room temperature over night, concentrated *in vacuo*, and to the residue was added water and chloroform. The chloroform layer was washed with water and dried over sodium sulfate. The chloroform solution was chromatographed over alumina to afford Va (50 mg).

Ethyl *O*-Benzoylhypothiaminate (Vb). *i) From I.* The same procedure and treatment were followed as described above. The reaction between I (840 mg) and absolute ethanol (20 m*l*) containing 0.1M hydrogen chloride afforded colorless prisms (620 mg), mp 118—

7) T. C. Bruice and S. J. Benkovie, "Bioorganic Mechanisms," Vol. 1, W. A. Benjamin, New York (1966), p. 21.

120°C. Recrystallization from ethanol-ether gave Vb as colorless prisms, mp 118—120°C.

Found: C, 56.26; H, 5.85; N, 12.64; S, 6.95%; mol wt (Rast), 450. Calcd for $C_{21}H_{26}O_5N_4S$: C, 56.49; H, 5.87; N, 12.55; S, 7.18%; mol wt, 446.5.

IR ($CHCl_3$) cm^{-1}; 1710 (C=O), 1665 (NCHO), 1115 (S=O), 1010 (S-O). NMR (in $CDCl_3$) τ: 5.75—6.50 (m $-\overset{O}{\overset{|}{S}}-O-CH_2-$), 5.50 (s $C-CH_2-N$).

ii) From III. A solution of III (4.36 g) dissolved in 7.2 g of acetic acid and ethanol (50 m*l*) was cooled to −10——15°C. To the mixture was added dropwise a chloroform solution (10 m*l*) containing chlorine (0.43 g), and then the mixture was titrated with a chloroform solution of dimethylamine to make it alkaline. The mixture was concentrated *in vacuo* and to the residue was added ethanol to separate crystals, which were identical in IR spectrum with III. The mother liquor was evaporated *in vacuo* and the residue dissolved in chloroform was washed with water and dried over sodium sulfate. The chloroform solution was chromatographed over alumina to yield Vb (0.60 g).

Oxidation of Vb with Hydrogen Peroxide. A solution of Vb (90 mg) dissolved in acetic acid (1 m*l*) and 30% hydrogen peroxide (0.1 m*l*) was allowed to stand at room temperature for 2 weeks. The mixture was concentrated *in vacuo*, and the residue was crystallized from 95% aqueous ethanol to yield colorless prisms (20 mg), which was identical in infrared spectrum with authentic sample (VI).

Sulfinothiamine (XII). *i) From IX.* Compound IX (1.1 g) was suspended in chloroform (10 m*l*) and ethyl chloroformate (0.35 g) was added. After the mixture was stirred for 2 hr at room temperature, it was washed with water and dried over sodium sulfate. The chloroform solution was chromatographed over alumina to afford crystals (0.13 g). Recrystallization from ethyl acetate gave colorless prisms mp 133—135°C.

Found: C, 47.94; H, 5.59; N, 18.77; S, 10.55%. Calcd for $C_{12}H_{16}O_3N_4S$: C, 48.64; H, 5.44; N, 18.91; S, 10.82%.

IR (KBr) cm^{-1}: 1110 (S=O), 990 (S-O). NMR (in $CDCl_3$) τ: 5.02 and 5.90 (q $C-CH_2-N$, $J=15$ cps), 5.00—5.50 (m $-\overset{O}{\overset{|}{S}}-O-CH_2-$).

ii) From VIII. A suspension of VIII (9.5 g) in chloroform (30 m*l*) was cooled to −3——5°C and thionyl chloride (0.38 g) was added. After the solution was stirred for 1 hr below 0°C it was alkalified under cooling by addition of a chloroform solution of triethylamine, and then allowed to stand until room temperature was reached. The mixture was washed with water and dried over magnesium sulfate. To the residue obtained by the evaporation of the solvent was added ethyl acetate to yield XII (30 mg).

iii) From XIV. A solution of XIV (3.4 g) dissolved in acetic acid (7.2 g) and chloroform (60 m*l*) was cooled to −10°C and a chloroform solution (5.5 g) containing chlorine (0.6 g) was added dropwise. The mixture was similarly treated as described above to afford XII (0.38 g).

iv) From X. A suspended solution of X (3.8 g) in chloroform (50 m*l*) was cooled to −10°C. After acetic acid (6.0 g) was added to the solution, a chloroform solution (13.0 g) containing chlorine (1.4 g) was added dropwise under cooling to −10°C. Similar treatment of the mixture to that descibed in *i)* gave XII (0.10 g).

Oxidation of XIII with Perbenzoic Acid. To a solution of XIII (280 mg, 1.0×10^{-3} mol) in chloroform (8 m*l*) was added a chloroform (2.4 m*l*) solution containing perbenzoic acid (1.2×10^{-3} mol). The mixture was allowed to stand for 30 min at room temperature, and was shaken with aqueous sodium bicarbonate solution, washed with water, and then dried over sodium sulfate. The residue obtained by the concentration of the chloroform solution was recrystallized from benzene to give XII (120 mg).

The authors wish to express their thanks to Professor S. Oae and Assistant Professor W. Tagaki of Osaka City University for their useful advice and discussion. They also thank Dr. K. Kotera for his NMR spectra determinations.

Reaction Intermediate in the Dimerization of Ethylene Catalyzed by a Palladium(II) Complex. NMR Spectral Evidence for the Formation of the π-Bonded Chloro-acetylacetonato-(1-butene)palladium(II) Complex

Keiji KAWAMOTO, Toshinobu IMANAKA and Shiichiro TERANISHI

Department of Chemical Engineering, Faculty of Engineering Science, Osaka University, Machikaneyama, Toyonaka, Osaka

(Received November 21, 1968)

In a previous paper,[1] it has been shown that bidentate ligands, such as β-diketones, have marked effects on the dimerization of ethylene to butene catalyzed by di-μ-chlorobis(ethylene)dipalladium (I), $(Pd(C_2H_4)Cl_2)_2$; that is, when bidentate ligands, especially β-diketones, are added to the ethylene-

palladium(II) chloride - acetic acid system, the additive increases the rate of the dimerization besides accelerating the reduction of palladium(II) to metallic palladium. The order of the acceleration effect was as follows: acetylacetone>ethyl acetoacetate>diethyl malonate.

Though various π-allyl-acetylacetonato-palladium complexes have been isolated by Robinson and Shaw,[2] no olefin-acetylacetone-palladium complex in which the olefin is coordinated with palladium by the π-bond has ever been reported. The present paper will report the NMR spectral evidence for the formation of the π-bonded chloro-acetylacetonato(1-butene)palladium (IV), $(Pd(C_5H_7O_2)(C_2H_5CH{=}CH_2)Cl)$, which is assumed to be an intermediate in the dimerization of ethylene in the presence of an acetylacetone additive. Moreover, a possible mechanism for the dimerization with an acetylacetone additive is also discussed on the basis of the present results.

The procedure of synthesizing complex IV was similar to that described for the synthesis of di-μ-chloro-bisacetylacetonatodipalladium (II), $(Pd(C_5H_7O_2)Cl)_2$, in the previous paper.[1] Into a reaction vessel there were charged complex I and acetylacetone (an equivalent mole to palladium), plus dichloromethane as a solvent, and then ethylene was bubbled into the solution under reflux for half an hour. The resulting solution was filtered and cooled at -40°C, and the solvent was removed. After the residue had been dried under 10^{-3}—10^{-4} mmHg at -40°C, a reddish-brown complex IV was obtained. This material was very unstable, and when warmed to room temperature, changed into a brown complex which was identified as complex II,[1] with a partial precipitation of metallic palladium.

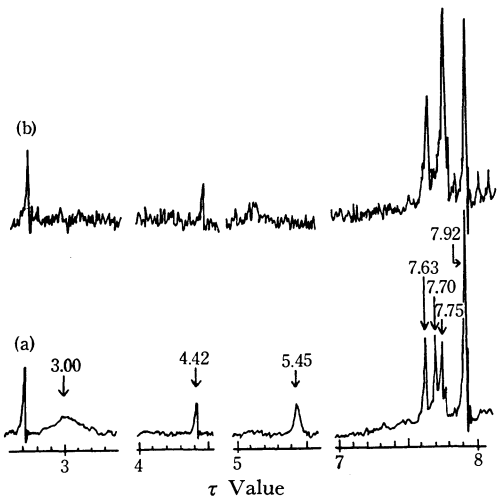

Fig. 1. NMR spectrum of complex IV.
(a) measured at -45°C in $CDCl_3$.
(b) After standing at room temperature for half an hour.

The NMR spectra*1 of the unstable reddish-brown complex IV are shown in Fig. 1, where (a) is measured at -45°C and where (b) is examined after the complex has stood at room temperature for half an hour, during which the complex IV decomposed, evolving butene gas*2 with the precipitation of metallic palladium. The assignment of the NMR spectrum is shown in Table 1. As

Table 1. Assignment of NMR spectrum

τ Value	Relative intensity -45°C	Relative intensity Room temp.	Assignment	Ref.
3.00	2	disappear	$=CH_2$ in 1-butene	2, 3
4.42	0.5		$\diagdown\!\!\diagup$C–H of acac* in complexes II and IV	2, 4, 5
5.54	1	disappear	–CH= in 1-butene	2, 3
7.63	2		$-CH_2-$ in 1-butene	2, 3
7.70	1.5	disappear	$-CH_3$ of acac* in complex IV	2, 4, 5
7.75	1.5	increase	$-CH_3$ of acac* in complex II	2, 4, 5
7.92	3	decrease	$-CH_3$ in 1-butene	2, 3

* acac=acetylacetonate group

is apparent from Table 1, the signals at τ 7.70, 7.75, and 4.42 (relative intensities 1.5 : 1.5 : 0.5) can be attributed to two methyl groups and one central methyne group respectively in the coordinated acetylacetonate group. In fact, the stable acetylacetonato-palladium complex II synthesized from acetylacetone and the ethylene-palladium complex I has NMR signals at τ 7.75 and 4.42 for the methyl and methyne groups respectively. In (b), the signal at τ 7.70 disappears with an increase in the intensity of the signal at τ 7.75; therefore, it can arise from a different methyl group besides that of complex II.

When warmed to room temperature, this complex IV evolves butene gas.*2 Therefore, the signals at τ 7.63, 3.00, 5.45, and 7.92 (relative intensities 2 : 2 : 1 : 3), which disappear or decrease at elevated temperatures were assigned to saturated methylene, olefinic methylene, olefinic methyne,

*1 NMR spectra were obtained with a JNM-4H-100 spectrometer, using tetramethylsilane as an internal standard.

*2 The composition of the gas was: *trans*-2-butene, 68 mol%; *cis*-2-butene, 27 mol%; 1-butene, 5 mol%.

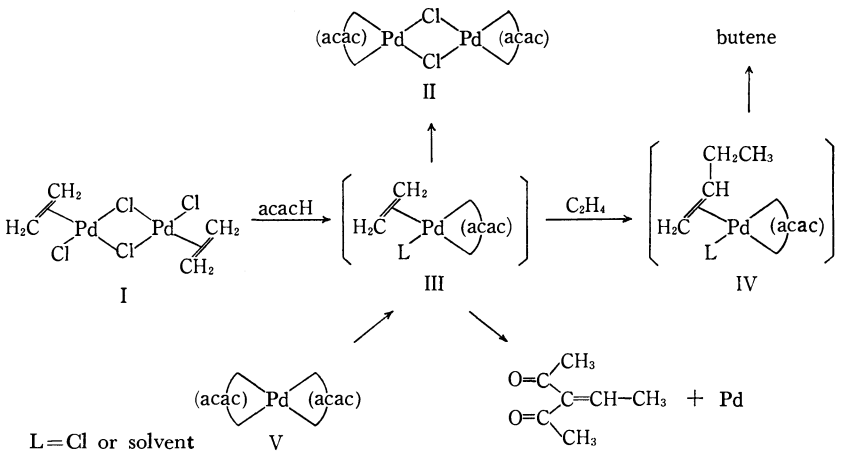

Scheme 1

and methyl groups respectively in 1-butene. However, the signals at τ 3.00 and 5.45 could also be assigned to olefinic methyne and methylene on account of these τ values. It is not clear at this time which assignment is best. The signals at τ 7.63 and 7.92 which remain in (b) might be due to a methyl group of the free acetylacetone or of the other products derived from the complex IV by decomposition, since the free acetylacetone has the signal at *ca.* τ 7.92. On the basis of these results, it could be concluded that the unstable complex obtained in the case of adding an acetylacetone was the chloro-acetylacetonato-(1-butene)palladium(IV).

Furthermore, in order to investigate the by-products of dimerization with an acetylacetone additive, acetylacetone (10 mol equivalents to palladium) was added to a solution of complex I dissolved in acetic acid, and then ethylene was bubbled into the solution for three hours. After work-up as usual, ethylideneacetylacetone was obtained in a 30% yield; it was identified through comparison with an authentic sample prepared from acetaldehyde and acetylacetone.[6] From the present results, it can be assumed that the dimerization with an acetylacetone additive proceeds *via* the two acetylacetonato-olefin-palladium complexes III and IV as is shown in Scheme 1.

Moreover, as the isomer of butene is in a nearly equilibrium composition, in which 2-butene is a main product,*[2] there might be a process of isomerization from coordinated 1-butene to free 2-butene. The intermediate complexes III and IV in the dimerization with an acetylacetone additive could not be successfully isolated, but the existence of an intermediate III could be verified from the following facts: (i) the dimerization of ethylene catalyzed by the bisacetylacetonato-palladium (V), $(Pd(C_5H_7O_2))_2$, gave butene, and also palladium metal was formed; (ii) the acetylacetonato-palladium complex II was isolated from the reaction mixture;[1] (iii) the NMR spectrum supported the idea of the formation of the intermediate complex IV, and (iv) ethylideneacetylacetone, which was the adduct of ethylene and acetylacetone, was obtained as the by-product.

Reaction of 2,3-Dihydro-4-pyridone

Noboru SUGIYAMA, Makoto YAMAMOTO and Choji KASHIMA

Department of Chemistry, Tokyo Kyoiku University, Otsuka, Tokyo

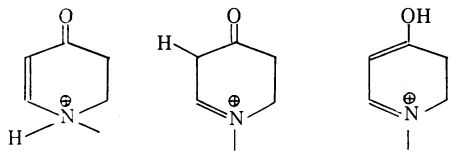
(Received December 4, 1968)

In a previous paper we described the synthesis of 2,3-dihydro-4-pyridones from a Schiff base and β-diketones in the presence of excess potassium amide in liquid ammonia.[1] 2,3-Dihydro-6-methyl-1,2-diphenyl-4-pyridone (I), which was synthesized

1) N. Sugiyama, M. Yamamoto and C. Kashima This Bulletin **42**, 1357 (1969).

from acetylacetone and benzylidenaniline, is a typical enamino ketone. The reactions of 2,3-dihydro-4-pyridone have so far not been found in literature. This paper deals with the reactions of I, especially protonation, oxidation and reduction.

Protonation. Generally, β-enamino ketones can be protonated on nitrogen atom, α-carbon atom or oxygen atom.[2] Thus, the protonation of I is expected to give one of the products of three types A, B or C.



A B C

The ultraviolet absorption spectrum of the hydrochloride (II) showed the absorption maximum at 325 mμ. Compared with the absorption maximum of I at 327 mμ, the chromophore of II is the same as that of I. The methine proton signal at C-2 carbon is broad triplet in the NMR spectrum of II.

If the protonated product is type A, the methine proton of C-2 carbon is coupled to NH proton and broadened. In the infrared absorption spectrum of II, the strong absorption band appeared at 2250 cm^{-1}, which was assigned to more strongly hydrogen bonded hydroxyl group or the tertiary ammonium group. But the infrared absorption spectrum of the hydrobromide (III) showed a strong absorption band at 2420 cm^{-1}, 170 cm^{-1} apart from that of II. The results also suggest that I is protonated as shown in A.[3]

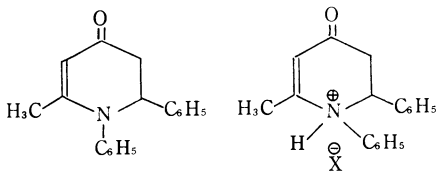
Oxidation. The dihydro heteroaromatic system containing nitrogen is known to play an important role as hydrogen donor in a biological oxidation-reduction system. By the hydrogen transfer reaction with chloranil, a typical hydrogen acceptor,[4] I gave a pyridone derivative, 6-methyl-1,2-diphenyl-4-pyridone (IV), which was synthesized by the condensation of 1-phenyl-1,3,5-hexanetrione with aniline.[5]

The treatment of I with mercuric acetate was also examined, because benzoquinolidine derivative, which has dihydropyridone neuclei, is oxidized to its hydroxypyridine derivative by mercuric acetate.[6] In this reaction IV was also produced.

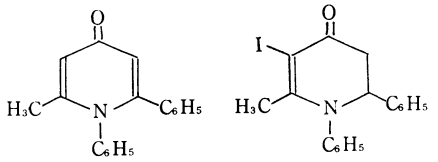
On the other hand, Kehrmann reported[7] that flavanes were oxidized with iodine to flavones. When the same oxidation method was applied to I, the expected oxidation product was not produced, an unexpected product being obtained.

The ultraviolet spectrum of product V showed the absorption maximum at 360 mμ. In the NMR spectrum, similar to I, the aromatic protons, methylene protons and the methine proton appeared at τ 2.70, τ 6.78 and τ 4.99 respectively. The methyl protons appeared as a singlet at τ 7.65, and olefinic proton disappeared.

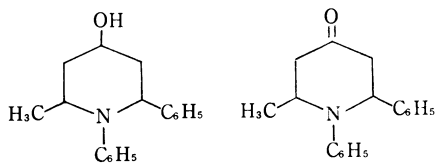
From these spectral data and the results of the elemental analyses, V was determined to be 2,3-dihydro-5-iodo-6-methyl-1,2-diphenyl-4-pyridone. In this reaction, it is supposed that iodine was added to the double bond of I and then was eliminated as hydroiodide.



(I) (II): X=Cl, (III): X=Br



(IV) (V)



(VI) (VII)

Reduction. By treatment of I with excess sodium borohydride, 6-methyl-1,2-diphenyl-4-piperidinol (VI) was obtained. The infrared spectrum showed the hydroxyl band at 3320 cm^{-1}, but no band of carbonyl and double bond. Both 240 mμ and 327 mμ disappeared in the ultraviolet spectra of VI. From these spectral data and the results of the elemental analyses, the structure of VI was determined.

On the other hand, the hydrogenation of I in acetic acid catalyzed by platinum oxide gave two

products, VI and 6-methyl-1,2-diphenyl-4-piperidone (VII). In the infrared spectrum of VII the carbonyl absorption band appeared at 1715 cm^{-1}, but the double bond band in the region of 1660—1600 cm^{-1} disappeared. In the NMR spectrum of VII, methyl protons are split to the doublet at τ 9.20. Two methylene protons appeared at τ 7.20 and 7.40, and C-2 methine proton appeared as a triplet at τ 4.10.

Under the same conditions, however, the hydrogenation of IV failed, and IV was quantitatively recovered. It is clear that the reduction of dihydropyridone is much easier than that of the corresponding pyridone.

All these reactions confirm that the dihydropyridone (I) favors the enamino ketone structure, but there exists some tautomeric iminoenol structure which is responsible for hydrogen transfer reaction.

Experimental

2,3-Dihydro-6-methyl-1,2-diphenyl-4-pyridone (I). In liquid ammonia, I was prepared by the procedure described in a previous paper,[1] mp 84—85°C.

IR(KBr): 1640, 1560 and 700 cm^{-1}. UV: λ_{max}^{EtOH} 240 mμ (ε 2180), and 327 mμ (ε 10400).

2,3-Dihydro-6-methyl-1,2-diphenyl-4-pyridone Hydrochloride (II). A mitxure of 200 mg of I and 0.1 m*l* of concentrated hydrochloric acid in 5 m*l* of ethanol was maintained for 5 min at room temperature. By the evaporation of solvent under reduced pressure, 150 mg of II was obtained, which was recrystallized from acetone to give analytical pure substance, mp 173°C (decomp).

IR (KBr): 3050, 2250, 1620, 1500, 1215, 760 and 680 cm^{-1}. UV: λ_{max}^{EtOH} 327 mμ (ε 16900).

2,3-Dihydro-6-methyl-1,2-diphenyl-4-pyridone Hydrobromide (III). III was obtained from I and hydrobromic acid by the same procedure for II, mp 153°C (decomp).

IR (KBr): 3050, 2420, 1615, 1500, 1210, 760 and 680 cm^{-1}. UV: λ_{max}^{EtOH} 327 mμ (ε 14200).

Oxidation of I by Chloranil. A solution of 120 mg of I and 120 mg of chloranil in 10 m*l* of tetrahydrofuran was refluxed for 4 hr. The reaction mixture was cooled and 50 mg of crystal was collected, mp 235°C (lit. 242°C[5]). This crystal was identified with the authentic sample, which was obtained by condensation of 1-phenyl-1,3,5-hexanetrione with aniline,[5] by means of thin layer chromatography, infrared and ultraviolet absorption spectra.

Oxidation of I by Mercuric Acetate. To a solution of 500 mg of I in 5 m*l* of acetic acid was added 640 mg of mercuric acetate. The mixture was refluxed for 2.5 hr and then mixed with 20 m*l* of water. The aqueous solution was neutralized with dilute ammonia and extracted with benzene. After removal of the solvent, the residue was identified with the sauthentic sample by means of thin layer chromatography.

2,3-Dihydro-5-iodo-6-methyl-1,2-diphenyl-4-pyridone (V). A mixture of 100 mg of I, 300 mg of iodine, 150 mg of anhydrous potassium acetate and 10 m*l* of ethanol was refluxed for 4 hr. The reaction mixture was mixed with 100 m*l* of water, made alkaline with aqueous ammonia, and extracted with ether. The ethereal solution was washed with aqueous sodium thiosulfate and water. After removal of ether, the residue was recrystallized from ethanol-water mixture to afford 100 mg of V, mp 151°C.

Found: C, 54.71, 54.77; H, 4.16, 4.15; N, 3.70, 3.51; I, 33.91%. Calcd for $C_{18}H_{16}INO$: C, 55.54; H, 4.14; N, 3.60; I, 32.61%.

IR (KBr): 3050, 1640, 1510, 1200, 730 and 710 cm^{-1}. UV: λ_{max}^{EtOH} 302 mμ (ε 3200), 352 mμ (ε 11700).

The Sodium Borohydride Reduction of I. A mixture of 130 mg of I, 36.5 mg of sodium borohydride in 10 m*l* of ethanol was stirred at room temperature. After 8 hr, the reaction mixture was acidified with hydrochloric acid and then neutraized with aqueous ammonia. This aqueous solution was extracted with ether. The ethereal layer was washed with water and dried over anhydrous sodium sulfate. After removal of the solvent, the residue was chromatographed by silica gel (Merck 7729) column with benzene-ethyl acetate (1 : 1 v/v) mixture. A fraction, which showed the R_f 0.49 on silica gel (Wako gel B-5) thin layer chromatography with benzene-ethyl acetate (1 : 1 v/v) mixture, was collected. After removal of the solvent, the residue was recrystallized from benzene, mp 84—85°C.

Found: C, 80.63; H, 8.04; N, 5.21%. Calcd for $C_{18}H_{21}NO$: C, 80.86; H, 7.92; N, 5.24%.

IR (KBr): 3320, 1600, 1370, 1020 and 695 cm^{-1}. UV: λ_{max}^{EtOH} 253 mμ (ε 1250), 259 mμ (ε 1020) and 265 mμ (ε 780).

The Catalytic Hydrogenation of I. In the presence of 14.1 mg of platinum oxide, 200 mg of I in 10 m*l* acetic acid was hydrogenated at 30°C and atmospheric pressure. After absorption of 20 m*l* of hydrogen the reaction was stopped. After the catalyst was filtered off, the filtrate was poured into water and made alkaline with aqueous ammonia, and was extracted with ether. The ethereal solution was washed with water and dried over anhydrous sodium sulfate. After removal of the solvent, the residue was separated on silical gel (Wako gel B-5) thin layer chromatograpny. The spots with the R_f 0.29 and 0.49 were identified with I and VI respectively. The product, which showed the R_f 0.71, was separated by means of silica gel (Merck 7729) column chromatography with benzene-ethyl adetate (1 : 1 v/v) mixture to give V.

IR (liquid film): 1715, 1600, 1375, 1220, 740 and 700 cm^{-1}.

NMR Spectra. NMR spectra were measured by a Hitachi H-60 high resolution Neuclear Magnetic Resonance Spectrometer. The solvent was deuterochloroform and TMS was used as the internal standard.

Infrared Absorption Bands of Benzalanilines Observed in the 1200—850 cm^{-1} Region

Katsumi TABEI and Etsurou SAITOU

Tokyo College of Pharmacy, Kashiwagi, Shinjiku-ku, Tokyo

(Received December 24, 1968)

Previous infrared studies of the azomethine derivatives have dealt with their carbon-nitrogen double-bond stretching mode, but there have been few references to the other vibration of the compounds.[1] As a part of the infrared studies of the aromatic molecule,[2] the spectra of twenty-nine kinds of *N*-(*p*-substituted-benzal)-anilines and *N*-benzal-*p*-substituted-anilines were measured; it was found that three characteristic absorption bands appear in the 1200—850 cm^{-1} region. In the present report, we wish to present the observed data and to assign them qualitatively.

In comparison with the spectra of *N*-benzylaniline, *N*-propylidenecyclohexylamine, azobenzene, acetophenoneoxime, *p*-nitrostilbene, benzalacetone, and styrene, the three absorption bands which appeared at about 1190 cm^{-1}, 975 cm^{-1}, and 880 cm^{-1} in the spectra of the present type of compounds seem to be characteristic of the benzalaniline skeleton. The wave numbers of the above observed characteristic absorption bands are listed in Table 1.

A sharp band at 1191 cm^{-1} in *N*-benzalaniline may be assigned to the aryl carbon-nitrogen (Ar-N) bond-stretching vibration, since the band is not observed in the spectra of *N*-benzylaniline; the corresponding Ar-N stretching mode of *N*-benzylaniline can be assigned to a sharp and strong absorption band at 1322 cm^{-1}.

In addition, the above reference compounds do not have an absorption band in the 1200—1170 cm^{-1} region with the exception of a few medium bands in the 1170—1100 cm^{-1} region which may be due to the aromatic C–H in-plane deformation vibration.

N-propylidenecyclohexylamine, on the other hand, has its carbon-nitrogen single-bond-stretching band at 1100 cm^{-1}.

As is listed in the table, the Ar-N stretching frequency of benzalanilines is far lower than that of aromatic amine, and also the frequencies are kept

Table 1. The characteristic absorption bands of benzalanilines

in a narrow range (1186—1196 cm^{-1}), even when a subsitutent is introduced into the para position of either the aniline or benzaldehyde ring. This fact can reasonably be understood by taking the non-planar structure of the benzalaniline molecule into account; the conjugation effect between the aniline ring and the benzalamino skeleton may be substantially interrupted, since the plane of the aniline ring is twisted from that of the benzalamino part, as is shown in Fig. 1.[3]

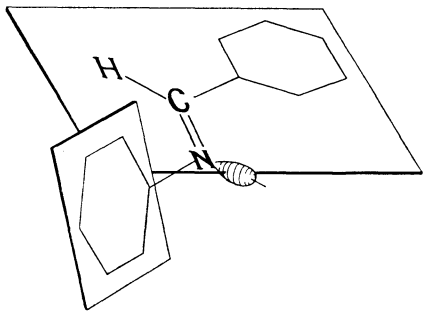

Fig. 1

That is to say, the above frequency region can safely be assigned to the stretching vibration of the non-conjugated sp^2 carbon-sp^2 nitrogen single bond which is expected to appear in the intermediate region between the C–N stretching frequency of aromatic amine and that of aliphatic amine.[4]

A strong electron-donating *p*-substituent in the aniline ring can, however, increase the Ar–N bond order by releasing an electron to the lone-pair lobe of the azomethine nitrogen, as is shown in Fig. 2. The ν_{Ar-N} of such derivative as *N*-benzal-*N'*, *N'*-dimethyl-*p*-phenylenediamine will then appear at a little higher frequency (1210 cm^{-1}). When this group is in the benzaldehyde ring, on the other hand, the ν_{Ar-N} shifts to a little lower frequency; the Ar–N stretching band of *p*-dimethylaminobenzal-aniline then appears at 1178 cm^{-1}. The above frequency shift is probably due to the fact that the electron-rich azomethine nitrogen can repel the aromatic ring of the aniline part.

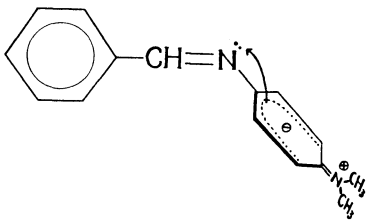

Fig. 2

It was also confirmed that the sharp absorption bands at about 972 cm^{-1} and 883 cm^{-1} give spectral information about the azomethine skeleton. The former is probably due to the C–H in-plane deformation vibration of the azomethine group, and the latter, to the C–H out-of-plane deformation mode, since the above pair of bands do not appear in the spectra of *N*-benzylaniline and other reference compounds. In the case of *N*-propylidenecyclohexylamine, the bands are observed at 956 cm^{-1} and at 845 cm^{-1} respectively. However, they have not been verified.

Experimental

Materials. Twenty-nine kinds of aromatic azomethines were prepared by usual condensation reactions between the corresponding aldehyde and amine, and were purified by recrystallization from methanol or ethanol or by distillation under reduced pressure.[5]

N-Propylidenecyclohexylamine was also prepared by the condensation of cyclohexylamine and propionaldehyde and was distilled repeatedly under reduced pressure. The purity of the materials was checked by thin-layer chromatography.

Infrared Spectra. The IR spectra of the above compounds were measured by using a JASCO DS-301 infrared spectrophotometer in a carbon tetrachloride or chloroform solution or in a disk of potassium bromide. The wave numbers determined in the present experiment are listed in Table 1, along with their physical constants.

The authors wish to express their deep gratitude to Mrs. Moriharu Nagase of the Tokyo College of Pharmacy for her helpful measurement of the infrared spectra.

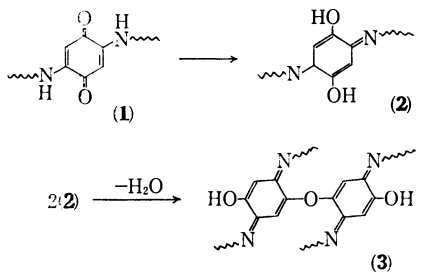
Amino-quinoid Polymeric System. The Thermal Reaction of 2,5-Bis(*n*-butylamino)-*p*-benzoquinone

Kazuyuki SUGITA*1 and Ju KUMANOTANI

The Engineering Research Institute, Faculty of Engineering, The University of Tokyo, Yayoi, Bunkyo-ku, Tokyo

(Received January 9, 1969)

Previously we have demonstrated that the 2,5-bis(aliphatic-amino)-*p*-benzoquinone nucleus (**1**), incorporated in the polymer chain, is quite sensitive to heat and can react to give (**2**) and (**3**), through isomerization and subsequent intermolecular condensation respectively, as follows:[1]



In order to elucidate the thermal reaction of (**1**) in detail, a model pyrolysis of 2,5-bis(*n*-butylamino)-*p*-benzoquinone was investigated at 195°C by means of IR spectroscopy, GLC, TLC, and pyrolytic gas chromatography. As the pyrolysis products, water, ammonia, *n*-butane and propane, 2-*n*-butylamino-*p*-benzoquinone, 2-amino-5-*n*-butylamino-*p*-benzoquinone, and 3-*n*-butylamino-7-hydroxy-9-*n*-butyl-carbazolquinone (1,4) were identified; unknown butylated butylamino-benzoquinoid and oligo-quinoid compounds were also separated.

On the basis of these results, the following reactions can be proposed for the pyrolysis reaction of 2,5-bis(*n*-butylamino)-*p*-benzoquinone: (a) the above reactions, isomerization and condensation, (b) the fission of the carbon and nitrogen bond in the alkylamino group and, (c) the migration reaction of the *n*-butylamino group. Furthermore, the distribution of the pyrolysis products and the change in the composition of the gaseous products as a function of time (see Fig. 1) show that the reactions (a) and (b) make a more significant contribution to the pyrolysis than (c), and that the reaction (a) precedes the reaction (b). This conclusion agrees well with those previously obtained for the amino-quinoid polyester system.[1]

Experimental

Materials. 2,5-Bis(*n*-butylamino)-*p*-benzoquinone (designated as Q-BuA), mp 163.5—164.5°C, was prepared by the known method[2] (Found: N, 11.19%, Calcd for $C_{14}H_{22}O_2N_2$: N, 11.16%).

Instrumental Analyses. The polarographic potential and the spectroscopic data were measured in the manner which has been described before.[3]

Pyrolysis of Q-BuA. The pyrolysis condition was established beforehand to give a major amount of the products in the minor components. Q-BuA (100 mg) in an evacuated ampoule (dia., 22 mm; length, 150 mm) fitted with a stop cock was pyrolyzed at 195°C for 3 hr in an oil bath and then cooled to room temperature.

Identification of Products. *Gaseous Products.* For IR spectroscopy the gaseous products generated in the ampoule were transferred through the cock to a cell which had previously been evacuated at 1 mmHg. The spectrum exhibits bands at 800—1200 cm^{-1} and 2880 and 2970 cm^{-1} that are characteristic of ammonia and alkanes respectively. The hydrocarbon was certified to be a mixture of *n*-butane and propane (4 : 1 in molar ratio) by the use of an Ohkura Chromatograph MS-1100 equipped with a Yanagimoto Active Alumina Column containing a tailing reducer (column temperature, 83°C; split temperature, 60°C; filament current, 120 mA; sensitivity, 1 mV; carrier gas, helium of 1.2 kg/cm^2).

Liquid Products. The liquid product that condensed on the inside wall of the ampoule was dissolved in dried methanol and submitted to GLC under conditions to be described later. The liquid product was thus revealed to be identical with water.

Solid Products. A solution of the solid products obtained from 5.00 g of Q-BuA in 200 m*l* of hot methanol was cooled to room temperature, refrigerated overnight, and filtered to give reddish crystals (4.28 g) and a mother liquor. The latter solution was concentrated to 50 m*l* at room temperature under the reduced pressure of an aspirator, refrigerated overnight, and filtered to give reddish crystals (0.40 g) and a methanol solution. The reddish crystals (4.68 g) were confirmed to be identical with Q-BuA by TLC using the same procedure

as that described for the separation of butylamino-toluquinones.[3] The methanol solution was applied in lines on 30 plates of the silica-gel layer (1.0mm thick). The separated zones on the gel layer were scraped off and extracted with 100 m*l* of chloroform and then with 100 m*l* of methanol. The extract was evaporated to dryness at room temperature *in vacuo*. The operation by TLC was repeated three or five times in order to obtain sufficiently-isolated zones. Finally *ca.* 50 mg of each product was obtained.

Upon the identification of the mono- and di-amino-quinoid compounds, the following data were applied:[3] for monoamino-quinoid derivatives, $\nu_{max}^{CHCl_3}$ 3350 cm^{-1} (m. ν_{N-H}), 1620—1640 and 1570—1600 cm^{-1} (s. $\nu_{C=O}$); $\lambda_{max}^{CHCl_3}$ (π-π^*), 270—300 mμ; $E(1/2)$ (*vs.* SCE), −0.3—−0.35 V; for diamino-quinoid derivatives, $\nu_{max}^{CHCl_3}$ 3350 (m. ν_{N-H}), 1640 (m. $\nu_{C=C}$), 1580 (s. $\nu_{C=O}$), 1505 (s. amido II-type band) and 1460 cm^{-1} (m. δ_{C-H} in plane); $\lambda_{max}^{CHCl_3}$ (π-π^*), 330—350 mμ; $E(1/2)$ (*vs.* SCE), −0.45—−0.6 V.

The compounds identified, together with the unknown compounds, are presented below, along with their physico-chemical constants and characteristic spectral data.

2,5-Bis(*n*-butylamino)-*p*-benzoquinone: R_f, 0.20; recrystallized from chloroform as reddish crystals, mp 163.0—164.5°C (Found: N, 11.20%). This compound was found to be identical with Q-BuA by the mixed-melting-point method.

2-*n*-Butylamino-*p*-benzoquinone: R_f, 0.26; recrystallized from chloroform as reddish crystals; $E(1/2)$, −0.33 V (*vs.* SCE). IR in a KBr disk: 3350 (s. ν_{N-H}), 1665 (m. $\nu_{C=C}$), 1630 and 1590 (s. $\nu_{C=O}$), and 1505 cm^{-1} (s. amido II-type band). UV: $\lambda_{max}^{CHCl_3}$ 282 and 488 mμ.

2-Amino-5-*n*-butylamino-*p*-benzoquinone: R_f, 0.03; recrystallized from a mixed solvent of pyridine-chloroform (1 : 9 by volume) as purple-brown scales, mp 225°C (decomp.); $E(1/2)$, −0.46 V (*vs.* SCE).

Found: C, 61.68; H, 7.26; N, 14.36%: mol wt (VPO), 207. Calcd for $C_{10}H_{14}O_2N_2$: C, 61.84; H, 7.27; N, 14.42%; mol wt, 194.

IR in $CHCl_3$: 3520 and 3390 (m. ν_{N-H}), 1655 (m. $\nu_{C=C}$), 1585 and 1550 (s. $\nu_{C=O}$), and 1515 cm^{-1} (s. amido II-type band).

UV: $\lambda_{max}^{CHCl_3}$ 337 (ε 30000), 500 mμ (ε 450).

NMR in dimethyl sulfoxide: 2.3—2.9 (2H, 2(N-H), broadened), 2.8—3.2 (1H, N-H, broadened), 4.68 (1H on the quinoid ring) and 4.86τ (1H on the quinoid ring); in pyridine: 6.8—7.1 (2H, -NH-C$\underline{H}_2$-CH_2-, quartet coupled with N-H and -C$\underline{H}_2$-), 8.3—9.0 (4H, two methylene groups) and 8.8—9.3 τ (3H, one methyl group).

3-*n*-Butylamino-7-hydroxy-9-*n*-butyl-carbazolquinone (1,4): R_f, 0.04; recrystallized from chloroform, yellowish-brown powder, mp 180.7—181.5°C; $E(1/2)$, −0.48 V (*vs.* SCE) (Found: N, 8.01%). This compound was identified because it showed no drop in melting point when mixed with the authentic sample that had been previously prepared by the present authors.[4]

Butylated butylamino-benzoquinoid compound: R_f, 0.08; recrystallized from chloroform as reddish-purple plates, mp 81—84°C; $E(1/2)$, −0.14 V (*vs.* SCE).

Found: C, 66.54; H, 9.02; N, 8.64%; mol wt (VPO), 311. Calcd for $C_{18}H_{30}O_3N_2$: C, 67.05; H, 9.38; N, 8.69%; mol wt, 322.

IR in $CHCl_3$: 3385 (m. ν_{N-H}), 1660 (m. $\nu_{C=C}$), 1590 (s. $\nu_{C=O}$), 1515 cm^{-1} (s. amido II-type band).

UV: $\lambda_{max}^{CHCl_3}$ 346 (ε 9400), 495 mμ (ε 1700).

NMR in $CDCl_3$: 3.57 (1H on the quinoid ring), 4.49 (1H on the quinoid ring), 6.2—6.6 (2H, >N-C$\underline{H}_2$-CH_2-, triplet coupled with -C$\underline{H}_2$-), 6.6—7.1 (2H, -NH-C$\underline{H}_2$-CH_2-, quartet coupled with N-H and -C$\underline{H}_2$-), 7.7—8.1 (2H, -C$\underline{H}_2$- adjacent to the N, O, or quinoid ring, quartet coupled with -C$\underline{H}_2$- and another proton), 8.1—8.9 (12H, six methylene groups) and 8.8—9.3 τ (9H, three methyl groups).

From the above data, it became evident that this compound has such groups as *n*-C_4H_9-, *n*-C_4H_9-N<, and *n*-C_4H_9-NH- and a *p*-benzoquinone nucleus.

Oligo-quinoid compound: obtained from the zone of the starting line; recrystallized from chloroform as a dark brown substance, mp 120—140°C; $E(1/2)$, −0.55V (*vs.* SCE).

Found: C, 63.83; H, 7.61; N, 9.01%; mol wt (VPO), 342.

IR in $CHCl_3$: 3200—3500 (broadened, ν_{O-H}), 2850—3050 (m. ν_{C-H}), 1580 (s. $\nu_{C=O}$), 1515 (m. $\nu_{C=N}$), 1460 (m. δ_{C-H} in plane) and 1220 cm^{-1} (m. ν_{C-O-C}).

UV: $\lambda_{max}^{CHCl_3}$ 260 (ε 13000), 330 (ε 11700), 465 (ε 2220), 495 (ε 2050) and 550 mμ (ε 1230).

The above results show that the compound has the following groups: OH, -O-, >C=NH, and >C=N-C_4H_9, and the *p*-benzoquinone nucleus (cf. (3)).

Distribution of Pyrolysis Products of Q-BuA. The distribution of the products obtained from 10.0 mg of Q-BuA was examined by the extraction of the zones developed on a thin-layer chromatogram: 8.9 mg (85 mol% for the starting material) of Q-BuA, 0.6 mg (4.4 mol%) of the oligo-quinoid compound, 0.2 mg (2.5 mol%) of 2-amino-5-*n*-butylamino-*p*-benzoquinone, 0.1 mg (0.7 mol%) of the carbazolquinone, and traces of 2-*n*-butylamino-*p*-benzoquinone and the butylated butylamino-benzoquinoid compound.

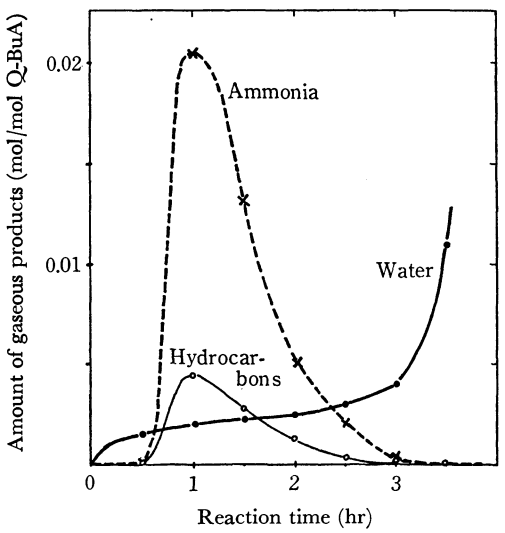

Fig. 1. The variation of the amount of gaseous products generated in the pyrolysis of Q-BuA at 195°C.

4) K. Sugita and J. Kumanotani, This Bulletin, **42**, 2043 (1969).

Pyrolytic Gas Chromatography. Its system was similar to that described by Yoshimi *et al*:[5] the pyrolytic cell was equipped with a Kotaki Super Fractioner GU-21. The column was prepared and the GLC operated in the manner reported by Amemiya.[6] Upon the pyrolytic gas chromatographic analysis, the peaks in a gas chromatogram of the products were assigned to *n*-butane, ammonia, and water. Q-BuA (100 mg) in a cell into which a stream of helium was introduced was heated in an oil bath kept at 110°C until no gas chromatographic peak of water could be detected. Then the cock was turned to close the sample cell and the cell was heated in an electric furnace kept at 195(±2)°C. The gaseous products which formed and accumulated in the cell over a 30-min period were run into the gas chromatograph with a stream of helium for a 10-sec interval by turning the cock, and then the cock was reversed in order to close the cell. The procedures of 30-min-pyrolysis and 10-sec-running of the gaseous products were repeated alternately for 3.5 hr. Thus, Fig. 1 was derived from the gas chromatograms where a normalization method was applied within a relative error of ±5%. Among the pyrolysis products, ammonia would be formed by the hydrolysis of the imino groups in the oligo-quinoid compound.

Studies of Thin-layer Chromatography of Inorganic Salts. II. Separation of Inert Cobalt(III) Complexes by Means of Thin-layer Chromatography on Alumina[1]

Tetsuo BABA,[2] Masayuki MUTO and Hayami YONEDA[3]

Department of Chemistry, Wakayama University, Masagocho, Wakayama

(Received January 13, 1969)

We were interested in the chromatographic behavior of inert metallic complexes and wrote two papers concerning the mechanism of separation of complexes both in paper[4] and in silica gel thin-layer[5] chromatography. According to these reports, complex salts are developed separately as cations and anions on the negatively charged surface of an adsorbent, so that the R_f value of the complex increases with the decrease of its positive ionic charge and reaches nearly unity in the case of complex anions.

In order to see whether a similar separation mechanism holds in other adsorbents, we studied the chromatographic behavior of twenty-two kinds of inert cobalt(III) complexes on alumina and found interesting features characteristic of alumina thin-layer chromatography.

Experimental

As an adsorbent Merck's alumina H, prepared for thin-layer chromatography according to Stahl's method was used without further purification. The compounds studied are listed in Table 1. The development was carried out at room temperature of 22—23°C. Spots of cobalt(III) complexes were detected by spraying potassium sulfide solution.

Results and Discussion

The R_f values of the complexes are summarized in Table I. As is seen from these data, the chromatographic behavior of the complex cation on alumina is in general similar to that on silica gel. All complex cations show R_f values smaller than those of neutral complexes. This indicates that alumina is charged negatively in contact with water and adsorbs complex cations more strongly than neutral complexes. On silica gel, all complex cations including monovalent ions are strongly adsorbed and remained nearly at the origin when developed with distilled water. However, the present R_f values obtained with alumina layers are 0.5—0.8 for monovalent cations and 0.8—0.9

for neutral complexes. Therefore it is supposed that alumina has less negative charge than that of silica gel.

While on silica gel the R_f value shows a monotonic increase in going from cations, through neutral species, to anions, a trend in R_f value variation on alumina has a maximum in neutral species and shows a decrease in anions. This suggests that the complex anion is more strongly adsorbed than the neutral complex and can be explained by assuming positively charged sites besides the negatively charged ones. We attribute this to the amphoteric nature of alumina. This idea of the coexistence of the positive and negative sites finds support from Schwab's report.[6] He showed that alumina adsorbed both NH_3 (base) and BF_3 (acid). In order to ascertain our idea, the complexes were developed with 0.5M HCOOH and 0.5M $(CH_3)_2NH$ aqueous solutions. With an acidic developer, hydrogen ions are expected to cover the negative sites of an adsorbent, so that the adsorptive power of alumina is expected to decrease towards cations and to increase towards anions, compared to those with a neutral developer. On the other hand, with a basic developer, hydroxide ions are expected to cover the positive sites, so that the adsorptive power of alumina is expected to increase towards cations and to decrease towards anions. As is seen in Fig. 1, this expectation is almost fulfilled. The R_f value varies regularly with the pH of developers. The R_f value increases in the order basic < neutral < acidic in the cases of tri- and divalent cations, and in the order acidic < neutral < basic in the case of monovalent anions.

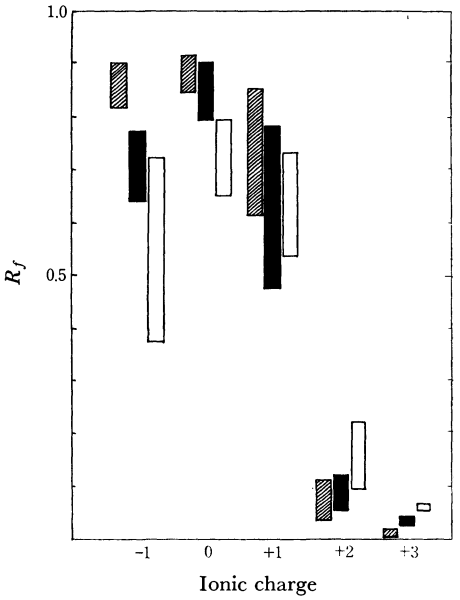

Fig. 1. pH dependency of R_f values. (Each block represents a range of R_f values.)
- developed with 0.5M HCOOH
- developed with 0.5M $(CH_3)_2NH$
- developed with distilled water

As is seen in Table 1, the cis diacido complexes show always smaller R_f values than those of the corresponding trans complexes. The trans complex has no dipole moment, while the cis complex must have a dipole moment. Therefore, this finding is acceptable if we assume that the adsorption is caused mainly by electrostatic attraction.

One of the authors, Baba, wishes to express his thanks to the Ministry of Education for a grant-in-aid for this study.

Application of a Mercury-Coated Platinum Electrode to the A.C. Stripping Analysis of a Trace Amount of Metal Ions

Mutsuo KODAMA and Tomohiko NODA

Department of Chemistry, Ibaraki University, Mito, Ibaraki

(Received January 20, 1969)

Previously,[1,2] we have studied the characteristics of a hanging mercury-drop electrode (HMDE) in alternating current (a.c.) polarography and have used this electrode for the a.c. stripping analysis of thallium(I). Although the HMDE has the advantages of a mercury electrode (high hydrogen overvoltage, reproducible surface, and suitability for multicomponent analysis), the loss of deposited metals by diffusion into the bulk of the electrode limits the application of HMDE to the stripping analysis of trace amounts of metals. In this connection, we tried to use the mercury-coated platinum electrode, which has been established not to have the above-mentioned disadvantage of a mercury-drop electrode. The preparation of mercury-coated platinum electrodes suitable for anodic stripping analysis has been reported by several authors.[3-5] In this work, we followed the continuous and simultaneous depositon procedure proposed by Bruckenstein and Nagai;[6] that is, mercury was plated by electrolysis on a platinum electrode, plated continuously and simultaneously with the deposition of the metals to be determined.

Experimental

Reagents. The way of preparing standard solutions of thallium(I), cadmium(II), lead(II), and copper(II) ions has been described in previous papers.[7,8] The standard solution of mercuric nitrate was prepared by dissolving a known amount of metallic mercury in dilute nitric acid (1+1) and by then removing the excess nitric acid by distillation under reduced pressure. All the other chemicals were of an analytical reagent grade and were used without further purification.

Apparatus and Procedure. The apparatus and the experimental procedures used were the same as those which have been described previously.[2] The platinum-base electrode to be coated with merculy was constructed by sealing a platinum wire 0.4 mm in diameter and 6 mm in length one end of a 6 mm soft-glass tube and by then bending it at right angles to the glass tube. Before use, the platinum base was treated with warm nitric acid (1+1) for 20 min and was then cathodized for 5 min in a sodium perchlorate solution containing 0.01 M $HClO_4$.

Results and Discussion

Mercury Plating. In order to prepare a mercury-coated platinum electrode suitable for a.c. anodic stripping analysis by the continuous simultaneous deposition of mercury, we first studied the current-voltage behavior of a platinum base in stirred solutions of constant pH values and ionic strengths (pH=2.0, 0.5M $NaClO_4$) but with varying concentrations of mercuric ion. Each solution was stirred by a magnetic stirring bar driven by a synchronous motor. Throughout the experiment an alternating-current potential (15 mV) was superposed on the d.c. potential; this superposition had little effect on the mercury plating or on the analysis. The a.c. base current was measured by scanning the potential of the platinum base in the anodic direction at a constnt rate (2.78 mV/sec) from the limiting-current region of the mercuric ion (−1.50 V *vs.* SCE). As the concentration of mercuric ions is increased, the a.c. base current, especially at negative potentials, decreases, whereas the a.c. peak-height due to the anodic dissolution of mercury at about +0.40 V *vs.* SCE increases. These facts clearly indicate that with an increase in the mercury-film thickness and the coverage of the platinum base with mercury, the overvoltage for the hydrogen evolution reaction is increased. At the mercuric ion concentration of 1.0×10^{-4}M, the hydrogen overvoltage almost approaches the limiting value, and in the concentration range from 1.0×10^{-4} to 1.0×10^{-3}M, a reproducible low base current could be obtained. At mercuric ion concentrations higher than 1.0×10^{-3}M, a droplet of mercury was formed.

8) M. Kodama and H. Ebine, *ibid.*, **40**, 1857 (1967).

As long as the potential scanning in the anodic direction is stopped at +0.50 V *vs.* SCE, the hydrogen overvoltage increases with the number of plating-stripping cycles of mercury. At mercuric ion concentrations higher than 1×10^{-4}M, reproducible a.c. base currents were obtained on repeated runs of the plating-stripping process. On the other hand, if the electrode is oxidized at potentials more positive than +1.0 V *vs.* SCE, the electrode gives a higher base current than that at a nude platinum base. These findings agree well with those by Hartley *et al.*[5] Thus, all the above examples of current-voltage behavior can be explained in the following manner. The mercury deposited on the platinum base interacts with the platinum base and can not be removed completely by anodizing the electrode at +0.50 V *vs.* SCE. However, by anodizing the electrode at potentials more positive than +1.0 V *vs.* SCE, the mercury on the platinum base is completely removed; the resulting platinum surface behaves much as a platinized platinum. It may also be concluded that the formation of intermetallic compounds between mercury and platinum[6] is essential for the formation of mercury film with the desirable properties. Mercury plating was also studied by varying the initial potential from which the potential of platinum base was scanned in the anodic direction. Initial potentials more negative than −1.50 V *vs.* SCE resulted in vigorous hydrogen evolution and gave only the mercury-coated platinum electrode, which behaves in a less reproducible fashion.

B: Stopped the stirring at −0.65 V *vs.* SCE

A.C. Stripping Analysis of Metal Ions. A.c. polarograms of thallium(I), lead(II), and cadmium(II) ions in solution containing 1.5×10^{-4}M mercuric ions were measured by scanning the potential of a platinum base in the anodic direction from −1.50 to +0.50 V *vs.* SCE. Reproducible, well-developed a.c. polarograms were obtained on repeated potential excursions. Typical polarograms of thallium(I) are given in Fig. 1. As in the case of HMDE,[2] by stopping the stirring at potentials 70 mV negative with respect to the summit potential, a remarkable increase in sensitivity could be obtained. The a.c. peak-height of the metal was a linear function of the effective pre-electrolysis time and increased exactly with the time according to the relation (1) in Ref. (2). As Table 1 shows, the a.c. summit potentials of a metal at a mercury-coated platinum electrode are located at potentials more positive than those at a nude platinum electrode. This may

B: Cadmium(II) system, stopped the stirring at −0.70 V *vs.* SCE

indicate that the anodic dissolution process of a metal at the mercury-coated platinum electrode is much more reversible than that at the bright platinum electrode.

By employing the above experimental technique, the relation between the concentration of a metal ion and the a.c. peak-height of the anodic dissolution wave was examined. In all cases, at a given initial potential the plot of the a.c. peak-height against the concentration of metal ions gave a straight line passing the point of origin. As is shown in Figs. 2 and 3, thallium(I) ions gave the linear relation in the concentration range from 2×10^{-8} to 1×10^{-6}M, and lead(II) and cadmium(II) ions, in the concentration range from 1×10^{-7} to 3×10^{-6}M. The effect of the presence of copper(II) ions on the a.c. peak-heights of thallium, lead, and cadmium was also studied. The 2×10^{-5}M copper(II) ion had no effect on the a.c. peak-heights of the 5×10^{-8}M thallium(I) or the 2×10^{-7}M lead(II) and cadmium(II) ions.

Although the present a.c. polarographic method has the disadvantage of being restricted to use with solutions not containing anions capable of forming insoluble mercury salts, one can apply this method to the determination of thallium(I), lead(II), and cadmium(II) ions in their micromolar solutions.

The authors wish to express their thanks to the Ministry of Education for the financial support granted for this research.

The Syntheses of Centaureidin and 5,7,3′-Trihydroxy-3,8,4′-trimethoxyflavone*1

Tokunaru HORIE

Department of Applied Chemistry, Faculty of Engineering, University of Tokushima, Tokushima

(Received January 27, 1969)

Centaurein (I) was first isolated from the roots of *Centaurea jacea* L. by Bridel and Charaux.[1] The hydrolysis of I with sulfuric acid afforded an aglycone, centaureidin (5,7,3′-trihydroxy-3,6,4′-trimethoxyflavone (II)).[2] Recently, II has also been isolated from the Centaurea species by Bohlmann and Zdero.[3] A structural isomer of II, jaceidin (III), has been isolated from the same plant.[3,4] The present author and his collaborators achieved the syntheses of III,[5] axillarin (IV),[6] and two

According to the method of Allan-Robinson's flavone synthesis, the condensation of the ketone VII with *O*-benzylisovanillic anhydride and potassium *O*-benzylisovanillate, followed by treatment with alcoholic potassium hydroxide, was found to afford two isomeric cyclization products, the 3′-benzyl ether (IX) of II and 3′-benzyloxy-5,7-dihydroxy-3,8,4′-trimethoxyflavone (X). After the usual acetylation of the above mixtures, the reaction products could be separated into two crystals, A and B, by fractional crystallization from ether. The crystal A (mp 159—160°C, $C_{29}H_{26}O_{10}$) gave a negative ferric chloride reaction, and there was no band attributable to a hydroxyl group in its infrared spectrum. Further, from a comparison of the NMR spectrum (Table 1)*2 of this compound with those of 5,7,8-oxygenated flavones,[7,8] the signal at δ 6.80 (1H) (singlet) can be assigned to the C_6–H at the A ring of the flavone nucleus. Thus, the crystal A is formulated as 3′-benzyloxy-5,7-diacetoxy-3,8,4′-trimethoxyflavone (XI).

The mild hydrolysis of the crystal B gave pale yellow needles (mp 131.5—132.5°C), 7-acetoxy-3′-benzyloxy-5-hydroxy-3,6,4′-trimethoxyflavone (XII), *via* a partial acetylation. The NMR spectrum exhibits two singlets, at δ 6.78 and 12.87, due to the C_8–H of the A ring and to the hydroxyl protons respectively. The treatment of XII with dilute alkali afforded the 3′-benzyloxy-5,7-dihydroxy-compound IX. The catalytic hydrogenolysis of IX over palladium charcoal gave the desired flavone, II, which was easily converted to the triacetate, XIII. The synthetic flavone, II, and its triacetate, XIII, were found to be identical with natural centaureidin*3 and its triacetate*4 in mixed-melting-point determinations and in infrared- and ultraviolet-spectral comparisons. The triethyl ether (XIV) of II was easily obtained with diethyl sulfate in anhydrous acetone. The ether, XIV, was also prepared from 4,6-diethoxy-5,ω-dimethoxy-2-hydroxyacetophenone (XV)[5] and

3-ethoxy-4-methoxybenzoic anhydride. The properties of the product were found to be identical with those of the above compound (XIV) by a direct comparison. The infrared and ultraviolet spectra of synthetic centaureidin superimpose on those of the natural compound (Figs. 1 and 2 and Table 2). A partial synthesis of the glucoside I[1] had been carried out earlier,[2] so the total synthesis of I is now accomplished.

On the other hand, the diacetoxy substance, XI, on treatment with dilute alkali, was easily converted to the 5,7-dihydroxyflavone, X. The catalytic debenzylation of X over palladium charcoal afforded the flavone, VIII. Its triacetate, XVI, and triethyl ether, XVII, were prepared by usual methods. The NMR spectrum of the triacetate, XVI, shows one proton signal corresponding to the C_6–H (δ 6.82) at a field higher than that of the C_8–H (δ 7.25) in the triacetate, XIII (Table I). They are in accordance with those shown in earlier reports.[8]

Experimental*5

3′-Benzyloxy-5,7-diacetoxy-3,8,4′-trimethoxyflavone (XI) and 7-Acetoxy-3′-benzyloxy-5-hydroxy-3,6,4′-trimethoxyflavone (XII). A mixture of the ketone (VII)[7] (2.0 g), *O*-benzylisovanillic anhydride (16 g), and potassium *O*-benzylisovanillate (7.5 g) was heated at 180°C under a vacuum for 10 hr. The reaction mixture was then cooled and refluxed with a solution of potassium hydroxide (10 g) in aqueous ethanol (75%; 350 m*l*) for 15 min. After the solvent had been evaporated in a vacuum, the residue was dissolved in water and saturated with carbon dioxide. The separated precipitate was collected, washed with water, and dried to give a crude flavone mixture.

A mixture of the crude flavones, acetic anhydride (10 m*l*), and anhydrous pyridine (1.0 m*l*) was heated at 110°C for 2 hr and then poured into water and extracted with ether. The ether layer (about 200 m*l*) was washed with a sodium carbonate solution and water, and allowed to stand in a refrigerator for one week. The separating crystals were collected to give the diacetate crystal B (about 0.9 g). The mother liquor was concentrated to 15—20 m*l* and then cooled at 0°C for one week. The separating crystals were corrected to give the diacetate crystal A (about 1.5 g).

The diacetate crystal A was recrystallized from methanol to give colorless needles of XI; mp 159—160°C, yield 330 mg (7%). It gave a negative ferric chloride reaction. IR: 1762, 1755, 1646 cm^{-1}. UV: λ_{max} mμ (log ε); (EtOH) 250 (4.04), 369 (4.22).

Found: C, 65.28; H, 4.82%. Calcd for $C_{29}H_{26}O_{10}$: C, 65.16; H, 4.90%

A solution of the diacetate crystal B in methanol (100 m*l*) was gently refluxed with aqueous potassium hydroxide (5%; 20 m*l*) for 3 min. After the solvent had then been evaporated under a vacuum, the resulting residue was dissolved in water and saturated with carbon dioxide. The precipitate thus separated was collected, heated with acetic anhydride-pyridine (10 : 1; 1.5 m*l*) for 2 min on a steam bath, cooled, and added to ether (10 m*l*). The crystals which separated were collected, washed with ether, and recrystallized from methanol to give pale yellow needles of XII; mp 131.5—132.5°C; yield, 210 mg(5%). It gave a dark green color with an alcoholic ferric chloride solution. IR: 1760, 1652 cm^{-1}. UV: λ_{max} mμ (log ε), (EtOH) 257 (4.64), 274_{sh} (4.50),*7 352 (4.60); ($EtOH-AlCl_3$) 259 (4.56), 360 (4.57). NMR:*2,5 12.87_{bs}(OH); 7.80_q (C-6′); 7.79_d(C-2′); 7.49_{bs}(5H, C_6H_5); $7.02_{d'}$(C-5′), 6.78_s(C-8); 5.28_s(2H, $C_6H_5CH_2$); 4.01_s, 3.96_s, 3.72_s (each 3H, CH_3O); 2.40_s(CH_3CO).

Found: C, 65.69; H, 4.66%. Calcd for $C_{27}H_{24}O_9$: C, 65.85; H, 4.91%.

3′-Benzyloxy-5,7-dihydroxy-3,6,4′-trimethoxyflavone (IX). A solution of XII (190 mg) in methanol (50 m*l*) was gently refluxed with aqueous potassium hydroxide (3%; 10 m*l*) for 2 min. The resulting solution was acidified with dilute hydrochloric acid, and the solvent was evaporated under a vacuum. The resulting precipitate was collected and recrystallized from methanol to give IX as pale yellow needles; mp 163—164°C; yield, 150 mg (86%). It gave a green color with an alcoholic ferric chloride solution. IR: 3350, 1658 cm^{-1}.

Found: C, 66.41; H, 4.90%. Calcd for $C_{25}H_{22}O_8$: C, 66.66; H, 4.92%.

Centaureidin (5,7,3′-Trihydroxy-3,6,4′-trimethoxyflavone) (II). A mixture of IX (130 mg) and Pd-C (5%: 150 mg) in methanol (70 m*l*) was shaken in an atmosphere of hydrogen until 1.1 mol of hydrogen

*5 All the melting points are uncorrected; the infrared spectra were mesured in Nujol.

*6 sh=shoulder.

had been absorbed. After the catalyst had been filtered, the filtrate was evaporated. The residue was recrystallized from aqueous methanol to give II as yellow needles; mp 196—197°C (reported[1] mp 196°C) (natural centaureidin,[*4,8] mp 196—197°C); yield, 85 mg (82%). It gave a dark green color with an alcoholic ferric chloride solution. IR: 3460, 3380, 1651 cm^{-1}. This was identified with natural centaureidin by a mixed-melting-point determination and by infrared- and ultraviolet-spectral comparisons.

Found: C, 59.79; H, 4.35%. Calcd for $C_{18}H_{16}O_8$: C, 60.00; H, 4.48%.

Centaureidin Triacetate (XIII): hot acetic anhydride-pyridine method; mp 174—175.5°C (colorless prisms from methanol) (Natural Centaureidin Triacetate,[*4] mp 174—175.5°C). IR: 1768, 1641 cm^{-1}. UV: λ_{max} mμ (log ε); (EtOH) 328 (4.00), 344 (4.06).

Found: C, 59.01; H, 4.62%. Calcd for $C_{24}H_{22}O_{11}$: C, 59.26; H, 4.56%.

Centaureidin Triethyl Ether (5,7,3′-Triethoxy-3,6,3′-trimethoxyflavone) (XIV). a) From Centaureidin (II). A mixture of synthetic centaureidin (II) (21 mg), anhydrous potassium carbonate (1.0 g), and diethyl sulfate (0.3 m*l*) in anhydrous acetone (20 m*l*) was refluxed for 20 hr, and then the reaction mixture was treated in the usual manner. Recrystallization from methanol give XIV as colorless prisms; mp 77—78°C; yield, 22 mg (85%).

After XIV had been dried at 70—80°C/0.1 mmHg for 1 hr, it had a mp of 104.5—105.5°C. IR: 1635 cm^{-1}. UV: λ_{max} mμ(log ε); 258_i(4.18),[*9] 358(4.10). NMR:[*2,5] 7.75_d (C-2′); 7.73_q (C-6′); $6.98_{d'}$ (C-5′); 6.72_s(C-8); 4.19_q (6H, J=7.0 Hz, $CH_3C\underline{H}_2O$); 3.95_s, 3.91_s, 3.84_s (each 3H, $C\underline{H}_3O$); 3.51_t (9H, J=7.0 Hz, $C\underline{H}_3H_2O$).

Found: C, 64.77; H, 6.24%. Calcd for $C_{24}H_{28}O_8$: C, 64.85; H, 6.35%.

b) From the Ketone XV. A mixture of XV[5] (1.0 g), 3-ethoxy-4-methoxybenzoic anhydride (3.0 g), and triethylamine (2 m*l*) was heated at 170°C for 8 hr. The reaction mixture was then cooled and refluxed with a solution of potassium hydroxide (1.5 g) in aqueous ethanol (80%; 100 m*l*) for 15 min. After the evaporation of the solvent under a vacuum, the residue was dissolved in water (60 m*l*). The resulting precipitate was collected and recrystallized from methanol to give colorless prisms of XIV; mp 77.5—78.5°C (after drying; mp 104.5—105.5°C); yield, 250 mg (16%). It was identical with the sample described in a).

3′-Benzyloxy-5,7-dihydroxy-3,8,4′-trimethoxyflavone (X). A mixture of XI (320 mg), methanol (10 m*l*), and aqueous potassium hydroxide (10%; 5 m*l*) was treated by a method similar to that used for IX. The crude product was recrystallized from methanol to give yellow needles of X; mp 148—149°C; yield, 230 mg (85%). It gave a green color with an alcoholic ferric chloride solution. IR: 3340, 1655 cm^{-1}. UV: λ_{max} mμ (log ε); (EtOH) 257.5 (4.30), 276 (4.27), 340 (4.20), 362_{sh}(4.20).

Found: C, 66.61; H, 4.91%. Calcd for $C_{25}H_{22}O_8$: C, 66.66; H, 4.92%.

5,7,3′-Trihydroxy-3,8,4′-trimethoxyflavone (VIII). A mixture of X (205 mg) and Pd-C (5%; 200 mg) in methanol (100 m*l*) was treated by a method similar to that used for III. The resulting precipitate was recrystallized from methanol to give yellow needles of VIII; mp 213.5—214.5°C; yield, 138 mg(84%). It gave a dark green color with an alcoholic ferric chloride solution. IR: 3400, 3300, 1648 cm^{-1}. UV: λ_{max} mμ (log ε); (EtOH) 260 (4.44), 275.5 (4.47), 360 (4.33).

Found: C, 59.91; H, 4.37%. Calcd for $C_{18}H_{16}O_8$: C, 60.00; H, 4.48%.

Triacetate (XVI): hot acetic anhydride-pyridine method; mp 144—145°C (colorless needles from methanol). IR: 1767, 1751, 1636 cm^{-1}. UV: λ_{max}mμ(log ε); (EtOH) 247_i(4.24), 351 (4.03), 360_{sh}(4.02).

Found: C, 59.16; H, 4.65%. Calcd for $C_{24}H_{22}O_{11}$: C, 59.26; H, 4.56%.

5,7,3′-Triethoxy-3,8,4′-trimethoxyflavone (XVII). A mixture of VIII (35 mg), anhydrous potassium carbonate (1.5 g), and diethyl sulfate (0.5 m*l*) in anhydrous acetone (15 m*l*) was treated in the usual manner. Recrystallization from methanol give XVII as colorless needles; mp 152.5—153°C; yield, 37 mg (76%). IR: 1633 cm^{-1}. UV: λ_{max} mμ (log ε); (EtOH) 253 (4.35), 272 (4.33), 353 (4.31). NMR:[*2,5] 7.87_q (C-6′); 7.84_d (C-2′); $7.00_{d'}$ (C-5′); 6.43_s(C-6); 4.17_q (2H), 4.23_q (4H) (each J=7.0 Hz, $CH_3C\underline{H}_2O$); 1.56_t(6H), 1.51_t (3H) (each J=7.0 Hz, $C\underline{H}_3CH_2O$).

Found: C, 65.12; H, 6.49%. Calcd for $C_{24}H_{28}O_8$: C, 64.85; H, 6.35%.

The author wishes to express his deep gratitude to Professor Kenji Fukui, Hiroshima University, for his guidance and encouragements throughout the course of this work, and also to Professor F. Bohlmann, University of Berlin, for supplying the natural centaureidin.

A Synthesis of 2-(2′-Hydroxyethyl)cyclopentanone by the Barton Reaction*1

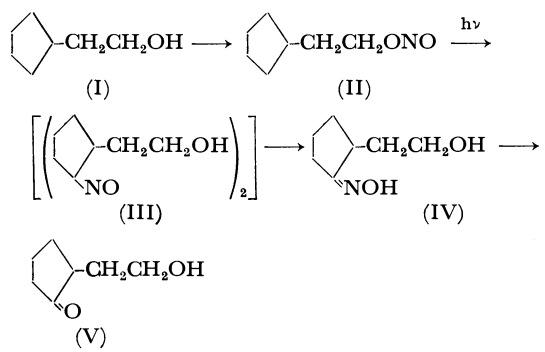
Heitaro OBARA and Hiroshi KIMURA

Department of Applied Chemistry, Faculty of Engineering, Yamagata University, Yonezawa

(Received January 31, 1969)

Previously, one of the present authors reported, during the course of his synthetic studies of aucubin,[1] the synthesis of 2-(2′-hydroxyethyl)cyclopentanone*2 (V) as an intermediate in the syntheses of five-membered cyclic ketals.

In the present investigation, we attempted the synthesis of V from 2-cyclopentylethanol (I) by the Barton reaction[2] according to the following scheme:



2-(2′-Hydroxyethyl)cyclopentanone oxime (IV) was obtained from 2-cyclopentylethyl nitrite (II) in a 20% yield as a white crystal, which was identified by a comparison of its IR spectrum with that of an authentic sample. A mild hydrolysis of IV with dilute hydrochloric acid gave 2-(2′-hydroxyethyl)cyclopentanone (V), which was identified by a comparison of its IR spectrum with that of the previously-synthesized specimen.[1]

Experimental

2-Cyclopentylethanol (I).[3,4] This alcohol was prepared in an 82% yield by the lithium aluminum hydride reduction of cyclopentylacetic acid.[5] Bp 180—182°C, n_D^{20} 1.4552 (lit.[3] bp 179—181°C, n_D^{20} 1.4615).

2-Cyclopentylethyl Nitrite (II). Into a suspension of 5.0 g of I and 15.0 g of sodium nitrite in 30 m*l* of water, a mixture of 2 m*l* of water and 5 m*l* of concentrated sulfuric acid was vigorously stirred, drop by drop, over a period of about 2 hr while being cooled by an ice-salt mixture.

The acid solution was then added slowly, and the temperature was kept at ±1°C. After the addition had been completed, the reaction mixture was allowed to stand in the ice-salt bath until it separated into two layers; the liquid layers were then decanted from the sodium sulfate into a separatory funnel.

The aqueous layer was removed, and the 2-cyclopentylethyl nitrite layer was washed with a 1% aqueous sodium bicarbonate solution and then with water, dried over anhydrous sodium sulfate, and evaporated to yield 4.5 g (72%) of II as a light green liquid; bp 50—51°C/15 mmHg; n_D^{18} 1.4346. IR (neat): 2940, 2860, 1643, 1603, 790 cm^{-1}.

Photolysis of 2-Cyclopentylethyl Nitrite (II). A solution of 3.07 g of II in 450 m*l* of dry benzene was irradiated by means of a 100-W high-pressure mercury arc lamp (model HLV-B, manufactured by Taika Kôgyô Co.) placed in a water-cooled quartz immersion well. The solution was slightly agitated by means of a stream of nitrogen, and the reaction temperature was kept near 25°C by regulating the temperature of the cooling water.

After 3 hr the solvent was removed *in vacuo*, and the residue was refluxed in *n*-butyl alcohol for 5 hr.*3 The solution was concentrated *in vacuo*, and the resulting viscous oil was chromatographed on a column of silica gel with ether. 2-(2′-Hydroxyethyl)cyclopentanone oxime (IV) was obtained as white crystals, which were then recrystallized from benzene. Yield, 0.625 g (20%); mp 80—82°C. This substance was found to be identical with the oxime of V which had previously been syn-

N-Alkylation of Metanilic Acid

Toshinari NAKAJIMA,[1] Nobuyuki GOTOH and Yoshio NAGAI[2]

The Institute of Industrial Science, The University of Tokyo, Roppongi, Minato-ku, Tokyo

(Received February 8, 1969)

While the alkylation reaction of amino compounds with alcohol in the presence of iodine is well known, the method does not always give satisfactory results. The present investigation was undertaken to see if a practical method could be worked out for the preparation of *N,N*-diethylmetanilic acid using iodine, red phosphorus and boric acid as a catalyst.[3]

Metanilic acid was treated with ethanol in the presence of iodine, red phosphorus and boric acid at 200—250°C for a few hours to give *N,N*-diethylmetanilic acid. The condition used in various alkylations and the yields of *N,N*-diethylmetanilic acid of individual reactions are given in Table 1.

In the reaction at 250°C, the main product was oily materials as a result of presumable desulfonation. Whereas at 210°C or below the reaction did not proceed. The best condition seemed to be heating at about 230°C (*cf.* DEM-5,10,11). An optimum reaction time was estimated to be 3 hr as a longer heating decreased the yield (*cf.* DEM-2,10). Without red phosphorus only 17.6% of metanilic acid was ethylated, and the rest was recovered unchanged. Both reactions without boric acid and without iodine and red phosphorus gave only unreacted metanilic acid. The best condition for the preparation of *N,N*-diethylmetanilic acid can be seen in run numbers DEM-10 and PE-7.

Table 1. Reaction condition and the yield of *N,N*-diethylmetanilic acid

Metanilic acid 8.88 g , Ethanol 39.4 g

mixture was heated at 230°C for 3 hr. After cooling the reaction mixture was filtered and washed with ethanol to give 10.17 g of a crude product. This product was dissolved in hot water. After removal of a hot-water-insoluble part, the filtrate was concentrated to yield 9.95 g of *N,N*-diethylmetanilic acid (84.7% of the theoretical amount). The purity of this product was estimated to be 96.5% by a functional group analysis. Thus total yield was calculated to be 81.8%.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 2707—2708 (1969)

An X-Ray Emission Spectroscopic Investigation of the Chemical Bond of Sulfur. II. The Number of Valence Electrons of the Sulfur Atom in Organic Compounds

Yoshihito TAKAHASHI, Katsumasa YABE and Toshio SATO

Goverment Industrial Development Laboratory, Hokkaido, Higashi-tsukisamu, Sapporo

(Received February 15, 1969)

We have calculated the number of valence electrons, N, of the sulfur atom in fifty compounds (or samples)[1] on the basis of this theoretical correlation; $\delta E=n(n+3)/8$,[2] where δE is the energy shift of the S$K\alpha$ line and where n is $N-6$. We also checked the reliability of the relation by using the dipole moment and structural data of several sulfur compounds.

Recently improved theoretical calculations have

TABLE 1. WAVELENGTH of S$K\alpha$ LINE AND MEAN NUMBER OF VALENCE ELECTRONNS OF SULFUR ATOM IN COMPOUNDS

Compound	Wavelength (Å)	Energy (eV)	ΔE (eV)	Mean number of valence electrons[a]
Rhombic sulfur, S_8[b]	5.37270	2307.55	0.00	6.00

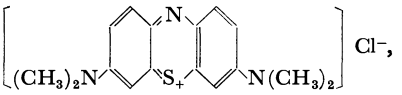
d) Benzene solution, 50%.

1) T. Sato, Y. Takahashi and K. Yabe, This Bulletin, **40**, 298 (1967).
2) C. A. Coulson and C. Zauli, *Mol. Phys.*, **6**, 525 (1963).

been made on this problem[3,4] on the same fundamental assumption that $\delta E=f(N)$; these calculations gave results a little different from the old one. Therefore, from the experimental point of view, it is important to obtain more accurate data on δE as a basis for discussion.

In this note, we will give new data on about thirty compounds and will give refined data on some compounds previously reported on. The measurements were carried out on the same apparatus and in the same manner as in a previous work.[1] Table 1 shows the mean value of at least three measurements; the precision of the wavelength measurements was thereby improved to an extent of $\pm 0.5'$ (2θ) (± 0.0001Å). On the measurements of the liquid samples, a sample holder with a Mylar film (10 μ thick) window was used. In the cases of sulfuryl chloride and thionyl chloride, the Mylar film was replaced by polyethylene film (30 μ thick), the precision being to the extent of $\pm 1.0'$ (2θ) (± 0.0002 Å).

The structure of the methylene blue molecule has thus far been given as follows:



of which the sulfur atom has a plus charge. However, our measurements led to the finding that the number of valence electrons of its sulfur atom is similar to those of rhombic sulfur and phenothiazine. Consequently, the above formula for the methylene blue molecule is not proper.

The molecular structures of aldehide-bisulfite adducts and 2-mercaptobenzimidazole, *etc.*, will be discussed on the basis of the wavelength value of the S$K\alpha$ line and the shape of the S$K\beta$ band in our next paper.[5]

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 2708—2710 (1969)

Preparation of Some Anilinosilanes

Toshio TAKIGUCHI and Masahiro SUZUKI

Department of Synthetic Chemistry, Kiryu College of Technology, Gunma University, Tenjin-cho, Kiryu

(Received February 25, 1969)

We wish to report on the preparation of some di- and trianilinosilanes from the reaction of aniline and the corresponding organochlorosilanes by the use of triethylamine as a hydrogen chloride acceptor. Most of the products were crystalline substances and gave the corresponding silanols or siloxanes when hydrolyzed in the presence of an acidic catalyst.

The products were triphenylsiloxytrianilinosilane, bis-triphenylsiloxydianilinosilane, vinyltrianilinosilane, vinylphenyldianilinosilane, vinylbutyldianilinosilane, diphenyldianilinosilane, and phenyltrianilinosilane, the first five being new compounds.

All the products were well-defined and were characterized by their IR spectra. As for the crystalline products, the X-ray powder patterns were determined in order to identify them rapidly.

Experimental

Organochlorosilanes. The triphenylsiloxytrichlorosilane, mp 47°C, and bis-triphenylsiloxydichlorosilane, mp 141°C, were prepared according to a method previously reported.[1] The vinylphenyldichlorosilane, bp 67°C/2 mmHg, and vinylbutyldichlorosilane, bp 65—66°C/20 mmHg, were prepared by the Grignard route.[2] The vinyltrichlorosilane, diphenyldichlorosilane, and phenyltrichlorosilane were obtained from the Shin-etsu Chem. Ind. Co. and were further purified by distillation immediately before use.

Preparation of Anilinosilanes. Typical procedures will be described in detail with the preparation of bis-triphenylsiloxydianilinosilane as an example.

To a stirred mixture of freshly-distilled aniline (19.7 g; 0.21 mol), triethylamine (28.4 g; 0.28 mol), and 200 m*l* of toluene, a toluene solution of bis-triphenylsiloxydichlorosilane (57.2 g; 0.09 mol) was added drop by drop. After the addition was complete, the mixture was further stirred for 10 hr, during which period the temperature was maintained at 100°C. After standing overnight, triethylamine hydrochloride was removed by filtration and the filtrate was evaporated to about 100 m*l*.

1) T. Takiguchi, M. Abe, K. Urano and T. Sakuma, This Bulletin, **40**, 2453 (1967).

2) T. Takiguchi and M. Abe, *Kogyo Kagaku Zasshi* (*J. Chem. Soc. Japan, Ind. Chem. Sect.*), **66**, 625 (1963).

The concentrate was then combined with 100 ml of warm *n*-hexane and cooled to room temperature to give a white crystalline mass from which 37.8 g (55%) of pure *bis-triphenylsiloxydianilinosilane* as white, acicular crystlas melting at 159—160°C, was obtained by recrystallization from boiling *n*-hexane.

Found: C, 75.06; H, 5.80; N, 3.41; Si, 11.05%; mol wt, 755 (determined cryoscopically in 1,4-dioxane). Calcd for $C_{48}H_{42}N_2O_2Si_3$: C, 75.55; H, 5.56; N, 3.67; Si, 11.04%; mol wt, 763.

The hydrolysis of the anilinosilane in the presence of sulfuric acid gave quantitatively a mixture of hexaphenyltrisiloxane-3,3-diol[1] and its condensation product.

Similar procedures were applied to other chlorosilanes to give the following anilinosilanes, the mean yield being 57%: triphenylsiloxytrianilinosilane, mp 201—202°C, vinyltrianilinosilane, mp 86—87°C, vinylphenyldianilinosilane, mp 87—88°C, vinylbutyldianilinosilane, a low melting solid, bp 149—150°C/1.5 mmHg, diphenyldianilinosilane, mp 161—162°C (lit. mp 153°C,[3] 166—167°C[4]), and phenyltrianilinosilane, mp 138°C (lit. mp 134—135°C[5]). All the anilinosilanes thus obtained were readily soluble in chloroform, acetone, a dioxane, were soluble in benzene and toluene, and were barely soluble in methanol and *n*-hexane.

Triphenylsiloxytrianilinosilane. Found: C, 74.87; H, 5.83; N, 7.57; Si, 9.72%; mol wt, 576. Calcd for $C_{36}H_{23}N_3OSi_2$: C, 74.57; H, 5.74; N, 7.24; Si, 9.69%; mol wt, 580.

Vinyltrianilinosilane. Found: C, 71.33; H, 6.40; N, 12.15; Si, 8.60%; mol wt, 338. Calcd for $C_{20}H_{21}N_3Si$: C, 72.47; H, 6.39; N, 12.68; Si, 8.47%; mol wt, 332.

Vinylphenyldianilinosilane. Found: C, 75.66; H, 6.60; N, 8.57; Si, 8.90%; mol wt, 322. Calcd for $C_{20}H_{20}N_2Si$: C, 75.90; H, 6.37; N, 8.85; Si, 8.87%; mol wt, 317.

Vinylbutyldianilinosilane. Found: C, 71.77; H, 8.20; N, 9.48; Si, 9.53%; mol wt, 289. Calcd for $C_{18}H_{24}N_2Si$: C, 72.92; H, 8.16; N, 9.45; Si, 9.47%; mol wt, 297.

Diphenyldianilinosilane. Found: C, 78.82; H, 5.87; N, 7.70; Si, 7.74%; mol wt, 370. Calcd for $C_{24}H_{22}N_2Si$: C, 78.64; H, 6.05; N, 7.64; Si, 7.66%; mol wt, 367.

Phenyltrianilinosilane. Found: C, 76.33; H, 6.17; N, 10.86; Si, 7.46%; mol wt, 395. Calcd for $C_{24}H_{23}N_3Si$: C, 75.55; H, 6.08; N, 11.01; Si, 7.36%; mol wt, 382.

Infrared Absorption Spectra and X-Ray Power Diffraction Data. The absorption bands due to Si–R bonding,[2,6-7] and aromatic secondary amine attached to Si[8,9] were distinctly observed throughout all the samples. The X-ray powder patterns were also satisfactorily recorded by using Cu$K\alpha$ radiation filtered by Ni.

Some Remarks on the Reactions of Ferricyanide Ions with Hydrogen Atoms in Alkaline Aqueous Solutions

Akira YOKOHATA, Katsuyuki HARAKON and Satoru TSUDA

Department of Chemistry, Faculty of Engineering, Hiroshima University, Senda-machi, Hiroshima

(Received March 3, 1969)

In the radiolysis of the deaerated alkaline aqueous solutions of potassium ferricyanide, there seems to be no doubt[1-4] that aquocomplex ($Fe(CN)_5H_2O^{3-}$) is formed *via* the reactions of ferricyanide ions with the reducing species (mainly e_{aq}^-). However, the role of hydrogen atoms in the formation of aquocomplex is not well known.[5] In order to make it clear, a technique introducing hydrogen atoms generated in a microwave discharge into the alkaline aqueous solution of potassium ferricyanide was used, and the mechanism of formation of aquocomplex was successfully investigated, in relation to the concentration of hydroxyl ions.

Experimental

The apparatus consists of a conventional discharge flow system. Hydrogen atoms were produced at a moderately high pressure (13—14 mmHg*1) by 2450 Mc/sec microwave generator feeding a resonant cavity. Hydrogen (purity: >99.95%) was used without further purification. Gas flow was controlled by a needle valve to maintain their velocity at 5×10^{-5} M/min through the reaction section. The reaction section consists of the discharge tube of quartz and the reaction vessel of hard glass (Fig. 1). The gas stream was finally removed from the line with a vacuum pump.

The experimental procedure was as follows. After the system was evacuated to $<10^{-3}$ mmHg, a stream of hydrogen was passed through the system. The electrical circuit to the discharge tube was then closed. A few minutes was required for sweeping out the residual air in the system with the hydrogen stream. As soon as the red hydrogen arc appeared in the tube, the current was shut off; then 10 m*l* of the pre-deaerated sample solution was introduced into the reaction vessel by a syringe through the rubber stopper. Electric power was usually adjusted to 100 W and the reaction vessel was maintained at about 3°C by means of an ice bath.

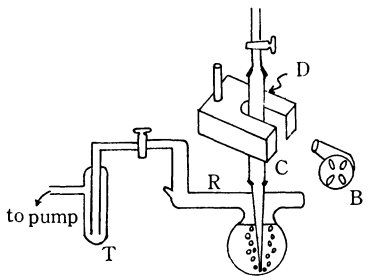

Fig. 1. Schematic diagram of apparatus.
B: blower C: cavity D: discharge tube
R: reaction vessel T: trap

Reproducible results were obtained only when the equipment was throughly cleaned before each run.

All reagents used were of research grade. Concentration of aquocomplex ($Fe(CN)_5H_2O^{3-}$) was determined spectrophotometrically by the method using NaN_3.[2,4]

Results and Discussion

A preliminary experiment of the effect of initial concentration of ferricyanide ions on the reduction yield of ferricyanide ions showed no effect in the range from 5×10^{-3}M to 5×10^{-2}M. This indicates that in this concentration range all hydrogen atoms reaching the solution are utilized to reduce ferricyanide ions. Thus, in this work the solution of 5×10^{-3}M or 1×10^{-2}M of ferricyanide ions was used.

Figure 2 shows the relation between the amount of aquocomplex formed and the duration of dis-

charge in the concentration range of hydroxyl ions from 0.1M to 3M. The increment of aquocomplex yield with increasing concentration of hydroxyl ions has been found.

The following reaction scheme can be expected in this system.*2

$$H + Fe(CN)_6^{3-} \rightarrow Fe(CN)_6^{4-} + H^+ \quad (1)$$
$$\searrow\ Fe(CN)_5H_2O^{3-} + CN^- + H^+ \quad (2)$$
$$H + OH^- \rightarrow e_{aq}^- \quad (3)$$
$$e_{aq}^- + Fe(CN)_6^{3-} \rightarrow Fe(CN)_6^{4-} \quad (4)$$
$$\searrow\ Fe(CN)_5H_2O^{3-} + CN^- \quad (5)$$

If reaction (2) is ignored,[4] Eqs. (6) and (7) result in.*3

$$Y(-Fe(CN)_6^{3-}) = Y(H) \quad (6)$$
$$Y(Fe(CN)_5H_2O^{3-}) = Y(H)\frac{1}{1+k_1/k_3\cdot[Fe(CN)_6^{3-}]/[OH^-]}\cdot\frac{1}{1+k_4/k_5} \quad (7)$$

Equation (7) can be reformed to Eq. (8)

$$\frac{1}{Y(Fe(CN)_5H_2O^{3-})} = \frac{1+k_4/k_5}{Y(H)}\left(1+\frac{k_1[Fe(CN)_6^{3-}]}{k_3[OH^-]}\right) \quad (8)$$

A good linearity of a plot of $1/Y(Fe(CN)_5H_2O^{3-})$ against $[Fe(CN)_6^{3-}]/[OH^-]$ (Fig. 3) gives a value

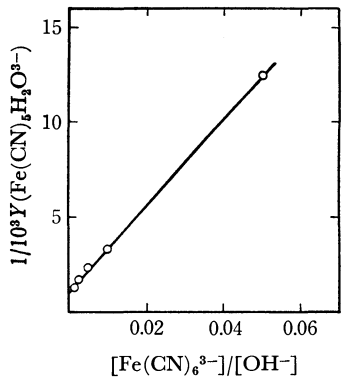

Fig. 3. A plot of $1/Fe(CN)_5H_2O^{3-}$ against $[Fe(CN)_6^{3-}]/[OH^-]$

of 230*4 for k_1/k_3 where $k_4/k_5\approx1$[4] and $Y(H)=2.0\times10^{-3}$M determined in this experiment are used. If we take $k_1=4\times10^9M^{-1}\,sec^{-1}$,[6] k_3 is estimated to be $\sim1.7\times10^7M^{-1}\,sec^{-1}$ which is almost consistent in order of magnitude with $2.3\times10^7M^{-1}\,sec^{-1}$ [7] obtained from the radiolytic experiment. In other words, these findings show that the assumption of exclusion of reaction (2) is allowable, at least in alkaline region.

It is our conclusion that (1) the increment of yield of aquocomplex with an increasing concentration of hydroxyl ions can be well interpreted in terms of the solvated electron formed *via* the reaction of hydrogen atoms with hydroxyl ions, and that (2) the contribution of hydrogen atoms themselves to the formation of aquocomplex can be ignored in alkaline region.

*2 Molecular hydrogen does not reduce ferricyanide.
*3 $Y(X)$ means the yield of product X formed during 4 min of the duration of discharge.
*4 This value can be expected to be independent of temperature, if the same activation energy (~5 kcal) for the reactions (1) and (3) is assumed, as seen in Navon's report: G. Navon and G. Stein, *J. Phys. Chem.*, **69**, 1384 (1965).

Studies of Actinium(III) in Various Solutions. III. Actinium(III) Complexes with Oxalate, Sulfate, Chloride, and Thiocyanate Ions in Perchlorate Media

Tatsuya SEKINE and Mitsuo SAKAIRI

Department of Chemistry, Science University of Tokyo, Kagurazaka Shinjuku-ku, Tokyo

(Received March 4, 1969)

In previous papers,[1-4] the stability of the complexes of lanthanum(III), europium(III), lutecium(III), and americium(III) with oxalate, sulfate, chloride, and thiocyanate ions has been determined by means of the metal chelate extraction method. The present paper studies the complex formation of actinium(III) in these aqueous systems in order to obtain further information about the stability of the complexes of trivalent lanthanides and actinides.

Experimental

All of the experiments were carried out in a thermostatted room at 25°C. The actinium-228 tracer was separated from radium-228 and purified by a solvent extraction method which was described in Paper I of this series.[5] Sodium salts of oxalate, sulfate, chloride, and thiocyanate were dissolved in water, and the concentration was analyzed by gravimetry or volumetry. The other reagents and the experimental procedures are the same as those described in Paper II of this series[6] or in other papers.[1-4]

Results and Discussion

As the statistical treatment of the experimental data was the same as in previous papers,[1-4,7] only the final form of the equations will be shown in this paper.

The stability constants for the "n-th" complex with the L^{l-} ligand are defined as;

$$\beta_n = \frac{[AcL_n^{3-nl}]}{[Ac^{3+}][L^{l-}]^n} \quad (1)$$

The net distribution ratio of the extraction with a chelating extractant, HA, in the absence of and in the presence of the complexing ligand is described as:

$$D_0 = \frac{[AcA_3]_{org}}{[Ac^{3+}]} \quad (2)$$

$$D = \frac{[AcA_3]_{org}}{[Ac^{3+}]+[AcL^{3-l}]+\cdots+[AcL_n^{3-nl}]} = \frac{D_0}{1+\beta_1[L^{l-}]+\cdots+\beta_n[L^{l-}]^n} \quad (3)$$

The extraction constant is defined as:

$$K_{ex} = D_0[H^+]^3[HA]_{org}^{-3} \quad (4)$$

When the extraction constant is determined in the absence of the complexing ligand, the stability constants are given by the following equation:

$$\frac{D[H^+]^3[HA]_{org}^{-3}}{K_{ex}} = (1+\beta_1[L^{l-}]+\cdots+\beta_n[L^{l-}]^n)^{-1} \quad (5)$$

When the $\log D[H^+]^3[HA]_{org}^{-3}K_{ex}^{-1}$ *vs.* $\log[L^{l-}]$ plot is made from the experimental data, the stability constants are determined by a curve-fitting method.[7]

The constants obtained from the experimental data are summarized in Table 1, together with the previous results on the other four ions. As the present results were analyzed by the graphic method, no range of error is included in the results.

It was reported in a previous work[6] that the extraction data of actinium(III) with TTA were reproducible only when a mixed extractant, TTA and TBP in a diluent, was used. This was confirmed in the present work. Moreover, it was also found that the formation of aqueous chelates could be prevented by the use of the mixed solvent.[8] The data on the experiments in the thiocyanate system scattered a little for some unknown reasons and so the constants for the thiocyanate complexes might be somewhat less accurate than the others.

Almost no work seems to have been done on the stabilities of the actinium(III) complexes.[9]

The results in Table 1 may be summarized as follows:

TABLE 1. STABILITY CONSTANTS OF COMPLEXES OF La(III), Eu(III), Lu(III), Ac(III) AND Am(III) WITH OXALATE, SULFATE, CHLORIDE AND THIOCYANATE IONS

The data of Ac(III) complexes were taken from the present work and the rests were taken from Refs. 1—4.

Ionic medium		Oxalate 1M $NaClO_4$	Sulfate 1M $NaClO_4$	Chloride 4M $NaClO_4$	Thiocyanate 5M $NaClO_4$
La^{3+}	$\log\beta_1$	4.26±0.11	1.45±0.07	−0.22±0.11	0.24±0.06
	$\log\beta_2$	7.85±0.12	2.46±0.08	−0.64±0.11	(<−0.62)
	$\log\beta_3$	10.27±0.21	—	—	−0.73±0.12
Eu^{3+}	$\log\beta_1$	4.77±0.10	1.54±0.06	−0.15±0.10	0.32±0.09
	$\log\beta_2$	8.72±0.09	2.69±0.05	−0.72±0.17	∼−0.1(<0.25)
	$\log\beta_3$	11.39±0.12	—	—	−0.36±0.15
Lu^{3+}	$\log\beta_1$	5.11±0.08	1.29±0.23	−0.35±0.07	0.45±0.09
	$\log\beta_2$	9.18±0.12	∼1.9(<2.49)	−0.57±0.05	∼−1.3(<−0.06)
	$\log\beta_3$	12.79±0.08	3.36±0.18	—	−0.14±0.23
Ac^{3+}	$\log\beta_1$	3.56[a]	1.36[a]	−0.04[b]	−0.75[c]
	$\log\beta_2$	6.16	2.68	−1.04	−0.46
	$\log\beta_3$	—	—	−1.26	—
Am^{3+}	$\log\beta_1$	4.63±0.08	1.57±0.09	−0.15±0.07	0.85±0.05
	$\log\beta_2$	8.35±0.09	2.66±0.08	−0.69±0.10	—
	$\log\beta_3$	11.15±0.07	—	—	0.55±0.15
	$\log\beta_4$	—	—	—	0.00±0.15

The range of the error is three times the standard deviation. The values in parentheses after $\log\beta_2$ give the value of $\log(\beta_2\pm3\sigma)$.

Composition of the organic phase and the extraction constant are as follows.

a) 0.03M TTA in CCl_4 with 0.2M TBP $\log K_{ex}=-5.04$

b) 0.2M TTA in CCl_4 with 0.3M TBP $\log K_{ex}=-5.55$

c) 0.015M TTA in CCl_4 with 0.1M TBP $\log K_{ex}=-5.93$

The dissociation constant of oxalic acid employed for the calculation is $pK_{a_2}=3.54$ (Ref. 2). The hydrogen ion concentration was 1×10^{-3}—3×10^{-4} except for the chloride system which contained 0.01M H^+.

(i) The actinium(III) complexes are more stable in the order: thiocyanate<chloride<sulfate<oxalate. (ii) The oxalate complexes of actinium(III) are less stable than those of the other metal ions. (iii) No very remarkable differences are observed among the sulfate or chloride complexes of actinium and those of the other ions. (iv) The thiocyanate complexes of actinium(III) are much weaker than those with the other ions.

It may be generally assumed that the actinium(III) ion forms the least stable complexes among the trivalent metal ions presented in Table 1, because it is the largest and the least basic ion. This assumption seems to hold in the oxalate complexes. However, it is not obviously true in the sulfate or chloride complexes. This may be due to the fact that the stabilities of weak complexes of analogous metal ions are influenced by many other factors, such as the hydration. Surls and Choppin[10] pointed out, on the basis of their ion-exchange data, that the trivalent actinides form more stable thiocyanate complexes than the trivalent lanthanides; this agrees with the prediction of Diamond[11] based on the assumption of f-orbital hybridization that thiocyanate ions should complex more strongly with actinides than with lanthanides. Similar results were obtained for the complexes of americium(III), as may be seen in Table 1. Actinium(III), however, forms less stable thiocyanate complexes than does lanthanum(III). One possible explanation for the lower stabilities of the actinium(III) thiocyanate complexes may be that the fourteen 5f-electrons enter the actinides beginning at thorium (or that the 5f-electrons enter beginning with thorium).[12] If so, 5f-electrons, which are connected with the fact that the stability of the thiocyanate complexes of americium(III) is greater than that of europium(III), should not contribute the formation of the actinium(III) thiocyanate complexes.

Part of this work has been carried out at the Laboratory of Nuclear Chemistry, Institute of Physical and Chemical Research. The authors are grateful to Professor Nobufusa Saito, the head of the Laboratory.

Electron Spin Resonance Studies of Photo-irradiated Aroylphosphonates

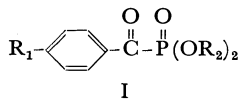
Ken-ichi TERAUCHI and Hiroshi SAKURAI

The Institute of Scientific and Industrial Research, Osaka University, Suita, Osaka

(Received March 5, 1969)

In a preceding paper,[1] we have shown that *para*-substituted benzoylphosphonates have a moderately strong n–π^* transition of the carbonyl group, involving a transition with the phosphorus *d*-orbitals in the 320—390 mμ, and that the n–π^* absorption maxima of these compounds are considerably affected by the powerful electron inductive abilities of *para*-substituents, such as the methoxy and chloro functions. The present investigation was undertaken to see if the ESR spectra of irradiated aroylphosphonates exhibit the effects of *para*-substituents on the aromatic ring in the magnetic parameters.

Another point of interest was the fact that there have been very few ESR studies of the organic phosphorus compounds[2] compared to those of the inorganic phosphorus compounds; especially little has yet been done with the ESR study of the UV-irradiated organophosphorus compounds.[3] In this paper, we wish to report the results obtained by the ESR measurements of UV-irradiated *para*-substituted aroylphosphonates Ia-d, which have never before been investigated by means of the ESR technique.



I

Ia, R_1=H; R_2=C_2H_5
b, R_1=Cl; R_2=C_2H_5
c, R_1=*t*-Bu; R_2=C_2H_5
d, R_1=CH_3O; R_2=C_2H_5

On UV-irradiation at 77°K through the filter cutting off below 3200 Å, each of the aroylphosphonates employed in this work showed unsymmetrical ESR signals. These ESR spectra have a large anisotropic doublet with a 53—128 gauss separation which is thought to be due to the interaction between an unpaired electron and the phosphorus nucleus, and a g value almost close to the free spin value. All of these spectra were quite stable at 77°K; upon a subsequent elevation of the temperature the hyperfine structure did not show any significant change except for a great decrease in the intensity during the ESR measurements. However, these signals completely vanished at 156°K. The observed g and A values in Compounds Ia—d are summarized in the Table 1.

TABLE 1. ESR RESULTS FOR THE PHOSPHORUS-CONTAINING RADICALS
(The A values are in gauss.)

Compound	$\bar{g}$	$A_\perp$	$A_{/\!/}$
Ia	2.004	127.8	5.33
b	2.005	143.4	36.9
c	2.005	125.7	52.3
d	2.005	124.6	58.6

As is obvious from the table, the *para*-substituents on the aromatic ring participate considerably in both the isotropic and anisotropic splittings of these radicals. Although such substituent effects have been extensively studied in mono- or disubstituted benzene radical anions by Bowers *et al.*,[4] it is of particular interest that similar effects have been found in the ESR spectra of irradiated aroylphosphonates.

These observations suggest that the extent of the anisotropic hyperfine interaction of substituted aroylphosphonates vary over a considerable range, depending upon the electron-withdrawing or electron-donating properties of the substituent groups on the aromatic ring. Thus, when calculating the orbital spin densities on the phosphorus atom of the observed radicals from the isotropic and anisotropic parts of the hyperfine coupling tensors, we have obtained the values of 0.30, 0.22, 0.29, and 0.32 for Ia, Ib, Ic, and Id respectively.

These results support the idea that the powerful electron-inductive abilities of the methoxy and chloro functions on the aromatic ring undoubtedly cause a change in the spin density on the phosphorus atom. Therefore, it seems interesting to compare these results with other spectroscopic data, such as the results of infrared, UV, or dipole moment measurements. Although it is recognized that ESR study, which involves excited states,

4) *Cf.* E. T. Kaiser and L. Kevan, "Radical Ions," Interscience Publishers, New York (1968), p. 211.

cannot normally be related to infrared or dipole moment data, which involve ground states only, the above findings are consistent with the view which has been suggested; in the dipole moment data, the values reported as 2.64D for Ib and 3.20D for Id,[5] it has been postulated that the powerful electron-inductive abilities of the methoxy and chloro functions induce a change in the electron density on the carbonyl carbon atom, and that the more the electron density on the carbonyl carbon increases, the more the lifetime of the conformation in which the carbonyl and phosphoryl groups are opposite increases. The UV and infrared data also provide evidence for the electron density on the C–P bond depending considerably upon the properties of those functions on the aromatic ring.[1] Therefore, it can be concluded that the findings of the ESR measurements are in comparatively good agreement with the other spectroscopic data.

On the other hand, these phosphorus hyperfine splittings prompt a question as to the preferred structure of the observed radicals. Since the n–π^* absorption maxima of benzoylphosphonates Ia–d show an average bathochromic shift of 50 mμ in comparison with those of the corresponding benzaldehydes, the π orbital on the carbonyl carbon atom might overlap with a vacant d orbital on phosphorus. Therefore, it may be reasonable to assume that the radicals which are produced photochemically from Compounds Ia—d contain such an extended conjugation that the electronic n–π^* excitation produces an unpaired electron, one which is probably partially delocalized over the P–O group, perhaps through the vacant d orbitals on phosphorus.

In connection with these observations, we will later report in detail on the results of our photochemical study of these compounds.

Experimental

The aroylphosphonates were synthesized by the reaction of triethylphosphite with acid chloride.[6] Repeated distillation under reduced pressure was used to purify all the compounds needed. The tests for purity were the same as those employed in a previous work.[1] A DMF solution of aroylphosphonate was pipetted into a Pyrex ESR tube; then the tube was degassed by conventional vacuum techniques before being sealed and irradiated at 77°K through a Toshiba UV-35 filter for 2 hr with a Toshiba 400-watt high-pressure mercury arc (Model HLS-4002A type). The ESR spectra were measured with a TDS Electronics Co. X-band ESR spectrometer (Model T-1000AX type), using a field modulation of 100 kc/sec and conventional elevating-temperature instruments.

Copper(II)-catalyzed Oxidation of Iron(II) by Molecular Oxygen in Tripolyphosphate Solution

Yoshimi KURIMURA and Keigo MURAKAMI

Chemical Laboratory, College of General Education, University of Ibaraki, Mito, Ibaraki

(Received March 6, 1969)

In a previous work on the oxygen oxidation of Fe(II) in tripolyphosphate solutions,[1] the anomalous results first obtained led us to suspect the presence of Cu(II) as an impurity. Actually the oxidation rate was subsequently proved to be markedly increased by the addition of small amounts of Cu(II). The effect of Cu(II) as a catalyst has been reported in the Fe^{2+}–O_2,[2-4] Mo(V)–O_2,[5] V(III)–Fe(III),[6] V(III)–O_2[7] and ascorbic acid-O_2[8-10] reactions. In connection with these studies,

the effect of Cu(II) on the oxidation reaction of Fe(II) in an excess of the triphosphate solution was studied spectrophotometrically, and the results thus obtained discussed, with a view to getting some information concerning the role of Cu(II) as a reaction accelerator.

Experimental

The Cu(II) solution was prepared from reagent-grade cupric sulfate. The sodium triphosphate ($Na_5P_3O_{10}\cdot 6H_2O$) was recrystallized five times from 25% aqueous ethanol solutions. Redistilled wster was used for the preparation of all the solutions. The hydrogen ion concentration of the triphosphate solution, in which certain amounts of Cu(II) were dissolved if necessary, was adjusted by adding dilute perchloric acid or dilute sodium hydroxide. Just before each run, the Fe(II) solution was prepared by the use of reagent-grade ferrous ammonium sulfate. By mixing 20 m*l* of the triphosphate and 1 m*l* of the Fe(II) solution, the reaction was initiated. The ionic strength of each reaction mixture was kept at 0.10 M $NaClO_4$. The oxidation reaction was followed spectrophotometrically at 20°C by determining the concentrations of the Fe(III), whose molar extinction coefficient at 260 mμ is 4620 M^{-1} cm^{-1} in the pH range employed in excesses of triphosphate solutions. The method of kinetic measurement used here was virtually identical with that described before.[1] All the oxidation rates used here were obtained from the slopes of the corresponding concentration-time curves, which are essentially linear in the first stage of the reactions.

Results and Discussion

The rate laws for the oxidation reaction of the Fe(II) in excesses of triphosphate solutions at particular pH values were obtained from the results of several series of runs; in each run one of the solute concentration was varied, while all the other concentrations remained constant. The rate laws thus obtained are defined by the following expressions, from (1) to (4). At a given concentration of the Cu(II) and at pH=3.0 under 1 atm of air ($p_{O_2}=0.21$ atm), a plot of the oxidation rate against the concentration of the Fe(II), [Fe(II)], gives a straight line with a zero intercept, which accounts for the rate expression:

$$\frac{d[Fe(III)]}{dt} = k_1[Fe(II)] \quad (1)$$

From the solpe of this particular line the pseudo-first-order rate constant, k_1, is calculated. Linear variations of the rate with the Fe(II) concentration were also obtained at other pH values studied. In the 2.0—3.0 pH range, the linear dependence of the rate on the Cu(II) concentration holds well; this indicates the catalytic behavior of the Cu(II). The rate equation obtained is:

$$\frac{d[Fe(III)]}{dt} = k_2+k_2'[Cu(II)] \quad (2)$$

At pH values lower than 2, however, the rate hardly increases at all with an increase in the Cu(II) concentration, showing the saturation of the catalytic effect of the Cu(II). At pH values higher than 2, the values of the rate constants of k_2 and k_2' are calculated from the intercept and from the slope of the straight line of the rate-[Cu(II)] curve respectively. The dependence of the rate on the partial pressure of oxygen shows that the rate increases slightly with an increase in the pressure, and the relationship between these gives a straight line. The rate law at given concentrations of the Fe(II) and the Cu(II) at pH=3.0 is of the form:

$$\frac{d[Fe(III)]}{dt} = k_3+k_3'p_{O_2} \quad (3)$$

A simillar rate dependence was also obtained at other pH values studied.

The oxidation reaction of Fe(II) in excesses of triphosphate solutions in the absence of Cu(II) has been studied previously.[1] In this case the rate law at a particular pH is expressed by:

$$\frac{d[Fe(III)]}{dt} = k_a[Fe(II)]p_{O_2} \quad (4)$$

This rate expression was also confirmed in the present study in the 1.5—3.0 pH range. The values of all the apparent rate constants in the four equations, (1) to (4), at pH=3.0 are summarized in Table 1. The results obtained are consistent with the following rate equation at a particular pH (pH =2.0—3.0):

$$\frac{d[Fe(III)]}{dt} = k_a[Fe(II)]p_{O_2}+k_b[Fe(II)][Cu(II)] \quad (5)$$

where k_a is the apparent rate constant of the uncatalyzed reaction path and, k_b, that of the catalyzed path. The correlation between the appatent rate constants in Eqs. (1)—(5), which were obtained separately from several series of runs, has been established within the range of experimental error. The rate profiles for the catalyzed and uncatalyzed reaction paths are shown in Fig. 1. A reaction mechanism which accounts for Eq. (5) can be expressed by following reactions in these equations the charges of all the complex species are neglected for the sake of simplification:

$$Fe(II) + O_2 \rightarrow Fe(III) + O_2^- \quad (6)$$

$$Fe(II) + Cu(II) \rightleftarrows Fe(III) + Cu(I) \quad (7)$$

$$Cu(I) + O_2 \text{ (or } O_2 + H^+) \rightleftarrows Cu(II) + O_2^- \text{ (or } HO_2) \quad (8)$$

$$O_2^- + H^+ \rightleftarrows HO_2 \quad (pK_{HO_2} = 3.3—4.7^{11}) \quad (9)$$

The rate-determining step of the uncatalyzed path may be (6), while that of catalyzed path may be (7). Reaction (7) indicates the initiation of

10^{-3}M triphosphate, μ=0.10M ($NaClO_4$)

the catalytic cycle; the resulting Cu(I) reacts rapidly with oxygen in (8).[2] The rapid back reaction in (7) was confirmed in the Cu(II)-catalyzed Fe^{2+}–O_2[2,3] and V(III)–Fe(III)[6] reactions, but this may be ignored in the initial stage of the reaction discussed here. The HO_2 and O_2^- radicals can either oxidize successively the Fe(II), as in the Weiss mechanism,[12] or react with the Cu(II) in (8).[2] The back reaction in (8) may account for the saturation of the oxidation rate as the Cu(II) concentration increases at pH values lower than 2.[2] The increase in the k_a value with an increase in the pH seems to be due to an increase in the concentration of such Fe(II)-triphosphate complexes as $Fe^{II}HL$,[1] where HL is the monoprotonated triphosphate anion ($HP_3O_{10}^{4-}$), which is oxidized more rapidly than the aquo ferrous ion by molecular oxygen. Under the present experimental conditions, the $Fe^{II}(HL)_2$ may be neglected.[1] Therefore, the main species susceptible to oxidation in (6) and (7) under the present experimental conditions may be Fe^{2+} and $Fe^{II}HL$.

12) J. Weiss, *J. Chim. Phys.*, **48**, C-6 (1951).

Though the stability constants of $Fe^{II}HL$ and $Fe^{II}(HL)_2$ have not yet been reported, this estimate also be supported by the consideration that the stability constant of $Fe^{II}HL$ may well be smaller than 10^5 since: i) the stability constant of $Cu^{II}HL$ reported[13] is $10^{5.2}$ (μ=0.1) and ii) the stability of a Fe(II) complex is generally lower than that of the corresponding Cu(II) complex (Irving-Williams order[14]).*1 The real features of the (6) reaction in the 1.5—3.0 pH range seem to be indicated by (6′) and (6″), and that of (7), by (7′), since the normal Cu(II) complex, Cu(II)L, is negligible in the pH region ($K_{Cu(II)L}=10^{7.3}$, μ=0.1[13]).*1

$$Fe^{2+} + O_2 \rightarrow Fe^{3+} + O_2^- \quad (6')$$

$$Fe^{II}HL + O_2 \rightarrow Fe^{III}HL + O_2^- \quad (6'')$$

$$\left\{\begin{matrix} Fe^{2+} \\ \uparrow\downarrow \\ Fe^{II}HL \end{matrix}\right\} + \left\{\begin{matrix} Cu^{2+} \\ \uparrow\downarrow \\ Cu^{II}HL \end{matrix}\right\} \rightleftarrows Fe(III) + Cu(I) \quad (7')$$

As the rate of (6′) may be influenced by the anions present,[2,3] and as the stability constant of $Fe^{II}HL$ is unknown, a precise analysis of the rate profiles of k_a and k_b was not undertaken at present. However, it may be suggested that the rate constant of (6″) is appreciably greater than that of (6′) since the k_a value increases markedly with an increase in the pH value. An increase in the k_b value with an increase in the pH may be attributed to the fact that the redox reaction between the Fe(II) and the Cu(II) is accelerated by the formation of the Fe(II) and Cu(II) complexes with triphosphate anions.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 2718—2719 (1969)

The Spectrophotometric Determination of Thorium(IV) with 4-(2-Thiazolylazo)-resorcinol*1

Takayoshi SAKAI*2 and Kôichi TONOSAKI

Chemical Department, Faculty of Science, Hirosaki University, Bunkyô-chô, Hirosaki

(Received March 7, 1969)

The reagent 4-(2-thiazolylazo)-resorcinol (TAR) is an azo-dyestuff with a thiazol ring; it has a structure and properties similar to those of 1-(2-pyridylazo)-2-naphthol (PAN) and 4-(2-pyridylazo)-resorcinol (PAR), both of which have been extensively employed as metallochromic indicators and as reagents for the spectrophotometric determination of various metals. TAR has also been used for the spectrophotometric determination of nickel,[1] niobium,[2] copper and bismuth,[3] uranium(VI),[4] and palladium.[5] Nickelss and his co-workers[6] have recently reported the formation constant of TAR complexes with many metals, but not of any metals including thorium(IV).

It is found that thorium(IV) reacts with TRA in a hexamethylenetetramine buffer solution to form a stable complex. The present paper will describe the fundamental conditions for the spectrophotometric determination of thorium(IV).

Experimental

Reagents and Apparatus. *TAR Solution.* A 1×10^{-3}M TAR solution was prepared by dissolving 0.0553 g of the Dotite TAR reagent in 250 m*l* of 50% v/v methanol.

Buffer Solution. About a 10% w/v hexamethylenetetramine-potassium nitrate-nitric acid system solution was used for the pH adjustment; potassium nitrate was added in order to maintain a constant ionic strength. All the investigations were carried out at a constant ionic strength of 0.6.

The solutions of thorium(IV) and diverse ions, and the apparatus, were the same as those used in a previous work.[7]

All the measurements were made at 25 ± 0.5°C.

Procedure. To a sample solution containing up to 95 μg of thorium in a 25-m*l* volumetric flask, 2.5 m*l* of a 1×10^{-3}M TAR solution and 15 m*l* of a 10% w/v hexamethylenetetramine buffer solution with a pH of 7.4 were added; then the solution was diluted to the mark with water. The absorbance of the solution was then measured in a 1-cm cell at 615 mμ, using the reagent blank as a reference.

Results and Discussion

Absorption Curves. The carmine red Th(IV)-TAR complex formed in the pH range from 4.5 to 5.0 has the peak of its absorption curve at 525 mμ. However, a precipitate is sometimes formed. The red-violet complex with the peak at 585 mμ was formed in the pH range from 6.8 to 8.5 without any precipitate. Some of the results are shown in Fig. 1. The latter complex was recommended for the determination at 615 mμ, where the absorption of TAR was negligible.

The Effect of pH. A constant absorbance is obtained over the pH range from 6.8 to 8.5, as

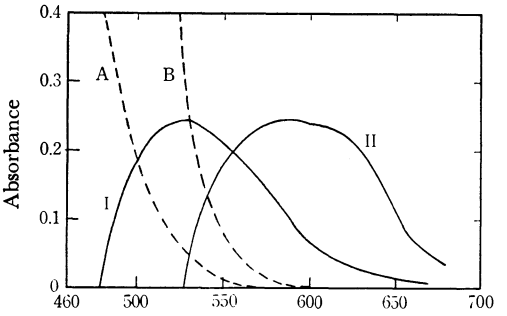

Fig. 1. Absorption curves of TAR and its thorium-(IV) complexes.

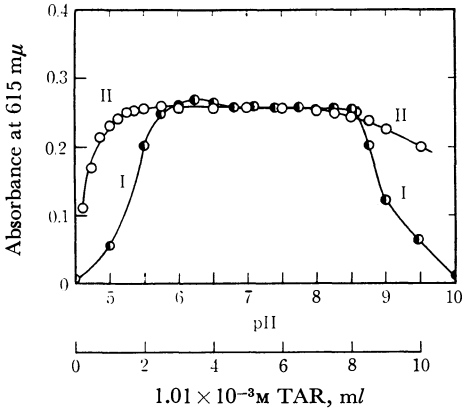

Fig. 2. Effects of pH and the amount of reagent.
Th(IV): 46.4 μg, Reference: reagent blank
I: pH, TAR: 1.01×10^{-4}M
II: Addition of TAR at pH 7.4

is shown in Fig. 2(I). The color development was, therefore, made at pH 7.4.

The Effect of the Amount of Reagent. It may be seen in Fig. 2(II) that a maximum and constant absorbance is obtained with 2 to 6 ml of a 1×10^{-3}M TAR solution. A 2.5-ml portion of the reagent was used in further experiments.

Color Stability. The absorbance of the solution containing the complex remained almost constant for at least 2 hr.

Calibration Curve. The color system follows Beer's law in the range from 2.4 to 95.2 μg of thorium in 25 ml. The molar absorptivity is 3.15×10^4. According to Sandell's notation,[8] the sensitivity of the reaction is 0.008 μg of thorium per cm^2 at 615 mμ. The reproducibility of the method was also examined. The standard deviation was calculated to be 0.003 (1.2%) in absorbance (mean of 10 determinations of 46.4 μg thorium).

The Effect of Diverse Ions. These results are listed in Table 1. Many elements interfere seriously.

A Comparison with Other Methods. Several methods have been summarized in a previous work;[7] the method proposed here is comparable with the quercetin method[9] in sensitivity and also in selectivity.

Composition of the Complex. The continuous-variation method and the mole-ratio method were used to determine the composition of the thorium-TAR complex. The results of the mole-ratio method are shown in Fig. 3. It seems that a 1 : 3*3 complex is mainly formed under the conditions investigated, although some lower complexes may also be formed when the ligand-to-metal ratio is less than three. According to the method of Harvey and Manning,[10] the apparent formation constant of the 1 : 3 complex was 7.4×10^{16} at pH 7.4.

Studies on Hydroxy Amino Acids. II.*1 The Optical Resolution of α-Amino-β-hydroxy-γ-benzyloxybutyric Acid*2

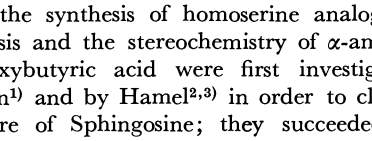
Kenji OKAWA, Kiyotaka HORI, Katsutoshi HIROSE and Yasuo NAKAGAWA

Department of Chemistry, Faculty of Science, Kwansei Gakuin University, Nishinomiya

(Received March 8, 1969)

The optical resolution of α-amino-β-hydroxy-γ-benzyloxybutyric acid (I_{ab}) into the four stereoisomers was investigated with success as a study related to the synthesis of homoserine analogues. The synthesis and the stereochemistry of α-amino-β,γ-dihydroxybutyric acid were first investigated by Niemann[1] and by Hamel[2,3] in order to clarify the structure of Sphingosine; they succeeded in synthesizing three isomers of this amino acid, the D-erythro, L-threo, and D-threo forms, from D-mannitol. However, another isomer, the L-erythro form, could not be obtained.

The present authors prepared α-amino-β-hydroxy-γ-benzyloxybutyric acid (I_{ab}) by the condensation reaction of copper glycinate[4] with benzyloxyacetaldehyde,[5] while diastereoisomeric DL-erythro and DL-threo forms were isolated by the partial crystallization from *s*-butyl alcohol. We studied the optical resolution of both of the racemic modifications; we thus confirmed that the DL-erythro form (I_a) could be resolved by the use of Takadiastase, but the threo form (I_b) could not, though the latter could be resolved by Vogler's method[6] using the diastereoisomeric salt formation of the *N*-acyl-DL-threo amino acid (III) with L-tyrosine hydrazide (Fig. 1).



I R=$CH_2C_6H_5$, R′=H
II R=H, R′=H
III R=$CH_2C_6H_5$, R′=$COOCH_2C_6H_5$ (CHA salt)

The four stereoisomers obtained were reduced by catalytic hydrogenation to give free α-amino-β,γ-dihydroxybutyric acids (II); γ-lactone derivatives (IV) of these isomers were also obtained by treatment with dry hydrogen chloride in methanol. The melting points and specific rotations of these isomers are summarized in Tables 1 and 2.

Experimental

α-Amino-β-hydroxy-γ-benzyloxybutyric acid (I_{ab}) was prepared by the glycine - copper method in a 14% yield; mp 205—207°C.

Found: C, 58.43; H, 6.63; N, 6.07%. Calcd for $C_{11}H_{15}O_4N$: C, 58.65; H, 6.71; N, 6.22%.

Separation of Diastereomers. A suspended solution of I_{ab} hydrochloride (29 g) in *s*-butyl alcohol (300 m*l*) was stirred for 2 hr at 50°C. The undissolved crystals, I_a hydrochloride (19 g), were then filtered off. From the mother liquor, I_b hydrochloride (10 g) was obtained. Both of the amino acid hydrochlorides were decomposed with a pyridine-methanol solution; subsequent recrystallization from hot water gave I_a (11 g; mp 202—203°C), and I_b (6 g; mp 195—196°C).

Resolution of Racemic I_a. *N*-Acetyl-I_a was prepared in an 88% yield by the usual Schotten-Baumann method, mp 151—153°C, as CHA*3 salt. The salt obtained (7.33 g, 0.02 mol) was dissolved in 2N sodium hydroxide, and the liberated CHA was extracted with ether. After the pH of the aqueous layer had been adjusted to 6.8, the solution was incubated with Taka-diastase at 37°C for 4 days. The precipitate was then filtered off, and the filtrate was concentrated under reduced pressure until crystals appeared. The crystals of I_{a-1} were obtained in a 67% yield and were recrystallized from hot water; mp 194—195°C; $[\alpha]_D^{23}$ +21.9° (*c* 5.7, 1N HCl).

Found: C, 58.62; H, 6.75; N, 6.20%. Calcd for $C_{11}H_{15}O_4N$: C, 58.65; H, 6.71; N, 6.22%.

The mother liquor of I_{a-1} was acidified to pH 2.0 and was extracted with ethyl acetate. *N*-Acetyl-I_{a-2} was obtained from the concentrated extract as CHA salt in an 84% yield. Recrystallization from methanol-ethyl acetate gave pure crystals; mp 145—146°C; $[\alpha]_D^{23}$ −12.5° (*c* 2.5, EtOH). The partial hydrolysis of the CHA salt of *N*-acetyl-I_{a-2} with 1N hydrochloric acid gave free amino acid I_{a-2} in a 82% yield; mp 194°C; $[\alpha]_D^{23}$ −21.9° (*c* 5.5, 1N HCl).

Found: C, 58.78; H, 6.67; N, 6.25%. Calcd for $C_{11}H_{15}O_4N$: C, 58.65; H, 6.71; N, 6.22%.

***N*-Carbobenzoxy-I_b (III).** *N*-Carbobenzoxy-I_b was prepared from I_b and carbobenzoxychloride by the usual method; it was obtained as CHA salt in a 79% yield; mp 158—159°C.

L-Tyrosine Hydrazide Salt of III. The free acid (III) was obtained from CHA salt (13.7 g, 0.03 mol) by the use of 3N hydrochloric acid and by ethyl acetate extraction. L-Tyrosine hydrazide (5.86 g, 0.03 mol) was added to a solution of III in methanol (50 m*l*), and the solution was warmed at 65°C. After the removal of insolubles, the solution was concentrated; the subsequent addition of ethanol gave L-tyrosine hydrazide salt of III in a quantitative yield (16.6 g), $[\alpha]_D^{23}$ +36° (*c* 1.0, water).

Four recrystallizations of this salt (5.96 g) from methanol gave a small amount (310 mg) of optically-pure L-tyrosine hydrazide salt (V_1), mp 158.5—159°C; $[\alpha]_D^{23}$ +30.6° (*c* 1.0, water). V_1 was used as the seed of the following partial crystallization.

Resolution of Racemic III. A solution of L-tyrosine hydrazide salt of III in methanol (50 m*l*) was similarly prepared from the CHA salt of III (6.88 g, 0.015 mol). After the insolubles had been filtered off, a small amount of V_1 was seeded to the filtrate; then the mixture was stirred for 1.5 hr and kept at 25°C for 22.5 hr. The precipitated first crop (V_1) was then collected (2.12g); mp 158.5°C; $[\alpha]_D^{23}$ +30.5° (*c* 1.0, water). The mother liquor was concentrated, and the resulting crystals were dissolved in methanol (50 m*l*). After the solution had been stirred at 25°C for 4 hr and then kept at 25—17°C for 20 hr, the second crop (V_2) was obtained (2.66 g, 64%); mp 163—165°C; $[\alpha]_D^{23}$ +39.3° (*c* 1.0, water). From the filtrate of V_2, an additional crop of V_1 was obtained; the total yield of V_1 was 73%.

III_1 was obtained from V_1 by treatment with 3N hydrochloric acid; it was purified as CHA salt; mp 138.0°C; $[\alpha]_D^{23}$ +10.9° (*c* 2.0, EtOH).

Found: C, 65.61; H, 7.60; N, 6.18%. Calcd for $C_{25}H_{34}O_6N_2$: C, 65.48; H, 7.47; N, 6.11%.

The CHA salt of III_2 was obtained from V_2 in the same way; mp 137—138°C; $[\alpha]_D^{23}$ −10.3° (*c* 2.0, EtOH)

Found: C, 65.62; H, 7.57; N, 6.14%.

α-Amino-β,γ-dihydroxybutyric Acids (II). A

*3 CHA=cyclohexylamine

mixture of I_{a-1} (675 mg, 3 mmol), water (10 m*l*), palladium charcoal (160 mg), and N hydrochloric acid (3 m*l*) was stirred for 5 hr at room temperature under the bubbling of hydrogen gas. After the removal of the catalyst, the solution was neutralized and subsequently concentrated under reduced pressure. The resulting crystals were recrystallized twice from water-methanol to give II_{a-1} (305 mg, 75%); mp 194—195°C; $[\alpha]_D^{23}$ −11.3° (*c* 7.2, water).

Found: C, 35.56; H, 6.77; N, 10.30%. Calcd for $C_4H_9O_4N$: C, 35.55; H, 6.71; N, 10.37%.

II_{a-2}, II_{b-1}, and II_{b-2} were obtained from I_{a-2}, III_1, and III_2 by the catalytic hydrogenation described above.

II_{a-2}: mp 194°C; $[\alpha]_D^{23}$ +11.3° (*c* 7.0, water).
Found: C, 35.99; H, 6.91; N, 10.63%.
II_{b-1}: mp 214°C; $[\alpha]_D^{23}$ −13.5° (*c* 2.0, water).
Found: C, 35.32; H, 6.72; N, 10.21%.
II_{b-2}: mp 214—215°C; $[\alpha]_D^{23}$ +13.6° (*c* 4.8, water).
Found: C, 35.61; H, 6.74; N, 10.98%.

α-Amino-β-hydroxy-γ-butyrolactone Hydrochlorides (IV). IV_{a-1}, IV_{a-2}, IV_{b-1}, and IV_{b-2} were prepared from II_{a-1}, II_{a-2}, II_{b-1}, and II_{b-2} respectively in the way described by Hamel and Painter.[2]

IV_{a-1}: mp 176°C; $[\alpha]_D^{23}$ +55.6° (*c* 1.5, water).
Found: C, 31.31; H, 5.24; N, 9.58; Cl, 22.73%. Calcd for $C_4H_8O_3NCl$: C, 31.28; H, 5.25; N, 9.12; Cl, 23.09%.
IV_{a-2}: mp 176.5—177°C; $[\alpha]_D^{23}$ −56.6° (*c* 1.5, water).
Found: C, 31.23; H, 5.51; N, 9.18; Cl, 23.05%.
IV_{b-1}: mp 173—174°C; $[\alpha]_D^{23}$ −26.2° (*c* 1.0, water).
Found: C, 31.24; H, 5.26; N, 9.13; Cl, 23.23%.
IV_{b-2}: mp 175—175.5°C; $[\alpha]_D^{23}$ +26.0° (*c* 1.0, water).
Found: C, 31.39; H, 5.27; N, 9.13; Cl, 23.15%.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 2722—2723 (1969)

Isomerization and Hydrogenation of Dimethyl Maleate and 1,5-Cyclooctadiene by Nickel Cyanide Complex

Hiroshi SAMEJIMA, Taiichi MIZUTA, Haruhiko YAMAMOTO and Takao KWAN

Faculty of Pharmaceutical Sciences, The University of Tokyo, Hongo, Tokyo

(Received March 12, 1969)

The selective isomerization and hydrogenation of monoenes, dienes and their derivatives by nickel cyanide complex and excess sodium borohydride were the subject of our investigations,[1,2] in which it was suggested that the stability of the intermediary hydridonickel or alkylnickel complex plays a significant role in determining the distribution of products. The present work was undertaken to confirm such selectivity revealed by nickel cyanide complex for the isomerization and hydrogenation of dimethyl maleate (DMM) and of 1,5-cyclooctadiene (1,5-COD), respectively.

Nickel complexes investigated here were dicyano(1,10-phenanthroline)nickel (II), $Ni(CN)_2(phen)$, tetracyanonickelate(II), $Ni(CN)_4^{2-}$, and dicyanobis(triphenylphosphine)nickel(II), $Ni(CN)_2(P\phi_3)_2$. Previous investigation[1] revealed that hydrogenation activity increases according to the sequence: $Ni(CN)_2(P\phi_3)_2 < Ni(CN)_4^{2-} < Ni(CN)_2(phen)$ while isomerization activity is reversed.

DMM or 1,5-COD was introduced in a water-isopropanol (10 : 25) solution containing a given nickel cyanide complex and excess sodium borohydride at 0°C or 10°C. After a certain reaction interval, products were extracted with chloroform for DMM and petroleum ether for 1,5-COD respectively and analyzed by gas chromatography. The method of preparation of the nickel cyanide complexes, apparatus and experimental procedure were almost the same as those described earlier.[1]

The isomerization and hydrogenation of DMM took place rapidly with the three nickel cyanide complexes, *i. e.* more than 90% DMM was found to convert to dimethyl fumarate (DMF) and dimethyl succinate (DMS) within 30 min. However, product distribution differed with the kind of nickel cyanide employed. Typical data, obtained after 30 min, are illustrated in Table 1.

TABLE 1. PRODUCT COMPOSITION FOR THE ISOMERIZATION AND HYDROGENATION OF DIMETHYL MALEATE BY THE NICKEL CYANIDE COMPLEXES AT 10°C

	Product composition %		Substrate converted %
	DMF	DMS	DMM
$Ni(CN)_2(phen)$	28	72	90
$Ni(CN)_4^{2-}$	88	12	89
$Ni(CN)_2(P\phi_3)_2$	95	5	95

It is apparent from Table 1 that $Ni(CN)_2(phen)$ gives rise to the hydrogenation of DMM in preference to $Ni(CN)_2(P\phi_3)_2$, while the latter is quite active for the isomerization of DMM to give DMF.

1) H. Samejima, T. Mizuta and T. Kwan, *Nippon Kagaku Zasshi* (*J. Chem. Soc., Pure Chem. Sect.*), **89**, 1028 (1968).

2) T. Mizuta, H. Samejima and T. Kwan, This Bulletin, **41**, 727 (1968).

This result is in line with that of the previous report[1] which concerned the isomerization and hydrogenation of 1-butene.

The isomerization and hydrogenation of DMM would probably follow the hydride elimination-addition mechanism:

$$\mathrm{NiH(CN)(P\phi_3)_2} + \begin{matrix}\mathrm{CH_3OOCCH}\\ \|\\ \mathrm{CH_3OOCCH}\end{matrix} \text{ or } \begin{matrix}\mathrm{CHCOOCH_3}\\ \|\\ \mathrm{CH_3OOCCH}\end{matrix} \rightleftarrows$$

$$\begin{matrix}\mathrm{CH_3OOCCH_2}\\ |\\ \mathrm{CH_3OOCCH\text{-}Ni(CN)(P\phi_3)_2}\end{matrix}$$

$$\downarrow +\mathrm{H}$$

$$\begin{matrix}\mathrm{CH_3OOCCH_2}\\ |\\ \mathrm{CH_3OOCCH_2}\end{matrix} + \mathrm{NiH(CN)(P\phi_3)_2}$$

Let us investigate 1,5-COD as the substrate; 1,5-COD is expected to convert to 1,4-COD and 1,3-COD or even to cyclooctene in the presence of the nickel cyanide complex and excess sodium borohydride. Indeed, experiments indicated that 1,4-COD is formed first and then followed by 1,3-COD. No cyclooctene was detected with $Ni(CN)_2(P\phi_3)_2$. On the other hand, cyclooctene was produced more or less with the other two complexes, of which $Ni(CN)_2$(phen) gave rise to more cyclooctene. The result is again consistent with the isomerization and hydrogenation data of DMM mentioned above.

In Fig. 1 is plotted the composition of 1,4-COD and 1,3-COD produced against the degree of conversion of 1,5-COD for $Ni(CN)_2(P\phi_3)_2$ at 0°C. Assuming now that the isomerization of 1,5-COD obeys a consecutive, reversible first-order kenetics as

$$\text{1,5-COD} \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} \text{1,4-COD} \underset{k_{-2}}{\overset{k_2}{\rightleftarrows}} \text{1,3-COD},$$

rate constants were calculated according to the Runge-Kutta-Gill method.[3] That is, k_{-1}, k_2 and k_{-2} were computed so as to best fit the experimental plots of Fig. 1 with the aid of the observed value for k_1, the k_1 being evaluated from the initial rates for 1,5-COD decay. These values are shown below.

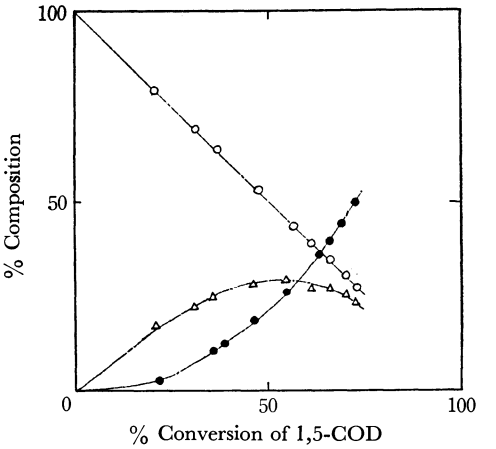

Fig. 1. Catalytic isomerization of 1,5-COD to give 1,4-COD and 1,3-COD in the presence of $Ni(CN)_2(P\phi)_2$ and excess $NaBH_4$ at 0°C.
1,5-COD: 8.3 mmol, $NaBH_4$: 2.0 mmol,
$Ni(CN)_2(P\phi_3)_2$: 0.1 mmol.
○: 1,5-COD, △: 1,4-COD, ●: 1,3-COD.

$$k_1 = 2.53\times10^{-3} \qquad k_{-1} = 4.25\times10^{-5}$$
$$k_2 = 4.25\times10^{-3} \qquad k_{-2} = 4.25\times10^{-6}\ \mathrm{sec^{-1}}$$

The solid lines of Fig. 1 refer to concentrations of substrate and products as calculated by the rate constants. Here, k_{-1} and k_{-2} should be regarded as only upper limit since lower values appeared also well suited. The validity of these values are still under investigation.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 2724—2725 (1969)

The Effect of Deuterium Exchange of Silica Gel on Dielectric Relaxation*1

Masa-aki MUROYA* and Seiichi KONDO**

* *Osaka Electro-Communication University, Neyagawa, Osaka*

** *Osaka University of Education, Tennoji, Osaka*

(Received March 14, 1969)

In a previous paper,[1] a study was made on the influence of adsorbed water and heat treatment of silica gel on its dielectirc properties with respect to surface structure. Two dielectric relaxations (Dispersion I and II) and one anomaly (Anomaly III) were found and interpreted as having close relation with the adsorbed water, the hydrogen-bond chain of surface silanol groups and free silanol groups, respectively.

This interpretation seems to have further experimental support by the dielectric investigation of deuterated silica gel shown in this paper.

Experimental

The material and the experimental procedure were the same as described.[1] The deuterium exchange of silica gel was carried out by repeating adsorption and desorption of heavy water of 99.8% purity 6 times.[2] The concentration of deuterium with respect to the original hydrogen content was estimated to be roughly 60 to 70% by assuming this concentration approximately equal to the ratio of the intensity decrease of the OH stretching vibration band at 3750 cm^{-1} to the original intensity.

Results and Discussion

The curves *a*, *b*, *c* and *d* in Fig. 1 show the relation of the values of tan δ at 1 kHz to the temperature of deuterated silica gel having 0.50 and 2.7 mmol D_2O per 1 g silica gel and heat-treated at 200°C and 500°C, respectively. The behavior of these curves seems very similar to the dotted curves *a'*, *b'*, *c'* and *d'* of ordinary silica gel having 0.56 and 2.9 mmol H_2O per 1 g silica gel (equal to 1.0 and 5.3 wt% H_2O respectively) and heat-treated at 200°C and 500°C, respectively. The tan δ anomalies of curves *a* and *b* can be considered as the dielectric relaxations (Dispersion I' and II') by the Cole-Cole arc plot calculated from these curves partly shown in Fig. 2. The shape and size of these arcs are almost similar to those of Dispersion I and II of light-water silica gel as also shown in Fig. 2. Disappearance of the higher temperature relaxation (Dispersion I') by

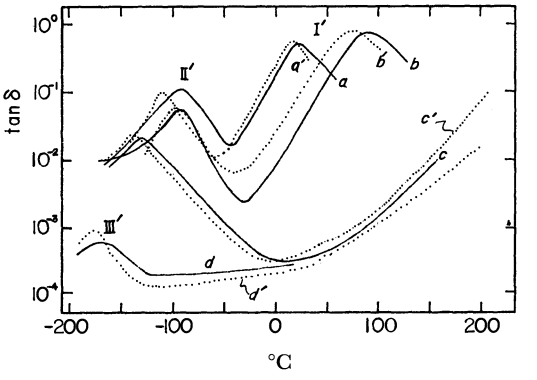

Fig. 1. The curves of tan δ *versus* temperature of deuterated and ordinary silica gel.
a and *a'*: 2.7 and 2.9 mmol D_2O and H_2O/1 g silica gel at 170°C, respectively. *b* and *b'*: 0.50 and 0.56 mmol D_2O and H_2O/1 g silica gel, respectively. *c* and *c'*: heat treatment at 200°C. *d* and *d'*: heat treatment at 500°C.

2) A. Soffer and M. Folman, *Trans. Faraday Soc.*, **62**, 3559 (1966); J. B. Peri and R. B. Hannan, *J. Phys. Chem.*, **64**, 1526 (1960).

heating at 200°C (see curve *c* in Fig. 1) shows that this relaxation originates in heavy water adsorbed, as seen analogously in the thermal behavior of Dispersion I. A similar discussion on Dispersion II′ leads to the view point that Dispersion II′ is caused by the shift of Dispersion II by deuterium exchange. The curves of ε' and ε'' versus frequency of Dispersion I′ and II′ show that these dispersions seem to be the same type as Dispersion I and II respectively. The tan δ anomaly (Anomaly III′) in curve *d* of Fig. 1 can be interpreted also as the shift of Anomaly III.

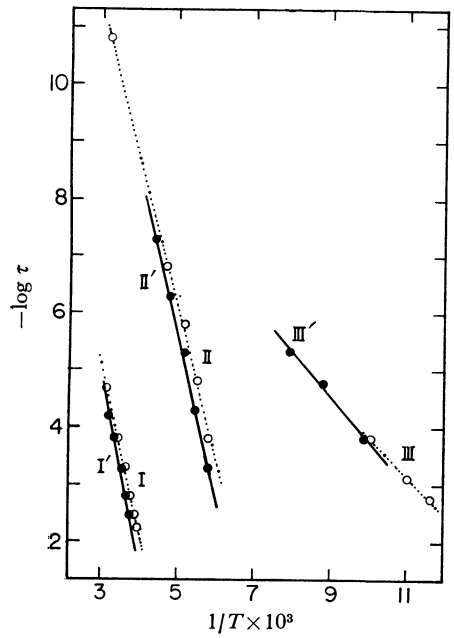

Fig. 3. The relationship of reciprocal temperature to log τ of Dispersion I′, I, II′ and II and log $\frac{1}{2}\pi f$ of Anomaly III′ and III.
●: D_2O exchange ○: H_2O-silica gel

The full lines of Fig. 3 show the relation of the relaxation times, log τ, of Dispersion I′ and II′ and the log $\frac{1}{2}\pi f$ of Anomaly III′, in which f is the frequency of ε'' maxima obtained from the ε''-temperature relation, to the reciprocal temperature $(1/T)$. The corresponding lines of light-water silica gel as shown by dotted lines in this figure are very close to the full lines. The activation energies ΔE and constants τ_0 of Dispersion I′, II′ and Anomaly III′ obtained from Fig. 3, together with those of Dispersion I, II and Anomaly III, are listed in Table 1. In reference to the effect of the amount of adsorbed water on the values of ΔE and τ_0 examined in a previous work,[1] the small difference of mol% of adsorbed water between heavy and light-water would not give an appreciable change in the values of ΔE and τ_0 of dielectric relaxation. In this table, the value of ΔE increases and τ_0 decreases by deuterium exchange. Further investigation is necessary for the more detailed discussion on the values of ΔE and τ_0 of these relaxation phenomena of deuterated silica gel.

Table 1. Activation energy ΔE and constant τ_0 of dispersion I′, I, II′, II, anomaly III′ and III of deuterated and ordinary silica gel

Dispersion	Water content or heat-treatment temperature	ΔE (kcal/mol)	τ_0 (sec)
I′	2.7 mmol D_2O/1 g SiO_2	14.8±0.2	3.3×10^{-16}
I	2.9 mmol H_2O/1 g SiO_2	13.5±0.2	2.8×10^{-19}
II′	0.50 mmol D_2O/1 g SiO_2	12.3±0.2	5.0×10^{-19}
II	0.56 mmol H_2O/1 g SiO_2	11.4±0.2	2.0×10^{-18}

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 2725—2728 (1969)

Chemical Studies of Minerals Containing Rarer Elements from the Far East. LXIII. Bastnaesite from Karasugawa, Fukushima Prefecture, Japan

Kin-ichi SAKURAI,* Hisanobu WAKITA,** Akira KATO* and Kozo NAGASHIMA**

* *Department of Geology, National Science Museum, Ueno Park, Tokyo*

** *Department of Chemistry, Faculty of Science, Tokyo Kyoiku University, Otsuka, Tokyo*

(Received March 18, 1969)

The chemical analysis of bastnaesite formed as an alteration product of allanite from a granite pegmatite at Karasugawa, Nashidaira, Fukushima Prefecture, gave: Rare earths 74.4, CO_2 12.8, F 6.4, $H_2O(+)$ 2.1, $H_2O(-)$ 1.5, Rem. 3.3, $-O=F$ 2.7, total 97.8%. The distribution pattern of lanthanide elements agreed well with that of the ordinary bastnaesite. The infrared absorption spectra indicate the vicarious substitution of OH^- for F^-.

Occurrence

The Karasugawa pegmatite is situated at Nashidaira, Fukushima City, and has been worked for feldspar and quartz for several years. It is in a biotite granodiorite body and is composed mainly of microcline-perthite and quartz with large tourmaline crystals. In this pegmatite β-fergusonite,[1,2] xenotime,[3] zircon, and monazite are known to occur. The present study has added bastnaesite to this list; this is the first reported occurrence of this mineral in Japan.

The bastnaesite found in the quarry dump occurs as an alteration product of allanite in microcline-perthite crystals containing quartz and muscovite, surrounding the allanite as a white, powdery crustification or replacing it. The other associated mineral is dark brown granular xenotime, with $a_0=6.91_8$Å and $c_0=6.06_0$Å, according to the X-ray powder study. Generally the allanite crystals are long and prismatic, less than one centimeter in length and two millimeters in diameter.

X-Ray Powder Diffraction and Optical Studies

The X-ray powder study was made on hand-picked material and gave the powder data shown in Table 1, in which the data for bastnaesite from Birthday Claim, Mountain Pass, California (Glass *et al.*, 1958)[4] are also tabulated for the sake of comparison. The present data are indexed with a hexagonal symmetry, with $a_0=7.10_1$Å and $c_0=9.75_0$Å; this satisfies the extinction rule required by the $P\bar{6}2c$ space group except for $(20\bar{2}2)$.

Under the microscope, it is seen to be an aggregate of very fine grains. For this reason, the refractive indices measured are not always accurate. They are $n_1=1.72\pm0.01$ and $n_2=1.82\pm0.01$ respectively, both very close to the ω and ε of values bastnaesites hitherto studied.

Chemical Composition

The results of chemical analysis carried out on about 20 mg of hand-picked material are given in Table 2, together with those on F- and OH-bastnaesite obtained in Aleksandrov's study[5] and with those of the ideal bastnaesite with the formula of $CeFCO_3$. The H_2O content of Karasugawa bastnaesite is higher than that of natural F-bastnaesite, but lower than that of natural OH-bastnaesite,

Table 2. Chemical analysis

suggesting partial replacement of F^- ions by OH^- ions.

The Distribution Pattern of Rare Earth Elements

The distribution of lanthanum-group elements was determined by the X-ray fluorescent method; we found lanthanum, cerium, praseodymium, samarium, and gadolinium, with the maxima at lanthanum and cerium. The quantitative estimation obtained as atomic percentages including a relative error of less than 10% is plotted the *versus* atomic numbers in Fig. 1; the figure shows a fundamental coincidence between the distribution pattern of the present bastnaesite and that called the "allanite type" by Goldschmidt and Thomassen.[6]

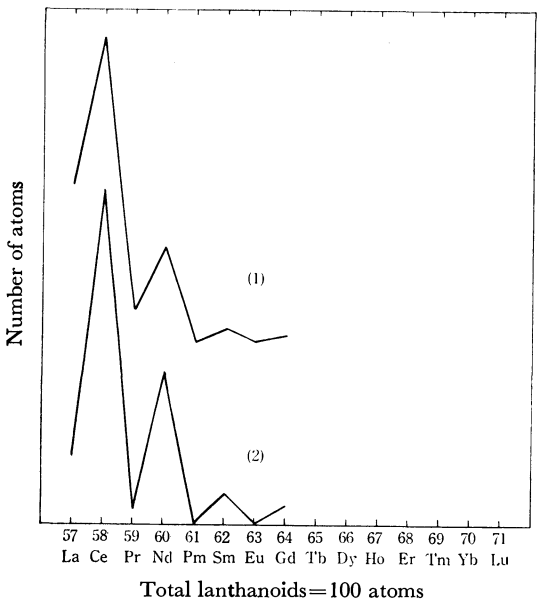

Fig. 1. Distribution of rare earth elements.

(2) Bastnaesite from Karasugawa (this work)

Infrared Spectroscopy

The presence of OH^- ions instead of F^- in bastnaesite is very probable, as is indicated by the X-ray diffraction study showing the isostructural relation between OH-bastnaesite and F-bastnaesite, both of which belong to the same space group, D_{3h}^4. The infrared spectrum of the natural OH-bastnaesite, composed of superposed two kinds of spectra[7], involves carbonate groups with a local symmetry of C_{3h} and with less symmetrical surroundings. The former gives rise to no band splitting, whereas the latter does as a result of the presence of OH^-.

In the infrared spectra of the present heated bastnaesite, there are absorption bands of strong or medium intensities at the following frequencies: 3630, 3470, 1450, 1020, 870, 730, and 680 cm^{-1}. Basically the spectrum is determined by the vibrations of the $(CO_3)^{2-}$ group, which has D_{3h} point symmetry and C_{3h} local symmetry in the unit cell of bastnaesite. The absorption bands at 3630, and 3470 cm^{-1} are attributable to absorption by the OH group, while that at 1020 cm^{-1} may be attributed to absorption by impurities in natural bastnaesite (SiO_2, Al_2O_3). The absorption at 1660 cm^{-1} due to molecular water is not strong. The spectrum of our sample was less split than that of M.V. Akhmanova. Chemical analysis shows that Karasugawa bastnaesite has a lower H_2O content than the OH-bastnaesite in Akhmanova's

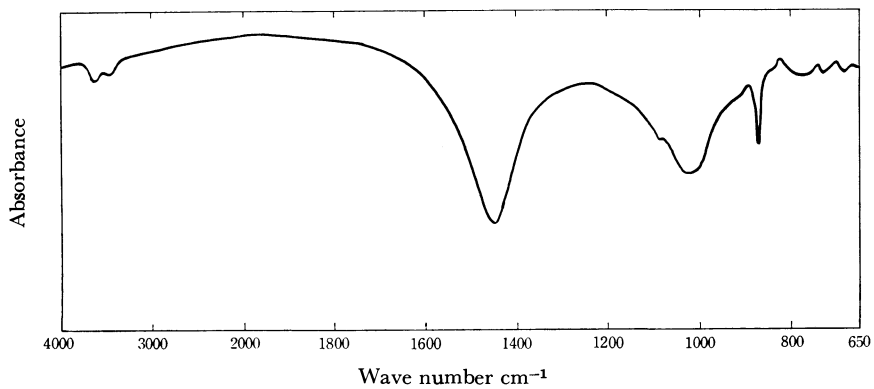

Fig.2. Infrared spectra of Karasugawa bastnaesite.

study, so the infrared spectrum of Karasugawa bastnaesite may be less split than that of Akhmanova.

The authors wish to express their thanks to Mr. Otokichi Nagashima for his interest in this work, and for his help in collecting the materials. We also wish to thank Mr. Kyuzaburo Furuhashi for determining water and carbon dioxide contents for us.

Alternate Copolymerization of Acrylonitrile and Isobutylene

Masanobu TANIGUCHI,* Akihiro KAWASAKI* and Junji FURUKAWA**

* *Maruzen Petrochemical Co., Ltd., Ichihara, Chiba*

** *Department of Synthetic Chemistry, Faculty of Engineering, Yoshida, Kyoto*

(Received March 20, 1969)

The polymerization of isobutylene and acrylonitrile was described in a patent,[1] in which copolymerization was carried out in the presence of $ZnCl_2$ as a complexing agent together with organic peroxide as an initiator, but the structure of the copolymer has not yet been established. Gaylord *et al.*[2] assumed the copolymer to be of an alternate structure from the fact that the copolymer is always of 1:1 composition irrespective of the variation of the composition of feed monomers, but no chemical evidence for the alternate structure was afforded.

Hirooka *et al.*[3] reported the preparation of 1 : 1 copolymer from acrylonitrile and α-olefin such as styrene and propylene and concluded the alternate structure by means of IR analysis. They found $AlEtCl_2$ to be a good complexing agent, which initiates polymerization without any initiator, but neither $AlEt_3$ nor $AlCl_3$ was effective.

We have made the 1 : 1 copolymer of isobutylene and acrylonitrile in good yield in a similar way to the patent except for using $AlCl_3$ and peroxide and have established the structure of the copolymer to be alternate.

The polymerization was carried out as follows. A 25 cc glass tube was charged with 2 cc of toluene, 0.5 mmol of benzoyl peroxide, 50 mmol of acrylonitrile containing 1 mmol of $AlCl_3$ and 50 mmol of isobutylene under nitrogen atmosphere at −78°C. Subsequently the tube was sealed and was subjected to polymerization at 25°C. After 20 hr, 0.256 g of white polymer was obtained. It was completely soluble in acetone and this fact indicates that the product is a copolymer since each homopolymer is insoluble in acetone. The polymer possesses an intrinsic viscosity of 0.15 dl/g at 30°C in chloroform and contains 52 mol% of acrylonitrile unit according to an elementary analysis.

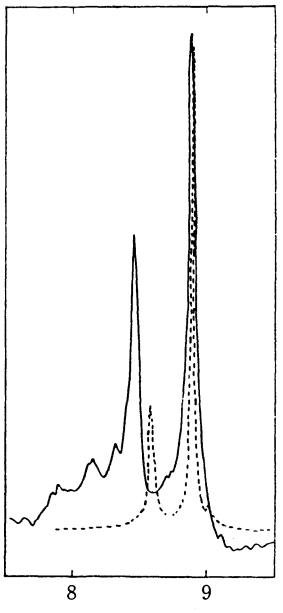

Fig. 1. NMR spectrum of alternate copolymer of acrylonitrile with isobutylene (——) and that of polyisobutylene (------).

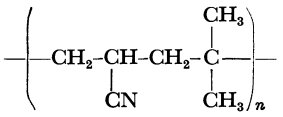
The NMR spectrum shown in Fig. 1 was obtained in deuterated chloroform at 25°C by using TMS as a standard. The peak at 8.60 τ of methylene protons of polyisobutylene disappears completely, showing no existence of an isobutylene-isobutylene repeating unit, and a new peak appears at 8.40 τ in the spectrum of the copolymer. The strong peak at 8.85 τ corresponds to the strong peak at 8.89 τ of homopolymer of isobutylene which is ascribed

1) G. E. Serniuk and R. T. Thomas, U. S. Pat. 3183217 (1965).

2) N. G. Gaylord and A. Takahashi, paper presented at ACS Meeting, San Francisco, April 1968.

3) M. Hirooka, H. Yabuuchi, S. Morita, S. Kawasumi and K. Nakaguchi, *J. Polymer Sci., B*, **5**, 47 (1967).

to methyl protons, because the ratio of peak area at 8.40 τ of methylene protons to that at 8.85 τ of methyl protons in the copolymer is 4 : 6, whereas the area ratio of the peak at 8.60 τ to that at 8.89 τ in homopolyisobutylene is 2 : 6. Accordingly the copolymer may be a 1:1 copolymer of acrylonitrile and isobutylene and the 8.40 τ peak may be ascribed protons of the alternate copolymer. The following is the structure of the alternate copolymer.



We wish to express our thanks to Nippon Electric Varian, Ltd. for their cooperation in obtaining NMR spectra.

A Convenient Method for the Preparation of Poly(Vinyl Alcohol) from Poly(*t*-Butyl Vinyl Ether)

Gentaro OHBAYASHI, Shun-ichi NOZAKURA and Shunsuke MURAHASHI

Faculty of Science, Osaka University, Toyonaka, Osaka

(Received March 29, 1969)

t-Butyl vinyl ether, like benzyl vinyl ether and trimethylsilyl vinyl ether, is known as a starting monomer for the synthesis of isotactic poly(vinyl alcohol). Poly(*t*-butyl vinyl ether) has been converted into poly(vinyl alcohol) by two methods. Fujii *et al.* converted poly(*t*-butyl vinyl ether) into ploly(vinyl acetate) by direct acetylation reaction with acetic anhydride and Lewis acid; they then saponified the resultant poly(vinyl acetate) to poly(vinyl alcohol).[1] Okamura *et al.* converted poly(*t*-butyl vinyl ether) into poly(vinyl alcohol) by the cleavage reaction of the ether bond with dry hydrogen bromide[2] in a manner similar to that used in the case of poly(benzyl vinyl ether).[3] However, since the reaction conditions are rather drastic, more or less colored poly(vinyl alcohol) specimens are usually obtained.

The present authors wish to report a more convenient method for the preparation of poly(vinyl alcohol) from poly(*t*-butyl vinyl ether) using a 46% aqueous solution of hydrogen fluoride. By this method, the procedure can be extremely simplified and colorless poly(vinyl alcohol) can be obtained.

t-Butyl vinyl ether was polymerized with $BF_3 \cdot O(C_2H_5)_2$ as an initiator in toluene at $-78°C$ under a nitrogen atmosphere. ($[M]_0=20$ vol%, $[Cat]=2\times10^{-3}$ mol/*l*). These reaction conditions are known to yield an isotactic poly(*t*-butyl vinyl ether). The resultant polymer was purified by reprecipitation into methanol from a toluene solution. The polymer thus obtained had an intrinsic viscosity $[\eta]$ of 0.356 (d*l*/g) in benzene at 30.4°C.

Found: C, 71.97; H, 12.03%. Calcd for $C_6H_{12}O$: C, 71.94; H, 12.08%.

The cleavage reaction of the polymer into poly(vinyl alcohol) was carried out in a polyethylene beaker. To 0.355 g of poly(*t*-butyl vinyl ether), 5 m*l* of a 46% aqueous solution of hydrogen fluoride was added. The reaction mixture was kept standing at room temperature and shaken occasionally. After 1 hr, the reaction mixture became homogeneous; it was kept standing for 2 more hours. The solution was then subjected to dialysis using a cellophane membrane. The dialyzate was freeze-dried to give 0.123 g of colorless poly(vinyl alcohol).

The poly(vinyl alcohol) obtained had a specific viscosity, η_{sp}, of 0.515 for a 0.905 g/d*l* aqueous solution at 30.0°C.

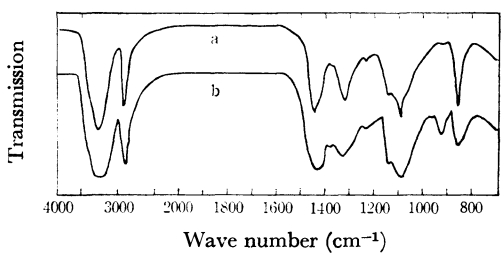

Fig. 1. Infrared spectra of isotactic (a) and atactic (b) poly (vinyl alcohol) prepared from poly(*t*-butyl vinyl ether).

3) S. Murahashi, H. Yuki, T. Sano, U. Yonemura, H. Tadokoro and Y. Chatani, *J. Polymer Sci.*, **62**, 77 (1962).

Found: C, 54.26; H, 9.14%. Calcd for C_2H_4O: C, 54.53; H, 9.15%. The results of elementary analysis make it clear that pure poly(vinyl alcohol) was obtained by this method. The infrared spectrum of a film prepared from an aqueous solution of the resultant poly(vinyl alcohol) showed that the conversion was complete; it coincided with that of the isotactic poly(vinyl alcohol) obtained previously.[4]

Atactic poly(vinyl alcohol) was similarly obtained from atactic poly(*t*-butyl vinyl ether), which had itself been obtained with $BF_3 \cdot O(C_2H_5)_2$ in methylene chloride at $-78°C$ ($[M]_0=20$ vol%, $[Cat]=2\times10^{-3}$ mol/*l*).

The infrared spectra of the isotactic and atactic poly(vinyl alcohol) thus obtained are shown in Fig. 1.

SHORT COMMUNICATIONS

Photolytic Formation of a Ferrocenyl Radical from Iodoferrocene[1]

Takeo SATO, Shigeru SHIMADA and Kazuo HATA

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya-ku, Tokyo

(Received July 11, 1969)

Although a number of studies have been carried out on ferrocene chemistry, not many of them deal with the generation and characterization of a ferrocenyl radical. Existence of the latter as a reactive intermediate in the reactions of metal derivatives, such as lithioferrocenes[2] and ferrocenylmercury derivatives[3] has been postulated by only a few authors.

We wish to report an attempt to generate the ferrocenyl radical by a photolytic method from iodoferrocene. Dilute solutions of iodoferrocene in appropriate solvents (*ca.* 8.5×10^{-3}M) were irradiated externally using a 100-W low-pressure (100-L) or 1-kW high-pressure lamp (1000-H). Since the ferrocene nucleus is sensitive to oxygen, especially upon illumination, all reactions have been carried out under nitrogen or using degassed solutions. Analysis of the reaction mixture was performed by gas chromatography using silicone grease on a Daichrom column.

Irradiation in cyclohexane resulted in the reductive deiodination to give ferrocene, which was obtained in 20% yield with 45 hr reaction (1000-H lamp, Pyrex filter):

$$FcI \xrightarrow{h\nu,\ C_6H_{12}} FcH$$

The rest of the material was recoverable as iodoferrocene. Irradiation in benzene produced phenylferrocene and a small amount of ferrocene:

$$FcI \xrightarrow{h\nu,\ C_6H_6} FcH + FcC_6H_5$$

The representative data are summarized in Table 1. Thus by using 253.7 mμ line (100-L), phenylferrocene was obtained in as high as 89% yield, which is far better than other methods so far described.[4] It is noteworthy that the reaction does not show any marked dependence on the wavelengths employed. A similar reaction carried out in toluene for 47 hr (1000-H lamp, quartz filter) produced ferrocene (24%) and tolylferrocenes (50%), together with bibenzyl (9%). These results are best interpreted by assuming the intermediacy of the ferrocenyl radical.

TABLE 1. PHOTOLYSES OF IODOFERROCENE IN BENZENE

New Addition Reactions of Acrylic Compounds with Fumaric Acid Esters Catalyzed by Tervalent Phosphorus Compounds

Ken-ichi MORITA and Tsuneo KOBAYASHI

The Basic Research Laboratory, Toyo Rayon Company, Kamakura

(Received April 11, 1969)

Dimerization of acrylonitrile or acrylic acid esters catalyzed by tervalent phosphorus compounds has been studied in great detail,[1,2] since the reaction furnishes industrially important products.[3] However, the study of the catalyzed reaction has been restricted only to dimerization.[4] In a previous paper,[5] we reported the reaction of acrylonitrile or acrylates with aldehydes to produce 2-(1-hydroxyalkyl)acrylonitriles or -acrylates in the presence of tertiary phosphines. This paper deals with the synthesis of 3-butene-1,2,3-tricarboxylic acid, a new tricarboxylic acid, and related compounds by the reaction of acrylic compounds with fumaric, or maleic acid esters.[6]

$$CH_2{=}CHX + ROOCCH{=}CHCOOR \xrightarrow{R_3P} \begin{matrix} CH_2{=}C(X) \\ | \\ CH(COOR) \\ | \\ CH_2(COOR) \end{matrix}$$

1 X=CO_2CH_3, R=C_2H_5
2 X=COOH, R=H
4 X=CN, R=C_4H_9

The reaction of 34.3 g (0.40 mol) of methyl acrylate, 67.0 g (0.39 mol) of diethyl fumarate and 1.5 g (5.4 mmol) of tricyclohexylphosphine in 100 m*l* of dioxane in an atmosphere of nitrogen at 70°C for 16 hr gave 95.7 g (95.5%, yield)[7] of 3-butene-1,2,3-tricarboxylic acid 1,2-diethyl-3-methyl ester (**1**) as a colorless liquid,[8] bp 101—102°C (3×10^{-3} mmHg); n_D^{20} 14502, $\lambda_{max}^{n\text{-hexane}}$ 213 mμ (ε, 5790); ν_{max}^{film} 1737 cm^{-1} (shoulder at 1721 cm^{-1}) (esters).

An acid hydrolysis of **1** gave 3-butene-1,2,3-tricarboxylic acid (**2**), mp 184—185°C: ν_{max}^{KBr} 1697, 1721 cm^{-1} (C=O); pK_1, 3.18, pK_2, 4.52, pK_3, 5.99. Catalytic hydrogenation of **1** over palladium charcoal followed by an acid hydrolysis furnished a mixture of diastereoisomers of 1,2,3-butanetricarboxylic acid (**3**), *i. e.*, a major component mp 181—182°C (lit., mp 182°C[9]; 184—185°C[10]) and a minor one, mp 147—148°C (lit.,[11] mp 146—147°C). Thermal decomposition of **2** at its melting point gave dimethylmaleic anhydride mp 94°C (lit.,[12] mp 95—96°C).

An analogous reaction of acrylonitrile with dibutyl fumarate in the presence of tricyclohexylphosphine at 100°C for 16 hr gave a mixture of dibutyl (1-cyanovinyl)succinate (**4**) and dibutyl (1-cyanoethylidene)succinate bp 128—129°C (0.1 mmHg); ν_{max}^{film} 1743 cm^{-1} (shoulder at 1723 cm^{-1}) (C=O), 2211 cm^{-1} (C≡N).

1) N. Takashima and C. C. Price [*J. Am. Chem. Soc.*, **84**, 489 (1962)] found that acrylonitrile is converted into 1,1,4,4-tetracyanoethyl-1,4-dicyano-*trans*-2-butene, in the presence of triphenylphosphine, and suggested a dimer of acrylonitrile to be probably a precursor of the hexamer.

Aromatic Benzoyloxylation with Benzoyl Peroxide - Iodine

Shizunobu HASHIMOTO, Wataro KOIKE and Masafumi YAMAMOTO

Department of Applied Chemistry, Doshisha University, Karasuma-imadegawa, Kamikyo-ku, Kyoto

(Received May 28, 1969)

Recently it was reported that the reaction products of benzoyl peroxide (BPO) with aromatic substrates could be modified by the presence of cupric chloride[1,2] or oxygen.[3] In such cases, BPO acted as an oxygenating agent on an unactivated aromatic nucleus. In 1945, Perret and Perrot[4] reported their findings on the reaction products of BPO with unsaturated compounds in the presence of iodine. With aromatic compounds, benzoic acid, the aryl benzoates, and the iodinated products were identified, but the yields of the monobenzoyloxylated products were poor. Little has been reported, however, about either the qualitative or mechanistic aspects of this reaction.

We wish here to report that aromatic compounds are benzoyloxylated in high yields by BPO in the presence of small amounts of iodine. Pure monooxygenated materials are obtained by this method of aromatic substitution; this suggests possible synthetic usefulness and also provides the possibility of a new route for aromatic oxygenation.

A toluene solution of BPO was mixed with iodine and heated at 80°C. Figure 1 shows the variation in the yields of phenyltoluenes, tolyl benzoates, and benzoic acid as a function of the initial concentration of iodine. In a control experiment with the peroxide and toluene, less than 3 mol% of the nuclear oxygenation product was found. As the initial concentration of iodine was increased, however, the formation of tolyl benzoates and benzoic acid became the major pathway. When the molar ratios of iodine to BPO are below 0.25, the amount of the oxygenation product decreased substantially. On the other hand, above this ratio the yield of tolyl benzoates and benzoic acid increased to 72—79 mol% and 80—92 mol% respectively. Small amounts of phenyltoluenes, iodobenzene, and iodotoluenes were also obtained.

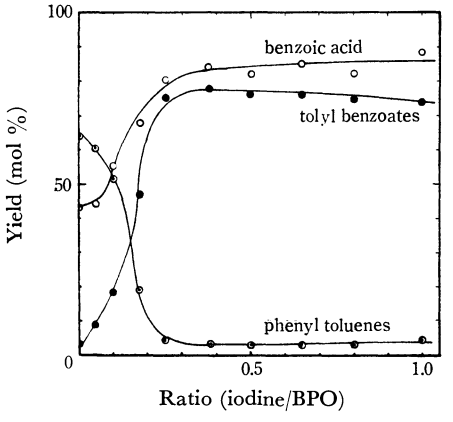

Fig. 1. Variation in iodine:BPO ratio.
BPO; 0.025 mol, Toluene; 100 ml, 80°C, 50 hr

The relative rates for this benzoyloxylation of a number of monosubstituted benzenoid compounds relative to benzene (obtained by the competitive method, using gas-liquid chromatography for the analysis of the products of the competition) were: PhOMe : PhEt : PhMe : PhPr-*i* : PhH : PhCl=6.27: 3.10 : 2.85 : 2.18 : 1 : 0.20. The isomer distribution and the partial rate factors (f) for toluene were *o*-, 53% *m*-, 16% and *p*-, 31%, and $f_o=4.53$ $f_m=1.37$ and $f_p=5.30$.

The effects of substituents on the peroxide were also examined by carrying out the reaction of *p,p'*-disubstituted benzoyl peroxide with benzene in the presence of iodine at 80°C. The mol% yields of phenyl *p*-substituted benzoate was OCH_3 : CH_3 : H : Cl : Br=86.5 : 84.0 : 75.3 : 94.6 : 95.0.

On the basis of our experimental findings, it seems that the oxidizing agent is not a polar intermediate but a benzoyloxy radical which exhibits electrophilic properties.[2] The ester could arise from the capture of **1** by iodine, an efficient radical scavenger, followed by the loss of hydrogen iodide. In the absence of iodine, the initially-formed free radical **1** is not sufficiently stable to allow the formation of the ester; hence, the benzoyloxy radical is free to undergo decarboxylation, with the resultant formation of phenylated products.

Fluorescence Spectra of High-purity Coronene Thin Film

Takashi KAJIWARA, Koichi OHNO, Satoshi IWASHIMA and Hiroo INOKUCHI

The Institute for Solid State Physics, The University of Tokyo, Roppongi, Tokyo

(Received June 13, 1969)

Commercial and synthesized crude coronene contains perylene as an impurity, and its fluoresence spectra depend much on the degree of purification.[1]

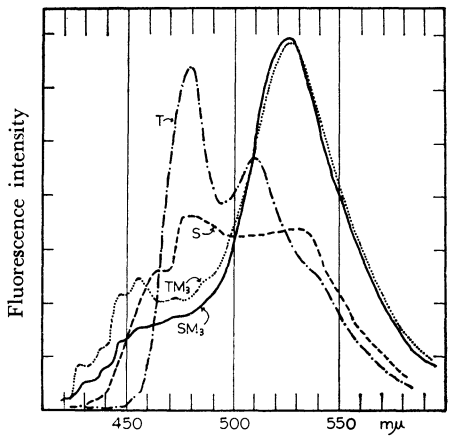

Fig. 1. The fluorescence spectra of the sublimed thin films of coronene of various degrees of purity at room temperature.
T: Commercial coronene, (crude).
S: Synthesized coronene, (crude).
TM_3: Commercial coronene purified by treatment with maleic anhydride for 3 hr (see text).
SM_3: Synthesized coronene purifide by treatment with maleic anhydride for 3 hr (see text).

Figure 1 shows the fluorescence spectra of sublimed thin films of coronene at room temperature. High-purity coronene (TM_3 and SM_3 in Fig. 1) shows a broad excimer-type fluorescence around 525 mμ, as do pyrene, α-type perylene, and benzo[*g,h,i*]perylene. The maxima around 480 mμ and 510 mμ of the fluorescence of crude coronene (T and S in Fig. 1) are due to those of perylene, because these maxima are enhanced as the concentration of perylene in the coronene matrix is increased.[2] The sample denoted as T in Fig. 1 contains about a 10^{-3} mol/mol concentration of perylene. Though benzo[*g,h,i*]perylene is also included in crude coronene, its influence on the fluorescence spectra of solid coronene is not obvious.

Figure 2 shows the temperature dependence of the fluorescence spectra of a sublimed thin film of high-purity coronene (SM_3). As the temperature decreases, the fluorescence bands around 446 mμ and 474 mμ gradually increase and the broad band around 525 mμ decreases. When the sample specimen is cooled to 4.2°K, the broad band disappears and the spectra with distinct vibrational structures appear; these spectra are similar to the fluorescence spectra in its *n*-heptane solution.[3] It is remarkable that the vibrational structures show a fairly good correspondence with the faint structures observed in the short-wavelength region (430 mμ—480 mμ) of the fluorescence spectra at room temperature. It is also interesting that the fluorescence spectra at 77°K are very different from those at 4.2°K. The measurement of the fluorescence spectra in the temperature region from 77°K to 4.2°K will now be undertaken.

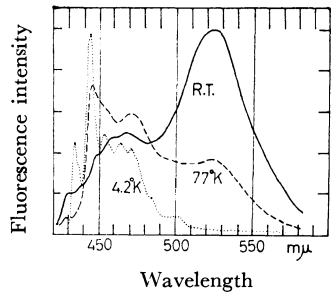

Fig. 2. Temperature dependence of the fluorescence spectra of a sublimed thin film of high purity coronene (SM^3). The relative fluorescence intensity is not corrected.
Fluorescence maxima: at 4.2°K, 434, 436, 443, 453, 464, 469, 484, and 502 mμ.

The method of purification is as follows.[4] A crude (commercial or synthesized) coronene is treated for more than 3 hr with maleic anhydride, upon which perylene and benzo[*g,h,i*]perylene change to carboxylic acid anhydride. These anhydrides are then eliminated by precipitation, making use of the fact that their solubilities in the solvent, xylene, are much less than that of coronene. Further, the coronene is purified by repeated recrystallizations and sublimations. The perylene concentration in the matrix can be decreased to less than 10^{-5} mol/mol by these procedures.

1) The same phenomena are observed in benzo[*g,h,i*]perylene. T. Kajiwara, I. Shirotani, H. Inokuchi and S. Iwashima, *J. Mol. Spectry.*, **29**, 454 (1969).

The Photochromism of Evaporated Photospiran

Hajime KOBAYASHI, Isamu SHIMIZU, Mitsunobu NAKAZAWA, Hiroshi KOKADO and Eiichi INOUE

Tokyo Institute of Technology, Imaging Science and Engineering Laboratory, Ookayama, Meguro-ku, Tokyo

(Received June 26, 1969)

Photochromism in spiropyrans has been extensively investigated. We have reported the photochromic properties of 1,3,3-trimethylspiro(indoline-2,2′-benzopyran) (I) on adsorbent,[1] in solution[2] and in polymer film,[3] however, any distinct photochemical reaction of microcrystalline spiropyrans has never been reported.

We should now like to report that the thin layer of spiropyrans prepared by means of vacuum evaporation revealed a distinguished reversible photochemical reaction (photochromism).

Photospirans used are listed in Fig. 1. The samples were prepared with a hand-made vacuum evaporator. Evaporation was carried out under a pressure of about 10^{-5} mmHg and at suitable temperatures. As the base materials, glass or quartz plates were used.

In most derivatives, evaporated photospirans formed transparent and colorless uniform layers under microscopic inspection. However, in some derivatives crystallization proceeded during the course of evaporation. Evaporated photospirans, as well as those in solution, have no absorption band in visible region, but have specific absorption bands in ultraviolet region. The colorless state is transformed into corresponding colored state by irradiation with ultraviolet light (Fig. 1). The absorption spectra of the colored state are shown in Fig. 2. They have maxima near 6000Å. This behavior is similar to the solution of spiropyran in a non-polar solvent such as benzene. This indicates that there are no important intermolecular interactions between spiropyran molecules. The dark decoloration of colored species of the evaporated spiropyran proceeded according to a first order mechanism. In Table 1, the rate constants and the activation energies of dark decoloration are shown. Apparently, the colored forms of spiropyrans in evaporated state are thermally more stable than in solution or in polymer film. The photodecoloration efficiency is about the same in solution or in polymer film.

Some spiropyran such as II, crystallized during evaporation. In such circumstances photocoloration efficiency became very low and absorption spectrum was broadened. However, it was observed that such crystallization effect could be avoided by evaporation of the mixture of the compound with another derivative of spiropyran.

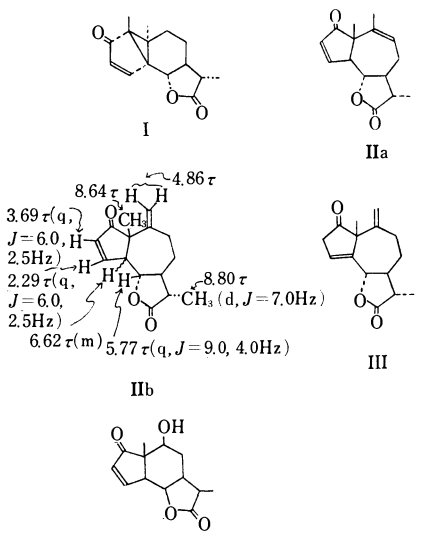
A Revised Structure of Pyrolumisantonin[1]

Tadashi SASAKI and Shoji EGUCHI

Institute of Applied Organic Chemistry, Faculty of Engineering, Nagoya University, Furo-cho, Chikusa-ku, Nagoya

(Received June 27, 1969)

The structure of pyrolumisantonin was given for the first time by Arigoni and his coworkers as IIa in 1957 on the basis of an ozonized product IV without NMR spectral evidence[2] and has been adopted again quite recently by Fisch and Richards.[3] During the course of our studies on the synthesis of some double bond derivatives of lumisantonin (I),[4] we have obtained pyrolumisantonin as a by-product, mp 127—129°C (lit.,[2] mp 126—127°C). It gave a satisfactory analysis (Found: C, 72.89; H, 7.30%. Calcd for $C_{15}H_{18}O_3$: C, 73.14; H, 7.37%) and had almost the same spectral data as those reported: $[\alpha]_D = -170°$ ($CHCl_3$, $c=0.265$, lit.,[2] $-171°$); λ_{max}^{EtOH} 219 mμ, log ε 4.06 (lit.,[2] λ_{max}^{EtOH} 220 mμ, log ε 4.07); ν_{max}^{KBr} 3090, 1843, 1635 and 920 ($C{=}CH_2$), 1769 (γ-lactone), 1705 and 1600 (cyclopentenone) cm^{-1} (the spectrum was superimposable on that reported[2]). In the NMR spectrum (Fig. 1), however, no signals due to an expected allylic methyl protons in the proposed structure IIa were observed but instead a sharp singlet signal integrated for two protons appeared at τ 4.86 which should be assigned to two *exo*-methylene protons and all other signals were compatible with the structure IIb. This led us to revise the structure of pyrolumisantonin from IIa to IIb. A double bond isomer (III) of pyrolumisantonin has been shown to isomerize to pyrolumisantonin by chromatography on alumina (neutral, grade II).[3] Our sample was treated similarly on an alumina (neutral, grade II) column using benzene as an eluent to afford needles, mp 128—130°C which showed no depression of a mixed melting point with a specimen before chromatography.



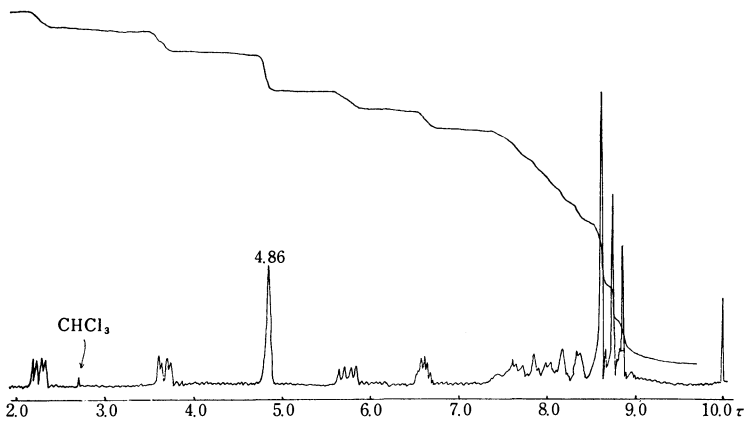


Fig. 1. NMR spectrum of pyrolumisantonin $CDCl_3$ (60 MHz).

Photochemical Benzoyloxylation with Labeled Benzoyl Peroxide

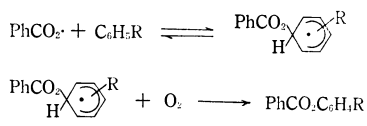
Michio KOBAYASHI, Hiroshi MINATO and Yoshikuni OGI

Department of Chemistry, Tokyo Metropolitan University, Fukasawa, Setagaya-ku, Tokyo

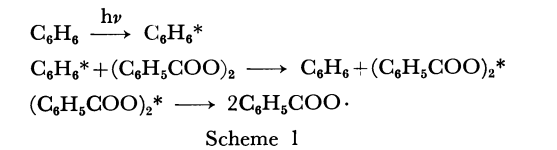
(Received July 3, 1969)

Nakata, Tokumaru and Simamura[1] studied the photochemical decomposition of benzoyl peroxide in aromatic solvents, and explained the formation of a considerable amount of aryl benzoate under oxygen atmosphere by the following mechanism.

All the experimental results were consistent with the above mechanism.

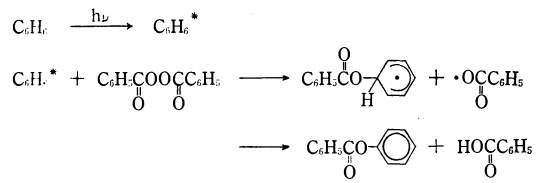


However, the mechanism of the photochemical excitation of benzoyl peroxide is not clear. On the basis of the findings that 1) very slow photolysis of benzoyl peroxide in cyclohexane was much accelerated by addition of benzene and 2) the decomposition of benzoyl peroxide was not retarded by the presence of oxygen, an effective quencher of triplet state excitation, they suggested that the decomposition of the peroxide in benzene was caused by the energy transfer from the benzene of an excited singlet state to the peroxide, followed by monomolecular decomposition of the peroxide, as shown in the following.



Scheme 1

Another possible mechanism is the direct attack of the excited benzene molecule upon the peroxide as shown in the following.



Scheme 2

By an analogy to the attack of trityl radical[2] and α-ethoxy-ethyl radical[3] upon the peroxide, the attack of the excited benzene is expected to take place on the peroxidic oxygen of the peroxide. If the benzoyl peroxide labeled with ^{18}O in the carbonyl oxygen were used, the phenyl benzoate produced *via* Scheme 1 should contain scrambled oxygen-18, whereas the phenyl benzoate produced *via* Scheme 2 should contain non-scrambled oxygen-18.

In an attempt to clarify the mechanism of the photochemical benzoyloxylation, we studied the products of decomposition of the benzoyl peroxide labeled with oxygen-18 in the carbonyl oxygen. A solution of 2.7 g of the labeled benzoyl peroxide in 500 m*l* of benzene (0.0223 mol/*l*) was irradiated with a high pressure mercury lamp either under a nitrogen atmosphere or with bubbling of oxygen gas (41 m*l*/min) at 18—20°C for 12 hr. By a separate experiment the half life of the peroxide under these conditions was found to be 55 min. After the reaction was over, the solution was evaporated to dryness, and the column-chromatographic separation of the residue gave 700 mg (in O_2) or 170 mg (in N_2) of pure phenyl benzoate. The carbonyl oxygen of phenyl benzoate or the starting peroxide was separated from alkoxy oxygen or peroxidic oxygen by the reaction with hydrazine. Benzhydrazide obtained was pyrolyzed and carbon dioxide evolved was assayed for oxygen-18 by mass spectrometry. The results are shown in Table 1.

They indicate that direct attack of excited benzene upon benzoyl peroxide does not occur to any appreciable extent. Therefore, as mechanism of the photochemical decomposition of benzoyl peroxide, Scheme 1 appears to be most probable.

Primary Kinetic Isotope Effect for Phenylation with Phenyl Radical[1)]

Michio KOBAYASHI, Hiroshi MINATO and Nobumasa KOBORI

Department of Chemistry, Tokyo Metropolitan University, Fukazawa, Setagaya-ku, Tokyo

(Received July 15, 1969)

Primary kinetic hydrogen isotope effect has been observed in the homolytic phenylation of aromatic compounds with the phenyl radical generated from benzoyl peroxide ($k_H/k_D=6.6$),[2)] but no primary isotope effect has been reported in the formation of biphenyls from the decomposition of phenylazotriphenylmethane or *N*-nitrosoacetanilide in deuteriobenzene. The isotope effect in the case of benzoyl peroxide has been attributed to the occurrence of disproportionation between phenylcyclohexadienyl radicals and the absence of isotope effect in the other two cases has been attributed to the non-occurrence of the disproportionation of phenylcyclohexadienyl radicals, which instead have suffered abstraction of hydrogen by triphenylmethyl radicals or phenylazooxide radicals.[3)]

TABLE 1. KINETIC ISOTOPE EFFECT FOR THE HOMOLYTIC AROMATIC PHENYLATION*

Run	Compound	k_H/k_D for the formation of substituted biphenyls		
		2-	3-	4-
1	PhC_6-d_5[a)]	1.10	1.13	1.23
2	$PhNO_2-d_5$[b)]	1.46	1.16	1.01
3	$PhNO_2-d_5$[c)]	2.3	—	1.06
		2,4-		2,6-
4	*m*-Dinitrobenzene-d_5[d)]	1.54		1.55

* All reactions were carried out at room temperature (20±3°C).

a) k_H/k_D was calculated from the partial rate factors which were determined gas-chromatographically from the competitive phenylations of C_6H_6-$C_6H_5NO_2$ and of C_6H_6 - $C_6D_5NO_2$.

b) k_H/k_D was determined by a mass spectrometer connected directly to the exit of a gas chromatograph to which nitrobiphenyl isomers obtained from the competitive phenylation of $C_6H_5NO_2$ - $C_6D_5NO_2$ were fed.

c) See text for method of determination.

d) The biphenyl isomers obtained from the competitive phenylation of *m*-dinitrobenzene - *m*-dinitrobenzene-d_4 were analyzed by the same method as that used for Run 3.

Our previous paper described the formation of phenyl radical from benzenediazonium tetrafluoroborate and sodium nitrite.[4)] We investigated the reaction with deuterated aromatics, and observed primary kinetic isotope effect in the phenylation with phenyl radical. Results are summarized in Table 1. The experimental procedure is described by use of Run 3 as an example. To a solution of nitrobenzene (40 mmol), pentadeuterionitrobenzene (40 mmol) and sodium nitrite (120 mmol) in DMSO (150 g), a solution of benzenediazonium tetrafluoroborate (34 mmol) in DMSO (70 g) was added at room temperature (20±3°C). A mixture of nitrobiphenyls obtained was separated to pure components by chromatography on an alumina column, and k_H/k_D was determined from the ratio of the parent peaks of a nitrobiphenyl and a tetradeuterionitrobiphenyl by mass spectrometry.

Quaterphenyls were not found in the product mixtures. The absence of the dimerization (and oxidation) product of phenylcyclohexadienyl radical must be due to efficient abstraction of hydrogen from phenylcyclohexadienyl radical.

The data in Table 1 may be explained on the basis of the steric effect. The larger values of k_H/k_D were observed for the formation of 2-nitrobiphenyl and 2,4- and 2,6-dinitrobiphenyls, all of which had a substituent at ortho position.

Another possible explanation is that with those substituents capable of stabilizing the intermediate phenylcyclohexadienyl radical by resonance the activation energy for the addition of phenyl radical to substituted benzene is lower and the addition step proceeds faster, and consequently the step of hydrogen abstraction makes greater contribution in the overall kinetic rate. It seems that in principle the isotope effect exists in the aromatic phenylation with phenyl radical and the isotope effect is observable only when the substituent is large enough and/or stabilizes the intermediate phenylcyclohexadienyl radical by resonance. We wish to propose the following mechanism, in which the addition of phenyl radical is reversible.

Reactions of Hydrazinium Thiocyanate with Alcohols

Isamu ARAI, Yasuo SATOH, Ichiro MURAMATSU and Akira HAGITANI

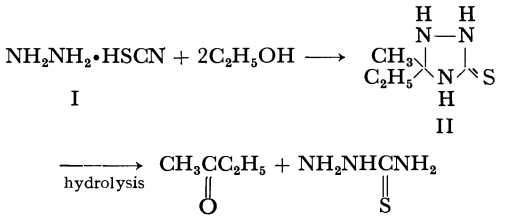
Department of Chemistry, Faculty of Science, St. Paul's University (Rikkyo Daigaku), Toshima-ku, Tokyo

(Received July 16, 1969)

During the course of an investigation of the reactions of thiocyanogen with acylhydrazines, it was found that hydrazinium thiocyanate (I) reacted with ethanol or 2-butanol, and in both cases an interesting heterocyclic compound, 3-ethyl-3-methyl-1,2,4-triazolidine-5-thione (II), was formed.

When a mixture of the aqueous solution of I and ethanol was allowed to stand at room temperature, white needles, II mp 116°C were obtained. The elemental analysis and MS spectral data of II gave a molecular formula $C_5H_{11}N_3S$. The IR spectrum (KBr) showed absorption bands at 3130, 2960, 2920, 2850, 1520, 1400, 1225, 1180, 960, and 830 cm^{-1}. The NMR spectrum (CD_3OD) exhibited peaks at τ 9.30 (3H, methyl-protons, triplet, $J=7.0$ cps), 8.63 (3H, methyl-protons, singlet), and 8.43 (2H, methylene-protons, quartet, $J=7.0$ cps), indicating that the methyl and the ethyl groups were both attached to the same carbon atom.

From these data and the results of the hydrolysis of II, the following structure was deduced.



The MS spectrum also supported the structure, *viz.*, it showed the molecular peak at *m/e* 145 and peaks at *m/e* 130 (M−15) and *m/e* 116 (M−29). The *m/e* 86 peak derived from the loss of HNCS showed the presence of an –NH·CS– group in the molecule. Peaks at *m/e* 100, 96, and 82 indicated the formation of a stable triazole skeleton.

When the reaction of I with ethanol was carried out in the absence of water, another product $C_{10}H_{18}N_4S_2$ (III), mp 180°C (dec.) was isolated in a significant quantity in addition to II. Sunner[1] reported this compound (III) to be the product in the reaction of methyl ethyl ketone with I. However, when we carried out the same reaction, II was obtained in a fairly large quantity together with III.

2-Butanol reacted also with I and gave only II, both in the presence and absence of water.

This type of cyclization does not occur with the lower *n*-alcohols, except ethanol.

The triazolidine formations from ethanol, 2-butanol, and methyl ethyl ketone seem to be related to each other, and the reaction mechanisms are now being studied.

Nuclear Quadrupole Resonance of Nitrogen-14 in Tetracyanoethylene and 7,7′,8,8′-Tetracyanoquinodimethane

Shinzaburo ONDA, Ryuichi IKEDA, Daiyu NAKAMURA and Masaji KUBO

Department of Chemistry, Nagoya University, Chikusa, Nagoya

(Received July 29, 1969)

The pure quadrupole resonance of ^{14}N in tetracyanoethylene (TCNE), $(CN)_2C{:}C(CN)_2$, and tetracyanoquinodimethane (TCNQ), $(CN)_2C : C_6H_4 : C(CN)_2$, was observed at liquid nitrogen temperature by means of a modified Pound-Watkins type spectrometer.[1] These compounds are known to be strong π-acids and form a number of unusually stable molecular complexes.[2] In attempting to discuss the nature of these chemical properties, it is worthwhile to reveal the local electronic structure of cyano groups in these compounds.

A commercial preparation of TCNE was purified by sublimation at about 80°C in a high vacuum. Purification was repeated until two closely spaced ν^{I} lines were well resolved. Commercial TCNQ was sublimed twice at about 220°C in a high vacuum and used for the observation of quadrupole resonance. Resonance frequencies were determined by frequency modulation using a TR-5178 universal counter from Takeda Riken Company. Observed resonance lines were assigned to ν^{I} and ν^{II} by Zeeman modulation. Results are shown in Table 1.

TABLE 1. PURE QUADRUPOLE RESONANCE FREQUENCIES, ν^{I} AND ν^{II}, QUADRUPOLE COUPLING CONSTANTS, eQq, AND ASYMMETRY PARAMETERS, η, OF ^{14}N IN TCNE AND TCNQ AT LIQUID NITROGEN TEMPERATURE

Compound	ν^{I}, kHz	ν^{II}, kHz	eQq, kHz	η,%
TCNE	3213.1±1.0 3210.2±1.0	3148.3±1.0 3090.5±1.0	4331	4.4
TCNQ	3151.6±0.1 3142.9±0.1	2888.7±0.1 2879.5±0.1	4021	13.1

Both TCNE and TCNQ show two sets of ν^{I} and ν^{II} lines. The appearance of multiplet lines indicates that there are two kinds of crystallographically nonequivalent nitrogen atoms in the crystals of each compound at liquid nitrogen temperature, although four nitrogen atoms are chemically equivalent in a molecule. X-Ray analysis carried out by Trueblood *et al.*[3,4] on TCNE and TCNQ has shown that both crystals are monoclinic with two and four centrosymmetric molecules, respectively, in a unit cell and that there are two crystallographically nonequivalent nitrogen sites in each crystal. The results of quadrupole resonance agree with those of X-ray analysis, provided that no phase transition takes place between liquid nitrogen and room temperatures.

The four resonance lines observed for TCNE were very broad (about 2 kHz or more in width) even after repeated sublimation. On the other hand, TCNQ showed unexpectedly sharp lines after it was sublimed only once. Since TCNE is less stable than TCNQ, field fluctuation due to decomposition products that contaminate the crystal lattice is a possible reason for the broad signals observed for TCNE. The large asymmetry parameter of TCNQ might be responsible for the appearance of sharp signals owing to quenching of dipolar broadening.[5]

For ^{14}N with its nuclear spin equal to unity, the quadrupole coupling constant and the asymmetry parameter can be calculated from observed frequencies, ν^{I} and ν^{II}. However, for both compounds showing closely spaced doublet lines, one-to-one correspondence could not be made between ν^{I} and ν^{II}. Therefore, the frequencies of doublet lines were averaged to calculate the quadrupole coupling constant and the asymmetry parameter as shown in Table 1.

It is noteworthy that the quadrupole coupling constant of TCNE is nearly the same as that of cyanogen[6] and is very large compared with that of nitrile derivatives.[7] The large asymmetry parameter observed for TCNQ is attributable to the nonequivalence of π-electron polarization between π-orbitals parallel and perpendicular to the plane of a molecule.

Concentration Polarization Phenomena in Ion-exchange Membrane Electrodialysis. II. The Effect of the Condition of the Diffusion-boundary Layer on the Limiting-current Density and on the Relative Transport Numbers of Ions*[1]

Reiichi YAMANE, Toshikatsu SATA, Yukio MIZUTANI and Yasuharu ONOUE

Tokuyama Soda Co., Ltd., Mikage-cho, Tokuyama, Yamaguchi

(Received July 15, 1968)

The effect of the condition of the diffusion-boundary layer in the ion-exchange membrane electrodialysis on the limiting-current density and on the relative transport numbers of ionic species with the same sign was studied. The limiting-current density in the laminar flow is approximately proportional to the first power of the concentration of the solution, the one-half power of the flow velocity of the solution, and, inversely, the one-half power of the membrane length in the direction of the flow. In the natural convection, it is proportional to the five-quarters power of the concentration of the solution. These experimental results agree with the relation of the equations of the limiting-current density for the electrode process. The change in the relative transport numbers of ionic species with the same sign, such as the magnesium and sodium ions or the sulfate and chloride ions, with the flow velocity, the concentration, and the temperature of the solution, the dimension of the membrane in the direction of the flow, and the current density were observed. The results were explained in terms of the change in the condition of the diffusion-boundary layer.

On the demineralization or concentration of sea water by ion-exchange membrane electrodialysis, one of the most serious problems is the concentration polarization phenomenon. In concentrating sea water especially, it is recognized that the concentration polarization on the desalting side of the membrane-solution interfaces causes a change in the relative transport numbers of ionic species with the same sign, an increase in the electric resistance of the electrodialysis cell, and often a change in the solution pH. Industrially, these changes are very important. The increase in the electric resistance makes necessary much more electric power, and the change in the relative transport numbers influences the current efficiency of the sodium ions and may cause the precipitation of calcium sulfate in the concentrating compartment of the cell. Also, when the pH-change of the solution occurs, carbonate and hydroxide of alkali earth metals are often precipitated on the membrane surfaces.

In this work, the effect of the condition of the diffusion-boundary layer on the limiting-current density and the relative transport numbers was studied.

The limiting-current density was obtained from the current-voltage curve in electrodialysis cells; we then investigated how the limiting-current density was affected by the flow velocity, the concentration and temperature of the solution, the dimensions of the membrane, and ionic species.

Moreover, the change in the relative transport numbers of the magnesium to sodium ions and of the sulfate to chloride ions was investigated in connection with the behavior of the diffusion-boundary layer when sea water was concentrated by electrodialysis.

Theoretical

The following equation shows the limiting-current density, i_{lim}, in the ion-exchange membrane electrodialysis:

$$i_{\mathrm{lim}} = \frac{\boldsymbol{F}DC_b}{\delta(t_m - t_s)} \tag{1}$$

where $\boldsymbol{F}$ is the Faraday constant; D, the diffusion coefficient of the electrolyte in the free solution; C_b, the concentration of the bulk solution; δ, the thickness of the diffusion-boundary layer, and t_m and t_s, the transport numbers of the counterion in the membrane and in a free solution respectively.

At current densities near the limiting-current density, the transport of ions consists mainly of diffusion and convection. Levich,[1] Wilke *et al.*,[2]

*1 Studies on ion-exchange membranes. XXVIII. Presented at the 17th Meeting CITCE (Comité International de Thermodynamique et de Cinetique Electrochemiques) held in Tokyo Japan, in September, 1966.

1) B. Levich, *Discussions Faraday Soc.*, **1**, 37 (1947).

2) C. R. Wilke, M. Eisenberg and C. W. Tobias, *J. Electrochem. Soc.*, **100**, 513 (1953).

and other investigators have given relations for the thickness of the diffusion-boundary layer in the electrode process at current densities near the limiting-current density. The membrane-solution system is similar to the electrode-solution system, as an ion-exchange membrane removes ions from the solution or adds ions to the solution. Accordingly, the relations in the electrode process can be used to explain the behavior of the diffusion-boundary layer in ion-exchange-membrane electrodialysis.

The equations for the thickness are as follows: for the laminar flow:

$$\delta = K_1\left(\frac{D}{\nu}\right)^{1/3}\left(\frac{\nu x}{V}\right)^{1/2} \tag{2}$$

for the natural convection:

$$\delta = K_2\left(\frac{\nu}{D}\right)^{-1/4}\left(\frac{g\alpha'}{\nu^2}\right)^{-1/4}x^{1/4}C_b^{-1/4} \tag{3}$$

where ν is the kinematic viscosity; g, the acceleration of gravity; x, the distance from the bottom edge of a membrane; α, the specific density coefficient of the electrolyte solution $\left(=\frac{1}{\rho}\frac{d\rho}{dc},\ \rho:\right.$ specific density$\left.\right)$; V, the flow velocity of the solution in the laminar flow, and K_1 and K_2, constants.

The limiting-current density, i_{lim}, in the laminar flow is given from Eqs. (1) and (2) as the following equation:

$$i_{lim} = \frac{1}{K_1}\frac{FDC_b}{(t_m - t_s)}\left(\frac{\nu}{D}\right)^{1/3}\left(\frac{V}{x\nu}\right)^{1/2} \tag{4}$$

On the other hand from Eqs. (1) and (3) in the natural convection it is given as the following equation:

$$i_{lim} = \frac{1}{K_2}\frac{FDC_b^{5/4}}{(t_m - t_s)}\left(\frac{\nu}{D}\right)^{1/4}\left(\frac{g\alpha}{\nu^2}\right)^{1/4}x^{-1/4} \tag{5}$$

Equation (4) indicates that the limiting-current density is proportional to the first power of the concentration of the bulk solution, the one-half power of the flow velocity, and, inversely, the one-half power of the membrane length in the direction of the flow. Equation (5) indicates that the limiting-current density is proportional to the five-quarters power of the concentration of the bulk solution.

The temperature of the solution affects the limiting-current density, for the diffusion coefficient and the kinematic viscosity are functions of the temperature. If the transport numbers of the counter ion in the membrane and free solution are constant, the temperature coefficient, β, of the limiting-current density in the laminar flow can be obtained by the following method; Equation (4) is differentiated with respect to the absolute temperature, T:

$$\beta = \frac{1}{i_{lim}}\frac{di_{lim}}{dT} = \frac{2}{3}\frac{1}{D}\frac{dD}{dT} - \frac{1}{6}\frac{1}{\nu}\frac{d\nu}{dT} \tag{6}$$

Using Nernst's equation of the diffusion coefficient (8), and also Walden's equation (9), the temperature coefficient of the diffusion coefficient is obtained as follows:

$$\frac{1}{D}\frac{dD}{dT} = -\frac{1}{\nu}\frac{d\nu}{dT} + \frac{1}{T} \tag{7}$$

$$D = \frac{\lambda RT}{F^2Z} \tag{8}$$

$$\lambda\nu = \text{constant} \tag{9}$$

where λ is the equivalent conductance of the electrolyte at an infinite dilution and where Z is the valence of the ions. Accordingly, the temperature coefficient, β, is:

$$\beta = \frac{1}{i_{lim}}\frac{di_{lim}}{dT} = \frac{2}{3}\frac{1}{T} - \frac{5}{6}\frac{1}{\nu}\frac{d\nu}{dT} \tag{10}$$

The viscosity of water can be used for ν, as the concentration on the desalting side at the membrane surfaces is low at current densities near the limiting-current density.

Experimental

Membranes. Throughout this investigation commercial ion-exchange membranes prepared by the "Paste Method,"[3-5] *i. e.*, two anion-exchange membranes, NEOSEPTA AV-4T and NEOSEPTA AVS-4T, and are cation-exchange membrane, NEOSEPTA CL-2.5T, were used. The characteristics of these membranes are shown in Table 1.

Cells. Five different electrodialysis cells were used. The cells 1, 2, 3 and 4 were used for the laminar flow experiments, and the cell 5 for the natural convection experiments. In the cells 1, 2 and 3, the thickness of the compartment in which the solution flows was 1.0 cm in order to eliminate the effect of the desalting of the solution on the current-voltage curve. The characteristics of the cells are shown in Table 2.

Procedures. *The Determination of the Current-voltage Curve.* The current-voltage curve was measured with a high-impedance valve voltmeter (Tōadempa Co., Ltd., Model PM-20) connected to a pair of silver-silver chloride or calomel probe electrodes situated on the opposite sides of the membrane. Silver-silver chloride probe electrodes were put close to a membrane (about 2 mm apart in the cell 1). Calomel probe electrodes were connected to luggin capillaries (about 2mm apart from the membrane surfaces) and were used in the cells 2, 3, 4 and 5. The current-voltage curve was obtained as follows: the current was increased gradually and the voltage between the probe electrodes was measured with a valve voltmeter. The current density at which the voltage increased abruptly in the current-voltage relation was defined as the limiting-current density in the cell.

*4 Lengths of the membrane are 250, 600 and 1200 mm.
*5 A means an anion-exchange membrane and C means a cation-exchange membrane.
*6 Thickness of the desalting compartment (mm).

The Determination of the Relative Transport Numbers of Ionic Species with the Same Sign. The relative transport numbers of ionic species with the same sign were determined by means of the concentration of sea water. The sample of the concentrated solution was taken after its composition attained an equilibrated condition (after the concentration had been carried out for about 12 hr). The chloride ions were analyzed by the Mohr method, and the magnesium and calcium ions, by the EDTA titration, while the potassium and sulfate ions were analyzed by the gravimetric method, using tetraphenyl borate and barium chloride respectively. The concentration of the sodium ions was calculated by subtracting the concentration of the magnesium, calcium and potassium ions from that of all the cations.

The relative transport numbers, P_B^A, were as follows:

$$P_B^A = \frac{(t_m^A/t_m^B)}{(C_b^A/C_b^B)}$$

where t_m^A and t_m^B are the transport numbers of the counterions, A and B, in the membrane, and C_b^A and C_b^B, the concentrations of A and B ions in the bulk solution.

Measurements. *The Effect of the Flow Velocity on the Limiting-current Density.* The measurements were made in the laminar flow at 30.0°C. The cells 1 and 2 were used for obtaining the current-voltage curve for a single membrane, NEOSEPTA AV-4T, AVS-4T or CL-2.5T, in a sodium chloride solution of 0.500 N and for a pair of membranes, NEOSEPTA AVS-4T and CL-2.5T, in diluted sea water (the concentration of chloride ions was 0.35 N) respectively.

The Effect of the Concentration of the Solution on the Limiting-current Density. Current-voltage curves in the laminar flow for NEOSEPTA AVS-4T at 30.0°C and in the natural convection for NEOSEPTA CL-2.5T at 25.0°C were measured in sodium chloride solutions of various concentrations by the use of the cells 2 and 5, respec-

tively.

The Effect of the Temperature on the Limiting-current Density. In this measurement a sodium chloride solution of 0.104 N was used in the laminar flow by the use of the cell 1. The temperatures of the measurement were 15.7, 25.0 and 35.5°C for NEOSEPTA AVS-4T, and 15.0, 25.0 and 35.0°C for NEOSEPTA CL-2.5T.

The Effect of the Membrane's Dimensions on the Limiting-current Density. The current-voltage curve was obtained by the use of the cells 3 and 4. The former cell contained a single membrane, NEOSEPTA AVS-4T or CL-2.5T, while the latter cell contained a pair of anion- and cation-exchange membranes, NEOSEPTA AVS-4T and CL-2.5T. The lengths of the membranes in the direction of the flow were 2.0, 8.0, 25.0 and 40.0 cm in the cell 3, and 25.0, 60.0 and 120.0 cm in the cell 4. Each measurement was made in a laminar flow of sea water (the concentration of chloride ions was 0.52 N) at 28.0°C.

The Effect of Ionic Species on the Limiting-current Density. Current-voltage curves in aqueous solutions of several ionic species were measured with the cell 5, containing an anion- or cation-exchange membrane, in the natural convection at 25.0°C. The ionic species were hydrogen, lithium, potassium, sodium, calcium, barium, ammonium, aluminium, ferric and cupric ions as cations, and chloride and sulfate ions as anions. All these ions had a concentration of 0.50 N.

The Change in the Relative Transport Numbers with the Condition of the Diffusion-boundary Layer. The change in the relative transport numbers of the magnesium to sodium ions or of the sulfate to chloride ions with the flow velocity, the concentration, the temperature of sea water, the dimensions of the membrane, and the current density was examined when sea water was concentrated by electrodialysis. The change in the relative transport numbers by all factors except the dimensions of the membrane was examined by concentrating sea water by the use of the cell 2. The change in the relative transport numbers by the membrane length was examined by the use of the cell 4 in which long membranes were inserted. The experimental conditions are shown in Table 3.

Results and Discussion

A typical current-voltage curve for a cation-exchange membrane, NEOSEPTA CL-2.5T, in a sodium chloride solution at 25.0°C is shown in Fig. 1. This measurement was carried out by the use of the cell 5.

Solution: 0.104 N NaCl solution

The relationship between the limiting-current density and the flow velocity is shown in Fig. 2. The following relation can be found in Fig. 2.:

$$i_{lim} = mV^n \qquad (11)$$

According to Eq. (4) the constant, n, corresponds to 1/2, but the experimental values of Table 4 do not necessarily agree with 1/2. This disagreement is probably due to the difference in the structure of the cell.

If the transport numbers of counterions in the membrane and in the free solution, the diffusion coefficient, and the kinematic viscosity are nearly constant with respect to the concentration of the bulk solution, the limiting-current density is proportional to the concentration of the bulk solution. The results for an anion-exchange membrane, NEOSEPTA AVS-4T, show that the limiting-current density in the laminar flow is proportional

to the concentration of the bulk solution, as is shown in Fig. 3. Equation (5) shows that the limiting-current density is proportional to the five-quarters power of the concentration in the natural convection. The experimental results in the natural convection agree with the theoretical value, as is shown in Fig. 4.

○ AVS-4T, ⊖ CL-2.5T

Figure 5 shows the effect of the temperature of the solution on the limiting-current density. The temperature coefficient of the limiting-current density at 25.0°C was calculated to be 2.1% from Eq. (10). However, the experimental values which were evaluated from Fig. 5 were 1.4% for the anion-exchange membrane, NEOSEPTA AVS-4T, and 1.2% for the cation-exchange membrane, NEOSEPTA CL-2.5T, at 25.0°C.

The effect on the limiting-current density of the length of a membrane in the direction of the flow is shown in Fig. 6. The concentration of the effluent decreases in comparison with that of the feed solution in the cell which contains long membranes. However, when sea water was concentrated using the cell 4 (the flow velocity of the solution was 6.0 cm/sec, the membrane length was 120 cm, and the current density was 35 mA/cm²), the concentration of the effluent decreased only about 2% in comparison with that of the feed solution. Accordingly, the effect of the desalting of the solution on the limiting-current density is negligible. Figure 7 shows current voltage curves measured at three different points from the bottom edge of a membrane 40 cm long. This figure demonstrates that the diffusion-boundary layer grows as the feed solution nears the upper edge of the membrane.

In the cell 3 the empirical equations of the limiting-current density to the length of the membrane show as follows:

for NEOSEPTA AVS-4T:

$$i_{lim} = 50L^{-0.45} \tag{12}$$

for NEOSEPTA CL-2.5T:

$$i_{lim} = 30L^{-0.45} \tag{13}$$

where L is the total length of the membrane in the direction of the flow (cm). For the cell 4 containing a pair of membranes, NEOSEPTA AVS-4T and CL-2.5T, the following equation is obtained:

$$i_{lim} = 35L^{-0.48} \tag{14}$$

These results show that the limiting-current density is approximately proportional, inversely, the one-half power of the membrane length in the laminar flow.

The concentration of the solution on both sides of the membrane was the same when the current-voltage curves were measured in the cells 1, 3 and 5. However, in practical electrodialyzers one side of the membrane is in contact with the concentrated solution, and the other, with the desalted. An electrolyte diffuses through the membrane from the concentrating compartment to the desalting. Accordingly, the effect on the limiting-current density of the diffusion of the electrolyte through the membrane must be considered in a practical electrodialyzer. If the amount of the electrolyte which diffuses through the membrane is introduced into Eq. (1), Eq. (1) is modified as follows:

$$i_{lim} = \frac{FC_b}{(t_m - t_s)\delta}\left\{D + \left(\frac{C_c}{C_b}\right)\left(\frac{D_m}{\delta_m}\right)\delta\right\} \tag{15}$$

where δ_m is the thickness of the membrane; D_m, the diffusion coefficient of the electrolyte through

the membrane, and C_c, the concentration of the concentrated solution. It was estimated from Eq. (15) that the limiting-current density increased about 4.7% in the cell 4 (the membrane length was 120 cm, the limiting-current density was 35 mA/cm², the concentration of the concentrated solution was 4.0 N, and D_m/δ_m was 2.7×10^{-6} cm/sec).

All the experiments mentioned above were performed in solutions of sodium chloride or sea water. It is apparent in Eqs. (4) and (5) that the limiting-current density changes with the ionic species as a result of the differences in the transport number and the diffusion coeffcient in the free solution, and in the viscosity of the solution. The relation of the limiting-current density in the natural convection to the diffusion coefficient and the transport numbers in various electrolytes (*e.g.*, sodium chloride, lithium chloride, potassium chloride, calcium chloride, hydrogen chloride, cupric chloride and ammonium chloride) is shown in Fig. 8; it agrees with the relation of Eq. (5).

With barium chloride, ferric chloride and aluminium chloride, the limiting-current density was not obtained because the current-voltage curve did not show any inflexion point or because their hydroxide precipitated on the surface of the membrane at a current density lower than the inflexion point.

If the current-voltage curve was measured in a solution containing two ionic species of the counterion, and if their limiting-current density differed from one another, the current-voltage curve might show two different limiting-current densities. An experiment was carried out with the anion-exchange membrane, NEOSEPTA AVS-4T, inserted in a mixed solution of sodium chloride and sodium sulfate. However, two different limiting-current densities were not observed; rather a limiting-current density was observed between the limiting-current densities observed in chloride and sulfate solutions.

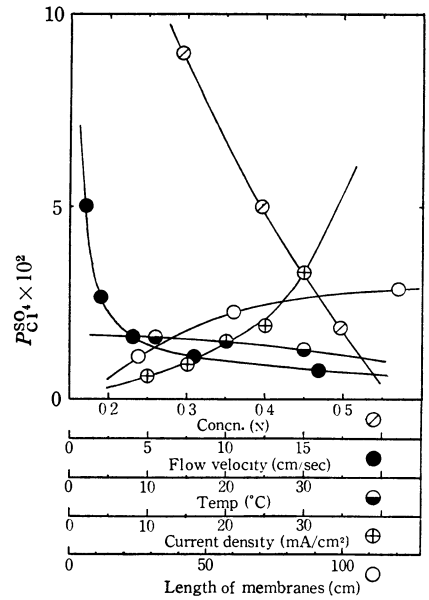

Fig. 9. The effect of conditions of the electrodialytic concentration of sea water on the relative transport numbers of SO_4^{2-} to Cl^-.
The conditions are shown in Table 3.

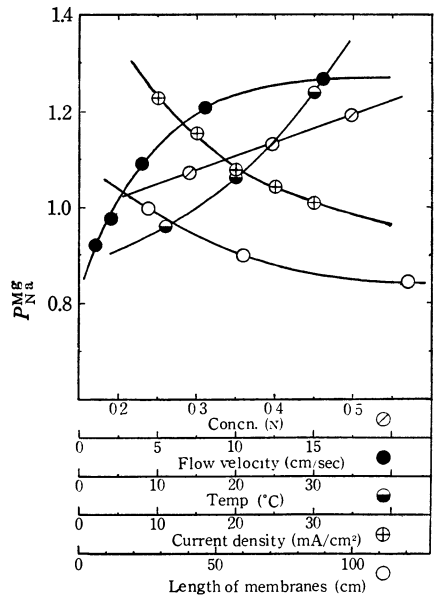

Fig. 10. The effect of conditions of the electrodialytic concentration of sea water on the relative transport numbers of Mg^{2+} to Na^+.
The conditions are shown in Table 3.

In a multiple-ionic-species system, the change in the diffusion-boundary layer causes a difference of the composition of ions at the membrane-solution interfaces from that in the bulk solution, so that the relative transport numbers between ions change. The concentration ratio at the desalting membrane-solution interface of sulfate to chloride ions, which pass through the anion-exchange membrane more easily than do sulfate ions, increases in comparison with that of the bulk solution when the electrodialysis is carried out at a low concentration, a low flow velocity, a low temperature, and a high current density and with a long membrane. Consequently, the transport number of sulfate ions increases, as is shown in Fig. 9. Inversely, the concentration ratio at the desalting membrane-solution interface of magnesium to sodium ions, which pass through the cation-exchange membrane with more difficulty than do magnesium ions, decreases in comparison with that of the bulk solution when the electrodialysis is carried out at a low concentration, a low flow velocity, a low temperature, and a high current density and with a long membrane. Consequently, the transport number of magnesium ions decreases, as is shown in Fig. 10. The condition of the diffusion-boundary layer has a remarkable influence on the relative transport numbers.

After all, the limiting-current density and the relative transport number are relative values; they vary with the condition of the diffusion-boundary layer.

The authors wish to thank Mr. S. Miyoshi for his valuable comments and advice.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 2748—2755 (1969)

A New Acidity Function, T_0, in Acid-catalyzed Reactions

Haruo TAKAYA, Naoyuki TODO and Tadasuke HOSOYA

The Government Chemical Industrial Research Institute, Tokyo, Shibuya-ku, Tokyo

(Received December 16, 1968)

In acid-catalyzed reaction systems a new acidity function, T_0, which is related to the first-order rate constant, k_1, by the equation $\log k_1 = C - T_0$ was defined by $T_0 = -\log (a_{H^+}/a_w^{h_5-h_1} f^{\neq})$ and was theoretically calculated in much the same manner as in Glueckauf's treatments on a salt solution but with the additional assumption that the character of a hydrated univalent activated complex is represented by that of a hydrated alkali metal cation. The calculated results show that T_0 in hydrochloric acid can be represented by:

$$T_0 = 2.4(3.9 - h_1 + h_5) \log a_w - \log m_a.$$

This equation shows that if the hydration number (the water molecules bound with an activated complex) of an activated complex, h_1, increases by one, the corresponding increment of T_0 becomes $-2.4 \log a_w$. It was also shown that the value of $f_{AH^+} f_B / f_A f_{BH^+}$ is not always constant, but depends on the hydration numbers of the AH^+ and BH^+ species as well as on the acid concentrations. The factors affecting the acidity function, T_0, were compared with those affecting the activity of water. The applicability of the T_0 was examined by means of the observed $\log k_1$ value reported by Bunnett.

The following mechanisms of acid-catalyzed[1] reactions in moderately concentrated acid solutions have been proposed by Bunnett,[2-5]

$$S(H_2O)h_5 + H^+(H_2O)h_2 \rightleftharpoons SH^+(H_2O)h_6 + (h_2 + h_5 - h_6)H_2O \quad (1)$$

$$SH^+(H_2O)h_6 + (h_1 - h_6)H_2O \rightleftharpoons [SH^+(H_2O)h_1]^{\neq} \xrightarrow{\text{A}} P \quad (2)$$

Adding Eq. (1) to Eq. (2) we obtain

$$S(H_2O)h_5 + H^+(H_2O)h_2 + (h_1 - h_2 - h_5)H_2O \overset{K_1}{\rightleftharpoons} [SH^+(H_2O)h_1]^{\neq} \quad (3)$$

$$[SH^+(H_2O)h_1]^{\neq} \xrightarrow{\text{A}} P \quad (4)$$

The reaction rate, v, can be expressed by Eq.(5):

$$v = km^{\neq} = \frac{kK_1 a_{H^+} f_S}{k_2 a_w^{h_5 - h_1} f^{\neq}} m_5 \quad (5)$$

where K_1, the equilibrium constant of Eq.(3), and K_2, the dissociation constant of protonated water, are given by Eq.(6) and Eq.(7) respectively:

$$K_1 = \frac{f^{\neq} m^{\neq}}{f_S m_5 a_{H^+(H_2O)h_2} a_w^{h_1 - h_2 - h_5}} \quad (6)$$

1) In this paper only strong univalent acids are considered as catalysts.

4) J. F. Bunnett, *ibid.*, **83**, 4973 (1961).
5) J. F. Bunnett, *ibid.*, **83**, 4978 (1961).

$$K_2 = \frac{a_{H^+}}{a_{H^+(H_2O)h_2} a_w{}^{-h_2}} = 1 \quad (7)^{6)}$$

Equations (5), (6) and (7) can also be summarized by Eq.(8):

$$\log k_1 = C - T_0 \quad (8)$$

where: $k_1 = v/m_5$,[7] (9)

$$C = \log (kK_1/K_2) \quad (10)$$

and $$T_0 = -\log (a_{H^+} f_S / a_w{}^{h_5 - h_1} f^{\neq}) \quad (11)$$

we can introduce T_0 as a new acidity function, while C is constant, independent of the concentration of acid.

Hammett and Deyrup defined the acidity function, H_0, as is shown in Eq. (12):

$$H_0 = -\log \frac{a_{H^+} f_A}{f_{AH^+}} \quad (12)$$

Its value was obtained by observing m_{AH^+} and m_A:

$$\log \frac{m_{AH^+}}{m_A} = C - H_0, \quad (13)$$

where they assumed $h_2=1$ and $h_5=0$. Furthermore they mainly determined the $f_A f_{BH^+}/f_{AH^+} f_B$ values of aromatic amines in acid solutions and found that these values were constant, independent of the A and B species as well as of the concentration and the sort of acid. Zucker and Hammett[9,10] have proposed a hypothesis which is useful in distinguishing A-1 mechanisms from A-2 mechanisms.

If the reaction proceeds according to an A-1 mechanism, h_1 is zero and Eq. (14) can be derived from Eq. (8):

$$\log k_1 = C + \log \frac{a_{H^+} f_S}{f_{SH^{\neq}}}$$

$$= C + \log \frac{a_{H^+} f_A}{f_{AH^+}} + \log \frac{f_S f_{AH^+}}{f_{SH^{\neq}} f_A} \quad (14)$$

The $-\log (a_{H^+} f_A / f_{AH^+})$ term is Hammett's acidity function, and $\log (f_S f_{AH^+}/f_{SH^{\neq}} f_A)$ is constant;[11,12] hence, Eq. (14) can also be expressed by Eq. (15):

$$\log k_1 = C - H_0 \quad (15)$$

If the reaction proceeds according to an A-2 mechanism, h_1 is one; they postulated empirically that $\log k_1$ is given by Eq. (16):

$$\log k_1 = C + \log m_a \quad (16)$$

while the Zucker-Hammett hypothesis described above, though it would be useful in distinguishing A-1 from A-2 mechanisms, has been sharply criticized by several authors[2,13,14] and has not been accepted as reasonable.

The Bunnett equation (Eq. (17))[3] can also be derived from Eq. (8); Eq. (18) is thus obtained:

$$\log k_1 = C - H_0 - w \log a_w, \quad (17)$$

$$\log k_1 = C + \log \frac{a_{H^+} f_A}{f_{AH^+}} + (h_5 - h_1) \log a_w + \log \frac{f_S f_{AH^+}}{f_{SH^{\neq}} f_A} \quad (18)$$

If the term of $f_S f_{AH^+}/f_{SH^{\neq}} f_A$ is constant, the last one in Eq. (18) becomes zero; Eq. (18), therefore, becomes equivalent to Eq. (17) when we replace w and H_0 with $(h_1 - h_5)$ and $-\log (a_{H^+} f_A / f_{AH^+})$ respectively. Bunnett discussed the reaction mechanism in terms of the value of w. Its value, however, can not be considered to be the hydration number contained in an activated complex, because such large values as 7 and 8 have been obtained. Hence, the value of w must be used only as an fitting parameter for experimental data.

The main features of this study are that an activated complex is considered to be a univalent cation and that the acidity function, T_0, is theoretically derived by applying the treatment described by

6) K_2 in Eq. (7) is put to be equal to 1. This was done in view of the following facts: in Hammett's treatment of a dilute acid solution, $H_0 = -\log m_a = \mathrm{pH}$ is defined. This automatically involves the $m_a = a_{H^+}$ relation: in other words, the acid concentration, m_a, is equal to the activity of the non-hydrated proton, a_{H^+}. Also, $a_{H^+(H_2O)h_2}$ and a_w can, as usual, be defined as being equal to m_a and 1 respectively.

However, in a dilute acid solution, the species related to m_a is not H^+ but $H^+(H_2O)_{h_2}$. Therefore, as a means to definition $m_a = a_{H^+}$ seems less reasonable than $m_a = a_{H^+(H_2O)h_2}$. The more reasonable definitions of T_0 and H_0 both of which are equal to $-\log m_a$ in dilute acid solutions, are given by Eq. (11a) and Eq. (12a) respectively:

$$T_0 = -\log (a_{H^+(H_2O)h_2} f_S / a_w{}^{h_2 + h_5 - h_1} f^{\neq}) \quad (11a)$$

$$H_0 = -\log (a_{H^+(H_2O)} f_A / a_w f_{AH^+}) \quad (12a)$$

Here, if $K_2=1$, Eq. (11a) and Eq. (12a) are equal to Eq. (11) and Eq. (12) respectively.

7) In the above calculation, the first-order rate constant, k_1, was defined as the v/m_5 quantity. This is an approximation of the correct expression, $k_1 = v/(m_1 + m_5 + m_6)$. However, in the relations now under consideration, and in ordinary acid-catalyzed reactions as well, both m_1 and m_6 are negligibly small as compared with m_5; hence, this approximation is reasonable.

10) L. Zucker and L. P. Hammett, *J. Am. Chem. Soc.*, **61**, 2791 (1939).

11) The value of $f_{SH^{\neq}}$ is assumed to very in essentially the same way as f_{SH^+} in both Hammett's and this paper.

12) It is doubtful whether we can extend the relation in which the $\log (f_{AH^+} f_B / f_A f_{BH^+})$ of Hammett base is constant to the S substrate, for S is not a Hammett base.

Glueckauf[15] and by Moriyama[16] who showed that an a thermal mixing assumed for the salt solutions led to a reasonable representation of the observed activity coefficients of salt and acids.[17] One of the features which distinguishes our treatment from Hammett's is the difference in the hydration number[18] of the proton: in Hammett's treatment, the value of the hydration number, h_2, must be 1, whereas the h_2 taken in our treatment is 3.9, a value which is widely accepted.[19] The calculated acidity function, T_0, has been represented as a function of the hydration number of an activated complex, the activity of water, and the concentration of the acid. From the calculated results it has been verified that the value of $f_A f_{BH^+}/f_{AH^+} f_B$ depends on the hydration numbers of AH^+ and BH^+ as well as on the concentrations of the acids. Our results, therefore, differ from Bunnett's because his results were obtained by assuming that the value of $f_A f_{BH^+}/f_{AH^+} f_B$ is constant, independent of the A and B species as well as of the concentration and the sort of acid.

Symbols Used

The following list gives the symbols used in this study.

h_1, h_2, h_3, h_5, h_6: hydration numbers of activated complex, proton, univalent anion, substrate, and protonated substrate respectively

$h=h_2+h_3$: hydration number of acid

a_{H^+}, $a_{H^+(H_2O)_{h_2}}$, $a_w=a_4$: activities of proton, hydrated proton, and water respectively

k, $k_1=v/m_5$: rate constant and the first-order rate constant respectively

n_1, n_2, $n_3=n_a=n_1+n_2$, n_4, $n_5=n_S$: numbers of molecules in hydrated activated complex, hydrated proton, hydrated univalent anion, free water, and hydrated substrate respectively

$m_1=m^{\neq}$, m_2, m_3, m_5, m_6: molalities of activated complex, proton, anion, substrate, and protonated substrate respectively

$m_a=m_3$: molality of acid

$n_w=n_1h_1+n_2h_2+n_3h_3+n_4+n_5h_5$: total number of water molecules

$n_R=n_1+n_5$: total number of substrates

$\bar{v}_1$, $\bar{v}_2$, $\bar{v}_3$, $\bar{v}_5$, $\bar{v}_4$: partial molar volumes of hydrated activated complex, hydrated proton, hydrated univalent anion, and hydrated substrate respectively, and that of free water. These values were treated as constant in this study.

$V=n_1\bar{v}_1+n_2\bar{v}_2+n_3\bar{v}_3+n_4\bar{v}_4+n_5\bar{v}_5$: total volume of the solution

μ_1, μ_2, μ_3, μ_5, μ_4: chemical potentials of hydrated activated complex, hydrated proton, hydrated anion, and hydrated substrate respectively, and that of free water

μ_i°: chemical potential in the standard state of ith species

$f_{SH^{\neq}}=f^{\neq}$, f_{SH^+}, f_S, f_A, f_B, f_{AH^+}, f_{BH^+}: activity coefficients of hydrated activated complex, hydrated protonated substrate, hydrated substrate, hydrated substrate A, hydrated substrate B, hydrated protonated substrate AH^+, and hydrated protonated substrate BH^+ respectively

S, A, B: substrates

SH^+, AH^+, BH^+: protonated substrates

k: Boltzmann's constant

T: absolute temperature

Theoretical

Model of the Reaction System. The acid-catalyzed reaction system consists of the following five kinds of species: hydrated activated complexes, hydrated protons, hydrated univalent anions, free water, and hydrated substrates. The Gibbs free energy of this system may be calculated in much the same manner as in Glueckauf's treatment of a salt solution, with additional assumptions. Since the structure of an activated complex is too complicated for its exact contribution to the Gibbs free energy to be evaluated, it is assumed that the character of a hydrated univalent activated complex is represented by that of a hydrated alkali metal cation. It is furthermore assumed that a substrate is neutral and that its volume[20] is that of alkali metal in solution. On the other hand, for a substrate the salting-out effect must be considered. Conway[21] theoretically calculated this effect by considering two phenomena: the hydration of ions and the change in the dielectric constant of water due to the solute present in the solution. The former is automatically taken into account in this study, because ions are always treated as

18) In this study the Gibbs free energy has been obtained by calculating the entropy; thus, the water molecules in hydration should be tightly bound with the ion.

19) 3.9 was taken from Ref. 12. Wicke, Eigen and Ackermann, *Z. Phys. Chem.*, **1**, 340 (1954). Th. Ackermann, *Discussion Faraday Soc.*, **24**, 180 (1957). M. Eigen and L. De Maeyer, "Article in the Structure of Electrolyte Solution," Ed. by W. J. Hamer, John Wiley and Sons, New York, N. Y. (1959).

20) In view of the co-volume effects of ions, Glueckauf obtained the activity of ions. On the other hand, the molar volume of a neutral substrate determines the dependency of its activity coefficient on the acid concentration.[24] Hence, among various physical properties belonging to a neutral substrate, the molar volume is the most predominant in the calculation of the activity.

21) B. E. Conway, J. E. Desnoyers and A. C. Smith, *Phil. Trans. Roy. Soc. London*, **256**, 389 (1964).

hydrated in the calculation of the Gibbs free energy. Therefore, only the contribution from the latter is formally introduced as $G^{s.o.}$ in the equation.

Taking the five species (four hydrated species and free water mentioned above) as the standard state in the calculation of the Gibbs free energy of the system, and subjecting them to athermal mixing, the Gibbs free energy of mixing, $\Delta G'^{mix.}$, is given by Eq. (19):

$$\Delta G'^{mix.} = \boldsymbol{k}T\sum_{i=1}^{5} n_i \ln \frac{n_i\bar{v}_i}{V}. \tag{19}$$

The fundamental equation of the total free energy of the mixing of the system can, therefore, be obtained by adding the electrostatic effect, $G^{el.}$,[22] caused by the interaction between ions, and $G^{s.o.}$ to Eq. (19):

$$\begin{aligned}\Delta G^{mix.} &= \sum_{i=1}^{5} n_1\mu_i - \sum_{i=1}^{5} n_i\mu_i^0 \\ &= \boldsymbol{k}T\sum_{i=1}^{5} n_i \ln \frac{n_i\bar{v}_i}{V} + G^{el.} + G^{s.o.}\end{aligned} \tag{20}$$

The Acidity Function, T_0. To find the equation of the acidity function, T_0, the variation in the free energy in the process of the formation of the activated complex must be evaluated. As is shown by Eq. (3), a hydrated activated complex molecule is formed by the consumption of one hydrated proton molecule and one hydrated substrate molecule, leaving free water molecules $(h_2+h_5-h_1)$. This process corresponds to the partial differentiation of the total free energy with respect to n_1 at constant n_w, n_3 and n_R values, as is shown by Eq. (21):

$$\begin{aligned}\left(\frac{\partial\Delta G^{mix.}}{\partial n_1}\right)_{n_w,\,n_3,\,n_R} &= (\mu_1-\mu_1^0) - (\mu_2-\mu_2^0) \\ &+ (h_2+h_5-h_1)(\mu_4-\mu_4^0) - (\mu_5-\mu_5^0) \\ &= \boldsymbol{k}T\left[\ln n_1 - \ln n_2 - \ln n_5 + (h_2+h_5-h_1)\ln\frac{n_4\bar{v}_4}{V}\right. \\ &+ \ln\frac{V}{\bar{v}_4} - \left(\sum_{i=1}^{5} n_i\right)\frac{(\bar{v}_1-h_1\bar{v}_4-\bar{v}_2+h_2\bar{v}_4-\bar{v}_5+h_5\bar{v}_4)}{V} \\ &\left.+ \ln\frac{\bar{v}_1\bar{v}_4}{\bar{v}_2\bar{v}_5} + (h_2+h_5-h_1) - 1\right] + \left(\frac{\partial G^{el.}}{\partial n_1}\right) \\ &+ \left(\frac{\partial G^{s.o.}}{\partial n_1}\right)\end{aligned} \tag{21}$$

From Eq. (21) the acidity function, T_0, can be derived:

$$\begin{aligned}T_0 &= -\log\frac{a_{H^+}f_S}{a_w^{h_5-h_1}f^*} \\ &= -\log m_a + (h_2+h_5-h_1)\log\frac{(1-0.018\,hm_a)}{(1+0.018\,rm_a)} \\ &+ \log(1+0.018\,rm_a) \\ &+ \frac{0.434\times0.018m_a(r+h-2)\Delta h}{1+0.018\,rm_a} \\ &+ \frac{0.434}{\boldsymbol{k}T}\left\{\left(\frac{\partial G^{el.}}{\partial n_1}\right)+\left(\frac{\partial G^{s.o.}}{\partial n_1}\right)\right\}\end{aligned} \tag{22}$$

22) The value of $G^{el.}$ takes account of the electrostatic interaction among ions in the aqueous solution when there is no neutral substrate in it.

where the term of $\ln(\bar{v}_1\bar{v}_4/\bar{v}_2\bar{v}_5)+(h_2+h_5-h_1)-\ln 0.018-\Delta h$ is omitted because this term is independent of the concentration of acid. The following six relationships were used for the sake of simplicity:

$$n_i = 0.018\,m_in_w \tag{23}$$

$$h = h_2 + h_3 \tag{24}$$

$$r\bar{v}_4 = (\bar{v}_2+\bar{v}_3) - (h_2+h_3)\bar{v}_4 \tag{25}$$

$$\Delta h\bar{v}_4 = (\bar{v}_1-h_1\bar{v}_4) - (\bar{v}_2-h_2\bar{v}_4) - (\bar{v}_5-h_5\bar{v}_4) \tag{26}$$

$$\mu_i - \mu_i^0 = \boldsymbol{k}T\ln a_i = \boldsymbol{k}T\ln f_im_i \tag{27}$$

$$m_1,\ m_5 \ll m_2 \tag{28}$$

$(0.434/\boldsymbol{k}T)(\partial G^{el.}/\partial n_1)$ in Eq. (22) corresponds to the difference in electrostatic contribution between a hydrated proton and a hydrated activated complex to the Gibbs free energy in an acid. This difference may be small because of the small difference in radius between a hydrated proton and a hydrated alkali metal cation.[23] Its approximate value can be calculated from the difference in the logarithms of the mean activity coefficients, $f_\pm^{el.}$, due to only the electrostatic effect between a hydrated proton in acid and a hydrated alkali metal cation in salt present in the solution. The value of $\log f_\pm^{el.}$ is represented as:

$$\log f_\pm^{el.} = -\frac{0.509\sqrt{I}}{1+0.329\times10^8a\sqrt{I}}$$

where I is the ionic strength and where "a" is the arbitrary parameter, which can be interpreted as the shortest distance from the center of a cation to that of an anion. We then obtain:

$$\begin{aligned}\frac{0.434}{\boldsymbol{k}T}\left(\frac{\partial G^{el.}}{\partial n_1}\right) &= -\frac{0.509\sqrt{I}}{1+0.329\times10^8a_1\sqrt{I}} \\ &+ \frac{0.509\sqrt{I}}{1+0.329\times10^8a_2\sqrt{I}}\end{aligned} \tag{29}$$

where a_1 and a_2 are arbitrary parameters of a salt and an acid respectively.

The $(0.434/\boldsymbol{k}T)(\partial G^{s.o.}/\partial n_1)$ term in Eq. (22) is neglected, for the molar volume of a neutral substrate (that of alkali metal in our model) is small.[24] Conway[21] also showed that this term was small for a small neutral substrate.

Results

Results of Calculation. For the calculation of the hydration terms in Eq. (22), the hydration numbers of Li^+, Na^+, K^+, and Rb^+ were taken from the results tabulated by Glueckauf.[15] The values of $\bar{v}_1$, $\bar{v}_2$, $\bar{v}_3$, and $\bar{v}_5$[19] were taken from the results computed by Noyes[25] and were treated as

constants.

The calculated values of T_0 at various concentrations of the hydrochloric acid solution for the formation of the activated complex ions are shown in Tables 1—4, where the activated complex ions are represented by Li^+, Na^+, K^+, and Rb^+. These tables show that the contribution from the hydration to T_0 is predominant, whereas that from the electrostatic is small. In Fig. 1 $-T_0$, $-H_0$, and $\log m_a$ are plotted against the acid concentration, m_a. In the case of Rb^+, the hydration number of which is zero, $-T_0$ is largest and the deviation of the T_0 from $\log m_a$ is nearly equal to H_0. On the contrary, in the case of Li^+, the hydration number of which is 3.4, $-T_0$ is small and nearly equal to $\log m_a$. In order to determine the correlation of $-T_0$ with the hydration number of the activated complex, the $-T_0$ values in a hydrochloric acid solution at a molality of 3 are plotted *versus* the hydration number in Fig. 2. Figure 2 shows that $-T_0$ increases linearly with the hydration number. Therefore, the T_0 can be represented as in Eq. (30):

$$T_0 = -0.161(3.9-h_1+h_5) - \log m_a, \qquad (30)$$

where h_2 is 3.9. Since the value of $\log a_w$ is −0.068 at the molality of hydrochloric acid of 3, Eq. (30) can be rewritten as:

$$T_0 = 2.4(3.9-h_1+h_5)\log a_w - \log m_a \qquad (31)$$

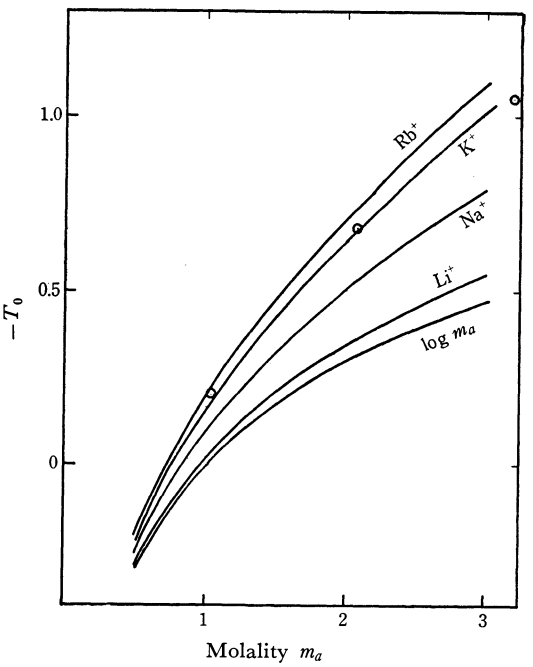

Fig. 1. $-T_0$, $-H_0$* and $\log m_a$ *versus* the molality of hydrochloric acid, m_a, at 25°C. Hydration number of Rb^+, K^+, Na^+, and Li^+ are 0, 0.6, 2.0, and 3.4 respectively.

○ observed $-H_0$

* M. A. Paul and F. A. Long, *Chem. Revs.*, **57**, 1 (1957).

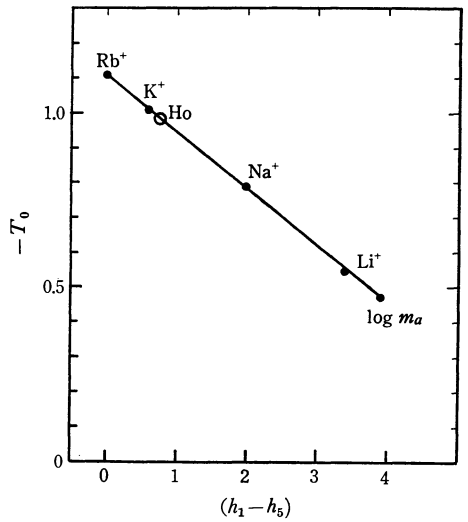

Fig. 2. $-T_0$ *versus* (h_1-h_5) at the molality of hydrochloric acid of 3 at 25°C. Since h_5, the hydration number of a substrate, can be assumed to be 0, (h_1-h_5) becomes equal to h_1, which is the number of water molecules contained in an activated complex. The hydration number of aromatic amines, which was used to determine H_0, becomes apparently 0.7 from this figure.

functions, T_0, for these solutions are given by Eqs. (32) and (33):
in nitric acid solutions:

$$T_0 = -0.148(3.9-h_1+h_5) - \log m_a$$
$$= 2.3(3.9-h_1+h_5)\log a_w - \log m_a \quad (32)$$

in perchloric acid solutions:

$$T_0 = -0.171(3.9-h_1+h_5) - \log m_a$$
$$= 2.3(3.9-h_1+h_5)\log a_w - \log m_a \quad (33)$$

The contribution from the electrostatic effect in these acid solutions is assumed to be the same as in hydrochloric acid solutions.

Discussion

Consideration with Respect to T_0. The most important conclusion is that if the h_1 increases by one, the corresponding increment of T_0 is $-2.4\log a_w$. If we considered only the behavior of water, however, the increment would be $-\log a_w$, because the disappearance of one molecule of free water is related to the increase of h_1 by one. In order to investigate this difference, let us compare the factors affecting the activity of water in the reaction system with those affecting the acidity function, T_0.

The activity of water can be determined from the

free-energy change due to the introduction of one molecule of water into the acid solution. The equation for this free-energy change can be obtained by differentiating Eq. (20) with respect to n_w at constant n_1, n_2, n_3, and n_5 values. The equation thus obtained is:

$$\left(\frac{\partial \Delta G^{mix.}}{\partial n_w}\right)_{n_1, n_2, n_3, n_5} = \left(\frac{\partial \Delta G^{mix.}}{\partial n_4}\right)_{n_1, n_2, n_3, n_5}$$

$$= \mu_4 - \mu_4^0 = \boldsymbol{k}T\left[\ln \frac{n_4\bar{v}_4}{V} + \left(1 - \frac{\sum_{i=1}^{5} n_i \partial V}{V\ \partial n_4}\right)\right] \quad (34)$$

The first term of Eq. (34) is the contribution due to the increase in the number of water molecules, while the second is that due to the volume increase of the solution caused by the increase in the number of water molecules. Using the relations represented by Eq. (23)—(28), we can obtain:

$$\log a_w = \log \frac{1-0.018\, hm_a}{1+0.018\, rm_a} + \frac{0.434\times 0.018(r+h-2)m_a}{1+0.018\, rm_a} \quad (35)$$

The first and second terms in Eq. (35) correspond to the second and fourth terms in Eq. (22) respectively. As is shown in Table 7, the value of each term in Eq. (35) is comparable in order to the absolute magnitude, while in Eq. (22) (see Table 4) the second term, responsible for the increase in the number of water molecules, contributes to T_0 predominantly, and the contribution of the fourth term, related to the increase in the volume of the system (which was caused by the formation of the activated complex), is small. The large increase in the volume in the calculation of water activity may be attributed to the introduction of a water molecule into the system from outside. While the small volume change in the calculation of T_0 is ascribed to the fact that the system is closed; the total numbers of the water molecule, n_w, the substrate, n_R, and acid, n_a, are constant. Since the number of water molecules freed from a hydrated proton upon the formation of an activated complex is $(h_2+h_5-h_1)$, the contribution of these water molecules to T_0 becomes $(h_2+h_5-h_1)\log a_w$. This means that the increase of h_1 by one contributes $-\log a_w$ to T_0. However, it is not enough to evaluate the small change in volume described above in the calculation of T_0 through only the value of $-\log a_w$.

$r=1.00$, $h=4.8$
I, $\log(1-0.018\, hm_a)/(1+0.018\, rm_a)$
II, $0.434\times 0.018(r+h-2)m_a/(1+0.018\, rm_a)$

Consideration of the Salting-out Effects. The activity coefficient of a neutral substrate in this study can be obtained by differentiating Eq. (20) with respect to n_5, with no change of n_1, n_2, n_3, and n_4 and with $h_5=0$:

$$\log f_5 = -\log(1+0.018\, rm_a) + \frac{0.434\times 0.018(\bar{v}_5/\bar{v}_4)(r+h-2)m_a}{1+0.018\, rm_a} \quad (36)$$

The calculated values of $\log f_5$ in the case of Rb have been tabulated in Table 8. The values are small, increase linearly with the concentration of acid, and are almost independent of the sort of acids. In Table 9 the observed values of $\log f$ of hydrogen are tabulated at the molality of 1.[24] It has been known that the salting-out effects increase almost linearly with the molar volume of a substrate.[24] The value of $\log f$ of Rb represented in Table 9 were, therefore, obtained by multiplying the $\log f$ of hydrogen by 0.65, the ratio of the molar volume of Rb to that of hydrogen. Good agreements between the calculated values of Tables 8 and 9 are observed in hydrochloric acid and in nitric acid, though there is a large discrepancy in perchloric acid. This discrepancy probably results from neglecting the $(0.434/\boldsymbol{k}T)(\partial G^{s.o.}/\partial n_1)$ term. If this term could be exactly estimated, the discrepancy might be adjustable.[26]

Table 8. $\log f_5$ of Rb calculated by Eq. (36) in acid solutions at 25°C

26) Conway[21] calculated the salting-out effect in view of the two phenomena mentioned above; however, further phenomena such as the structure-making influence of non-polar solutes[21] must be taken into account in calculating the exact value of the salting-out effect.

The Value of $(f_A f_{BH^+}/f_{AH^+} f_B)$. As was described in the first paragraph, Hammett and Deyrup found that the value of $(f_A f_{BH^+}/f_{AH^+} f_B)$ determined with aromatic amines was constant, independent of the species, A or B, as well as of the concentrations and of the sort of acids. However, it can be shown by the following procedure that this value is not always constant. The value of the acidity function, T_0, of the "0" system is compared with that of the "1" system at the same concentration of hydrochloric acid, where the "0" system and the "1" system are defined as the systems of $(h_1-h_5)=0$ and 1 respectively. From Eq. (31) we can obtain:

$$\Delta T_0 = T_{00} - T_{01} = 2.4 \log a_w \tag{37}$$

where the $_0$ and $_1$ subscripts represent the "0" system and the "1" system respectively. From the definition of T_0, in Eq. (11):

$$\Delta T_0 = -\log \frac{a_{H^+} f_{S_0}}{f_0^{\ddagger}} + \log \frac{a_{H^+} f_{S_1}}{a_w^{-1} f_1^{\ddagger}}$$

$$= -\log \frac{f_{S_0} f_1^{\ddagger}}{f_0^{\ddagger} f_{S_1}} + \log a_w \tag{38}$$

From Eqs. (37) and (38), Eq. (39) can then be derived:

$$-\log \frac{f_{S_0} f_1^{\ddagger}}{f_0^{\ddagger} f_{S_1}} = 1.4 \log a_w \tag{39}$$

Eq. (39) shows that the values of $(f_A f_{BH^+}/f_{AH^+} f_B)$ is not always constant,[12] but depends on the hydration number of the AH^+ and BH^+ species as well as on the acid concentration.

Bunnett's equation (17) was derived by considering the relation $(f_A f_{BH^+}/f_{AH^+} f_B)$ to be constant. If the w or (h_1-h_5) is increased by one, the increment of $\log k_1$ is $\log a_w$ in his treatment, but 2.4 $\log a_w$ in our treatment.

Comparison between the Observed $\log k_1$ and the T_0. Using Eq. (8), Eq. (31), and the dependence of $\log k_1$ upon the concentration of acid, we can obtain the hydration number of an activated complex or the number of water molecules contained in an activated complex.[18] The applicability of T_0 can be examined by comparing the T_0 and the observed $\log k_1$. Bunnett reported that, for many reactions, the values of w were fairly evenly distributed from -2 to $+8$.[2] If the hydration number of an activated complex increases from 0 to 3.9 in hydrochloric acid at the molality of 3, T_0 varies from -1.106 to -0.477; also, this variation in T_0 corresponds to that in w from -1.8 to 9.2. The fact that the ranges of the distribution of w observed for many reactions agree with those of the variation in T_0 indicates that the dependence of $\log k_1$ on the concentration of acid is effected mainly through the hydration number of an activated complex, because, as is shown in Tables 1—6, the variation in T_0 can be explained mainly by the hydration effect. Also, this fact would allow us to obtain the approximate number of water molecules contained in an activated complex by the application of T_0 to $\log k_1$. The more accurate numbers must be obtained by estimating the value of the salting-out effect exactly.

The relation between H_0 and T_0 is much the same as that between T_0 and $\log k_1$. The hydration number of aromatic amines, which was used to determine H_0, apparently becomes 0.7 when we apply T_0 to H_0, as is shown in Fig. 2.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 2756—2762 (1969)

Effects of Substitution on the Phosphorescence Process of Aromatic Carbonyl Compounds

Takeshi TAKEMURA and Hiroaki BABA

Division of Chemistry, Research Institute of Applied Electricity, Hokkaido University, Sapporo

(Received December 29, 1968)

Phosphorescence and absorption spectra, phosphorescence- and excitation-polarization spectra and phosphorescence lifetimes were measured at 77°K for benzaldehyde, acetophenone and their eight derivatives with a halogen atom, or a hydroxyl, methoxyl or amino group as a substituent at the *para* position. In chloro- and bromo-derivatives, the phosphorescent triplet state is of the (n, π^*) type, and is mixed with the $^1L_a(\pi, \pi^*)$ state by direct spin-orbit interaction, as in the case of the parent carbonyls. In addition, owing to the heavy-atom effect, it gains its singlet character by the mechanism

$$^1(\sigma, \pi^*) \text{ or } ^1(\pi, \sigma^*) \overset{\text{S.O.}}{\longleftrightarrow} {}^3L_a(\pi, \pi^*) \overset{\text{Vib.}}{\longleftrightarrow} {}^3(n, \pi^*)$$

which accounts for the observation that the phosphorescence spectrum involves out-of-plane-polarized vibrational bands. Substitution of a more electron-donating hydroxyl, methoxyl, or amino group brings about a change of the phosphorescent state from the $^3(n, \pi^*)$ state to the $^3L_a(\pi, \pi^*)$. The following mechanisms are shown to be important to the $^3L_a(\pi, \pi^*)$ state:

$$^1(n, \pi^*) \overset{\text{S. O.}}{\longleftrightarrow} {}^3L_a\ (\pi, \pi^*)$$

$$\begin{array}{ccc} & ^1(n, \pi^*) & \\ \overset{\text{Vib.}}{\nearrow}\downarrow & & \overset{\text{S.O.}}{\nwarrow}\downarrow \\ ^1L_a(\pi, \pi^*) & & {}^3L_a(\pi, \pi^*) \\ \underset{\text{S.O.}}{\nwarrow}\downarrow & & \underset{\text{Vib.}}{\nearrow}\downarrow \\ & ^3(n, \pi^*) & \end{array}$$

These account for two progressions with mutually perpendicular polarizations observed in the phosphorescence spectrum. The lifetimes for the transitions from the $^3L_a(\pi, \pi^*)$ state to the ground state of the substituted carbonyls were found to be substantially shorter than the corresponding lifetimes in aromatic hydrocarbons. This fact is quantitatively interpreted as due to the presence of a low-lying $^1(n, \pi^*)$ state.

The radiative process in aromatic carbonyl compounds has been a subject of considerable interest.[1-8] In typical aromatic carbonyls such as benzophenone and acetophenone, the lowest triplet state is of (n, π^*) character, and this fact is believed to lead not only to the characteristic phosphorescence with a short lifetime but also to the high photochemical reactivity of these compounds.[9-11] Perturbation by a suitable substituent or a polar solvent may produce a change in the lowest triplet state from an (n, π^*) to a (π, π^*) type, and this change is expected to be accompanied by an essential change in both the spectral and chemical behaviors of the carbonyl compounds. Studies along these lines have recently been reported.[7-12] In particular, even for weakly perturbed acetophenones like *p*-bromo- and *p*-

methylacetophenone, the lowest triplets were assigned to (π, π^*) states on the basis of S→T absorption spectra obtained by the phosphorescence excitation method.[7,11]

In this study the effects of substitution on the phosphorescence process of aromatic carbonyl compounds have been examined through spectroscopic analysis, polarization and lifetime measurements. Special attention was paid to the polarization of phosphorescence and excitation in relation to the mechanism of spin-orbit coupling. Several *para*-substituted benzaldehydes and acetophenones were investigated. Hydroxyl and amino derivatives display emission characteristics that are definitely ascribable to the lowest triplet state of (π, π^*) type, while the phosphorescent states of halogen derivatives appear to be of (n, π^*) from the results of polarization measurements.

An extensive polarization study was made by Shimada and Goodman[4] on carbonyl compounds including the unsubstituted benzaldehyde and acetophenone.

Experimental

Materials. All the reagents used were obtained from Wako Pure Chemical Industries, Osaka. Benzaldehyde, acetophenone and *p*-chloroacetophenone were purified by vacuum distillation, and *p*-chlorobenzaldehyde, *p*-bromobenzaldehyde and *p*-bromoacetophenone by repeated zone melting. *p*-Hydroxybenzaldehyde, *p*-hydroxyacetophenone and *p*-aminoacetophenone were recrystallized from water and from ethanol, and were further purified by vacuum sublimation. *p*-Methoxybenzaldehyde was fractionally crystallized several times.

Isopentane was refluxed over phosphorus pentoxide, and subjected to fractional distillation. Methylcyclohexane of spectroscopic quality was used without further purification. Ethyl ether was refluxed over metallic sodium, distilled, and was then passed through a freshly activated alumina column.

Apparatus and Procedure. Absorption spectra were obtained with a Hitachi EPS-3 spectrophotometer at 77°K or at room temperature. Emission and excitation spectra and their polarization were measured at 77°K with an apparatus which was constructed in our laboratory.[13] Emission spectra obtained were uncorrected for the spectral sensitivity of the detector. In polarization measurements, monochromatic light, obtained from a combination of 150-W xenon lamp and a grating monochromator (Hitachi G-3), passed through a Frank-Ritter-prism polarizer and irradiated the sample. The light emitted perpendicular to the excitation beam passed through another Frank-Ritter prism as analyzer and a quartz-prism monochromator (Hitachi EPU-2A), and it was then detected by a 1P-28 photomultiplier tube. The polarized spectra were recorded on an X-Y recorder.

The degree of polarization, P, is defined as

$$P = (I_{\parallel} - I_{\perp})/(I_{\parallel} + I_{\perp})$$

where $I_{\parallel}$ and $I_{\perp}$ are the intensities of the emitted light polarized respectively parallel and perpendicular to the exciting light which is polarized with the electric vector perpendicular to the plane formed by the excitation beam and the emission beam. The P values were corrected in the usual manner[14] for instrumental and other factors.

All the absorption and emission measurements at 77°K were carried out on rigid-glass samples in a 1-cm square quartz cell placed in a glass Dewar with quartz windows.

Phosphorescence lifetimes were measured using a Becquerel type phosphoroscope combined with a synchroscope.

Results

Figures 1—5 show absorption spectra (A), phosphorescence spectra (P), phosphorescence-polarization spectra (PP) and excitation-polarization spectra (EP) with respect to phosphorescence for benzaldehyde and its derivatives, *p*-chloro-, *p*-bromo-, *p*-hydroxy- and *p*-methoxybenzaldehyde (abbreviated to Cl-, Br-, OH- and OMe-benz-

respectively.

All these spectra were measured at 77°K in an isopentane-methylcyclohexane-ether (PME) mixture (volume ratio, 7.7 : 1.3 : 1). Although it was desirable to use the hydrocarbons alone as the solvent for reducing the solvent perturbation, ether had to be added so that the solute might have the minimum solubility. Nevertheless, no well-

resolved absorption spectra could be obtained at 77°K in the lowest frequency ($n\rightarrow\pi^*$) region, because of the still low solubility at that temperature. However, the excitation spectra were obtained with a good resolution in the same region.

Detailed spectral data on the excitation polarization in the $n\rightarrow\pi^*$ region for two representative compounds, benzaldehyde and OH-benzaldehyde are shown in Fig. 11, together with the absorption

Table 1. Observed and calculated phosphorescence lifetimes

Compound	τ_{obs} sec	τ_{calc} sec

p-Aminoacetophenone	0.86	0.58

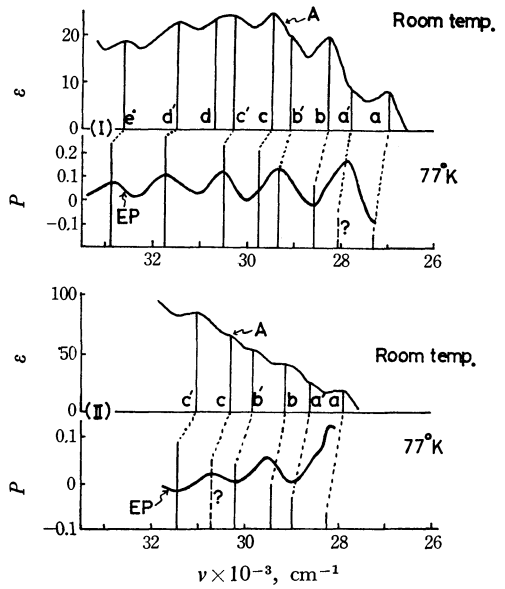

Fig. 11. Excitation-polarization spectra with respect to the phosphorescence 0-0 band in PME at 77°K and absorption spectra in PME at room temperature for benzaldehyde (I) and *p*-hydroxybenzaldehyde (II) in the region of the $n\rightarrow\pi^*$ transition. The location of absorption peaks is shown by vertical lines, the lengths of which represent the molar extinction coefficients, ε. The scale of ε values for the absorption peaks at 77°K is the same as that for the peaks at room temperature.

peaks observed at 77°K. For the sake of comparison, the absorption spectra at room temperature are also given in this figure.

The results of the polarization measurements for benzaldehyde and acetophenone are essentially the same as those reported by Shimada and Goodman,[4] although they employed EPA as the solvent.

The results of the phosphorescence lifetime measurements are recorded in Table 1.

Discussion

Spectral Changes due to Substitution. Benzaldehyde shows three electronic absorption bands in the near ultraviolet region (Fig. 1). The weak absorption band located at 30000 cm^{-1} is due to an $n\rightarrow\pi^*$ transition, and the other two to $\pi\rightarrow\pi^*$ transitions. The bands at 35000 cm^{-1} and 40000 cm^{-1} are assigned respectively to $^1A\rightarrow{}^1L_b$ and $^1A\rightarrow{}^1L_a$ (or an intramolecular charge-transfer) transitions.[4]

The ionization energies of the substituents concerned in this study are in the order $Cl\gtrsim Br> OH\gtrsim OCH_3> NH_2$.[15] The ^1L_a band is markedly

15) F. A. Matsen, "Chemical Applications of Spectroscopy," ed. by W. West, Interscience, New York (1956), p. 673.

shifted to lower frequencies with the decrease of the ionization energy of the substituent (Figs. 2—5). On the other hand, substitution produces no appreciable change in the position of the ^1L_b band, and thus in OH- and OMe-benzaldehyde the latter band is almost hidden under the stronger ^1L_a band. The substitution has no appreciable effect on the position of the $n\rightarrow\pi^*$ band. It may be noted, however, that the $n\rightarrow\pi^*$ band is slightly displaced to the red by chlorine and bromine and to the blue by OH and OMe groups.

The unsubstituted benzladehyde exhibits a phosphorescence spectrum with a well-defined and simple vibrational structure, but the structures of the phosphorescence spectra of the substituted benzaldehydes are more or less complicated.

The foregoing descriptions of the absorption and phosphorescence spectra of benzaldehyde and its derivatives apply on the whole to the spectra of acetophenone and its derivatives (Figs. 6—10).

Polarization. The polarization behaviors of the spectra of the carbonyl compounds studied can be classified into two types, one represented by benzaldehyde and the other by OH-benzaldehyde. Actually, these compounds belong to the symmetry group C_s, but their electronic structure may be discussed in terms of the structure of C_{2v} molecules. The resolution of the representations of C_{2v} into those of C_s is shown in Table 2, the coordinate axes being given in Fig. 12. It should be noted that for the carbonyl compounds concerned the lowest vacant π orbital is of b_1 type,[16] and the n orbital is of b_2 type.

Table 2. Resolution of representations

C_{2v}	C_s
$A_1(z)$	$A'(y, z, R_x)$
$A_2(R_z)$	$A''(x, R_y, R_z)$
$B_1(x, R_y)$	$A''(x, R_y, R_z)$
$B_2(y, R_x)$	$A'(y, z, R_x)$

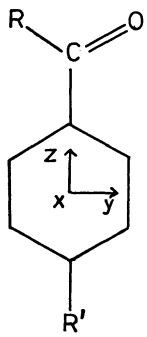

Fig. 12. Structure and coordinate axes for the carbonyl compounds. The x axis is perpendicular to the molecular plane.

16) K. Inuzuka and T. Yokota, This Bulletin, **37**, 1224 (1964).

The $^1A\rightarrow{}^1L_a$ and $^1A\rightarrow{}^1L_b$ transitions are $^1A_1\rightarrow{}^1A_1$ and $^1A_1\rightarrow{}^1B_2$ analogue transitions, respectively. The $n\rightarrow\pi^*$ band is due to a $^1A_1\rightarrow{}^1A_2$ analogue transition, which is forbidden in the C_{2v} molecules but changes to a symmetry-allowed transition $^1A'\rightarrow{}^1A''$ as a result of the lowering of symmetry from C_{2v} to C_s. Thus, in each of the two representative molecules, benzaldehyde and OH-benzaldehyde, the vibrational progression a, b, c, *etc.* (see Fig. 11) is attributable to the symmetry-allowed transition, with the band a as the 0—0 band. On the other hand, the $n\rightarrow\pi^*$ transition may steal intensity from the $^1A\rightarrow{}^1L_a$ through a vibronic interaction involving an a_2 analogue vibration.[4] This mechanism may account for the second progression a′, b′, c′, *etc.* of the $n\rightarrow\pi^*$ transitions.

To sum up, the $^1A\rightarrow{}^1L_a$ absorption and the a′-progression of the $n\rightarrow\pi^*$ absorption are polarized along the long axis (z) of the molecule and the $^1A\rightarrow{}^1L_b$ is along the short axis (y), while the a-progression of the $n\rightarrow\pi^*$ absorption should be polarized perpendicular to the molecular plane (x axis).*1

For benzaldehyde (Figs. 1 and 11), the excitation-polarization spectrum with respect to emission at the phosphorescence 0-0 band, α, is consistent with the view that the phosphorescence 0-0 band is polarized in the molecular plane and along the long axis.[4] The degree of polarization, P, of the phosphorescence with respect to excitation into the $^1A\rightarrow{}^1L_a$ absorption shows highly positive values which are nearly constant throughout the phosphorescence spectrum. This implies that the phosphorescence spectrum of benzaldehyde consists almost of a single progression, α, β, *etc.*, with the 0—0 band α as its first member.

The excitation-polarization spectra of Cl- and Br-benzaldehyde are essentially the same as that of benzaldehyde. Thus the phosphorescence 0-0 band, α, of the halo-derivatives must be polarized along the long axis. On the other hand, the phosphorescence-polarization spectra of these derivatives show distinct variations in the P value. This fact together with the features of their phosphorescence spectra suggests that the phosphorescence spectra involve a progression which differs in polarization from the main progression including the 0-0 band.

The excitation- and phosphorescence-polarization spectra of acetophenone and its chloro- and bromo-derivatives are on the whole similar to the corresponding spectra of benzaldehyde and its chloro- and bromo-derivatives, respectively. Therefore, the preceding discussions on the latter molecules are applicable to the former as well. It is to be noted, however, that in acetophenone the phosphorescence-polarization spectrum shows an

*1 The progressions starting from the bands a and a′ are called a- progression and a′-progression, respectively.

appreciable variation in the P value, which is not found in the case of benzaldehyde.

The situation is radically changed on going from benzaldehyde to OH-benzaldehyde. Thus, with respect to emission at the phosphorescence 0-0 band, α, the excitation-polarization spectrum of OH-benzaldehyde shows negative P values in the region of the $^1A \rightarrow {}^1L_a$ band and minimum values of P at the vibrational peaks of the a'-progression, whereas the P values are positive at the peaks of a-progression (Figs. 4 and 11). Further, the P values appear to be negative in the region of $^1A_1 \rightarrow {}^1L_b$ absorption, which is not clearly separated from the $^1A_1 \rightarrow {}^1L_a$ absorption. These observations lead to the conclusion that the phosphorescence 0-0 band α is polarized perpendicular to the molecular plane.

Inspection of the phosphorescence and phosphorescence-polarization spectra of OH-benzaldehyde shows that, in addition to the out-of-plane-polarized α-progression, there is an inplane-polarized progression, α', β', *etc.*, which is polarized along the long axis. The spacing between successive bands of each of the α- and α'- progressions is about 1550 cm^{-1}. The origin (band α') of the latter progression is situated about 900 cm^{-1} from the 0-0 band to the red.

The polarization characteristics and spectral features of OCH_3-benzaldehyde, and OH- and NH_2-acetophenone (Figs. 5, 9 and 10) are similar to those of OH-benzaldehyde mentioned above.

Mechanisms of Spin-Orbit Coupling and Assignment of the Phosphorescent States. The polarization data may be explained by considering the mechanisms of spin-orbit coupling in the carbonyl compounds. The following discussions are based on a few assumptions.[1] (1) The perturbation of the ground state by triplet states is negligible. (2) The first-order spin-vibronic perturbation is negligible. (3) The spin-orbit operator, H_{SO}, can be approximated as a sum of one-electron operators. According to these assumptions, spin-orbit coupling through H_{SO} occurs only between electronic states resulting from one-electron excitations which take place either from the same occupied molecular orbital or to the same vacant orbital. The phosphorescent state of benzaldehyde can be assigned to the $^3A_2(n, \pi^*)$ analogue,[4] which couples directly with the $^1A_1$ (π, π^*) state through the first order spin-orbit perturbation, $H_{SO}(R_z)$. We can write as

$$^1L_a(\pi, \pi^*) \overset{\text{S.O.}}{\longleftrightarrow} {}^3(n, \pi^*) \qquad (1)$$

The above mechanism accounts for the polarization features in the compounds of the benzaldehyde type, namely, the long-axis polarization of the α-progression, including the 0-0 band, of the phosphorescence spectra. The effective spin-orbit perturbation of the first order along with the high intensity of the $^1A \rightarrow {}^1L_a$ transition should result in very short phosphorescence lifetimes for these compounds. This is indeed the case, as seen in Table 1.

The aromatic carbonyl compounds are considered to have the $^3L_a(\pi, \pi^*)$ state close to the $^3(n, \pi^*)$ state. Because of the small energy difference between the two triplet states, an effective vibronic interaction involving an a_2 analogue vibration is expected to occur, so that the $^3(n, \pi^*)$ state will be mixed with singlet states through the second-order spin-orbit-vibronic perturbation. In most aromatic hydrocarbons, $^3(\pi, \pi^*)$ states are known to gain their singlet characters by direct coupling with $^1(\sigma, \pi^*)$ or $^1(\pi, \sigma^*)$ states.[1] Thus, in addition to mechanism (1), the following may also be responsible for the transition $^3(n, \pi^*) \rightarrow S_0$ (ground state):

$$^1(\sigma, \pi^*) \text{ or } {}^1(\pi, \sigma^*) \overset{\text{S.O.}}{\longleftrightarrow} {}^3L_a(\pi, \pi^*) \overset{\text{Vib.}}{\longleftrightarrow} {}^3(n, \pi^*) \qquad (2)$$

In the absence of a heavy atom, mechanism (2) is negligible as compared with mechanism (1). When the molecule contains a heavy atom, the spin-orbit interaction between ^3L_a and $^1(\sigma, \pi^*)$ or $^1(\pi, \sigma^*)$ will be enhanced to increase the relative importance of mechanism (2).[17] Accordingly, the $^3(n, \pi^*) \rightarrow S_0$ transition will be provided with an out-of-plane transition moment.

In the chloro- and bromo-derivatives of benzaldehyde, the phosphorescence-polarization spectra show variations in the P values; there appear minima in the positive P curves. Furthermore, the vibrational structures of the phosphorescence spectra of the halo-derivatives are more or less irregular. These observations can reasonably be explained in terms of mechanism (2).

By following the same reasoning, we can interpret the phosphorescence and phosphorescence-polarization spectra of the chloro- and bromo-derivatives of acetophenone. If this interpretation is correct, however, one problem will remain unsolved. That is, as has been pointed out, the phosphorescence-polarization spectrum of the unsubstituted acetophenone exhibits a variation. This cannot be attributed to mechanism (2), since the acetophenone molecule has no heavy atom. On the other hand, the phosphorescence spectrum itself is fairly simple as in the case of benzaldehyde. This fact suggests that the out-of-plane component should be negligible in the phosphorescence polarization of acetophenone. In any case, further studies are necessary for understanding fully the polarization behavior of the phosphorescence of acetophenone.

The radical changes in polarization produced by substitution of OH, OCH_3 and NH_2 groups can be best understood by taking account of possible

17) M. A. El-Sayed, *J. Chem. Phys.*, **43**, 2864 (1965).

changes in the phosphorescent state. Substitution of such electron-donating groups leads to a considerable lowering of the energy level of the ^1L_a state and to a slight rise of the $^1(n, \pi^*)$ level. If the ^3L_a and $^3(n, \pi^*)$ states behave similarly, the positions of the ^3L_a and $^3(n, \pi^*)$ levels are expected to be reversed, with the result that the ^3L_a state is the lowest triplet in the compounds of the OH-benzaldehyde type.

The mechanisms of the spin-orbit coupling in these molecules were examined on the assumptions mentioned before and also on the premise that the direct spin-orbit coupling between $^1(\pi, \pi^*)$ and $^3(\pi, \pi^*)$ states is vanishingly small.[1] Of the several possible mechanisms the following two seem to be most important:

$$^1(n, \pi^*) \overset{\text{S.O.}}{\longleftrightarrow} {}^3L_a(\pi, \pi^*) \tag{3}$$

$$\begin{array}{ccc} & ^1(n, \pi^*) & \\ \text{Vib.}\nearrow\swarrow & & \nwarrow\text{S.O.} \\ ^1L_a(\pi, \pi^*) & & ^3L_a(\pi, \pi^*) \\ \text{S.O.}\nwarrow\searrow & & \nearrow\swarrow\text{Vib.} \\ & ^3(n, \pi^*) & \end{array} \tag{4}$$

As will be seen later, the lifetime data show that the coupling mechanism which is important for the phosphorescent $^3(\pi, \pi^*)$ state of aromatic hydrocarbons is not operative in the carbonyl compounds in question. Thus, the direct spin-orbit interaction between $^3L_a(\pi, \pi^*)$ and $^1(\sigma, \pi^*)$ or $^1(\pi, \sigma^*)$ is not considered here.

As regards mechanism (3), the transition between the ground state and the perturbing singlet, $^1(n, \pi^*)$, is forbidden in the C_{2v} molecules, but it becomes symmetry allowed in the actual C_s molecules. On the other hand, a large absolute value is anticipated for the matrix element of H_{SO} between the $^1(n, \pi^*)$ and ^3L_a states. Thus, the mechanism (3) plays a major role in the phosphorescence transition, and it accounts for the out-of-plane polarization of the α-progression that includes the 0-0 band.

Mechanism (4) involves second-order interactions. Its importance is considered to be comparable with the importance of mechanism (3), since in the singlet $n\rightarrow\pi^*$ absorption the intensities of the a- and a'-progressions are of comparable magnitudes. Mechanism (4) results in the appearance of the α'-progression which is vibronically induced and is polarized along the long molecular axis.

Mention should be made here of the assignment of the triplet states which was made by Kearns and Case on the basis of singlet→triplet absorption spectra.[7] According to their results, the lowest triplet state is a $^3(n, \pi^*)$ state for benzaldehyde, Br-benzaldehyde and acetophenone, and is a $^3(\pi, \pi^*)$ state for OH-acetophenone, in agreement with the present assignment. As to Br-acetophenone, they assigned the lowest triplet state as a $^3(\pi, \pi^*)$ state, whereas we regard it as a $^3(n, \pi^*)$. Our assignment is based on the observation that the phosphorescence 0-0 band of Br-acetophenone is highly positively polarized with respect to excitation into the $^1A\rightarrow{}^1L_a$ absorption band. Inspection of Figs. 3 and 8 will show that there is no substantial difference in the polarization spectra between Br-benzaldehyde and Br-acetophenone, so that the latter compound should have the same type of phosphorescent state as the former, *viz.*, an (n, π^*) type of phosphorescent state. It should be noted that the discrepancy between the two assignments might result from the difference between the samples employed. (Kearns and Case used a crystalline sample of Br-acetophenone doped with naphthalene.)

Lifetimes. As seen in Table 1, the molecules with the phosphorescent triplet state of (π, π^*) type have relatively long lifetimes. However, they are still markedly shorter than the lifetimes of the $^3(\pi, \pi^*)\rightarrow S_0$ phosphorescence emissions in aromatic hydrocarbons. This problem has recently been noticed by several authors[7,12,18,19] in aromatic azines and carbonyls, and has been discussed from the viewpoint of participation of a low-lying $^1(n, \pi^*)$ state in the spin-orbit coupling.

The matrix element

$$\langle\, ^1(n, \pi^*)|\, H_{SO}\, |^3L_a(\pi, \pi^*)\,\rangle \tag{5}$$

which is associated with mechanisms (3) and (4) can be equated to

$$\langle\, ^1L_a(\pi, \pi^*)|\, H_{SO}\, |^3(n, \pi^*)\,\rangle \tag{6}$$

provided that $^1(n, \pi^*)$ and $^3(n, \pi^*)$ have the same spatial configuration.[20]

In a previous paper,[12] we assumed the matrix element (6) of OH-benzaldehyde to be approximately equal to the corresponding element for the unsubstituted benzaldehyde (*cf.* mechanism (1)), and thus calculated the phosphorescence lifetime of OH-benzaldehyde. Similar calculations were made for molecules whose phosphorescent states have been assigned to the $^3(\pi, \pi^*)$ states in this study. The calculated lifetimes, τ_{calc}, which correspond to the observed lifetimes (rather than to the natural lifetimes) were obtained by assuming that the substitution leads to no change in the phosphorescence quantum yield. This assumption is based on the observation that the phosphorescence intensity was not appreciably changed by substitution. The results are shown in Table 1. In spite of the assumptions involved, the τ_{calc} values are in good agreement with the τ_{obs} values.

The Excited States of Acridine Dyes. I. An ESR Study of the Triplet State

Yukio KUBOTA*1 and Masaji MIURA

Department of Chemistry, Faculty of Science, Hiroshima University, Hiroshima

(Received January 8, 1969)

The lowest triplet state of acridine dyes has been studied by an ESR technique over a wide range of concentration and in various solvents. The ESR spectra of the triplet state have been observed at a resonance field of *ca.* 1550 gauss, corresponding to the $\Delta M=2$ transitions. The ESR data characteristic of the triplet state depend on the dye concentration; this has been interpreted as being due to the association of dye molecules. The values of the zero-field splitting parameter, D^*, calculated from the $\Delta M=2$ transition spectra lead to the assignment of the lowest triplet state of acridine dyes as the $(\pi-\pi^*)$ state.

Since the first observation of the ESR spectra of the phosphorescent triplet state of naphthalene molecules in a single crystalline matrix[1] and the ESR observations of the triplet state of randomly-oriented molecules in rigid glass solutions for the forbidden ($\Delta M=2$) transitions[2] and for the allowed ($\Delta M=1$) transitions,[3,4] the ESR technique has provided a powerful tool for the investigation of the triplet states of aromatic, heteroaromatic, and biological molecules. From the ESR measurements, information regarding the zero-field splitting (ZFS) parameters, D and E, the lifetime of the triplet state, and so on may be obtained.

Acridine dyes are of biological interest with regard to their photodynamic and mutagenic actions. It is of great significance to ascertain the nature of the excited states of acridine dyes, since their excited states, especially triplet states, are considered to play an important role in the primary process of photodynamic action.[5]

For this paper, the lowest triplet state of several acridine dyes, mainly acridine orange, proflavine, and acriflavine, have been investigated by the ESR technique over a wide range of concentration and in various solvents.

Experimental

Materials. The acridine orange (Tokyo Kasei) was precipitated as a free base from the aqueous solution by adding a dilute sodium hydroxide solution. The resulting precipitate was dissolved in chloroform, and then the solution was passed through an activated alumina column in chloroform.[6] The eluate containing a main band was filtered to remove any alumina particles. The free base was precipitated by evaporating chloroform under a reduced pressure and was then recrystallized three times from an ethanol-water mixture.

The proflavine (Tokyo Kasei) was also precipitated as a free base in a similar manner. The resulting free base was recrystallized twice from an ethanol-water mixture.

The acriflavine (Tokyo Kasei) was treated twice with freshly-precipitated silver hydroxide in order to remove the proflavine[7] and was then recrystallized twice from methanol.

The acridine (Tokyo Kasei) was recrystallized three times from ethanol. The acridine yellow and acridine red (Tokyo Kasei) were used without further purification. The anthracene (Tokyo Kasei) was recrystallized from ethanol, and the naphthalene (Wako Junyaku) was purified by the sublimation method.

The methanol, ethanol, ether, and ethylene glycol (EG; G. R. of Wako) were purified according to the usual methods. The glycerine (G. R. of Wako) was used without further purification.

Apparatus and Procedures. The ESR spectra were measured by using a JES-3BS-X spectrometer with a field modulation of 100 kc/sec and with a TE_{011} mode cavity; the spectrometer had been manufactured by the Japan Electron Optics Laboratory. The microwave frequency was 9100—9200 Mc/sec, and the amplitude of the modulation field was 12—20 gauss (G), peak to peak. The sample solution was kept in a quartz tube (3 mm in inner diameter) and was kept at 77°K in a quartz Dewar. Glucose glasses were made by rapid cooling after fusing an appropriate

mixture of glucose and dye; they were then kept in a desiccator with phosphorus pentoxide. Measurements were carried out at 77°K and at higher temperatures. The temperature, except at 77°K, was controlled by varying the flow rate of cold nitrogen gas through the cavity. The light sources were as follows: (1) a 750-W tungsten projector lamp with a filter (1 cm thick) containing 10% $CuSO_4$ aqueous solution, and (2) a 1-kW high-pressure mercury lamp with a filter (5 cm thick) containing a 0.1 M $NiSO_4$ aqueous solution and with two quartz lenses. The latter was used for the excitation of acridine, naphthalene, and anthracene, and the former, for the excitation of the other substances.

The absorption spectra were measured at room temperature with a Shimadzu QV-50 spectrophotometer. The phosphorescence measurements were performed at 77°K with a Hitachi MPF-2A fluorescence spectrophotometer (R-136 photomultiplier) with an attachment for the phosphorescence measurements.

Results and Discussion

The ESR spectra of the triplet state of acridine dyes were observed at a resonance field of *ca.* 1550 G corresponding to the $\Delta M=2$ transitions, which are shown in Fig. 1 for acridine orange, proflavine, and acriflavine. According to van der Waals and de Groot,[2] the position of the peak on the low-field side of the derivative spectrum (H_{min}) is related to the root-mean-square ZFS parameter, D^*, by the following equation:

$$D^* = (D^2+3E^2)^{1/2} = \sqrt{3}\,[1/4(h\nu)^2-(g\beta H_{min})^2]^{1/2}$$

where h is Plank's constant; ν, the microwave frequency; g, the spectroscopic splitting factor, and β, the Bohr magneton. The ESR results are summarized in Tables 1 and 2, where ΔH denotes the linewidth determined as the peak-to-peak distance of the derivative spectrum and where τ is the decay time of the ESR signal after the light has been extinguished; τ should be equal to the measured lifetime of phosphorescence.

ZFS Parameters. Each D^* value for acridine dyes is constant within the range of experimental error, regardless of the dye concentration and of the kind of solvent at relatively low concentrations. At higher concentrations and in solvents containing water, however, the D^* value tends to decrease with an increase in the dye concentration. This will be discussed later. The D^* values given in Table 2 are the averages at low dye concentrations where the decrease of D^* value does not occur. These values are of the same order of magnitude as those of anthracene and naphthalene;[8] they may, therefore, make it possible to assign the lowest triplet state of acridine dyes to the $(\pi-\pi^*)$ state. For acridine, its D^* value also suggests that the lowest triplet state is the $(\pi-\pi^*)$ state.

In addition to the $\Delta M=2$ transition spectra, we could observe the $\Delta M=1$ transition spectra consisting of six lines associated with three molecular axes. The latter spectra were, however,

relatively broader and much less intense than the former spectra because of their anisotropic character. From the $\Delta M=1$ transition spectra, the values of the ZFS parameters, D and E, were calculated;[3,4] they are presented in Table 2. The D^* values obtained from these D and E values, 0.0693 and 0.0795 for acridine orange and proflavine respectively, are in fairly good agreement with those obtained from the $\Delta M=2$ transition spectra.

In order to examine the temperature dependence of the D^* value, ESR measurements of glucose glass containing acridine dyes were carried out over the temperature range from 77 to 300°K. The intensities of both the phosphorescence and the ESR signal at the $\Delta M=2$ transition decrease with an increase in the temperature. The signal-to-noise ratio at 300°K was 4 : 1 for acridine orange. For proflavine and acriflavine, no ESR signals of the triplet state were observed at room temperature; instead, another strong green luminescence (probably α-phosphorescence) was observed for these dyes. As may be seen in Fig. 2 for acridine orange and acriflavine, it was found that the D^* values decrease with a rise in the temperature; namely, the plot of D^* against the temperature in each case gives an approximately straight line with a slope of -2×10^{-5} cm^{-1} deg^{-1}. This phenomenon, similar to that of coronene in a plastic matrix,[9] seems general in the triplet state of aromatic molecules.

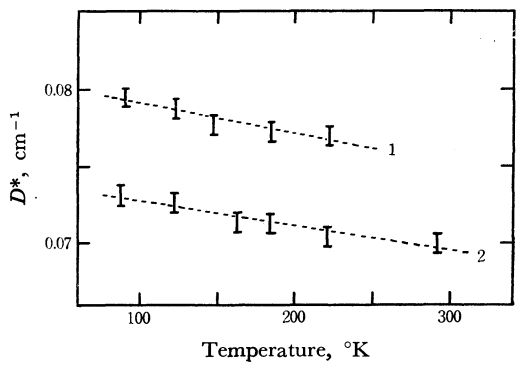

Fig. 2. Variation of D^* with temperature.
(1) Acriflavine, (2) Acridine orange

Lifetime of the Triplet State. As an example, the decay curve of the triplet state of proflavine is shown in Fig. 3 (a). The decay curve was generally exponential except for the first stage, up to 0.3 sec; this deviation may be due to the response time (0.3 sec) of the recorder. As is shown in Fig. 3(b), a plot of the logarithm of the signal intensity against the time gives a straight line; the lifetime of the triplet state can be calculated from the slope of this line. The lifetime, generally, tends to decrease with an increase in the dye concentration and is in good agreement with the results obtained from the phosphorescence measurements (see Fig. 5).

Dependence of the ESR Data on the Dye Concentration. As may be seen from Table 1, the ESR data characteristic of the triplet state seem to depend on the dye concentration. Figure 4 shows the concentration dependence of the D^* and ΔH values in the case of acridine orange. In general, D^* decreases and ΔH increases with an increase in the dye concentration. This phenomenon, depending on the kind of solvent, was more remarkable in glycerine than in EG. As is well known,[6,10,11] acridine dyes easily form the dimer and higher aggregates at high concentrations in both water and organic solvents. First, the absorption spectra were measured at various concentrations in order to establish the associative properties of acridine dyes. These dyes were found, by the method of Zanker[10] and Mataga,[11] to exist in a monomer-dimer equilibrium in glycerine and EG.

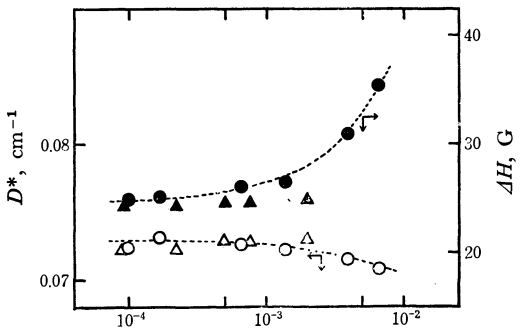

Fig. 4. Variation of D^* and ΔH with concentration of acridine orange at 77°K.
○ ●: in glycerine, △ ▲: in EG

The equilibrium constants for the dimerization of acridine orange were estimated to be about 450, 100, and 460 M^{-1} in glycerine, EG, and EG-water (1 : 1 by volume) respectively. Further, the association tendency is considerably enhanced by a drop in the temperature.[10] Second, the ΔH value was unchanged irrespective of the triplet-state concentration, which was controlled by varying the intensity of the exciting light. This fact appears to rule out the possibility that the broadening of the linewidth arises from the interaction between triplet-state molecules, even though the intermolecular distance may be expected to be shortened at a high concentration. Next, the interaction between triplet-state molecules and radicals formed during irradiation may give rise to the broadening of the linewidth. The radical concentration was, however, too low to permit the identification of the radicals, and so this effect may be disregarded. Finally, the ESR data were independent of the concentration in the case of aromatic hydrocarbons which do not tend to associate, while they were concentration-dependent in the case of acridine dyes.

In view of these facts, it seems reasonable to assume that the association of acridine dyes is responsible for the apparent decrease in the D^* value and the apparent increase in the ΔH value

11) N. Mataga, This Bulletin, **30**, 375 (1957).

with an increase in the dye concentration. As may be noticed from Fig. 1 for acridine orange, the ESR spectra are presumed to be made up by the superposition of the spectrum due to the triplet state of a monomer and that due to the triplet state of a dimer; the latter, having a D^* value smaller than that of the former, becomes marked with an increase in the dye concentration. In agreement with this argument, in solvents containing water, where acridine dyes form aggregates more easily than in pure organic solvents, this phenomenon is pronounced. A possible explanation for the decrease in the D^* value is the delocalization of two unpaired electrons in a dimer molecule. This theory is, of course, still speculative. If so, however, the resulting increase in the interelectronic separation (r_{12}) may lead to a decrease in the D^* value since:

$$D \propto |\langle(r_{12}^2-3z_{12}^2)/r_{12}^5\rangle| \text{ and } E \propto |(\langle y_{12}^2-x_{12}^2)/r_{12}^5\rangle|.^{12)}$$

ESR measurements clarify the nature of the triplet state itself through the magnetic dipolar interaction between unpaired spins, whereas phosphorescence measurements give information regarding the triplet-singlet transition and the energy level of the triplet state. Therefore, phosphorescence measurements have been carried out to establish further details of the triplet state of acridine dyes in connection with their association. As preliminary findings, Fig. 5 shows the phosphorescence spectra of acridine orange and proflavine. In both cases, the maximum of phosphorescence spectra shifts to a longer wavelength with an increase in the dye concentration. The phosphorescence lifetime has been found to be dependent on the dye concentration and on the wavelength (both emission and excitation). Further study is in progress and will be reported elsewhere.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 2767—2772 (1969)

Hybridization of Carbon and Equilibrium Distance

Tomoo MIYAZAKI and Hidehito OHBAYASHI

Department of Applied Chemistry, Faculty of Science and Engineering, Waseda University, Nishi-Ohkubo Shinjuku-ku, Tokyo

(Received February 20, 1969)

The CNDO/2 method, an approximate self-consistent molecular orbital theory, has been applied to the calculation of equilibrium distances of the carbon-hydrogen bond and the normal and hypothetical carbon-carbon single or double bonds which are usually considered te-te, tri-tri, di-di and te-tri single bonds or tri-tri and di-di double bonds between carbon hybrids. The electronic interaction energies between non-adjacent atomic orbitals for sigma system considering appropriate carbon hybrids have been estimated. From the results of these calculations, it follows that the carbon-carbon bond length of sigma system is little affected by the types of hydbridization of carbon atoms.

It is noteworthy that the CNDO/2 mthod,[1-3] the self-consistent molecular orbital method based on the neglect of differential overlap for all valence orbitals, leads to generally good agreement with experimental values for the bond lengths and bond angles of di, tri and tetra-atomic molecules. The CNDO/2 treatment satisfies the requirement that the molecular wave function and the orbital energies are invariant under orthogonal transformations of the atomic orbital basis set such as the replacement of s, p orbitals by hybrids. This type of approximation makes it possible to discuss a relationship between the lengths of single bonds in equilibrium and the types of hybridization of carbon atoms.

The carbon-carbon bond lengths for some conjugated hydrocarbons have been studied with the pi bond order (P_{pi}) - bond length (R) relationship for bonds in equilibrium.[4-6] It must be

remembered that the P_{pi}-R relation is based on the following two assumptions; separability of the sigma and pi energies and localization of sigma bonds formed by the overlap of two hybridized orbitals (localization of sigma electron). These assumptions are generally adopted but they will be avoided in this paper.

The relative importance of pi electron resonance and hybridization in the shortening effect for the bond lengths of conjugated hydrocarbons has been discussed by many investigators. Among others, Mulliken[7] suggested that the bond shortening effect of hybridization is of comparable magnitude to that of conjugation for butadiene C_2–C_3 bond distance, and he estimated the C–C bond length with given types of hybridization to be 1.45 Å for a di-di, 1.51 Å for a tri-tri and 1.54 Å for a te-te C–C single bond. It has been generally accepted that the shortening of the covalent radius in the C–C single bond is due to the increased *s* character in the bond orbital. The shortening of C–H distances for diagonal, trigonal and tetrahedral hybrids of the carbon atom can also be explained by this effect.[8]

However, it appeared of interest to investigate further the problem described above for the following reasons. Since little attention has so far been paid to the sigma electron delocalization effects, it was thought advisable to calculate C–C equilibrium distances for given types of hybrid by the molecular orbital method which explicitly treats sigma and pi orbitals together. The calculations were performed on several hydrocarbons; methane, ethane, propane, butane, ethylene, propylene, butadiene and acetylene. It may be concluded from the results of these calculations that the equilibrium lengths of C–C single bonds are little affected by the hybridization of carbon atoms.

Methods of Calculation

In the CNDO/2 approximation, the molecular orbitals, which are approximated as linear combination of valence atomic orbitals, and their energies can be obtained by solving the appropriate set of secular equations and the corresponding secular matrix. The elements of the SCF energy matrix are given in this method by

$$F_{\mu\mu} = H_{\mu\mu} + \left(P_{AA} - \frac{1}{2}P_{\mu\mu}\right)\gamma_{AA} + \sum_{(A\neq B)} P_{BB}\gamma_{AB}, \quad (1)$$

$$F_{\mu\nu} = H_{\mu\nu} - \frac{1}{2}P_{\mu\nu}\gamma_{AB}, \qquad (\mu \neq \nu) \quad (2)$$

$$H_{\mu\mu} = -\frac{1}{2}(I_\mu + A_\mu) - \left(Z_A - \frac{1}{2}\right)\gamma_{AA} - \sum_{A\neq B} Z_B\gamma_{AB}, \quad (3)$$

$$H_{\mu\nu} = \frac{1}{2}S_{\mu\nu}(\beta^0_A + \beta^0_B), \quad (4)$$

where $H_{\mu\nu}$ is the matrix element of the one-electron Hamiltonian which includes the kinetic energy and the electrostatic potential energy due to the core, the term $-1/2(I_\mu+A_\mu)$ is the core integral, P_{AA} and $P_{\mu\mu}$ are the atomic and orbital electron densities, respectively, $P_{\mu\nu}$ is the orbital bond order, Z_A is the core charge of atom A, γ_{AB} is the average electron-repulsion integral, β^0_A and β^0_B are empirically determined resonance integrals characteristic of atoms A and B, respectively, and $S_{\mu\nu}$ is the overlap integral between atomic orbitals μ and ν. The derivation of the method and the mathematical definitions of all quantities can be found in the original CNDO paper.[1-3] The total electronic energy of the valence electrons is

$$E_{electronic} = \frac{1}{2}\sum_{\mu,\nu} P_{\mu\nu}(H_{\mu\nu} + F_{\mu\nu}). \quad (5)$$

The total energy of the molecule is obtained by adding the repulsion energy between cores to the total electronic energy. The repulsion energy between cores is approximated by a point-charge model. The result is

$$E_{total} = E_{electronic} + \sum_{A<B}\sum Z_A Z_B/R_{AB}, \quad (6)$$

where R_{AB} is the A–B inter-nuclear distance.

The total energy and wave functions were calculated by varying the particular bonding distance considered, while the other bonds in the molecule were held fixed at their observed equilibrium distances. An equilibrium bond length was determined by minimizing the total energy with respect to the distance.

It was assumed that the hypothetical carbon-carbon equilibrium distances of molecules which include the broken pi bonds can be estimated by the following three types of calculations. The hypothetical carbon-carbon bonds are those which are usually considered to be the tri-tri, di-di and te-tri C–C single bonds or the di-di C–C double bond.

Calculation A. The contribution of pi bonding energies can be eliminated from the total energies of ethylene and acetylene in the manner

$$E^\dagger = E_{total} - \frac{1}{2}\sum_{\substack{\mu,\nu \\ (\mu\neq\nu)}}{}^{\pi} P_{\mu\nu}(H_{\mu\nu} + F_{\mu\nu}), \quad (7)$$

where the summation $\sum^\pi$ is over pi atomic orbitals. Since the summation does not include the term $\mu=\nu$, the energy $E^\dagger$ contains the energies of unpaired electrons in the pi atomic orbitals of carbons. The calculation can be performed under the condition that each pi electron density is equal to the number of atomic valence pi electrons. The treatment is confined to the calculation of ethylene and acetylene, because pi electron densities of larger conjugated hydrocarbons are non-uniformly distributed according to the CNDO/2 calculation.

7) R. S. Mulliken, *Tetrahedron*, **6**, 68 (1959).
8) "An Epistologue on Carbon Bonds," *ibid.*, **17** Nos. 3/4 (1962).

The equilibrium distances of C–C single bond are determined from the $E^{\dagger}$-R relationship.

Calculation B. Another calculation can be performed to estimate C–C single bond lengths. In the first step of calculation, the overlap integrals between pi orbitals are set equal to zero. The degenerate orbitals for pi electrons resulting from this assumption have an unpaired electron. This configuration is an open shell, but the CNDO/2 method which was designed for the closed shell configuration was used in this approximate calculation. The total energies which contain the energies of unpaired pi electrons are used to estimate the bond distances of tri-tri, di-di and te-tri C–C single bonds or di-di C–C double bond.

Calculation C. The population and energy matrices can be transformed to new matrices by the transformation

$$\boldsymbol{M}' = \boldsymbol{OMO}^{-1}, \tag{8}$$

where $\boldsymbol{M}$ is the population ($\boldsymbol{P}$) or energy ($\boldsymbol{F}$ and $\boldsymbol{H}$) matrix, $\boldsymbol{M}'$ is the matrix in the new basis, and $\boldsymbol{O}$ is an orthogonal transformation matrix.

The total electronic energy is invariant under the transformation

$$E_{\text{electronic}} = \frac{1}{2}\sum_{\mu,\nu} P_{\mu\nu}(H_{\mu\nu} + F_{\mu\nu}) = \frac{1}{2}\sum_{\mu,\nu} P'_{\mu\nu}(H'_{\mu\nu} + F'_{\mu\nu}) . \tag{9}$$

Selecting an appropriate transformation matrix, we can separate the off-diagonal matrix elements of the sigma system into two groups. The matrix elements between bonding orbitals —*e.g.* φ_1 and φ_4 in Fig. 1— form one group (group I). The matrix elements between non-bonding orbitals —*e. g.* φ_1 and φ_5—form the other group (group II). The group I matrix elements can be interpreted as representing localized bonds and the group II elements as representing non-localized bonds. In the local bond approximation in which the group II matrix elements are neglected, the total energy E^* is given by

$$E^* = \frac{1}{2}\sum\nolimits^{*}_{\mu,\nu} P'_{\mu\nu}(H'_{\mu\nu} + F'_{\mu\nu}) + \sum_{A<B}\sum Z_A Z_B / R_{AB} , \tag{10}$$

where $\sum^*$ describes the summation over the diagonal and the group I matrix elements. The equilibrium bond lengths which are determined by the E^*-R relationship are shifted in comparison with the bond lengths determined by "calculation B."

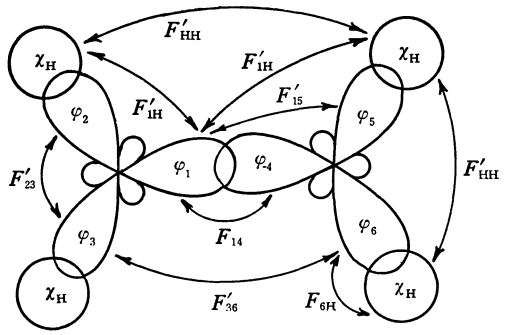

Fig. 1. Energy matrix elements of sigma systems for ethylene.
χ are atomic orbitals of hydrogens.
φ are hybridized orbitals of carbons.
$\boldsymbol{F}$ indicate the matrix elements between the bonding orbitals (group I), $\boldsymbol{F}'$ the matrix elements between the non-bonding orbital (group II).

Results and Discussion

The results of the calculations are given in Tables 1, 2 and 3. The calculated bond lengths are in reasonable agreement with their experimental values. From the calculations, the C–C single bond length is 1.476±0.006 Å, double bond length 1.317 Å, triple bond length 1.198 Å. For the C–H distances of the diagonal, trigonal and tetrahedral carbon hybrids, the agreement between the calculated and observed distances is quite satisfactory. On the basis of this set of data and the transformation properties of the CNDO method, it is felt that the CNDO/2 method is an effective approximate method for determining the relative importance of hybridization and pi electron resonance in the bond shortening effect for conjugated hydrocarbon.

The tri-tri single bond equilibrium distance of ethylene having two unpaired pi electrons was 1.475 Å by "calculation A" and "calculation B." The di-di single bond equilibrium distance of acetylene having four unpaired pi electrons was 1.476 Å. The equilibrium distances of di-di and tri-tri single bonds were longer than that of te-te single bond (ethane) by 0.005 Å and 0.004 Å.

The equilibrium distances of C_1–C_2 and C_2–C_3 single bonds of propylene were 1.487 Å and 1.480Å respectively by "calculation B" in which overlap integrals between pi orbitals were neglected. These equilibrium distances are practically in agreement with that of propane as given in Table 2. The result obtained indicates that the shortening effect for C_1–C_2 bond of propylene is only dependent upon the hyperconjugation between the double bond and the methyl group.

The equilibrium distances of C_1–C_2 and C_2–C_3 single bonds of butadiene having four unpaired pi electrons were 1.482 Å and 1.486 Å respectively by "calculation B" in which all overlap integrals between pi orbitals were set equal to zero. The equilibrium distances of C_1–C_2 and C_2–C_3 bonds of butane were 1.482 Å. The calculated shortening effect for the C_2–C_3 bond of butadiene depends little on hybridization. The results of the calculation indicate that te-te, tri-tri, di-di and te-tri C–C single bonds are substantially in agreement with one another in the range of error in the CNDO/2

Table 1. The equilibrium distances of carbon-carbon bonds between several types of carbon hybrids for C_2 hydrocarbons

Type of bond	Equilibrium distance (Å)

calculation.

The di-di double bond equilibrium distance of acetylene having two unpaired pi electrons was 1.323 Å by "calculation A" and "calculation B." The equilibrium distance of the C_2–C_3 bond of butadiene including two localized double bonds was 1.323 Å by "calculation B" in which the overlap integrals between pi orbitals were set equal to zero except for S_{12} and S_{34} pi overlap integrals. The equilibrium distance of di-di double bond is longer than the tri-tri double bond (ethylene) equilibrium distance by 0.006 Å. The difference is in the range of the error of CNDO calculation for bond distance.

On the basis of this calculation, it seems reasonable to assume that the carbon-carbon bond length is little affected by hybridization of the carbon atom.

From the electron densities of s and p orbitals, the types of hybridization of methane, ethane, ethylene and acetylene were essentially sp^3, sp^3, sp^2 and sp hybrids respectively as given in Table 4.

The population ($\boldsymbol{P}$) and energy ($\boldsymbol{F}$ and $\boldsymbol{H}$) matrices of methane, ethane, ethylene and acetylene were transformed to the new matrices ($\boldsymbol{P}'$, $\boldsymbol{F}'$ and $\boldsymbol{H}'$) with the hybrid basis set (sp^3 sp^2 and sp). In the new matrices, the group II matrix elements represent the electronic interaction energies between new non-bonding orbitals. These group II interaction energies were further classified into the two following types: those between neighboring atoms and those between non-neighboring atoms. The former was termed an N type interaction and the latter an N–N type interaction as given in Table 5.

The N type interaction energies between carbon hybrid and hydrogen were 0.0200 eV, 0.2574 eV, 0.3540 eV and 0.0552 eV for methane, ethane, ethylene and acetylene respectively, and those of N–N types were −0.8010 eV, −0.0332 eV and 0.5910 eV for ethane, ethylene and acetylene respectively.

The interaction energies (N type) between carbon hybrids were −4.6901 eV, −4.6725 eV and −0.8389 eV for ethane, ethylene and acetylene respectively. By minimization of total energies neglecting the group II matrix elements, the carbon-hydrogen equilibrium distances shifted from

b) The N type interaction energies refer to the interactions between the neighboring atoms, the N-N types refer to the interactions between the non-neighboring atoms.

1.114 Å to 1.121 Å, 1.117 Å to 1.114 Å, 1.106 Å to 1.102 Å, 1.088 Å to 1.085 Å for methane, ethane, ethylene and acetylene respectively. Also, the carbon-carbon single bond equilibrium distances in a similar manner shifted from 1.471 Å to 1.621 Å 1.475 Å to 1.569 Å, 1.476 Å to 1.479 Å for ethane, ethylene and acetylene type single bonds respectively. In the calculation described above, the intra-atomic (carbon) off-diagonal elements were not neglected, because these calculations were performed to investigate the precision of the local bond approximation between specific atoms. The results of other types of calculation in which all the group II matrix elements were neglected are listed in Tables 1 and 3.

According to this approximation, the carbon-hydrogen bond distance remained unaltered, but the carbon-carbon single bond distance shifted significantly. The length of carbon-carbon single bond distance is di-di <tri-tri <te-te. The *s* character in the hybrids decreases in the same order. The result obtained neglecting the non-localized effect of the sigma electrons agrees with the usual conclusion concerning the equilibrium length of the sigma bond.

The sum total (ε) of the electronic interaction energies between non-adjacent atomic orbitals considering appropriate carbon hybrides is generally effective in stabilizing the molecule, but the effective factor in determining the equilibrium distance is the gradient of variation of the interaction energy ε with the change of the interatomic distance rather than the magnitude of its absolute value.

When the electronic interaction energy ε is neglected in the local bond approximation, the effect on the carbon-hydrogen bond length is negligible. However, for the carbon-carbon bond, the calculated distance lengthens by the neglect of the interaction energy ε because it is effective in shortening the equilibrium distance. Therefore, the idea of localized sigma bonds between pairs of atoms is not appropriate in determining the carbon-carbon bond length.

From a different point of view, however, the result of the calculation in this paper may be an example of defects which are introduced by the CNDO (complete neglect of differential overlap) approximation. If it is the case, it may be due to the following approximations of the CNDO/2 method. The arresting features about approximations of the CNDO/2 method are that the off-diagonal bonding parameters (β^0) are given the same value for resonance integrals between sigma orbitals and those between pi orbitals, the one-center exchange integrals are neglected, and the electronic interaction integrals are assumed to depend only on the atoms and not the actual type of orbital (all electron-repulsion integrals are calculated as coulomb integral involving valence *s* functions). If the calculated equilibrium distances are shifted by the introduction of one-center exchange integrals which play a crucial role in determining the electron distribution in molecule as mentioned by Cook *et al.*,[9] the problem of this paper should be re-examined by the INDO or NDDO method [1,10] which includes the one-center exchange integrals explicitly.

Conclusion

The CNDO/2 method has been applied in the present work to calculate the equilibrium interatomic distances of the hypothetical carbon-carbon single and double bonds. The equilibrium distances of the tri-tri, the di-di and also the te-tri carbon-carbon single bonds are not much different from the te-te single bond. It is also shown the di-di double bond distance is of almost the same magnitude as the tri-tri double bond distance. These results indicate that the carbon-carbon bond length of sigma system is little affected by the state of hybridization of carbon atom.

The above unexpected conclusion is largely dependent upon the validity of the CNDO/2 method employed in this calculation. It has been generally accepted that the model of localized sigma bonds is appropriate in discussing the equilibrium bond length of the sigma system. We find that this approximation is surely satisfactory for the carbon hybrid-hydrogen bond. For the bonds between carbon hybrids, however, this approximation is not reasonable because the bonds between non-adjacent atomic orbitals are appreciably effective in determining the equilibrium distances.

However, it should be emphasized that the above conclusion is obtained as a result of the CNDO/2 method under specific conditions and the result of further elaborate calculation on the problem of this paper may be a subject for future studies.

The authors wish to thank Professor K. Higasi for suggesting this problem and for his continuous interest and encouragement. They are also grateful to Professor K. Ohno (Hokkaido University) for many helpful comments and discussions regarding the manuscript. Thanks are due to Dr. J. H. Gallagher who read the manuscript and corrected the English.

(Received March 15, 1969)

In order to obtain information on the dispersion state of W/O type emulsions, the steady-flow viscosity in a wide shear range has been studied using a capillary type viscometer. Emulsions prepared by using Arlacel 83 or Arlacel 60, are classified according to the kind of hydrocarbon used as the suspending fluid, *i.e.*, benzene, cyclohexane, liquid paraffin, isopropyl myristate, and squalane systems, respectively. Although all systems show the so-called shear thinning flow, shear dependence of the viscosity is not only influenced by the disperse phase concentration and emulsifier concentration, but is also much effected by the kind of suspending fluid. Such non-Newtonian behavior is observed markedly in benzene systems. It may thus be assumed that the water droplets in benzene have a tendency to form a large aggregate not easily redispersed under shear. The formation of aggregate may be facilitated by the disturbance of the orientation of the adsorbed emulsifier molecules at the interface due to the mutual interaction between the π-electron in benzene molecule and the emulsifier molecule.

The study of rheological properties of W/O type emulsion is of utmost importance for the quality control in the fields of pharmaceutics, foods and cosmetics. However, only few reports have been presented on this subject, compared with those on O/W type.

According to Albers *et al.*[1-3] water-in-benzene emulsions, in which energy barriers between the water droplets can be calculated theoretically, are not stable against aggregation by an adsorbed layer of emulsifier and show non-Newtonian flow.

Furthermore, the relative viscosity of W/O type emulsion is found to be influenced by the species of suspending fluids, although the result was obtained by the so-called one-point method under steady shearing stress.[4] Thixotropy in the W/O type emulsion reported by Vól'fenzon[5] could not be accepted as a general phenomenon, because the sample used was a mixture of seed oil, bees wax, spermaceti and lanolin as the oil phase.

In order to observe the relationship between the rheological properties of W/O type emulsions and their components, the authors tried adjusting the W/O emulsion of different components by making various combinations of emulsifiers and oil components. The emulsions which were relatively stable were chosen to observe how their viscosity changes with the rate of shear, and how the dispersion state changes with oil composition.

Experimental

Sample. Table 1 shows emulsifiers and suspending fluids of emulsions used. In order to prevent the so-called creaming of the emulsion due to density difference between the disperse phase and continuous phase, the density of the oil phase was adjusted to that of water by addition of carbon tetrachloride. No emulsifier listed in the table, however, produced a well stabilized emulsion which has higher alcohol or cast or oil as its suspending fluid. Likewise emulsions prepared with other oil components in which emulsifiers other than sorbitan fatty acid ester were used, could not be used as a sample for viscosity measurement, because of excessive rate of coalescence of suspending droplets. Thus systems of hydrocarbon as their suspending fluid and sorbitan fatty acid ester as their emulsifier were employed for the viscosity measurements. Details of the preparation of the sample are as follows. A given quantity of oil containing the emulsifier was mixed with the specified amount of water (from 0.1 to 0.6 in its volume fraction) and then stirred at a rotational speed of 9000 rpm for 5 min by an homogenizer (manufactured by Tokushu Kika Kogyo).

Droplet size and size distribution of the system were

obtained by means of microscopy.

Viscosity Measurement. Capillary viscometer of Maron-Belner type[6] was used for all viscosity measurements. By this viscometer the viscosity of a fluid in the range from a relatively high shear stress to a low stress can be obtained continuously by a single measurement. The principle and procedure of the measurement and the dimensions of the viscometer are given in a report[7] on polyvinylpyrrolidone solution.

All measurements were made at 32°C ± 0.01°C in a constant temperature bath.

The relative viscosity (η_{rel}) was calculated as the ratio between the viscosities of emulsion and suspending fluid (containing no emulsifier).

Results and Discussion

The relative viscosity of both cyclohexane and benzene systems stabilized by Arlacel 60 and Arlacel 83 is shown in Figs. 1 and 2. Non-Newtonian flow of each sample is observed throughout the range measured. It can be mentioned from the results that the dependence of viscosity on the rate of shear of the samples is noticeable in the benzene system. It is also noted that the dispersed droplets in the system form large aggregates in the low rate of shear. This fact may be responsible for the generation of a viscosity curve as represented diagramatically in broken line due to a heterogeneity of the disperse phase concentration in the capillary of viscometer. Such a tendency appears markedly in the system using Arlacel 60 as its emulsifier, where the value of maximum shear stress at which dispersed droplets form large aggregates, not entering in the capillary tube, *i.e.*, yield value, increases with increasing diperse phase concentration as indicated in Table 2.

In the emulsion using hydrocarbon other than benzene, as the suspending fluid, no large aggregates of droplets were observed, although aggregates consisting of a small amount of dispersed droplets can be detected by means of microscopy. Dependence of viscosity of the system on the rate of shear is similar to that of the cyclohexane system shown in Figs. 1 and 2. From this it may be sug-

gested that the non-Newtonian flow shown by these W/O type emulsions is due to the variation in the number of droplets forming the aggregates of respective flow units with the rate of shear.

At a fixed disperse phase concentration, the values of relative viscosity of various samples are different as shown in Fig. 3.

The relationships between the relative viscosity and the rate of shear at different concentrations of the emulsifier, at a constant disperse phase concentration, are shown in Figs. 4 and 5 for the cyclohexane and benzene systems, respectively. In both cases, emulsifier concentration has no effect upon the dependence of relative viscosity on the rate of shear, although the value of relative viscosity in a whole range of rate of shear increases with increasing emulsifier concentration. This increase may be due to the increase of viscosity in the suspend-

ing fluid. In the case of the benzene system stabilized by Arlacel 60, the yield value tends to become smaller with increasing emulsifier concentration as shown in Table 3. This may be brought about by the increase in the amount of the adsorbed emulsifier on the surface of the dispersed droplets with the increase of the amount of the emulsifier used. In the benzene system stabilized by Arlacel 83, the tendency to form large aggregate of droplets seems to be smaller compared with that in the system using Arlacel 60 as an emulsifier. The surface of water droplets of emulsion stabilized by Arlacel 83, containing sesquioleate chains per sorbitan molecule, is more densely covered with oleophilic chains than in the case of emulsion stabilized by Arlacel 60 containing one stearic chain per sorbitan molecule. Thus, the size of aggregate of the former emulsion could be smaller than in the case of the latter emulsion owing to the steric effect of the oleophilic group.

All viscosity measurements were made with two-day old samples. Further aging tests of sample revealed no effect upon the dependence of viscosity on the rate of shear, although a slight decrease in viscosity by aging was noted in all samples. This tendency seems more noticeable in the benzene system. This may be caused by the change in the droplet size distribution resulting from the coalescence of dispersed droplets. Microscopic examination of the size distribution of the dispersed droplets reveals the transition from mono disperse to poly disperse immediately after preparation (refer to Fig. 6 for sample with Arlacel 83 as emulsifier and Fig. 7 for sample with Arlacel 60 as emulsifier). Such transition is slightly faster in the case of the benzene system. Therefore, as a result of coalescence of the droplets, the number of droplets in an aggregate changes with time. Since any change in the dependence of the viscosity on the rate of shear could not be observed, the decrease in viscosity by aging would be brought about by the broadening of the droplet size distribution.

Thus, it can be said that the benzene system shows an extraordinary characteristic in contrast to all other samples studied.

It is known that aromatic hydrocarbon indicates various affinity or peculiar solvating effects irrespective of its nonpolar character. It has been found in recent years that such an effect is due to π-electron possessed by the aromatic hydrocarbon reacting as proton acceptor of hydrogen bond, similar to lone electron-pair possessed by oxygen atom. Previously one of us (S.M.) proved that, in the case of O/W type emulsion, the dispersion state of aromatic hydrocarbon as the oil com-

applicable to W/O type emulsions. UV absorption spectrum of benzene shifts towards shorter wavelength by the addition of Arlacel 60 or Arlacel 83, as shown in Fig. 8. This fact suggests that there is an interaction between the hydrophilic group of the emulsifier molecules adsorbed on the surface of dispersed droplets and the π-electrons of benzene. It is probable that the orientation of emulsifier on the surface of the droplet is disturbed and the resistance to the occurence of aggregation or coalescence of the droplets in the emulsion is reduced. Thus emulsions having benzene as oil component are regarded as extraordinary.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 2778—2790 (1969)

Studies of the Direct Dissolution of Metal in a β-Diketone Reagent*[1]

Kimitaka SATO and Ohiko KAMMORI

Tokyo Research Institute, Yawata Iron and Steel Co., Ltd., Ida, Kawasaki

(Received March 31, 1969)

As it was found that metallic iron is dissolved in acetylacetone (Hacac), the interaction between the solute and the solvent in the dissolution phenomena, together with the process of the dissolution of metal, were examined in detail in order to apply it to analytical techniques. The factors of the oxygen, the co-existing water, and the dissociated proton in acetylacetone were shown to be effective in the dissolution. With typical β-diketones, the exception of acetylacetone, such as trifluoroacetylacetone (HTFA), hexafluoroacetylacetone (HHFA), benzoyltrifluoroacetone (HBTA), 2-furoyltrifluoroacetone (HFTA), and 2-thenoyltrifluoroacetone (HTTA), were also employed; they were shown to have the same properties as the above one. The relationship between the solubilities of metals and the effect of adding an organic solvent, the equilibrium reactions of fluorine-containing β-diketones with water or alcohols, or the preferred enol forms of trifluorosubstituted β-diketones, were also discussed, paying attention to the accelerating effects of the solvents on the dissolution.

In general, water is employed as the solvent in the chemical analysis of iron and steel. Sometimes, however, troubles rise because of the use of an aqueous solution; for example, sometimes minute extracts float on the liquid surface in the case of separation by a centrifuge in electro-analysis. It is necessary to utilize an organic solvent effectively in solving the difficult points, so a method of electrolysis in non-aqueous solution has already been attempted.[1)]

Since β-diketone was found, in fundamental studies of the production of ultrapure iron by means of an organochemical technique in our laboratory,[2)] to have the property of dissolving metals, the present investigation was undertaken to apply the dissolution phenomena to the analysis of iron and steel. It is possible to apply the phenomena extensively to various fields of analysis. Thus, it is expected that new, simple analytical techniques can be developed by using, together with chemical analysis, gas chromatography, polarography, *etc.*[3,4)] For the above-mentioned reasons, basic problems in the phenomena were studied in detail from the point of view of analytical chemistry.

β-Diketone is well known to have the following keto-enol tautomerism[5–10)] (Eqs. (1) and (2)). Consequently, the dissociated proton is expected to have some effect on the dissolution of metal in β-diketone, as in the case of inorganic acids. On the other hand, Charles and Barnartt[11,12)] studied

the rate theory in the reaction by concentration on the effect of oxygen in the dissolution of metals in acetylacetone. It is presumed, however, that there are other important factors in the dissolution phenomena, but the general properties have never been established in detail.

In the present paper, we will present the detailed results of an investigation made of the phenomena and the related reactivities as well as of the characteristics of β-diketone.

Experimental

Materials. The β-diketones employed are listed in Table 1. The acetylacetone was a commercial product and was also purified by distillation under reduced pressure. Hexafluoroacetylacetone obtained from the Pierce Chemical Company (U.S.A.) and the other β-diketones were used without further purification. The organic solvents and Fe(acac)$_3$ were commercially-available products of sufficient purity.

The metals were all extra-pure, commercially-available products. The metals, aluminum, beryllium, copper, manganese, molybdenum, nickel, lead, silicon, titanium, tungsten, and zinc, were sheets in shape, while the specimens of calcium and iron were granular, those of cerium, cobalt, and chromium were massive, and that of magnesium was coil-like.

Measurements. *The UV and Visible Spectra* were taken with a Cary model 14 recording spectrometer. A quartz absorption cell, 10 mm long, was used, but the measurements of absorbance in the experiment of dissolution were carried out with a Tokyo-Koden model ANA-7E colorimeter, using a glass cell of 20 mm long.

The NMR Spectra were measured at room temperature with a JNM C-60 high-resolution nuclear magnetic resonance spectrometer, using as the internal standards tetramethylsilane (TMS) in proton resonance and monofluorotrichloromethane in fluorine resonance.

Gas Chromatography was performed with a Perkin-Elmer 154 vapor fractrometer by using a column of Carbowax 1500/chromosorb W, with helium as the carrier gas.

The gas evolved in the dissolution was confirmed with a CEC 21-103C mass spectrometer.

Effective Factors in the Dissolution

When acetylacetone (Hacac) was left alone on the steel plate, a part of the iron is dissolved and red crystals appear. In order to explain the dissolution phenomena, external factors in the dissolution system and the chemical properties inside the system must be taken into consideration. We have already cited as the factors: 1) the proton dissociated in the β-diketone molecule, 2) the co-existing water in β-diketone, and 3) the oxygen dissolved in β-diketone.[3)]

Effect of Proton Dissociated in β-Diketone Molecule. β-Diketone exists as an equilibrium mixture of keto-enol tautomers. The NMR method is most favorable for determining the enol

ratio, which was found to be 81.4% in Hacac[13] and 100% in HTFA or HHFA.[14] Moreover, the degree of the dissociation of the proton in enolized β-diketone is appraised as the acid strength, pK_a, the values of which are, respectively, 9.7 and 6.7 in Hacac and HTFA.[15] Therefore, the proton is regarded as taking part in the dissolution as in the decomposition of metal by hydrochloric acid and sulfuric acid. The keto-enol ratio of β-diketone also changes according to the kind of solvent[16] and according to the ratio of mixing with water, as is shown in Table 2.

The metals are more or less readily dissolved in solutions containing β-diketone in a greater enol ratio, but it is hard to dissolve them in a solution of β-diketone with a smaller enol ratio. The tendency of the metallic iron to dissolve was examined in HTTA-methanol solutions with different contents of HTTA, as is shown in Fig. 1. Iron is dissolved well as the concentration becomes larger. It may be concluded from the results that the proton contributes effectively to the dissolution.

Effect of Oxygen Dissolved in β-Diketone. Oxygen may be considerably dissolved in liquid β-diketone. Though the solubility of oxygen in water and typical organic solvents has already been measured, the solubility for liquid β-diketone has never been measured; however, it may be estimated to be equal to that for acetone, which is about ten times more than that of water.[17]

On the effect of oxygen, Charles and Barnartt[11] have already studied it in relation to the catalytical reaction. We investigated the same problem in

detail from the point of view of analytical application. It was confirmed qualitatively, by the Winkler method, that considerable oxygen is dissolved in Hacac. Oxygen in 10 m*l* of liquid is removed, to the extent that no more could be detected by polarographic waves, by blowing nitrogen gas into the liquid for about 20 min. Accordingly, the effect of oxygen was investigated by blowing nitrogen gas into the solution for 30 min in order to compare the solvency of iron in the absence and presence of oxygen. Figure 2 shows the effect of oxygen in the dissolution of iron in commercial Hacac, which is expressed as the dotted line. The effects of oxygen in the case of adding 0.1 and 1.0 m*l* of water to the Hacac are shown in Figs. 3 and 4 respectively. The effect was found to become somewhat smaller when a lot of water was added. These results clearly show that oxygen is one of the important factors in the phenomena. Since it was observed that the solubility of iron increases with the quantity of water added to Hacac, as will be discussed later, the effect was further examined by adding ammonium persulfide, which acted effectively in oxidation. The correlation between the ammonium persulfide content and the dissolving time of iron obtained is shown in Fig. 5. The addition of ammonium persulfide was easily found to be more effective. Ammonium persulfide is dissolved into water as follows (Eq. (3)):

$$(NH_4)_2S_2O_8 + H_2O \rightleftarrows (NH_4)_2SO_4 + H_2SO_4 + (O) \quad (3)$$

Consequently, a lot of nascent oxygen may occur and play an effective role, together with sulfuric acid, in the dissolution of iron.

gas chromatography. A trace of water which could not easily be removed was found to be present

in the Hacac. The dissolution curve in Fig. 6 shows that only the co-exsisting water is clearly effective, even in the case of Hacac in the absence of oxygen.

Table 3. Determination of water in acetylacetone

Commercial	1/1500	6.86
Purified	1/4800	2.08
Purified	1/8000	1.25

The tendency toward much greater solvency upon the addition of water was further examined. Figure 7 shows an example of the experimental results regarding the effect of the solvency of iron in Hacac containing 0.02—1.0 m*l* of water. Water, 0.04 m*l*, is dissolved completely into 10 m*l* of Hacac, but when there is more than 0.05 m*l* of water the solution is separated into two layers. In terms of solubility, the metal was found to be dissolved effectively in such a solution. Figure 8 shows the solvency of iron in a solution containing Hacac and water, the total quantity of which is definite. The solvency was found to be best in a solution consisting of Hacac : water=3 : 1 (vol.).

Phenomena of Dissolution

Solubilities of Various Kinds of Metals in Acetylacetone. The solubilities in Hacac were studied with 17 kinds of metals. In our experiments, the size of the metal sample was 1 cm^2 in the case of a sheet, and the sample was prepared so as the surface area became equal to that of the sheet in the cases of metals with other shapes. We attempted to initiate dissolution by agitating at 70°C in 10 m*l* of Hacac. The dissolution rate was determined by weighing insoluble metal fragments taken out at definite intervals. As is shown in Fig. 9, nine (aluminum, beryllium, cobalt, chromium, copper, molybdenum, nickel, titanium, and tungsten) of the 17 kinds of metals examined were scarcely dissolved at all in six hours. A similar experiment was made by Barnartt *et al.*[12]; their results were almost the same as ours. The tendencies toward the ionization of soluble metals in dissolution were found to be larger than that of hydrogen. Though the standard potentials of the elements in Hacac have never been measured, Strehlow[18] measured the potential of various metals in a non-aqueous solvent; the tendency he found agrees fairly well with that shown in Fig. 9.

Product of the Dissolution of Iron in Acetylacetone. The solution becomes red, when iron is dissolved in Hacac. The absorption spectra of both the above solution and the $Fe(acac)_3$-Hacac solution obtained in the visible region (340—600 m*μ*) are shown in Fig. 10. The above results show that the product of the dissolution is $Fe(acac)_3$, for the spectrum of the solution is in good agreement with that of $Fe(acac)_3$.

Process of the Dissolution of Iron in Acetylacetone. The variations in the absorption spectra in the process of the dissolution of iron in Hacac are shown in Fig. 11. In the earlier steps, the absorption band at 354 mμ can not be discriminated clearly. With the passing of time, however, the absorbances at 354 and 435 mμ become larger, and at last the intensities of these two absorption bands become equal. Therefore, the spectrum may be regarded as coinciding with that of Fe(acac)$_3$.

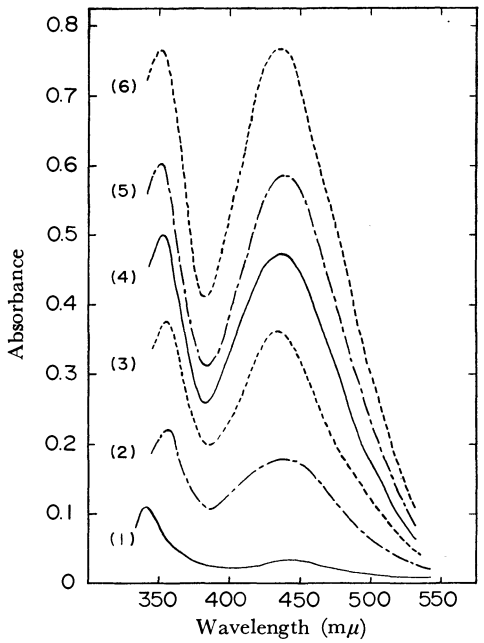

Fig. 11. Variations of the visible absorption spectrum of the solution of iron in Hacac.

On the other hand, the variations in the absorption spectra of Fe(acac)$_2$ formed from the standard iron(II) solution and Hacac are shown in Fig. 12. The behavior of the spectra shown in Fig. 12 is almost the same as that in Fig. 11. Since the Fe(acac)$_2$ with a four-coordinated-plane structure formed in the earlier step of the dissolution is stereochemically unstable, the stable form of Fe(acac)$_3$ with the octahedral six coordination is thought to be gradually formed in the solution.

In order for Fe(acac)$_2$ to be formed in a solution, it is necessary for Fe^{2+} ions to be present. Consequently, metallic iron is ionized to become Fe^{2+} ions by the action of some factor (Eq. (4)):

$$Fe \rightleftarrows Fe^{2+} + 2e^- \quad (4)$$

where the proton set free in Hacac is thought to act as follows (Eq. (5)):

$$Fe + 2H^+ \rightleftarrows Fe^{2+} + H_2 \quad (5)$$

Moreover, it was confirmed by mass spectrometry that hydrogen gas is formed during the process of

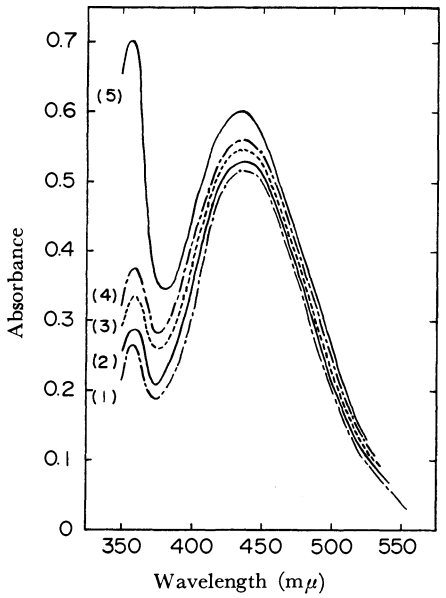

Fig. 12. Variations of the visible absorption spectrum of Fe(acac)$_2$.

the dissolution. In view of the above facts, the following reaction mechanism may be proposed for the dissolution of iron in Hacac:

$$Hacac \rightleftarrows acac^- + H^+ \quad (6)$$

$$Fe + 2H^+ \rightleftarrows Fe^{2+} + H_2$$

$$Fe^{2+} + 2acac^- \rightleftarrows Fe(acac)_2 \quad (7)$$

$$Fe(acac)_2 + acac^- \rightleftarrows Fe(acac)_3 + e^- \quad (8)$$

Dissolution of Metal in β-Diketones Except Acetylacetone. The acid strengths of β-diketones involving fluorine (HHFA, HFTA, HBTA, HTTA, *etc.*) are smaller than that of Hacac, which is 9.7.[15] Accordingly, it was thought that metal might be more readily dissolved in such fluorine-containing β-diketone solutions than in acetylacetone. Thus, its tendency in such a β-diketone solution was studied. The liquid β-diketones, such as HTFA, HHFA, and HFTA, were used in the liquid state, while the solid β-diketones, like HTTA and HBTA, were used in a solution, in which they were more enolized. The results showed that the dissolution rate of iron in a fluorine-containing β-diketone solution is ten or more times faster than that in Hacac. HHFA especially shows a powerful solubility.

On the other hand, metals were hardly dissolved at all in a solution in which a β-diketone interacted with solvents such as triethylamine and diethylamine. This fact can be explained in terms of a strong intermolecular hydrogen bond being formed between the β-diketone and the solvent.[19]

19) Ref. 16, p. 437; L. W. Reeves and W. G. Schneider, *Can. J. Chem.*, **36**, 793 (1958).

Accelerating Effect in the Dissolution

In the solvent extraction, the accelerating effect of the added ingredient is called "the synergistic effect."[20] A similar accelerating effect may be expected to appear in the dissolution of metals in a β-diketone solution.

Accelerating Effect of Adding an Organic Solvent in the Dissolution Phenomena. Figure 13 shows the synergistic effect observed in the case of adding another solvent to Hacac. The above experiment showed that carbon tetrachloride and glacial acetic acid were both effective as added solvents. The enol ratio of Hacac is 100% in triethylamine and 75—88% in the other solvents. The lack of solubility in triethylamine results from the strong intermolecular hydrogen bonding between solute and solvent, as has been mentioned above.[19] As a proton may be partially set free even in acetic acid, much as in Hacac, its effect is expected to persist in the solution. The above results clearly proved the dissolution of metal to be more effective in a solution containing an organic solvent than in an Hacac alone.

The solubility of iron in a solution containing HBTA was also examined as an example of solid β-diketones; the investigation showed that methanol was more effective than the other solvents, as is shown in Fig. 14.

In order to ascertain the accelerating effect of alcohols, the tendency toward solubility of a metal in the solution was studied in detail. The results of the experiment in which eleven kinds of alcohols were employed as solvents are summarized in Table 4.

Equilibrium Reaction and Solubility of Metal in β-Diketone Involving the Fluorine-Alcohol System. We mentioned above that the effect is accelerated by adding water or alcohol in liquid β-diketone during the dissolution of metal. It must be noted that various chemical reactions can occur in a mixture. Such a point of view is important in discussing the accelerating effect in the phenomena.[9,21]

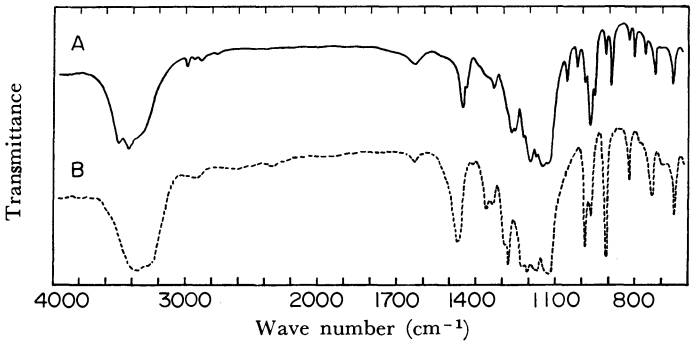

Fig. 15. Infrared spectra of the reaction product of HHFA with methanol (A) and of hexafluoroacetylacetone dihydrate (B). (KBr disk)

A white crystal was found to separate by the reaction of HHFA with water or methanol.[21] The configuration of the reaction product of HHFA with water[22] has already been studied by Schultz and Larsen,[23] who confirmed it to be hexafluoroacetylacetone dihydrate (IV), but the reaction product of HHFA with methanol has never been reported. The structure of the compound was identified on the basis of the results of elemental analysis and of the spectral investigation.

Elemental analysis showed that the compound has the formula $C_7H_{10}O_4F_6$ (Found: C, 30.77; H, 3.70%. Calcd for $C_7H_{10}O_4F_6$: C, 30.89; H, 3.57%). The IR spectrum shows absorptions at 1121 cm^{-1}(vs) due to the vibration, ν_{C-O}, of tertiary alcohol, and at 1051(w) and 1009 cm^{-1} (w) due to the ν_{C-O} of the C–O–C bond, which is illustrated in Fig. 15.

Figure 16 shows the NMR spectrum, in which signals are observed at τ 7.80, 7.66, and 4.29,

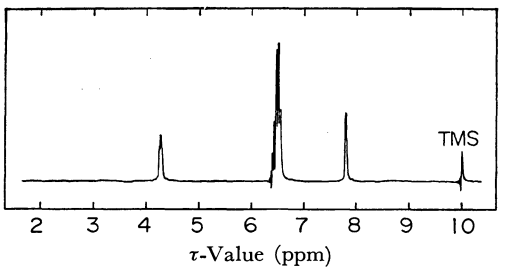

Fig. 16. Proton magnetic resonance spectrum of the reaction product of HHFA with methanol in C_2Cl_4 at 60 Mc.

with relative intensities of 1 : 3 : 1 respectively; these signals can be assigned to those due to the protons at $-CH_2-$, $-O-C_3H$, and $-OH$ respectively. The UV spectrum showed no absorptions. In view of the above facts, the most reasonable identification of the compound is as 1,1,1,5,5,5-hexafluoro-(2,4-dioxy-2,4-dimethoxy)-pentane (V).*2

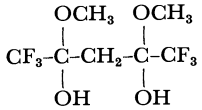
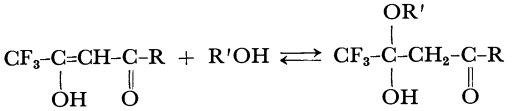
IV



V

The equilibrium reaction of β-diketone involving fluorine with water or alcohol was also examined.[9,21] The behavior in the fluorine resonance spectra of the solution consisting of trifluoro-substituted β-diketone and water or alcohol, is summarized in Table 5. The β-diketone was clearly found to react with water or alcohol. The proton resonance spectra are shown in Figs. 17—19. A signal was observed at about δ 3 due to the methylene group, which is a singlet in water and an AB quartet in alcohol. From a consideration of the above facts, it seems most reasonable to conclude that an equilibrium reaction occurs in the solution as follows (Eq. (9)):



(9)

R=CH_3, , ,

R'=H, CH_3, C_2H_5, C_3H_7, $(CH_3)_2CH$, C_4H_9, $(CH_3)_2CHCH_2$, $ClCH_2CH_2$, $BrCH_2CH_2$, $CNCH_2CH_2$, $CH_2=CHCH_2$, $CH\equiv CCH_2$, $PhCH_2$

The equilibrium reaction of pivaloyltrifluoroacetone with water or alcohol has already been studied.[24]

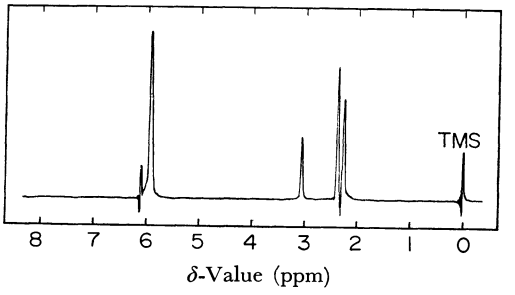


Fig. 17. Proton magnetic resonance spectrum of HTFA aqueous solution at 60 Mc.

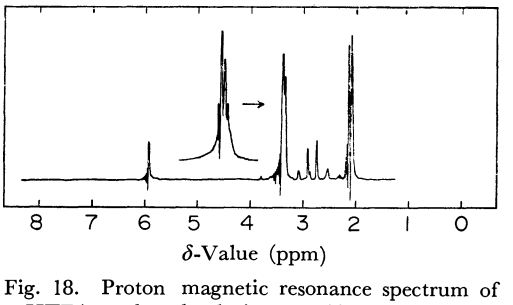

Fig. 18. Proton magnetic resonance spectrum of HTFA-methanol solution at 100 Mc.

24) K. Sato, H. Ochi and K. Arakawa, This Bulletin, **42**, 1747 (1969).

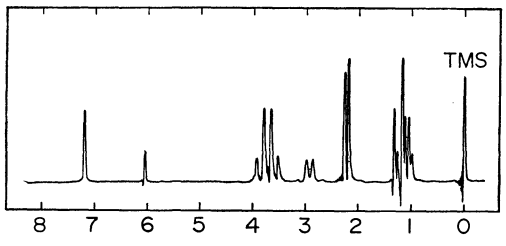

Fig. 19. Proton magnetic resonance spectrum of HTFA-ethanol solution at 60 Mc.

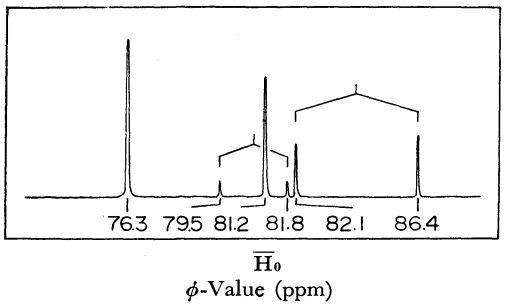

Fig. 20. Fluorine magnetic resonance spectrum of HHFA-ethylenebromohydrin solution at 56.45Mc with $CFCl_3$ as internal standard.

Equilibrium reactions different from the above results were seen with HHFA.[21] The reaction was also confirmed by NMR spectroscopy. The fluorine resonance data of the solution of HHFA obtained with alcohol are summarized in Table 6, while the existence ratio of each state is listed in Table 7. An example of these spectra is also shown in Fig. 20. The data suggest that equilibrium states with three types, states A, B, and C, exist in the course of the reaction.

The fluorine resonance spectrum clearly proved that only a reaction on the state A is preferred in an HHFA ethanol solution. The state A may be represented by Eq. (10):

$$CF_3\text{-}C(OH)=CH\text{-}C(=O)\text{-}CF_3 + 2R'OH \rightleftarrows CF_3\text{-}C(OR')(OH)\text{-}CH_2\text{-}C(OR')(OH)\text{-}CF_3 \quad (10)$$

R′ = C_2H_5, n-C_3H_7, i-C_3H_7, n-C_4H_9, $CH_3(CH_2)_6CH_2$, $BrCH_2CH_2$, $CNCH_2CH_2$, $CH_2=CHCH_2$, $CH\equiv CCH_2$, $PhCH_2$

since the signal was observed at δ 2.30 with a singlet in the proton resonance spectrum. Furthermore, the AB quartets at about δ 3.30 may be due to the following reaction (Eq. (11):

$$CF_3\text{-}C(OH)=CH\text{-}C(=O)\text{-}CF_3 + R'OH \rightleftarrows CF_3\text{-}C(OR')(OH)\text{-}CH_2\text{-}C(=O)\text{-}CF_3 \quad (11)$$

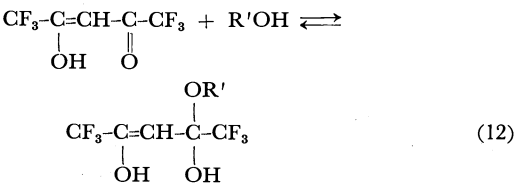
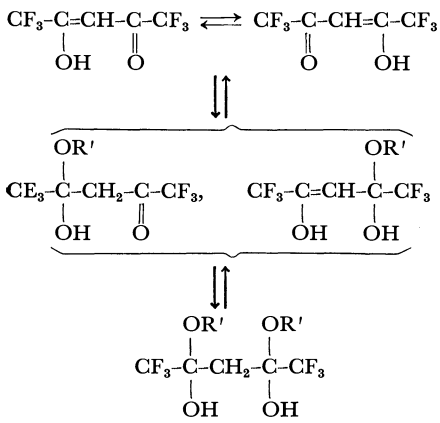
† These values were not measured.

while the multiplet at about δ 4.70 is due to the methine group formed by the following reaction (Eq. (12)):



(12)

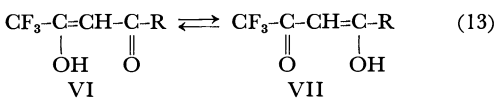
In the proton resonance spectrum of the isopropanol solution, the signal intensity at δ 3.30 with the AB quartet is greater than that at about δ 4.70. The reactions involving the states B and C were found to be due to the reactions (12) and (11) respectively. From these results, the correlation in the equilibrium of HHFA with various alcohols may be summarized as follows:



R'=C_2H_5, C_3H_7, $(CH_3)_2CH$, $BrCH_2CH_2$, $CNCH_2CH_2$, $CH_2=CHCH_2$, $CH\equiv CCH_2$, C_4H_9, C_8H_{17}, $PhCH_2$

Fluorine-containing β-diketones are generally reactive. The reactivity may be explained by considering that the carbon atom adjacent to the trifluoromethyl group is activated by the *I* effect of the functional group with the fluorine atom, which has a strong electro-negativity. The dissolution of metal in such solutions is remarkably accelerated, as has been mentioned above. The reason for this is, however, not clear; the cause may be in the acid strength of β-diketone alone or in the presence of such an equilibrium.

Preferred Enol Form of Trifluorosubstituted β-Diketone and Solubility of Metal. β-Diketones with a trifluoromethyl group are thought to take the following enol forms (Eq. (13)):[5-9]



(13)

The question of which form of the above enols is preferred is an interesting problem, which has been discussed in only a few reports.[5,8,25] On the basis of the assumption that a conjugate system must be formed between the R ring and the carbonyl group in the β-diketone molecule and the UV spectrum may become remarkable due to the polarity of the solvent;[26] the investigation discussed below was undertaken in order to determine the preferred enol form.[10]

The UV spectra of HBTA and HTTA in various solvents are illustrated in Figs. 21 and 22 respectively. In view of the absorption band at about 260 mμ, the behavior of HBTA is clearly different from that of HTTA: the intensity of absorption varies in HBTA, but not in HTTA. The variations according to polar and non-polar solvents suggest that a conjugate system with a carbonyl group is formed adjacent to the aromatic ring. Accordingly, the preferred enol forms of HBTA and HTTA may be regarded as being VI and VII respectively. The results of the above studies support the theory which Pukanic *et al.*[26] derived from their study on the interaction between

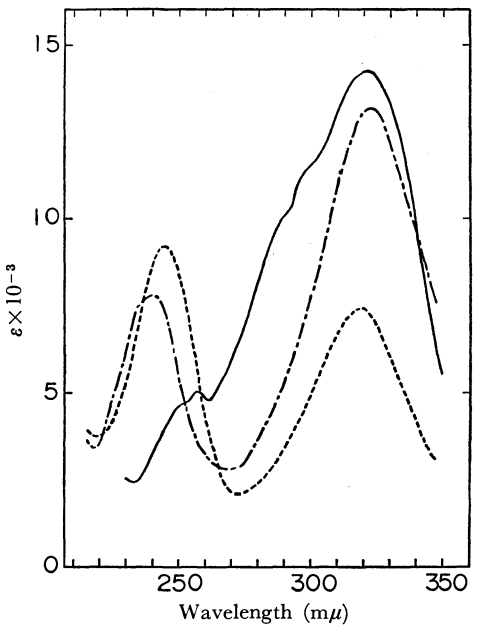


Fig. 21. UV spectrum of HBTA.
Solvent: ——, *n*-heptane
——, ethanol
----, water

25) Pukanic *et al.* have shown from the fluorine magnetic resonance frequency of enolic HTTA and HHFA in CCl_4, in the absence and in the presence of various concentrations of TBP, that the preferred enol form of HTTA is VII; G. Pukanic, N. C. Li, W. S. Brey, Jr., and G. B. Savitsky, *J. Phys. Chem.*, **70**, 2899 (1966).

26) For one of the examples, see M. Hirota, "The Interpretations of UV and Visible Spectra," Kyoritsu Shuppan, Tokyo (1967), p. 81.

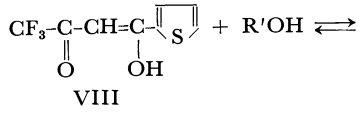
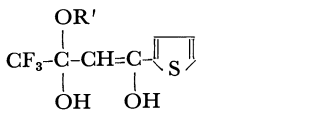
Solvents: ——, *n*-heptane
—·—, ethanol
– – –, water

HTTA and tributylphosphate (TBP) by means of the fluorine resonance spectra.

As Figs. 21 and 22 show, no special abnormalities are recognized in the so-called "*enol absorption band*" in the region with wavelengths longer than 300 mμ, so it may be concluded that the above equilibrium reaction exerts an essential influence on the molar extinction coefficient (ε). This influence must, therefore, be explained as the mutual effect of the keto-enol tautomerism with the equilibrium reaction in the solution. As the enol form of VII is preferred in the HTTA solution, the following equilibrium is also possible between HTTA and alcohol (Eq. (14)):



VIII



(14)

R'=H, CH_3, $(CH_3)_2CH$, $CNCH_2CH_2$, $PhCH_2$, *etc.*

However, it is conceivable that only the enol form of VIII, which is presumed, preferentially contributes to the equilibrium reaction, since the above fluorine resonance data are consistent with those of the HTFA and HBTA solutions.

Since HTTA behaves uniquely in comparison with other β-diketones, it may be interesting to discuss fundamentally the dissolution of metal in a mixed system of HTTA with Hacac.

Conclusion

Concerning the dissolution of metal in a β-diketone solution, the effective factors, the process of the dissolution, and the accelerating effect in dissolution were studied in detail. The effective factors were shown to be oxygen, co-existing water, and the dissociated proton in the solution.

The phenomena of the dissolution were expected to be applied effectively not only to the analysis of iron and steel, but also of other metals and alloys. For example, it is possible to establish new analytical methods by using these phenomena together with gas chromatography, polarography, the atomic absorption method, and so on. Part of an attempt to do so has already been reported.[27–32]

The problems related to the preferred enol forms of trifluorosubstituted β-diketones and the equilibrium reactions of fluorine-containing β-diketones with water or alcohols are interesting even in the field of organic chemistry; moreover, the solubilities of metals in these solutions must also involve a large number of significant problems.

The unique behavior of HTTA is seen not only in the dissolution of metal, but also in the solvent extraction. A thorough investigation, from a similar point of view, may be expected to establsih the cause of the series of phenomena, so the problem may be left as an interesting one for the future.

We wish to thank Professor Yojiro Tsuzuki, Science University of Tokyo, for his kind encouragement and much valuable advice. For their helpful discussions and kind encouragements, our thanks are also extended to Dr. San-ichiro Mizushima, Director of this institute, and Professor Kiichi Arakawa, Showa University.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 2791—2796 (1969)

The Molecular and Crystal Structure of *trans*-Dinitrotetramminecobalt(III) Nitrate Monohydrate

Isao OONISHI, Fumio MUTO and Yoshimichi KOMIYAMA*1

Department of Applied Chemistry, Faculty of Engineering, Yamanashi University, Kofu, Yamanashi

(Received April 4, 1969)

The crystal structure of *trans*-dinitrotetramminecobalt(III) nitrate monohydrate $[Co(NO_2)_2(NH_3)_4]NO_3 \cdot H_2O$ has been determined from three dimensional X-ray diffraction data. The dimensions of orthorhombic unit cell are: $a=10.02$ Å, $b=6.02$ Å, $c=16.84$ Å, and $Z=4$. The space group is $P2_12_12_1$. The structure has been refined by the three dimensional Fourier and least-squares method to $R=0.103$. The complex ion has a slightly distorted octahedral coordination with six N atoms at about 1.98 Å (two are N atoms of nitro groups and the others ammonium groups). The complexes are tightly bound together by N-H···O and O-H···O interactions, constructing a three dimensional network.

Crystal structures of various nitroamminecobalt(III) complexes of the type, $[Co(NO_2)_m(NH_3)_{6-m}]^{3-m}$ have been determined, where $m=1$,[1] 3,[2] 4,[3] and 6.[4] Nitropentamminecobalt(III) salts ($m=5$) have not yet been synthesized, whereas for dinitrotetramminecobalt(III) complexes ($m=2$) *cis*- and *trans*-isomers are well known.

However, no crystal structure analysis of these salts has yet been reported. Knowledge of the crystal structures of the whole series of nitroamminecomplexes evidently is an important basis for the understanding of the stereochemistry of nitroamminecomplexes and their structural principles. We have initiated a study of the structure of dinitrotetramminecobalt(III) nitrate.

The crystal structure of the *trans* form is reported in this paper. That of the *cis* form will be described in the following paper.

Experimental

The crystals were prepared by the method of Jörgensen.[5]

Recrystallization from water containing a small amount of acetic acid yielded thin tabular or needle-like crystals, the latter being found to be twinned. The unit cell dimensions were determined from higher-order reflections of Weissenberg photographs (Ni$K\alpha$, $\lambda=1.6591$Å). The systematic absences were: $h00$ for h odd, $0k0$ for k odd and $00l$ for l odd. Hence the space group was unequivocally determined. The crystal data are listed in Table 1. Sets of multiple film equi-inclination Weissenberg photographs were taken about the b-axis (0 to 5th layers), the a- and c-axes (0th layer). Ni$K\alpha$ radiation was used throughout. The intensities were estimated visually with a standard film strip and were converted to $|Fo(hkl)|^2$ and $|Fo(hkl)|$ by applying the usual Lorentz, polarization and spot shape corrections. 998 independent reflections were observed. They are about two-thirds of those within the nickel sphere. The crystal used was a rod $0.2 \times 0.06 \times 3.0$ mm. No correction was made for absorption or extinction.

Structure Analysis

At first Patterson projections $P(xz)$, $P(xy)$ were synthesized.

These led us to fix the position of Co at 0.2500, 0.0, 0.3750. Preliminary Fourier projections of electron density upon (010) and (001) were synthesized using $F(h0l)$s with $2h+l=4n$ ($n=0, 1, 2, 3, \cdots$) and $F(hk0)$s with $h+k=2n$, respectively, the signs of which were calculated from the parameter values of the cobalt atom. Approximate orientations of

the complex ion could be assigned from these projections. They were in good accord with the conclusion drawn from Patterson projections $P(xz)$ and $P(xy)$. However, from the Fourier maps the atoms of nitrate ion and water molecule could not be fixed. Atomic parameters of nitrate ion were assigned by packing consideration. After inclusion of the parameters of the nitrate ion and the water oxygen atom in the structure factor calculation, considerable improvement was made in the agreement between the observed and calculated structure factors. Fourier projections of electron density upon (001) and (010) were then synthesized using all $F(hk0)$s and $F(h0l)$s, respectively, the signs of which were calculated from the parameter values of all the atoms. On the Fourier maps all the atoms were found on the expected location. At this stage the discrepancy factor R became 0.20. The structure thus obtained was refined by three dimensional difference synthesis with isotropic temperature factor to $R=0.14$, later by a block diagonal least-squares method with HBLS program written by T. Ashida.

In this least-squares method anisotropic temperature factors were introduced and four cycles of refinement were carried out.

A weighting scheme was employed:

$w = 0.2$ if $F_o \leqq F_{\min.}$ $(=4.0)$

$w = 1.0$ if $F_{\min.} < F_o \leqq F_{\max.}$ $(=100.0)$

$w = F_o/F_{\max.}$ if $F_o > F_{\max.}$

The final discrepancy factor, $R=\sum||F_o|-|F_c||/\sum|F_o|$ was 0.103 for all the reflections. Atomic scattering factors were taken from International Tables for X-ray Crystallography.[6]

Final atomic parameters and their standard deviations are summarized in Table 2. The observed and calculated structure factors are listed in Table 3.

Description of the Structure and Discussion

A perspective drawing of the complex ion, $[Co(NO_2)_2(NH_3)_4]^+$, is illustrated in Fig. 1. The bond lengths and bond angles with their e.s.d.'s calculated on the basis of the atomic parameters in Table 2 are listed in Table 4. A projection of the

contents of one unit cell onto the (010) plane is presented in Fig. 2, and important intermolecular contacts (*i. e.*, those$\leqq$3.5 Å) are listed in Table 5. The interatomic distances and bond angles were calculated by using program RSDA-4 written by T. Sakurai (1965).

The cobalt atoms are surrounded by nitrogen atoms of two nitro groups and of four ammonia molecules, which form a slightly distorted octahedron. Two nitrogen atoms of nitro groups are coordinated to a cobalt atom in *trans* positions.

The complex ion has an approximate symmetry *mmm*, with the first mirror containing the two nitro groups, the second containing N(3), N(4), N(5), and N(6), and the last perpendicular to the other two mirrors. In Table 6 are compared the distances between cobalt and ligand atoms and N–O distances in various complex ions. The distances are in agreement with those found in the related compounds. It is to be noted here that the Co–NO_2 distances are likely to increase with increase in number of the nitro groups. This may be partly due to the steric hindrance. Generally, the Co–N distances in Co–NH_3 seem to be longer than that in Co–NO_2.

TABLE 6. COMPARISON OF BOND LENGTHS IN VARIOUS NITROAMMINE COMPLEXES

	Co–NO_2	Co–NH_3	N–O
$[Co(NO_2)(NH_3)_5]^{2+}$ 1)	1.921 Å	1.977 Å	1.161 Å

$[Co(NO_2)_3(NH_3)_3]$ 2)	1.97	1.98	1.26
$[Co(NO_2)_4(NH_3)_2]^-$ 3)	1.96	1.98	1.23
$[Co(NO_2)_6]^{3-}$ 4)	2.03		1.11

Nitrate ion has an approximate three fold axis and N atom is 0.034 Å apart from the plane composed of three O atoms. The structure is built up of complex cations $[Co(NO_2)_2(NH_3)_4]^+$, nitrate ions and water molecules, thus being essentially ionic. The arrangement of the cobalt atoms themselves has approximately the symmetry D_{2h}^{25}-*Immm*. This characteristic feature seems to be mainly due to the presence of spatial network consisting of the complex ions. The water molecules and nitrate ions also appear to play an important role. The binding force between complex ions is mainly due to the N–H···O interactions between NH_3 and NO_2 groups. Figure 3 illustrates a network of the

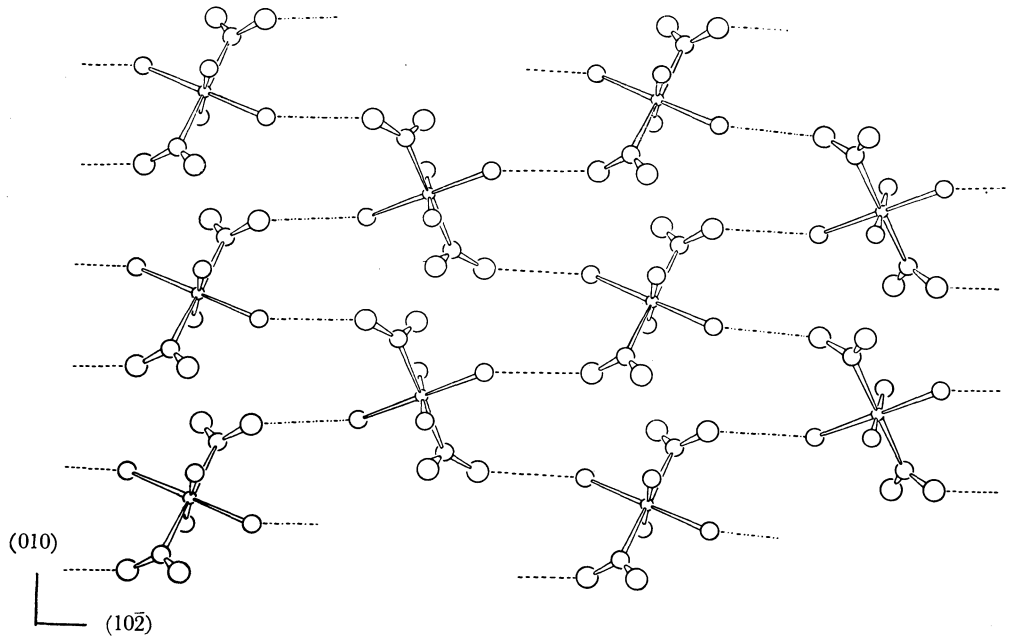

Fig. 3. Two dimensional network of complex ions found in crystal of $[Co(NO_2)_2(NH_3)_4]NO_3 \cdot H_2O$.
——: linkages of 3.041 Å; —·—: linkages of 3.068 Å; —··—: linkages of 3.031 Å

complex ions found in this structure. Each complex ion forms four N–H···O bonds with four neighboring complex ions in a similar manner to that of binding found in the structure of $[Co(NO_2)_3(NH_3)_3]$. One of the two oxygen atoms of NO_2 groups is used to form N–H···O bonds of 3.068 Å, 3.031 Å, and 3.041 Å with NH_3 of the adjacent complex ions, thus two dimensional network parallel to the plane (10$\bar{2}$) being formed. At the same time the other oxygen atom is used to form another network with N–H···O distances of 3.068 Å, 3.031 Å, and 3.117 Å in the latter, parallel to the plane (102).

Thus these layers form a three dimensional network.

The distances between two layers parallel to (10$\bar{2}$) and (102), 6.45 Å, and 6.44 Å, respectively are the same as the corresponding ones, 6.48 Å, and 6.49 Å found in the crystals of $NH_4[Co(NO_2)_4(NH_3)_2]$, but longer than that in $[Co(NO_2)_3(NH_3)_3]$ (5.10 Å). In this three dimensional network four oxygen atoms of each complex form weak N–H···O bonds with four NH_3 groups of upper and lower complex ions in the direction of the *b*-axis (3.103 Å, 3.113 Å, 3.114 Å, and 3.121 Å). This fact seems to account for the tendency for the crystal to grow along the *b*-axis. Water molecules form O–H···O hydrogen bond with oxygen of upper and lower nitrate ions in the direction of the *b*-axis (3.026 Å, and 2.851 Å). The water molecules and nitrate ions form N–H···O bond with NH_3 groups of complex ions (3.160 Å, 3.114 Å, 3.096 Å, *etc.*). These facts seem to support the conclusion drawn by Komiyama[3] that two nitro groups in *trans*-position are more likely to form N–H···O bonds than those nitro groups which are coordinated to the central cobalt atom in *trans*-positions with respect to different ligands.

The numerical calculations were carried out on the HITAC 5020 at the Computation Center, the University of Tokyo.

Part of the cost of this investigation has been defrayed by a Scientific Research Grant of the Ministry of Education, to which the authors' thanks are due.

The Adsorption of Cobaltous Ions on Glass Beads from Extremely Dilute Aqueous Solutions

Tsutomu SEIMIYA, Hisako KOZAI and Tsunetaka SASAKI

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya-ku, Tokyo

(Received April 4, 1969)

The adsorption of cobaltous ions on fine glass beads was measured for dilute aqueous $^{60}CoCl_2$ solutions with pH values from 2 to 10 and with concentrations from 10^{-6} to 10^{-10} mol/*l*. The amount of the adsorption of cobaltous ions on glass showed a maximum at pH near 9, and it was zero at both ends of the pH region for all the initial concentrations studied. This fact is considered to confirm the theory of radiocolloid formation by the so-called adsorption method. The mechanism of radiocolloid formation was further discussed in detail. The formation of radiocolloids was explained by the adsorption of cobaltous ions on foreign particles, while the formation of insoluble cobaltous hydroxide was ruled out. It was estimated from these measurements that a very minute amount of foreign particles is sufficient to adsorb cobaltous ions and to change a large franction of the solute to radiocolloid. It was emphasized that such an estimation can be made only by the measurement of the adsorption, expressed by the unit of mol/cm^2 as in the case of the present experiment, instead of the conventional unit of cpm/g or percent adsoı ption.

Several workers have reported that the radioisotope in a very dilute aqueous solution often behaves as a colloid or a coarser dispersion rather than as a true solution. Such a disperse system, called radiocolloid by Paneth,[1] forms far below the concentration usually believed to be the solubility of the substance in question. Two possibilities have been proposed for the formation: a true colloid formation from a supersaturated solution of the radioisotope,[1] and a colloid formation by the adsorption of dissolved radioisotopes on small colloid particles of a foreign substance which are accidentally introduced into the solution as fragments of the container wall[2,3] or as impurities present in the reagent or water used.

The formation of radiocolloids has been detected by means of filtration,[4] adsorption,[5] dialysis,[1,6] electrophoresis,[1,2] diffusion,[7] precipitation,[8] and by several other methods.[9] However, considerable ambiguities are inevitably introduced in the measurement of the concentration because of the extremely low concentration at which these experiments are carried out, and because of adsorption of the solute to the wall of the container or other surfaces that might come into contact with the solution. Thus, the published reports on radiocolloids are more or less qualitative in nature; quantitative studies concerning the behavior of the main constituent of radiocolloids are few. Recently, however, a radiotracer study of manganese adsorption on glass was reported, and radiocolloid formation was inferred.[10] Nevertheless, here, as in the other reports, the amount of adsorption and the concentration of solute are expressed in relative or conventional units which are unsatisfactory for the purposes of a more quantitative discussion. The present report will deal with a study of the radiocolloidal behavior of cobaltous ions paying attention to these facts. The cobaltous ion was chosen since the radiocolloid formation of cobalt has not yet been reported in spite of the wide use of 60-Co as a radiotracer. The explanation of the radiocolloid formation of 60-Co based upon the adsorption mechanism was attemtped. For this purpose, very many small glass spheres were added to an aqueous solution of $^{60}CoCl_2$ of a known concentration, and the amount of adsorption was exactly determined in the unit of mol/cm^2 at the

extremely dilute equilibrium concentration thus attained. These data enabled us to estimate the amount of foreign particles, which is extremely small but sufficient for adsorbing a large fraction of the cobaltous ions in a dilute solution and changing them into the radiocolloid.

Experimental

Solution. The radioisotope of cobalt was supplied by The Radiochemical Center, England, as a cobaltous chloride with a specific activity of 144 mCi/mg; it was isotopically diluted by an analytical-grade non-radioactive cobaltous chloride before use.

The water used was doubly distilled from a Hysil flask with nothing added after the reflux boiling and distillation with acid and alkaline permanganate respectively. Here, the adsorption of cobaltous ions by the wall of the container and the accidentally-introduced dust particles usually produce an error in the measurement at extremely low concentrations. To avoid this, a large quantity of carefully prepared fine glass beads was used as an adsorbent which had a far larger surface area than the surface area of the wall and of the dust particles introduced with the solvent water or reagents. The probable error due to the fine particles introduced together with the glass beads also turned out to be immaterial, as will be mentioned later. The present experiment enabled us to eliminate such an error and to attain an extremely dilute solution of a known concentration. The initial concentration was chosen in the range from 10^{-6} to 10^{-8} mol/*l*, and the equilibrium concentrations finally attained ranged from 10^{-8} to 10^{-10} mol/*l*. The concentration of cobaltous ions in the initial solution was determined by EDTA titration, using murexide as an indicator, while the amount of adsorption was determined from the change in the radioactivity of the supernatant solution due to the adsorption. Here, the loss of a solute by the adsorption on the wall of the pipet or of the container used for analysis was proved to be negligible, as will be discussed later.

Glass Beads. Beads of soda lime glass, ranging between 40 and 44 μ in diameter and with a specific surface area of about 593 cm^2/g, were used as an adsorbent. It is well known[11] that the glass surface has a considerable buffer action, and also that it often takes a fairly long time to attain the adsorption equilibrium. It was confirmed in the present study that, after the contact between the glass and the solution, a gradual change in the pH of the solution with the time was observed together with the change in the concentration of the cobaltous ions. Such a complication is not desirable for the present purpose of studying the adsorption behavior of cobaltous ions at various concentrations and pH values. For this reason, the glass beads were previously cleaned and equilibrated with the buffer solution according to the procedures shown in Fig. 1.

The pH of the buffer solution in this figure was taken to be equal to that of the solution used for the adsorption measurement. The adsorption measurement

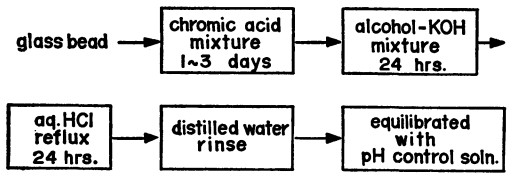

Fig. 1. Pretreatment of glass beads before adsorption.

was performed by immersing 2 g of the treated glass beads in 8 m*l* of 10^{-6} to 10^{-8} mol/*l* aqueous solution of cobaltous ions, and then by keeping it at 25±2°C with gentle stirring. At proper time intervals, the concentration of cobaltous ions of the supernatant solution was determined by radioactivity measurement using a Ten SA-100 Geiger Müller counter, the steady value of the counting rate was taken as the equilibrium. In this measurement, an aliquot of the solution was taken out by means of a constant-volume micropipet of 40 μl, placed on a circular Indian paper affixed to a glass plate, and dried completely under an infrared lamp before counting. The experiment previously performed by the present authors proved this counting technique to be satisfactory, especially for the measurement of 60-cobalt.[12] The errors due to the adsorption of cobalt on the glass surface of the pipet, errors which are unavoidable in this operation, turned out to be negligible when we compare the very slow rate of adsorption, which takes about 20 hr to attain equilibrium, with the short time of contact between pipet and solution.

Results and Discussion

The amount of the adsorption of cobaltous ions on a unit of the surface of glass, Γ, is expressed as the difference between the concentration of the solution before and after the adsorption multiplied by the volume of the solution:

$$S\Gamma = (C_i - C_e)V$$

or

$$\frac{S\Gamma}{C_i V} = 1 - \frac{C_e}{C_i} \qquad (1)$$

where S expresses the total surface area of the glass beads; C_i and C_e, the initial and equilibrium concentrations respectively of the solution used for the adsorption experiment, and V, the volume of the solution. Equation (1) expresses the linear relation between C_e and $S\Gamma/C_iV$, the latter being the ratio of the total amount of adsorption to the total amount of the solute. This linearity is shown in Fig. 2 as a straight line for the three C_i's chosen in the present experiment. With the aid of this straight line we can obtain the $S\Gamma/C_iV$ values, and therefore Γ, from the observed C_e values. In the present experiment, starting from relatively high concentrations of 10^{-6} to 10^{-8} mol/*l*, low equilibrium concentrations of 10^{-8} to 10^{-10} mol/*l* were

○ $\times 10^{-7}$ □ $\times 10^{-8}$ △ $\times 10^{-9}$

attained by adding a sufficient amount of an adsorbent. The points on the straight lines were located corresponding to the equilibrium concentrations thus obtained. The deviation of several plots from the straight line is due to the slightly different values of the corresponding C_i from those indicated in Fig. 2. The numbers indicated at the points in Fig. 2 show the pH values of the solutions at which the adsorption was equilibrated. The pH dependence of the adsorption of cobaltous ions on the glass surface is shown in Fig. 3. In this figure, the circles, squares, and triangles indicate the amounts of adsorption for the solutions of three different initial concentrations, 1×10^{-6}, 1×10^{-7}, and 1×10^{-8} mol/l respectively. The amounts of adsorption from these solutions are in the order of magnitude of 10^{-12}, 10^{-13} and 10^{-14} mol/cm^2 respectively, as is shown by the ordinate of this diagram. It may be noted that the use of glass beads as in the present experiment makes it possible to express the amount of adsorption in moles per area of glass surfaces instead of as cpm per weight of the powders or as mere percentages of the adsorption of the total solute present in the system, as has usually been done in similar studies.

As is shown in Fig. 3, all these plots can be brought near a common curve by a proper choice of the unit of the ordinate for each group of solutions with a different initial concentration. Thus, the adsorption behaviors of these solutions are quite similar towards the pH change in spite of the wide difference in initial concentrations and in the amount of adsorption. No indication of adsorption was observed at any pH lower than about 3. The adsorption increased with the pH and showed its maximum at a pH of about 9, regardless of the initial cobaltous-ion concentration. A further increase in pH sharply decreased the adsorption to zero at pH values of about 10. The amount of adsorption at its maximum is more than 90% of the total amount of solute——for instance, 95% of the cobaltous ions adsorbed from a 10^{-8} molar solution at pH values from 8 to 9, leaving a 10^{-10} molar solution in equilibrium with it. Here, we can confirm that a proportionality such as that expressed by;

$$\Gamma = kC_e \qquad (2)$$

holds as a whole at any given pH and especially well at the pH of maximum adsorption. We can further confirm, at least from the 95% adsorption at pH values of about 9, that the fine dust particles which might be introduced together with the glass beads are negligible in amount, since the dust particles of such an origin, if they existed in a considerable amount, would adsorb as many cobaltous ions and keep them in a suspended state. Such a state should markedly increase the supernatant cobaltous-ion concentration and reduce the (apparent) fraction of the amount of adsorption far below 95%. As to the radiocolloid formation of cobalt, we can take the appearance of an adsorption maximum near pH 9 as a confirmation by the so-called adsorption method. The explanation based upon the mechanism of the formation of true insoluble colloidal particles of cobaltous hydroxide was first considered, but this is unacceptable since the equilibrium concentrations studied in the present experiment (at least 10^{-10} mol/l) are far below the solubilities of cobaltous hydroxide, $10^{-5.6}$—$10^{-7.4}$ mol/l, at pH values of about 9 as calculated from its solubility product.[13,14] The formation of cobaltic hydroxide, which is far more insoluble than cobaltous hydroxide, is also unlikely

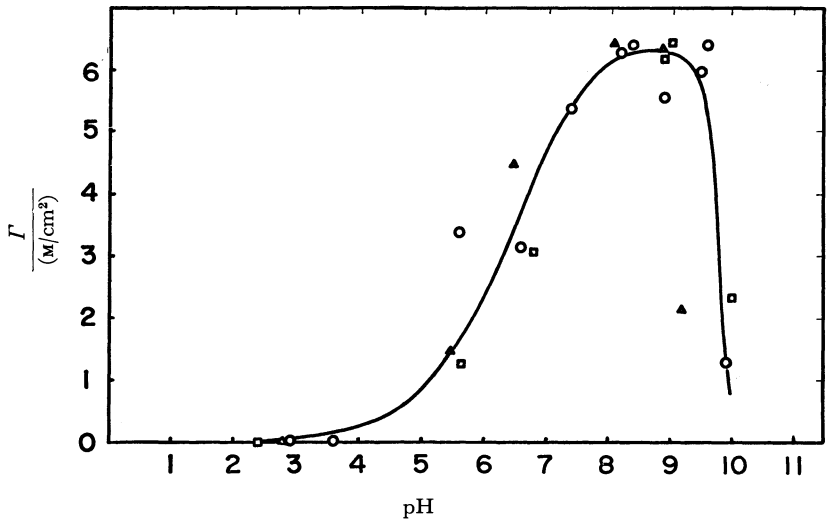

Fig. 3. Adsorption of cobaltous ion on glass beads.

	Γ	C_i
○	$\times 10^{-12}$	1.0×10^{-6}
□	$\times 10^{-13}$	1.0×10^{-7}
△	$\times 10^{-14}$	1.0×10^{-8}

considering the cobaltic-ion concentration in equilibrium with the cobaltous ion, which is calculated from the oxidation reduction potential measured for the solution used in the present experiment. Further, the electrodialysis data for the 10^{-4} molar cobaltous chloride solution which one of the present authors has formerly reported[6] showed that the colloid formation of cobaltous hydroxide is limited to the pH region slightly below the solubility of cobaltous ions calculated from the solubility product. From these facts, it can safely be concluded that true colloid of cobaltous hydroxide in any form cannot be considered to exist below the cobaltous-ion concentration of 10^{-9} mol/*l* at pH 9 and at 25°C.

On the contrary, though, we can numerically show the possibility of radiocolloid formation due to the adsorption of cobaltous ions on foreign particles. As has already been shown in the preceding section, about 95% of the solute is adsorbed by two grams of glass beads from 8 m*l* of a 10^{-8} molar aqueous solution at pH 9. Here the total area of the beads is 1186 cm². Now, simple calculation shows that as small an amount as about 6×10^{-6} g of glass particles of colloidal size (10^{-7} cm) in a 1 m*l* solution gives a 1186 cm² surface for an 8 m*l* sample solution, which just adsorbs 95% of the cobaltous ions in solution and keep them in a radiocolloidal state. It is quite conceivable that dust particles in such a small amount exist in ordinary water. Thus, the results of the above adsorption experiment with coarse glass beads indicate the possibility that the radiocolloid formation of cobalt in a dilute aqueous solution is due to the adsorption of the solute on a very small amount of foreign particles.

It should be emphasized in conclusion that the radiocolloid formation can be confirmed only by the exact measurement of the amount of adsorption expressed in the unit of moles per square centimeter and by using an adsorbent with a clearly defined total area and pH condition. Such a confirmation is impossible by the so-called adsorption method usually adopted; here the results are expressed merely by the percentage of adsorption or by the unit of moles per weight of the adsorbent, using irregular particles of an ill-defined surface area.

Effects of Cation Vacancies of the Diffusion of Nickel Ions in Defective Spinels

Goro YAMAGUCHI, Mitsuko NAKANO and Mamoru TOSAKI

Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received April 7, 1969)

In order to clarify the influence of composition-dependent cation vacancies in defective spinels on the diffusion, the diffusion rates of Ni^{2+} in several kinds of defective spinels ($MgO \cdot xAl_2O_3$, where $x=1.1$, 1.2, 1.3, 1.4 and 1.5) and a perfect spinel ($MgO \cdot Al_2O_3$) were measured by the use of an electron probe micro-analyzer, and the diffusion coefficients were obtained. The diffusion coefficients were found to be linear to the concentrations of the composition-dependent vacancies. The so-called activation energies which were calculated from the Arrhenius plot were about 70 kcal/mol for the defective spinels and 106 kcal/mol for the perfect spinel. It may be concluded that composition-dependent cation vacancies govern the diffusion of cations in the defective spinel, while temperature-dependent vacancies probably predominate in the perfect spinel.

The diffusion in ionic crystals has been well investigated with regard to sodium chloride.[1] It has been shown that there are two ranges in the Arrhenius plot of the self-diffusion coefficients of Na^+ in sodium chloride. This phenomenon may be explained as follows: in the lower temperature range the concentration of the vacancies which are caused by impurities and which govern the diffusion is much larger than that of the temperature-dependent vacancies, while in the higher temperature range the temperature-dependent vacancies predominate. The same phenomenon was found with regard to the self-diffusion of O^{2-} in aluminum oxide,[2] and it is thought that the vacancies caused by impurities contribute to the diffusion in the case of oxide as well.

As for the effect of impurities, the influence of impurities (Fe_2O_3, Cr_2O_3 and CoO) on the diffusion of Ni^{2+} in magnesium oxide has been reported.[3] It was found that when Fe_2O_3 or Cr_2O_3 was added to MgO the diffusion of Ni^{2+} in MgO was promoted. The phenomenon can be explained by the fact that, when Mg^{2+} is replaced with Fe^{3+} or Cr^{3+}, the difference in the valence causes cation vacancies which then contribute to the diffusion.

The no-cation sites in oxide crystals may be classified into the three groups: the structural no-cation sites, the temperature-dependent vacancies, and the composition-dependent vacancies. An example of a structural no-cation site is the no-Al octahedral site in alpha-Al_2O_3. The vacancies caused by impurities belong to the composition-dependent vacancy, and the temperature-dependent vacancy is thermally formed. Composition-dependent vacancies can be intentionally realized and controlled in a complex oxide with a fairly wide solid-solution range such as spinel. Such vacancies caused by structural nonstoichiometry are expected to contribute to the diffusion, but no study of this problem has yet been reported. This paper will report the results of an experiment investigating the influence on the diffusion of cation vacancies occuring in a spinel solid solution.

The $MgAl_2O_4$-Al_2O_3 system has a large region of a

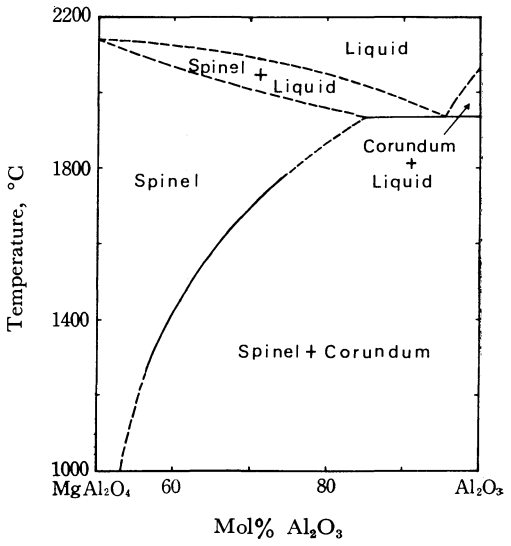

Fig. 1. Phase diagram for the system $MgAl_2O_4$-Al_2O_3.[4]

3) G. Yamaguchi and T. Tokuda, *J. Ceram. Assoc. Japan*, **76**, 350 (1968).

solid solution on the side of spinel, as may be observed in the phase diagram[4] (Fig. 1). In this report this solid solution will be called the "defective spinel,"[5] while the spinel with a perfect spinel structure will be called the "perfect spinel." It is thought that excessive oxygen causes cation vacancies with an increase in the Al_2O_3 concentration in the defective spinel[6] and that they are composition-dependent vacancies. Because of the wide range of solubility, the concentration of composition-dependent vacancies can be much larger than that of temperature-dependent defects. Since the concentration gradient was found in the spinel layer at the time of practical formation from magnesium oxide and aluminum oxide,[7] the defective spinel whose composition varies continuously is thought to constitute the product layer. The material transport through the product layer controls the reaction rate in a solid state reaction such as spinel formation. Accordingly, it is important in the study of the solid state reaction to examine the influence on the diffusion of cation vacancies present in the defective spinels.

In this report the diffusion rates of Ni^{2+} in several kinds of defective spinels ($MgO \cdot xAl_2O_3$, where $x=1.1$, 1.2, 1.3, 1.4 and 1.5) and the perfect spinel are investigated using an electron probe micro-analyzer, and the influence on the diffusion of composition-dependent cation vacancies in defective spinels is clarified. Spinels also have many structural no-cation sites, such as no-Al sites in alpha-Al_2O_3; this experiment might be able to suggest the nature of the effect of those no-cation sites on the cation diffusion.

Experimental

Preparation of Specimens. The spinels whose compositions are listed in Table 1 were synthesized from basic magnesium carbonate, basic nickel carbonate, and gibbsite. Ten per cent of the Mg^{2+} of the spinels designated as M1, M2, M3, M4, M5, and M6 were replaced with Ni^{2+}; these spinels were designated as N1, N2, N3, N4, N5, and N6 respectively. The degrees of defectiveness or the concentrations of the composition-dependent cation vacancies of Nj may be expected to be equal to that of Mj, where $j=1$, 2, 3, 4, 5, and 6. The calculated concentrations of such vacancies are shown in Table 1.

Mg^{2+} and Ni^{2+} are similar in valence, ionic radius, and chemical property, and the concentrations of Ni^{2+} in the spinels of the N series are not large. Therefore, the properties of the spinels of the N series are thought to be very similar to those of the M series. Therefore, when M1 and N1, M2 and N2, and so on are paired as

diffusion couples, the degree of defectiveness does not vary at the time of diffusion treatment and Ni^{2+} ions may be expected to diffuse with the same diffusion coefficient on both sides of the diffusion interface. These spinels were pressed into pellets and heated at 1650°C for several hours. Specimens were sintered densely so that they had less than 5% of porosity to avoid its influence as much as possible. The lattice constants of these spinels were measured accurately by an X-ray diffractometer. The measured values are shown in Fig. 2, along with the lattice constants previously reported.[6,8-11] It was found that the lattice constants varied linearly with the compositions in both series, M and N, so that the spinels whose cation-vacancy concentrations are equal to the calculated value may be supposed to have been synthesized. These pellets were polished with silicon carbide grains and diamond paste. Magnesium aluminum spinels were paired with spinels containing Ni^{2+} whose cation-vacancy concentrations were equal to the former, such as M1-N1. Their polished faces were placed in contact, and they were pressed perpendicularly to the contact face under a pressure of about 3 kg/cm² for 15 min at the temperature of 1500°C. After this treatment, the pellets were stuck together.

The specimens prepared as mentioned above were polycrystalline and contained grain boundaries. In order to estimate the influence of grain boundaries on the cation diffusion, two kinds of single crystal spinels were treated in the same way as the sintered specimens. The compositions of these single crystals were $MgO \cdot Al_2O_3$ and $MgO \cdot 1.5Al_2O_3$; they were designated as M1(S) and M6(S) respectively. M1(S) was paired with N1, and M6(S) with N6, and they were jointed in the same way as the other couples.

Heat Treatment for Diffusion. The six couples prepared as described above were heated in a controlled electric furnace for from 48 to 216 hr. The heat-treating temperatures were 1305±10, 1372±10, 1477±10, and 1527±10°C.

Analyzing Method. Each specimen was buried in resin after the heat treatment and cut perpendicularly to the diffusion interface with a diamond cutter. The cut surface was polished carefully with silicon carbide grains and diamond paste, and then coated with beryllium by vacuum spattering in order to get the electric conductivity. Specimens were mounted on the sample holder and analyzed by the electron probe micro-analyzer. At the time of measurement specimens were moved perpendicularly to the diffusion interface at a velocity of 20 μ/min, while the electron beam was fixed; then the intensity profile of the characteristic X-rays of Ni was obtained.

For the standard samples the spinels whose compositions are described as $(Mg_{1-x}Ni_x)O \cdot Al_2O_3$, where $x=0.0$, 0.01, 0.02, and 0.05, were synthesized. They were sintered, polished, and coated with beryllium in the same way as in the case of diffusion couples. With these standard samples, the intensities of the Ni$K\alpha$ rays were measured by the electron probe micro-analyzer. It was found that the plot of the intensities of the Ni$K\alpha$ rays against the concentrations of Ni^{2+} was almost linear, as is shown in Fig. 3. Therefore, it might be supposed that the intensity profile of Ni$K\alpha$ rays obtained

by the measurement about the diffusion couple represents the concentration distribution of Ni^{2+} as it really is.

Results and Calculation of Diffusion Coefficients

The intensity profiles of Ni$K\alpha$ rays measured by the electron probe micro-analyzer can be grouped into the following three classes on the basis of the features of the diffusion interface and its neighborhood. The first class consists of the profiles which have no clear falling of intensity at the position of the diffusion interface. In the couples of this group the pellets are thought to be stuck very fast; such an adhesive condition is represented by the sign A. The second class consists of the profiles which have clear fallings of intensity at the position of the diffusion interface, but in which the Ni$K\alpha$ intensities on both sides are nearly equal. In this case the pellets are thought to be stuck quite fast; such an adhesive condition is represented by the sign B. The third class consists of the profiles which have clear fallings at the position of the diffusion interface and in which there are gaps of Ni$K\alpha$ intensities on both sides of the diffusion interface. Such an adhesive condition is represented by the sign C. Examples of the original profiles belonging to all three classes recorded by the electron probe micro-analyzer are shown in Fig. 4. The experiments whose results have the profiles represented by the adhesive signs A and B were thought to be established well enough, and so the results were used as data for the calculation of the diffusion coefficients. The results of the experiments belonging to the class represented by the adhesive sign C were not used, however, because in this case the adhesive condition was thought to be not so good.

The intensity profile was smoothed so as to average the statistical fluctuations; it can now be thought of as a smoothed profile to represent the concentration distribution of Ni^{2+} in the diffusion couple as it really is. The concentration distribution curves of Ni^{2+} in the diffusion couples which are thought to be well establsihed are shown in

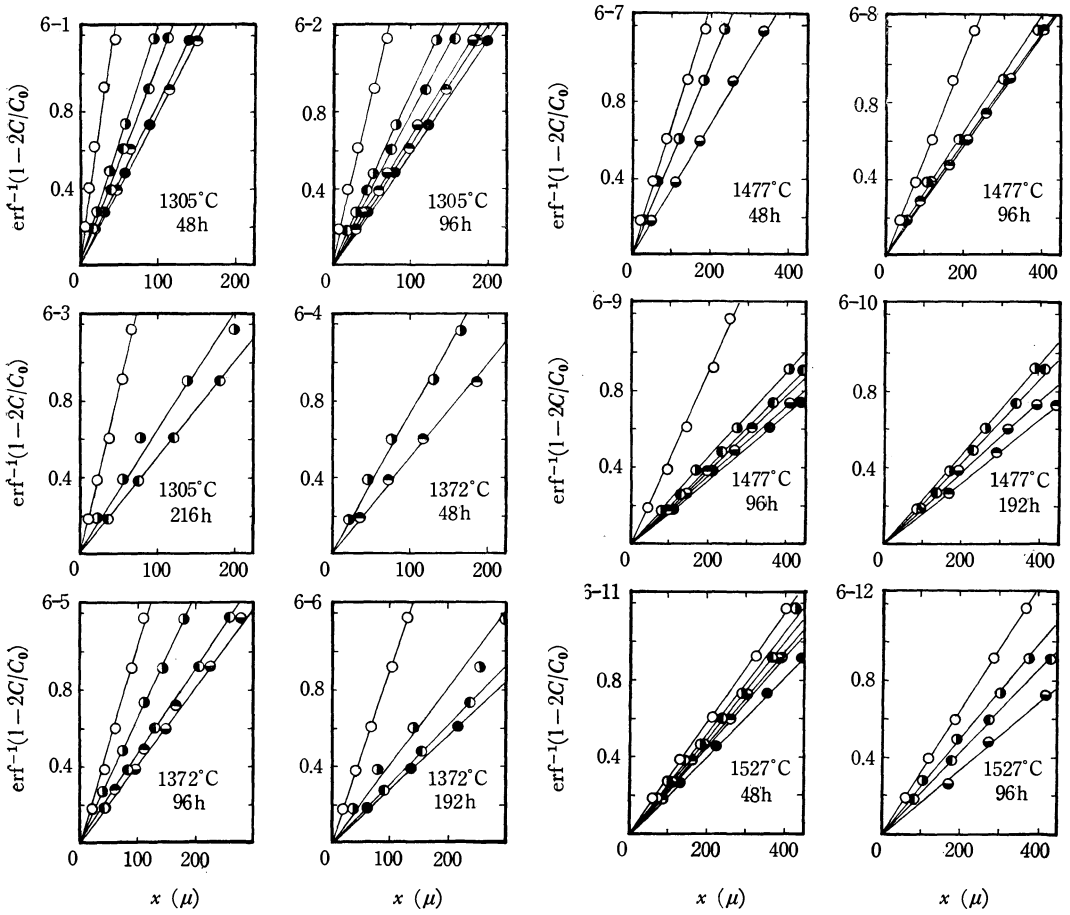

Fig. 6. Plots of $\mathrm{erf}^{-1}(1-2C/C_0)$ *vs.* x.

○, M1-N1; ◑, M2-N2; ◐, M3-N3; ◒, M4-N4; ◓, M5-N5; ●, M6-N6

Figs. 5-1 to 5-12. The shapes of the curves are symmetrical, as is shown in Figs. 5-1 to 5-12; on both sides of the diffusion interface the equal values of the diffusion coefficient of Ni^{2+} were calculated by the method to be described below.

In obtaining the diffusion coefficients, it was assumed that the diffusion follows Fick's law. Considering the initial state, the concentration, C, of Ni^{2+} at a certain distance, x, from the diffusion interface after time t is given by:

$$C = C_0/2 \cdot \{1-\mathrm{erf}(x/2\sqrt{Dt})\}$$

Therfore,

$$\mathrm{erf}^{-1}(1-2C/C_0) = x/2\sqrt{Dt},$$

where D is the diffusion coefficient of Ni^{2+}, C_0 is the initial concentration of Ni^{2+} at $x<0$, $\mathrm{erf}(\xi)$ is Gauss' error function, and $\mathrm{erf}^{-1}(\zeta)$ is the inverse function of Gauss' error function. Plots of $\mathrm{erf}^{-1}(1-2C/C_0)$ against x based on the results shown in Figs. 5-1 to 5-12 are shown in Figs. 6-1 to 6-12. In every plot good straight lines are obtained; from the slope of these lines, that is $1/2\sqrt{Dt}$, the diffusion coefficients can be calculated. The diffusion coefficients of Ni^{2+} obtained in the way described above were arranged for every couple and every heat-treatment temperature; the results are shown in Table 2. In order to estimate the influence of grain boundaries, the diffusion coefficients were calculated from the measurements of M1(S)-N1 and M6(S)-N6; it was found that they were nearly equal to the values obtained from M1-N1 and M6-N6 respectively. The plots of $\mathrm{erf}^{-1}(1-2C/C_0)$ *vs.* x for M1(S)-N1 and M6(S)-N6 are shown in Fig. 7, along with the plots about M1-N1 and M6-N6. Accordingly, it seems that there is no influence of grain boundaries on the diffusion in such an experiment using a sintered specimen fired at a temperature above 1650°C.

Discussion

The plots of the diffusion coefficients of Ni^{2+} *vs.* the concentrations of the composition-dependent vacancies are shown in Fig. 8. The figure shows that the diffusion coefficients of Ni^{2+} are linear to

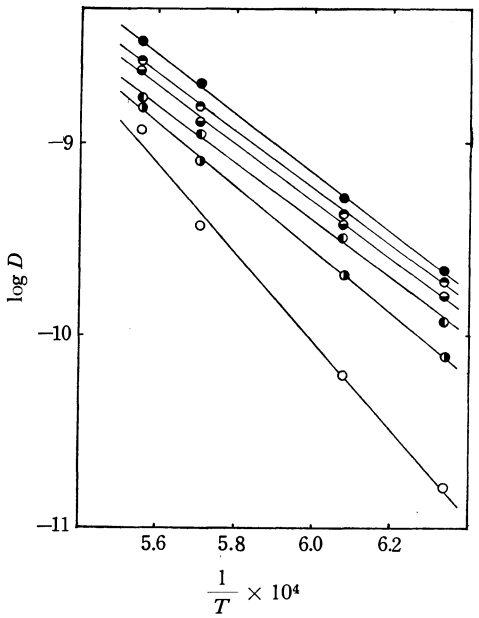

Fig. 9. Arrhenius plot of the diffusion coefficient.

◒, M4-N4; ◓, M5-N5; ●, M6-N6

the concentrations of the composition-dependent vacancy. The Arrhenius plot for each couple is shown in Fig. 9. The so-called activation energies obtained from the Arrhenius plots are listed in Table 3. The activation energy is 106 kcal/mol for the M1-N1 couple with a perfect spinel structure, while it is about 70 kcal/mol for the couples containing composition-dependent vacancies, M2-N2, M3-N3, M4-N4, M5-N5, and M6-N6. Therefore, it was confirmed that the composition-dependent vacancies contribute to the cation diffusion in the defective spinel. In the perfect spinel the temperature-dependent vacancy or the structural no-cation site is thought to contribute to the cation diffusion. The fact that the diffusion

Table 3. The temperature dependence of the diffusion coefficients
(the so-called activation energy)

Couple of specimens	So-called activation energy (kcal/mol)
M1-N1	106
M2-N2	75
M3-N3	69
M4-N4	68
M5-N5	67
M6-N6	69

constants of Ni^{2+} in the perfect spinel are fairly small compared with the values in the defective spinels suggests that, if there exists a diffusion caused by the structural no-cation sites, the contribution of those no-cation sites to the diffusion will seem small. However, the effects of the temperature-dependent vacancies and the strucutral no-cation sites could not be discriminated in this experiment. Therefore, according to the genral interpretation, it was assumed that the diffusion in the perfect spinel was caused by the temperature-dependent vacancies. The diffusion coefficient D in M1-N1 can, then, be represented as follows:

$$D = D_0 \exp\left(-\frac{U+E}{RT}\right)$$

where U is the energy necessary for the movement of Ni^{2+} and where E is the energy necessary to form the temperature-dependent vacancy contributing to the diffusion. The so-called activation energy for the perfect spinel, $U+E$, is 106 kcal/mol, as is shown in Table 3. In defective spinels the diffusion coefficient, D, is represented as follows:

$$D = D_0' \exp\left(-\frac{U}{RT}\right)$$

where U is the energy necessary for the movement of Ni^{2+}. The so-called activation energy is about 70 kcal/mol for the defective spinel, as is shown in Table 3. Therefore, the tentative values of $U=70$ kcal/mol and $E=36$ kcal/mol were obtained. This value of E is about 1.6 times larger than the value reported for Na^+ in NaCl, that is, 23 kcal/mol,[1] this ratio does not seem unreasonable. In the case of the diffusion of Ni^{2+} in MgO containing Cr_2O_3, 70 kcal/mol was obtained as the extrinsic activation energy;[3] this is almost equal to the value found in the present investigation.

Conclusion

The diffusion of Ni^{2+} in several kinds of defective spinels and the perfect spinel were investigated using an electron probe micro-analyzer. It was found that the diffusion coefficient of Ni^{2+} in the defective spinel increased linearly with the increase in the concentration of the composition-dependent cation vacancies. The so-called activation energy calculated from the Arrhenius plot for the defective spinel was different from that for the perfect spinel; the difference between them was 36 kcal/mol. The results support the suggestions that the composition-dependent cation vacancies govern the cation diffusion in the defective spinel, while the temperature-dependent vacancies predominate in the perfect spinel.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 2808—2814 (1969)

ESR Studies of the Negative Ions of Biphenyl Derivatives. III. Restricted Rotation of Alkyl Group in Some *ortho* or *para* Higher Alkylated Biphenyl Anion Radicals*[1]

Kazuhiko Ishizu,* Kazuo Mukai,* Hideo Hasegawa,** Koichi Kubo,** Hiroaki Nishiguchi*** and Yasuo Deguchi***

* *Department of Chemistry, Faculty of Science, Ehime University, Bunkyo-cho, Matsuyama*
** *Japan Electron Optics Laboratory, Akishima-shi, Tokyo*
*** *Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto*

(Received April 9, 1969)

The electron spin resonance has been observed for the anion radicals of 4,4′-diethyl biphenyl, 4,4′-diisopropyl biphenyl, 4,4′-dicyclohexyl biphenyl, 2,2′-diethyl biphenyl, and 2,2′-diisopropyl biphenyl. Both of the β- and γ-proton coupling constants of alkyl groups have been precisely determined, and the positive temperature dependence has been verified for the β-proton coupling constant of 4,4′-dialkyl biphenyls. The ratio (R) of β-proton coupling constant of the other alkyls to the methyl proton coupling constant has been derived, and the evidence of the restricted rotation has been widely established for each derivative based on the angular dependence of the β-proton coupling constant, which can be expressed as follows:

$$a_i^{\beta} = \rho_{\pi} < Q >, \quad Q = B_0 + B\cos^2\theta$$

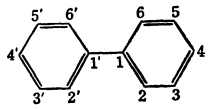
The minimum R value obtained for 2,2′-diethyl biphenyl enabled us to assume that a rotation of the alkyl group would be tightly locked at the *ortho* position. The R value of 2,2′-diisopropyl biphenyl revealed that the isopropyl β-proton would lie on the biphenyl aromatic plane. The anomalous R values associated with the *ortho*-alkylated biphenyls can be well understood as resulting from the facts that anion radicals have a more dominant character than do neutral molecules to reduce a twisting angle between the two phenyls, and that the free rotation of the alkyl group is strongly restrained by the steric hindrance between the alkyl group and the closely-oriented *ortho*-ring proton.

The theory of hyperconjugation has been widely accepted for numerous radicals based on the ESR observation of the methyl-proton splitting.

In many cases the observed methyl splitting has been successfully explained in terms of McLachlan's splitting parameter[1] on the assumption that a methyl group is freely rotating. In the case of the other alkyl derivatives, however, it has been established that the quantities of the β-*[2] proton splitting for alkyl groups differ from molecule to molecule because of the restricted rotation of the alkyl group.

In this study, ESR observations are made of anion radicals of 4,4′-diethyl biphenyl, 4,4′-diisopropyl biphenyl, 4,4′-dicyclohexyl biphenyl, 2,2′-diethyl biphenyl, and 2,2′-diisopropyl biphenyl.

The coupling constants of both the β- and the γ-*[2] proton in each alkyl group are determined, and the temperature dependence of the β-proton coupling constant is studied, in order to establish the relation between the preferred conformation of the alkyl groups and their proton splitting in these radicals. Our investigation of *ortho* derivatives is continuing, and we are likely to demonstrate that the rotation of the alkyl group can be strongly hindered at the *ortho* position. The general structure of a biphenyl ring is:



Experimental

The *ortho*- or *para*-alkylated biphenyls were made by an Ullman reaction on either *ortho* or *para* iodo alkyl

*[1] A part of this work was presented at 17 th Annual Meeting of the Chemical Society of Japan, Tokyo, April, 1964 and at the 18th Annual Meeting, Osaka, April, 1965.

*[2] The hydrogen atoms bonded to the sp^3 hybridized carbon atom at either the β- or γ-position are described as β-protons or γ-protons, as is shown in the illustration. The coupling constants are denoted as a_i^{β} and a_i^{γ}.

benzene, according to the following process. The iodo compound (0.04 mol) was heated with 0.22 mol of activated copper powder in a bath kept at *ca.* 230—280°C for 15 hr. The organic product was extracted with *n*-hexane. After the removal of the solvent, the residue was fractionated under reduced pressure or recrystallized from ethyl alcohol. The materials thus obtained were all purified by silica gel chromatography, using *n*-hexane as the solvent. The physical constants[2,3] of the materials are listed below:

4,4′-diethyl biphenyl, mp 82.5°C; 4,4′-diisopropyl biphenyl, 64.8°C; 4,4′-dicyclohexyl biphenyl, mp 199°C; 2,2′-diethyl biphenyl, bp 110.5—111.2°C/7 mmHg, n_D^{21} =15649; 2,2′-diisopropyl biphenyl, mp 68°C.

The anion radicals were prepared in a solution of dimethoxyethane by reduction with potassium metal held in an acetone - dry ice bath.

The ESR spectrometer employed here and its operating conditions have been described in a previous paper.[4]

Results and Discussion

4,4′-Diethyl Biphenyl. In Fig. 1(a), we show the ESR spectrum of the 4,4′-diethyl biphenyl anion measured at 0°C. The observed hyperfine structures were adequately analyzed, and the hyperfine coupling constants of the ring protons, a_i^H, and the alkyl proton, a_4^β, were determined in the manner described before,[4] that is:

$a_4^\beta = 3.99$, $a_2^H = 2.68$ and $a_3^H = 0.51$ gauss.

The analyzed spectrum given in Fig. 1(b) is in good accordance with the observed spectrum.

With a depression in the temperature, the spectrum changed the hyperfine structures; Fig. 1(c) was recorded at −50°C. Both the a_i^H and a_4^β values were confirmed by the reconstruction of

the spectrum, as is shown in Fig. 1(d).

$a_4^\beta = 3.76$, $a_2^H = 2.65$ and $a_3^H = 0.42$ gauss.

In the present experiments, the γ-proton splitting of the ethyl group could never be detected.

On the basis of a comparison of the hyperfine coupling constants obtained in the two cases, one may say that the modified hyperfine structures are caused by a diminution of the value for a_4^β with a lowering of the temperature, whereas either a_2^H or a_3^H remains constant or has only a minor change.

4,4'-Diisopropyl Biphenyl. The spectrum measured at −30°C is given in Fig. 2(a), in which one may see that the smallest splitting (0.09 gauss) resulted from the isopropyl γ-proton. The spectrum consists of seven groups, whose relative intensity ratios are 1:6:15:20:15:6:1; the separation between the neighboring groups is about 2.6 gauss. This means that the a_4^β of isopropyl groups has the closing quantity of a_2^H, the *ortho* proton coupling constant.

The coupling constants deduced by the trial-and-error calculation of the line intensity are given as follows:

$a_4^\beta = 2.85$, $a_4^\gamma = 0.09$, $a_2^H = 2.66$
and $a_3^H = 0.45$ gauss.

When the observation temperature was lowered to −50°C, a reduction of the value for a_4^β was again noted and the hyperfine structures of the spectrum varied as is shown in Fig. 2(b). There is probably a smaller variation in the value for a_4^γ at the same

time, but we had failed to detect any important change in the value for a_4^{γ} anywhere. The hyperfine coupling constants determined at $-50°C$ are:

$$a_4^{\beta} = 2.66,\ a_4^{\gamma} = 0.09,\ a_2^{H} = 2.66$$
$$\text{and } a_3^{H} = 0.47 \text{ gauss.}$$

4,4′-Dicyclohexyl Biphenyl. In Fig. 3, we give the observed spectrum of the 4,4′-dicyclohexyl biphenyl anion recorded at room temperature. Except for a_4^{γ}, the other hyperfine coupling constants, a_4^{β}, a_2^{H}, and a_3^{H}, were very similar to those for 4,4′-diisopropyl biphenyl; that is,

$$a_4^{\beta} = 2.92,\ a_4^{\gamma} = 0.24\ a_2^{H} = 2.60$$
$$\text{and } a_3^{H} = 0.47 \text{ gauss.}$$

The value of a_4^{γ} is interesting, for it is much larger than that of 4,4′-diisopropyl biphenyl. The large value of a_4^{γ} for 4,4′-dicyclohexyl biphenyl can probably be attributed to the fact that the methylene groups are tightly locked in the cyclohexyl ring, although it freely rotates in the case of isopropyl groups.

2,2′-Diethyl Biphenyl. The ESR measurement was carried out at $-70°C$, as is shown in Fig. 4. The ethyl proton splitting, a_2^{β}, was easily estimated from the quintet splitting of 1.02 gauss. The other four sets of triplet splitting (4.97, 2.19, 0.59 and 0.18 gauss) assumed here were found to be very close to those for *o,o′*-bitolyl already studied;[5] the values for a_4^{H}, a_6^{H}, a_5^{H}, and a_3^{H} were determined to be as follows:

$$a_4^{H} = 4.97,\ a_2^{\beta} = 1.02,\ a_6^{H} = 2.19,$$
$$a_5^{H} = 0.59 \text{ and } a_3^{H} = 0.18 \text{ gauss.}$$

2,2′-Diisopropyl Biphenyl. In Fig. 5, we show the spectrum of the 2,2′-diisopropyl biphenyl anion radical observed at $-70°C$. In this case, one may specify two sets of triplet splitting (5.41 and 2.17 gauss) which are close to those of a_4^{H} and a_6^{H} for *o,o′*-bitolyl on the one hand. On the other hand, in the terminal group of the spectrum, one may see eleven lines equally spaced at 0.28 gauss, and the splitting has the relative intensity ratio of 1 : 2 : 5 : 8 : 10 : 12 : 10 : 8 : 5 : 2 : 1. This suggests that either a_2^{β} or a_5^{H} is equal to 0.58 gauss and that a_3^{H} is nearly half the value of a_5^{H}.

The hyperfine coupling constants thus estimated are:

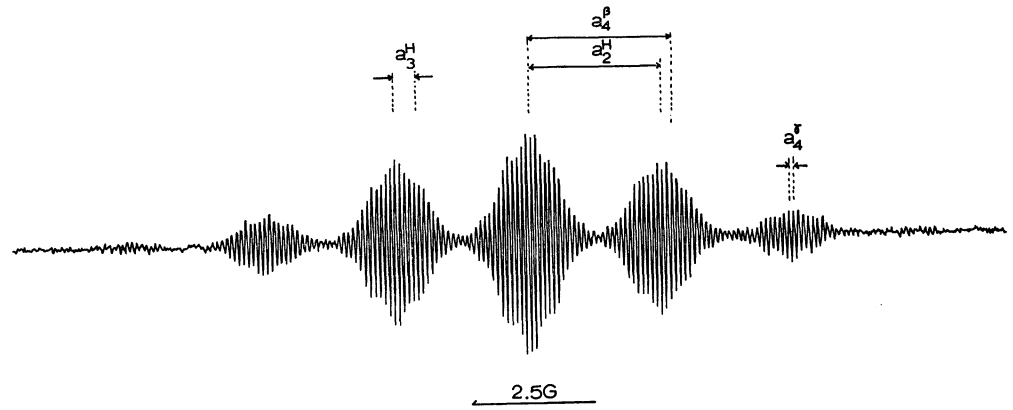

Fig. 2(a)

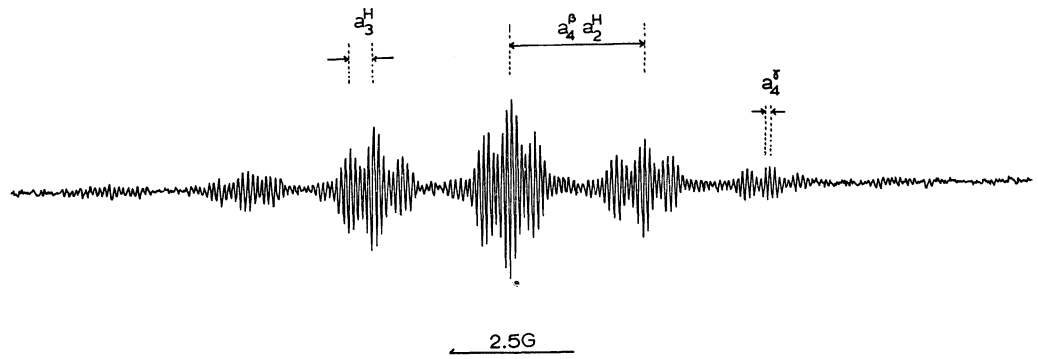

Fig. 2(b)

Fig. 2. 4,4′-Diisopropyl biphenyl.
(a) ESR spectrum recorded at $-30°C$. (b) ESR spectrum recorded at $-50°C$.

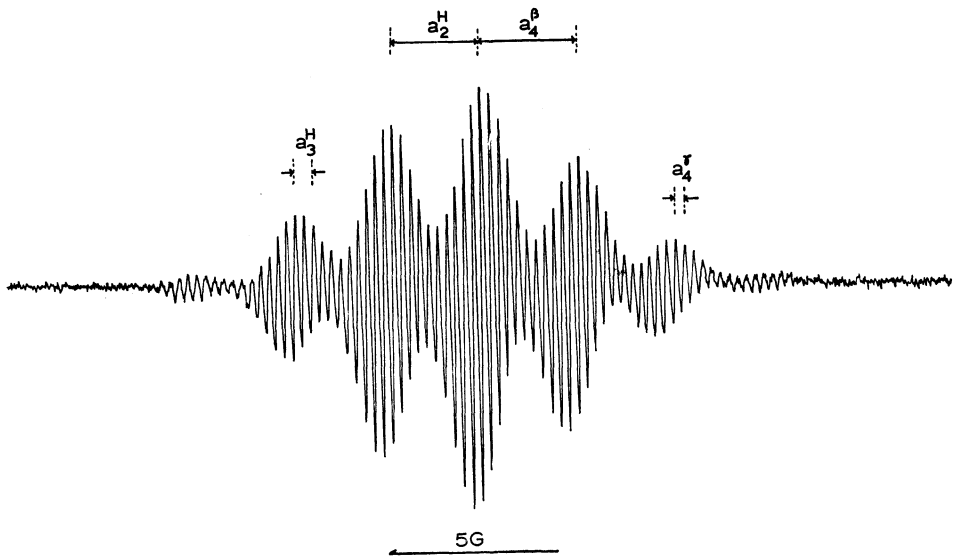

Fig. 3. 4,4'-Dicyclohexyl biphenyl.

$a_4^H = 5.14$, $a_6^H = 2.17$, $a_5^H = a_2^\beta{}_4 = 0.85$ and $a_3^H = 0.28$ gauss.

The observed proton splittings for alkylated biphenyl anion radicals are summarized in Table 1.

Ring-proton Splitting. A small perturbation is usually caused in the unpaired π distribution by an alkyl substitution into an aromatic ring. Indeed, as is shown in Table 1, this is also true for all the alkyl derivatives studied in the present work. In the case of *ortho* derivatives, however, it should be particularly noticed that the same magnitude of the ring-proton splitting can be observed regardless of the alkyl substitution; this is because the magnitude of the ring-proton splitting for *ortho* derivatives is a measure of not only an inductive effect due to the alkyl group, but also of the degree of steric hindrance between the two phenyl groups. The relation between the HMO spin density on the biphenyl π orbital and the steric hindrance between the two phenyls has already been established, and the ring-proton splitting ratios, a_4^H/a_6^H, have been taken as a parameter for estimating the degree of steric hindrance in the twisted biphenyls.[5]

Table 1. Proton coupling constants of alkyl biphenyl anion radicals (gauss)

4,4'-Dialkyl biphenyl

	a_2^H	a_3^H	a_4^β	a_4^γ	$\frac{a_4^\beta}{a_4^{CH_3}}$
p,p'-Bitolyl[a]	2.66	0.51	5.63	—	—
4,4'-Diethyl	2.68	0.51	3.99	—	0.71
4,4'-Diisopropyl	2.66	0.45	2.85	0.09	0.51
4,4'-Dicyclohexyl	2.60	0.47	2.92	0.24	0.52

2,2'-Dialkyl biphenyl

	a_2^β	a_3^H	a_4^H	a_5^H	a_6^H	$\frac{a_2^\beta}{a_2^{CH_3}}$
o,o'-Bitolyl[b]	2.20	0.28	5.12	0.56	2.20	—
2,2'-Diethyl	1.02	0.18	4.97	0.59	2.19	0.46
2,2'-Diisopropyl	0.58	0.28	5.14	0.58	2.17	0.26

Observation temperatures: a) room temperature, b) −15°C

Compared with the a_4^H/a_6^H ratio for *o,o'*-bitolyl (2.32) and those for 2,2'-diethyl biphenyl (2.27) and 2,2'-diisopropyl biphenyl (2.37), one may speculate that the biphenyl ring in the present anion radicals has a conformation which more or less resembles that for *o,o'*-bitolyl, in which two phenyls are twisted by 30—45°. From this point of view, our present results may be accepted as additional evidence to support the previous proposal that the anion radicals have a more greater tendency than do the neutral molecules to hold the biphenyl ring in a coplanar conformation.[6] Furthermore, the present results establish a base for a direct discussion of alkyl proton splitting with relation to the restricted rotation of an alkyl group.

Alkyl-proton Splitting. It has been pointed out that the β-proton coupling constant can be expressed by the following equation:[7]

$$a_i^\beta = <Q>\rho_\pi \quad (1)$$

$$Q = B_0 + B\cos^2\theta \quad (2)$$

where θ is the angle between the carbon-hydrogen

bond and axis of the ring carbon $2p_z$ orbital; $<Q>$, the average quantity in Eq. (2), and ρ_π, the π electron spin density on the atom to which the alkyl group is bonded. The splitting parameter, B_0, defining a contribution from spin polarization is regarded as small in comparison with B, the parameter for hyperconjugation.[8] The methyl group in a radical has been thought to be freely rotating; thus, $<Q>$ becomes $B/2 \approx 25$ gauss, since $<\cos^2\theta> = 1/2$.

If the other alkyl groups were freely rotating, their β-proton splitting would have the same quantity for the methyl proton splitting. A large discrepancy has, however, been observed between the β-proton splitting of a methyl and those of the other alkyl groups; this has been discussed in terms of a preferred conformation of alkyl groups resulting from restricted rotation.[9]

For ease of comparison, the ratio, R, of the β-proton coupling constant to the methyl-proton coupling constant has been tabulated in Table 1.

The observed R value for 4,4'-diethyl biphenyl has been found to be close to those for such *para*-substituted benzene derivatives as 4-ethyl nitrobenzene ($R=0.74$) and 4-ethyl phenoxyl ($R=0.85$).[10]

According to this model, the theoretical R value for the ethyl group should be equal to either 0.5 or 1.50 if it is rigidly locked in the conformation illustrated in Fig. 6(a) and (b). The present R value (0.71) for 4,4'-diethyl biphenyl suggests

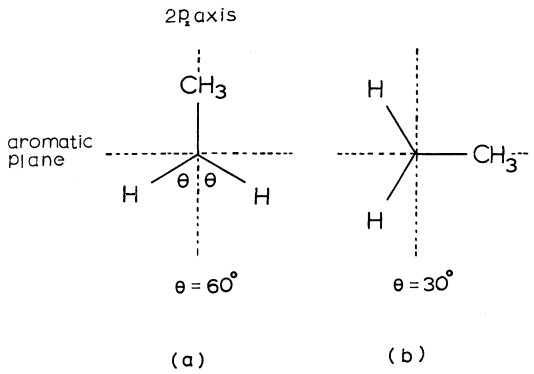

Fig. 6. Equilibrium confomation of a rotating ethyl group.

that alkyl groups more likely take the position of Fig. 6(a) rather than that of Fig. 6(b), but retain some residual rotation about their equilibrium positions.

From this assumption, the positive temperature dependence of a_4^β can be well understood as resulting from the thermal acceleration of a rotation. A similar temperature dependence has been reported for the hexaethyl benzene cation radical.[11] The β-proton coupling constant for either 4,4′-diisopropyl or 4,4′-dicyclohexyl biphenyl indicates that the β-proton would be oriented at $\theta=60°$, as calculated by Eqs. (1) and (2). These observed R values are nearly equal to those for the 4-isopropyl nitrobenzene anion ($R=0.56$)[9] and 4-isopropyl phenoxyl ($R=0.50$).[10]

In the case of 2,2′-diethyl biphenyl, the observed R value is much like those of ethyl cyclooctatetraene ($R=0.49$),[12] the 9-ethyl anthracene ($R=0.58$)[13] anion radical, and the hexaethyl benzene cation radical[11] ($R=0.46$), in which the rotation of the ethyl group has been considered to be strictly restrained, forcing it to take the preferential conformation illustrated in Fig. 6(a). The large diminution in the observed R value for 2,2′-diisopropyl biphenyl in comparison with the value for 4,4′-diisopropyl biphenyl indicates that the isopropyl β-proton is closer to the aromatic plane of biphenyl.

A molecular model is set up for 2,2′-diisopropyl biphenyl; it shows that the isopropyl free rotation is greatly restricted, when the two phenyls are twisted by about 45° taking account of the results for hindered methyl biphenyls.[5,6]

One may see that the isopropyl β-proton comes into contact with the 2′-*ortho* proton and nearly falls on the aromatic plane, as is illustrated in Fig. 7.

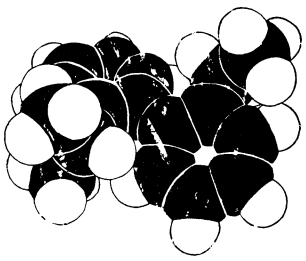

Fig. 7. A Stuart model of 2,2′-diisopropyl biphenyl anion radical.

The anomalous decrease in R values obtained for the present *ortho* derivatives can thus be attributed to the fact that the free rotation of the alkyl group is greatly restricted by the steric hindrance at the *ortho* position, where the alkyl groups are assumed to behave as torsional oscillators rather than rotators. The present results for the *ortho* alkyl proton-splitting also provide new experimental evidence to justify the previous proposal concerning hindered methyl biphenyls.

The authors wish to thank Professor Hideo Takaki for his encouragement through the course of this work. They are also indebted to Mrs. Ikuyo Higuchi for her assistance in the preparation of the samples.

Vapor Pressure of Carbon Monoxide in Condensed Phases*[1]

Takako SHINODA

Government Chemical Industrial Research Institute, Tokyo, Shibuya-ku, Tokyo

(Received April 11, 1969)

A theoretical vapor pressure equation of the form $\log P+(3/2)\log T=a+b/T$ for a diatomic molecule was applied to carbon monoxide in condensed phases. The two parameters in the equation determined from experimental vapor pressure data were used to obtain values of the static lattice energy E_0, the zero point energy E_Z, the geometric mean frequency ω_g and the mean frequency of molecular rotation ω_R in the respective phases by the information of lattice vibrations at low temperatures. From the mean values of molecular rotation frequencies, the hights of the potential barrier for hindered rotations were estimated to be 360, 230±10 and 110 cal/mol respectively.

Molecular rotations in the condensed phases of carbon monoxide have been theoretically and experimentally investigated by several authors.[1-5] However, there is little quantitative information about the state of hindered molecular rotation. Calorimetric studies showed that crystalline CO undergoes phase transition at 61.57°K and melts at 68.15°K.[6,7] The low- and high-temperature phases are denoted by α and β, respectively.

We have measured vapor pressures[7] of CO in two crystalline phases and liquid in the vicinity of the melting point. We will analyze these experimental vapor pressure data in terms of the quasi-harmonic theory of molecular vibrations, in which the normal modes of vibration are assumed to be harmonic, but have frequencies dependent upon the volumes of the solid and liquid. Values of the static lattice energy E_0 and the geometric mean frequency of the lattice vibrations ω_g in the respective phases of CO might be obtained from the analysis of vapor pressure. We will estimate the zero point energy E_Z and the mean frequency of molecular rotation ω_R or the height of the hindering potential V_0 by making use of the results of numerical calculation[8] of lattice vibrations for solid carbon monoxide at low temperatures.

Vapor Pressure Equation for Carbon Monoxide

The theory of the vapor pressure of a diatomic crystal was derived by Salter[9] along with monoatomic crystals, and applied to alkali halides by Leadbetter and Newsham.[10] According to their results, the vapor pressure of a diatomic crystal at high temperatures can be related to the temperature by an equation of the form

$$\ln P + (3/2)\ln T = a + b/T \qquad (1)$$

The measurement for the vapor pressure of CO was made in the region 55° to 72°K as previously reported,[7] and the results are listed in Table 1. An attempt has been made to find coefficients a and b which would make Eq. (1) fit these observed values in the α, β and liquid phases. The final equations are given in the following:

i) 55°K $< T <$ transition point

$$\log_{10}P + (3/2)\log_{10}T = -439.66/T + 11.27820, \qquad (2)$$

ii) transition point $< T <$ triple point

$$\log_{10}P + (3/2)\log_{10}T = -426.03/T + 11.06503, \qquad (3)$$

iii) $T >$ triplet point

$$\log_{10}P + (3/2)\log_{10}T = -384.90/T + 10.46265. \qquad (4)$$

At temperatures near melting point the contribution by the formation of lattice vacancies must be considered. Unfortunately no information on vacancy formation for CO crystal has been obtained

* These data were omitted on analysis.

from analysis of the thermal properties at high temperatures, because the transition point for CO crystal is considerably close to its triple point. We have, therefore, omitted the vapor pressure data at temperatures right below the melting point. The deviation of the calculated values(horizontal line), using Eqs. (2), (3) and (4), from the observed ones is shown by open circles in Fig. 1.

Quasi-harmonic Analysis

The constants a and b of Eq. (1) give values of the static lattice energy E_0 and the geometric mean frequency for the translational and rotational lattice modes ω_g (ω_{gT} and ω_{gR}) on the basis of the theory for ideal gas, liquid and crystal, as follows:

$$\left.\begin{aligned} a &= 3\ln\omega_{gT} + 2\ln\omega_{gR} \\ &\quad + \tfrac{1}{2}\ln[(m/(2\pi))^3(1/\boldsymbol{k})] + \ln[(2\boldsymbol{I})/\boldsymbol{k}], \\ b &= E_0/(\boldsymbol{N}\boldsymbol{k}). \end{aligned}\right\} \quad (5)$$

Here m is the molecular mass, $\boldsymbol{k}$ Boltzmann's constant, $\boldsymbol{I}$ its moment of inertia and $\boldsymbol{N}$ Avogadro's number. As the quantities E_0 and ω_g are temperature dependent, the values obtained by Eqs. (1) and (5) correspond to a certain mean temperature T_m in the respective phases. If we use the quasi-harmonic approximation, the effects of the change in volume of solid and liquid must be considered, but their variation over the respective temperature range of the analysis will be small. For the translational part of lattice vibrations we may expect the quasi-harmonic approximation to be adequate, because the most important parts in the translational motions of molecules are the spherical attractive dispersion and repulsive force between molecules.[8]

We first calculated the static lattice energy $E_0(V_0)$ referring to the 0°K volume V_0 in terms of the same molecular interaction potential[8] as used in the calculation of lattice vibrations for solid CO. The geometric mean frequency for the translational lattice modes $\omega_{gT}(0)$, and the translational and rotational zero point energies $E_{ZT}(V_0)$ and $E_{ZR}(V_0)$ referring to the 0°K volume have been estimated from frequency distributions in the harmonic approximation[8] as is shown in Fig. 2.

On the other hand, the heat of sublimation of CO crystal at 0°K, $\Delta H_0(V_0)$, was calculated from experimental data on thermodynamic properties.[6,7] The result is summarized in Table 2. The $E_0(V_0)$ can also be obtained from the relation

$$-E_0(V_T) = \Delta H_0(V_T) + E_{ZT}(V_T) + E_{ZR}(V_T), \quad (6)$$

where V_T is the volume at T°K. The values of $E_0(V_0)$ calculated are −2337 cal/mol and −2423 cal/mol. The discrepancy between them is probably due to the uncertainty on the rotational potential energy of molecular interaction. We have therefore used the mean value of these values, −2380 cal/mol, as the value of $E_0(V_0)$, and then the difference, 43 cal/mol, has been subtracted from the value of the zero point energy due to rotation of molecules

TABLE 2. CALCULATION OF HEAT OF SUBLIMATION AT 0°K (in units of cal/mol)

$\int_0^{bp} c_p(\text{solid})\mathrm{d}T$	1003
Heat of vaporization (at bp)	1444
$\int_0^{bp} C_p(\text{gas})\mathrm{d}T$	−568
Correction for gas imperfection	17
Heat of sublimation at 0°K, $\Delta H_0(V)$	1896

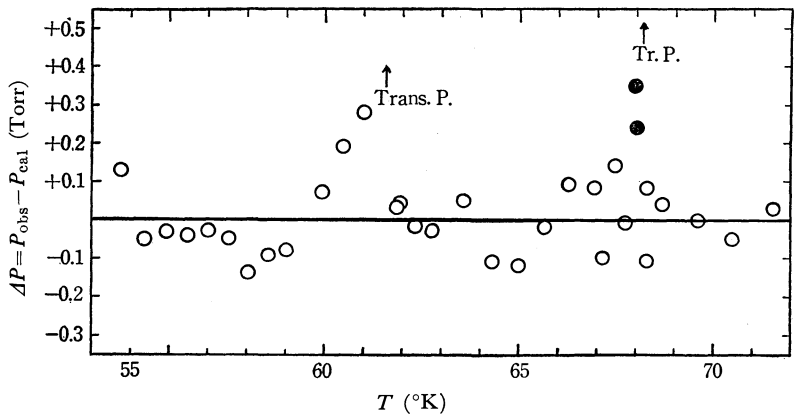

Fig. 1. Deviation of observed vapor pressure of CO from the calculated one by using Eqs. (2), (3) and (4). The black circles are data excluded on analysis.

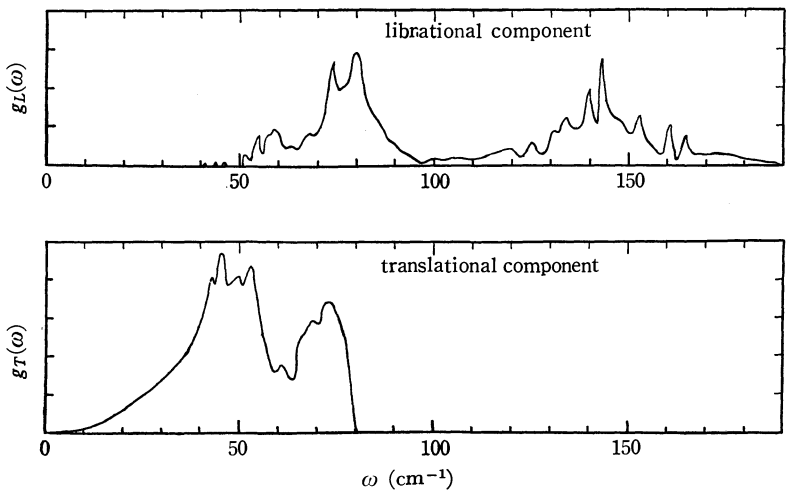

Fig. 2. The separated "translational" and "librational" distributions for CO crystal at 0°K, taken from Fig. 3 of Ref. 8.

$E_{ZR}(V_0)$ obtained by frequency distributions to make it consistent with other quantities.

To check the validity of the method adopted to estimate $E_0(V_0)$, $E_Z(V_0)$ and $\omega_g(0)$, the shape of the curve of the $\nu_D(n)$ function

$$\left.\begin{aligned} \nu_D(n) &= [(1/3)(n+3)\mu_n]^{1/n}, \\ \mu_n &= (1/5N)\int_0^\infty \omega^n g(\omega)\mathrm{d}\omega, \end{aligned}\right\} \tag{7}$$

where μ_n is the nth moment, has been established against n as is shown in Fig. 3 through use of the lattice frequency distributions in solid CO, since the $\nu_D(n)$ curve should be smooth, and $\nu_D(-3)$, $\nu_D(0)$ and $\nu_D(1)$ can be related to θ_0, ω_g and $E_Z(V_0)$ respectively, where θ_0 is the Debye characteristic temperature at 0°K and can be obtained from analyses of low temperature heat capacity data.[6,7]

The values of $E_0(V_0)$, $\omega_{gT}(V_0)$ and $E_Z(V_0)$ given above, have been used to analyze the vapor pressure for CO in the respective phases as fixed reference

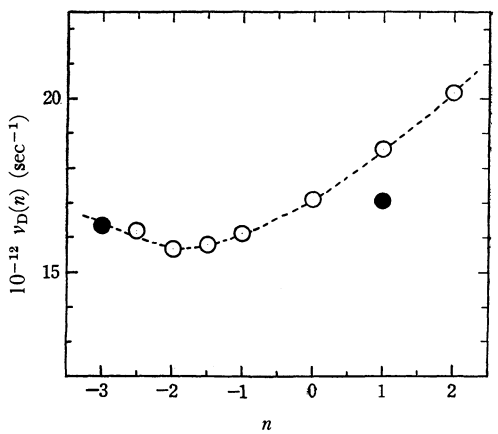

Fig. 3. The function $\nu_D(n)=[(1/3)(n+3)\mu_n]^{1/n}$ for CO. The open circles have been obtained from calculations and the black circles by analysis of the thermodynamic properties.

values.

The α-form; (54.8—61.0°K, T_m=57.9°K). The value of static lattice energy $E_0(V_{T_m})$ referring to the volume V_{T_m} at T_m in harmonic librational case has been estimated in the same way as for $E_0(V_0)$. In the quasi-harmonic approximation we may assume that the volume dependence of the static lattice energy is described by that of the zero point energy (*i.e.*, $\partial E_0/\partial V \simeq \partial E_Z/\partial V$). We may therefore estimate the zero point energy due to harmonic translation and libration of molecules corresponding to the mean temperature T_m, $E_Z(V_{T_m})(=E_{ZT}(V_{T_m})+E_{ZR}(V_{T_m}))$, by the approximate formula

$$E_0(V_{T_m})/E_0(V_0) \simeq E_Z(V_{T_m})/E_Z(V_0). \quad (8)$$

We may also obtain $\Delta H_0(V_{T_m})$ as the difference between $|E_0(V_{T_m})|$ and $E_Z(V_{T_m})$ values from Eq. (6).

The deviation of the value of static lattice energy $E_0(V_{T_m})$ in harmonic libration from that derived directly by the constant a of Eq. (2), might be interpreted as CO molecules being in the state of not harmonic but anharmonic libration (or hindered rotation) at the mean temperature T_m. Thus, the difference between the two $E_0(V_{T_m})$ values has been treated as the decrease in the rotational zero point energy $E_{ZR}(V_{T_m})$. The general treatment for the anharmonic contribution to the lattice vibration has not been given. Barron[11] suggested that as a first approximation the anharmonic effects may be represented by a frequency shift in the quasi-harmonic expression. We have calculated $\omega_R(T_m)$, which can be replaced by the sum of the harmonic librational frequency plus the anharmonic frequency shift, using the resultant value of $E_{ZR}(V_{T_m})$ on the basis of the Einstein model of lattice vibration.

The geometric mean frequency for the rotational lattice modes $\omega_{gR}(T_m)$, has been obtained from the coefficient b in Eq. (2) using Eq. (5). We have assumed that the translational modes of lattice vibrations are harmonic but with frequencies dependent upon the volume, and the effect of the change in volume is expressed by that of the zero point energy due to translation of molecules. If we assume that

$$\omega(0)/\omega_g(0) \simeq \omega_R(T_m)/\omega_{gR}(T_m), \quad (9)$$

where $\omega(T)=(1/5N)\int_0^\infty \omega g(\omega)d\omega$, then the resultant value of $\omega_{gR}(T_m)$ can give the value of $\omega_R(T_m)$. This value, 29.3 cm^{-1}, is in excellent agreement with the value of $\omega_R(T_m)$ obtained from $E_{ZR}(V_{T_m})$, 29.4 cm^{-1}.

The β-form; (61.9—67.7°K, T_m=65.0°K). If the rotation of CO molecules in the β-phase is free, then the zero point energy due to rotation $E_{ZR}(V_{T_m})$ is zero and the translational lattice vibrations still possess the zero point energy $E_{ZT}(V_{T_m})$. The structure of CO crystal was studied by Vegard.[12] The molecular centers are located in face-centered cubic lattice sites in the α-phase, and in hexagonal close packed sites in the β-phase. The face-centered cubic and the hexagonal close-packed structures may be regarded as equivalent arrangement, as illustrated in Fig. 4. The β-phase crystal may therefore be taken as the face-centered cubic lattice which has the same density as the actual crystal at T_m. Since the major forces of interaction potential for the translational motion of molecules are the spherical dispersion and repulsive forces.[8] We may assume that the change in $E_{ZT}(V_{T_m})$ due to the α–β-phase transition is the only effect corresponding to the volume change. In the case of free rotation the static lattice energy $E_0(V_{T_m})$ can be calculated using $E_0(V_0)$ in free rotation at 0°K as the reference value, where $|E_0(V_0)|$ is equal to the sum of $\Delta H_0(V_0)$ plus $E_{ZT}(V_0)$. The difference between the value of static energy $E_0(V_{T_m})$ obtained from the slope a of vapor pressure Eq. (3) and that in the case of free rotation is equivalent to the zero point energy $E_{ZR}(V_{T_m})$ due to rotation of molecules in the β-phase. By the treatment described in analysis for the α-form, this value of $E_{ZR}(V_{T_m})$ gives the rotational frequency $\omega_R(T_m)$ of 22.0 cm^{-1}. Estimate of the value of $\omega_R(T_m)$ using the geometric mean frequency for the rotationals modes $\omega_{gR}(T_m)$ in the β-phase, which has been derived from the intercept b of Eq. (3), gives the resultant value of 23.7 cm^{-1}.

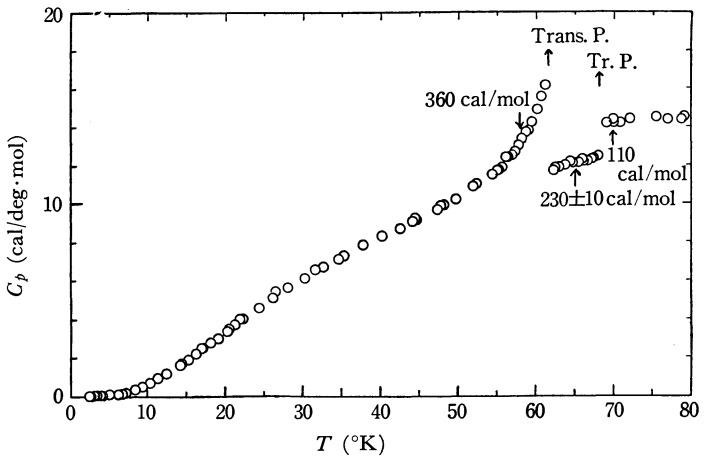

Fig. 5. The hindering potential barriers in the condensed phases, together with the experimental heat capacity curve of CO.

The Liquid in the Vicinity of the Melting Point; (T_m=69.9°K). We have adopted the cluster model for the liquid CO in the vicinity of its melting point. It may be assumed that the liquid consists of clusters containing 13 molecules,*2 and that the spatial arrangement of molecular centers in each cluster is the same as in a hypothetical solid, which has the density value at T_m determined by the extrapolation from the observed values. This is an approximation, which may be justified by the fact that only a continuous change in infrared spectral characteristic of CO occurs during the transition from liquid to solid.[1] In such liquids at least four different distances between the nearest neighboring molecules R_S, R_L, (R_L+R_{L-S}) and (R_L+2R_{L-S}) may be taken into consideration, where R_S is the nearest neighbor distance in a lattice having the density of a hypothetical solid, R_L in a lattice having the observed density of liquid CO at T_m, and R_{L-S} is the difference between R_S and R_L. We have assumed that all molecules in liquid are arranged with the statistical weights of these nearest neighbor distances of 6/13, 4/13, 2/13 and 1/13, respectively. The values of $E_0(V_{Tm})$, $E_{ZT}(V_{Tm})$ and $\Delta H_0(V_{Tm})$ in both harmonic libration and free rotation have been evaluated by the same treatment as was used in the solid phases. The value of $E_{ZT}(V_{Tm})$ evaluated as the difference between

*2 This is equal to the number of nearest neighbor molecules in addition to the one at center in face-centered cubic lattice.

$E_0(V_{Tm})$ obtained from the constant a in Eq. (4) and that in free rotation, leads to $\omega_R(T_m)=$ 14.7 cm^{-1}. This value is compared with the value of 13.9 cm^{-1} for $\omega_R(T_m)$ obtained from the constant b in Eq. (4).

Results and Analysis

Results of calculations are summarized in Table 3.

Discussion

Analysis of experimental vapor pressure data for CO has given us useful information about molecular motions in condensed phases. The values of $\omega_R(T_m)$ obtained in the respective phases may give the corresponding potential barriers, V_0, in which molecules are understood as the double-minimum two-dimensional rotators in a potential field of the type

$$V = (1/2)V_0(1 - \cos 2\theta). \tag{10}$$

The Schrödinger equation for the rotational motion is

$$-(\hbar^2/2I)\left(\frac{1}{\sin\theta}\frac{\partial}{\partial\theta}\sin\theta\frac{\partial\psi}{\partial\theta}+\frac{1}{\sin^2\theta}\frac{\partial^2\psi}{\partial\phi^2}\right) + (1/2)V_0(1 - \cos 2\theta)\psi = E\psi. \tag{11}$$

Curl *et al.* have recently solved this problem and given a table of its energy levels.[13] If the above $\omega_R(T_m)$ corresponds to the separation of the two lowest levels, the values of the hindering potential, V_0, can be calculated by the help of Pitzer's table. The results are given in Fig. 5, together with the experimental heat capacity curve of CO.[6,7] There are no values available in literature to compare with the $\omega_R(T_m)$ or V_0 values derived here except for the V_0 in the region 10—30°K and in liquid, which were estimated to be 1.7 kcal/mol and 120 cal/mol by Curl *et al.*[13] and Ewing[1] from the low temperature heat capacity data and the band intensity of infrared spectra for liquid. The present values of V_0 are not unreasonable for the respective phases.

Although we have analyzed in terms of quasi-harmonic lattice theory, the static lattice energy, the geometric mean frequency, the zero point energy and the molecular rotational frequency (or hindering potential barrier) may serve to investigate molecular rotational state in the condensed phases for CO when the treatment of anharmonic effects is not clear. However, it must be noted that the derived values all correspond to some mean values over whole molecules in crystal and liquid CO at some mean temperature T_m over the temperature range of analysis. Much more exact treatment will be made by analysis of heat capacity data shown in Fig. 5 on the basis of the statistical theory taking into account cooperative phenomena in the condensed phases, in which adjacent molecules appear to rotate together like meshed gears.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 2820—2827 (1969)

Electrophotographic Properties of Titanium-Dioxide Resin Dispersion Layers

Takeaki IIDA and Hiroshi NOZAKI

The Institute of Industrial Science, The University of Tokyo, Roppongi, Minato-ku, Tokyo

(Received April 15, 1969)

The electrophotographic properties of titanium dioxide-polymer dispersion layers were studied. The titanium dioxide powder of the rutile type and three well-known polymers, polyvinyl acetate, polyvinyl chloride, and polystyrene, were used. The measurements were done on the corona-charging properties, *e. g.*, the resistivity and the capacitance of the layer, the rising gradient of the surface potential, and the fatigue effect of pre-illumination. The results make it clear that the analysis of an equivalent circuit can be applied to the interpretation of the rising gradient of the surface potential and to that of the dark decay to some extent. Moreover, it is found that the logarithm of the potential of the dark decay decreases proportionally to the cube root of the time at the initial step, while, at the next following step, it decays proportionally to the square root of the time. The mechanism of the dark decay of the surface potential is also discussed.

Titanium dioxide is famous as a white pigment, and it is one of the compounds of the transition elements. Therefore, this material has many interesting properties; for example, titanium dioxide ceramics have a high dielectric constant (114), and titanium dioxide has a photoconductivity at the wavelength of around 410 mμ.[1] At first we used this material as a photoconductor. Then we

have developed an Electrofax method,[2] in which titanium dioxide was used as a photoconductor instead of zinc oxide; we have obtained many good results with this method. Moreover, the image quality could thus be improved to the same quality as that of the zinc-oxide paper.

On the other hand, in the Electrostatic Recording method, a quite new application has recently been discovered;[3] that is, the addition of titanium dioxide to the recording paper improves the image quality of the electrostatic recording process, in which a pin tube is used as the recording head.[4] It is considered that the electrical capacity of the recording layer is increased by the addition of titanium dioxide; the real impedance of the layer against a pulse signal is then decreased. It results that an electron beam emitted from the pin head can easily pass through the recording paper, and the tailing phenomenon of a signal,[5] which is caused by the residual potential at the pin head, decreases greatly. Then the signal-to-noise ratio of the image is increased and the image quality is improved. The electrostatic recording methods have been applied in many fields, *e. g.*, in making of the facsimiles of newspapers, in the recording method of an electronic computer,[6] in the recording of TV images,[7] and in the use of an electrostatic printer.[8]

In view of these points, it is very important to study the electrophotographic properties of the dispersion layer of titanium dioxide. The electrophotographic properties of the zinc oxide-resin dispersion layer were studied by Inoue[9] and by Tashiro *et al.*,[10] and the mechanism of the corona charging was discussed by Amick[11] to some extent. Therefore, we investigated the electrophotographic properties of the titanium dioxide-resin dispersion layer on various titanium-dioxide contents. We believe that these studies will contribute as fundamental data to the industrial applications of the Electrostatic Recording technique.

Experimental

Sample. *Titanium Dioxide.* Titanium dioxide powder of the rutile type was produced by the hydrolysis of titanium tetrachloride.[12] The purity of this powder corresponded to spectro grade. The major impurities detected by chemical analysis were as follows: Fe, less than 0.005%, As, less than 0.0005%, and Pb, less than 0.002%. The average crystal size of this powder was from 0.2 to 0.7μ. The specific surface area of this powder, as determined by the B.E.T. method, was 1.57 m^2/g.

Organic Polymers. These were used as a powder's binder. In order to make an experiment on a definite

system, pure polymers were used. The properties of these polymers are shown in Table 1.

Solvents. Solvents purified by repeated distillations were used; ethyl acetate was used for polyvinyl acetate; cyclohexanone, for polyvinyl chloride, and benzene, for polystyrene.

Procedures for Making the Dispersion Layer. The powder of titanium dioxide and the polymer solution were mixed in a blender for ten hours. The suspension of these materials was coated uniformly on a domestic aluminium foil (7 cm × 10 cm) by means of a film applicator of the Baker type. These specimens were dried at 110°C for two hours, and then they were preserved in a dark chamber for 48 hr or more; the relative humidity was controlled at about 20%, and the temperature was between 15 and 25°C. The thickness of the coated layer was between 15 and 20 microns. The weight of the titanium dioxide against the weight of the polymer changed between 0% and 90%.

The Measurement of the Electrical Resistivity and the Electrostatic Capacity of the Disperison Layer. At first silver metal was evaporated with a vacuum evaporator on the layer surface. This specimen was fixed in a dark chamber in which the relative humidity was controlled with a silica gel powder. An electrode of stainless steel was put on the sample surface. The weight of the electrode was 10.0 g/cm^2. The electrical resistivity was directly measured with a Keithley electrometer of the 610-B type. The electrostatic capacity was measured with a Wheatstone's bridge, applying an alternative current of 1 kc.

The Measurement of the Corona-charging Potential. The measurement was done by the turn-table method. A block diagram of the experimental equipment is shown in Fig. 1.

All the measurements were done at room temperature in air with a relative humidity of about 20%. The table was rotated at a speed of 78 rpm; the surface potential was measured with a surface potentialmeter of the chopper type, and the corona discharge was done with three steel wands, 0.1 mm in diameter, which were fixed 5 mm above the turn-table. The conditions of the corona discharge were as follows: the discharge voltages were −6.0 kV and 6.5 kV at the negative and at the positive corona discharge respectively; the current of the corona discharge was maintained at a constant current of 4.2×10^{-5} A and the corona discharge was done for one minute. After the dark decay had been observed for one minute, the tungsten light of 200 lux at the sample surface was lighted until the surface potential disappeared. In the case of the measurement of the light-fatigue effect, the sample was irradiated with a tungsten light of 1200 lux for two minutes, and then, the above measurements were made. The potential change was recorded with an electrical recorder, as is shown in Fig. 1. One of the examples of the potential change against the time is shown in Fig. 2. The full line corresponds to the surface potential on fresh layers, and the dotted line, to the surface potential measured after irradiation with a light of 1200 lux for two minutes as a pre-illumination.

The notations of the electrophotographic properties are shown in Table 2.

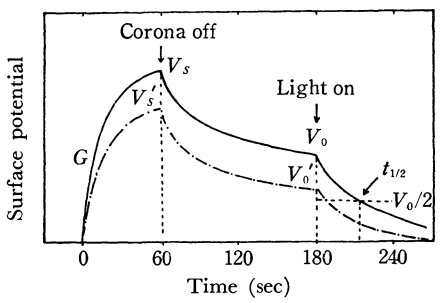

Fig. 2. The time dependence of the surface potential of the corona charging.

TABLE 2. SYMBOLS

Notation	Unit	Meaning
V_s	volt	saturation surface potential
E_s	volt/μ	saturation potential per one micron thickness
V_0	volt	initial surface potential
G	volt/sec	rising gradient of surface potential
$t_{1/2}$	sec	half-time of light decay
V_0/V_s	—	quantity of dark decay
V'_s/V_s	—	quantity of fatigue effect by pre-illumination

Results

The specific resistivity of the dispersion layer decreases with an increase in the titanium-dioxide contents, as is shown in Fig. 3. The resistivity of these dispersion layers is situated between 10^{13} and 10^{15} Ω cm. The polystyrene dispersion layer has the highest resistivity, while the polyvinyl acetate layer has the lowest resistivity. Each curve has a minimum resistivity at around 50% of the titanium-dioxide contents.

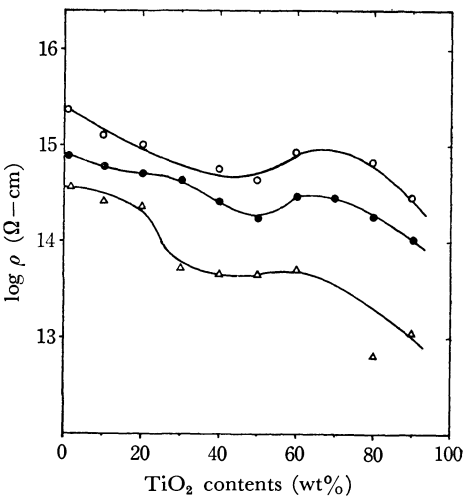

Fig. 3. Relations between the specific resistivity of the dispersion layer and the titanium-dioxide contents.
○ P. S. ● P. V. C. △ P. V. Ac.

The electrostatic capacities of the dispersion layer are plotted against the contents of titanium dioxide. The capacity was calculated with the normalization of a unit area of 1 cm^2 and of a unit thickness of one micron. As can be seen in Fig. 4, the capacity of the plyvinyl acetate layer is the highest, while that of the polyvinyl chloride layer is slightly lower than that of the polyvinyl acetate layer. The capacity of the polystyrene layer has the lowest value of the three. The dielectric constants of the rutile ceramics is 114, but that of these dispersion layers of the titanium-dioxide contents of between 80% and 90% takes a value as small as between 30 and 40. The dielectric constants gradually decreases with a decrease in the titanium-dioxide contents.

The corona charging was done with both the negative and the positive corona discharging, but in the case of the titanium-dioxide dispersion layer, the potential of the positive corona charging can hardly be observed. Therefore, all the following results are the properties of the negative corona charging.

The rising gradients of the surface potential in the negative corona charging decrease with an increase in the titanium-dioxide contents. The rising gradients of the surface potential are plotted against the titanium-dioxide contents in Fig. 5. The order of the rising gradients of these dispersion layers is as follows: the polystyrene dispersion layer>the polyvinyl chloride dispersion layer>the polyvinyl acetate dispersion layer.

The relations between the saturation potential of the negative corona charging per micron of thickness and the titanium-dioxide contents are shown in Fig. 6. The saturation potential decreases with an increase in the titanium-dioxide contents. The polyvinyl chloride layer takes the value of the highest potential; the next is the polystyrene layer, and the polyvinyl acetate layer takes the smallest potential.

The quantities of the dark decay, measured one minute after the turn-off of the corona discharge, are shown in Fig. 7. The dark decay increases with an increase in the titanium-dioxide contents. The polystyrene layer has the slowest decay, and the polyvinyl acetate has the quickest.

The half-time of the light decay decreases with an increase in the titanium-dioxide contents, as is shown in Fig. 8. At the lower contents of titanium dioxide of between 0% and 30%, the order of the speed of the light decay is as follows: the polystyrene dispersion layer > the polyvinyl acetate dispersion layer > the polyvinyl chloride dispersion layer. At high contents of titanium dioxide (between 40% and 90%), no clear differences in the light decay are detected among these dispersion layers.

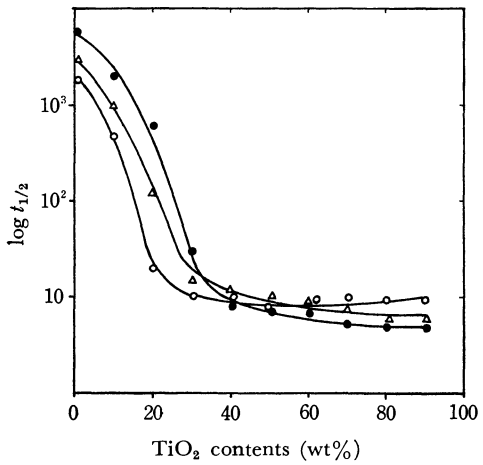

Fig. 8. The logarithm of the half-time of the light decay plotted against the titanium-dioxide contents.
○ P. S. △ P. V. Ac. ● P. V. C.

The quantities of the fatigue effect produced by pre-illumination are shown in Fig. 9. As can be seen in the figure, the fatigue effects of the polyvinyl acetate layer and the polyvinyl chloride layer increase with an increase in the titanium-dioxide contents, reaching a maximum at contents of around 80%. However, the fatigue effect of the polystyrene layer is somewhat different from the former two binders; it has its maximum at contents of around 40%.

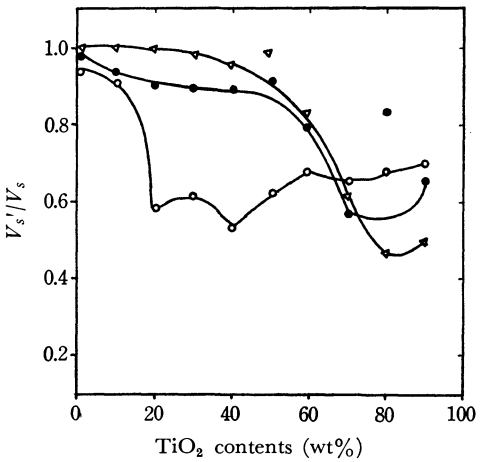

Fig. 9. The quantity of the fatigue effect by a pre-illumination.
△ P. V. Ac. ● P. V. C. ○ P. S.

The relations between the logarithm of the surface potential in the dark decay and the square root of the time, which were measured in the case of 0% contents of titanium dioxide, are shown in Fig. 10. In the region from 1 min to 9 min, the surface potential does not decay proportionally to the square root of the time, but in the region from 9 min to 80 min the surface potential does decay so. The decay gradient of $-\mathrm{d}\log V/\mathrm{d}t^{1/2}$ are evaluated as follows: the polyvinyl chloride layer is 0.216, the polystyrene layer is 0.316, and the polyvinyl acetate layer is 0.533.

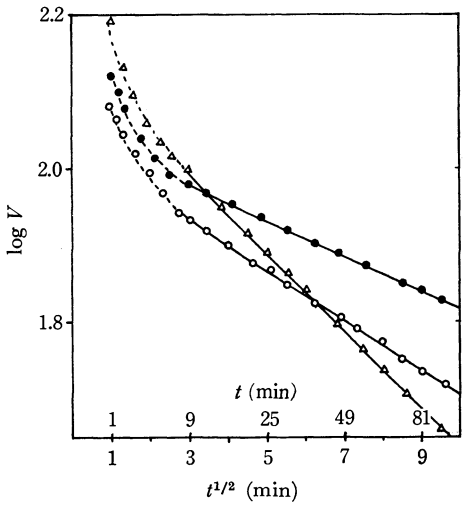

Fig. 10. The relations between the logarithm of the dark decay potential on the polymer layer of 0% titanium-dioxide contents and the square root of the time.
Polymer 100% ● P. V. C.
○ P. S.
△ P. V. Ac.

The same measurements were made on the dispersion layers of 30% contents of titanium dioxide. the results are shown in Fig. 11. In this case the proportionality between the logarithm of the surface potential in the dark decay and the square root of the time starts about six minutes after the turn-off of the corona discharge.

As has been mentioned above in discussing the results of Fig. 10, the logarithm of the surface potential does not decay proportionally to the square root of the time in the region from 1 min to 9 min. Therefore, we tried to plot the logarithm of the potential decay of this region against the cube root of the time. The results are shown in Fig. 12. As can be seen in the figure, the logarithm of the surface potential does indeed decay proportionally to the cube root of the time.

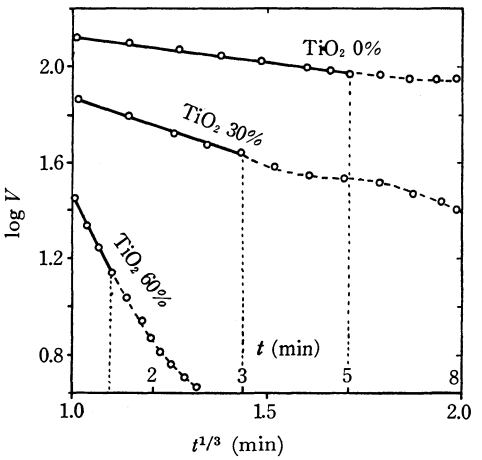

Fig. 13. The relations between the logarithm of the dark decay potential at the initial step on the polystyrene dispersion layer of the various titanium dioxide contents and the cube root of the time.

The period for which the proportionality of the relation between log V and $t^{1/3}$ is retained depends on the contents of titanium dioxide. As an example, the relations between the log V and $t^{1/3}$ of the polystyrene layer at various titanium-dioxide contents are shown in Fig. 13. The polystyrene layer of 0% contents of titanium dioxide retains the proportionality for 5.0 min, that of 30% contents of titanium dioxide does so for 3.0 min, and that of 60% contents of titanium dioxide does so for 1.5 min. Therefore, it is found that the period of the proportionality decreases with an increase in the titanium-dioxide contents.

Discussion

The charging properties were studied by the use of three different polymers, and it was found that the charging properties depend considerably on the polymer used as a binder. As is shown in Table 1, the mean degrees of polymerization and the molecular weights of these polymers are not very different, but the dielectric constants and the dipole moments of these polymers are quite different. A polymer which has a high dipole moment generally has a high dielectric constant. It is quite reasonable that a layer's capacity, as measured by direct measurements, increases with an increase in the dielectric constant of the polymer, as is shown in Fig. 4. Moreover, the resistivity of the layers is

shown in Fig. 3. We can, therefore, see the resistivity and the capacity of the layer. It is reasonable to explain these charging properties qualitatively with the use of an equivalent circuit, which is shown in Fig. 14.

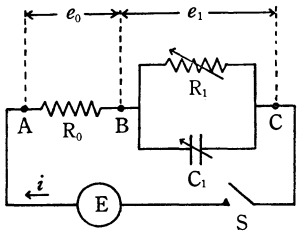

Fig. 14. The equivalent circuit of the dispersion layer in the corona charging process.
e_0: potential difference between A and B
e_1: potential difference between B and C
R_0: resistance of the circuit
R_1: variable resistance which corresponds to the resistance of the layer
C_1: variable capacity which corresponds to the capacity of the layer
E: electric source
S: switch

When the switch, S, is turned on, and a voltage, E, is applied to the circuit, the change in the potential between B and C is derived as the following equation:

$$e_1 = \frac{ER_1}{R_0 + R_1}\left[1 - \exp\left\{-\frac{1}{C_1}\left(\frac{1}{R_0} + \frac{1}{R_1}\right)t\right\}\right] \quad (1)$$

When e_1 is differentiated by the time, the rising gradient of the potential between B and C is obtained:

$$G = \frac{de_1}{dt} = \frac{ER_1^2C_1R_0}{(R_0 + R_1)^2} \exp\left\{-\frac{1}{C_1}\left(\frac{1}{R_0} + \frac{1}{R_1}\right)t\right\} \quad (2)$$

From Eq. (2) it can be deduced that G decreases with an increase in C_1, if R_1 is kept as a constant value. It can also be deduced from Eq. (2) that G decreases with an increase in R_1 if C_1 is kept as a constant value. As is shown in Fig. 5, the order of G is as follows: the polystyrene dispersion layer> the polyvinyl chloride dispersion layer>the polyvinyl acetate dispersion layer. This means that the rising gradient of the corona charging decreases with an increase in the capacity of the layer. Therefore, it can be clarified that the rising gradient of the corona charging depends greatly on the capacitance of the layer.

In the case of the discharging process, when the switch is turned off the potential between B and C decreases, because the discharging current flows through the resistance of R_1. Therefore, the speed of the dark decay of the surface potential depends greatly on the resistance of R_1. Figure 7 shows that the speed of the dark decay of the dispersion layer which has the low resistance is high, while that of the dispersion layer which has the high resistance is low; therefore, it is evident that the dark decay depends greatly on the resistance of the layer.

The saturation potential of the layer can not be explained directly from Eq. (1), for the measurements were done by the turn-table method and so the corona discharge was applied on the layer intermittently. Another reason is that the surface potential depends on many complex factors, *i. e.*, the charge density of the corona ions, which are chemisorbed on the layer surface,[16] the injection of electrons from corona ions into the layer, and the orientation of the dipole moment of the binder. Therefore, it is not possible to explain this property from this equivalent circuit model.

The differences in the light decay and in the fatigue effect upon pre-illumination among these polymers' layers can not easily be explained from this model. The only thing we can describe is the experimental results. However, we assume that the photo-phenomena on the surface of titanium dioxide[16] can be explained to some extent by analogy to the case of the zinc-oxide dispersion layer.[17]

The results show that the surface potential of the dark decay decreases proportionally to the square root of the time in the region from 9 min to 80 min. It is impossible to derive the equation in which the surface potential of the dark decay depends on the squre root of the time with the use of the equivalent circuit shown in Fig. 14. Moreover, it is quite significant that this phenomenon appears not only in the dispersion layer, but also in the polymer layer which does not contain titanium dioxide. Inoue proposed an experimental equation in which the decay decreases proportionally to the square root of the time in the zinc-oxide dispersion layer.[9] However, the theoretical meaning of this equation has not yet been clarified. We are now studying the theoretical reason for this time dependency from various viewpoints, but we assume that the diffusion of the corona ions through the layer plays an important role in this phenomenon.

Moreover, it is found in the titanium-dioxide dispersion layer that the logarithm of the surface potential in the dark decay decreases proportionally to the cube root of the time, that it is retained for 4—6 min, and that the period of the proportionality of $\log V$ to $t^{1/3}$ depends on the titanium-dioxide content. These phenomena have not been found in the zinc-oxide dispersion layer. It is first time to find such phenomena in the dark decay as electrophotographic properties.

16) T. Iida and H. Nozaki, This Bulletin, **42**, 243 (1969).
17) E. Inoue and T. Yamaguchi, *Electrophotography* **5**, 65 (1964).

These phenomena can not be analyzed easily by the simple model, so we can only describe the experimental results. However, it can be ascribed that there are two different steps in the process of the dark decay of the titanium-dioxide dispersion layer.

The gradient of the dark decay is quite small in the case of the polyvinyl chloride dispersion layer, as is shown in Fig. 10. Therefore, it can be said that polyvinyl chloride is the best material for the electrostatic recording.

At any rate, the corona-charging phenomena of the dispersion layer are quite complicated. We think that the major factors which govern the corona-charging properties are given as follows: (1) the degree of the dispersion between titanium dioxide powder and the polymer, (2) the covering power of the polymer over the surface of titanium dioxide, (3) the chemisorption of corona ions on the layer, (4) the injection of electrons from corona ions into the layer, and (5) the orientation of the dipole moment of the polymer. Therefore, in the future we should study these factors in detail in order to clarify the mechanism of the corona-charging phenomena of the dispersion layer.

Radical Conversions in γ-Irradiated 3-Methylpentane-Isobutene Systems

Kozo Tsuji*1 and Seizo Okamura

Department of Polymer Chemistry, Faculty of Engineering, Kyoto University, Kyoto

(Received May 1, 1969)

Radical conversions in γ-irradiated 3-methylpentane-isobutene systems were observed by means of the electron spin resonance method after keeping the sample at -196°C for a few days, or by subjecting it to ultraviolet irradiation. One of the changes was caused by hydrogen atom abstraction from neighboring molecules by original free radicals. The other change was attributed to dissociation of the free radicals from 3-methylpentane by ultraviolet irradiation.

There have been several studies on photoinduced radical conversions. Among them the photoinduced dissociations of alcohol radicals are well known.[1,2] Recently several authors reported photoinduced conversions of hydrocarbon radicals; photoinduced conversions of allyl radicals to alkyl radicals in γ-irradiated polyethylene by Ohnishi *et al.*,[3] isomerization of *t*-butyl radicals to isobutyl radicals in γ-irradiated isobutyl bromide,[4] a similar isomerization in γ-irradiated polypropylene by Iwasaki *et al.*,[5] and the photoinduced conversion of allylic radicals to other allylic radicals in γ-irradiated 2-methylpentene-1 (2MP-1) by Smith and Pieroni.[6] Smith *et al.*[7] also observed radical conversions in a γ-irradiated 3-methylpentane (3MP)-2MP-1 (15 mol%) mixture by storing the sample for 24 hr at -196°C and ultraviolet irradiation. After receiving a 1 Mrad dose from Co-60 γ-rays, the 3MP-2MP-1 mixture became blue and the ESR spectrum consisted of a narrow intense singlet superimposed on the central line of the spectrum of the 3-methylpentyl radical $CH_3CH_2\dot{C}(CH_3)CH_2$-$CH_3$. The ESR singlet and blue color were easily eliminated by visible light illumination. After keeping the sample for 24 hr at -196°C, the spectrum converted to that of an allylic radical. Upon subsequent UV photolysis, the ESR spectrum changed to that which has been attributed to the 3-methylpentyl radical.[8] It was concluded[7] that ultraviolet light induces the allylic radical from 2MP-1 in 3MP to abstract a hydrogen atom from a neighboring 3MP molecule.

We have reported[9] that $\dot{C}(CH_3)_2$-CH_2-R radicals with two different conformations and relatively

stable trapped electrons were observed in γ-irradiated 3MP-isobutene (IB) systems. The latter was easily bleached out by visible light illumination, and only neutral free radicals remained. In the present investigation we report that these neutral free radicals convert to other ones by keeping the sample at -196°C for a few days or by ultraviolet irradiation as in the 3MP-2MP-1 mixtures.[7]

Experimental

Commercial 3-methylpentane was distilled over sodium after passing through activated alumina. It was dried four times with Na-K alloy. Isobutene was dried with Na-K alloy after passing through potassium hydroxide.

Samples were made in ESR sample tubes by vacuum distillation and sealed off after evacuating to about 10^{-4} mmHg. Irradiation was carried out by γ rays from Co-60 (6×10^5 R/hr). Ultraviolet photolysis was carried out at -196°C with a high pressure mercury lamp (Toshiba Electric Company, Ltd., H-400-p, 400W).

A conventional X band ESR spectrometer was used with 100 Kc field modulation. Microwave power was less than 1 mW. γ-Irradiations and ESR measurements were carried out at -196°C in the dark.

Results

A mixture of 3MP-IB (2.4 mol%) forms a transparent colorless glass at -196°C. When it was irradiated to a dose of 2×10^5 R in the dark at -196°C, it turned blue and gave the ESR spectrum shown in Fig. 1a, which consists of an eight-line spectrum with a hyperfine separation of 23 gauss and a sharp singlet spectrum at the center. The former is attributed probably to the free radical $R\text{-}CH_2\text{-}\dot{C}(CH_3)_2$ with a certain conformation.[9] The sharp singlet spectrum and blue color were easily bleached out by visible light illumination, and they were attributed to trapped electrons.[9] The intensities of both the singlet and eight-line spectra are proportional to dose up to 3×10^5R. After photolysis with visible light, only the eight-line spectrum (Fig. 1a dotted line) remained, and after 7 days, this converted at -196°C to the other spectrum shown in Fig. 1b, where the five-line spectrum with a coupling constant of about 13 gauss due to allylic radicals (arrow marks) and another spectrum (maybe 6 lines) were observed. This spectrum further changed by subsequent ultraviolet irradiation into the spectrum shown in Fig. 1c without any decrease of radical concentration; both six- and four(arrow marks)-line spectra were observed, and the latter decayed out at -168°C as shown in Fig. 1d. The coupling constant of the six-line spectrum is about 22 gauss, and the

d) same sample as c) measured at -168°C.

spectrum is the same as that produced by γ-irradiation of 3MP. Thus this spectrum is attributed to the free radicals produced from 3MP($CH_3\text{–}CH_2\text{–}\dot{C}(R)\text{–}CH_2\text{–}CH_3$, R=H or CH_3). The four-line spectrum is attributed to methyl radicals because of its coupling constant (23 gauss) and intensity ratio (1 : 3 : 3 : 1). Methyl radical production, however, was slow and methyl radical concentration seemed to saturate at a certain ratio to that of 3MP radicals.

A mixture of 3MP-IB (61 mol%) made an apparent transparent glass at -196°C. After γ-irradiation, only a fifteen-line spectrum was obtained, and neither a sharp singlet nor blue color were observed. The fifteen-line spectrum shown in Fig. 2a has been attributed to the free radicals $\cdot C(CH_3)_2\text{–}CH_2\text{–}R$ formed with two conformations.[9] This spectrum did not change by keeping the sample at -196°C for a few days, but converted

9) K. Tsuji, H. Yoshida, K. Hayashi and S. Okamura, *J. Polymer Sci.*, **B5**, 313 (1967).

to the five-line spectrum due to allylic radicals by subsequent ultraviolet irradiation as shown in Fig. 2b. The intensity of the allylic radicals decreased with the increase of the time of irradiation,

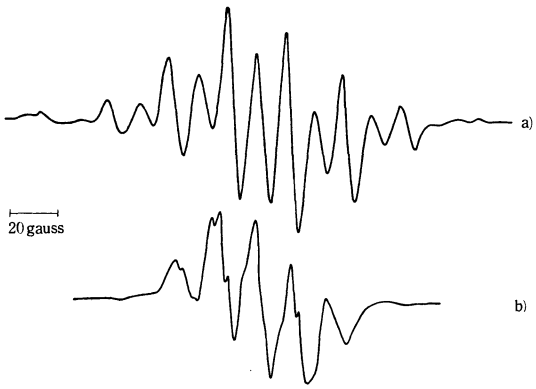

Fig. 2. ESR spectra of 3MP-IB (61 mol%) irradiated to a dose of 2×10^5R at -196°C.

but no methyl radicals were observed.

For an intermediate case 3MP-IB (12 mol%), an eight-line spectrum and a sharp singlet were initially observed after γ-irradiation as shown in Fig. 3a. The sharp singlet at the center was removed by visible-light illumination (Fig. 3a dotted line), but the eight-line spectrum remained unchanged. After keeping the sample at -196°C for a few days, however, the eight-line spectrum changed into the superposition of 15 lines observed for 3MP-IB (61 mol%) and five lines (arrow marks) due to allylic radicals as shown in Fig. 3b. By subsequent ultraviolet irradiation, the spectrum converted to the same one as observed for 3MP-IB (2.4 mol%), the radical concentration remaining constant.

Discussion

We observed two kinds of radical conversions. One proceeds by keeping the sample at -196°C for a few days, and the other by subsequent ultraviolet irradiation. They could be explained by intermolecular reactions with original free radicals and by dissociation of the free radicals.

When IB concentration in 3MP is low (2.4 mol%), radical conversions were observed at -196°C without UV irradiation, and the five-line spectrum due to allylic radicals and the other spectrum which seemed to be attributed to the free radicals from 3MP were obtained. This could be explained in terms of hydrogen atom abstraction by the original free radicals from both neighboring IB and 3MP molecules.

$$\left.\begin{array}{l} \mathrm{CH_3} \\ \cdot\mathrm{C}-\mathrm{CH_2}-\mathrm{R} \\ \mathrm{CH_3} \end{array}\right\} \begin{cases} + \text{ IB} \rightarrow \mathrm{CH(CH_3)_2\text{-}CH_2R} \\ \qquad + \mathrm{CH_2{=}\overset{\mathrm{CH_3}}{\overset{|}{C}}\text{-}\dot{C}H_2} \qquad (1) \\ + \text{ 3MP} \rightarrow \mathrm{CH(CH_3)_2\text{-}CH_2R} \\ \qquad + \mathrm{CH_3\text{-}CH_2\text{-}\overset{\mathrm{R'}}{\overset{|}{\dot{C}}}\text{-}CH_2\text{-}CH_3} \\ \qquad (\mathrm{R'{=}H \text{ or } CH_3}) \qquad (2) \end{cases}$$

These reactions might be caused by the mobility of free radicals in the glass. Reaction (1) is very similar to that observed in the 3MP-2MP-1 system,[7] although the original free radicals were 3-methylpentyl radicals in this case. It seems reasonable to conclude that a hydrogen atom is abstracted more readily from IB than from 3MP, since even at low concentrations of IB, allylic radicals were produced and at higher concentration only allylic radicals were produced. This might be caused by the stability of allylic radicals.

Methyl radicals were produced by subsequent ultraviolet irradiation. Since 3MP does not absorb UV light, any reactions through an excited 3MP molecule can be ruled out. In fact although unirradiated 3MP gave methyl radicals and other free

radicals by ultraviolet irradiation under the same conditions employed for the γ-irradiated 3MP-IB systems, the intensity was negligible compared with the present intensity. Methyl radical production is thought to be caused by dissociation of the free radical from 3MP(CH_3–CH_2–$\dot{C}$(R)–CH_2–CH_3), since the same change was observed for γ-irradiated 3MP.[10]

$$CH_3\text{–}CH_2\text{–}\dot{C}(R)\text{–}CH_2\text{–}CH_3 \rightarrow CH_3\text{–}CH_2\text{–}C(R)=CH_2 + \cdot CH_3 \quad (3)$$

Allylic radicals disappeared by ultraviolet irradiation and new alkyl radicals (CH_3–CH_2–$\dot{C}$(R)–CH_2–CH_3) were observed, besides methyl radicals. This result is consistent with that reported for 3MP-2MP-1 systems,[7] and could be explained in terms of intermolecular hydrogen abstraction by allylic radicals from neighboring 3MP molecules. In the case of irradiated polyethylene, allyl radicals converted to alkyl radicals by UV irradiation. This was, however, explained by intramolecular hydrogen atom shift.[3] But it may also occur by an intermolecular hydrogen atom abstraction mechanism.

Some of the free radicals CH_3CH_2–$\dot{C}$(R)–CH_2CH_3 produced in the course of UV photolysis of allylic radicals would be photolyzed to produce methyl radicals by the mechanism (3). The concentration of methyl radicals, however, was not so large and no significant increase was observed with longer time of irradiation. This might be caused by the recombination of methyl radicals.

When IB concentration was high (61 mol%), no change in the spectrum was observed by keeping the sample at -196°C for a few days in contrast to the systems with lower IB concentration (2.4 mol%). This seems to be due to a smaller mobility of free radicals as the glass of this mixture is close to the polycrystalline state, as could be supposed from the fact that no trapped electrons were observed.[11]

A spectrum change was observed by subsequent ultraviolet irradiation, and only allylic radicals were observed. This is caused by hydrogen atom abstraction only from an IB molecule. It is reasonable to expect that hydrogen atom abstraction by UV irradiation proceeds only from IB molecules as IB molecules are present close to the parent free radicals because of high IB concentration, and because IB is more reactive than 3MP for hydrogen abstraction.

It should be noted that the eight-line spectrum gradually converted to the fifteen line spectrum when the sample with intermediate IB concentration (12 mol%) was stored at -196°C for a few days. According to our tentative interpretation,[9] this is caused by changes in the conformations of the free radicals. Therefore the conversion from the eight-lines to the fifteen lines seems to be a kind of relaxation process. On the other hand, if the two conformations have an intimate relation with the chain length,[9] a spectrum change could be caused by the propagation of post-polymerization at -196°C.

The authors wish to thank Professor I. Sakurada for his kindness in permitting them to carry out the work at Osaka Laboratories, Japanese Association for Radiation Research on Polymers (now Osaka Laboratories for Radiation Chemistry, Japan Atomic Energy Research Institute). Thanks are also due to Professor K. Hayashi, Dr. H. Yoshida, and Mr. H. Kamiyama for their helpful discussions, and to Professor F. Williams for reading the manuscript.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 2831—2835 (1969)

Separation and Identification of Chlorocomplexes of Technetium(IV) formed in Hydrochloric Acid Solutions

Yoshihiko KANCHIKU*1

Faculty of Science, Kyoto University, Sakyo-ku, Kyoto

(Received November 2, 1968)

The chemical behavior of $TcCl_6^{2-}$ in HCl solutions of different concentrations has been investigated. It was confirmed that $TcCl_6^{2-}$ is sensitive to ultraviolet and visual light, giving a series of aquated species the quantities of which depend on the HCl concentration. Those technetium(IV) chlorocomplexes were isolated by means of ion-exchange and paper electrophoresis, and the composition of each species was determined by measuring the Cl/Tc ratio and the charge per species. The absorption spectra of isolated species were also measured.

A number of compounds of technetium are known for the valency states from +7 to −1.[1-3] In the field of the solution chemistry of technetium, the chemical behavior of pertechnetate(VII) ion has been investigated more extensively than the chemical species of any other valency state.

The lower oxidation states of technetium which result from the pertechnetate ion by the reduction have not been quantitatively investigated except for their reactions with special analytical reagents[4] and their magnetic properties.[5] The pertechnetate ion is gradually reduced to lower valency states by halides in acidic solution.[1] Lederer *et al.* have qualitatively investigated the reduction products of pertechnetate by chloride and bromide by separating them by means of paper chromatography.[6] In a previous communication[7] it was pointed out, on the basis of an analysis of the change of its absorption spectra, that hexachlorotechnetate(IV) underwent a photochemical aquation associated with a small quantity of oxidation in hydrochloric acid solution.

The present work will deal with the quantitative details of technetium(IV) chlorocomplex formation in hydrochloric acid solution. K_2TcCl_6 obtained by reducing the pertechnetate ion was dissolved in hydrochloric acid solutions of various concentrations. The experiments have proved that several new technetium chlorocomplexes are formed, step by step, during the aquation. These complexes were separated from each other by means of ion exchange, and the ratios of technetium to chloride were determined by analysing them. The electrical charges of the complex ions were determined by the ion-exchange equilibrium method.[8,9]

From the results obtained, the photo-aquation of $TcCl_6^{2-}$(1) is regarded as the main sequence in the formation of a variety of aquo-chlorocomplexes:

$$TcCl_6^{2-} + xH_2O \rightleftarrows TcCl_{6-x}(H_2O)_x^{(2-x)-} + xCl^- \quad (1)$$

The effects of light absorption were interpreted in terms of an equilibrium condition among the technetium chlorocomplex species in hydrochloric acid.

Experimental

Apparatus. All the absorption spectra were measured on a Shimadzu Recording Spectrophotometer, Model SV-50A, using quartz cells.

The radioactivities of technetium-99 were measured by a Osaka Dempa GM-Counter, Model GM-2.

Reagents. The technetium-99 had been obtained from Oak Ridge National Laboratory (U. S. A.). The chemical form was NH_4TcO_4 solution. The solution was standardized by gravimetry, using tetraphenylarsonium chloride as the precipitant.

The hydrochloric acid was a Koso Chemicals special grade reagent in which no impurities absorbing the

UV light were detected.

K_2TcCl_6: Ammonium pertechnetate (100 mg) was mixed with 0.2 g of KCl and 10 m*l* of concentrated hydrochloric acid, and then the mixture was heated on a water bath while being refluxed for 20 hr. After evaporation to near dryness, the technetium residue was dissolved in concentrated hydrochloric acid. The absorption spectrum of the solution was identical with that of the K_2TcCl_6 solution obtained by the KI reduction of NH_4TcO_4.[10]

Formation of Other Chlorocomplexes of Technetium. K_2TcCl_6 was dissolved in 12 M, 8 M, 6 M, 3 M, 1 M, and 0.1 M HCl. One group of acid solutions was kept at room temperature in the dark, while another group was irradiated by luminescent lamps (Toshiba 10w×4) at 20°C in a thermostat. The absorption spectra of the two groups were measured at regular intervals.

In spite of the varied concentrations of the acid, the group kept in the dark showed the absorption spectrum of $TcCl_6^{2-}$ constantly, while the group irradiated with the luminescent lamps showed different absorption spectra according to the acid concentrations. This variation seemed to be caused by the formation of aquo-chlorocomplexes of technetium. Their spectra reached equilibria after two weeks under the experimental conditions.

Isolation of the Complexes by Ion-exchange Resin. Samples which had been irradiated for two weeks and had already been in equilibrium were subjected to ion-exchange separation.

The sample solutions were first passed through an anion exchange column (Dowex 2×8, 50—100 mesh, R-ClO_4 type, 15ϕ×200mm) in order to remove any anionic species. The cationic and neutral species were thoroughly washed with pure water and 0.1 M $HClO_4$.

The eluted fractions, containing cationic and neutral species, were again passed through a cationic exchanger column (Dowex 50×8, 100—200 mesh, R-H type, 15ϕ×200 mm). From the cation exchanger column, the neutral species was readily removed by 0.1 M $HClO_4$, while the cationic species were eluted by 1 M $HClO_4$. These species were eluted in discrete bands that could be detected by measuring their characteristic absorption spectra.

Analysis of Technetium. The technetium in the effluent was distilled as pertechnetate with concentrated sulfuric acid and was spectrophotometrically determined by measuring the absorbance at 244 mμ[1]; a molar extinction coefficient of 6220 was used for pertechnetate at this wavelength. It was also determined by the diphenylcarbazide method.[11]

Analysis of Chloride. The chloride of the eluted species was analyzed by titration with mercuric ion, using diphenylcarbazone as an indicator.[12] Prior to the titration, the complexes had been hydrolyzed by making the solution alkaline with the addition of potassium hydroxide and had been boiled for five minutes in order to liberate the chloride ion.

Measurement of Charge per Species. The charge per species was measured according to the method of Connick and Cady.[9]

The technetium distribution was obtained by measuring the radioactivities of ^{99}Tc. Before these measurements, the solutions were neutralized with NH_4OH in order to avoid the vaporization of pertechnetate as Tc_2O_7 and were dried up in glass counting dishes.

Separation of the Species by Paper Electrophoresis. The species, spotted on paper strips (Toyo No. 53, 40×2 cm) which had been immersed in an electrolytic solution (0.1 M $NaClO_4$+0.1 M HCl), were separated by high voltage (500 V). The heat generated during electrophoresis was removed by cooling the strips through a glass vessel filled with ice water. Electrophoretic patterns were obtained by autoradiography.

Results and Discussion

When K_2TcCl_6 was dissolved in hydrochloric acid and the solutions were irradiated with visible or UV light, the absorption spectra of the solutions changed and reached equilibria depending on the hydrochloric acid concentrations and the intensity of light. The spectrum of the 12 M HCl solution, however, did not change upon photo-irradiation, and so it was identified as the original species.

The spectra of the solution equilibrated by photolysis are shown in Fig. 1, where the 12 M, 8 M, 6 M, and 3 M HCl solutions show two isosbestic points at 311 mμ and 362 mμ. The isosbestic points can be employed to determine the total amount of technetium(IV) in the solution.

From the hydrochloric acid solutions, two anionic, one neutral, and one cationic species of technetium chlorocomplex were isolated by the ion-exchange method.

Prior to the following experiments, the stability of the separated species in perchloric acid solution was examined. From the fact that the absorption spectra remain unchanged for several days, the separated species seems to be stable in the elutant, perchloric acid, if they are kept in the dark. The degradation of the complexes during the spectrophotometric procedure is too small to be detected.

The distribution of the anionic and cationic species between ion-exchange resins and aqueous perchloric acid are shown in Figs. 2 and 3, these data can be used in calculation the values of the charge per ion.

The ratios of technetium to chloride for two anionic species are shown in Table 1, along with the charge per species. The ratios for the cationic and neutral species could not be determined by analysing technetium and chloride, because it was impossible to separate the two forms of technetium from chloride by either the ion-exchange or precipitation method without any destruction of the complexes in question. For the neutral species, however, it is reasonable to assume that the ratio of Tc to Cl is 1 : 4.

The spectra of the four isolated technetium complex species are shown in Fig. 4, while their wave lengths of maximum absorption and extinction coefficients are tabulated in Table 2. From these results, it can be quantitatively explained that the change in the absorption spectra of $TcCl_6^{2-}$ solution upon irradiation is due to the aquation of the complex in question.

Figure 5 presents electrophoretic patterns which give evidence of the isolation of four different species.

Four main spots, A, B, C, and D, appear in the figure. From their mobilities, it is probable that these spots correspond to the following species:

A-anionic species (−2)
B-anionic species (−1)
C-neutral species (0) and precipitated TcO_2
D-cationic species (+1)

The species could not, however, be assigned definitely because the interaction between the paper and each species is not always the same. The pertechnetate and cupric ions which were used as pilot ions gave clear spots and did not have any tailing.

The spots at the original points appeared in the electrophoretic patterns of the samples of 12 M, 8 M, and 6 M HCl solutions where no zero-charge species were detected by means of the ion-exchange method. The reason for this is not clear, but it is assumed that complexes partly hydrolyze during the electrophoresis as a result of the local heating at the original point. The electrophoresis, however, provides a qualitative figure of the species in the solutions.

In Fig. 6, the abundances of the species are plotted against the hydrochloric acid concentrations. It shows the distribution of complexes found in the solution by the ion-exchange method. It seems that TcO_4^- is formed in the dilute hydrochloric acid by the photochemical formation of the Tc(IV) complex and its subsequent disproportionation reactions. This figure, however, represents only the distribution of technetium complexes under the experimental conditions employed here, as will be discussed later.

As has been mentioned previously, this experiment was performed in order to identify the species of technetium(IV) chlorocomplexes in hydrochloric acid solution.

The photochemical reaction was used to produce different chlorocomplexes in solution. By taking into account the experimental results of electrical charges and the Cl/Tc ratios of complexes, it may be concluded that the main reaction induced by the irradiation is not reduction but the step-by-step substitution of chloride with water molecules. Therefore, the four isolated species can be assigned to the group of chemical forms indicated in Table 1. Furthermore, it is confirmed that the backward reaction (1) proceeds almost quantitatively without any influence of photons; this supports the theory that the reaction taking place is not a redox type reaction but a substitution reaction.

However, the charge-transfer reaction in the primary step of the reaction sequence can not be excluded, for the technetate ion is detected in 0.1 M and 1 M HCl solutions in which the backward reaction can practically be ruled out.

It should be noted that the reaction system used here does not provide a thermodynamic equilibrium, but a transient one. The rates of the forward and backward reactions of the first step in Eq. (1) are expressed as follows:

$$R_f = K_f[TcCl_6^{2-}] \quad (2)$$

$$K_f = K_{df} + f \cdot q \quad (3)$$

$$R_b = K_b[TcCl_5^-][Cl^-] \quad (4)$$

where R_f: rate of forward reaction,
R_b: rate of backward reaction,
K_f: forward reaction constant,
K_{df}: forward reaction constant in the dark,
K_b: backward reaction constant,
f: flux of photon,
q: quantum yield

at the apparent equilibria:

$$R_f = R_b. \quad (5)$$

Therefore,

$$(K_{df} + f \cdot q)[TcCl_6^{2-}] = K_b[TcCl_5(H_2O)^-][Cl^-] \quad (6)$$

$$\frac{[TcCl_5(H_2O)^-]}{[TcCl_6^{2-}]} = \left(\frac{K_{df}}{K_b} + \frac{f \cdot q}{K_b}\right) \Big/ [Cl^-] \quad (7)$$

From Eq. (7), it is clear that the $[TcCl_5(H_2O)^-]/[TcCl_6^{2-}]$ ratio in a given solution is proportional to the light flux irradiated and also inversely proportional to the concentration of chloride in the solution.

To elucidate the reaction mechanism and also to determine the thermodynamic constants, more quantitative experiments from the kinetic point of view are necessary.

The author wishes to express his hearty thanks to Professor Taitiro Fujinaga and Dr. Mutsuo Koyama for their helpful advice and encouragement throughout this work.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 2835—2840 (1969)

The Chromium(III) Complexes with β-Aminoethylsulfonic-*N*,*N*-diacetic Acid and Aspartic-*N*,*N*-diacetic Acid*[1]

Akira UEHARA, Eishin KYUNO and Ryokichi TSUCHIYA

Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa

(Received January 31, 1969)

The following chromium(III) complexes with the β-aminoethylsulfonic-*N*,*N*-diacetic acid (AEDA) and aspartic-*N*,*N*-diacetic acid (ASDA) were newly prepared; $K_3[Cr(aeda)_2]\cdot 4H_2O$ (pale red) (I), $[Cr(OH)(Haeda)(o\text{-phen})]\cdot 2H_2O$ (orange) (II) and $[Cr(Hasda)(H_2O)_2]\cdot H_2O$ (reddish purple) (III). From the results of spectral measurments, it was found that AEDA acts as a quadridentate ligand as well as a terdentate one in an aqueous solution, but only as a terdentate ligand in a crystal state, and that the coordinating ability of the oxygen atom of sulfonic radical in AEDA is weaker than that of carboxylic radical in ammoniapropionicdiacetic acid (APDA). In Complex III, ASDA behaved as a quadridentate ligand rather than as a quinquedentate. Complexes II and III showed some interesting thermal decomposition processes. The former lost one mole of water at 110°C from the hydrogen atom in free sulfonic acid radical and the coordinated OH group, accompanied with the increase of coordination number of AEDA from 3 to 4. In the latter, one mole of crystalline water was lost first, and then the carboxylic acid bound to the methylene group at β-position in the ligand was decomposed to liberate carbon dioxide, and the coordinated asda was changed into apda.

Preparations and properties of chromium(III) complexes with ammoniatriacetic acid (ATA),[1] ammoniapropionicdiacetic acid (APDA) and ammoniaisopropionicdiacetic acid (AIPDA)[2] have already been reported. These ligands have one nitrogen and three oxygen atoms capable of coordinating. Thus their maximum coordination number is commonly four. But it has often been pointed out that their coordinating behaviors are somewhat different from each other because of the differences in their structures and in their chemical properties such as acid dissociation constants.[1,2]

Although the complexes of (A) and (B) types in Fig. 1, which shows the possible structures of complexes, were obtained in an aqueous solution with all three ligands, the crystals of (A) type were obtained only with APDA. One reason for this may be due to the small solubility of APDA complex. The (B) type complex containing ATA or AIPDA instantly changed to (C) type when they were dissolved in water, but the (C) type complex could not be obtained in the case of APDA. This sug-

gests that the complex containing 5-, 5- and 6-membered chelate rings with ligand such as APDA is more stable than that having three five-membered rings with ligand such as ATA or AIPDA. The complex assigned to (D) type could not be obtained only with AIPDA. This suggests that some steric hindrance due to a methyl group exists in the case of AIPDA.[2]

β-Aminoethylsulfonic-*N,N*-diacetic acid and aspartic-*N,N*-diacetic acid (abbreviated as AEDA and ASDA, respectively) were selected as the related ligand to ATA, APDA and AIPDA in the present work. Rational formulas of these ligands are shown in Fig. 2.

This study was undertaken (1) to investigate how AEDA and ASDA behave toward metal in these complexes, (2) to prepare various complexes containing these ligands and (3) to compare the complexing properties of AEDA and ASDA with those of ATA, APDA or AIPDA.

Experimental

Preparation of Ligands. *β-Aminoethylsulfonic-N,N-diacetic Acid Dihydrate*: $C_6H_{11}O_7NS \cdot 2H_2O$. The method described here is the modified one reported by Schwarzenbach *et al.*[3] Twenty five grams of taurin were neutralized with 100 m*l* of water containing about 8 g of sodium hydroxide. Thirty-nine grams of monochloroacetic acid were dissolved in 200 m*l* of water and 34 g of sodium bicarbonate was gradually added to it. The two solutions were mixed, the mixture was heated on a water bath up to about 70°C, and 16 g of sodium hydroxide in 50 m*l* of water was added. Heating was continued about one hour. After cooling, gradual addition of concentrated hydrochloric acid and scrubbing by a glass rod, produced white powdered crystals. Recrystallization was achieved from water. Yield about 15 g.

Found: N, 4.96; C, 25.78; H, 5.38%. Calcd for $C_6H_{11}O_7NS \cdot 2H_2O$: N, 5.05; C, 25.99, H; 5.45%.

Aspartic-N,N-diacetic Acid: $C_8H_{11}O_8N$. Twenty six grams of aspartic acid were suspended in about 200 m*l* of water, and 35 g of sodium bicarbonate was added little by little under magnetic stirring. Thirty eight grams of monochloroacetic acid were neutralized with about 200 m*l* of water containing 35 g of sodium bicarbonate. After the two solutions were mixed, the mixture was heated on a water bath at 70—80°C, and then 50 m*l* of water containing 15 g of sodium hydroxide was added. Heating was continued for 1 hr in order to complete the reaction. After cooling, the solution was made acidic with concentrated hydrochloric acid, and then evaporated to a half volume. The sodium chloride was filtered off whenever it was separated out. After the filtrate was concentrated up to syrupy state, a small amount of acetone was added, and the solution was kept for several days in a refrigerator. White powdered crystals were obtained. The crude products were recrystallized from an acetone-water (1 : 1) mixture. Yield about 3 g.

Found: N, 5.49; C, 38.22; H, 4.37%. Calcd for $C_8H_{11}O_8N$: N, 5.62; C, 38.56; H, 4.44%.

Preparation of Complexes. *Potassium Bis(β-aminoethylsulfonic-N,N-diacetato)chromate(III) Tetrahydrate*: $K_3[Cr(aceda)_2] \cdot 4H_2O$ (I). Two and a half grams of chromium chloride hexahydrate were dissolved in 200 m*l* of water and then 2.5 g of AEDA was added. The mixture was heated on a water bath. The color of the solution changed from green to purple as the reaction proceeded. Two and a half grams of AEDA and 3 g of potassium bicarbonate were added and the solution was heated. When the color of the solution became red, the pH was adjusted to *ca.* 6. The pale red crystals were obtained from the cooled solution. The crude products were recrystallized from water. Yield about 1 g. The use of ammonium carbonate instead of potassium bicarbonate gave the ammonium salt.

Found: N, 3.81; C, 20.06; H, 3.25%. Calcd for $K_3[Cr(aeda)_2] \cdot 4H_2O$: N, 3.90; C, 20.07; H, 3.37%.

Hydroxohydrogen-β-aminoethylsulfonic-N,N-diacetato-o-phenanthrolinechromium(III) Dihydrate: [Cr(OH)(Haeda)-(*o*-phen)]·$2H_2O$ (II). The procedure was the same as mentioned above until the purple solution was obtained. To the resulting solution, 2 g of *o*-phenanthroline was added. The pH of the solution was adjusted to 4—5 by adding an appropriate amount of potassium bicarbonate. Orange crystals were obtained from the cooled resulting solution. Recrystallization was achieved from an aqueous solution. Yield about 1.5 g.

Found: N, 8.32; C, 41.25; H, 4.14%. Calcd for [Cr(OH)(Haeda)(*o*-phen)]·$2H_2O$: N, 8.01; C, 41.22; H, 4.23%.

3) G. Schwarzenbach, H. Ackermann and P. Ruckstull, *Helv. Chim. Acta*, **32**, 1175 (1949).

Hydrogenaspartic-N,N-diacetatodiaquochromium(III) Monohydrate: $[Cr(Hasda)(H_2O)_2]\cdot H_2O$ (III). The mixture of five grams of ASDA and an appropriate amount of chromium hydroxide was suspended in water, and was heated on a water bath almost to dryness. The residue was dissolved in a small amount of water, and the reddish purple filtrate was concentrated. The resulting solution was adjusted to pH 2, and after adding a small amount of acetone, it was kept in a refrigerator for a few days. Reddish purple crystals were obtained. Recrystallization was carried out from water-acetone (70 : 30) mixture. Yield about 0.5 g.

Found: N, 3.81; C, 27.59; H, 3.83%. Calcd for $[Cr(Hasda)(H_2O)_2]\cdot H_2O$: N, 3.97; C, 27.28; H, 3.99%

Instruments. The instruments used in this work were the same as described previously.[2]

Results and Discussion

Observation on Thermal Decomposition Processes by using a Derivatograph and an IR Spectrometer. Some interesting thermal decomposition processes were observed by using a derivatograph and an IR spectrometer. Their derivatograms measured in a nitrogen stream with a heating rate of *ca.* 1°C/min are shown in Fig. 3. About 500 mg of the sample was used for each run. Figures 4 and 5 give the IR spectra of these complexes and of the samples taken out at several heating steps.

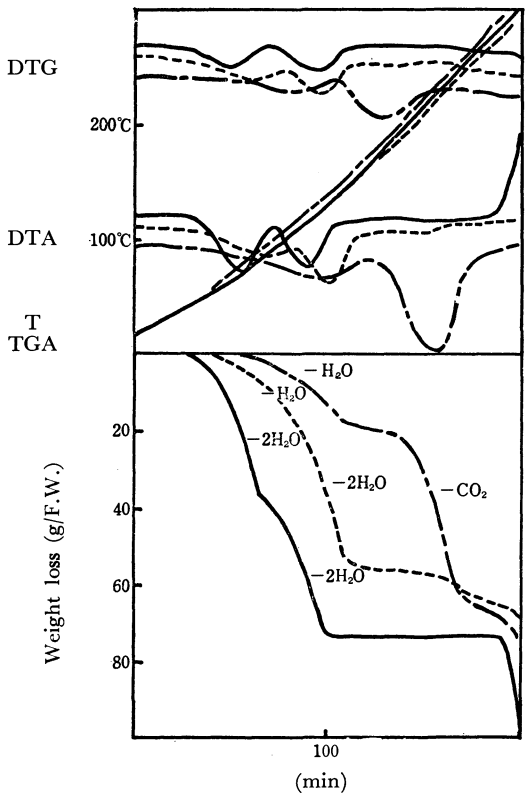

Fig. 3. Derivatograms for I (——), II (----) and III (—·—).

As shown in Fig. 3, Complex I lost 4 mol of crystalline water in two distinct steps: the first two moles were removed at *ca.* 80°C and the last two, at 135°C. A violent decomposition started at *ca.* 280°C.

For Complex II, though TGA curve shows the weight loss corresponding to 3 mol of water from 65 to 150°C, both DTA and DTG curves indicate the split peaks below and over *ca.* 110°C. The corresponding difference could also be detected in IR spectra, which is shown in Fig. 4. The split bands at *ca.* 1200 cm^{-1} probably assigned to sulfonate ion changed to one peak when the complex was heated at 110°C, and the band due to H_2O (3400—3200 cm^{-1}) disappeared at 150°C. These facts combined with the TGA curve mean that the weight loss at the first step until 110°C is due to the evolution of one mole of water from the hydrogen ion of free sulfonic acid and the hydroxyl group and that at the second step over 110°C corresponds to the liberation of two moles of the crystalline water.

From Complex III, the weight loss corresponding to the liberation of one mole of water and to that of one mole of carbon dioxide can be observed at 75—155°C and 180—250°C on TGA curve in Fig. 3, respectively. As shown in IR spectral features in Fig. 5, both the bands at 1730 and at 1610 cm^{-1} could be detected in the sample before heating; the former has been assigned to non- and the latter, to coordinated carboxylic acid.[4]

The sample at 155°C shows the same pattern, but the band at 1730 cm^{-1} disappears at 250°C. Nevertheless, the band at 3500 cm^{-1} due to the OH stretching vibration can be seen in all these samples. The results suggest that the crystalline water is lost first, and then the free carboxylic acid attached to the methylene group at β-position in the ligand is decomposed to produce carbon dioxide without losing any coordinated water, and the coordinated asda is changed into apda.

Visible and UV Absorption Spectra. All the measurements of absorption spectra were carried out in aqueous solutions. In Fig. 6, the spectrum of Complex I and that of the corresponding ATA complex are shown. The spectra of the purple solution obtained by the reaction of $CrCl_3\cdot 6H_2O$ with AEDA and of the solution of $[Cr(ata)(H_2O)_2]$ are shown in the figure. Figure 7 gives the spectra of Complex II and Complex III. The numerical data of their absorption maxima are summarized in Table 1, together with those measured in Complex III by a diffuse-reflectance method. As seen in Fig. 6, the spectrum of Complex I is quite similar to that of the corresponding ATA complex, indicating that they may have the analogous structure. Although it is known that the gradual

Table 1. Absorption maxima

Complex	$\nu_1(10^{13}/\text{sec})$ (log ε_1)	$\nu_2(10^{13}/\text{sec})$ (log ε_2)
Purple solution of $[Cr(aeda)(H_2O)_2]$	54.1 (1.89)	74.4 (2.01)
Purple solution of $[Cr(ata)(H_2O)_2]$	54.9 (1.91)	74.1 (2.03)
I	60.0 (1.54)	83.3 (1.39)
$K_3[Cr(ata)_2]\cdot 4H_2O$[1]	60.1 (1.65)	83.6 (1.48)
II	59.0 (1.51)	88.2 (2.02)
III	58.4 (1.64)	86.9 (2.25)
III*	54.5	75.0

* This absorption maximum was measured by a diffuse-reflectance method.

decomposition from $[Cr(ata)_2]^{3-}$ to $[Cr(OH)(ata)(H_2O_2)]^-$ proceeds in an aqueous solution even at room temperature,[1] no change in the spectrum could be observed even in the solution kept for a few days in the case of Complex I.

The spectrum for the purple solution of AEDA is very similar to that of $[Cr(ata)(H_2O)_2]$, showing that they may have an analogous structure, and that AEDA acts as a quadridentate ligand in an aqueous solution only in this complex.

As shown in Fig. 7, Complex II gives a rather complicated spectrum due to the coordinated *o*-phenanthroline. The spectrum of Complex III in an aqueous solution has the maxima at 58.4 and 86.9×10^{13}/sec, whereas that in a solid state measured by a diffuse-reflectance method shows the maxima at 54.5 and 75.0×10^{13}/sec. This considerable deviation may indicate that Complex III has a different structure in an aqueous solution and in a solid state. The numerical data given in Table 1 show that the bands in a solid state of Complex III are very close to that of $[Cr(ata)(H_2O)_2]$. In other words, Complex III will have a coordinating structure similar to that of $[Cr(ata)(H_2O)_2]$ in a solid state. In an aqueous solution, however, the coordinating structure is still unkown.

Molar Conductivities and pH Values. In Table 2, the values of molar conductivities and pH were listed together with the behaviors toward ion exchangers. The sign + means the adsorption of the complex by ion exchangers, and −, the reverse. All three complexes in solution were adsorbed by Cl-form anion exchangers. For Complex I, the pH value and molar conductivity were 6.8 and 383.1 mho cm^{-1}, respectively, showing that it is a 1 : 3 type electrolyte.

The solution of Complex II was acidic (pH 3.4) and molar conductivity was 161.3 mho cm^{-1}. It suggests that the hydrogen ion is partly dissociated from Haeda in an aqueous solution.

For Complex III, the values of considerably low pH (pH 1.8) and of the higher conductivity (481.2 mho cm^{-1}) were observed, which may indicate that the strong dissociation of hydrogen ion in free carboxylic acid takes place in an aqueous solution.

Table 2. Some properties of the complexes

Complex	Adsorption to the ion exchanger		Molar conductivity* (mho cm^{-1})	pH**
	Na-form	Cl-form		
I	−	+	383.1	6.8
II	−	+	161.3	3.4
III	−	+	481.2	1.8

* 1.0×10^{-3} mol/*l* aqueous solution was used.
** 1.0×10^{-2} mol/*l* aqueous solution was used.

Possible Structures of the Complexes. From the results, the possible structures proposed are depicted in Fig. 8. The purple solution formed from the reaction of chromium chloride hexahydrate with AEDA may have (a) type structure, in which AEDA acts as a quadridentate ligand. For Complex I, (b) type may be assigned, where the sulfonic acid is not coordinated. The (c) type structure having some interaction between the hydrogen atom in the sulfonic acid and the oxygen atom in the coordinated hydroxyl group seems to be reasonable for Complex II.

When ASDA acts as a quadridentate ligand, two kinds of characteristic coordinating structures are expected. One makes three five-membered chelate rings, and the other two five- and one six-membered chelate rings. However, as it has already been reported,[2,5] the latter case makes a more stable complex formation than the former, so that the preferable structure for Complex III is the (d) type.

Comparisons among AEDA-, ATA-, AIPDA-, and APDA-Complexes. As the structure of AEDA resembles that of APDA, it was expected that AEDA forms a stable complex in which AEDA acts as a quadridentate ligand. However, this was proved not to be the case by the following results. Firstly, the complex in which AEDA acts as a quadridentate ligand was formed in an aqueous

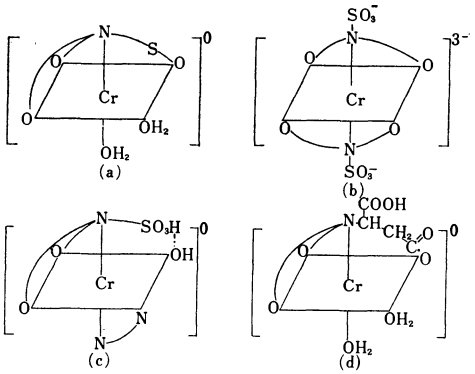

Fig. 8. Possible structures.

5) E. Martell and S. Chaberek, Jr., *J. Am. Chem. Soc.*, **75**, 2888 (1953).

solution, but not in a crystal state. Secondly, in the mixed complexes, ATA, AIPDA and APDA behaved only as a quadridentate ligand, whereas AEDA acts as a terdentate ligand owing to the non-coordination of the sulfonic acid. Thirdly, although the ATA and APDA complexes gradually decomposed in an aqueous solution from $[Cr(ata)_2]^{3-}$ and $[Cr(apda)_2]^{3-}$ to $[Cr(OH)(ata)(H_2O)_2]^-$ and $[Cr(OH)(apda)(H_2O)]^-$ respectively, the coordinating AEDA complex I underwent no change in an aqueous solution. These facts suggest that the coordinating ability of the oxygen atom of sulfonic acid in AEDA is smaller than that of carboxylic acid in APDA. They are in good agreement with the result that APDA has larger stability constants than AEDA in the bivalent metal complexes.[6]

Possible Thermal Decomposition Processes. The possible thermal decomposition processes for Complexes II and III are described schematicaly in Fig. 9. Complex II lost one mole of water at 110°C from the hydrogen atom in free sulfonic acid and the coordinated hydroxyl group, resulting in the increase of coordination number of AEDA from 3 to 4. Such phenomena have also been observed in APDA complex, $[Cr(OH)(Hapda)(H_2O)_2]$.[2] On the other hand, for Complex III, one mole of crystalline water is first lost and then

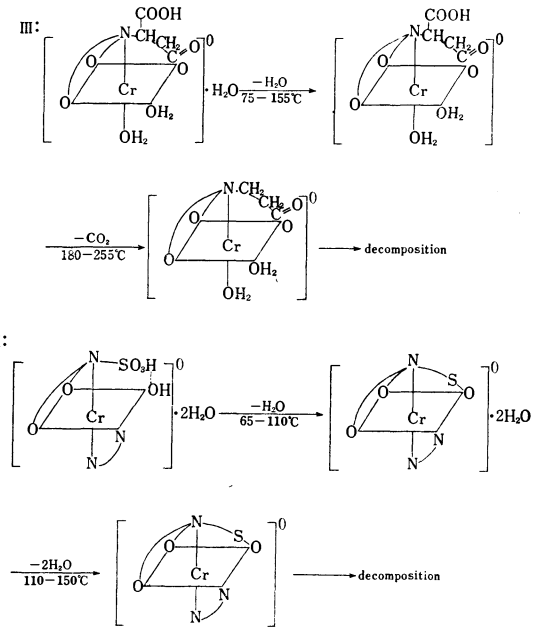

Fig. 9. Possible thermal decomposition schemes for II and III.

the carboxylic acid attached to the carbon atom at β-position in the ligand may be decomposed into carbon dioxide, and the coordinated asda is changed into apda.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 2841—2843 (1969)

The Kinetics of the Ligand-substitution Reactions of Nitrilotriacetatoniccolate(II) Complexes with *trans*-1,2-Cyclohexanediaminetetraacetate Ions

Masaru KIMURA*1

Department of Applied Chemistry, Yamagata University, Jonan, Yonezawa-shi

(Received February 3, 1969)

The kinetics of the ligand-substitution reactions of the nitrilotriacetatoniccolate(II) complexes with *trans*-1,2-cyclohexanediaminetetraacetate (CyDTA) ions were studied polarographically from pH 4.8 to 5.8 at an ionic strength of 0.2 and at 25°C. The reactions were found to proceed only through the dissociation reactions of the nitrilotriacetatoniccolate(II) complexes. The rate constants of the dissociation reactions were also determined. In contrast to the reactions of the same complex with ethylenediaminetetraacetate (EDTA) ions and *N*-2-hydroxyethylenediaminetriacetate (HEDTA) ions, there were no direct reactions of the nitrilotriacetatoniccolate(II) complexes with CyDTA ions. The reaction was of the first order in respect to the concentration of the nickel-complex and independent of the CyDTA concentration; the reaction of the complex with CyDTA ions was found to have the different mechanisms from the similar reaction with EDTA and HEDTA, and to be due to the steric effect of the cyclohexane ring in the CyDTA molecule.

In a previous paper[1] the kinetics of the ligand-substitution reactions of nickel(II)-nitrilotriacetate (NTA) complexes with EDTA ions and HEDTA ions were dealt with. Both reactions were found to proceed through four reaction paths, involving two paths of the dissociation reactions of Ni(II)-NTA complexes. Recently, it has been reported that the reactions of copper(II) ion with Ni(II)-CyDTA complexes,[2] and those of cadmium(II) ion with Ca(II)-CyDTA complexes,[3] behave different kinetically from the similar reactions with EDTA complexes.[3-5] These phenomena could be explained by the fact that the cyclohexane ring in CyDTA prevents the free rotation about the ethylenic bond between the two nitrogen atoms; with this steric restriction it is impossible to bond a different metal ion to each iminodiacetate segment of CyDTA, although such reaction intermediates are possible with EDTA.[2,3] It seems to be important and also interesting to examine whether a similar kinetic behavior holds in the case of the ligand-substitution reaction, particularly in the case of the reaction using CyDTA as the entering ligand. Thus, the ligand-substitution reactions of Ni(II)-NTA complexes with CyDTA ions have been investigated in the present study. The reaction mechanisms have been compared with those of the similar reactions with EDTA and HEDTA, and also with the metal-substitution reactions described above.

Experimental

The solutions of dipotassium nitrilotriacetate and dipotassium *trans*-1,2-cyclohexanediaminetetraacetate were prepared from commercial nitrilotriacetic acid (DOTITE NTA) and *trans*-1,2-cyclohexanediaminetetraacetic acid (DOTITE CyDTA) respectively, and were standardized against a standard solution of nickel(II) nitrate by amperometric titration. The standard solution of nickel(II) nitrate was prepared by dissolving an appropriate amount of pure nickel metal in reagent-grade nitric acid. The concentration of the nickel(II) solution was determined by the conventional gravimetric method, using dimethylglyoxime.[6] Commercial guaranteed reagents were used for acetate buffer solution and supporting electrolytes without further purification.

The rate of the reaction of nickel(II)-NTA complex with CyDTA was determined by measuring the decrease of the polarographic anodic diffusion-limiting currents of CyDTA ions with time.

Current-time curves were obtained with a Yanagimoto-PA-102 pen-recording polarograph. The dropping-mercury electrode had an m value of 1.9 mg/sec and a drop time, t_d, of 4.3 sec in an air-free solution contain-

ing 0.2 M potassium nitrate at 25°C and at −0.5 V *vs.* SCE.

Measurements were made at 25°C in an acetate buffer solution containing 0.04 M acetate ion. The ionic strength of the solution was adjusted to 0.2 with potassium nitrate. Gelatin (0.005% in concentration) was added as a maximum suppressor. The pH of the solution was measured after the polarographic measurements with a Hitachi-Horiba Model F-5 pH meter equipped with a glass electrode.

Results and Discussion

The overall ligand-substitution reactions between nickel(II)-NTA complexes and CyDTA ions can apparently be expressed by:

$$NiX^- + \left\{\begin{matrix} Z^{4-} \\ \downarrow\uparrow \\ \vdots \\ \downarrow\uparrow \\ H_4Z \end{matrix}\right\} \overset{V_i^+}{\rightleftharpoons} NiZ^{2-} + \left\{\begin{matrix} X^{3-} \\ \downarrow\uparrow \\ \vdots \\ \downarrow\uparrow \\ H_3X \end{matrix}\right\} \quad (1)$$

Where X^{3-} and Z^{4-} denote a tervalent NTA anion and a tetravalent CyDTA anion respectively.

The concentrations that can be determined polarographically, [CyDTA] are given by:

$$[CyDTA] = \sum_{j=0}^{4} [H_jZ^{(4-j)-}]$$

Under the present experimental conditions, the rate of the reaction given by Eq. (1) was so slow that the initial rate of the forward reaction, $-\Delta[CyDTA]_i/\Delta t$, could be determined accurately. The subscript i indicates the initial state.

Table 1 shows the characteristics of the reaction of Ni(II)-NTA complexes with CyDTA ions, which were obtained from the preliminary measurements of the initial rate under varied conditions.

Judging from these characteristics, the reaction mechanism of the ligand-substitution reaction between Ni(II)-NTA complex and CyDTA ions may be considered to be as follows:

$$NiX^- \underset{k_a^-}{\overset{k_{NiX}}{\rightleftharpoons}} Ni^{2+} + X^{3-} \quad (2)$$

$$NiX^- + H^+ \underset{k_b^-}{\overset{k^H_{NiX}}{\rightleftharpoons}} Ni^{2+} + HX^{2-} \quad (3)$$

$$Ni^{2+} + \left\{\begin{matrix} Z^{4-} \\ \downarrow\uparrow \\ \vdots \\ \downarrow\uparrow \\ H_jZ^{(4-j)-} \end{matrix}\right\} \overset{k_j^+}{\rightleftharpoons} NiZ^{2-} + jH^+ \quad (4)$$

Consequently, it was found that the relations of:

$$\sum_{j=0}^{4} k_j^+[H_jZ^{(4-j)-}] \gg k_a^-[X^{3-}] + k_b^-[HX^{2-}]$$

are satisfactorily fulfilled under the present experimental conditions from the series No. 3 in Table 1, and that there are no paths of the direct reaction of CyDTA ions with the complex from the series No. 4 in Table 1. Therefore, the overall reaction rate for the reaction the (1) is expressed by:

$$-\Delta[CyDTA]_i/\Delta t \equiv V_i^+ = [NiX^-]_i\{k_{NiX} + k^H_{NiX}[H^+]\} \quad (5)$$

Determination of the Rate Constant. The initial rate of the reaction (1), $-\Delta[CyDTA]_i/\Delta t$, was determined under the conditions given by series No. 1 in Table 1. The values of $V_i^+/[NiX^-]_i$ were plotted against $[H^+]$ according to Eq. (5). These plots gave straight lines, as shown in Fig. 1, from which the values of the rate constants in Eq. (5) were determined. The rate constants obtained are given in Table 2, together with the values previously reported.[1)]

In Table 2 it can be seen that the values obtained in the present study are in good agreement with those obtained from the other reaction systems. The

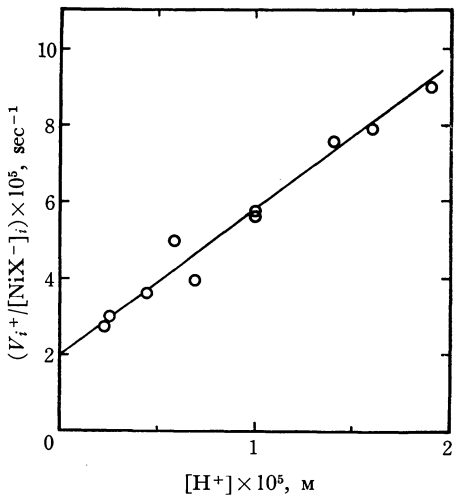

Fig. 1. $V_i^+/[NiX^-]_i$ as a function of the hydrogen ion concentration in acetate buffer-potassium nitrate solutions of ionic strength 0.2 at 25°C. Initial concentrations are $[NiX^-]_i = 2.02\times10^{-3}$ M and $[CyDTA]_i = 4.49\times10^{-4}$ M. Concentration of uncomplexed NTA is $[NTA]_f = 2.6\times10^{-4}$ M.

NiX-CyDTA	2.0×10^{-5}	3.8	This study

reactions of Ni(II)-NTA complex with EDTA and HEDTA were of the first-order in the concentrations of EDTA and HEDTA.[1] However, the reaction of the same complex with CyDTA was independent of the concentration of CyDTA. Experimental examples of this behavior are shown in Fig. 2. Margerum and Bydalek[2] reported that the metal-substitution reaction of copper(II) ion with Ni(II)-CyDTA complex does not include copper ion attack of Ni(II)-CyDTA complex; the absence of any copper dependence may be attributed to the inability of the copper(II) ion to form binuclear intermediates such as [Ni-CyDTA-Cu] because of hindered rotation and steric blocking due to the cyclohexane ring. Recently, Kuempel and Schaap[3] reported similar behavior in the reaction of the cadmium(II) ion with Ca(II)-CyDTA complex. The results obtained in the present study on the ligand-substitution reaction, using CyDTA as an entering ligand molecule, may be consistent with those of the two previous papers on metal-substitution reactions involving CyDTA.

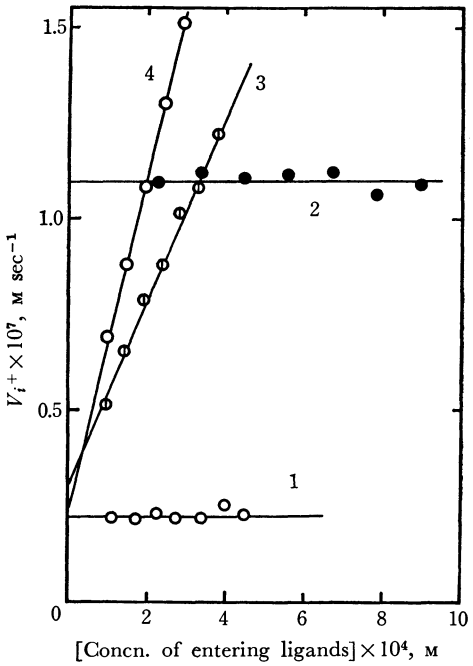

Fig. 2. V_i^+ as a function of the concentrations of the entering ligands. The conditions are the same as for Fig. 1. The entering ligands are CyDTA (1 and 2), EDTA (3) and HEDTA (4). The initial concentrations of complexes, $[NiX^-]_i$ are 0.81 mM (1), 2.02 mM (2) and 0.40 mM (3 and 4). The pH values of the solutions are 5.70 (1), 5.10 (2), 5.00 (3) and 5.26 (4).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 2844—2848 (1969)

The Kinetics of the Ligand-substitution Reactions of Nitrilo(diacetic)-propionato- and Nitrilo(diacetic)isopropionatoniccolate(II) Ions with EDTA, and of Taurin-*N*-diacetatoniccolate(II) Ions with EDTA and CyDTA

Masaru KIMURA*1

Department of Applied Chemistry, Yamagata University, Jonan, Yonezawa-shi

(Received February 24, 1969)

The kinetics of the reactions of nickel(II)-nitrilo(diacetic)propionate (NDAP) and nickel(II)-nitrilo(diacetic)isopropionate (NDAIP) complexes with ethylenediaminetetraacetate (EDTA) ions, and those of the nickel(II)-taurin-*N*-diacetate (TDA) complex with EDTA and *trans*-1,2-cyclohexanediaminetetraacetate (CyDTA) ions, have been studied polarographically in solutions with pH 4.8—6.0 at 25°C and at an ionic strength of 0.2. All the reactions except those with CyDTA proceeded through four reaction paths, and the rate constants for the reaction paths were determined. The reaction of the nickel(II)-TDA complex with CyDTA was found to proceed only through the complete dissociation of the Ni(II)-TDA complex. There was not a direct reaction of the complex with CyDTA. Consequently, the overall reaction with CyDTA became much slower than that of the same complex with EDTA. The rate constants obtained were compared with those of the similar reactions of the nickel(II)-nitrilotriacetate (NTA) complex with EDTA and CyTDA which had been reported previously. The rate of the dissociation reaction of nickel(II) complexes increased in the order: NDAIP≦NDAP<NTA<TDA. Especially, the rate of the Ni(II)-TDA complex was about 30 times that of Ni(II)-NTA complex.

The metal-chelating tendencies of the chelating agents, nitrilo(diacetic)propionic acid (NDAP) and taurin-*N*-diacetic acid (TDA), which are resulted from the substitution of one acetate group in nitrilotriacetic acid (NTA) have been extensively investigated.[1-3] Recently, a new agent, nitrilo(diacetic)-isopropionic acid (NDAIP) was synthesized by Uehara *et al.*[3] In previous studies,[4,5] the kinetics of the reaction of the nickel(II)-NTA complex with ethylenediaminetetraacetate (EDTA) ions, *N*-hydroxyethylethylenediaminetriacetate(HEDTA) ions, and *trans*-1,2-cyclohexanediaminetetraacetate (CyDTA) ions were dealt with. Since it seems important and necessary to extend the study to the investigation of the effect of various ligands on the reaction rate and the mechanism, the reactions of several nickel(II) complexes with EDTA and/or CyDTA were carried out in the present study. The rate constants of the dissociation of the nickel(II) complexes were compared with the metal-chelating tendencies of the chelating agents.

The reaction of the nickel(II)-TDA complex with CyDTA was run for the purpose of determining the rate constant of the dissociation reaction of the nickel complex; this study aimed to determine the rate constants of the ligand-substitution reactions and also those of the dissociation reactions of the nickel complexes. In a previous paper,[4] the kinetics of the reaction of the nickel(II)-NTA complex with CyDTA were dealt with and compared with those of the reaction of the same complex with EDTA. Changes in the reaction mechanism and a large decrease in the overall rate were observed when EDTA was replaced by CyDTA. The reasons for this were discussed in the previous paper.[4]

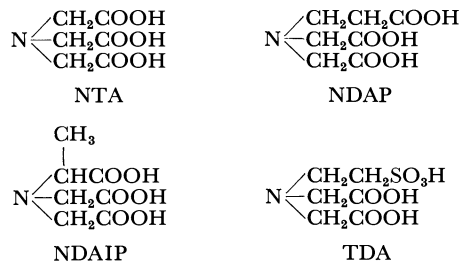

Fig. 1. Structural formulas of the chelating agents.

Experimental

The chelating agents, NDAIP,[3] NDAP[6] and TDA,[7] were prepared by the procedures reported by Uehara *et al.* Uehara's method for the syntheses of NDAP and TDA was a modification of Schwarzenbach's.[1] All the other chemicals and the apparatus used were the same as had been described in previous papers.[4,5] The rate of the reaction was measured by a method which was, in principle, the same as that employed in previous studies.[4,5] The temperature was maintained at 25°C. The ionic strength was adjusted to 0.2 with potassium nitrate.

Results

The overall reaction of Ni(II)-NDAP, Ni(II)-NDAIP, and Ni(II)-TDA complexes with EDTA or CyDTA may be expressed as:

$$\left\{\begin{matrix}NiX^{-}\\ \downarrow\uparrow\\ NiHX\end{matrix}\right\}+\left\{\begin{matrix}Y^{4-}\\ \downarrow\uparrow\\ \vdots\\ \downarrow\uparrow\\ H_4Y\end{matrix}\right\}\overset{V_i^{+}}{\rightleftharpoons}\left\{\begin{matrix}NiY^{2-}\\ \downarrow\uparrow\\ NiHY^{-}\end{matrix}\right\}+\left\{\begin{matrix}X^{3-}\\ \downarrow\uparrow\\ \vdots\\ \downarrow\uparrow\\ H_3X\end{matrix}\right\} \qquad (1)$$

Where X^{3-} indicates *ndap*$^{3-}$, *ndaip*$^{3-}$ and *tda*$^{3-}$, which are tervalent anions of NDAP, NDAIP, and TDA respectively, and where Y^{4-} indicates edta^{4-} and cydta^{4-}, which are tetravalent anions of EDTA and CyDTA respectively. The concentrations of EDTA and CyDTA that can be determined polarographically are those of the uncomplexed EDTA and CyDTA, which are given by the equation:

$$[\text{EDTA}]=\sum_{j=0}^{4}[H_jY^{(4-j)-}] \qquad (2)$$

(or [CyDTA])

Under the present experimental conditions, all the reactions of Eq. (1) except that of the Ni(II)-TDA complex with EDTA were so sluggish that the initial rate, $-\Delta[\text{EDTA}]_i/\Delta t$ or $-\Delta[\text{CyDTA}]_i/\Delta t$ could be measured accurately (the subscript i indicates the initial state). Two experimental examples of the current-time curve of the reaction of the Ni(II)-TDA complex with EDTA and CyDTA are given in Fig. 2. The initial rates (V_i^+) were obtained under various experimental conditions. The initial rates of the reactions of nickel(II)-NDAP and nickel(II)-NDAIP complexes with EDTA were: (1) independent of the concentration of uncomplexed NDAP or NDAIP (see Table 1); (2) proportional to the initial concentration of the complex, [Ni *ndap*$^{-}$]$_i$ or [Ni *ndaip*$^{-}$]$_i$; (3) linear to the initial concentration of the entering

6) A. Uehara, E. Kyuno and R. Tsuchiya, This Bulletin, **41**, 2385 (1968).

7) A. Uehara, E. Kyuno and R. Tsuchiya, presented at the 18th Symposium on Coordination Compounds, Kyoto, Japan, Oct. 1968.

ligand, $[EDTA]_i$ and $[edta^{4-}]_i$ (see Figs. 3,4 and 5), and (4) in a first- and second-order relation to the hydrogen-ion concentration (see Eq. (8), Figs. 6 and 7). On the basis of these results, the reaction mechanism of the ligand-substitution reactions of nickel(II)-NDAP, -NDAIP, and -TDA complexes with EDTA was assumed to be as follows:

$$NiX^- + HY^{3-} \overset{k_{NiX}^{HY}}{\rightleftharpoons} \begin{Bmatrix} NiY^{2-} \\ \downarrow\uparrow \\ NiHY^- \end{Bmatrix} + HX^{2-} \quad (3)$$

$$NiX^- + H_2Y^{2-} \overset{k_{NiX}^{H_2Y}}{\rightleftharpoons} \begin{Bmatrix} NiY^{2-} \\ \downarrow\uparrow \\ NiHY^- \end{Bmatrix} + H_2X^- \quad (4)$$

$$NiX^- \underset{k_a^-}{\overset{k_{NiX}}{\rightleftharpoons}} Ni^{2+} + X^{3-} \quad (5)$$

$$NiX^- + H^+ \underset{k_b^-}{\overset{k_{NiX}^H}{\rightleftharpoons}} Ni^{2+} + HX^{2-} \quad (6)$$

$$Ni^{2+} + \begin{Bmatrix} Y^{4-} \\ \downarrow\uparrow \\ \vdots \\ \downarrow\uparrow \\ H_4Y \end{Bmatrix} \overset{k_j^+}{\rightleftharpoons} \begin{Bmatrix} NiY^{2-} \\ \downarrow\uparrow \\ NiHY^- \end{Bmatrix} + jH^+ \quad (7)$$

On the other hand, the initial rate of the reaction of the nickel(II)-TDA complex with CyDTA was: (1) independent of the concentration of uncomplexed TDA and also of the initial concentration of CyDTA (see Fig. 3); (2) proportional to the initial concentration of the Ni(II)-TDA complex, and (3) linear to the hydrogen-ion concentration (see Fig. 8). These results indicate that the reaction of the nickel(II)-TDA complex with CyDTA proceeds only through the complete dissociation of the Ni(II)-TDA complex, as is shown in Eqs. (5)—(7). The relation of $\sum_{j=0}^{4} k_j^+[H_jY^{(4-j)-}] \gg k_a^-[X^{3-}]+k_b^-[HX^{2-}]$, was fulfilled because the initial rate was independent of the concentrations of uncomplexed NDAP, NDAIP, and TDA. Judging from the equilibrium constant,[8] the protonated complex, NiHX, in Eq. (1) was not expected to be present in any appreciable concentration under the present experimental conditions.

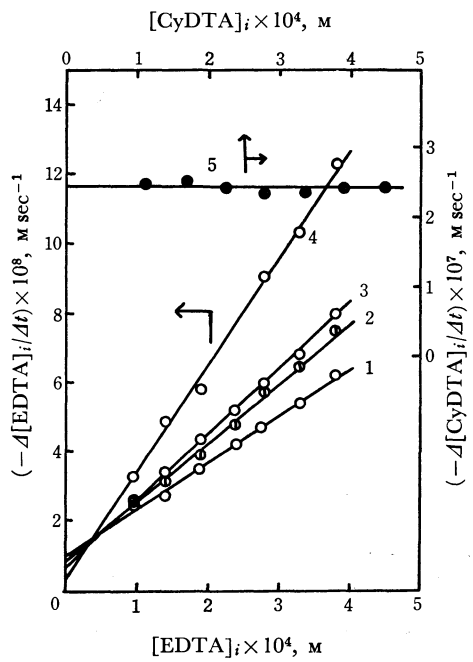

Fig. 3. Initial rates (V_i^+) as a function of the concentrations of entering ligands ($[EDTA]_i$ and $[CyDTA]_i$) in acetate buffer-potassium nitrate solutions of ionic strength 0.2 at 25°C. Initial concentrations of Ni(II)-NDAP and Ni(II)-TDA complexes are 3.09×10^{-4} M (curves 1, 2, 3 and 4) and 2.06×10^{-4} M (curve 5) respectively. The pH's of the solutions are (1) pH 5.08, (2) pH 5.30, (3) pH 5.46, (4) pH 5.81 and (5) pH 5.52.

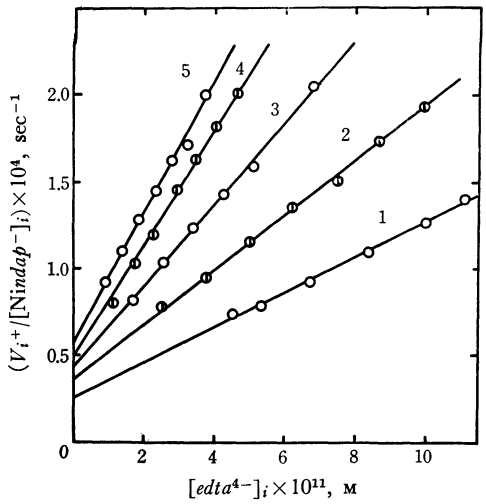

Fig. 4. $V_i^+/[Ni\,ndap^-]_i$ as a function of $[edta^{4-}]_i$ in acetate buffer-potassium nitrate solutions of ionic strength 0.2 at 25°C. Initial concentration of Ni(II)-NDAP complex is 6.18×10^{-4} M. The pH's of the solutions are (1) pH 5.17, (2) pH 5.04, (3) pH 4.95, (4) pH 4.88 and (5) pH 4.82.

From the reaction mechanism, the expressions for the rates of decrease from the initial concentration, $[EDTA]_i$ and $[CyDTA]_i$, can be derived as:

$$-\Delta[EDTA]_i/\Delta t = [NiX^-]_i\{k_{NiX} + k_{NiX}^H[H^+] + (k_1[H^+]+k_2[H^+]^2)[Y^{4-}]_i\} \quad (8)$$

where

$$k_1 = k_{NiX}^{HY}/K_{HY},\ k_2 = k_{NiX}^{H_2Y}/(K_{HY}K_{H_2Y}),$$

$$[Y^{4-}]_i = [EDTA]_i/\alpha_H$$

$$\alpha_H = 1 + [H^+]/K_{HY} + [H^+]^2/(K_{HX}K_{H_2Y}) + [H^+]^3/(K_{HY}K_{H_2Y}K_{H_3Y}) + [H^+]^4/(K_{HY}K_{H_2Y}K_{H_3Y}K_{H_4Y}) \quad (8')$$

and

8) N. Tanaka and M. Kimura, *Sci. Repts. Tohoku Univ. Ser. I*, **50**, 203 (1967).

$$-\Delta[\mathrm{CyDTA}]_i/\Delta t = [\mathrm{NiX}^-]_i(k_{\mathrm{NiX}} + k^{\mathrm{H}}_{\mathrm{NiX}}[\mathrm{H}^+]) \quad (9)$$

In these equations, the initial concentrations, $[\mathrm{EDTA}]_i$, $[\mathrm{NiX}^-]_i$ and $[\mathrm{CyDTA}]_i$, are substituted for [EDTA], [NiX$^-$], and [CyDTA] respectively. The changes in their concentrations during the period of the measurement of the initial rate of the reaction were considered to be negligibly small under the present conditions. Equation (8) indicates that if the values of $V_i^+/[\mathrm{NiX}^-]_i$ are plotted against $[\mathrm{Y}^{4-}]_i$ (or $[\mathrm{EDTA}]_i$) when all quantities but $[\mathrm{EDTA}]_i$ are kept constant, a straight line should be obtained with an intercept at $[\mathrm{Y}^{4-}]_i=0$ given by:

$$(\mathrm{Intercept}) = k_{\mathrm{NiX}} + k^{\mathrm{H}}_{\mathrm{NiX}}[\mathrm{H}^+] \quad (10)$$

and a slope given by:

$$(\mathrm{Slope}) = k_1[\mathrm{H}^+] + k_2[\mathrm{H}^+]^2 \quad (11)$$

Therefore, if the values of the intercept and the slope obtained at various concentrations of hydrogen ion are plotted against the hydrogen-ion concentrations, the values of the rate constants in Eq. (8) can be determined. In the case of the reaction of the nickel(II)-TDA complex with CyDTA, the $V_i^+/[\mathrm{NiX}^-]_i$ obtained from Eq. (9) corresponds to Eq. (10) itself.

Determination of the Rate Constants of the Reactions of Ni(II)-NDAP and Ni(II)-NDAIP Complexes with EDTA. The initial rate (V_i^+) was measured for the reactions of nickel(II)-NDAP and -NDAIP complexes with varied concentrations of EDTA, but a constant concentration of other species present and at constant pH. Several examples of the plots of V_i^+ *vs.* $[\mathrm{EDTA}]_i$ and $V_i^+/[\mathrm{NiX}^-]_i$ *vs.* $[\mathrm{Y}^{4-}]_i$ are given in Figs. 3, 4, and 5 (Fig. 3 shows one example of V^+ *vs.* $[\mathrm{CyDTA}]_i$ together with the plots of V_i^+ *vs.* $[\mathrm{EDTA}]_i$).

The intercepts and the slopes of the plots, $V_i^+/[\mathrm{NiX}^-]_i$ *vs.* $[\mathrm{Y}^{4-}]_i$, correspond to Eqs. (10) and (11) respectively. The intercepts and the slopes were also plotted against the hydrogen-ion concentrations according to Eqs. (10) and (11). These plots are shown in Figs. 6 and 7, from which the values of the rate constants in Eq. (8) were determined.

The rate constants for reactions (3) and (4) were calculated from the relations given in Eq. (8′). The results are shown in Table 2.

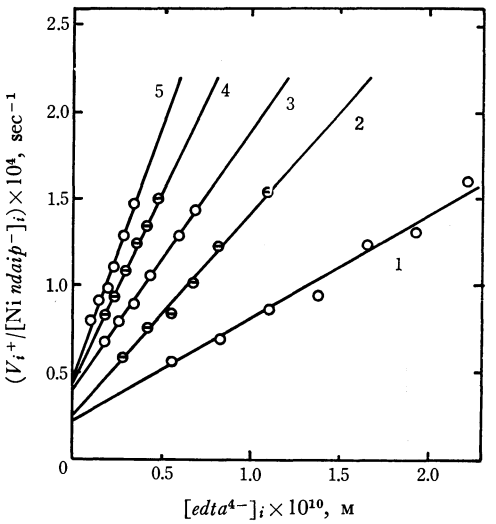

Fig. 5. $V_i^+/[\mathrm{Ni}\ ndaip^-]_i$ as a function of $[edta^{4-}]_i$ in acetate buffer-potassium nitrate solutions of ionic strength 0.2 at 25°C. Initial concentration of Ni(II)-NDAIP complex is 6.18×10^{-4} M. The pH's of the solutions are (1) pH 5.22, (2) pH 5.08, (3) pH 4.94, (4) pH 4.86 and (5) pH 4.82.

The acid dissociation constants of EDTA, K_{HY}, $K_{\mathrm{H_2Y}}$, $K_{\mathrm{H_3Y}}$, and $K_{\mathrm{H_4Y}}$, which were used in the calculation of $k^{\mathrm{HY}}_{\mathrm{NiX}}$, $k^{\mathrm{H_2Y}}_{\mathrm{NiX}}$, and α_{H} are the same values as those employed in a previous study.[5]

Determination of the Rate Constants of the Reaction of the Ni(II)-TDA Complex with CyDTA. The initial rate, $-\Delta[\mathrm{CyDTA}]_i/\Delta t$, was measured at varied concentrations of hydrogen ion and at two different concentrations of $[\mathrm{Ni}\ tda^-]_i$ and $[\mathrm{CyDTA}]_i$. The values of $(-\Delta[\mathrm{CyDTA}]_i/\Delta t)/[\mathrm{Ni}\ tda^-]_i$ were then plotted against the hydrogen-ion concentrations. The results are given in Fig. 8. The rate constants of the dissociation reactions, (5) and (6), were obtained from the intercept and the slope in Fig. 8. The results are given in Table 2, together with the rate constants obtained from the other reaction systems.

Discussion

Eigen[9,10] reported that, with most of the divalent transition metal ions in the first series, the rate of a complex-forming reaction of a metal ion with a ligand is independent of the nature of the ligand. If this assumption is satisfied, the rate of the dissociation reaction of a metal complex is expected to be dependent on the stability of the complex. The rate constants of the dissociation reactions of

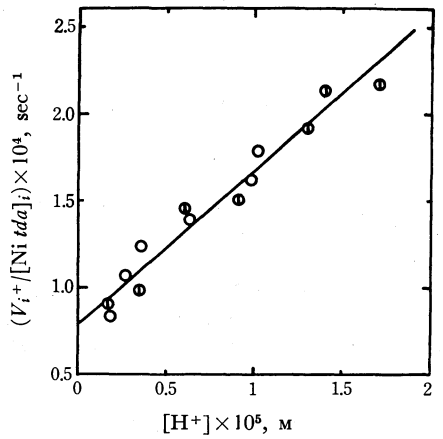

Fig. 8. $(-\Delta[\text{CyDTA}]_i/\Delta t)/[\text{Ni } tda^-]_i$ as a function of the hydrogen ion concentrations in acetate solutions of ionic strength 0.2 at 25°C. Initical oncentrations are $[\text{Ni } tda^-]_i = 2.06\times10^{-4}$ M (○) and 1.03×10^{-4} M (◑), and $[\text{CyDTA}]_i = 4.49\times10^{-4}$ M (○) and 2.25×10^{-4} M (◑). The concentrations of uncompleyed TDA are $[\text{TDA}]_f = 2\times10^{-5}$ M (○) and 1×10^{-5} M (◑).

nickel complexes in Table 2 indicate that the reaction becomes fast in the order of: NDAIP≦NDAP<NTA<TDA, which seems to be opposite to the order of the stability of the complex. Schwarzenbach *et al.*[1] reported that the third acid dissociation constant of TDA ($pK_{\text{H}tda}=8.16$) was larger than that of NTA ($pK_{\text{H}nta}=9.73$), and that the formation constants of the alkaline earth metal complexes with TDA were smaller than those of the corresponding complexes with NTA. These facts are consistent with the fact that the dissociation reaction of the TDA complex is faster than that of the NTA complex. The segment groups, CH_3 | $-CHCOOH$ in NDAIP and $-CH_2CH_2COOH$ in NDAP, seem to bond more strongly than any acetate group in NTA. This fact may be consistent with the statements by Chaberek and Martell,[2] and by Uehara *et al.*[3,6] that there is a considerable strain on the nitrogen atom in NTA coordinated with three five-membered rings, while a formation with one six-membered ring reduces the strain in NDAP, giving a more stable complex.

The author wishes to thank Professor N. Tanaka of Tohoku University for affording facilities for the elementary analysis and infrared measurements. He is also grateful to Drs. E. Kyuno and A. Uehara, Kanazawa University, for their kind advice concerning the syntheses of the chelating agents.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 2849—2853 (1969)

Spectroscopic Studies of the Mixture of Dialkylaluminum 2-Aminoethoxide $(AlR_2OCH_2CH_2NR'_2)_2$ and Trialkylaluminum $(AlR''_3)_2$*1

Hideo SATO, Ryokichi TARAO and Hiromi HIGASHI

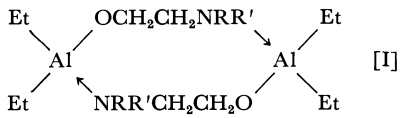
The Central Research Laboratories, Chisso Co., Ltd., Kamariya, Kanazawa-ku, Yokohama

(Received March 10, 1969)

The proton magnetic resonance and infrared spectra of the mixtures of dialkylaluminum 2-aminoethoxide $(AlR_2OCH_2CH_2NR'_2)_2$ and trialkylaluminum $(AlR''_3)_2$ were measured. Special attention was paid to the infrared frequencies of the NH_2 stretching and scissors bands and to the chemical shifts of the methyl groups attached to the aluminum and nitrogen atoms. From the results it was concluded that $(AlR''_3)_2$ reacts with $(AlR_2OCH_2CH_2NR'_2)_2$ to form a 1 : 1 coordination compound $AlR_2OCH_2CH_2NR'_2 \rightarrow AlR''_3$ quantitatively. At the same time, the redistribution and exchange reactions of the alkyl groups were observed.

It is known that trialkylaluminums $(AR''_3)_2$ such as $(AlMe_3)_2$ and $(AlEt_3)_2$ are associated to dimers and that rapid inter- and intramolecular exchanges of alkyl groups take place.[1,2] These exchange reactions are due to the weak bonding between aluminum atom and carbon atom of the bridged alkyls. $(AlR''_3)_2$ also forms 1 : 1 coordination compounds with ethers and amines. Although the bonding between aluminum atom and electron donors seems to be stronger than that between aluminum atom and carbon atom of the bridged alkyls, the alkyl group exchange is still observed in the mixture of such a coordination compound and $(AlR''_3)_2$.[3-5]

One of us obtained the crystals of the dimers of diethylaluminum 2-aminoethoxides $(AlEt_2OCH_2CH_2NRR')_2$ by reacting $(AlEt_3)_2$ with several aminoethanols $HOCH_2CH_2NRR'$; R,R'=H, alkyl, cycloalkyl, and/or aryl groups.[6] We investigated the structures of these comopunds spectroscopically and concluded that their structures could reasonably be repoesented by formula I with two NRR' $\rightarrow$Al coordination bonds.[7]



[I]

The behaviors of the mixture of $(AlR_2OCH_2CH_2NR'_2)_2$ and $(AlR''_3)_2$ seemed to be very interesting in comparison with the mixture of two trialkylaluminums——$(AlR_3)_2+(AlR'_3)_2$——and the mixture of trialkylaluminum and an electron donor, because $(AlR_2OCH_2CH_2NR'_2)_2$ may act as an electron donor ($-NR'_2$ group) and as an electron acceptor ($-AlR_2$ group) simultaneously. Therefore the mixture was studied by IR and NMR spectroscopically.

Experimental

Preparation of the Samples. $(AlEt_2OCH_2CH_2NH_2)_2$ and $(AlEt_2OCH_2CH_2NMe_2)_2$ were prepared by the reaction of $(AlEt_3)_2$ with the corresponding alkanolamine following the synthetic methods described previously.[7] $(AlMe_2OCH_2CH_2NMe_2)_2$ was obtained by the reaction of $(AlMe_3)_2$ with dimethylaminoethanol $HOCH_2CH_2NMe_2$ as white crystals (mp 116.5°C—118.5°C; Found: Al, 18.48%; mol wt, 304.7. Calcd for $Al_2C_{12}H_{32}O_2N_2$: Al, 18.58%; mol wt, 290.4). $(AlEt_3)_2$ and $(AlMe_3)_2$ were purchased from Ethyl Corp. and fractionally distilled before use.

Measurements of IR and NMR Spectra. The IR spectra of the dilute benzene solutions of the samples (the concentrations of the solutions were 1.10 g/100 m*l*) were measured in the 4000—420 cm^{-1} region by using KRS-5 liquid fixed cell of 0.5 mm thickness. A Japan Spectroscopic Co. Model DS-402G infrared spectrophotometer was used.

The NMR spectra were run on a Varian A-60A high resolution NMR spectrometer equipped with variable temperature accessories. About 0.5 m*l* of the solution of the sample (10% weight/volume solution) was injected into the sample tube by a hypodermic syringe under nitrogen atmosphere and sealed. Benzene was used as solvent for room temperature measurements

and toluene for high temperature measurements. The solvents were also used as internal references. The signal intensities were usually measured by an integrator.

Results and Discussion

The IR Spectra of the System $(AlEt_2OCH_2CH_2NH_2)_2+(AlEt_3)_2$. The IR spectrum of the benzene solution of $(AlEt_2OCH_2CH_2NH_2)_2$ is shown in Fig. 1a. The spectra of the mixtures of $(AlEt_2OCH_2CH_2NH_2)_2$ and $(AlEt_3)_2$ are shown in Figs. 1b, 1c and 1d together with the spectrum of triethylaluminum-*n*-propylamine $AlEt_3\cdot n\text{-}PrNH_2$ in Fig. 1e. For $(AlEt_2OCH_2CH_2NH_2)_2$, the bands at 3375 and 3309 cm^{-1} have been assigned to the NH_2 antisymmetric and symmetric stretching vibration and a sharp band at 1590 cm^{-1} to the NH_2 scissors respectively in a previous paper.[7]

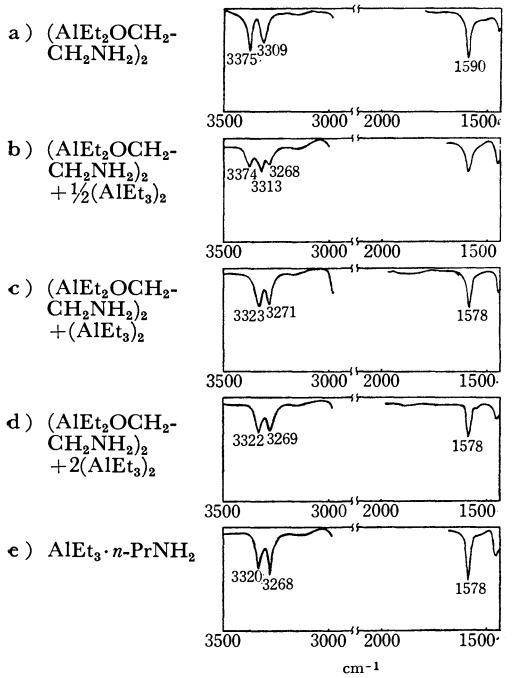

Fig. 1. The IR spectra of the systems $(AlEt_2OCH_2CH_2NH_2)_2+(AlEt_3)_2$.

The spectrum of the 1 : 1 mixture of $(AlEt_2OCH_2CH_2NH_2)_2$ and $(AlEt_3)_2$, Fig. 1c, shows the bands of the NH_2 stretching vibrations at 3323 and 3271 cm^{-1}, and the NH_2 scissors at 1578 cm^{-1}. These frequencies are almost equal to the values of the corresponding bands of $AlEt_3\cdot n\text{-}PrNH_2$, Fig. 1e, 3320, 3268 and 1578 cm^{-1} respectively. This fact is reasonably interpreted by the assumption that the NH_2 group in $(AlEt_2OCH_2CH_2NH_2)_2$ coordinates to the Al atom of $(AlEt_3)_2$. The NH_2 stretching vibrations of the 1 : 0.5 mixture, Fig. 1b, are clearly a superposition of those of Figs. 1a and 1c. The spectrum of the 1 : 2 mixture, Fig. 1d, shows the bands of NH_2 stretching vibrations at the same frequencies as those of the 1 : 1 mixture shown in Fig. 1c.

These observations lead to the conclusion that $(AlEt_3)_2$ forms a 1 : 1 coordination compound with $(AlEt_2OCH_2CH_2NH_2)_2$ quantitatively.

The NMR Spectra of the System $(AlMe_2OCH_2CH_2NMe_2)_2+(AlMe_3)_2$. The NMR spectra of the benzene solutions of the mixtures of $(AlR_2OCH_2CH_2NR'_2)_2$ and $(AlR''_3)_2$ (R=Me, Et, R'=H, Me, Et, R''=Me, Et) support the above conclusion obtained from the IR spectra. The result for the particular case where R, R' and R'' are methyl group will be described in detail, although similar conclusions are reached for all other cases. In Fig. 2a, the spectrum of the benzene solution of $(AlMe_2OCH_2CH_2NMe_2)_2$ is given. The 7.83 and the 5.28 ppm peaks are due to the methyl group attached to the Al atom and the N atom (hereafter abbreviated as the Al–Me group and the N–Me group) respectively. Two triplets at 5.14 and 3.67 ppm are assigned to the N-methylene group and O-methylene group respectively by taking the assignments given in Ref. 7 into consideration.

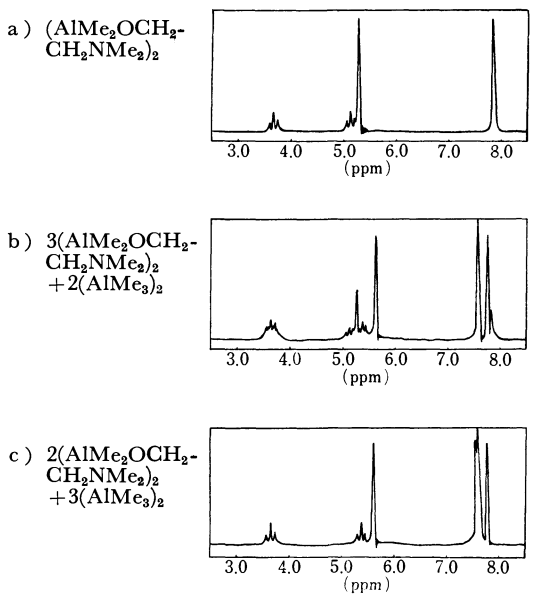

Fig. 2. The NMR spectra of the mixtures of $(AlMe_2OCH_2CH_2NMe_2)_2$ and $(AlMe_3)_2$.

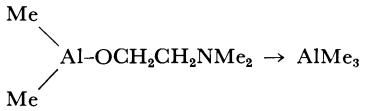
The NMR spectrum of the 3 : 2 mixture of $(AlMe_2OCH_2CH_2NMe_2)_2$ and $(AlMe_3)_2$ is shown in Fig. 2b. There appear two new peaks due to the Al–Me group at 7.77 and 7.56 ppm, and also one new peak due to the N–Me group at 5.63 ppm.

The areas of the 7.77 ppm and the 5.63 ppm peaks are equal and the ratio of the areas of the 7.77 ppm and the 7.56 ppm peaks is 2 : 3. Thus the 7.56 ppm peak is assigned to the Al–Me group of $(AlMe_3)_2$ which is coordinated by the N atom in $(AlMe_2OCH_2CH_2NMe_2)_2$. The spectrum of

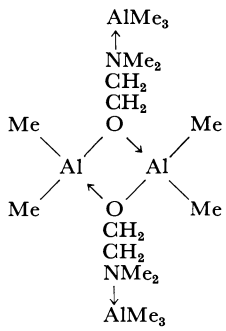
the 2 : 3 mixture is shown in Fig. 2c. The 7.83 ppm peak due to the Al–Me group and the 5.28 ppm peak due to the N–Me group of $(AlMe_2OCH_2CH_2NMe_2)_2$ disappear and excess $(AlMe_3)_2$ gives the peak at 7.53 ppm.

These observations support the conclusion that $(AlMe_2OCH_2CH_2NMe_2)_2$ and $(AlMe_3)_2$ form a 1 : 1 coordination compound quantitatively.

The Molecular Weight of the 1 : 1 Coordination Compound of $(AlMe_2OCH_2CH_2NMe_2)_2$ and $(AlMe_3)_2$. As to the structure of this coordination compound, there are two possible formulas II (monomeric) and III (dimeric).

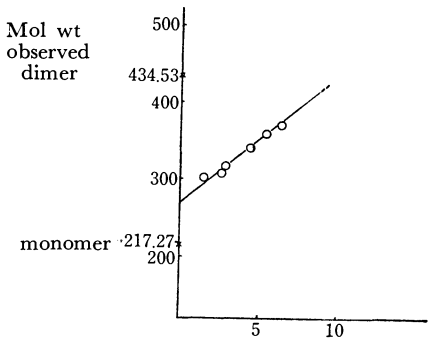


[II]



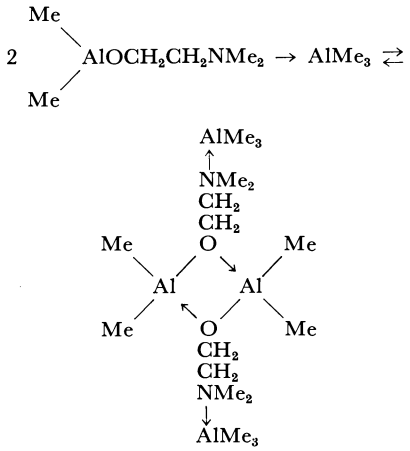
[III]

In order to determine which formula is preferable, the freezing point depression of the benzene solution of the 1 : 1 mixture of $(AlMe_2OCH_2CH_2NMe_2)_2$ and $(AlMe_3)_2$ was measured. The results are shown in Fig. 3. The molecular weight obtained by extrapolation to the infinite dilution is a little larger than the value calculated by assuming the monomeric formula II. If the coordination compound is a mixture of species represented by formulas II and III, two triplets due to the *O*-methylene group should be expected, but only one triplet is observed. Therefore the coordination compound might exist in an equilibrium represented by Eq. (1) in the benzene solution.



$AlMe_2OCH_2CH_2NMe_2 \rightarrow AlMe_3$ wt%
$(AlMe_2OCH_2CH_2NMe_2\ 50\pm2$ mol%)

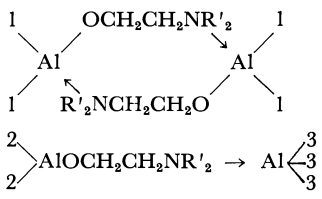
Fig. 3. Concentration dependence of molecular weight of the coordination compound $AlMe_2OCH_2CH_2NMe_2 \rightarrow AlMe_3$.



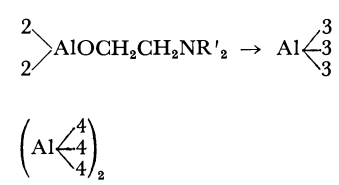
(1)

Although the possibility of the existence of the dimeric species could not be completely excluded, the molecular weight extrapolated to infinite dilution apparently suggests the predominance of monomeric species; so, in the following discussion, the structure of the coordination compound will be considered as given by formula II (monomeric).

The Redistribution Reactions of the Alkyl Groups. As described previously, there exist the following species in the mixture of $(AlR_2OCH_2CH_2NR'_2)_2$ and $(AlR''_3)_2$ depending on the molar ratio.



when $(AlR_2OCH_2CH_2NR'_2)_2$ is in excess



when $(AlR''_3)_2$ is in excess

(The numbers 1, 2, 3 and 4 mean the sites to be occupied by the Al–R groups. For example, the methyl group at site 1 will be hereafter abbreviated as 1-Me.)

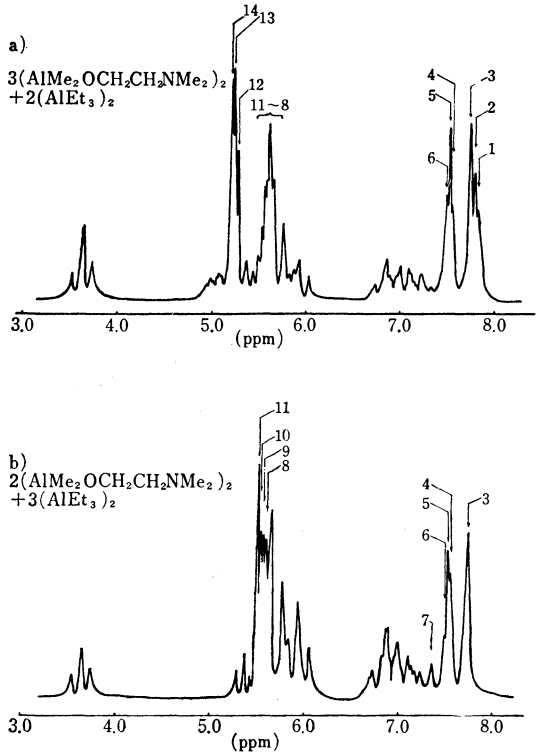


Fig. 4. The NMR spectra of the mixtures of $(AlMe_2OCH_2CH_2NMe_2)_2$ and $(AlEt_3)_2$.

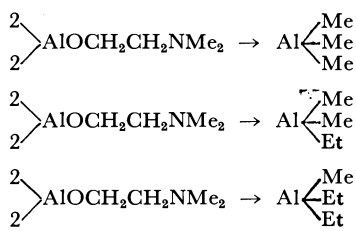
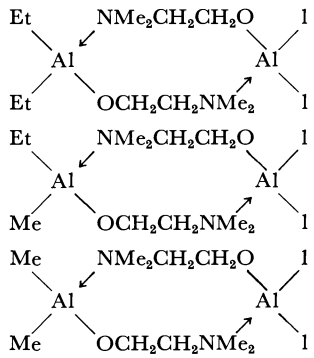
When R differs from R″, the redistribution of the alkyl groups is observed in the NMR spectra. The NMR spectra of the benzene solutions of the mixtures of $(AlMe_2OCH_2CH_2NMe_2)_2$ and $(AlEt_3)_2$ are shown in Figs. 4a and 4b. If the redistribution of the alkyl groups does not take place, 3-Me peak would not be observed. In Figs. 4a and 4b, however, the 7.56 ppm peak is reasonably assigned to the 3-Me by taking the assignments of the spectrum of the mixture of $(AlMe_2OCH_2CH_2NMe_2)_2$ and $(AlMe_3)_2$ into consideration. These observations show clearly the existence of the redistribution of the Al-R groups.

The 3-Me group gives a fine structure of three peaks corresponding to the following formulas respectively as the result of the redistribution of



the alkyl groups. Also, the 5.28 ppm peak due to the N-Me group in $(AlRR'OCH_2CH_2NMe_2)_2$ gives a fine structure of three peaks corresponding to the following formulas respectively.



These fine structures of the N-Me group owing to the redistribution of the Al-R groups provide a strong evidence that N atom in $(AlR_2OCH_2CH_2NR'_2)_2$ coordinates to the Al atom and supports the conclusion reported as to the structures of these compounds in Ref. 7. The assignments of the N-Me and Al-Me groups in Figs. 4a and 4b are summarized in Table 1.

Table 1. The assignments of the Al-Me and N-Me peaks in the NMR spectra of the mixtures of $(AlMe_2OCH_2CH_2NMe_2)_2$ and $(AlEt_3)_2$

No. of peak	Assignment	Chemical shift*
1	1-Me ($AlEtMe$)	7.85
2	1-Me ($AlMe_2$)	7.83
3	2-Me ($AlMe_2$+$AlEtMe$)	7.77
4	3-Me ($AlEt_2Me$)	7.58
5	3-Me ($AlEtMe_2$)	7.57
6	3-Me ($AlMe_3$)	7.56
7	4-Me	7.38
8	N-Me (NMe_2 → $AlMe_3$)	5.63
9	N-Me (NMe_2 → $AlEtMe_2$)	5.60
10	N-Me (NMe_2 → $AlEt_2Me$)	5.58
11	N-Me (NMe_2 → $AlEt_3$)	5.55
12	N-Me (NMe_2 → $AlMe_2O$-)	5.28
13	N-Me (NMe_2 → $AlEtMeO$-)	5.26
14	N-Me (NMe_2 → $AlEt_2O$-)	5.24

* ppm from benzene peak.

In the mixture of $(AlMe_3)_2$ and $(AlEt_3)_2$, a rapid exchange of the alkyl groups is observed, and it has been shown that the methyl group prefers to occupy the bridge position from six to seven times as much as the ethyl group.[8] In the system under investigation, there are four sites to be occupied by the alkyl groups. To see if such a selectivity exists among the four sites as observed in the system of $(AlMe_3)_2$ and $(AlEt_3)_2$, the distribution of the methyl group among the four sites was measured. The results are shown in Figs. 5a and 5b. The dotted lines are theoretical curves obtained by as-

suming that the methyl and ethyl groups distribute to the four sites at random and expressed by the following equations. We have for the mixture of $(AlMe_2OCH_2CH_2NMe_2)_2$ and $(AlEt_3)_2$

$$y = \frac{200x}{300-x}, \tag{2}$$

and for the mixture of $(AlEt_2OCH_2CH_2NMe_2)_2$ and $(AlMe_3)_2$

$$y = \frac{300(100-x)}{300-x}, \tag{3}$$

where x is molar ratio (per cent) of $(AlR_2OCH_2CH_2NMe_2)_2$ and y is the ratio (per cent) of the methyl group. The agreement of the experimental data with the theoretical curves (Fig. 5) shows that the methyl and ethyl groups distribute to the four sites at random.

The Exchange Reactions of the Alkyl Groups. After the redistribution reaction took place, the rapid exchange of the alkyl group is not observed at room temperature except for the 4-alkyl group. Chemical shifts of the 4-Me signals in the mixture of $(AlR_2OCH_2CH_2NMe_2)_2$ and $(AlR''_3)_2$ are shown in Fig. 6. These tendencies observed in Fig. 6 could be explained according to the fact that the methyl group prefers to occupy the bridge position from six to seven times as much as the ethyl group in the mixture of $(AlMe_3)_2$ and $(AlEt_3)_2$.

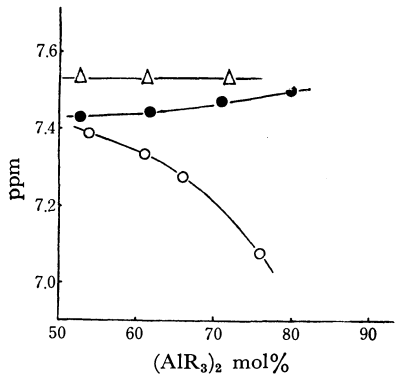

Fig. 6. Chemical shifts of the 4-Me signals in the mixture of $(AlR_2OCH_2CH_2NMe_2)_2$ and $(AlR''_3)_2$.

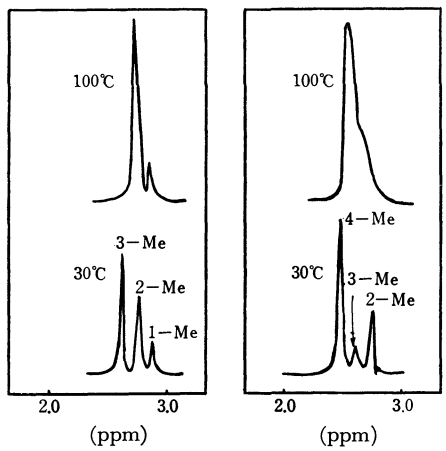
○ $(AlMe_2OCH_2CH_2NMe_2)_2+(AlEt_3)_2$

When the temperature of the system is raised to 100°C, the rapid exchanges of the alkyl groups are observed except for the 1-alkyl group. The NMR spectra of the Al-Me group of the mixtures of $(AlMe_2OCH_2CH_2NMe_2)_2$ and $(AlMe_3)_2$ are shown in Figs. 7a and 7b. In Fig. 7a, the 2-Me



a) $3(AlMe_2OCH_2CH_2NMe_2)_2 + 2(AlMe_3)_2$
b) $(AlMe_2OCH_2CH_2NMe_2)_2 + 4(AlMe_3)_2$

and the 3-Me peaks coalesce into a single peak, while the 1-Me peak only broadens slightly. This fact suggests that the 1-alkyl group is less mobile than the alkyl groups at any other site.

The authors are indebted to Dr. Osamu Yamamoto and Miss Kikuko Hayamizu of the Government Chemical Industrial Research Institute, Tokyo, and to Professors Takehiko Shimanouchi and Ichiro Nakagawa of the University of Tokyo for valuable discussions.

They would also like to express their thanks to Mr. Tsutomu Kinoshita for his continued interest in this work.

Thermal Decomposion Reactions of Chromium(III) Complexes. Hexammine, Chloropentammine and *cis*-Dichlorotetrammine Complexes

Nobuyuki TANAKA

Department of Chemistry, Faculty of Science, Tohoku University, Katahira-cho, Sendai

and Kenzo NAGASE

Department of Chemistry, College of General Education, Tohoku University, Kawauchi, Sendai

(Received March 14, 1969)

The thermal decomposition reactions of $[Cr(NH_3)_6]Cl_3$, $[CrCl(NH_3)_5]Cl_2$ and *cis*-$[CrCl_2(NH_3)_4]Cl$ in solid state were studied by the manometric, infrared spectroscopic and reflectance spectroscopic methods. The decomposition of these complexes in vacuum was initiated by substitution of an outer-sphere chloride ion for a coordinated ammonia. The rate constants, activation energies and activation entropies of these substitution reactions were obtained and the possible reaction processes were discussed. The products *cis,cis*-$[CrCl_3(NH_3)_3]$ and *cis,trans*-$[CrCl_3(NH_3)_3]$ were obtained on the heating of *cis*-$[CrCl_2(NH_3)_4]Cl$.

The thermal decomposition of ammine complexes of chromium(III) has been extensively investigated. Generally, these complexes were found to lose ammonia upon heating and to form non-electrolytes. Schlesinger *et al.*[1,2] obtained a green insoluble product $[CrCl_3(NH_3)_3]$ on the heating of $[CrCl(NH_3)_5]Cl_2$ in an atmosphere of dry hydrogen chloride but its structure has not been proposed. The complex of the same composition, $[CrCl_3(NH_3)_3]$, had been prepared by Werner and Halben[3] from an aqueous solution, but it was described as a blue-green solid.

Wendlandt and Chou[4] studied the thermal properties of several hexamminechromium(III) complexes by means of thermogravimetric analysis, differential thermal analysis and reflectance spectroscopy. They reported that the decomposition took place according to the equations

$$[Cr(NH_3)_6]X_3 \rightarrow [CrX(NX_3)_5]X_2 + NH_3 \quad (1)$$

$$[CrX(NH_3)_5]X_2 \rightarrow [CrX_3(NH_3)_3] + 2NH_3 \quad (2)$$

$$4[CrX_3(NH_3)_3] \rightarrow 3CrX_3 + CrN + 3NH_4X + 8NH_3 \quad (3)$$

where X represents Cl or Br.

Stembridge[5] prepared the triammine intermediate in an atmosphere of hydrogen chloride, ammonia and nitrogen, and reported that each preparation gave an identical compound as determined by X-ray diffraction and differential thermal analysis.

In the present paper, the kinetic studies of the substitution reaction between a coordinated ammonia and an outer-sphere chloride ion are presented. The formation of the blue and the green type of $[CrCl_3(NH_3)_3]$ on the heating of *cis*-$[CrCl_2(NH_3)_4]Cl$ is described, and their infrared and reflectance spectra are demonstrated.

Experimental

Apparatus and Procedure. Pressure-time curves of amminechromium(III) complexes were obtained with the apparatus reported in a previous paper.[6] The temperature of the furnace was kept within $\pm 0.5°C$. The pressure was measured with an accuracy of 1/100 mmHg by means of a mercury manometer and a microscope. The samples which were smaller than 200 mesh in size weighed 2 to 10 mg in each measurement.

The sample in a small crucible of about 1 m*l* in volume was placed in the reaction tube. The system of about 300 m*l* in volume was evacuated by a rotary pump for 1 hr. Then, the system was closed by operating a cock and the temperature of the furnace was rapidly elevated to that at which the reaction was to be investigated. After the temperature of the sample reached that of the furnace (about 20 min), the change of pressure with time was measured.

Results

$[Cr(NH_3)_6]Cl_3$. Figure 1 shows pressure-time curves which were obtained with various amounts of $[Cr(NH_3)_6]Cl_3$. The initial rate was found to increase linearly with the increase of the sample amount. A series of kinetic runs for $[Cr(NH_3)_6]Cl_3$ in a temperature range from 174°C to 210°C are given in Fig. 2, where the term α means the mole fraction of liberated ammonia to chromium(III) complex. The results in Fig. 2 suggest that $[Cr(NH_3)_6]Cl_3$ liberates one mole of ammonia below 190°C, but three moles of ammonia at higher temperatures. The infrared spectra of the product obtained at 190°C were identical with those of $[CrCl(NH_3)_5]Cl_2$. The product obtained at 210°C was green in color as reported by Schlesinger,[1,2] but was found to be accompanied by a small amount of ammonium chloride. The analytical data of the green compound after being washed with cold water agreed with the calculated values for $[CrCl_3(NH_3)_3]$. These results support the processes of Eqs. (1) and (2) which were reported by Wendlandt.[4] The first-order rate constants for the reaction of Eq. (1) were calculated from the plots given in Fig. 3.

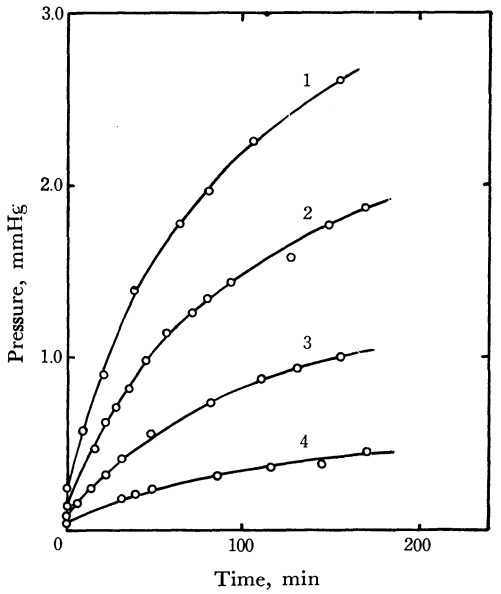

Fig. 1. Reaction rates with various sample amounts for $[Cr(NH_3)_6]Cl_3$ at 178°C.
(1) 15.2, (2) 10.1, (3) 5.0 and (4) 2.2 mg

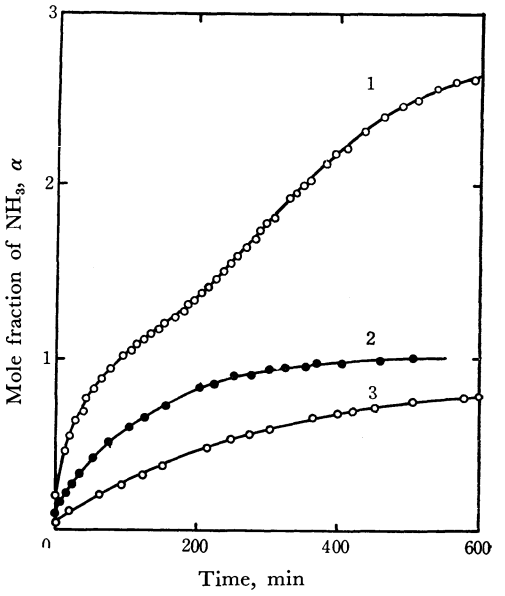

Fig. 2. Fractional decomposition curves of $[Cr(NH_3)_6]Cl_3$ at (1) 210, (2) 190 and (3) 174°C.

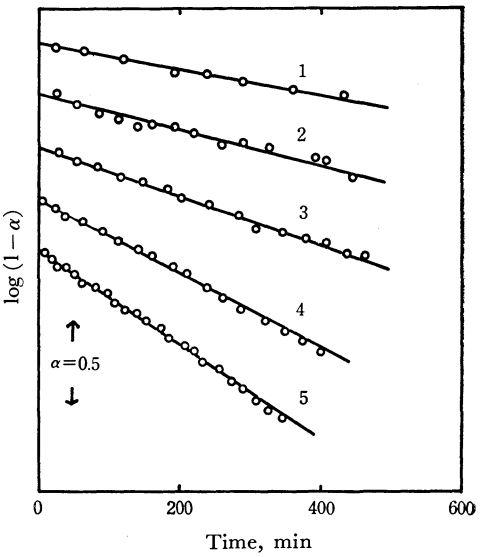

Fig. 3. Plots of the first-order rate function for $[Cr(NH_3)_6]Cl_3$ at (1) 170, (2) 174, (3) 177, (4) 183 and (5) 188°C.

$[CrCl(NH_3)_5]Cl_2$. In Fig. 4 are shown fractional decomposition curves of $[CrCl(NH_3)_5]Cl_2$ measured at various temperatures. The curve at 222°C indicates that $[CrCl(NH_3)_5]Cl_2$ liberates about two moles of ammonia. The product was green and its infrared spectra agreed with those of the product obtained from $[Cr(NH_3)_6]Cl_3$. On the curve at 210°C, however, the inflection point was observed, which suggests that an intermediate such as $[CrCl_2(NH_3)_4]Cl$ exists. In order to detect the intermediate, $[CrCl(NH_3)_5]Cl_2$ was heated at 220°C for 5 hr in a sealed tube. A green product was formed, and when it was treated with cold water, part of it was dissolved to give a green solution, suggesting the formation of *trans*-$[CrCl_2(NH_3)_4]Cl$.

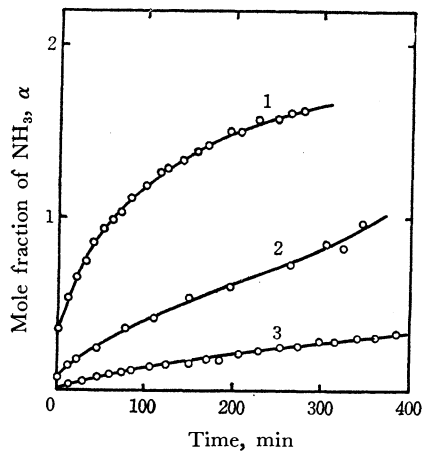

Fig. 4. Fractional decomposition curves of $[CrCl(NH_3)_5]Cl_2$ at (1) 222, (2) 210 and (3) 191°C.

***cis*-$[CrCl_2(NH_3)_4]Cl$.** In Fig. 5 are shown fractional decomposition curves of *cis*-$[CrCl_2(NH_3)_4]Cl$ measured at various temperatures. One mole of ammonia was liberated from *cis*-$[CrCl_2(NH_3)_4]Cl$. The product which was obtained by treating at 153°C for 3 hr was blue and its analytical data agreed with the calculated values for $[CrCl_3(NH_3)_3]$. When this blue compound was heated at 153°C for 3 days, the blue color gradually changed into green without any decomposition. The infrared spectra of both compounds are shown in Fig. 6. The blue compound gives symmetric deformation bands at 1280 and 1255 cm^{-1} and the NH_3 rocking bands at 780, 735 and 700 cm^{-1}, whereas the green compound gives the corresponding bands at 1280 and 735 cm^{-1}, respectively.

The reflectance spectra of both compounds are shown in Fig. 7. The blue compound in solid state has two absorptions at 17200 (the first band) and 23300 cm^{-1} (the second band), whereas the

2.398	f	2.730	m

s, strong; m, medium; f, fine

green compound has three absorptions. The weak absorption in a low energy region (13400 cm^{-1}) may be due to the spin-forbidden transition ($^4A_{2g} \rightarrow {}^2E_g$). The absorptions in the region of the second band split into three parts. The X-ray diffraction pattern of the blue compound was different from that of the green compound as shown in Table 1.

When *cis*-$[CrCl_2(NH_3)_4]Cl$ was heated at 165°C for 10 days in a sealed tube, a product which was partly dissolved in cold water to give a green solution was obtained. This fact suggests that the product contained an electrolyte such as *trans*-$[CrCl_2(NH_3)_4]Cl$.

Discussion

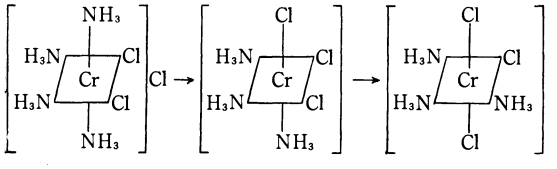
The kinetic parameters of the substitution reactions in solid state are given in Table 2. The order of increasing rates of reaction was as follows:

$$[CrCl(NH_3)_5]Cl_2 < [Cr(NH_3)_6]Cl_3 < cis\text{-}[CrCl_2(NH_3)_4]Cl$$

Table 2. Kinetic parameters for the substitution reaction of some chromium(III) complexes in solid state

Complex	$k \times 10^5$, sec^{-1} (Temp, °C)	E_a kcal/mol	ΔS^* e.u.
$[Cr(NH_3)_6]Cl_3$	4.0(174), 8.5(183)	30	−12
$[CrCl(NH_3)_5]Cl_2$	2.8(198), 7.7(210)	39	1.4
cis-$[CrCl_2(NH_3)_4]Cl$	11 (136), 16 (142)	31	−2.3

From the standpoint of a steric hindrance, *cis*-$[CrCl_2(NH_3)_4]Cl$ may most easily lose ammonia coordinated at the *cis*-position to both chloride ions. This led to the conclusion that trichlorotriammine complex obtained by heating of *cis*-$[CrCl_2(NH_3)_4]Cl$ must have a *cis,cis*-configuration. The *cis,cis*-configuration, however, is less stable than the *cis,trans*-configuration, if a steric hindrance is considered. Therefore, *cis,cis*-$[CrCl_3(NH_3)_3]$ will convert to *cis,trans*-$[CrCl_3(NH_3)_3]$ by heating for a long time.



These considerations suggest that the blue and the green compounds obtained in the present study correspond to *cis,cis*-$[CrCl_3(NH_3)_3]$ and *cis,trans*-$[CrCl_3(NH_3)_3]$, respectively. The reflectance spectra shown in Fig. 7 also support the above consideration, *i. e.*, the absorption bands of the blue compound are symmetrical and their maxima are at higher frequencies than those of the absorption bands of the green compound.

Hexamminechromium(III) chloride had a small activation entropy, which suggests the possibility of a seven-coordinated activated complex. If the substitution reactions of hexammine complexes take place through a seven-coordinated state, kinetic parameters must be strongly influenced by an outer-sphere ion. Actually, the results obtained with $[Cr(NH_3)_6]Cl_3$ greatly differed from those obtained with $[Cr(NH_3)_6]Br_3$. The kinetic parameters for $[Cr(NH_3)_6]Br_3$ are:

$$k = 2.2 \times 10^{-5}\ sec^{-1} \text{ at } 192°C,$$
$$E_a = 43\ kcal/mol$$
and $$\Delta S^* = 12\ e.u.$$

From the above results and consideration, possible reaction processes of ammine chromium(III) complexes could be represented as follows:

$$[Cr(NH_3)_6]Cl_3 \xrightarrow{-NH_3} [CrCl(NH_3)_5]Cl_2 \xrightarrow{-NH_3}$$

$$\underset{\text{cis,trans-}[CrCl_3(NH_3)_3]}{\text{trans-}[CrCl_2(NH_3)_4]Cl} \xrightarrow[-NH_3]{\text{isomerization}} \underset{\text{cis,cis-}[CrCl_3(NH_3)_3]}{\text{cis-}[CrCl_2(NH_3)_4]Cl}$$

(A) (B)

However, the formation of *trans*-$[CrCl_2(NH_3)_4]Cl$ is not yet confirmed. As the process (B) was strongly depressed by the pressure of ammonia, *cis,cis*-$[CrCl_3(NH_3)_3]$ was obtained only by heating in vacuum. Therefore, the process (A) takes place to a considerable extent when *cis*-$[CrCl_2(NH_3)_4]Cl$ is heated under the pressure of ammonia.

The authors wish to express their thanks to Mr. Yoroshi Tsuda in the arrangement of the apparatus. They also thank the Ministry of Education for financial support.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 2858—2862 (1969)

Nitrosyl Complexes of Bis(acetylacetone)-, and Bis(benzoylacetone)-ethylenediimine Cobalt(II)

Motonori TAMAKI, Isao MASUDA and Koichiro SHINRA

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamada, Suita, Osaka

(Received March 27, 1969)

Square, planar bis(acetylacetone)-, and bis(benzoylacetone)-etylenediimine-Co(II) chelates with a low-spin d^7 electron structure yield nitrosyl complexes with the chelate : NO molar ratio of 1 : 1. On the basis of the IR spectra and the NMR spectra, and on the basis of molecular-weight determinations, these nitrosyls have been considered as being penta-coordinate cobalt complexes with square-pyramidal configuration. The nitrosyls are diamagnetic, indicating an electron-pairing bond between the central Co(II) and the NO molecule. The NO groups in these nitrosyls have been postulated to be predominantly neutral. In the electronic spectra, these penta-coordinate, diamagnetic Co(II) complexes show a characteristic absorption band at 18—20×10^3 cm^{-1} with $\log\varepsilon\fallingdotseq3$.

The transition metal complexes of the bis(acetylacetone)-ethylenediimine Schiff base are considered to undergo two types of reaction with nitric oxide: i) at γ-carbon atoms in the chelate rings, and ii) at the central metal atom. The nickel(II) and palladium(II) complexes, in which the central metal ion has a spin-paired, d^7 electron structure, have already been shown to react with nitric oxide to produce oxime-type complexes such as are shown in Fig. 1.[1] This type of complex may be regarded as a product of i reaction.

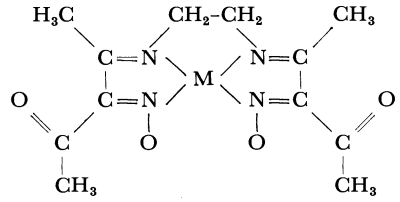


Fig. 1. M=Ni(II), Pd(II), Cu(II)

In the present work, divalent, low-spin cobalt(II) complexes with one unpaired electron will be shown to react with nitric oxide to form nitrosyl complexes, which are regarded as products of the ii reaction. These nitrosyl complexes are diamagnetic, and they are supposed to be penta-coordinate, square-pyramidal Co(II) complexes (Fig. 4) where the Co-NO bonding is essentially a σ-bond formed by one unpaired electron of NO and one of Co(II).

A copper(II) chelate with bis(acetylacetone)-ethylenediimine possessing one unpaired electron on the central metal ion yields either nitrosyl- or oxime-type complexes, depending on the experimental conditions.[1,2]

Experimental

Materials. *The bis(acetylacetone)ethylenediimine*, AEH_2 *and bis(benzoylacetone)ethylenediimine*, BEH_2*[1] were prepared according to the method of the literatures.[3,4] AEH_2; recrystallized from water, mp 110—110.7°C. BEH_2; recrystallized from ethanol, mp 179.5—180.5°C.

Bis(acetylacetone)ethylenediimino-Co(II),[3] CoAE; purified by recrystallization from hot ether and then dried at 100°C *in vacuo* over P_2O_5; reddish yellow crystals.

Bis(benzoylacetone)ethylenediimino-Co(II),[4] CoBE; recrystallized from an acetone or benzene solution, and dried *in vacuo* over P_2O_5, at room temperature.

The nitric oxide was generated and purified by the method reported previously.[1]

Preparations of Nitrosyl Complexes. *Bis(acetylacetone)ethylenediimino-nitrosyl-cobalt(II)*, $Co^{II}AENO$.*[1] The complex can be prepared by the following three methods:

A) 2.8 g (0.01 mol) of CoAE were dissolved in 50 m*l* of dichloromethane. Nitric oxide was bubbled through this solution with ice cooling for about half an hour, by which time the solution had turned from reddish yellow to brown. Then, the nitric oxide in the solution was expelled with nitrogen gas. The addition of 250 m*l* of petroleum ether to the solution gave a precipitate of brownish-black compounds, which were then purified by recrystallization from a large volume of ether to give black crystals (complex I). The complex I is insoluble in water, and soluble in such

** Prepared by method C

common organic solvents as ether, chloroform, dimethylformamide, and dimethyl sulfoxide. The results of the elementary analysis given in Table 1 correspond to that of the formula shown in Fig. 4.

B) CoAE, in the solid state, absorbs nitric oxide and yields the nitrosyl complex. Crystalline CoAE was allowed to stand in a nitric oxide atmosphere under a pressure of 760 mmHg, and at room temperature. The CoAE thereupon took up the nitric oxide and turned brownish-black. The recrystallization of this product from ether gave black crystals. Elementary analyses and a study of the IR spectrum indicated that the black compound obtained was identical with the complex I prepared by the method A.

C) The complex I was most expeditiously prepared by the following procedure. 2.5 g (0.01 mol) of cobaltaous acetate tetrahydrate were dissolved in 50 m*l* of methanol, and the air was expelled from the solution and reaction flask by flushing with nitrogen. Then the solution, with ice cooling, was saturated with nitric oxide until it had turned from a reddish violet to a dark violet. Then AEH_2 (2.3 g, 0.01 mol) dissolved in 50 m*l* of acetone was stirred into this dark-violet solution, drop by drop. The solution thereupon turned black. The nitric oxide in the solution was then driven off by nitrogen. The addition of petroleum ether to the solution gave a black precipitate of the crystalline, nitrosyl complex. The complex was proved by elementary analyses and by a study of the IR spectral data to be identical with the complex I.

Bis(benzoylacetone)ethylenediimino-nitrosyl-cobalt(II), Co^{II}-BENO.*[1] This complex was prepared according to the method C. In this case, however, because of the poor solubility of BEH_2, 3.5 g (0.01 mol) of it were suspended in 50 m*l* of acetone; then the mixture was saturated with nitric oxide, followed by the addition of 2.5 g (0.01 mol) of cobaltous acetate tetrahydrate in 50 m*l* of methanol. The black precipitate was recrystallized from acetone to give 2 g of black needles (complex II). The elementary analyses agreed with the formula shown in Fig. 4. The complex II is insoluble in water and soluble in common organic solvents, but it is, unlike the complex I, insoluble in ether.

Bis(salicylaldehyde)enthylenediimino - nitrosyl - cobalt(II), Co^{II}(Salen)NO.*[2] This complex has already been presented by Earnshaw *et al.*[5] In the present study it was prepared according to the method C. The complex obtained showed, in its IR spectrum, the same characteristic frequencies as those reported by Earnshaw,[5] and the analysis of the complex agreed with the structure written above.

Measurements and Results

Molecular weight was determined in chloroform solution at 25°C, with a Mechrolab vapor pressure osmometer 302. The results are listed in Table 2.

The magnetic measurements were carried out at room temperature by the Gouy method, using an aqueous nickel(II) chloride solution as the standard. The magnetic susceptibilities obtained at 20°C for solid samples were; -0.42×10^{-6} emu/g for the complex I, and -0.39×10^{-6} emu/g for the complex II. These values indicate that the complexes are diamagnetic.

Table 2. Molecular weight in $CHCl_3$

	Calcd*	Found
Complex I	311	303
Complex II	435	429

* Calculated on the basis of the formula shown in Fig. 4.

The thermogravimetric analysis (TGA) and the differential thermal analysis (DTA) were carried out by using a Rigakudenki thermobalance at a heating rate of about 2°C/min. The curves thus obtained are shown in Figs. 2 and 3. In the TGA curve of the complex I, the weight loss of

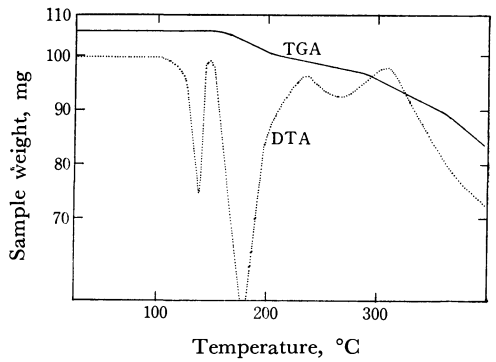

Fig. 2. DTA and TGA curves of complex I.

5) A. Earnshaw, P. C. Hewlett and L. F. Larkworthy, *J. Chem. Soc.*, **1965**, 4718.

about 9% observed between 160°C—200°C corresponds to the calculated value of 9.7%; the weight loss is assumed to be caused by the loss of the nitric oxide in the complex (Fig. 4). In the case of the complex II, no weight loss was observed below 200°C, as is shown in Fig. 3, indicating that the complex II is more stable than the complex I.

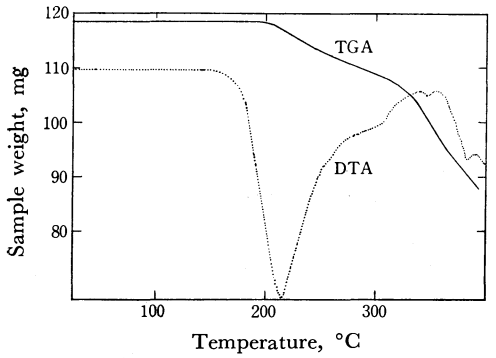

Fig. 3. DTA and TGA curves of complex II.

The NMR spectra were obtained with a Japan Electron Optics JNM-3H-60 spectrometer, at 60 Mc/sec, using tetramethylsilan (TMS) as the internal reference. The NMR spectrum of complex I in a 5 wt% $CDCl_3$ solution is, in Fig. 5, compared to the spectrum of the NiAE complex.

The IR spectra were measured in Nujol or in hexachlorobutadiene, using a Hitachi EPI-2G spectrometer for the 4000—650 cm^{-1} region. The IR spectra obtained for the complex I and II are shown in Figs. 6 and 7. The electronic absorption spectra of the complexes I and II, which were determined in chloroform using a Hitachi EPS-3 spectrophotometer, are shown in Fig. 8.

Discussion

The elementary analyses for the complexes I and II agreed well with those of the mono-nitrosyl derivatives of CoAE and CoBE respectively, as is shown in Fig. 4. The molecular weight, determined in chloroform, is consistent with this formula:

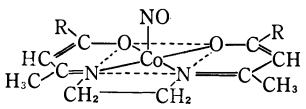

Fig. 4. Complex I: $R=CH_3$
Complex II: $R=C_6H_5$

NMR and IR Spectra. The above formulation of the complexes was examined further by the following considerations of the NMR and IR spectral evidence. As may be seen in Fig. 5, the NMR spectra of the complex I in $CDCl_3$ shows four peaks, at τ; 5.1, 6.5, 7.8, and 7.95, with an integral

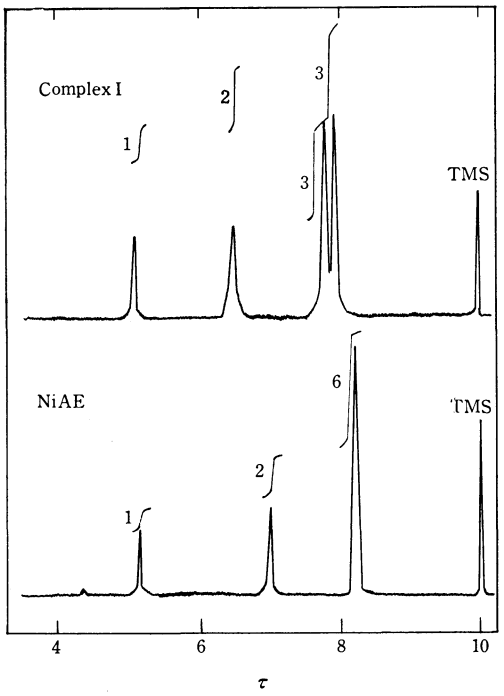

Fig. 5. NMR spectra of complex I and NiAE.

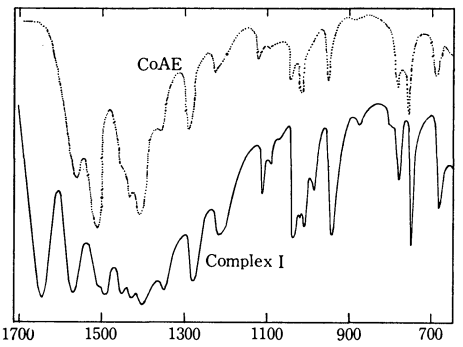

Fig. 6. IR spectra of complex I and CoAE.

ratio of 1 : 2 : 3 : 3 from the lower-side field. The features of this spectrum are quite similar to those of NiAE or $[CoAE(NH_3)_2]Cl$;[6] the above four resonances may, therefore, be assigned to the CH group, to the CH_2CH_2 group, and to two types of CH_3 groups of the complex (Fig. 4, $R=CH_3$) respectively.

A comparison of the IR spectrum of the complex I in the 1700—700 cm^{-1} range with that of the CoAE indicates that, as is shown in Fig. 6, the complex I has essentially the same pattern of frequencies as the CoAE, with the exception of a

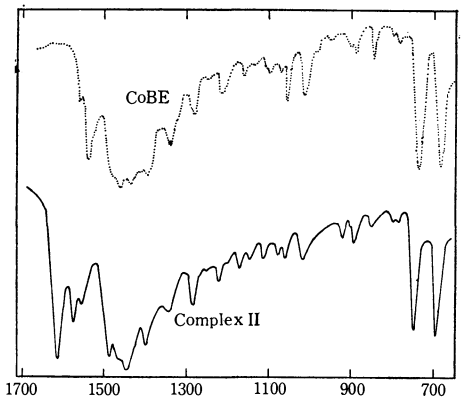

Fig. 7. IR spectra of complex II and CoBE.

new frequency at 1654 cm^{-1}. Similarly, the complex II shows the same frequencies as those of the CoBE except for a new frequency at 1635 cm^{-1}, as may be seen in Fig. 7. The new frequencies will be discussed later as being due to the nitric oxide group in the complexes (Fig. 4).

Thus, from the above-described NMR and IR spectral evidences and from the analytical results, we may assume such a nitrosyl structure for the two complexes, I and II, as is shown in Fig. 4, where the cobalt atom in the planar chelate is bound to a nitric oxide group to form a penta-coordinate, square pyramidal configuration. The nitrosyl complexes are monomeric in chloroform and contain, in the solid state, no solvent, as is indicated by the TGA curves (Figs. 2 and 3).

Most of the nitrosyl complexes have so far been characterized by a strong, nitrosyl-stretching frequency. Lewis *et al.*[7] have surveyed numerous nitrosyl complexes of transition metals on the basis of the nitrosyl frequencies in the IR spectra. In general, the position of the nitrosyl frequency is susceptible to the electronic structure of the nitrosyl group in the complex and to the nature of the central metal ion. For example, the NO frquency is observed at 1626 cm^{-1} for $\{(CH_3)_2NCS_2\}_2CoNO$, at 1673 cm^{-1} for $\{(C_2H_5)_2NCS_2\}_2FeNO$, and at 1845 cm^{-1} for $\{(CH_3)_2NCS_2\}_3RuNO$.[7] Hecne, it would be more appropriate to take into account analogous nitrosyl complexes containing the same metal ion when the nitrosyl frequency is taken as an indication of the structure of the complex. Table 3 lists the cobalt-nitrosyl complexes, along with the positions of their NO stretching frequencies. As can be seen in this table, most of these nitrosyl complexes, which are apparently penta-coordinate and diamagnetic, show the characteristic NO frequency in the 1623—1705 cm^{-1} range. As has been described before, the complexes I and II, which are penta-coordinate and diamagnetic, show new absorption bands at 1654 and 1635 cm^{-1} respectively. These new bands can reasonably be assigned to the NO stretching frequency on the basis of the facts presented in Table 3.

Lewis *et al.*[7] postulated two types of NO groups existing in complexes; the $(NO)^-$ anion which shows a $(NO)^-$ stretching frequency at around 1200 cm^{-1}, exemplified by $[Co(8\text{-aminoquinoline})_2NO]Cl_2$ (Table 3), and the $(NO)^+$ cation which is said to show a characteristic frequency over the

wide range from 1626 to 1938 cm^{-1}.[7] Accepting their point of view, the complexes I and II should contain $(NO)^+$ and, consequently, Co(I). However, the complexes are actually more stable than Co(I) complexes might be expected to be. The polarographic behavior*3 indicated that these complexes contained neutral NO and Co(II). Thus, it seems more probable to ascribe the new bands observed at 1654 or 1635 cm^{-1} in the present complexes to the stretching frequency of predominantly neutral NO. The NO molecule shows the stretching frequency at 1878 cm^{-1},[15] and one would expect a shift towards the lower-wave number region upon complexation. On the other hand, the nitrosonium ion $(NO)^+$ is known to show the frequency at $\sim$2220 cm^{-1}.[16] Therefore, in the case of the nitrosyl complexes that shown the NO frequency in the wave number region higher than 1878 cm^{-1}, the NO group may be regarded as being $(NO)^+$, as is seen in $[Fe^{II}(CN)_5(NO)]^{2+}$ (1938 cm^{-1}).[7] As far as cobalt-nitrosyls are concerned, there are but a few examples which show NO frequencies in a wave number region higher than 1800 cm^{-1}.[7]

Electronic Spectra. It has been well established that the electronic absorption spectra in the near-infrared region of Co(II) complexes are informative of the structure of the complexes. Nishikawa and Yamada[17] established that the square-planar Co(II) complexes with one unpaired electron exhibit a sharp peak at about 8.3×10^3 cm^{-1} ($\log\varepsilon\fallingdotseq1.3$). As may be expected from the above fact, the CoBE shows a sharp peak at 8.7×10^3 cm^{-1} ($\log\varepsilon\fallingdotseq1.3$), as is shown in Fig. 8. On the contrary, a similar absorption band is not

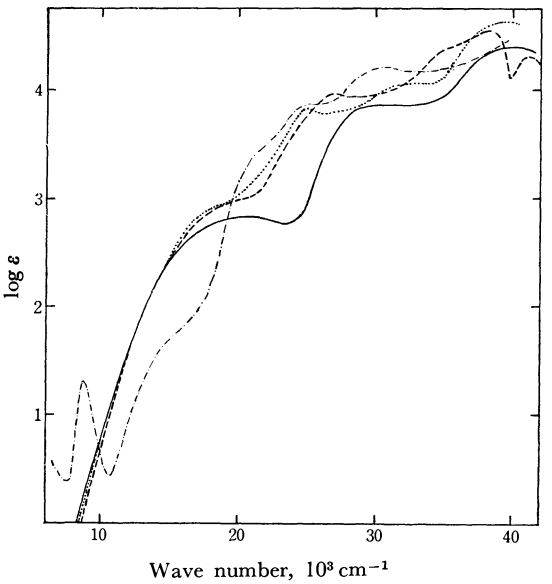

Fig. 8. Electronic spectra of complex I, complex II, Co(Salen)NO and CoBE.

——— Complex I ----- Complex II
..... Co(Salen)NO —·—· CoBE

observed for either complex, I or II (Fig. 8), suggesting that the complexes have a symmetry different from that of the planar configuration of the parent complexes. This is consistent with the anticipation from the diamagnetic properties of the complexes I and II. As to the Co(Salen)NO*2, an absorption band representative of square-planar, low spin Co^{II}(Salen)[17] was not observed either. In the case of these nitrosyl complexes, an absorption band with $\log\varepsilon\fallingdotseq2.8$ appeared at 18—20×10^3 cm^{-1}; this may be considered to be characteristic of the diamagnetic Co(II) complexes with square-pyramidal configuration. It is of interest to note that penta-coordinate alkyl derivatives of bis(acetylacetone)ethylenediimine cobalt complexes with a square-pyramidal configuration are reported to show absorption maxima at about 15×10^3 cm^{-1} ($\log\varepsilon\fallingdotseq2.9$).[18]

*3 The polarogram of the CoBE in DMF gave a one-step reduction wave at -1.46 V (applied potential), whereas the complex II gave a two-step reduction wave, one step at -1.04 V which can be ascribed to the reduction of NO in the complex and one at -1.43 V that is almost equal to that (-1.46 V) of CoBE and which can be ascribed to the reduction of Co(II) in the complex. The details will be published later.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 2863—2869 (1969)

Absorption Spectra and Circular Dichroisms of Metal Complexes. IV.*1 Dichloro-diamine Type Complexes of Platinum(II) and Palladium(II)

Haruko Ito, Junnosuke Fujita and Kazuo Saito

Department of Chemistry, Faculty of Science, Tohoku University, Katahira-cho, Sendai

(Received April 3, 1969)

Absorption (AB) spectra of dichloro(*l*-tetrahydrogenpropylenediaminetetraacetato)platinum-(II) and palladium(II) and dichloro(*d*-hydrogendiaminopropionato)platinum(II) and palladium(II) were interpreted on the basis of a comparison of their circular dichroism (CD) spectra with those of dichloro(*l*-propylenediamine)platinum(II) and palladium(II). The *d-d* bands of $edtaH_4$ and *l*-$pdtaH_4$ complexes shifted to longer wavelength as compared with those of *l*-pn complexes. The shift was discussed, based on the effects of the weaker ligand field strength and apical interaction of the acetato groups of these ligands.

In the first paper of this series,[1] we examined the absorption spectra of dichloro(*l*-propylenediamine)-platinum(II) and palladium(II)*2 and found that the analysis of ciruclar dichroism spectra gave useful information about the assignment of the absorption bands of these metal complexes. Bailar and Busch[2] prepared dichloro(tetrahydrogen-ethylenediaminetetraacetato) platinum(II) and palladium(II) pentahydrate, $[PtCl_2(edtaH_4)]\cdot 5H_2O$ and $[PdCl_2(edtaH_4)]\cdot 5H_2O$, and predicted that ethylenediaminetetraacetic acid coordinated to the metal ions as a bidentate ligand. The structure was recently confirmed by X-ray analysis for the palladium compound.[3] However, no spectroscopic study of such complexes has been reported. In this paper AB and CD spectra of $[PtCl_2(l\text{-}pdtaH_4)]\cdot 5H_2O$ and $[PdCl_2(edtaH_4)]\cdot 5H_2O$ are interpreted by comparing them with those of dichloro-diamine complexes of platinum(II) and palladium(II).

Experimental

Ligands. *l*-Propylenediamine was obtained by resolving its commercial racemate.[4] *l*-Propylenediaminetetraacetic acid and *d*-diaminopropionic acid were prepared according to Dwyer's[5] and Karrer's[6] method, respectively.

Preparations of the Complexes. *(1) Dichloro-(l-tetrahydrogenpropylenediaminetetraacetato) platinum(II) pentahydrate*, $[PtCl_2(l\text{-}pdtaH_4)]\cdot 5H_2O$ and *dichloro (l-tetrahydrogenpropylenediaminetetraacetato)palladium(II) pentahydrate*, $[PdCl_2(l\text{-}pdtaH_4)]\cdot 5H_2O$ were prepared by Busch and Bailer's method[2] for the corresponding $edtaH_4$ complexes.

Found: C, 19.94; H, 4.69; N, 4.02%. Calcd for $C_{11}H_{28}N_2O_{13}Cl_2Pt$: C, 19.95; H, 4.26; N, 4.88%.

Found: C, 22.42; H, 5.32; N, 5,12%. Calcd for $C_{11}H_{28}N_2O_{13}Cl_2Pd$: C, 23.03; H, 4.92; N, 4.88%.

(2) Dibromo(l-tetrahydrogenpropylenediaminetetraaceta-to)platinum(II), $[PtBr_2(l\text{-}pdtaH_4)]$, was obtained by recrystallizing $[PtCl_2(l\text{-}pdtaH_4)]$ twice from hot 3 M hydrobromic acid.

Found: C, 19.86; H, 3.44; N, 3.95%. Calcd for $C_{11}H_{18}N_2O_8Br_2Pt$: C, 19.98; H, 2.74; N, 4.24%.

(3) Dichloro(d-hydrogendiaminopropionato)platinum(II) $[PtCl_2(d\text{-}dampH)]$. A mixture of 1 g of $K_2[PtCl_4]$, 0.34 g of *d*-diaminopropionic acid monohydrochloride and 0.33 g of K_2CO_3 in 30 ml of water was heated on a water bath at 80°C for two hours and then cooled to room temperature. Purple crystals of Magnus type salt produced during the reaction were filtered off and the filtrate was evaporated to dryness on a water bath. The residue was dissolved in a minimum amount of hot water and filtered. To the filtrate were added a few drops of concentrated hydrochloric acid. Yellow crystals were formed on cooling. They were recrystallized from 2 M hydrochloric acid.

Found: C, 9.83; H, 2.52; N, 7.50%. Calcd for $C_3H_8N_2O_2Cl_2Pt$: C, 9.74; H, 2.18; N, 7.57%.

(4) Dichloro(d-hydrogendiaminopropionato)palladium(II), $[PdCl_2(d\text{-}dampH)]$. Five hundred milligrams of

6) P. Karrer and A. Schlosser, *Helv. Chim. Acta*, **6**, 415 (1913).

$K_2[PdCl_4]$ was dissolved in a small amount of water, and then 0.25 g of *d*-diaminopropionic acid monohydrochloride in 5 m*l* of water was added dropwise with stirring. A gelatinous substance appeared, and crystallized gradually. The product was filtered off, washed with cold water, ethanol and ether.

Found: C, 13.25; H, 3.05; N, 9.68%. Calcd for $C_3H_8N_2O_2Cl_2Pd$: C, 12.80; H, 2.80; N, 9.95%.

(5) Dichloro(dihydrogenethylenediaminediacetato)palladium(II), $[PdCl_2(eddaH_2)]$. An aqueous solution containing 1 g of $K_2[PdCl_4]$ and 0.54 g of ethylenediaminediacetic acid was heated on a water bath (about 80°C) for half an hour and cooled. Orange yellow precipitate was filtered off, dissolved in hot water, cooled to room temperature rapidly, and treated with several drops of concentrated hydrochloric acid, the wall of the vessel being scratched to induce crystallization. The crystals were filtered off, and washed with cold water, ethanol and ether.

Found: C, 20.83; H, 3.49; N, 7.79%. Calcd for $C_6H_{12}N_2O_4$: C, 20.39; H, 3.42; N, 7.93%.

(6) Dichloro(N, N'-dimethylethylenediamine)palladium(II), $[PdCl_2(NN'\text{-Meen})]$. One gram of $[Pd(NN'\text{-Meen})_2]Cl_2$, which was obtained by a similar method to that described for $[Pd(en)_2]Cl_2$, was dissolved in 3 m*l* of water, and treated with 3 m*l* of concentrated hydrochloric acid under cooling in an ice bath. The solution was filtered to remove a small amount of unknown product, and then ethanol was added to the filtrate. Orange yellow precipitate was filtered off. Chemical analysis of the product shows the following compound, $[PdCl_2(NN'\text{-MeenH})_2]Cl_2$. Found: C, 22.59; H, 5.77; N, 13.22%. Calcd for $C_8H_{24}N_4Cl_4Pd$: C, 22.74; H, 5.25; N, 13.26%. This was dissolved in a small amount of hot water and cooled to room temperature, and treated with 6 M hydrochloric acid to produce 0.5 M hydrochloric acid solution. Orange yellow crystals precipitated on cooling. They were filtered off, and washed with water, ethanol and ether.

Found: C, 18.60; H, 4.39; N, 10.58%. Calcd for $C_4H_{12}N_2Cl_2Pd$: C, 18.24; H, 3.83; N, 10.63%.

Other complexes were prepared according to the methods described in literature.[1,7,8]

Measurements. Visible and ultraviolet absorption spectra were obtained with a Hitachi 124 recording spectrophotometer. The CD curves were recorded with a Model ORD/UV-5 spectrophotometer of Japan Spectroscopic Co. with its CD attachment. The diffuse reflectance spectra were measured with a Hitachi EPU-2A spectrophotometer with appropriate attachment. All the measurements were made at room temperature.

To avoid the aquation of coordinated halides, dichlorodiamine platinum(II) complexes were dissolved in 2 M hydrochloric acid, $[PtBr_2(l\text{-pn})]$ in 2 M hydrobromic acid, $[PtBr_2(l\text{-pdtaH}_4)]$ in 3 M hydrobromic acid and dichloro-diamine palladium(II) complex in 0.2 M potassium chloride solution, unless otherwise stated.

Proton magnetic resonance (PMR) spectra were measured with a Varian A-60 spectrometer in deuterated methanol, with tetramethylsilane (TMS) as internal reference. For the PMR measurement, the complex $[PtCl_2(edtaH_4)]\cdot 5H_2O$ and $[PdCl_2(edtaH_4)]\cdot 5H_2O$ were dehydrated at 60°C *in vacuo*.

Results and Discussion

The AB and CD spectra of the complexes are shown in Figs. 1—6. Numerical data are summarized in Tables 1—3.

Complexes Containing *d*-Diaminopropionic Acid. The infrared absorption spectra indicate that the *d*-diaminopropionic acid of $[PtCl_2(d\text{-dampH})]$ and $[PdCl_2(d\text{-dampH})]$ coordinates through two amino groups, though it is a potential terdentate ligand with two amino groups and a carboxyl group;[9] the band at 1754 cm^{-1} must correspond to antisymmetric stretching frequency of uncoordinated carboxylic acid.

The absolute configuration of this ligand is compared with that of D-(−)$_D$-propylenediamine in Fig. 7. Recent conformational analysis on the

basis of PMR study[10] has shown that in diamagnetic cobalt(III), palladium(II) and platinum(II) complexes, the *l*-propylenediamine coordinates to the metal ions to form a fixed λ-gauche chelate with the methyl group equatorial direction to the chelate ring even in an aqueous solution at room temperature. If the carboxyl group of *d*-diaminopropionic acid also required such an equatorial conformation, the gauche form of the chelate in its platinum(II) and palladium(II) complex should also be of λ-type. The CD spectra of these complexes shown in Figs. 1 and 6 are quite similar to those of *l*-pn complexes, though the intensities are smaller, to

10) S. Yano, H. Ito, Y. Koike, J. Fujita and K. Saito, *Chem. Commun.*, **1969**, 460.

indicate that the chelate ring of *d*-dampH is of λ-gauche form.

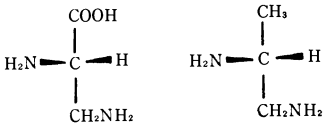

Fig. 7. Absolute configurations of D-(−)D-propylenediamine and L-(+)D-diaminopropionic acid.

Complexes Containing *l*-Propylenediaminetetraacetic Acid. Recent kinetic study[7] has shown that acetato groups participate in the elimination reaction of the chloride ions from $[PtCl_2(eddaH_2)]$. Such participation of a neighboring group and anchimeric assistance is expected to be more remarkable in platinum(II) and palladium(II) complexes containing $edtaH_4$ and *l*-$pdtaH_4$. For example, the spectrum of $[PtCl_2(l\text{-}pdtaH_4)]$ in 0.1 M hydrochloric acid is subject to a rapid change to reach a constant curve after about 80 min at room temperature. During the reaction isosbestic points appear at 345, 320 and 250 mμ

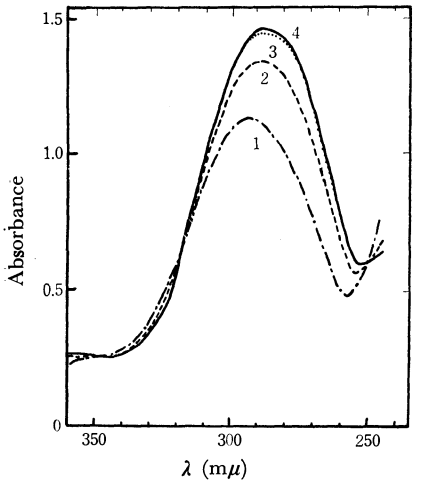

Fig. 8. Change in the spectrum of $[PtCl_2(l\text{-}pdtaH_4)]\cdot 5H_2O$ in 0.1 M hydrochloric acid with time. After (1), 10 min; (2), 20 min; (3), 30 min; (4), after equilibrium is reached.

and the absorption peak shifts to 288 mμ, as shown in Fig. 8. The spectral change may correspond to the following equilibrium shift.

$$[PtCl_2(l\text{-}pdtaH_4)] \rightarrow [PtCl(l\text{-}pdtaH_3)] + H^+ + Cl^-$$

Thus, the spectrum of $[PtCl_2(l\text{-}pdtaH_4)]$ was measured in 6 M hydrochloric acid.

The spectra of the complexes $[PtCl_{4-n}(NH_3)_n]^{(n-2)+}$ in the *d-d* band region consist of four bands, which are denoted as band 1, band 2, band 3 and band 4 from longer to shorter wavelength.[11] They were assigned to triplets of $d_{xy} \rightarrow d_{x^2-y^2}$ and d_{xz}, $d_{yz} \rightarrow d_{x^2-y^2}$, and singlets of $d_{xy} \rightarrow d_{x^2-y^2}$ and d_{xz}, $d_{yz} \rightarrow d_{x^2-y^2}$, respectively.[1,11] As in the case of *cis*-$[PtCl_2(NH_3)_2]$, $[PtCl_2(l\text{-pn})]$ gives a peak at 33100 cm^{-1} (band 3) and a shoulder at about 37000 cm^{-1} (band 4), while $[PtCl_2(l\text{-}pdtaH_4)]$ gives a peak at 32700 cm^{-1} and presumably a shoulder band at the longer wavelength side (at about 31000 cm^{-1}). The energy difference of these two neighboring bands are 3900 and about 2000 cm^{-1} for $[PtCl_2(l\text{-pn})]$ and $[PtCl_2(l\text{-}pdtaH_4)]$, respectively.

When the *l*-$pdtaH_4$ coordinates to the metal with the methyl group equatorial, the structure of chelate ring should be of λ -type, which is the same as that of the chelated *l*-pn. Therefore, the CD spectra of *l*-$pdtaH_4$ and *l*-pn complex should have the same sign in a corresponding transition band. Figure 1 suggests that the positive peak at 33300 cm^{-1} of $[PtCl_2(l\text{-}pdtaH_4)]$ corresponds to the positive peak of $[PtCl_2(l\text{-pn})]$ at 37000 cm^{-1} (band 4).

In order to examine the large difference in the spectral shape and the transition energy of the band 4 between *l*-pn and *l*-$pdtaH_4$ complex, the absorption spectra of a series of $[PtCl_2(en)]$, $[PtCl_2(NN'\text{-Meen})]$ and $[PtCl_2(Me_4en)]$ and a series of $[PtCl_2(en)]$, $[PtCl_2(eddaH_2)]$ and $[PtCl_2(edtaH_4)]$ are compared in Figs. 2 and 3. The trend of change in spectra is similar in the two series: (1) The intensity of band 4 relative to that of band 3 increases with increase in the number of the substituents on the nitrogen atoms.

(2) The absorption maxima of the bands 3 and 4 of *N,N,N',N'*-tetrasubstituted ethylenediamines shift to a longer wavelength as compared with those of *N,N'*-disubstituted and non-substituted compounds. This phenomenon is also observed for palladium(II) complexes in 0.2 M potassium chloride solution (Table 3).

These results further support the fact that the positive CD peak at 33300 cm^{-1} of $[PtCl_2(l\text{-}pdtaH_4)]$ corresponds to band 4 and the absorption shoulder at about 31000 cm^{-1} to band 3. Such an assignment leads to the conclusion that the ligand field strength of $pdtaH_4$ and $edtaH_4$ is considerably weaker than that of the other diamines, because the energy of band 3 ($d_{xy} \rightarrow d_{x^2-y^2}$) corresponds approximately to the so-called 10 *Dq*. It is known that the treatment of $[PtCl_2(en)]$ and $[PtCl_2(eddaH_2)]$[12] with aqueous ammonia produces $[Pt(NH_3)_2(en)]Cl_2$ and $[Pt(NH_3)_2(eddaH_2)]Cl_2$, respectively. For $[PtCl_2(l\text{-}pdtaH_4)]$, however, the same treatment gave $[Pt(NH_3)_4]^{2+}$. Such a difference in chemical reaction suggests a weaker bond between platinum(II) and nitrogens of $edtaH_4$ and *l*-$pdtaH_4$. In the diffuse reflectance spectra

11) J. Chatt, G. A. Gamlen and L. E. Orgel, *J. Chem. Soc.*, **1958**, 486.

12) C. F. Liu, *Inorg. Chem.*, **3**, 680 (1964).

shown in Fig. 4, the absorption peak of $[PdCl_2(l\text{-}pdtaH_4)]\cdot 5H_2O$ is also shifted to longer wavelength as compared with those of $[PdCl_2(l\text{-}pn)]$ and $[PdCl_2(eddaH_2)]$.

The shift of band 4 to longer wavelength in $edtaH_4$ and l-$pdtaH_4$ complexes seems to be abnormally large. According to the X-ray analysis of $[PdCl_2(edtaH_4)]\cdot 5H_2O$, two oxygen atoms of the acetato groups on each nitrogen atom are present above and below the palladium atom (distance 3.04 Å). Such a structure may also cause the spectra red shift. If two acetato groups were coordinated weakly to form a distorted octahedral complex, chemical environment of two acetato groups on one nitrogen atom would be non-equivalent and would give PMR spectrum with two different methylene signals. However, the PMR spectrum of $[PdCl_2(edtaH_4)]$ in deuterated water reported by Aochi and Sawyer,[13] and that of $[PtCl_2(edtaH_4)]$ in 6 M deuterium chloride solution reported by Erickson *et al.*[14] indicate no such difference. We also measured the spectra of these complexes in deuterated methanol as shown in Fig. 9. No difference between the four acetato groups were observed either; the singlets at 3.39 ppm of the palladium complex and 3.58 ppm of the platinum complex, and the qualtets centered at 4.31 ppm (J= 17.7 Hz) of the palladium complex and 4.43

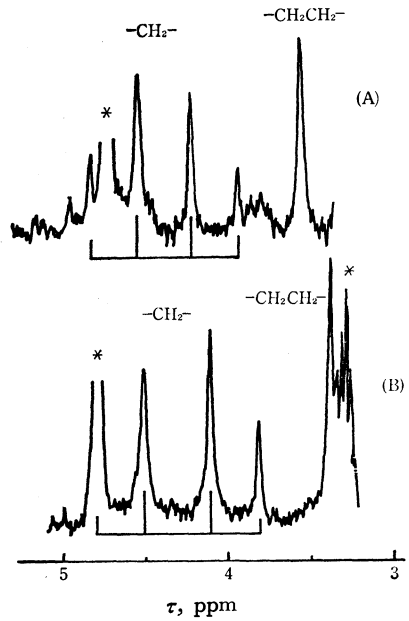

Fig. 9. PMR spectra of $[PtCl_2(edtaH_4)]$ (A) and $[PdCl_2(edtaH_4)]$ (B) in deuterated methanol, TMS as internal reference. (* indicates signals of solvent)

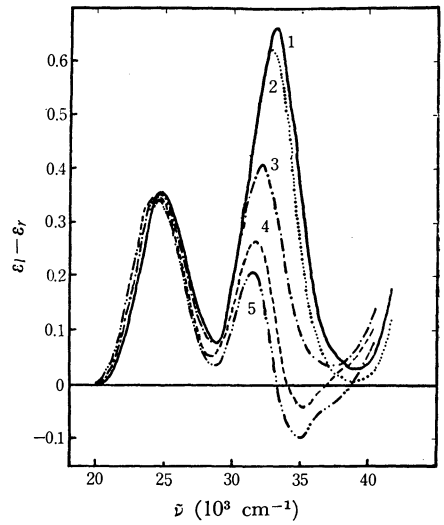

Fig. 10. CD spectra of $[PtCl_2(l\text{-}pdtaH_4)]\cdot 5H_2O$ in mixtures of ethanol and water containing abont 2 mol/l of hydrogen chloride: (1), 10%; (2), 55%; (3), 82%; (4), 100% ethanol.

ppm (J=17.3 Hz) of the platinum complex were assigned to signals of the ethylene and the methylene protons, respectively. Such an equivalence for the four acetato groups may not necessarily reject the electrical perturbation from apical positions to cause spectral red shift. Whenever one acetato oxygen parts from palladium or platinum, oxygen of the other acetato group on the same nitrogen atom can occupy the site in its place. This may be reflected in the rapid elimination reaction of the chloride ions in the complex, $[PtCl_2(l\text{-}pdtaH_4)]$, as stated before. The signals at about 3.8 ppm of the platinum complex may be due to the satellites corresponding to ^{195}Pt.

As mentioned before, bands 3 and 4 were assigned to $d_{xy} \rightarrow d_{x^2-y^2}$ and $d_{xz}, d_{yz} \rightarrow d_{x^2-y^2}$, respectively, therefore the spectral red shift is considered to be larger for band 4 than that for band 3, since the presence of very weakly attracted dipolar molecules in the apical positions destabilizes d_{z^2}, d_{xz} and d_{yz} orbitals to a greater extent than d_{xy} and $d_{x^2-y^2}$ orbitals. In fact the energy difference between bands 3 and 4 is smaller for $[PtCl_2(l\text{-}pdtaH_4)]$ (about 2000 cm^{-1}) than that for $[PtCl_2(l\text{-}pn)]$ (3900 cm^{-1}).

The absorption spectrum of $[PtCl_2(l\text{-}pdtaH_4)]$ in ethanol solution shifts to longer wavelength as a whole as compared with that in hydrochloric acid (Fig. 1). Such a shift was also observed for $[PtCl_2(NN\text{-Eten})]$ in hydrochloric acid and ethanol (Table 1). On the other hand, the shape of the CD spectrum in ethanol is quite different from that in hydrochloric acid (Fig. 1). A negative CD peak (35200 cm^{-1}) appears at shorter wavelength side of a positive CD peak (31700 cm^{-1}) in ethanol, which corresponds to the positive one at 33300 cm^{-1}

13) Y. O. Aochi and D. T. Sawyer, *ibid.*, **5**, 2085 (1966).

in hydrochloric acid. The CD spectra in methanol, dioxane and tetrahydrofuran are quite similar to that in ethanol. Figure 10 shows the CD spectra in mixtures of water and ethanol containing about 2 M hydrogen chloride. With increase in the intensity of the negative CD component, the positive CD peak shifts to longer wavelength and its intensity decreases.

In Fig. 5 the AB and CD spectrum of [$PtBr_2$-(*l*-pn)] in 2 M hydrobromic acid, and those of [$PtBr_2$-(*l*-pdtaH_4)] in 3 M hydrobromic acid and in ethanol are shown. The spectrum of [$PtBr_2$(*l*-pn)] is quite similar to that of [$PtCl_2$(*l*-pn)] in acid solution except that the corresponding bands appear at longer wavelengths for the dibromo complex. In AB spectrum of [$PtBr_2$(*l*-pdtaH_4)] in hydrobromic acid, apparently four absorption bands are observed at about 23500, 29000, 31000 and 37300 cm^{-1}. The AB and CD spectra are compared to those of the corresponding dichloro complex, and the band at 23500 cm^{-1} can be assigned to the spin forbidden band (band 2) and the bands at 29000 and 31000 cm^{-1} to bands 3 and 4, respectively. The band at 37300 cm^{-1} may be due either to $d_{z^2} \rightarrow d_{z^2-y^2}$ transition or a charge transfer transition. A fairly strong positive CD appears in this region (in ethanol). Since $d_{z^2} \rightarrow d_{x^2-y^2}$ transition is magnetic dipole forbidden, the CD strength of the band corresponding to $d_{z^2} \rightarrow d_{x^2-y^2}$ transition should be weak. Therefore, this absorption peak can be assigned to a charge transfer band involving *p* orbitals of the bromide and $d_{x^2-y^2}$ orbital of the platinum(II).*[1,1] The location of the band corresponding to $d_{z^2} \rightarrow d_{x^2-y^2}$ transition remains uncertain.

The difference of the CD spectra of [$PtBr_2$(*l*-pdtaH_4)] in the band 4 region between hydrobromic acid and ethanol solution is striking; the signs of CD in the two solvents are different (Fig. 5). Considering that the AB and CD peaks of chloro- and bromo-platinum(II) complexes in ethanol appear at longer wavelengths than those in hydrochloric or hydrobromic acid, the negative CD band of the bromo-complex at 31700 cm^{-1} in ethanol seems to correspond to the negative CD band (35200 cm^{-1}) of [$PtCl_2$(*l*-pdtaH_4)] in ethanol. In the bromo-complex, the positive component around band 4 may be canceled by the adjacent strong negative component with unknown nature. Such a remarkable CD difference in the two solvents is not clear at present.

The AB and CD spectra of [$PdCl_2$(*l*-pdtaH_4)] in a mixed solution (ethanol : conc. HCl=99 : 1 v/v) are shown in Fig. 6. Corresponding to the absorption peak at 24100 cm^{-1}, a positive and a negative CD appear at 23700 and 26300 cm^{-1}. The positive CD component at longer wavelength can be assigned to spin forbidden transition. The CD spectrum seems to be similar to that of the corresponding platinum complex in ethanol. The complex decomposed rapidly in 1 M hydrochloric acid to give $[PdCl_4]^{2-}$. Beer's law did not hold even in dehydrated ethanol. The CD spectrum of a solution 4.07×10^{-3} mol/*l* in ethanol is quite similar to that in the mixed solvent. However, in a very dilute solution, the absorption peak corresponding to [PdCl(*l*-pdtaH_3)] was observed.

Pyrolysis-Gas Chromatographic Determination of Chlorine in Chlorine-Containing Synthetic Polymers

Shin TSUGE, Tadaoki OKUMOTO and Tsugio TAKEUCHI

Department of Synthetic Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya

(Received April 10, 1969)

A new, simple and rapid method for determining chlorine in chlorine-containing polymers was investigated by means of pyrolysis-gas chromatography. Hydrogen chloride evolved during the thermal degradation of the polymers was eliminated by a NaOH precut column, and only the organic compounds sensitive to flame ionization detector were separated to record the pyrograms. Chlorine content of the polymers was calculated from the relative yield of the degradation products using a theoretical equation deduced from the degradation mechanisms of the polymers. This unique method permits very rapid determination of chlorine with the use of about 0.1 mg of the sample without either the use of calibration curves or weighing of the samples.

Various kinds of chlorine-containing polymers with C–C bond in the backbone chains are now available. The routine determination of chlorine in the polymers is carries out by means of either ordinary chemical method or elemental analysis. Although these methods are excellent for accuracy, they are troublesome and time-consuming.

Recently, we have presented a series of studies[1–4] on polymers by pyrolysis-gas chromatography (PGC), in which we proposed a method to obtain characteristic and reproducible pyrograms with the use of an improved pyrolyzer,[1] and successfully characterized the microstructures of such chlorine-containing polymers as vinyl chloride-vinylidene chloride copolymers[2], chlorinated polyethylene[3] and chlorinated polyvinylchlorides[4].

The present work describes a new method for the simple and rapid determination of chlorine in various kinds of chlorine-containing polymers by means of PGC.

Experimental

Materials. Four kinds of chlorine-containing polymers were prepared. Chlorinated polyethylenes (CPE) were obtained by chlorination of polyethylene with the use of CCl_4-solution method proposed by Campbell and Lyman.[5] Chlorinated polybutadienes (CPB) and chlorinated polyvinylchlorides (CPVC) were synthesized by chlorination of polybutadiene and polyvinylchloride, respectively, utilizing the $CHCl_3$-solution method.

Vinyl chloride-vinylidene chloride copolymers were prepared by suspension polymerization using azobisisobutyronitrile as a catalyst.

Apparatus. A furnace type pyrolyzer was used to decompose the polymers. Figure 1 shows a schematic diagram of the pyrolyzer. It was directly attached to the inlet port of the gas chromatograph, Yanagimoto Model GCG-550F with dual flame ionization detectors. The sample holder of the pyrolyzer was so modified as to obtain characteristic and reproducible pyrograms by reducing its heat capacity.[1] Hydrogen chloride evolved during the thermal decomposition of the polymers was eliminated by a NaOH precut column whose temperature was maintained at about 200°C. To minimize the change of the pyrolysis temperature, which influences the reproducibility of the results, a voltage-stabilizer was used for the pyrolyzer. A sample weighing about 0.1—0.3 mg was pyrolyzed under a flow of carrier gas (N_2) at fixed pyrolysis temperatures for 1 min which was sufficient for complete pyrolysis.

Gas Chromatographic Conditions. Gas chromatographic conditions and the method of identification of the peaks appearing on the pyrograms are the same as described previously.[2–4] Separation columns (3 mm i.d. ×2 m) containing 10 wt% of Carbowax 6000 coated on Diasolid L (80—100 mesh) were used. The column temperature was first programed from 50 to 210°C at a rate of 16°C/min, and then operated isothermally at 210°C. The flow rate of carrier gas (N_2) was maintained at 40 ml/min at 50°C. Hydrogen flame was made by means of 40 ml/min of H_2 and 700 ml/min of air. As the flame ionization detector responds nearly to the number of carbon atoms in the component, the relative yield (wt%) of the degradation products was calculated from the relative peak area on the pyrogram by making weight sensitivity corrections of each component for the flame ionization detector.

Results and Discussion

In order to obtain characteristic, reproducible and sharp pyrograms, the optimum pyrolysis temperatures were decided experimentally; 400°C for P(VC-VDC) and CPVC, 490°C for CPB and 660°C for CPE. The relatively high pyrolysis temperature of 660°C reflects a fairly good thermal stability of CPE.

Figure 2 shows typical pyrograms of CPE, CPB, P(VC-VDC) and CPVC. The degradation products appearing on the pyrograms can be divided into two classes. The first consists of the products formed mainly by simple thermal scissions of the polymer chains; lower hydrocarbons (C_1-C_6) and vinylidene chloride. For example:

$$-CH_2-CH_2-CH_2-CCl_2- \rightarrow CH_2=CH_2 + CH_2=CCl_2$$

The second consists of those formed by dehydrochlorination followed by cyclization; aromatic hydrocarbons and some chlorine-substituted benzenes. For example:

dehydrochlorination

$$-CH_2-CHCl-CHCl-CHCl-CH_2-CHCl- \rightarrow -CH=CH-CH=CCl-CH=CH- + 3HCl$$

cyclization

$$-CH=CH-CH=CCl-CH=CH- \rightarrow$$

In this case, it is assumed that the dehydrochlorination reaction occurs to form the conjugated polyene-structures along the chain of the polymers. Consequently, to make the latter type of degradation products correspond to the original structures of the polymer, we have to consider the products together with the eliminated 3 mol of hydrogen chloride. For the sake of simplicity, lower hydrocarbons were regarded as mono-olefines, and a small amount of toluene, styrene and naphthalene was converted into benzene in the calculation and added to the observed yield of benzene.

From these degradation mechanisms of the polymers, we obtain a calculation table (Table 1) and the following equation for the determination of chlorine in the polymers:

$$\text{Cl wt\%} = \frac{\sum_{i=2}^{7} \frac{C_i Y_i D_i}{A_i}}{\sum_{i=2}^{7} \frac{C_i Y_i}{A_i} + Y_1} \qquad (1)$$

where A is the molecular weight of the degradation product, C is the molecular weight of the original structure before dehydrochlorination, D is chlorine content (wt%) in C, Y is the observed yield (wt%) of the degradation product and the suffix i designates the component number in Table 1.

a) Determined chemically.
b, c, d) Refer to Table 1.
e) Calculated from Eq. (1).

Figure 3 shows the analytical results obtained by PGC against those by chemical analysis. The relatively good linearity of the calibration curve may support the assumptions implicit in this method. Statisticaly evaluation of the method is presented in Table 2. Three observations were made with each polymer sample. As might be expected from the small relative standard deviations, the reproducibility of the method is good, but not the accuracy data expressed as absolute deviations. This method tends to give a lower chlorine content than that obtained chemically except in the case of P(VC-VDC). This tendency is especially conspicuous with CPE. This phenomenon is related to the thermal stability and the relatively high pyrolysis temperature of the polymer. With pyrolysis temperature lower than 660°C, however, CPE did not decompose to give quantitative results. As shown in Table 2, it is possible to determine the chlorine content of CPB, P(VC-VDC) and CPVC,

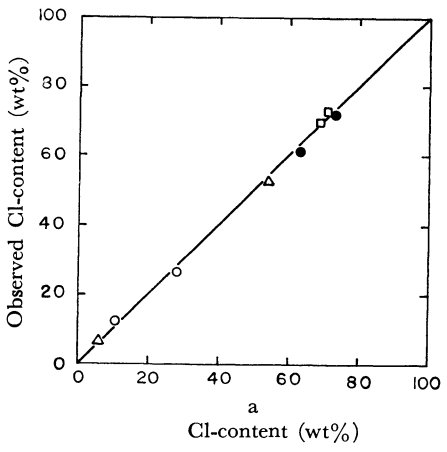

Fig. 3. Calibration curve for chlorine-containing polymers.
○, CPE; △, CPB; □, P(VC-VDC); ●, CPVC; *a*, chlorine content obtained chemically

whose optimum pyrolysis temperatures lie between 460 and 490°C, within 1% of relative standard deviation. To attain good reproducibility, the pyrolysis temperatures must be regulated by the voltage-stabilizer for the pyrolyzer.

This technique is very simple and rapid, and needs neither calibration curves nor weighing of the sample. Moreover, a very small amount of the polymer sample (0.1—0.3 mg) is sufficient.

The authors thank Professor Yuya Yamashita of Nagoya University for his supply of the copolymers (P(VC-VDC)). One of the authors (S.T.) wishes to thank the Sakkokai Foundation.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 2873—2877 (1969)

Preparation and Properties of the Mixed Dinitro Complexes of Cobalt(III) with the Carbonato or Oxalato Ligand*1

Hiroyasu ICHIKAWA and Muraji SHIBATA

Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa

(Received May 10, 1969)

Three new tervalent dinitro complexes of cobalt(III) have been prepared by the use of a tricarbonatocobaltate(III) solution or a similar solution as the starting material. These complexes, $[Co(NO_2)_2(CO_3)_3]^{3-}$, $[Co(NO_2)_2(OX)_2]^{3-}$ and $[Co(NO_2)_2CO_3OX]^{3-}$ are characterized by their absorption spectra in solution. The geometrical structures of these complexes have been determined as of the *cis*-form on the basis of their IR spectra. The compounds were not stable against decomposition in aqueous solutions: the bis(oxalato) compound was most unstable against the decomposition to the Co(II) state. The stability has been discussed in connection with the specific absorption band of the coordinated NO_2^- ligand.

A number of mixed dinitro complexes of cobalt(III) have already been prepared. The tetraammine-type and bis(ethylenediamine)-type[1] complexes are quite familiar and are typical univalent cationic complexes. For these complexes, *cis* and *trans* isomers are known. On the other hand, as the univalent anionic complexes the bis(acetylacetonato)[2-4] and the bis(glycinato)[5] complexes are known in only the *trans*-form and in only the *cis*-form respectively. Furthermore, the oxalato (or carbonato)diammine(or ethylenediamine)-type complexes[6,7] have also been reported, and a none-electrolyte complex *cis*-dinitroglycinatoethylenediaminecobalt(III)[5] has been prepared.

In the present work, the preparation of tervalent anionic dinitrocomplexes containing carbonato or oxalato ligands, or both, was undertaken. The complex $[Co(NO_2)_2(CO_3)_2]^{3-}$ was obtained from a reaction mixture of potassium tricarbonato cobaltate(III)[8] and potassium nitrite. The complexes $[Co(NO_2)_2(OX)_2]^{3-}$ and $[Co(NO_2)_2CO_3OX]^{3-}$ were obtained by the reaction of potassium nitrite with a green solution produced by oxidizing the Co^{2+} ion with hydrogen peroxide in the presence of potassium oxalate and bicarbonate. The geometrical structures of these complexes were determined as of the *cis*-form on the basis of the IR spectra.

Experimental

Preparation. *1) Potassium Dinitrodicarbonatocobaltate(III) Monohydrate*, $K_3[Co(NO_2)_2(CO_3)_2]\cdot H_2O$. To a green solution of tricarbonatocobaltate(III) ($CoCl_2\cdot 6H_2O$ 10 g scale, 0.048 mol), which had been prepared by the usual method,[8] 13 g (0.15 mol) of potassium nitrite was added. The reaction mixture was then stirred under an iced condition for 3—4 hr. A large amount (100 ml) of ethanol was added to the resulting red solution, and the whole was kept in a refrigerator for a day to precipitate the crude product. The precipitates was recrystallized by dissolving them in a minimum amount of cold water and by then adding

ethanol. The complex was violet-red needle-shaped crystals. The yield was about 3 g.

Found: C, 6.21; N, 6.95; H, 0.55%. Calcd for $K_3[Co(NO_2)_2(CO_3)_2]\cdot H_2O$: C, 5.91; N, 6.90; H, 0.50%.

2) Potassium Dinitrobis(oxalato)cobaltate(III) Monohydrate, $K_3[Co(NO_2)_2(OX)_2]\cdot H_2O$. Twenty-seven grams (0.15 mol) of potassium oxalate monohydrate and 5 g (0.05 mol) of potassium bicarbonate were dissolved in a minimum amount of hot water (50°C). Separately, 10 g (0.042 mol) of cobalt chloride hexahydrate were dissolved in a minimum amount of hot water. After cooling, 15 m*l* of hydrogen peroxide (30%) were added. This latter solution was added, drop by drop to the 40—50°C warmed oxalate-bicarbonate solution. To the resulting green solution there were added 9 g (0.10 mol) of potassium nitrite; the mixture was stirred at 40—50°C for 2—3 hr, whereupon the solution turned red. On the ice cooling of the solution, the desired complex was precipitated. This was filtered, washed with methanol, and then dried in air. On the other hand, the filtrate was used for another complex of 3). The product was needle-shaped crystals; the yield was about 7 g. Found: C, 10.45; N, 6.27; H, 0.55%. Calcd for $K_3[Co(NO_2)_2(OX)_2]\cdot H_2O$: C, 10.39; N, 6.08; H, 0.44%. The complex was not recrystallized from water because of its rapid decomposition to cobalt(II) oxalate.

3) Potassium Dinitrocarbonatooxalatocobaltate(III), $K_3[Co(NO_2)_2CO_3OX]$. To the filtrate of 2), ethanol (*ca.* 20 m*l*), was added, and the whole was kept in a refrigerator for a few hours in order to precipitate some of the bis(oxalato) complex and potassium oxalate. After the removal of these precipitated salts, an additional 50 m*l* portion of ethanol was added to the filtrate and the whole was kept in a refrigerator for a day. The red crystals thus precipitated were purified twice by dissolving them in a minimum amount of cold water and by adding ethanol. The final product was red stick-form crystals. The yield was about 4 g.

Found: C, 8.62; N, 6.80%. Calcd for $K_3[Co(NO_2)_2CO_3C_2O_4]$: C, 8.65; N, 6.73%.

Measurements. The infrared absorption spectra in the 4000—650 cm^{-1} region were measured as KBr disks using a Japan Spectroscopic Co., DS-301 infrared spectrometer. The visible and near-ultraviolet absorption spectra were measured with a Hitachi Perkin-Elmer 139 UV-VIS spectrophotometer, using a 0.10 M potassium bicarbonate aqueous solution as the solvent for the dicarbonato complex, a 0.10 M potassium oxalate aqueous solution for the bis(oxalato) complex, and a 0.05 M bicarbonate - 0.05 M oxalate mixed aqueous solution for the carbonatooxalato complex.

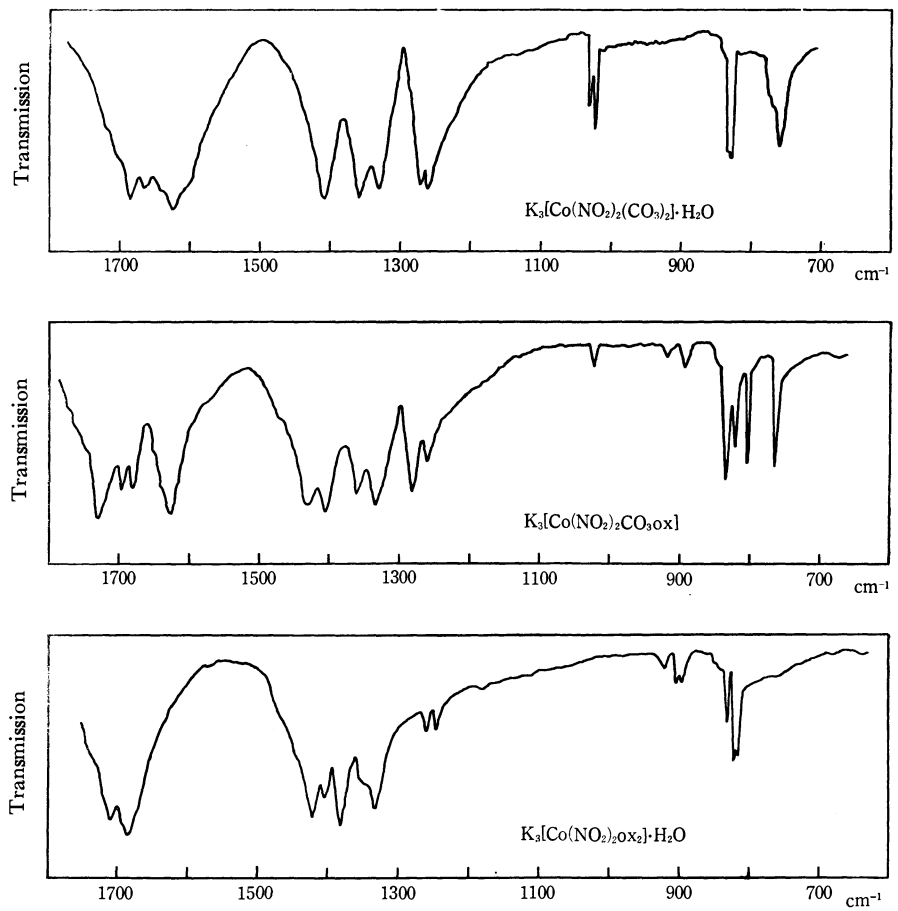

Fig. 1. Infrared absorption spectra of the *cis*-$K_3[Co(NO_2)_2(CO_3)_2]\cdot H_2O$, *cis*-$K_3[Co(NO_2)_2CO_3OX]$, and *cis*-$K_3[Co(NO_2)_2(OX)_2]\cdot H_2O$.

Results and Discussion

Preparation. The green solution which is used for the preparation of the bis(oxalato) and carbonatooxalato complexes is prepared in the same way as the tricarbonatocobaltate(III) solution.[8] The attempt to isolate the complexes from the green solution failed because of the high solubility of the complex species, but the absorption spectrum of the solution suggested the formation of such mixed complexes as $[Co(CO_3)_n(OX)_{3-n}]^{3-}$ ($n=1, 2$). When a cold solution of $CoCl_2$ containing H_2O_2 was added not to a warmed but to an ice-cold solution of potassium oxalate and bicarbonate, a large quantity of the Durrant's salt,[9,10] $K_4[(C_2O_4)_2Co\langle^{OH}_{OH}\rangle Co(C_2O_4)_2]\cdot 4H_2O$, was precipitated. Furthermore, when H_2O_2 was added toan ice-cold oxalate-bicarbonate solution which had previously mixed with a $CoCl_2$ solution, the Durrant's salt was almost quantitatively precipitated. When the reaction was carried out at 40—50°C, tris(oxalato)cobaltate(III) was precominantly formed.

IR Spectra. The IR spectra of three new complexes are shown in Fig. 1, while the numerical data are given in Table 1 with the related complexes. In the spectra of the dicarbonato and carbonatooxalato complexes, the key bands indicating the existence of the coordinated carbonate ion are observed as one or two sharp bands attributable to the CO symmetrical stretching vibration in the 1050—1020 cm^{-1} region——at 1033 and 1024 cm^{-1} for the dicarbonato complex and at 1022 cm^{-1} for the monocarbonato complex. If the carbonate ion is acting as a monodentate ligand, the corresponding CO vibration will appear in a higher-wave-number region.[11] The key bands indicating the existence of the coordinated oxalate ion are the C–C symmetrical stretching vibrations appearing in the 900 cm^{-1} region; the monooxalato complex has two distinct bands at 920 and 894 cm^{-1}, and the bis(oxalato) complex, at 902 and 892 cm^{-1}. If the oxalate ion is acting as a monodentate ligand, the corresponding C–C stretching vibration will appear in a higher-wave-number region.[11,12] Although the nitrite anion can coordinate to a central atom through the N- or O-atom, the present three complexes are coordinated through the N-atom, because of the absence of a nitrito characteristic band at 1050 cm^{-1}.[13,14] The absorption peaks appearing at 833, at 833 and at 824 cm^{-1} for the dicarbonato, carbonatooxalato, and bis(oxalato) complexes respectively, are undoubtedly due to the overlapping of the absorptions due to the oxalato, carbonato, and nitro ligands.

Several methods have been employed to distinguish between *cis* and *trans* isomers of dinitro complexes of cobalt(III).[3,15–18] It is said that the *cis* isomer gives a more complicated spectrum than the corresponding *trans* isomer because of the lower symmetry of the former.[15–18] For example, the IR spectrum of *trans*-$[Co(NO_2)_2(NH_3)_4]^+$ shows one band attributable to the NO_2^- symmetrical stretching vibration, whereas the spectrum of the *cis* isomer shows two bands.[15,18] The spectrum of *trans*-$[Co(NO_2)_2en_2]^+$ also shows one band attributable to the NO_2^- bending mode, whereas the *cis* isomer shows two bands.[16] Furthermore, *trans*-$[Co(NO_2)_2(acac)_2]^-$ exhibits one band each attributable to the NO_2^- symmetrical stretching and bending vibrations.[3] Each of the present complexes has two clear bands attributable to the NO_2^- symmetrical stretching vibration; the dicarbonato complex has them at 1360 and 1323 cm^{-1}; the carbonatooxalato one, at 1360 and 1332 cm^{-1}, and the bis(oxalato) one, at 1386 and 1327 cm^{-1} (with a 1346 cm^{-1} shoulder). From this evidence, it may be concluded that the present new complexes have *cis* structures.

UV Spectra. The absorption spectra in solution are shown in Fig. 2, while the numerical data are listed in Table 2. The maximum values of the first absorption bands (ν_1) for the present

complexes are regularly shifted to a higher frequency in order of the dicarbonato, carbonatooxalato, and bis(oxalato) complexes, with 1.2—1.3$\times 10^{13}$ sec^{-1} intervals. Those of *cis*-dicarbonato, carbonatooxalato, and bis(oxalato)diamminecobalt(III) complexes are also shifted to a higher frequency in the same order with regular intervals (0.9×10^{13} sec^{-1}).[8] These regularities can be expected from "the spectrochemical series."[19] However, the maximum values for these complexes themselves differ considerably from those calculated on the basis of "the rule of average environment";[20] calcd maxima, 53.8 for $[Co(NO_2)_2(OX)_2]^{3-}$; 52.8 for $[Co(NO_2)_2CO_3OX]^{3-}$; 51.7 for $[Co(NO_2)_2(CO_3)_2]^{3-}$. Perhaps the reason for this poor agreement is the value (62.0×10^{13} sec^{-1})[21] for the hexanitro complex, which is much lower than the expected value from "the spectrochemical series." On the other hand, the maximum frequencies (ν_{sp}) of the specific band of coordinated NO_2^- are shifted lower from the dicarbonato complex to the bis(oxalato) complex. In other words, the maximum positions of the first and specific bands move in an opposite direction from the dicarbonato to bis(oxalato) complexes. Accordingly, the values of $\nu_{sp}-\nu_1$ are calculated as a measure of the shifts; they are given in Table 2. The value for the dicarbonato complex is the largest one (32.35×10^{13} sec^{-1}) in the reported dinitro complexes. This fact seems to be interesting.

The frequency values of a number of dinitro complexes were inspected; they are diagrammatically represented in Fig. 3. From this inspection it was found that the maxima of the specific bands for the dinitro complexes shift to a lower frequency with the order of the ligands; en, NH_3 edda gly, CO_3^{2-}, NO_2^- and OX^{2-}. Since this order differs from that in the spectrochemical series, we can not discuss the stability of dinitro complexes in terms of the ligand-field theory.[22] However, as far as the present three complexes are concerned, they are less stable than the tris(oxalato)cobaltate(III) complex in their aqueous solutions and rapidly decompose to the cobalt(II) state. Among the three complexes, the dicarbonato complex is the most stable and the bis(oxalato) complex is the least stable. It is well known that the hexanitrocobaltate(III) complex is not stable in solution. Considering these facts, the order of CO_3^{2-}, NO_2^-, and OX^{2-} ligands seems to represent the stability of the dinitro complexes against decomposition to the cobalt(II) state. Furthermore, if these decompositions depend upon the photochemical reaction, it can be said that these dinitro complexes will sensitively react to light in the 80.0—83.0$\times 10^{13}$ sec^{-1} region.

In addition, it is interesting that in the dicarbonato or bis(oxalato) complex only the *cis* isomer is known in the case of present complexes as well as in the case of the diammine complexes.[8]

Reaction of Titanium Tetrahalides with Phenylhydrazones

R. C. AGGARWAL and S. K. SINGH

Chemistry Department, Lucknow University, Lucknow, India

(Received October 22, 1968)

Titanium tetrafluoride reacts with benzaldehyde phenylhydrazone to yield 1 : 1 adduct and with benzophenone phenylhydrazone 1 : 2 as well as 2 : 1 adducts, while other tetrahalides form 1 : 1 adducts with both the phenylhydrazones. All these complexes are coloured and stable at room temperature. The infrared spectral studies of phenylhydrazones and their titanium (IV) complexes have been made in the 4000—200 cm^{-1} region.

Snyder and Smith[1] have investigated the reactions of boron trifluoride with a number of phenylhydrazones containing α-methylene group and they showed that these reactions lead to the formation of indoles presumably through the intermediate formation of 1 : 1 adducts.

Recently Aggarwal and Makhija[2] in this laboratory prepared 1 : 1 adducts of tin tetrachloride with benzaldehyde phenylhydrazone and studied their structures from infrared spectral measurements. This work has now been extended to the reactions of titanium tetrahalides and the results obtained are described in the present communication.

Experimental

Titanium tetrahalides and organic solvents were purified and made anhydrous by standard literature methods. Benzaldehyde phenylhydrazone[3] and benzophenone phenylhydrazone[4] were prepared as described in literature and recrystallized from methanol (mp 157°C) and ethanol (mp 105°C) respectively.

Preparation of Complexes. *i) Titanium Tetrafluoride - Benzaldehyde Phenylhydrazone Complex.* 1—5% tetrahydrofuran solutions of TiF_4 and phenylhydrazone were mixed together and shaken vigorously. The reaction mixture was refluxed for 30 min and excess of solvent removed. The greenish-yellow solid mass thus obtained was washed repeatedly to remove excess of the base, and dried *in vacuo*.

ii) Titanium Tetrafluoride - Benzophenone Phenylhydrazone Complexes. Greenish-brown titanium tetrafluoride-benzophenone phenylhydrazone complex was prepared in a similar way as described above. Another complex (brown) was isolated from the filtrate of the above complex by the removal of excess of the solvent and washing the residual solid with a mixture of chloroform and tetrahydrofuran.

iii) Titanium Tetrachloride - Phenylhydrazone Complexes. On adding dropwise (1—5%) solution of phenylhydrazone in chloroform to a solution of titanium tetrachloride in the same solvent, coloured precipitate was obtained which was allowed to settle for several hours, filtered, washed and dried under reduced pressure.

iv) Titanium Tetrabromide - Phenylhydrazone Complexes. These complexes were prepared just like the titanium tetrachloride complexes.

No definite complexes of titanium tetraiodide with phenylhydrazones could be isolated from reactions carried out in chloroform and benzene solutions.

Complexes thus prepared were analysed for titanium, halogen, and nitrogen. Analytical results and general behaviour of the complexes are given in Table 1.

Infrared spectra measurements were carried out on a Beckman infrared spectrophotometer, Model IR-8. The spectra were recorded in Nujol mulls using sodium chloride plates. The far infrared spectra were taken on a Perkin Elmer-621 spectrophotometer in Nujol mulls using cesium iodide cells. The results obtained are included in Tables 2 and 3.

Discussion

Titanium tetrafluoride reacts with benzaldehyde phenylhydrazone to yield 1 : 1 adduct and with benzophenone phenylhydrazone 1 : 2 as well as 2 : 1 adducts, while other tetrahalides form 1 : 1 adducts with both the phenylhydrazones.

Titanium tetrahalides produce intense coloration with phenylhydrazones. The appearance of colour probably may be due to the existence of an equilibrium between the colourless phenylhydrazone and coloured phenylazo tautomer depicted below as titanium tetrahalide adducts:

The adducts are intractable, insoluble in common organic solvents and do not possess sharp melting points.

There are two sites for coordination in phenylhydrazones *viz.*, N^I and N^{II} as shown below:

$$R_1R_2C{=}N^{II}{-}N^IHC_6H_5 \rightleftharpoons R_1R_2CHN^{II}{=}N^IC_6H_5$$
(I) (II)

In titanium tetrahalide complexes of phenylhydrazones, one would expect changes in N–H, N–N, C=N and /or N=N and Ti-X stretching frequencies as compared with the location of these bands in the parent bases and Lewis acids, and appearance of new band characteristic of ν(Ti-N).

N–H Stretching Bands. Spectra of benzaldehyde and benzophenone phenylhydrazones recorded in the present work contain two bands at 3290, 3090 cm^{-1} and 3310, 3110 cm^{-1} respectively assigned to N-H stretching modes.[5,6]

A negative shift in ν(N–H) would be expected if coordination takes place through N^I of the isomer-I. An intramolecular change in phenylhydrazones would yield isomer-II containing no >NH group and hence the infrared spectra of this isomer and its complexes should show no absorptions characteristic of >NH group.

The presence of N–H stretching bands in the spectra of $TiF_4{\cdot}C_6H_5CH{=}NNHC_6H_5$, $(TiF_4)_2{\cdot}(C_6H_5)_2C{=}NNHC_6H_5$, and $TiF_4{\cdot}2(C_6H_5)_2C{=}NNHC_6H_5$, therefore, indicates that the adducts are formed mainly with tautomeric form-I.

In the infrared spectra of titanium tetrachloride and tetrabromide complexes of phenylhydrazones, the N–H stretching bands almost disappear. This indicates that the adduct formation takes place mainly with phenylazo tautomeric form-II.

C=N, N=N and N–N Stretching Frequencies. Weak bands observed in the spectra of the phenylhydrazones in 1620—1652 cm^{-1} region are assigned to ν(C=N).[7-10]

A tautomeric change in phenylhydrazones would be expected to give a new band corresponding to N=N stretching vibration. The specific assignment of the N=N stretching modes in aromatic azo compounds is difficult due to the interference of C=C ring vibrations.[8]

The N–N stretching modes are absent in the titanium tetrachloride and tetrabromide complexes, further supporting the adduct formation with isomer-II. The presence of N–N stretching bands of medium intensity in titanium tetrafluoride complexes supports the existence of the phenylhydrazones mainly in the isomeric form-I in these complexes.

Ti–N and Ti–X Stretching Bands. The new bands occurring in 570—513 cm^{-1} region in the complexes are tentatively assigned to ν(Ti-N).[11,12] The magnitude of the ν(Ti-N) is in good agreement with the thermal stability of complexes.

The occurrence of ν(Ti-X) modes in the octahedral region in the spectra of the complexes shows that they have octahedral geometry.[13,14]

Configuration of 1,3-Dipolar Cycloaddition Products of Nitrones with *N*-Phenylmaleimide

Yoshio IWAKURA, Keikichi UNO and Tatsuhiko HONGU

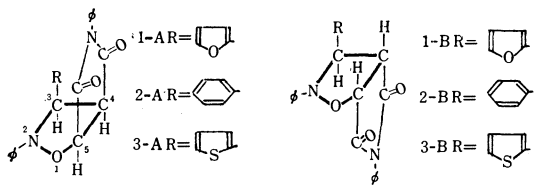
Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received October 30, 1968)

1,3-Dipolar cycloaddition reaction of aldonitrones such as *C*-2-furyl-*N*-phenyl-, *C,N*-diphenyl-, and *C*-2-thienyl-*N*-phenylnitrone with *N*-phenylmaleimide was carried out. The product was separated into two stereo isomers, *cis* and *trans* isoxazolidines with respect to H_3 and H_4, which were identified by NMR spectra. Spin-spin coupling of protons on C_3 and C_4 of isoxazolidine ring was found to be 8.4—9.0 cps for *cis* isomers and to be zero for *trans* isomers.

In a series of studies on the synthesis of new polymers, we have reported syntheses of polymers through 1,3-dipolar cycloaddition reaction.[1] As a basic study of these polymer formation reaction, the reaction of nitrones with *N*-phenylmaleimide was examined. There are some reports on the synthesis of isoxazolidines by 1,3-dipolar cycloaddition reaction of nitrones with C–C double bond.[2-6] However, few studies were carried out from a structural viewpoint. Recently, Huisgen reported the reaction of nitrones with norbornene, and two stereo isomers were isolated in the reaction of *C,N*-diphenylnitrone with norbornene.[7]

We found that *C,N*-diphenylnitrone, *C*-2-furyl- and *C*-2-thienyl-*N*-phenylnitrone gave two kinds of stero isomers, *cis*- and *trans*-isoxazolidines, in each reaction with *N*-phenylmaleimide. NMR spectra of these compounds confirmed their configurations. Details are described in this paper.



A *cis* B *trans*

Scheme 1

Results and Discussion

Two configurations, *syn* and *anti* forms, are expected for the structure of nitrone.

anti form *syn* form

However, only an *anti* form has been shown to actually exist for aldonitrone by UV and NMR spectroscopy by Hamer and Macaluso.[4] Analytical and physical data of nitrones used are shown in Table 1.

Only one signal was observed as a methine proton in the NMR spectrum of each nitrone. The nitrones used in the present study can therefore be considered to be pure and their configurations *anti* according to Hamer and Macaluso.

The reaction of nitrones with *N*-phenylmaleimide was carried out by heating a mixture of both reagents in anhydrous tetrahydrofuran (THF). The results, analytical and physical data of these products are summarized in Table 2.

Elemental analysis for the paired products gave the same values in spite of their different melting points. Therefore, it is reasonable that these paired compounds are isomers with each other. The ratio of the isomers was determined by comparing the weight of the separated product, and the value obtained was in good agreement with the ratio determined by NMR. Some NMR spectra are shown in Figs. 1 and 2.

Signals observed in lower magnetic fields than $\tau 3$ were assigned to protons on benzene and hetero-

aromatic rings. Signals of protons on isoxazolidine ring were observed as three groups in a field from τ4 to 6. The ratios of the integrated intensities of signals of protons on aromatic rings and those of isoxazolidine rings were 13/3 for 1-A, 13/3 for 1-B, 15/3 for 2-A, 15/3 for 2-B, 13/3 for 3-A, and 13/3 for 3-B. These values were the same as theoretical values 13/3, 15/3, and 13/3 for compounds 1, 2, and 3, respectively.

Signals observed around τ6 could be assigned to the protons on C_4 of isoxazolidine ring as the atoms of both sides of C_4 are carbon. It is generally accepted that the spin-spin coupling of protons in *cis* position is larger than that in *trans*. In oxazolidine obtained here, the relative position of protons on C_4 and C_5 is to be *cis* position because C_4 and C_5 are also ring members of succinimide at the same time. Therefore, it is reasonable to consider that coupling constants of protons on C_4 and C_5 are comparatively large, and their values are the same independent of the position and kind of substituent on the isoxazolidine ring.

As shown in Table 2 and Fig. 1, compounds obtained could be divided into two groups by the figure of the signal (H_3) of isoxazolidine which was observed in the lowest magnetic field. Compounds 1-B, 2-B, and 3-B belong to group B only, in which signals (H_3) appear as a singlet. On the other hand, compounds 1-A, 2-A, and 3-A form another group A in which signals (H_3) are observed as a doublet.

In group B, signals (H_3) were assigned to those of protons on C_3, because protons on C_4 and C_5 should be *cis* and give doublet signals. Signals (H_4) observed around τ6 were assigned to those of protons on C_4 on the assumption described above,

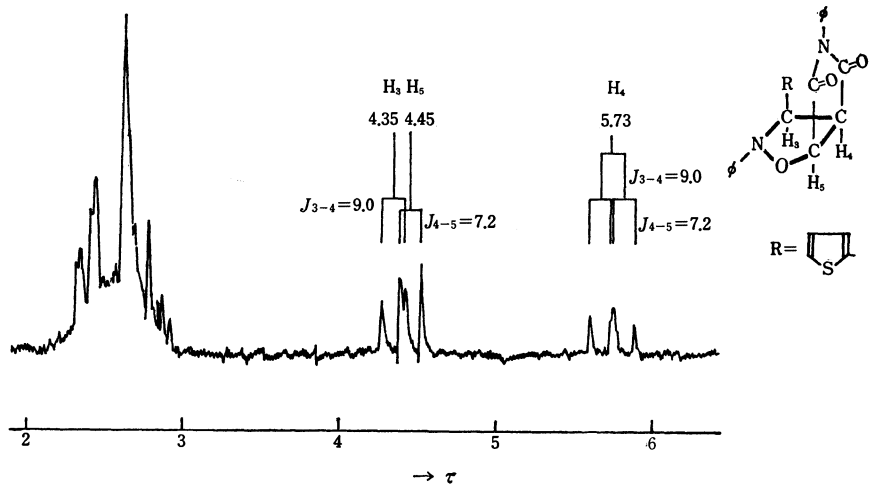

Fig. 1. NMR spectrum of cycloadduct 3-A in DMSO-d_6 by 60 Mc.

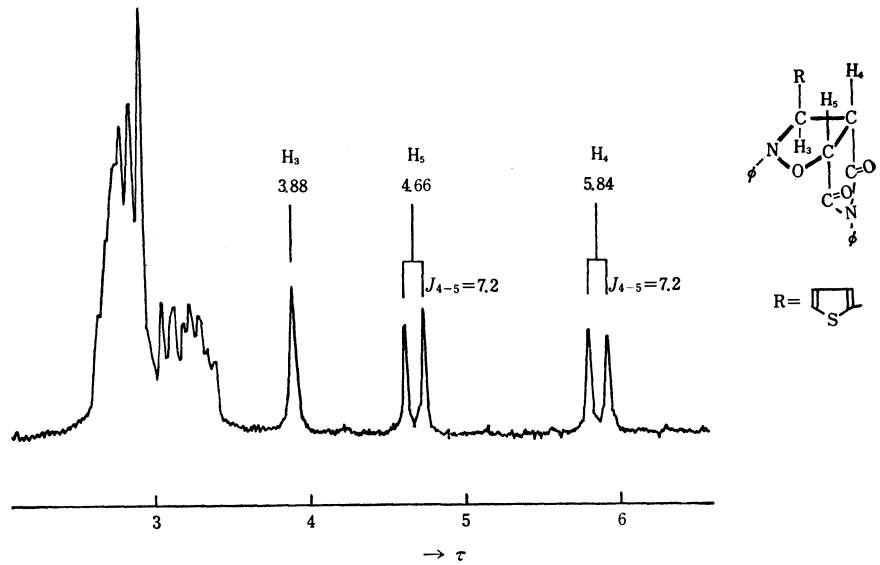

Fig. 2. NMR spectrum of cycloadduct 3-B in DMSO-d_6 by 60 Mc.

and were observed as doublets with spacing of 7.2 cps. The residual signals (H_5) which were observed around τ4.5 were assigned to those of protons on C_5 and were observed as doublets with spacing of 7.2 cps. The same spacing (7.2 cps) of H_4 and H_5 appeared to confirm the above consideration. As the protons on C_4 and C_5 are in *cis*-position, the coupling constants of 7.2 cps are reasonable for the structure. Thus the configuration of compounds in group B was concluded to be *trans* as shown in Scheme I.

In group A, the signals of the protons on isoxazolidine ring were observed as three groups, two doublets and a quartet, as shown in Table 2 and Fig. 2. Coupling constants of these protons were found to be large. Therefore, the relative position of these protons on a ring seems to be *cis*-position. Assignment of the signals in the highest magnetic field to the proton on C_4 may be reasonable because the signals are quartet.

If we assume that the relative position of the protons on C_4 and C_5 is the same, then the coupling constant of the protons on C_4 and C_5 will be independent of the position and the kind of substituent on isoxazolidine ring. Therefore, coupling constants 7.2 cps, which were concluded as that of the protons on C_4 and C_5 in group B may be attributed to the protons on C_4 and C_5 in group A. As shown in Table 2, little variation in values of the chemical shifts of H_5 and H_4 was observed. However, a large variation appeared in the chemical sihft of H_3.

The proton on C_5 is always placed on the opposite side of carbonyl group and far from other groups. Therefore, the difference in relative position between the proton and other groups gave a weak effect on the chemical shift of the proton. On the other hand, the proton on C_3 is located very near the carbonyl group in the compounds of group B, but the distance between the proton and the carbonyl group is great in the compounds of group A. The variation of the distance and relative position between the proton and carbonyl group is known to influence the chemical shift of the proton. Accordingly, the chemical shift of the proton on C_3 was expected to be different according to whether the compound belongs to group A or B. The results obtained were interpreted well by the configuration in Scheme 1.

Experimental

Nitrones. A typical example of the reaction of *C*-2-furyl-*N*-phenylnitrone is as follows. To 150 m*l* of ethanol 22 g (0.23 mol) of 2-furfural and 30 g (0.275 mol) of phenylhydroxylamine were added. The mixture was allowed to react at room temperature over night. The product was obtained by removing the solvent. Recrystallization three times from petroleum ether gave 27 g (63%) of needles, mp 89°C.

1,3-Dipolar Cycloaddition Reaction. The reaction was carried out in a closed tube. To a 30 m*l* of anhydrous THF, 3 g (0.015 mol) of *C*-2-furyl-*N*-phenylnitrone and 2.19 g (0.015 mol) of *N*-phenylmaleimide were dissolved in the presence of a small amount of *β*-naphthylamine which is an inhibitor of radical polymerization. The tube was sealed and heated at 100°C, for 10 hr. The solvent evaporated under reduced pressure to give white mass. It was recrystallized from benzene - hexane to yield white crystals, mp 142—167°C. The crystals were extracted with hot ethanol, and the ethanol solution was cooled to give white needles, mp 142—150°C, which were recrystallized twice from benzene - *n*-hexane to give B, mp 142—144°C. The fraction insoluble in ethanol was recrystallized twice from benzene - *n*-hexane to give A, mp 185—186°C. The reaction of *C*,*N*-diphenylnitrone or *C*-2-thienyl-*N*-phenylnitrone with *N*-phenylmaleimide was carried out by a similar procedure.

NMR Spectra Measurements. The NMR spectra were taken with a Japan Electron Optics C-60 spectrometer at a frequency of 60 Mc using about 10% solution of the sample in $CDCl_3$ or DMSO-d_6 with tetramethylsilane as an internal standard.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 2885—2894 (1969)

Configuration and Conformation of So-called Bis(alkylidenearylamines)

Masuo FUNABASHI, Masaharu IWAKAWA and Juji YOSHIMURA

Laboratory of Chemistry for Natural Products, Faculty of Science, Tokyo Institute of Technology, Meguro-ku, Tokyo

(Received November 27, 1968)

The proposed structures of the dimeric products obtained from aliphatic aldehydes and arylamines were reexamined by IR and NMR spectra. The 1,2,3,4-tetrahydroquinoline structure was ascertained in the case of acetaldehyde or propionaldehyde, and aldolic structure was confirmed in the case of *n*-butyraldehyde. It was observed that the latter readily isomerizes to the former type in the presence of acetic acid. Conformational analysis of a racemic pair of the former (IIIa—c: 2,4-disubstituted, IIId- 2,3,4-trisubstituted) indicated that two isomers of IIIa—c (one has 2-equatorial, 4-quasi-equatorial and the other 2-equatorial, 4-quasi-axial substituents) have a flattened half-chair conformation and two isomers of IIId (one has 2,3-diequatorial, 4-quasi-equatorial, and the other 2-equatorial, 3-axial, 4-quasi-axial substituents) have a more remarkably flattened half-chair, *i. e.* a nearly plane structure. The acylation of ring nitrogen enhanced this tendency, and one of the 1-acetyl derivatives of III was deduced to have a twist half-boat conformation.

On the structure of so-called bis(alkylidene-arylamines) which have been regarded as one of the key-intermediates[1] in the Doebner-von Miller synthesis of quinolines from arylamines and aliphatic aldehydes, the following three formulas have been proposed; the acyclic structure of the aldol type (I), the enamine structure due to the isomerization of I (II) and the cyclic structure having 1,2,3,4-tetrahydroquinoline skelton (III).

Scheme 1

For a long time, structure I has been accepted without any definite evidences.[2] However, Minkin and Tumakoba[3] have recently proposed that, on the basis of IR and UV spectral investigation, both bis(ethylideneaniline) and bis(propylideneaniline) are of structure III, and bis(butylideneaniline), to which Kharasch *et al.*,[4] had given structure I, is of structure II.

In a previous paper,[5] the authors have reported the easy dimerization of *N*-phenyl-acetone-D-glyceraldimine to 4-anilino-1,2,3,4-tetrahydroquinoline derivatives in the presence of catalytic amount of acetic acid, and the determination of their partial absolute configuration by chemical degradation and spectral measurements.

These results stimulated us to determine the configuration and conformation of general bis(alkylidenearylamines) and their isomers by IR and NMR spectral studies, in connection with the mechanism of Doebner-von Miller reaction. The results obtained are discussed in this paper.

Results and Discussion

Configuration of Bis(alkylidenearylamines). The structures I, II, and III would be easily distinguished by the presence or absence of a characteristic absorption of C=C and C=N bonds in IR spectra, and azomethine and olefinic proton signals in NMR spectra. The results obtained indicated that bis(ethylideneaniline)[2] (IIIa), bis(ethylidene *p*-toluidine)[6] (IIIb), bis(ethylidene *m*-xylidine)[7] (IIIc) and bis(propylideneaniline)[2] (IIId) have structure III, because they showed the absence of C=C and C=N absorption band in IR spectra and the absence of azomethine and olefinic proton signals in NMR spectra, and furthermore, their monoacyl derivatives still showed the presence of NH absorption band at *ca.* 3300 cm^{-1}. The NMR spectra of these compounds will be shown and discussed in the next paragraph.

Contrary to Minkin's findings, NMR spectrum of bis(butylideneaniline) (I) shown in Fig. 1 indicated that it has aldol type structure. Irradiation of Ha caused Hc to collapse to a quartet, and reversal irradiation of Hc caused Ha to collapse to a seemingly narrow triplet with a long range coupling. Therefore, the quintet at τ 7.43, the quartet at τ 6.3 and the doublet at τ 2.2 (J=6.25) can be assigned to Hc, Hb and Ha, respectively.

The chemical shift of Ha is too low for that of olefinic proton and moreover, the coupling constants, which remained unchanged by addition of deuterium oxide, are too large to expect a long range coupling of the olefinic proton in structure II. The following examples of the chemical shifts of azomethine protons may also support the above conclusion; τ 1.65 in benzylideneaniline,[8] τ 2.37 in ethylidenepropylamine,[8] τ 2.56—3.16 in acetoaldoxime.[9] On the other hand, 2-ethylhexylideneaniline (IV), which is partially analogous to I and obtained from aniline and 2-ethylhexaldehyde, showed the presence of azomethine proton signal at τ 2.4 (J=6.5).

It has thus become clear that acetaldehyde or propionaldehyde give type III in the condensation with arylamines even in the absence of an acid catalyst, and a higher aldehyde such as *n*-butyraldehyde gives acyclic type I. In order to clarify such an effect of acid catalyst as was observed in a previous study[5] and the relationship between I and III, a catalytic amount of acetic acid was added to a solution of I in $CDCl_3$ (Fig. 2). The azomethine proton signal (Ha) disappeared promptly and a ring proton signal of 1,2,3,4-tetrahydroquinoline appeared at τ 5.62. This fact suggests the conversion of I to III, whose structure was also ascertained by UV (λ_{max} 251, 302 mμ) and IR (the disappearence of the absorption

band of C=N and the increase of the intensity of the absorption band of NH), and moreover, by the fact that 1-tosyl derivative of IIIe still showed NH absorption band at 3300 cm^{-1}. Besides, distillation of I caused the β-elimination of aniline to give 2-ethyl-2-hexenylideneaniline (V). Such a phenomenon is characteristic for structure I, but not for III.

The Doebner-von Miller synthesis of quinolines from arylamines and lower aliphatic aldehydes has been done in a strongly acidic condition at a high temperature, and two reaction mechanisms[1] have been postulated for it; one includes the formation of α,β-unsaturated aldehydes due to the aldol condensation, the β-addition of arylamines and cyclization similar to that of the Skraup synthesis, and the other the intermediate such as I formed by the aldolic addition of alkylidenearylamines. The results described above seem to be closely related to the latter mechanism, and more detailed work is being undertaken.

Conformation of Bis(ethylidenearylamines) and Bis(propylidenearylamines). It is known that there are usually two isomers in bis-(ethylideneaniline). Some workers[10] considered them to be a pair of geometric isomers of structure II. However, it is now obvious that they should be the diastereomer of substituted 1,2,3,4-tetrahydroquinolines. Minkin and Gorelob[11] distinguished them from

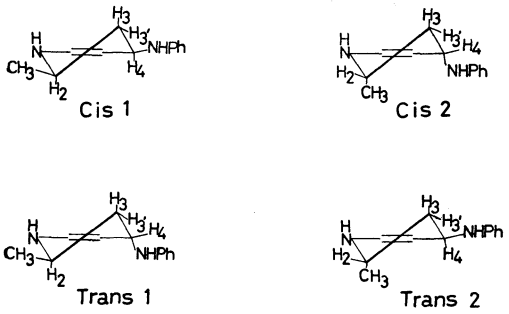
10) A. Eibner, *Ann.*, **318**, 58 (1901).

11) V. I. Minkin and M. I. Gorelob, *Zh. Obschch. Khim.*, **33**, 647 (1963); *Chem. Abstr.*, **59**, 2624f (1963).

their dipole moment, but the results are doubtful becasse of fundamental misunderstanding of stereochemistry. Therefore, the authors attempted to analyse the conformation of known and some new tetrahydroquinolines with NMR technique.

It has been concluded by X-ray analysis[12] that the cyclohexene molecule preferentially exists as a half-chair conformation, and the result has been applied to the conformational analysis of 1,2,3,4-tetrahydroquinolines,[13] glucal triacetate,[14] shikimic acid[15] and 1,2,3,4-tetrahydroisoquinolines.[16]

a) Conformation of Bis(ethylidenearylamines). Theoretically, there are two *cis* and two *trans* racemic stereoisomers, respectively in bis(ethylidenearylamines), *i.e.*, 1,2,3,4-tetrahydro-2,4-disubstituted-quinolines. Two substituents at C_2 and C_4 are equatorial and quasi-equatorial, or axial and quasi-axial in the case of *cis*-1 and *cis*-2, and equatorial and quasi-axial, or axial and quasiequatorial*1 in the case of *trans*-1 and *trans*-2, respectively.



Scheme 2

The order of the stability of four conformation will be empirically given as follows; *cis*-1, *trans*-1, *trans*-2 and *cis*-2. As has been pointed out by Booth[13] that the methyl group of 1,2,3,4-tetrahydro-2-methylquinoline prefers an equatorial orientation, it is probable that the favoured conformations of two known isomers of bis(ethylideneaniline) should be *cis*-1 and *trans*-1. The coupling constants of each ring protons, which can be calculated from the angle parameters of cyclohexene[17] and are listed in Table 1, make it possible to distinguish them. The order of the chemical shifts (τ) of ring protons will be given; H_3 (a), H_3' (e), H_2 and H_4 from higher to lower field.

Table 1. The expected dihedral angles[a] for 2,4-disubstituted 1,2,3,4-tetrahydroquinolines and the corresponding coupling constants[b]

a) obtained from Bucourt's parameters
b) calculated from Abraham's equation[18] (Lemieux's equation[19])

The NMR spectrum of the one isomer of 1,2,3,4-tetrahydro-4-anilino-2-methylquinoline ($IIIa_1$, mp 126°C) is shown in Fig. 3. Inspection of this chart indicates that the $\delta\nu/J$ is sufficiently large to allow a first-order analysis. The quartet at τ 8.50, which is partly superimposed on the methyl proton signal, the octet at τ 7.67, the multiplet at τ 6.4, and the quartet at τ 5.2 are easily assigned to H_3 ($J_{3,3'}=J_{3,2}=J_{3,4}=11.5$ Hz), $H_{3'}$ ($J_{3',4}=5.0$, $J_{3',2}=2.5$ Hz), H_2 and H_4 respectively. Comparison of the above data with that of Table 1 clearly demonstrated that $IIIa_1$ belongs to *cis*-1 conformation. The dihedral angles of $IIIa_1$ are estimated from the equation of Abraham[18] as follows; (H_2, H_3)=(H_3, H_4)=155°, (H_2, $H_{3'}$)=63° and ($H_{3'}$, H_4)=51°.

The NMR spectrum of another isomer ($IIIa_2$, mp 86°C) is shown in Fig. 4. In this case, the sextet at τ 8.57 and τ 7.93, the multiplet at τ 6.63 and the quartet at τ 5.58 are assigned to H_3 ($J_{3,3'}=J_{2,3}=11.3$, $J_{3,4}=3.75$ Hz), $H_{3'}$ ($J_{2,3'}=J_{2',4}=2.5$ Hz), H_2 ($J_{2,CH_3}=6.5$ Hz) and H_4, respectively. The results indicate that $IIIa_2$ belongs to *trans*-1 conformation, and the dihedral angles are estimated in the similar manner: (H_2, H_3)=152°, (H_2, $H_{3'}$)=($H_{3'}$, H_4)=63° and (H_3, H_4)=58°.

The analytic data of IIIa, IIIb, IIIc and their 1-acyl derivatives, and 1,2,3,4-tetrahydro-2,6-dimethyl-4-hydroxyquinoline[2] (III'a; *trans*), 1,2,3,4-tetrahydro-1-acetyl-4-acetoxy-2,6-dimethylquinoline[2] (III'b; *cis*) and 1,2,3,4-tetrahydro-1-acetyl-4-ethoxy-2-phenylquinoline (III'c; *cis*) are summarized in Table 2. The ratio of the formation

*1 Axial, equatorial, quasi-axial and quasi-equatorial are abbreviated to a, e, qa and qe, respectively.

of $IIIa_1$ and $IIIa_2$ in the crude product was estimated from the intensity of each H_4 proton signal, to be 1 : 1, whereas, in the case of IIIc, *trans*-1 type was preferentially formed. The latter case will be probably due to the allylic strain[20] between the carbon atom at C_5 and *m*-xylidine residue at C_4 bulkier than phenyl.

The phenomenon that the spiltting number of the methylene proton in 4-ethoxy group of III'c is not a quartet, but a double quartet, suggests the presence of such a hindrance.

The fact that the dihedral angles (H_2, H_3) and (H_3, H_4) are less than that of cyclohexene indicates a considerable flattening of the typical half-chair conformation. A more remarkable tendency to flatten the conformation has been observed in the case of 1-acyl derivatives of IIIa, IIIb and IIIc, in which the coupling constants between H_2 and H_3 are generally smaller than those of the parent compounds. For example the coupling constant: $J_{2,3}$ (7.5 Hz) of 1-acetyl derivative of IIIc indicates the decrease of the angle from 156° to 136°. This change will be attribuable to the 1,2-skew interaction of acetyl group at C_1 and methyl group at C_2, and also to the allylic strain between acetyl group and methyl group at C_8.

As a general tendency of the NMR data (see Table 2), H_4 proton (qa) of 1-acyl derivatives of *cis*-1 type shifts to a higher magnetic field than H_4 proton of the parent compounds free of acyl group.

20) F. Johnson, *Chem. Revs.*, **68**, 378 (1968).

However, it is scarcely changed in the case of *trans*-1 type. H_3 proton also indicates a similar tendency. The former case is consistent with the report of Lambert[21] *et al.*, in which they indicated that the anticoplanarity between H_γ proton and axial lone pair electron of nitrogen atom in the *N*-substituted piperidine ring causes the chemical shift of H_γ (τ) to a higher magnetic field.

b) Conformation of Bis(propylidenearylamines). In the case of bis(propylidenearylamines), *i. e.*, 1,2,3,4-tetrahydro-4-anilino-2-ethyl-3-methylquinoline, eight half-chair conformations of racemic diastereoisomers are theoretically possible, and among them, the most favored ones will be the two having C_2-e, C_3-e, C_4-qe or C_2-e, C_3-e, C_4-qa substituents. Miller *et al.*[2] have found only one isomer ($IIId_1$; mp 103°C). However, another one should exist as in the case of bis(ethylidene-aniline), and in fact, we have succeeded in isolating one ($IIId_2$) as a syrup from the mother liquor of $IIId_1$. The IR spectrum of $IIId_2$, which is very similar to that of $IIId_1$, showed absence of C=C or C=N absorption band, and that of 1-acyl derivative of $IIId_2$ still showed NH absorption band at 3320 cm^{-1}.

In the NMR spectrum of $IIId_1$ shown in Fig. 5,

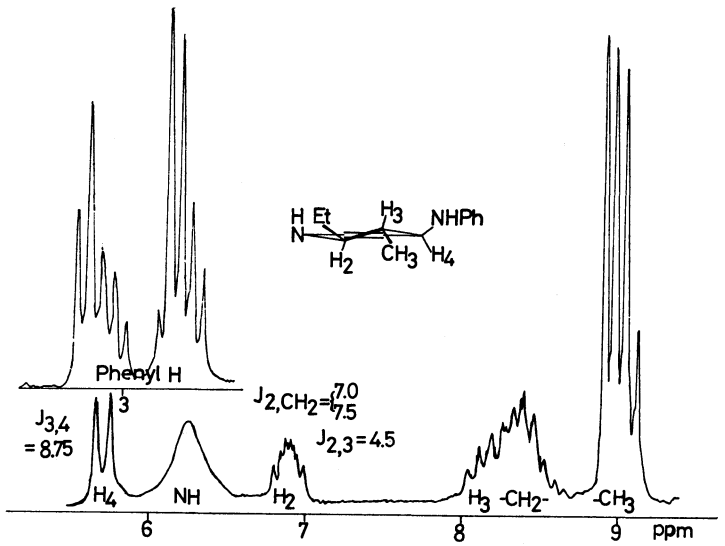

Fig. 5. NMR spectrum of 1,2,3,4-tetrahydro-4-anilino-2-ethyl-3-methylquinoline ($IIId_1$) [bis(propylideneaniline): 2,4-*cis*] (100 Mc, $CDCl_3$).

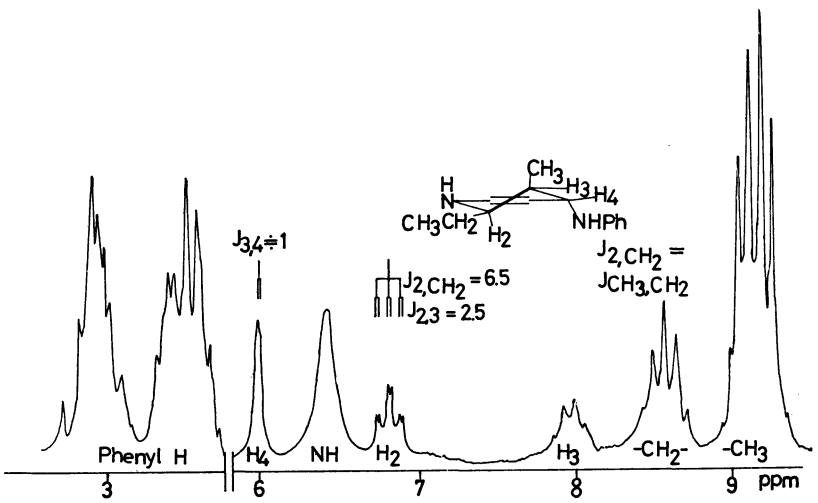

Fig. 6. NMR spectrum of 1,2,3,4-tetrahydro-4-anilino-2-ethyl-3-methylquinoline ($IIId_2$) [bis(propylideneaniline): 2,4-*trans*] (100 Mc, $CDCl_3$).

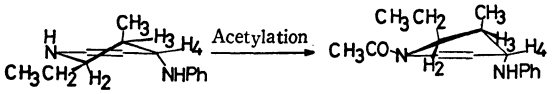
the multiplet at *ca.* τ 8.2, which is partly superimposed on C_3 methyl proton signal, the octet at τ 6.90 and the doublet at τ 5.72 are assigned to H_3 ($J_{2,3}=4.5$ Hz), H_2 ($J_{2,CH_2}=7.0$, 7.5 Hz) and H_4 ($J_{3,4}=8.75$), respectively. The irradiation of H_3 caused H_4 proton signal to collapse to a singlet. The coupling constants mentioned above roughly support the fact that the substituents of $IIId_1$ at C_2, C_3 and C_4 are e, e and qe. The dihedral angles of ring protons; (H_2, H_3)=124° and (H_3,H_4) =141° indicate a more remarkably flattened half-chair (rather plane) conformation than that of IIIa.

In the NMR spectrum of the other isomer ($IIId_2$) shown in Fig. 6, a multiplet centered at τ 7.97, a triplet doublet at τ 6.80 and a narrow doublet at τ 5.95 are assigned to H_3, ($J_{2,3}=2.5$ Hz), H_2 ($J_{2,CH_2}=6.5$ Hz) and H_4 ($J_{3,4}=ca.$ 1 Hz), respectively. The dihedral angles are similarly estimated to be (H_2, H_3)=114° or 64° and (H_3, H_4)=105° or 74°. The most profitable conformation to be justified by these angles is a flattened half-chair having C_2-e, C_3-a and C_4-qa substituents or a rather contracted half-boat conformation having C_2-e, C_3-e and C_4-qa substituents, but not a half-chair having C_2-e, C_3-e and C_4-qa which was mentioned above as a stable one. Among the two probable conformations, however, the latter is not adoptable because of the instability factor due to the constraction strain. Therefore, the former is preferable to $IIId_2$.

This conclusion will be supported by the following considerations. If $IIId_1$ and $IIId_2$ can be formed through the structure of type I, as in the case in which I cyclizes to IIIe, racemic *threo* and *erythro* isomers of type I should exist in the intermediate step. The *threo* isomer will preferentially cyclize to the conformation having C_2-e and C_3-e substituents. However, the *erythro* isomer should give a half-chair conformation having C_2-a or C_3-a substituent. Though C_4 configuration can not be estimated unless the transition state of such a cyclization is clarified, we can understand that $IIId_1$ is preferentially formed, so far as stability is concerned. However, in the case of *erythro*, two stable conformations are equally possible from the standpoint of the nonbonded interaction. The following consideration may be allowed: there are four possible conformations to be formed by the cyclization of the *erythro* intermediate;

A) C_2-a, C_3-e and C_4-qe, B) C_2-a, C_3-e and C_4-qa, C) C_2-e, C_3-a and C_4-qe, D) C_2-e, C_3-a and C_4-qa. The instability factor of the substituents can be roughly estimated as follows: A; 3 skews (C_2-a and C_3-e, C_2-a and C_3-C_4 bond, C_3-e and C_4-e), B; 4 skews (C_2-a and C_3-e, C_2-a and C_3-C_4 bond, C_4-a and C_3-e, C_4-a and C_2-C_3 bond) and 1,3-diaxial interaction (C_2-a and C_4-a), C; 4 skews (C_3-a and C_2-e, C_3-a and C_2-N bond, C_3-a and C_4-e, C_3-a and C_4-$C_{benzene}$), and D; 4 skews (C_3-a and C_2-e, C_3-a and C_4-$C_{benzene}$, C_3-a and C_2-N bond, C_4-a and C_2-C_3 bond), respectively. Among these skew interactions, C_2-a and C_3-C_4 bond, C_3-e and C_4-e, C_3-a and C_2-N bond, C_3-a and C_4-$C_{benzene}$, C_4-a and C_2-C_3 bond interactions will be weakened by flattening of half-chair conformation (enlargement of the dihedral angles), and others will be enhanced because of the eclipse effect of the substituents. Therefore, both A and D conformations are almost equivalent with respect to the instability factor. The A conformation, however, is rejected so far as NMR is concerned, because the coupling constant ($J_{3,4}$) of $IIId_2$ is too small (*ca.* 1 Hz) for that of A conformation (H_3 and H_4; *trans*-diaxial). Accordingly, D conformation is preferable to $IIId_2$.

The formation ratio of $IIId_1$ (*threo*) and $IIId_2$ (*erythro*) was measured from the intensity of each H_4 protons in the crude mixture to be 55 : 45. The coupling constants of ring protons of acetyl derivatives of $IIId_1$ and $IIId_2$ shown in Table 3 indicate that the conformation of $IIId_1$ remained almost unchanged. However, $J_{3,4}$ value of $IIId_2$ changed remarkably from *ca.* 1 to 11.3. This change may be explained by the conversion of the conformation from half-chair to a twisted half-boat or by the conversion to A conformation, in order to avoid 1,2-interaction between acetyl and ethyl group.



$IIId_2$

Scheme 3

On the other hand, the NMR data in Table 3 indicate that H_4 proton of 1-acetyl derivative of $IIId_1$ (2,4-*cis*) shifts to a higher magnetic field than that of $IIId_1$ as in the case of IIIa or IIIb. This phenomenon may be of use for the conformational analysis of 4-, or 2,4- or 2,3,4-substituted 1,2,3,4-tetrahydroquinolines and others.

A general conclusion may be given for the conformation of the substituted 1,2,3,4-tetrahydroquinolines that; 1) 2,4-disubstituted 1,2,3,4-tetrahydroquinolines have a flattened half-chair conformation (C_2-e, C_4-qe or C_2-e, C_4-qa). 2) 2,3,4-Trisubstituted 1,2,3,4-tetrahydroquinolines have a remarkably flattened half-chair or twisted half-boat conformation (C_2-e, C_3-e and C_4-qe or C_2-e, C_3-a and C_4-qa). 3) 1-Acyl derivatives of the substituted 1,2,3,4-tetrahydroquinolines have a more flattened half-chair than the acyl free derivatives.

Experimental

All the aliphatic aldehydes and arylamines were purified before use by distillation of the commercial

products. The melting points were uncorrected. The measurements of NMR spectra were effected with JEOL JNM-4H-100 in deuteriochloroform by using TMS as an internal reference. IR spectra were measured with Hitachi EPI-G2. UV spectra were measured with Hitachi EPS-3T in methanol solution. TLC was carried out on layers of silica gel (WAKO-GEL B-Q) on glass plates, using benzene (system A) or benzene-ligroin (3 : 1, system B) as developers and 2% aqueous potassium permanganate-sodium carbonate or chromic-sulfuric acid (5%-$K_2Cr_2O_7$ in 40% H_2SO_4) as spray reagents. R_a value is the rate of movement of the 1,2,3,4-tetrahydroquinolines relative to aniline.

Bis(butylideneaniline) (I : 3-anilino - 2 - ethylhexylideneaniline). Equimolar amount of freshly distilled aniline and *n*-butyraldehyde was mixed and allowed to stand at room temperature for 24 hr according to the method of Kharasch *et al.*[4] White crystals were obtained in a yield of 55%. Mp 92°C (lit, 92.5°C). I in an alcoholic solution gradually isomerized to 1,2,3,4-tetrahydro-4-aniline-3-ethyl-2-propylquinoline (IIIe) and the yield decreased.

1,2,3,4-Tetrahydro-4-anilino-3-ethyl -2- propylquinoline (IIIe). To a solution of bis(butylideneaniline) (I: 2.94 g, 10 mmol) dissolved in chloroform (10 m*l*) was added two drops of acetic acid and the solution was allowed to stand at room temperature overnight, neutralized with an aqueous sodium hydrogene carbonate, washed with water and dried over Na_2SO_4. Evaporation of chloroform gave a pale yellow syrup (2.9 g), which shows no absorption band of imine at *ca.* 1650 cm^{-1}. UV: λ_{max}^{MeOH} 251 mμ (log ε=4.43), 302 mμ (log ε=3.87).

1-Tosyl Derivative of IIIe. IIIe was tosylated with *p*-toluenesulfonyl chloride (1.2 times mole of IIIe) in pyridine in an usual manner to give 1,2,3,4-tetrahydro-4-anilino-3-ethyl-2-propyl-1-tosylquinoline in a yield of 22% (crystals). Mp 210—211°C (recrystallized from acetone). IR; 3400 cm^{-1} (NH), 1340, 1162cm^{-1} (*N*-tosyl).

Found: C, 72.04; H, 7.33; N, 6.50; S, 7.42%. Calcd for $C_{27}H_{32}O_2N_2S$ (448): C, 72.29; H, 7.19; N, 6.29; S, 7.15%.

2-Ethyl-1-hexylideneaniline (IV). 2-Ethylhexaldehyde (12.8 g, 0.1 mol) was added to aniline (9.3 g, 0.1 mol) with cooling in an ice-water and the mixture was allowed to stand at room temperature overnight. After drying over Na_2SO_4, distillation of the reaction product was effected under 1 mmHg to give a pale yellow oil (15.8 g, 77.6%). Bp 92—95°C/1 mmHg.

Found: C, 82.75; H, 10.19; N, 6.76%. Calcd for $C_{14}H_{21}N$: C, 82.70; H, 10.41; N, 6.89%.

Pyrolysis of Bis(butylideneaniline)(I) to 2-Ethyl-2-hexenylideneaniline (V). I (3 g, 10.2 mmol) was filled in a sealed tube and heated in an oil bath at 120—140°C for 12 hr. Distillation of the reaction product *in vacuo* gave an oil (V) (1.5 g, 74%) having bp 142—147°C/11 mmHg (lit,[4] 146—148°C/15 mmHg). Refluxing of the acidic ethanol solution of V with 2,4-dinitrophenylhydrazine for 2 hr gave 2,4-dinitrophenylhydrazone (red crystals). Mp 118°C (lit,[4] 119—120°C).

Bis(ethylideneaniline) (1,2,3,4 - Tetrahydro - 4 - anilino-2-methylquinoline: $IIIa_1$ and $IIIa_2$). $IIIa_1$ (*cis*) and $IIIa_2$ (*trans*) were prepared from aniline (0.1 mol) and acetaldehyde (0.1 mol) in a mixture of ethanol (150 m*l*) and water (100 m*l*) in a yield of 20% ($IIIa_1$) and 22% ($IIIa_2$), respectively, by the Method of Minikin and Tumakoba.

$IIIa_1$: mp 121—124°C (lit,[2] 126°), R_a 1.64 (system A).

$IIIa_2$: syrup (lit,[2] 85.5°), R_a 2.07 (system A).

(Found of $IIIa_2$: C, 80.45: H, 7.92; N, 11.40%. Calcd for $C_{16}H_{18}N_2$: C, 80.63; H, 7.61; N, 11.78%).

1-Acetyl derivative of $IIIa_1$. To a solution of $IIIa_1$ (0.3 g, 1.26 mmol) in pyridine (2 m*l*), acetic anhydride (1 g, 10 mmol) was added and the mixture was allowed to stand at room temperature for 2 days, and then poured into ice-water. The precipitated crystalline products were filtered, washed with water, dried and recrystallized from ethanol. Yield, 0.3 g (84.6%). Mp 110.5—111°C.

Found: C, 77.40; H, 6.92; N, 9.52%. Calcd for $C_{18}H_{20}N_2O$: C, 77.11; H, 7.19; N, 9.99%.

1-Benzoyl derivative of $IIIa_1$: mp 216—217°C (lit,[2] 218°C).

1-Benzoyl derivative of $IIIa_2$: mp 156—157°C (lit,[2] 186°C).

Bis(ethylidene *p*-toluidine) [1,2,3,4-Tetrahydro-2,6-dimethyl-4-(*p*-toluidino)quinoline: IIIb]. IIIb (*cis*) was prepared by the method of Jones *et al.*[6] in a yield of 43%. Mp 113—114°C (lit, 114—116°C).

1-Acetyl derivative of IIIb; mp 141—143°C, yield 57.5%.

Found: C, 77.38; H, 7.65; N, 8.74%. Calcd for $C_{20}H_{24}N_2O$: C, 77.88; H, 7.85; N, 9.08%.

Bis(ethylidene *m*-xylidine) [1,2,3,4-Tetrahydro-2,6,8 - trimethyl - 4 - (*m*-xylidino)quinoline: IIIc]. IIIc was prepared by the method of white *et al.*[9] in a yield of 97%. Mp 141—143°C (lit, 145°C). 1-acetylation was difficult probably because of the steric hindrance due to the 8-methyl group. Yield, 15%. Mp 142—143°C (lit, 145°C).

1,2,3,4-Tetrahydro-4-hydroxy-2,6-dimethylquinoline (III'a : *trans*): mp 107.5—110°C (lit,[2] 108—110°C).

1,2,3,4-Tetrahydro-4-acetoxy -1- acetyl-2,6 - dimethylquinoline (III'b : *cis*): mp 119—119.5°C (lit,[2] 117—119°C).

1,2,3,4-Tetrahydro -1- acetyl -4- ethoxy -2- phenylquinoline (III'c : *cis*). A mixture of 1,2,3-4-tetrahydro-4-ethoxy-2-phenylquinoline[22] (1 g, 3.93 mmol), acetic anhydride (10 m*l*) and pyridine (1 m*l*) was refluxed for 15 min, allowed to stand at room temperature for 2 hr and then poured into ice-water. Precipitated oil was extracted with chloroform, and organic layer was neutralized with aqueous $NaHCO_3$, washed with water and dried over Na_2SO_4. Evaporation of chloroform gave a syrup, which was purified with a silica gel column (WAKO-GEL Q-50). From the fraction of benzene and benzene-acetone (10:1), crystalline product was obtained in a yield of 53%. Mp 120—121°C.

Found: C, 76.89; H, 6.83; N, 4.57%. Calcd for $C_{19}H_{21}NO_2$: C, 77.26; H, 7.17; N, 4.74%.

Bis(propylideneaniline) (1,2,3,4 - Tetrahydro - 4 - anilino-2-ethyl-3-methylquinoline: $IIId_1$ and $IIId_2$). To a cold solution of aniline (9.3 g, 0.1 mol) in ethanol (25 m*l*), propionaldehyde (5.8 g, 0.1 mol) was added and

22) V. I. Grigos, L. S. Povarov and B. M. Mikhailov, *Izv. Akad. Nauk. SSSR, Ser. Khim.*, **1965**, 2163; *Chem. Abstr.*, **64**, 9680c (1966).

the reaction solution was allowed to stand in a refrigerator for 2 days. The white crystalline mass was filtered and the crude product ($IIId_1$, 4.8 g) was recrystallized from ethanol. Mp 104—105°C (lit,[2] 103°C), R_a 2.46 (system B). The mother liquor, scarcely containing any $IIId_1$, was evaporated *in vacuo* to a syrup ($IIId_2$, 5.2 g) and the small amount of remaining aniline was distilled off. R_a 2.88 (system B).

Found: C, 80.99; H, 8.31; N, 11.42%. Calcd for $C_{18}H_{22}N_2$: C, 81.16; H, 8.33; N, 10.52%.

Acetylation of $IIId_1$ and $IIId_2$ with acetic anhydride and pyridine gave 1-acetyl derivatives respectively in good yields.

1-Acetyl derivative of $IIId_1$: mp 135—136°C.

Found: C, 78.09; H, 7.86; N, 8.73%. Calcd for $C_{20}H_{24}N_2O$: C, 77.88; H, 7.84; N, 9.08%.

1-Acetyl derivative of $IIId_2$: mp 175—175.5°C.

Found: C, 78.12; H, 8.10; N, 9.27%. Calcd for $C_{20}H_{24}N_2O$: C, 77.88; H, 7.84; N, 9.08%.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 2894—2898 (1969)

Reaction of *p*-Nitrophenyl Benzenesulfonates with Thiophenoxides

Waichiro TAGAKI, Takehiko KURUSU and Shigeru OAE

Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sumiyoshi-ku, Osaka

(Received December 29, 1968)

The reaction of *p*-nitrophenyl benzenesulfonates has been investigated in dioxane-water solvent. The overall rate constant, k_A, was separated into two composite rate constants, k_{Ar}, and k_{SO_2}, corresponding to the cleavage of C–O and S–O bonds respectively. The reactivities of hydroxide and thiophenoxide in this reaction were compared. The overall rate constant was found to be several times larger with OH^- than with PhS^-. The reactivity of OH^- was largely due to its higher reactivity toward sulfur, while its reactivity toward carbon atom was comparable to that of PhS^-. Substituent effect of the nucleophile, thiophenoxide and of the substrate shed some light on the mechanism of this reaction.

The nucleophilic substitution reaction of sulfonic acid esters is well known. The attacking site of the ester is either the sulfur atom (S–O bond cleavage) or the phenolic or alcoholic carbon atom (C–O bond cleavage), or both, depending on the type of the ester, nucleophiles and reaction conditions. For the substitution reaction on sulfur, there are two possible mechanisms. One is the S_N2 type synchronous mechanism and the other is the two step mechanism, *i.e.* addition and elimination, using a low energy 3*d*-orbital of sulfur atom. The latter possibility, however, has been ruled out for the alkaline hydrolysis of phenyl benzenesulfonate on the basis of our ^{18}O tracer study,[1] and the former S_N2 type substitution has been found to be the main reaction pathway. The C–O bond cleavage is well known in aliphatic compounds. However, for unsubstituted phenyl benzenesulfonate, such C–O bond cleavage is not important, and becomes significant only with *p*-nitrophenyl benzenesulfonte. In an extreme case, Bunnett[2] has shown that 2,4-dinitrophenyl benzenesulfonate undergoes exclusive C–O bond cleavage when thiophenoxide is used as the nucleophile, while such C–O bond cleavage become less significant, when phenoxide is used as the nucleophile. Meanwhile the nucleophilic substitution reaction of 4-nitrohalobenzene has been investigated rather extensively.[3] The most reasonable mechanism for this reaction seems to be the two step mechanism, *i.e.* addition of a nucleophile to the benzene ring (bond forming) followed by the cleavage of the group (bond breaking) to be substituted. According to Bunnett[4] the bond forming step is the rate limiting for most of the substrates and nucleophiles.

During the course of our studies on the mechanism of the nucleophilic reduction of sulfur atom in sulfate and sulfonate by thiol compounds, we became interested in the reaction of *p*-nitrophenyl benzenesulfonate with thiophenol. We began the present study to investigate the following questions: the reactivities of hydroxide and thiophenoxide anions, the relative rate of the reactions on

sulfur and carbon, and the relative importance of bond forming and bond breaking steps. Another purpose was to compare this reaction with the alkaline hydrolysis of thiolsulfinate and thiolsulfonate as described in the preceding two papers.[5]

Results and Discussion

Products. The major reaction pathways can be formulated as in the Eqs. (1)—(3). The product analysis was carried out for the reaction of *p*-nitrophenyl *p*-toluenesulfonate (X=CH_3) with thiophenoxide (Y=H).

All the possible products shown in Eqs. (1)—(3) except thiolsulfonate III, were identified (Table 1); the tabulated yields are the total yields.

The relative rate of the initial two reactions, k_{SO_2} and k_{Ar} could be judged from the relative yield of *p*-nitrophenol IV, and *p*-nitrophenyl *p*-tolyl sulfide VI, respectively. Although quantitative sepatation of IV and VI was not attempted, it was possible to estimate the amounts of IV and VI and found to be comparable from the measurement of optical density of the UV absorption of the reaction mixture at around 340 mμ. The rate of the reaction of thiolsulfonate III (Eq. (3)) is presumably

greater than that of I in view of the fact that III undergoes rapid alkaline hydrolysis.[6] The relative amounts of sulfonic acid salt V and sulfinic acid salt VII, were not determined. However, their amounts should be the same as those of IV and VI.

Kinetics and Substituent Effects. The UV spectra of the starting ester and the two products, *p*-nitrophenol IV and *p*-nitrophenyl *p*-tolyl sulfide VI, are shown in Fig. 1. Their spectral shapes and the extinction coefficients were nearly the same as for the other substituted compounds.[5] The spectra of the other products, salts V and VII and disulfide VIII, are found in the same spectrum region of the ester, but are different from those of IV and VI. Therefore the rate of the reaction could be followed easily by observing the increase of the optical density near 320 mμ due to the formation of IV and VI (as the total) where the absorption by the ester is negligible. A typical example of the plot of optical density change against the reaction time is shown in Fig. 2. In order to

avoid complication from the rest of the reactions shown in Eq. (3), only the initial rate was used for the calculation of the rate constant using Eq. (4).

$$\text{Initial rate} = k_A\,(RS^-)_0\,(\text{Ester})_0 \qquad (4)$$

$k_A = k_{Ar} + k_{SO_2}$

$(RS^-)_0$ = Initial concentration of thiophenoxide

$(\text{Ester})_0$ = Initial concentration of the ester

Details of the kinetic procedures and the modification of Eq. (4) for the actual calculation are described in the experimental part. In Eq. (4), one needs to know the initial concentration of thiophenoxide anion, $(RS^-)_0$, which is not necessarily the same as that of added salt, sodium thiophenoxide II. In order to calculate the concentration of thiophenoxide ion, the apparent pK_a of unsubstituted thiophenol was determined spectrophotometrically as a function of solvent composition in dioxane-water mixture. The pK_a of thiophenol thus obtained increased substantially as the dioxane content increased: water, 6.65 : 40% dioxane-water (v/v), 7.78; 60% dioxane-water, 8.70. From these values, one can obtain the concentration of the anion when one knows the pH of the reaction mixture. It is also possible to observe the change of the ratio of $(PhS^-)/(PhSH)$ as a function of the concentration of added salt (PhS^-Na^+). These two methods indicate that the added salt exists essentially as dissociated anion even in 80% dioxane-water, provided that the concentration of the added salt is kept around 0.005—0.015 M.

The effect of the composition of dioxane-water mixture on the rate has been examined as shown in Table 2. Although the rate increased as the solvent polarity increased, the effect was rather small. Therefore, the rates were determined for comparison in 80% dioxane-water, in which organic substrates can be readily dissolved.

60	7.53
70	6.66
80	5.50

The rate constants thus obtained are the overall rate constants including both that of the C–O bond cleavage, k_{Ar}, and that of the S–O bond cleavage, k_{SO_2}. The separation of the two rates was next attempted. The value of k_{Ar} was calculated using the change of optical density at 360 mμ where the absorption by the ester is negligible and that by IV is small compared to that by VI. The rate constant, k_{SO_2}, was then computed by substracting k_{Ar} from the overall rate constant, k_A. Although the reproducibility of k_A was quite satisfactory, high accuracy of the subsequent separation may not be expected, since the absorption at 360 mμ is not

at λ_{max} but at a declinging slope. In spite of this limitation, the results were quite reproducible.

The rate constants observed for the reaction of *p*-nitrophenyl *p*-toluenesulfonate with four different thiophenoxides are shown in Table 3. The rate constants for the reaction of *p*-nitrophenyl *p*-substituted - benzenesulfonate with thiophenoxide are shown in Table 4. The correlation of these rate constants with Hammett σ constants are shown in Figs. 4 and 5.

Table 3 and Fig. 4 indicate that an electron donating substituent at the *p*-position of nucleophile increased the overall rate (k_A), giving Hammett ρ value $= -0.63$. The separation of k_A into k_{Ar} and k_{SO_2} revealed that the overall rate change is

○ $\rho = -0.63$ (k_A, the overall rate)
● $\rho = -2.11$ (k_{Ar}, C–O bond cleavage)

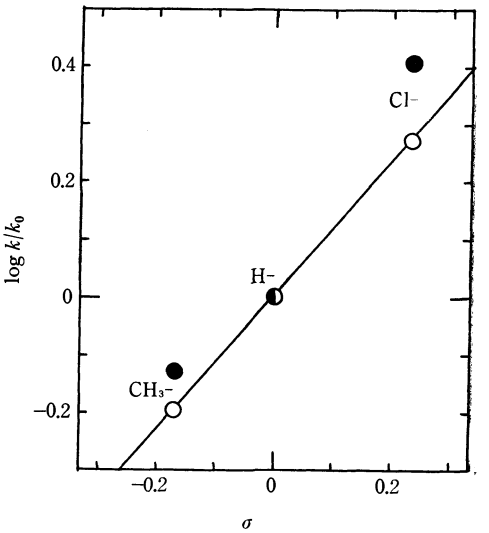

Fig. 5. Hammett plot for the reaction of *p*-nitrophenyl *p*-substituted - benzenesulfonates with thiophenoxide in 80% dioxane-water at 50°C.
○ $\rho = 1.18$ (k_A, the overall rate)
● $\rho = 1.38$ (k_{SO_2}, S–O bond cleavage)

caused mainly by the change of k_{Ar} ($\rho = -2.11$). That is, the C–O bond cleavage is more susceptible to the change of nucleophile than the S–O bond cleavage, and the C–O bond cleavage appears to increase with increasing nucleophilicity of the nucleophile. The results in Table 4 and Fig. 5 indicate that the effect of substituent X is larger for the S–O bond cleavage than for the C–O bond cleavage.

In nucleophilic substitution reactions of *p*-substituted nitrobenzene derivatives, one of the criteria for the rate limiting step is the effect of the leaving group.[3,4] The rate limiting step would be the bond formation (the addition of nucleophile to the benzene ring), if the reaction is insensitive to the leaving group. According to this criteria, the rate limiting step of this reaction would be also the addition of thiophenoxide anion to the benzene ring in line with the results in Table 4. The bond forming step also seems to be more important in the nucleophilic reaction on the sulfur atom, as the k_{SO_2} increases with an increasing electron withdrawing group (Table 4), although the effect of the nucleophile (Table 3) is not in line with this argument. The reaction of *p*-chloronitrobenzene was also carried out under the same condition. The results (Table 4) indicate that the abilities of chloride and sulfonate anion are comparable with those of the leaving group, suggesting also the indifference of this reaction to the nature of the leaving group.

In Table 5, the rates of the alkaline hydrolysis and the reaction with thiophenoxide are compared. The overall rate of the alkaline hydrolysis is about

3—4 times higher than that of the reaction with thiophenoxide ($X=CH_3$). The separation of the overall rate (from ^{18}O data) then revealed that in alkaline hydrolysis the rate is largely due to the cleavage of the S–O bond, while in the reaction of thiophenoxide the rates of both the C–O and the S–O bond cleavage are of a comparable magnitude.

Experimental

Material. Substituted *p*-nitrophenyl benzenesulfonate was prepared by the reaction of *p*-nitrophenol with substituted benzenesulfonyl chloride in pyridine. The produced esters were recrystallized from ethanol: *p*-$XC_6H_4SO_2OC_4H_4NO_2$-*p*; X=H, mp 87°C (lit, 88—89°C) *p*-CH_3, mp 95—96°C (lit, 97°C); *p*-Cl, mp 112—113°C (lit, 110°C). Dioxane was purified just before use by treating with hydrochloric acid and metallic sodium under N_2 gas.[7]

***p*-Substituted Sodium Thiophenoxide.** Thiophenol was dissolved in benzene and to this was added a slightly less amount of sodium hydroxide than that required in order to avoid inclusion of any excess sodium hydroxide in the product. The mixture was refluxed for 3 hr under stirring. The water formed was distilled off with benzene and the resulting white powder was collected by filtration and washed with benzene and dried.

Product Analysis. Reaction of *p*-Toluenesulfonate with Sodium Thiophenoxide in 80% Dioxane-Water. *p*-Nitrophenyl *p*-toluenesulfonate (0.2 g) and thiophenoxide (0.2 g) were dissolved in 80% dioxane-water (10 m*l*) in an ampoule. The ampoule was sealed under N_2 atmosphere and then kept at 50°C for 12 hr. The reaction mixture was made slightly acidic and extracted with ether. Treatment of the ether layer gave 0.21 g of the mixture of *p*-nitrophenol, phenyl *p*-nitrophenyl sulfide and diphenyl disulfide. The water layer gave a mixture of sodium *p*-toluenesulfonate and *p*-toluenesulfinate (0.18 g). The yield of *p*-nitrophenol could also be measured spectrophotometrically in an alkaline solution.

Kinetic Experiment. Solution of both *p*-nitrophenyl benzenesulfonate (0.01—0.02 M), 10 m*l*, and thiophenoxide (0.01—0.02 M) in dioxane-water were kept separately in a constant temperature bath for over 10 min. Then 10 m*l* of thiophenoxide solution was added to the ester solution, and 1 m*l* aliquots of this reaction mixture were pipetted out at suitable time intervals and quenched with 0.01 N HCl - ethanol solution in 50 m*l* volumetric flask to give an assay solution. Thus the concentration of this assay solution was 1/50 of that of the reaction mixture.

Since the reactions were not simple (Eqs. (1)—(3)), only the UV absorption due to the formation of both *p*-nitrophenol (IV) and phenyl *p*-nitrophenyl sulfide (VI) was followed. Figure 1 indicates that both IV and VI give the same molar extinction coefficient at 320 mμ in acidic solution. Therefore the initial change of the optical density of the above assay solution at 320 mμ should be proportional to the change of the total concentration of IV and VI which should then be proportional to the initial concentrations of the ester and thiophenoxide as formulated in

$$\frac{\mathrm{d(O.D.\ at\ 320\,m\mu)}}{\mathrm{d}t} = \frac{\varepsilon_0}{\alpha}\frac{\mathrm{d((IV)+(VI))}}{\mathrm{d}t} \quad (5)$$

$$\frac{\mathrm{d((IV)+(VI))}}{\mathrm{d}t} = \frac{\alpha}{\varepsilon_0}\frac{\mathrm{d(O.D.)}}{\mathrm{d}t} = k_A\,(RS^-)_0(E)_0 \quad (6)$$

where $(E)_0$=initial concentration of the ester, $(RS^-)_0$=initial concentration of the thiophenoxide, ε_0=molar extinction coefficient at 320 mμ, α=dilution factor of the reaction mixture for recording of optical density, and k_A=the overall second order rate constant.

A typical example of the plot of optical density change against reaction time is shown in Fig. 2. A plot of the initial slope of optical density change as a function of the initial concentration of ester gives a straight line as shown in Fig. 3, from which one can obtain k_A.

The above k_A is the overall rate constant including both of the C–O and S–O bond cleavages. Their separation was then attempted by recording the absorbance change at 360 mμ which corresponded to the formation of V.

The applicability of the absorption above 320 and 360 mμ for these kinetics was checked for several known mixtures of IV and V at the same total concentrations, and it was confirmed that Beer's law holds and the accuracy is satisfactory. The error involved in the graphical reading of the slope (Fig. 2) sometimes amounted to ±5%. However, the rate constants (k_{obs}) shown in Fig. 3 were surprisingly reproducible; the deviation was generally within ±3%.

The alkaline hydrolysis was also carried out by the same method. The results are shown in Tables 3, 4 and 5.

pK_a of Thiophenol in Dioxane-Water of Different Composition. Undissociated thiophenol has an absorption maximum at around 240 mμ (ε=7425) and the dissociated anion at around 270 mμ (ε=14500). Based on these absorptions the pK_a value of thiophenol was determined spectrophotometrically using phosphate buffer in three different dioxane-water mixtures at 25°C: water, 6.65; 40% dioxane-water (v/v), 7.78; 60% dioxane-water, 8.70.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 2899—2903 (1969)

Alkaline Hydrolysis of Aryl Benzenethiolsulfinates

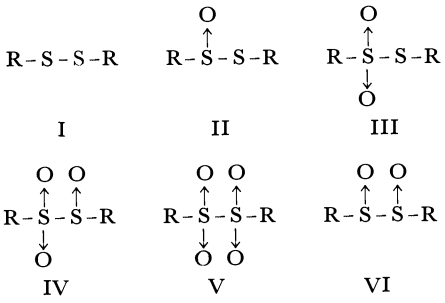
Shigeru OAE, Yoichiro YOSHIKAWA and Waichiro TAGAKI

Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sumiyoshi-ku, Osaka

(Received December 29, 1968)

The alkaline hydrolysis of substituted phenyl benzenethiolsulfinates has been kinetically investigated. The rates were correlated with the second order kinetic equation, first order with respect to each of the hydroxide and the ester concentration. The second order rate constant for the unsubstituted ester was found to be 3.17×10^3 *l*/mol sec (water, 30°C). The Hammett ρ values were found to be $\rho_{X,Y=H}=2.4$ and $\rho_{Y,X=H}=1.6$ for Y-  -X respectively.

Bond forming and scission of sulfur-sulfur linkage are important not only in industrial chemistry but also in biochemistry since the disulfide bridge is most frequently involved in the building up structures of proteins and enzymes and its formation and cleavage play an important role in controlling protein structures and the catalytic activities of enzymes.[1] The compounds which have S-S linkage undergo various reactions and may be classified into the following types (I—VI).[2] These compounds are involved in such reactions as hydrolysis, oxidation reaction and disproportionation of various organosulfur compounds. For



I II III

IV V VI

example, in the alkaline hydrolysis of diphenyl thiolsulfonate, the following consecutive reaction steps seem to be involved.

$$Ph\text{-}SO_2\text{-}S\text{-}Ph + OH^- \xrightarrow{-H^+} PhSO_2^- + PhSO^- \quad (1)$$

$$2PhSO^- \xrightarrow{+2H^+} Ph\text{-}\overset{\overset{O}{\uparrow}}{S}\text{-}S\text{-}Ph + H_2O \quad (2)$$

$$Ph\text{-}\overset{\overset{O}{\uparrow}}{S}\text{-}S\text{-}Ph + OH^- \xrightarrow{-H^+} PhSO_2^- + PhS^- \quad (3)$$

$$Ph\text{-}SO_2S\text{-}Ph + PhS^- \longrightarrow PhSO_2^- + PhSSPh \quad (4)$$

$$Ph\text{-}\overset{\overset{O}{\uparrow}}{S}\text{-}S\text{-}Ph + PhS^- \xrightarrow[etc.]{} PhSO^- + PhSSPh \quad (5)$$

The product analysis and the qualitative rough kinetic estimation of the rates of the nucleophilic substitution of these compounds, particularly with hydroxide ion, have been subjects of continued investigation.[3] Recently Kice has reviewed the chemistry involved in the cleavage of S-S linkage in the substitution reactions of various sulfur compounds whose central sulfur atoms are S^{II}, S^{III}, S^{IV}, *etc.*

It is believed that thiolsulfinate (II) and thiolsulfonate (III) are substantially more reactive than the corresponding disulfide (I) toward common nucleophile. However, no rate of alkaline hydrolysis of thiolsulfinate (II) or thiolsulfonate (III) has ever been determined.

From our interest in organic sulfur compounds and their biological significance, we have investigated the alkaline hydrolyses of II and III together with a related reaction of phenyl benzenesulfonate with thiophenoxide which gives III as the intermediate.

This paper describes the results for substituted phenyl benzenethiolsulfinate (II). The other two papers[4] will describe the results for substituted phenyl benzenethiolsulfonate (III) and aryl

benzenesulfonate, respectively.

Results and Discussions

Products. According to Vinkler and Klivenyi,[5] the products of alkaline hydrolysis of aryl benzenethiolsulfinate are arenesulfinic acid and diaryl disulfide. We confirmed their result. However, it is difficult to visualize how these products are formed. Presumably a part or all of the reactions shown in Eqs. (1)—(5) (and more) take place in a competitive manner to result in the products. Thus the overall reaction appears rather complicated. However, as for the very initial reaction there are only two possibilities, the attack of hydroxide ion on sulfinyl sulfur, Eq. (3)[6] and that on the divalent sulfur atom Eq. (6). Of the two, Eq. (3) is certainly more important than, Eq. (6),

$$\mathrm{Ph\text{-}\overset{\uparrow}{\underset{\mathrm{O}}{S}}\text{-}S\text{-}Ph} + OH^- \xrightarrow{-H^+} \mathrm{Ph\text{-}\overset{\uparrow}{\underset{\mathrm{O}}{S}}\text{-}O^-} + PhS^- \qquad (3)$$

$$\mathrm{Ph\text{-}\overset{\uparrow}{\underset{\mathrm{O}}{S}}\text{-}S\text{-}Ph} + OH^- \xrightarrow{-H^+} 2\,\mathrm{Ph\text{-}S\text{-}O^-} \qquad (6)$$

since hydroxide being a hard base, would preferentially attack the harder acidic sulfinyl sulfur than the sulfenyl sulfur atom[7] and moreover the sulfenate anion formed would regenerate the starting ester according to Eq. (2).[8] Therefore the initial rate of this hydrolysis can be taken as the rate of the displacement of thiophenoxide ion by the attack of hydroxide ion on the sulfinyl sulfur. This is the basic assumption for the present kinetics.

Kinetics for the Phenyl Benzenethiolsulfinate. The rates of alkaline hydrolyses of all the compounds examined were found to be very great. The kinetic experiments were therefore carried out in a pH-controlled buffer solution, the concentration of the ester being kept around 10^{-4} M. The buffer chosen was *N*-ethylmorpholine *N*-ethylmorpholine sulfate which was advantageous in view of its inertness to the reaction system, and its fair solubility in 60% ethanol-water solvent (no precipitation).

The kinetic measurement was carried out by observing the disappearance of a characteristic UV absorption band of a strating ester (*e.g.* 282 mμ for phenyl benzenethiolsulfinate) spectrophotometrically, and the initial rate was then determined graphically (Fig. 1). The initial rate should be proportional to the initial concentrations of both the ester and hydroxide ion as expressed by

$$-\frac{d(\mathrm{Ester})}{dt} = k_{obs}(E)_0 = [k_0 + k_{OH^-}(OH^-)_0](E)_0 \qquad (7)$$

where k_0 and k_{OH^-} are the rate constants for spontaneous and alkaline hydrolyses, respectively, and $(OH^-)_0$ and $(E)_0$ the initial concentrations of hydroxide and the ester, respectively. Since the hydrolysis was not observed in 60% ethanol-water solvent (pH≈5) without buffer, the contribution of k_0 must be small.

The first order dependence of the rate on the initial concentration of the ester is shown in Fig. 2. The first order dependence of the k_{obs}, obtained from the slope in Fig. 2, on the hydroxide ion concentration is shown in Fig. 3. The error involved in the graphical reading of the initial slope was within ±3% for duplicate or triplicate runs and the deviation of the rate constants was generally within ±3%.

8) Benzenesulfenic acid has never been isolated, and hence must be a very unstable compound. In the hydrolysis of benzenesulfenyl chloride, the products are known to be sufinic acid and disulfide, where the initial intermediate must be sulfenic acid.

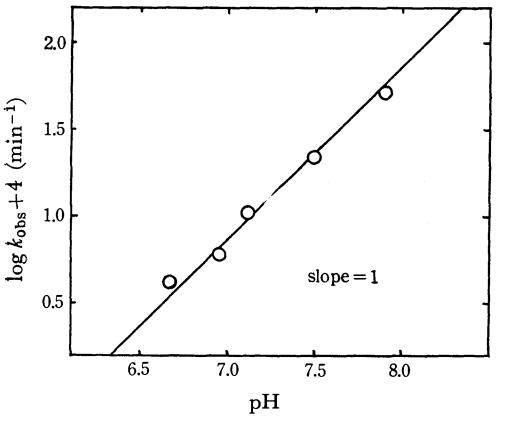

Fig. 3. Plot of log k_{obs} *vs.* pH; ester, PhS(O)SPh; solvent, 60% ethanol-water; 30°C $(E)_0 = 1.10 \times 10^{-4}$ M.

The intercept gives the value of log k_{OH^-} K'_w based on:

$$\log k_{obs} = \log k_{OH^-}(OH^-)_0 = \log k_{OH^-}K'_w + pH \quad (8)$$

In order to determine k_{OH^-} one has to know the ion product, K'_w in 60% ethanol-water solvent. Meanwhile it is possible to extrapolate the k_{obs} found in 60% ethanol-water solvent to that in water by changing the solvent composition, using the same buffer ratio and concentration.[9] Figure 4 shows that such an extrapolation gives k_{obs} in water and permits the calculation of k_{OH^-} in water using $pK_w = 13.83$ (30°C).[10]

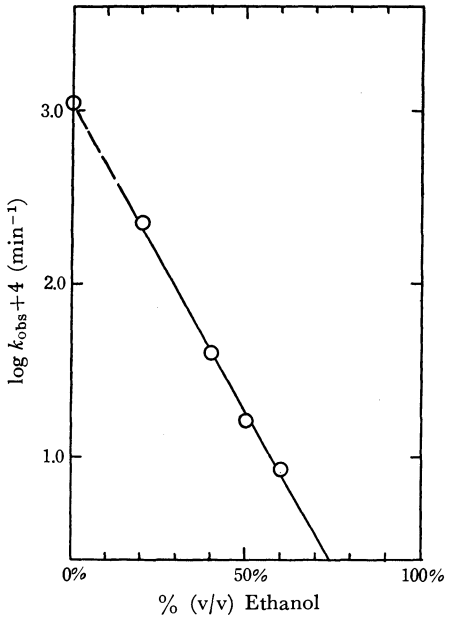

Fig. 4. Plot of log k_{obs} *vs.* percent of ethanol in the solvent; ester, PhS(O)SPh; 30°C pH=7.59 in water.

The k_{OH^-} value thus obtained for unsubstituted phenyl benzenethiolsulfinate is 3.17×10^3 *l*/mol sec at 30°C. From the Arrhenius plot shown in Fig. 5, E_a and $\Delta S^{\neq}$ were calculated to be 13 kcal/mol and −3 e.u. (at 30°C), respectively, for the unsubstituted phenyl benzenethiolsulfinate.

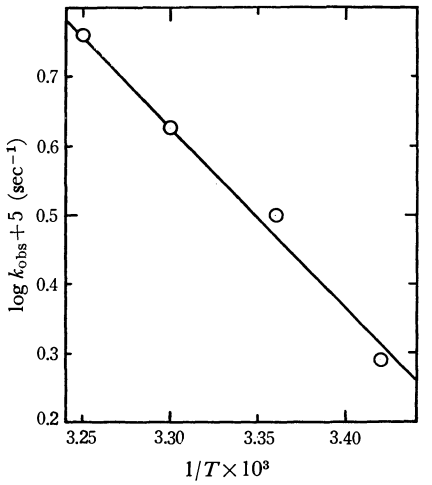

Fig. 5. Arrhenius plot; ester, PhS(O)SPh; solvent, 60% ethanol-water; pH=7.5 in 60% ethanol-water.

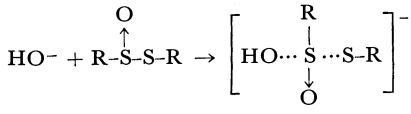
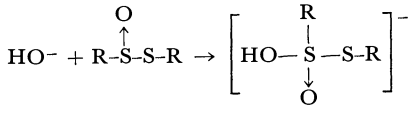
Substituent Effect. As shown in Fig. 6, introduction of an electron-withdrawing substituent into *p*-position of either one of the two benzene rings of the thiolsulfinate accelerated the rate, while an electron-releasing substituent retarded, giving Hammett ρ values of $\rho_{X,Y=H} = 2.4$ and $\rho_{Y,X=H} = 1.6$ respectively.

As discussed already, the above rates are those of the reaction 3, *i. e.*, the reaction on sulfinyl sulfur. A question may arise whether the reaction proceeds in one step mechanism (a) or through a pre-equilibrium formation of an unstable addition complex involving sulfur 3*d*-orbital (b). The observed substituent effect unfortunately does not answer these questions.



$$\xrightarrow{-H^+} RSO_2^- + RS^- \quad (a)$$



$$\xrightarrow{-H^+} RSO_2^- + RS^- \quad (b)$$

● $\rho_X=2.4$, ○ $\rho_Y=1.6$

Thiolsufinates are known to be rather unstable. They undergo thermal disproportionation at relatively low temperatures,[11] and are very susceptible to the acid catalyzed nucleophilic reactions.[2] This unstable nature of the thiolsulfinates is partly responsible for its unusually high reactivity, $k_{OH^-}=3.17\times10^3$ M^{-1} sec^{-1} (30°C) and the relatively low activation energy ($E_a=13$ kcal/mol).[12]

Experimental

Materials. *Substituted Phenyl Benzenethiolsulfinates* were prepared by the reaction of benzenesulfinyl chloride with thiophenol in the presence of pyridine according to the method of Backer and Kloosterziel.[13] The products were recrystallized from petroleum ether-chloroform mixed solvent. Their properties are listed in Table 1.

N-Ethylmorpholine. Commercial sample (Nakarai Co.) was distilled, bp 135—136°C/760 mmHg.

Ethanol. Commercial sample was treated with calcium oxide and rectified.

Buffer Solutions. Stock solutions of *N*-ethylmorpholine *N*-ethylmorpholinesulfate buffer, 0.1 M, were made by mixing 0.2 M solution of *N*-ethylmorpholine with 0.2 N sulfuric acid in several buffer ratios, log-(BH$^+$)/(B) = −0.955—+0.477.

Kinetic Experiment. A solution of 1 m*l* of phenyl benzenethiolsulfinate (5×10^{-3} M) in absolute ethanol was added to the mixture of 29 m*l* of ethanol and 20 m*l* of the above buffer stock solution, the latter mixture being kept in a constant temperature bath prior to the addition of ester. Aliquots of this reaction mixture were withdrawn and recorded for the optical density near 280 mμ, using Hitachi 124 double beam spectrophotometer.[14] The change of optical density was plotted against reaction time. The initial slope obtained graphically was proportional to the initial rate of the reaction with proportionality constant, ε, the molar extinction coefficient of the ester at the wavelength, near 280 mμ, as shown in Eq. (7′). A typical

Alkaline Hydrolysis of Aryl Benzenethiolsulfonates

Shigeru OAE, Ryuichi NOMURA, Yoichiro YOSHIKAWA and Waichiro TAGAKI

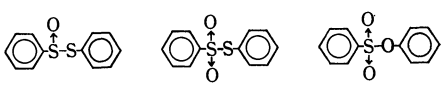
Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sumiyoshi-ku, Osaka

(Received December 29, 1968)

The alkaline hydrolysis of substituted phenyl benzenethiolsulfonates has been investigated. The rate was found to be first order with respect to both hydroxide and ester. The second order rate constant for the unsubstituted ester was found to be 3.2×10^3 M^{-1} sec^{-1} (water 45°C). The Hammett ρ values were found to be $\rho_{X,Y=H}=2.1$ and $\rho_{Y,X=H}=1.1$ for  respectively. The reactivities of three esters, *i. e.* phenyl benzenethiolsulfonate, -thiolsulfonate and -sulfonate were compared.

The bond forming and breaking of sulfur-sulfur linkage are very important in biochemistry as well as in organic syntheses. However, the substitution reactions on S^{II}, S^{III}, S^{IV} are relatively unexplored.[1]

In a previous paper, we have shown that the alkaline hydrolysis of substituted phenyl benzenethiolsulfinate (I) is very rapid and proceeds mainly by the attack of hydroxide ion on the sulfinyl sulfur to give sulfinic acid and disulfide.[2] A compound closely related to I is phenyl benzenethiolsulfonate (II) which is known also to give sulfinic acid and disulfide in alkaline hydrolysis.[3] However, there is an important difference between the two esters. While II appears thermally more stable than I, the attacking site of hydroxide is



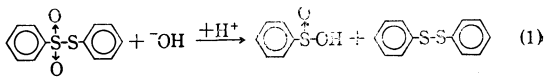
I II III

considered to be the sulfenyl sulfur atom in the case of II, unlike the case of I[3] although detailed features of these chemistries are yet to be clarified.

The present investigation has been undertaken to disclose the nature of the alkaline hydrolysis of the substituted derivatives of II, by means of the kinetic determination of the rates and a comparison with those of I and the related compound III.

Results and Discussion

Product. Phenyl benzenethiolsulfonate (II) was found to give 1.7 mol of benzenesulfinic acid and a small amount of diphenyl disulfide from one mole of the ester in the reaction with an excess amount of sodium hydroxide in 96% ethanol.



(1)

1 mol excess 1.7 mol detected

Attempts to confirm the possible formation of the corresponding sulfonic acid have failed as was the case with other workers.[3] The formation of more than equimolar amount of the sulfinic acid from the ester used may be rationalized if one assumes the following consecutive reactions.

$$PhSO_2SPh + OH^- \xrightarrow{-H^+} PhSO_2^- + PhSO^- \quad (2)$$

1) J. L. Kice, *Accounts of Chemical Research*, **1**, 58 (1968).

2) S. Oae, Y. Yoshikawa and W. Tagaki, This Bulletin, **42**, 2899, (1969).

3) R. Otto and A. Rossing, *Ber.*, **19**, 1235 (1886).

$$2PhSO^- \xrightarrow{+2H^+} PhS(O)SPh + H_2O \quad (3)$$

$$PhS(O)SPh + OH^- \xrightarrow{-H^+} PhSO_2^- + PhS^- \quad (4)$$

$$PhSO_2SPh + PhS^- \longrightarrow PhSO_2^- + PhSSPh \quad (5)$$

Kinetics. From product analysis, the attacking site of hydroxide ion is most likely the sulfenyl sulfur atom. (Eq. (2)). However, there still remains a question as to sulfenic acid. The rates of the alkaline hydrolyses of all the compounds examined were also found to be very rapid. Therefore the kinetic measurements were carried out in a pH-controlled buffer solution. The buffer used was *N*-ethylmorpholine *N*-ethylmorpholine sulfate which did not react with the ester under the same reaction condition and did not precipitate in 60% ethanol-water solution.

The kinetic rates were followed by observing the amounts of disappearance of the starting ester (see experimental). Since the reaction was expected to be complicated as illustrated in Eqs. (2)—(5), only the initial rate was used for the calculation of the rate constants based on

$$\frac{-d(Ester)}{dt} = k_{obs}(E)_0 = [k_0 + k_{OH^-}(OH)_0](E)_0 \quad (6)$$

where k_0 and k_{OH^-} are the rate constants for both spontaneous and alkaline hydrolyses respectively, and $(OH^-)_0$ and $(E)_0$ are the initial concentrations of hydroxide and the ester, respectively.

The first order dependence of the rate on the initial concentration of II and on pH was observed to be similar to that in the hydrolysis of the corresponding sulfinate.[2] In order to obtain an extrapolated value of the rate in water, k_{obs} was plotted against ethanol concentration in the solvent under the same buffer ratio to give a straight line, as shown in Fig. 1.

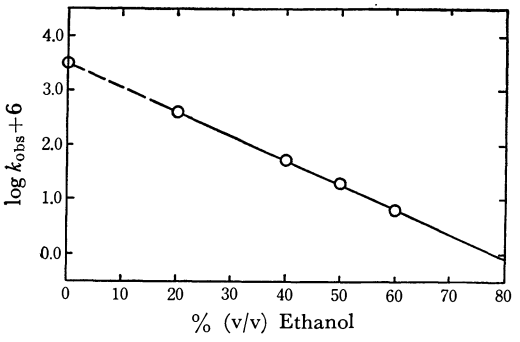


Fig. 1. Plot of pseudo first-order rate constants k_{obs} *vs.* percent of ethanol in the solvent; ester, $PhSO_2SPh$; $(E)_0 = 3.60 \times 10^{-3}$; 45°C; pH=7.5 in 60% ethanol-water.

From Fig. 1 the second order rate constant of the alkaline hydrolysis of II in water was calculated to be 3.2×10^3 *l*/mol sec at 45°C. Meanwhile the Arrhenius plot gave E_a and $\Delta S^{\neq}$ values to be 10 kcal/mol and −13 e.u. (at 45°C), respectively, in 60% ethanol-water. The error involved in the rate constant was within, +5% *i. e.*, the same order of magnitude as in the previous paper.

Substituent Effect. Introduction of an electron-withdrawing substituent at *p*-position of either one of the two benzene rings of the ester accelerated the rate while that of an electron-releasing substituent retarded. The results are shown in Table 1 and their Hammett plot is shown in Fig. 2. From Fig. 2 Hammett ρ values were calculated to be $\rho_X = 2.1$ and $\rho_Y = 1.1$.

Although the results so far described are not sufficient to allow any detailed discussion on the mechanism of the overall hydrolysis reaction, it is interesting to compare the initial rate of the hydrolysis of the following three closely related esters which are summarized in Table 2.

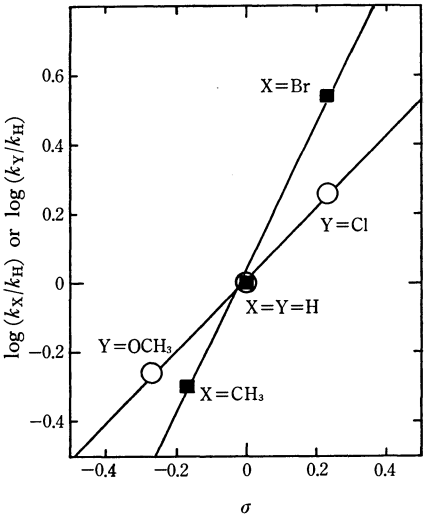

Fig. 2. Hammett plot; plot of $\log(k_X/k_H)$ or $\log(k_Y/k_H)$ for hydrolysis of *p*-substituted phenyl-benzenethiolsulfonates in 60% ethanol-water at pH 7.5 and 45°C *vs.* σ.

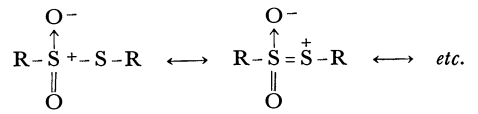
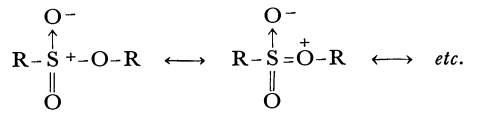
In order to correlate the rates and the substituent effects, it is necessary to know the attacking site of hydroxide ion for each of the esters. In the case of sulfonate (III), the attacking site is known to be exclusively the sulfonyl sulfur atom from the ^{18}O tracer study, except for the ester bearing $X=NO_2$ which undergoes significant C–O bond cleavage (about 20%) by the attack of hydroxide ion on the benzenoid carbon of phenolic part.[5]

For the other two esters, I and II, the assignment of the attacking site is by no means clear, since in both cases the reactions appear to be so complicated that the product analysis alone cannot give a conclusive answer. However, the assignement is possible if one limits the discussion to only the very initial stage of the reactions. Since no sulfonic acid was detected in the hydrolysis of II, the rate of its initial reaction must be that of the initial attack of hydroxide on the sulfenyl sulfur, whereas in the case of I, the reaction is either an exclusive attack on the sulfinyl sulfur or a competitive attack on both the sulfinyl and the sulfenyl sulfur. Since the hydrolysis products of I are benzenesulfinic acid and diphenyl disulfide, the attack on the sulfenyl sulfur to give the sulfenic acid must be followed by other succeeding reactions. The probable reaction of the sulfenic acid in neutral or acidic media is self-condensation to regenerate the starting ester, I (Eq. (3)). Therefore, the rate of the hydrolysis of I becomes the same as that of the initial attack of hydroxide ion on the sulfinyl sulfur. The ρ_X values are identical for all the three esters in spite of the wide range of their reactivities, while the ρ_Y values vary somewhat more widely. The fact that both ρ_X and ρ_Y are almost the same for sulfonates (III) appears to be in line with the one step S_N2 mechanism which has been suggested from our previous ^{18}O tracer study.[6] The same mechanism might also be applied in the hydrolysis of I and II although the ρ_Y is smaller than ρ_X. A smaller ρ_Y for II could be due to the difference in the attacking site, and the effect of ρ_Y may be weakened by the presence of sulfonyl group inserted between the reaction centers.

The most important finding is an enormous rate difference between the sulfonate and the other two sulfur analogs. Both the heat and entropy of activation seem to be responsible for this rate difference. Unfortunately the data for substituted phenyl benzenesulfinates are not yet available for a comparison with those of thiolsulfinate (I). Both thiolsulfonate (II) and sulfonate (III) are presumed to be stabilized by the following type of resonance that involves an extra π-bond formation with the central sulfur atoms.



II



III

Generally, however, the electron donating conjugation of sulfur is smaller than that of oxygen.[7]

4) a) R. V. Vizgert, *Zhur Obshch. Khim.*, **28**, 1873 (1958). b) R. V. Vizgert and E. K. Savchuk, *ibid.*, **26**, 2268 (1956).

5) S. Oae, T. Fukumoto and R. Kiritani, This Bulletin, **36**, 346 (1963).

6) D. R. Christman and S. Oae, *Chem. & Ind.*, **1959**, 1251.

7) C. C. Price and S. Oae, "Sulfur Bonding," Donald Press, New York (1962).

Therefore the S–O bond in III would be stronger than the S–S bond in II, thus resulting in a large rate difference of the rates of the hydrolyses. Sulfonamides are also known to be very stable toward alkali. The higher stability of sulfonamide linkage is also due mainly to the stronger electron donating ability of nitrogen than oxygen and sulfur. In addition to the difference of the bond strengths, the approach of hydroxide anion to the attacking site should be much easier in I and II than in III because of the smaller electrostatic repulsion between sulfonyl oxygen and the hydroxide anion (in II), and also because of the electron accepting ability of the sulfur atom using one of its vacant 3*d*-orbitals.

Experimental

Materal. Substituted phenyl benzenethiolsulfonates were prepared by the reaction of benzenesulfenyl chloride with sulfinic acid in dry ether.[8] The products were recrystallized from methanol or ethanol: *p*-$XC_6H_4SSO_2C_6H_5$; X=H, mp 44—45°C (lit[9] 44—45°C); CH_3, 54°C (52—54°C); Br, 85°C; NO_2, 103—105°C (104—105°C).
p-$YC_6H_4SO_2SC_6H_5$: Y=CH_3, 78°C (77—78°C): Cl, 82—82.5°C (81°C), OCH_3, 54°C (54—55°C).

N-Ethylmorpholine buffer and the solvent ethanol were described in the preceding paper.[2]

Product. Unsubstituted ester (2.5 g, 0.01 mol) and potassium hydroxide (1.2 g, 0.2 mol) were dissolved in 50 m*l* of 96% ethanol-water solvent and the mixture was refluxed for 5 hr. Ethanol was removed from the reaction mixture and the residue was dissolved in ether and extracted with water. A part of the water extract was used for the detection of sulfonic acid by converting it to the thiuronium salt.

But no thiuronium salt was formed. The water extract was also titrated with 0.2 N sodium nitrite and the formation of 0.017 mol of sulfinic acid was observed. From the ether layer was isolated 300 mg of diphenyl disulfide which accounted for 14% of the total sulfur, while 0.017 mol of sulfinic acid accounted for 85% of the total sulfur in the starting ester. Thiophenol was not detected in any significant amount either in water or the ether layer. These results clearly indicated that the reaction leads to the quantitative formation of sulfinic acid and disulfide, and the formation of the sulfonic acid was negligible if none at all.

Kinetics. A solution of the thiolsulfonate (3×10^{-3} M) in 30 m*l* of 60% ethanol-water (v/v) and 30 m*l* of the *N*-ethylmorpholine buffer, in 60% ethanol-water were mixed after temperature equilibration in a constant temperature bath. Aliquot (5 m*l*) of this reaction mixture was added to a separating funnel containing 20 m*l* of chloroform and 25 m*l* of acidic water. The chloroform layer was washed and the upper water layer was removed by suction. Two more washings with 25 m*l* each of water were repeated. The optical density of this chloroform solution of the UV absorptions at 270 mμ was recorded and plotted against reaction time. The initial rate was then obtained graphically. The other methods for the treatment of the kinetic data were essentially the same as described in the preceding paper.[2]

Reactive Species in the Explosion of Silver Acetylide. I. Reaction with Saturated Hydrocarbon

KO TAKI

The Institute of Physical and Chemical Research, Yamato-machi, Saitama

(Received February 5, 1969)

The reactive species produced by the explosion of silver acetylide were found to react with hydrocarbon and to give acetylene and ethylene as the main products. The reactive species must be carbon oligomers. Since, in the reactions with higher hydrocarbons, acetylene and ethylene are also produced, their formation process may be the decomposition of the adduct of the reactive species. From the product distributions, the phase dependence of the ratio of ethylene to acetylene, and the effect of such moderator as carbon dioxide and inert gas, the reactive species are considered to be not only the monoatomic carbon (C_1) but also the diatomic carbon (C_2). The effect of a NO radical scavenger in the reactions of both ethane and propane is also described.

Thermally-unstable materials, especially solid explosives, usually decompose with the generation of gaseous products, but silver acetylide yields only solid decomposition products. The decomposition is represented by the following equation:

$$Ag_2C_2 \rightarrow 2Ag(s) + 2C(s) \qquad \Delta H = -83 \text{ kcal}^{1)}$$

A few studies[2,3] of the explosions of silver acetylide

(Ag_2C_2) have been reported recently. McCowan showed[2] that the activation energy of explosions of silver acetylide was 41 kcal/mol and that it decomposed also upon exposure to light. Some detailed studies have been performed by several workers,[4,5] but no work has been reported about the reaction of the reactive species produced by the explosion of silver acetylide.

Recently there have been intensive investigations of the reaction of hydrocarbons with free carbon atoms produced by the nuclear recoil reaction,[6,7] the photoreaction,[8] the vaporization of carbon (carbon arc),[9] and the laser-induced reaction.[10] In the reaction of these carbon atoms with hydrocarbons, however, the products and their distributions vary greatly from case to case. In this paper the reactions of the carbon species which are formed by the explosion of silver acetylide will be investigated, and some comparisons of the carbon atoms produced by the other methods cited above will be made.

Experimental

1) Preparation of Silver Acetylide. Silver acetylide was prepared by passing acetylene into an ammoniacal solution of silver perchlorate (Junsei Co.). The precipitate of silver acetylide thus obtained was washed with water containing acetylene and finally with methanol. Then it was spread out on a filter paper (it should not be filtered off because it often explodes when it is pulverized to a fine powder) and dried in a dark room. Irradiation by light darkens the surface of silver acetylide very quickly. The very fine powder, when it was irradiated, turned black within a few minutes, but it was still explosive after several days' exposure.

2) Apparatus for the Explosion of Silver Acetylide. In the gas-phase and solid-phase reactions, the explosion of silver acetylide was performed in a specially-designed flask such as is shown in Figs. 1 and 2.

In the solid-phase (cold-film) reaction, about 0.1—

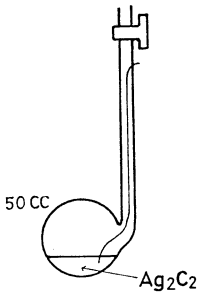

Fig. 1. Explosion vessel for gas-phase reaction.

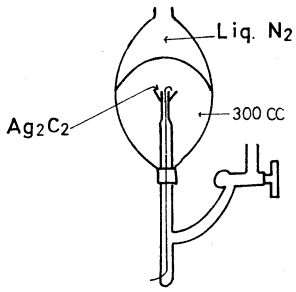

Fig. 2. Explosion vessel for solid-phase reaction.

0.3 g of silver acetylide was placed on the top of the gas inlet tube, as is shown in Fig. 2; the substrate was then introduced as cold film on the glass wall cooled by liquid nitrogen under a pressure of less than 10^{-3} Torr. The explosion was started by the use of a Tesla coil. In the explosion technique described here, 0.1 g of Ag_2C_2 can be exploded perfectly safely in this flask at a pressure of 500 Torr.

When neopentane was condensed on the bottom of the flask, as is shown in Fig. 3, no products were detected. In this reaction vessel the reactive species can not collide with the substrate. Therefore, the direct collision of the reactive species with the substrate is necessary for the formation of the products.

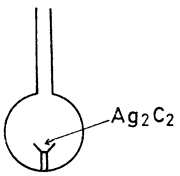

Fig. 3

3) Analyses. The products were analyzed by gas chromatography using silica gel and squalane columns. Quantitative analyses were performed by the internal-standard system, using neopentane as the standard.

4) Ageing of Silver Acetylide. In order to examine the ageing effect of silver acetylide, neopentane ($2.1—2.5\times10^{-4}$ mol) was used as the substrate in the solid-phase reaction. The gases produced by explosion were mainly acetylene and methane. The yields of acetylene and methane from aged silver acetylide (0.10 g) were as follows:

1) F. R. Bichowsky and F. D. Rossini, "The Thermochemistry and Chemical Substances," Reinhold Pub. Co. (1951), p. 79.

2) J. D. McCowan, *Trans. Faraday Soc.*, **59**, 1860 (1963).

3) V. D. Hogan and S. Gordon, U. S. Dept. Com. Office Tech. Serv. A. D. 419625, 15 pp. (1960).

4) W. E. Baker and F. Hoese, *Chem. Eng. News*, **43** (49), 46, 48 (1965).

5) Y. Tanaka and Y. Mizushima, *Kogyo Kagaku Kyokaishi*, **24**, 206 (1963).

6) M. Marshall, C. MacKay and R. Wolfgang, *J. Am. Chem. Soc.*, **86**, 4741 (1964).

7) H. J. Ache and A. P. Wolf, *ibid.*, **88**, 888 (1966).

8) K. D. Bayes, *ibid.*, **84**, 4077 (1962).

9) P. S. Skell and R. R. Engel, *ibid.*, **88**, 3749 (1966).

10) K. Taki, P. H. Kim and S. Namba, This Bulletin, **42**, 823 (1969).

Ageing time	1d	4d	6d	10d
Yield of C_2H_2 ($\times 10^{-5}$ mol)	0.7	1.2	1.1	1.4
Yield of CH_4 ($\times 10^{-5}$ mol)	0.8	1.6	1.8	1.8

From the above results, it can be said that the explosion of silver acetylide will give reproducible results within 10 days (after preparation).

Results

1) Impurities in Silver Acetylide. In the explosion of the above silver acetylide, 2—5 mol% of gases were produced. Mass spectrometrical analyses showed that the gases were 30% hydrogen, 50—60% nitrogen, and 10—20% carbon monooxide, plus a small amount of hydrocarbons (methane and ethane). They must be the decomposition products from the impurities in Ag_2C_2.

2) Reaction with Na Film. Silver acetylide (0.2 g) was exploded under a 10^{-4} Torr pressure in a 50-cc flask (Fig. 1) with walls coated with sodium film. After the decomposition of the reaction products with Na film by the use of water, ethylene and a small amount of acetylene were found. These experiments show that some carbon species produced by the explosion of silver acetylide react with sodium film to make sodium carbide, which in turn produces acetylene during decomposition by water. Ethylene will be formed by the hydrogenation of acetylene according to the following reaction sequence:

$$Ag_2C_2 \rightarrow 2Ag + 2C$$

$$2Na + 2C \rightarrow Na_2C_2$$

$$Na_2C_2 + 2H_2O \rightarrow C_2H_2 + 2NaOH$$

$$2Na + 2H_2O \rightarrow 2H + 2NaOH$$

$$C_2H_2 + 2H \rightarrow C_2H_4$$

3) Reaction of the Reactive Species Produced by the Explosion of Silver Acetylide with Hydrogen Sulfide. In the solid-phase reaction of the reactive species with hydrogen sulfide, the principal products were methane and acetylene, as is shown in Fig. 4. The detection of other sulfide compounds were not performed. Carbon species gave acetylene with H_2S.

Caution: Avoid the contact of hydrogen sulfide with silver acetylide, because silver acetylide explodes in a hydrogen sulfide atmosphere.

Discussion

Judging from the facts that, in the reaction with sodium film, sodium carbide was produced and that acetylene was produced by the reaction with hydrogen sulfide, carbon oligomers (C_1, C_2, C_3,$\cdots$) must be reactive species. As has been shown in 2) of the Experimental section, the reaction products are obtained only by the direct collision of reactive species with the substrate. In the reactions with hydrocarbons as the substrate in both the gas and solid phases, acetylene and ethylene were produced as the principal products. The ratio of ethylene to acetylene was larger in the solid phase than in the gas phase. Since the reactive species did not react with carbon dioxide, the reaction was also carried out in a carbon dioxide matrix.[11] The main products here were also ethylene and acetylene, but the ratio of ethylene to acetylene was lower in the CO_2 matrix than in the solid phase. The results are listed in Tables 1 and 2.

These results were compared with the results of the reaction of a free carbon atom produced by a nuclear reaction which is apparently the reaction of monoatomic carbon.

In the hot-atom reaction, the reaction of the carbon atom with methane, ethane, and propane produces mainly acetylene and ethylene, as is shown in Table 3.[12,13] By the fact that methane also gives acetylene, the most primary process has been considered to be the decomposition of the excited insertion intermediate (the energy-rich complex) of the carbon atom to acetylene and ethylene according to this scheme: $CH_4+C\rightarrow CH_3-\dot{C}-H\rightarrow CH_2=CH_2$ or $CH\equiv CH+H_2$. These acetylene and ethylene formation processes have also been confirmed by the evidence that the yields of acetylene and ethylene decrease with the change in phase from gas to solid and that, in the moderation of the carbon atom by an inert gas mixture,[14] the ratio of ethylene to acetylene increases with the change in phase from gas to solid. The formation mechanism[15] of ethylene in the hot atom reaction has also been considered to be the hydrogen abstraction of the vinyl radical or the reaction of the CH radical as follows:

$$R-CH_2-\dot{C}-H \rightarrow R\cdot + CH_2=\dot{C}H \rightarrow C_2H_4$$

$$CH + R-CH_3 \rightarrow R-CH_2-\dot{C}H_2 \rightarrow C_2H_4$$

These formation mechanisms of acetylene and ethylene do not conflict with the above experimental results (Table 3).

Since the phase dependence of the yield of ethylene relative to that of acetylene in this explosion reaction was in qualitative agreement with that in hot-atom chemistry, the formation processes of acetylene and ethylene might be considered to be the reaction of monoatomic carbon, as in the hot-atom reaction. However, the results with the CO_2 matrix conflicted with those of the monoatomic reaction, as has previously been described.

15) J. Dubrin, C. MacKay and R. Wolfgang, *ibid.*, **86**, 959 (1964).

If monoatmoic carbon is the only reactive species, the moderation of the carbon atom should show an increase in the C_2H_4/C_2H_2 ratio. Moreover, in the gas-phase reaction, the pressure dependence of the C_2H_4/C_2C_2 and CH_4/C_2H_4 ratios in the presence of ethane or helium was not observed, as Tables 4 and 5 show. It seems that the moderation of reactive species is not sufficient. Therefore, helium gas was used as the moderator in the solid-phase reaction. The results showed the decrease in the C_2H_4/C_2H_2 ratio shown in Table 6. These results also conflict with those for the reaction of the free carbon atom.

In order to examine the lifetime of the species, the CH_4/C_2H_4 and C_2H_4/C_2H_2 ratios were plotted as functions of the distance from the explosion position to the solid substrate, as is shown in Fig. 5.

$\frac{C_2H_4}{C_2H_2}$	2.7	2.2	2.5
$\frac{CH_4}{C_2H_4}$	0.7	0.7	0.75

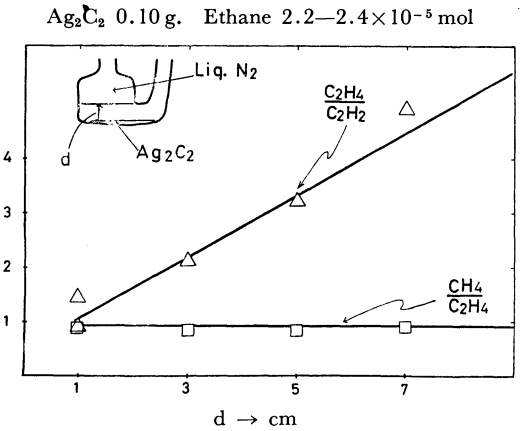

Fig. 5. C_2H_4/C_2H_2 and CH_4/C_2H_2 ratios plotted as a function of distance from explosion position.

Naturally the yields of products decreased with an increase in the distance, but the ratio of ethylene to acetylene increased and the ratio of methane to ethylene was constant, as was previously shown in helium moderation.

The constancy of the CH_4/C_2H_4 ratio and the increase in the C_2H_4/C_2H_2 ratio suggest that both methane and ethylene are formed from a common precursor, but that at least a part of the acetylene is formed from a different precursor. Moreover, the lifetime of the acetylene precursor is considered to be shorter than that of methane and ethylene precursor. Similar results were also observed in the reactions with propane and neopentane.

In comparison with the reactions of the carbon arc,[16] the product distributions are quite different. In the carbon arc reaction, it is considered that monoatomic carbon is also the reactive species and that products are formed by the further reaction of the carbon-atom-insertion intermediates, but acetylene is not detected.

Reaction with Cyclopropane. The reaction of the reactive species with cyclopropane gave ethylene, acetylene, and propylene as the main products. The ratio of ethylene to acetylene was 0.5 in the solid phase and 0.7 in the CO_2 matrix. The yield of ethylene was smaller than that of acetylene.

The reaction of a free carbon atom-^{11}C produced by nuclear reaction with cyclopropane[12] has been known to give a 65% yield of acetylene. This result was explained by the mechanism in which the insertion intermediate ($\triangle$-$^{11}\dot{C}$-H)[17] decomposes to almost an equivalent amount of radioactive acetylene-^{11}C and nonradioactive ethylene.

If the monoatomic carbon is the reactive

16) P. S. Skell and R. R. Engel, *J. Am. Chem. Soc.*, **88**, 4883 (1966).
17) P. B. Shevlin and A. P. Wolf, *ibid.*, **88**, 4735 (1966).

species in this work, ethylene may be expected to be formed in a yield almost equivalent to that of acetylene. The experimental result was, however, quite different from that expectation. From these results it seems that the reaction species involve not only monoatomic carbon (C_1) but another polyatomic carbon, such as diatomic carbon (C_2), which abstracts the hydrogen atom from hydrocarbon to produce acetylene.

Effect of Scavenger. The nitric oxide radical scavenger did not inhibit the formation of the ethylene and acetylene; rather, it promoted it in the gas-phase and solid-phase reactions of ethane, as is shown in Table 7.

Table 7. The effect of NO in gas and solid ethane

Ag_2C_2 0.10 g
Ethane 2.5×10^{-4} mol (100 Torr)

Product ($\times10^{-5}$ mol)	Gas Phase NO %		
	0	7.3	18.1
C_2H_4	10.4	10.8	8.3
C_2H_2	4.4	4.7	4.7
C_3 products	0.3	0.2	0.1
Butadiene	0.02	0.02	0

Product ($\times10^{-5}$ mol)	Cold Surface −196°C NO %				
	0	14.8	20.8	24.0	34.6
C_2H_4	5.4	8.2	7.1	7.1	7.0
C_2H_2	2.0	2.2	3.6	3.3	1.8
C_3 products	1.06	0.20	0.16	—	0.14
Butadiene	0.10	—	0.004	—	—

These observations indicate that the elimination of the radicals causes an increase in the yields of acetylene and ethylene.

On the basis of these results, it can be said that acetylene and ethylene may be produced by molecular processes, while C_3 products and butadiene may be formed by radical processes inhibited by the NO scavenger. Similar facts were also observed in the reaction with propane. The data are listed in Table 8.

Emission Spectrum. Since the emission spectrum in the explosion of silver acetylide showed a continuous band from 4000 to 6500 Å, C_2 Swan bands[18] were not detected. Unfortunately, the presence of C_2 was not confirmed spectroscopically.

Table 8. The effect of NO in propane

Ag_2C_2 0.10 g
Propane 2.5×10^{-4} mol (100 Torr)

Product ($\times10^{-5}$ mol)	Gas Phase NO %		
	0	6.9	13.5
CH_4	5.5	5.2	6.3
C_2H_6	0.82	0.95	0.40
C_2H_4	7.6	8.80	7.3
C_2H_2	2.4	3.0	2.8
Propylene	1.4	1.8	1.4
Butadiene	0.13	0.14	0.11

From the above observations, it may be concluded that the explosion of silver acetylide involves the formation of two kinds of reactive species, probably mono and diatomic carbons. The reaction products are mainly ethylene and acetylene, the formation of which is not inhibited by the NO radical scavenger.

The reaction of the C_2 diatomic carbon produced by the photolysis of diacetylene was reported by Pontrelli[19] to give triacetylene in the insertion process with diacetylene, while the reaction of C_2 produced by laser-induced reaction[10] with hydrocarbon gave acetylene and ethylene. Moreover, the reaction of carbon vapor produced by carbon arc with methanol, propanol, and *t*-butyl chloride gave acetylene and ethylene. By the technique[20] employing carbon electrodes enriched in ^{14}C, the presence of a C_2 reaction to form acetylene and ethylene has been confirmed.

The presence of a diatomic carbon reaction in this explosion reaction was confirmed by other experimental evidence that the reaction with 1,3-butadiene gave benzene. The details will be described in a second paper.

The author wishes to thank Professor S. Murahashi for his useful discussions and suggestions and Miss K. Motegi for the valuable assistance with this work, as well as to express his appreciation to Mr. S. Satooka for the mass spectrometrical analyses and to Dr. P. H. Kim for the spectroscopic analyses of the explosion emission of silver acetylide.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 2912—2917 (1969)

A Structural Study of the Catalytic Activity in Formaldehyde Polymerization in Liquid Carbon Dioxide

Tsutomu KAGIYA and Kōzō NARITA

Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received February 17, 1969)

The catalytic activities of various acids, bases, and salts in formaldehyde polymerization in a liquid carbon dioxide solution were studied in connection with the structures of the catalysts. The activity of the catalysts increased with decreases in the pK_a of Brönsted acids and in the ion-dissociation energy of alkyl acetates, and with increases in the pK_a' of organic compounds containing a nitrogen or oxygen atom, such as triethylamine or diethyl ether, and in the pK_a of the conjugated acids of sodium salts. The activity of the salts obtained from a strong acid with various bases increased with a decrease in the pK_a' of the bases, while that of the salts from weak acids with weak bases decreased with an increase in the summation of the pK_a values of acids and the pK_a' values of bases, reaching a minimum point and then increasing. The activity of various salts decreased with an increase in the pH in an aqueous solution, reached a minimum point at pH 6, then increased.

It has been established that formaldehyde easily forms polymers with various catalysts.[1] Yokota *et al.* reported[2] that a high polymer of formaldehyde was obtained in liquid carbon dioxide. The present authors reported[3] previously that the formaldehyde polymerization in liquid carbon dioxide was initiated by the formic acid produced by the pyrolysis of α-polyoxymethylene or paraformaldehyde, and no polymer was obtained with the monomer removed from the formic acid.

The purpose of this paper is to determine quantitatively the relationship between the catalytic activity and the structure and thermodynamic nature of the catalyst, and to discuss the mechanism of polymerization on the basis of an energetic study of the catalytic activity in ionic polymerization.[4]

Experimental

Materials. Formaldehyde in liquid carbon dioxide was prepared by means of a two-step method reported previously.[3] Eighteen hundred grams (paraform), 1000 g of polyethylene glycol (degree of polymerization of about 10) (PEG), and 1.8 mol of calcium carbonate were put into a 3000 m*l* decomposer and heated at 110 to 160°C under a carbon dioxide stream (flow rate: 160 m*l*/min). The polyethylene glycol hemiformal (PEGH) was prepared by bubbling the mixed gas thus obtained into a 3000 m*l* absorber (95—110°C) containing 2000 g of PEG. Eight hundred grams of PEGH were placed in a 1000 m*l* decomposer and pyrolyzed at 130 to 180°C under a carbon dioxide stream (flow rate: 160 m*l*/min). The mixture of formaldehyde and carbon dioxide was passed through a tube cooled at −20°C and then liquefied in the monomer reservoir at −78°C. The alkyl acetates (commercial) were dried over calcium chloride and distilled before use. The Brönsted acids and bases (commercial) were purified in the usual ways. The sodium borate was dehydrated by heating before use. The other sodium compounds were used without further purification. *N*-Phenylethylenimine was prepared according to the method of the literature[5] from β-bromoethylaniline hydrobromide, it was dried over sodium sulfate and fractionated twice before use (bp 70—70.5°C/13 mmHg). The salts (commercial) were recrystallized from ethanol, methanol, or ethyl acetate. Triethanolamine nitrate was prepared by the reaction[6] of potassium nitrate with triethanolammonium borofluoride, and was recrystallized from ethanol (mp 99°C). Aniline trichloroacetate was prepared by the neutralization of aniline with trichloroacetic acid in ethanol, and was recrystallized from ethanol (mp 147°C). The other solid salts, which were not obtained commercially, were prepared by the same method as was triethanolamine nitrate. The aniline salt of methanol, nitroethane, or nitromethane (liquid) was used as an equimolar mixture of aniline and methanol (nitromethane or nitroethane). The dimethyl ether acetate was prepared by

the reaction[7] of monochloromethyl ether with potassium acetate, and was purified by distillation (bp 117—118°C).

Polymerization Procedure. A stainless-steel autoclave with a capacity of 30 m*l* (16 mm×150 mm) was used as the reaction vessel. Into the vessel, which had been degassed *in vacuo* and cooled with liquid nitrogen, 0.22 mmol of the catalyst and 10 m*l* of a carbon dioxide solution of formaldehyde were introduced, after which the mixture was maintained at 20±1°C for one hour. After the polymerization, the unreacted monomer and carbon dioxide gas were purged out. The white powdery polymer thus obtained was sufficiently washed with cooled diethyl ether, dried *in vacuo* at room temperature, and then weighed. The catalytic activity of the catalyst is defined as the value of the ratio of conversion (%) to the reaction time (hr) under definite conditions.

Analysis. The number-average degree of polymerization of the polymer was measured in a manner which has been described previously.[3] The melting point of the polymer was visually determined under a nitrogen atmosphere in an electric heater. The infrared spectrum was obtained by using the potassium bromide pellet technique on a Japan Spectroscopic infrared spectrophotometer, Model DS-402G. The pH of the salt in an aqueous or ethanol solution with a 0.1 g equivalent/*l* was determined on a Hitachi Horiba pH meter, type M-4.

Results and Discussion

The Catalytic Activity of Brönsted Acids. The catalytic activities of various Brönsted acids in the polymerization in a liquid carbon dioxide solution were determined under definite conditions. As is shown in Fig. 1, the acids whose pK_a values are over 15 show little catalytic activity, while the activities of the acids with less than that value increased with a decreased with a decrease in pK_a.*1 It has previously been reported[8] that this polymerization system belongs to a group of no-termination polymerizations with rapid initiations.

It is observed that the catalytic activity of the Brönsted acid (HB) is proportional to the rate of the propagation of the initiating species ($HOCH_2B$)

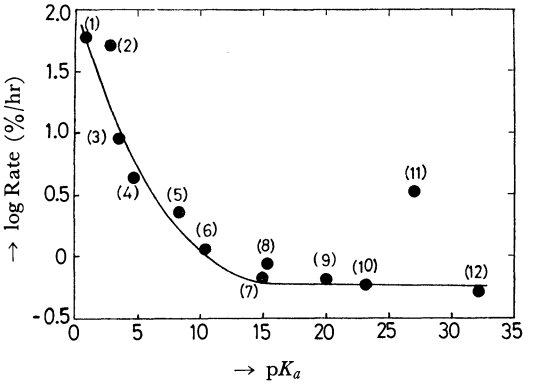

Fig. 1. Catalytic activity and pK_a of Brönsted acids: temp., 20°C; time, 60 min; monomer, 6 g; carbon dioxide, 4 g; additive/monomer (mole ratio), 1/1000; reaction vessel, 30 m*l*-autoclave.

produced by the reaction of formaldehyde with the acid. The propagation rate increased with a decrease in the ion-dissociation energy of the initiating species, which may be proportional to the pK_a value of the Brönsted acid. The results shown in Fig. 1 are in accordance with this theory.

The Catalytic Activity of Alkyl Acetates. Methyl acetate has little catalytic activity, while the dimethyl ether acetate produced by the reaction of methyl acetate with formaldehyde has a high catalytic activity,[9] one 20 times that of methyl acetate (Table 1). Moreover, the infrared spectrum of the polymer produced with a large quantity of benzyl acetate as a catalyst indicated the characteristic peaks of both the phenyl group (1500 (shoulder), 755, 703 cm^{-1}) and the carbonyl group (1740 cm^{-1}) (Fig. 2). These results indicate that, in this polymerization, the initiating species is

Table 1. The catalytic activity of dimethylether acetate

methyl alkyl ether acetate ($ROCH_2OOCCH_3$), and that the reaction of alkyl acetate ($ROOCCH_3$) with the monomer to produce the initiating species is the rate-determining step.

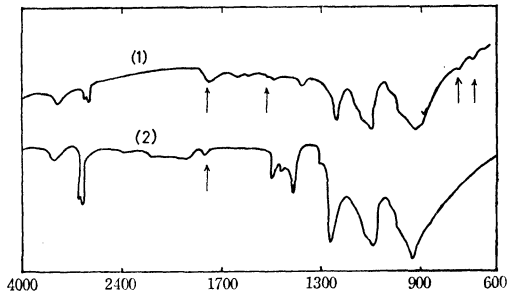

Fig. 2. The infrared spectrum of the polyoxymethylene obtained by the catalysts of both benzyl acetate and acetic acid.

The catalytic activities of various alkyl acetates increased with a decrease in the ion-dissociation energy of alkyl chloride ($D(R^+,Cl^-)$) (Fig. 3). In view of the fact that the ion-dissociation energy of alkyl acetate is proportional to that of alkyl chloride,*2 it may be concluded that the rate of initiation reaction increases with a decrease in the ion-dissociation energy of alkyl acetate.

The Catalytic Activity of Organic Compounds Containing a Nitrogen or Oxygen Atom. As has been described previously (Fig. 1), aniline has a strong catalytic activity, though its pK_a value is large (27). In order to clarify the role of aniline, the catalytic activities of various organic compounds containing a nitrogen or oxygen atom, such as amines, ethers, ketones, or amides were studied. As is shown in Fig. 4, those substances with values less than the zero of pK_a',*3 such as diethyl ether, have little catalytic activity, while the activities of those with values more than 0 increased with an increase in pK_a'.

On the other hand, it is known that the shift of

(9) *n*-butyl amine (10) triethylamine
(11) diethylamine

the O–D vibrational band of methanol-D in liquid organic compounds increases with an increase in the pK_a values of the compounds.[10] In view of the facts presented above, it can be suggested that, in the polymerization by a basic substance (B) such as amine or ether, the initiating species

*2 The ion dissociation energy of organic compound (RX) is expressed as $D(R^+, X^-)=D(R\cdot, X\cdot)+I_p(R\cdot)-E_a(X\cdot)$, where $D(R\cdot, X\cdot)$ is the dissociation energy of RX; $I_p(R\cdot)$, the ionization potential of the alkyl radical, and $E_a(X\cdot)$, the electron affinity of the X radical Therefore, the ion-dissociation energy of alkyl acetate ($D(R^+, {}^-OOCH_2)$) is expressed as $D(R^+, {}^-OOCH_3)=D(R^+, Cl^-)+\{D(R\cdot, CH_3COO\cdot)-D(R\cdot, Cl\cdot)\}-\{E_a(CH_3COO\cdot)-E_a(Cl\cdot)\}$, The difference between $D(R\cdot, CH_3COO\cdot)$ and $D(R\cdot, Cl\cdot)$ is about 7—9 kcal/mol, while the value of $D(R^+, Cl^-)$ is 150—225 kcal/mol.

10) T. Kagiya, Y. Sumida and T. Inoue, This Bulletin, **41**, 773 (1968).

*3 The pK_a' is the negative logarithm of the ion-dissociation constant of the reaction: $BH^+ \overset{K_a'}{\rightleftharpoons} H^+ + B$. Moreover, the pK_a' values of bases plotted in the figure were obtained as the values in water (25°C) according to the following equation: $pK_a'=14.17-pK_b$.

($HOCH_2OHB$) is produced by the reaction of the water in the system, the monomer, and the basic substance:

$$H_2O + CH_2O + B \rightleftarrows HOCH_2OB$$

As is suggested by the mechanism of the polymerization by Brönsted acids, the rate of the initiation reaction by amine or ether may be much larger than that of the propagation. Since the structure of the propagating species depends on the kind of basic substance, the catalytic activities of amines or ethers are proportional to the propagation rate, and increase with a decrease in the ion-dissociation energy of the initiating species, which itself may increase proportionally with a decrease in the pK_a' of amines or ethers.

The Catalytic Activity of Salts. The catalytic activity of sodium salts obtained from a strong base (sodium hydroxide) with various acids, hydrochloride salts from a strong acid (hydrochloric acid) with various bases (amines), acetate or nitrate from weak acids (acetic acid or nitric acid) with various bases (amines), and aniline salts with various acids were observed under definite condition.

a) The Activity of Sodium Salts. As is shown in Fig. 5, the activity of sodium salts increased with an increase in pK_a the in an aqueous solution of the conjugated acids of sodium salts. In the polymerization by sodium salt (NaB), two mechanisms of the initiation reaction may be proposed. One of them involves the polymerization by the initiating species (BCH_2ONa) produced by the reaction of sodium salt with monomer. The other involves that by the initiating species ($HOCH_2ONa$) formed by the reaction of the monomer with the sodium hydroxide produced by the hydrolysis of sodium salt with water in the system.

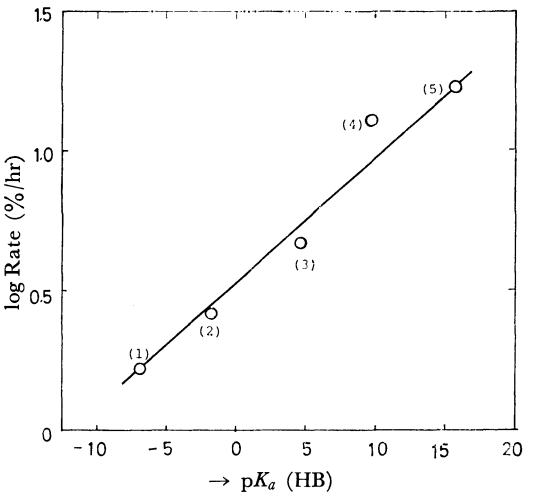

Fig. 5. Catalytic activity and pK_a of the conjugated acids of sodium salts: the condition is the same as in Fig. 1.
(1) sodium chloride (2) sodium nitrate
(3) sodium acetate (4) sodium borate
(5) sodium methoxide

The infrared spectrum of the polymer obtained with a large amount of the sodium acetate catalyst did not show the characteristic peak at 1750 cm^{-1} of the carbonyl group, but that at 3640 cm^{-1} of the hydroxy group. Therefore, it may be concluded that this polymerization proceeds by means of the initiating species of $HOCH_2ONa$. If this polymerization proceeds by the initiating species ($HOCH_2ONa$), the structure of the end group of the propagation species is the same in the polymerization with sodium salt. Furthermore, the catalytic activity of sodium hydroxide was 1.6 times that of sodium methoxide. On the basis of these facts, the formation of the initiating species may be considered to be the rate-determining step.

The rate of the formation of the initiating species may be proportional to the concentration of the hydroxy anion. On the other hand, in the hydrolysis of sodium salt, the logarithm of the concentration of the hydroxy anion is proportional to the pK_a (in an aqueous solution) of the conjugated acid of the salt.*4 These considerations lead to the conclusion that the catalytic activity of sodium salts increases with an increase in the pK_a of the conjugated acid of the sodium salt.

b) The Catalytic Activity of the Hydrochloride Salts. The activities of the salts obtained from hydrochloric acid with various amines increased with a decrease in the pK_a' values of the amines

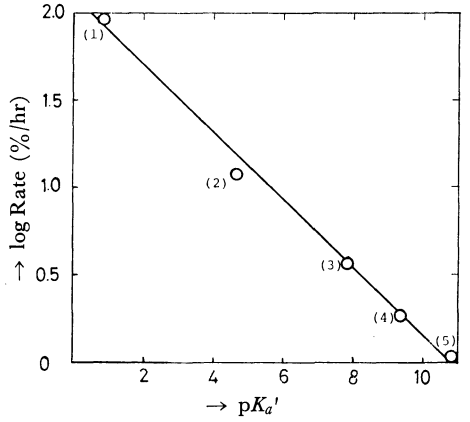

Fig. 6. Catalytic activity of hydrochloride salts and pK_a' of amines: the condition is the same as described in Fig. 1.
(1) diphenylamine hydrochloride
(2) aniline hydrochloride
(3) triethanolamine hydrochloride
(4) ammonium hydrochloride
(5) triethylamine hydrochloride

*4 In the reaction of $NaB+H_2O \rightleftharpoons Na^+ + OH^- + HB$, the concentration of the hydroxy anion (OH^-) is expressed as: $\sqrt{K_w(H_2O)(B^-)/K_{HB}}$, where K_w is the ionic product of water.

(Fig. 6). The salt obtained from hydrochloric acid with an amine such as R_3NHB may produce a proton and a counter anion (B^-) by hydrolysis.*5 Moreover, the initiating species ($HOCH_2B$) is considered to be produced by the reaction of a proton with a monomer in this polymerization. Just as in the polymerization by sodium salt, the formation reaction of the initiating species may be also the rate-determining step. Moreover, the rate of initiation is proportional to the concentration of the proton which increases proportionally with a decrease in the pK_a' values of the amines. This consideration is in accordance with the results shown in Fig. 6.

c) The Catalytic Activity of the Salts Obtained from Weak Acids with Various Amines. As is shown in Fig. 7, the activity of the acetate or nitrate salts decreased with an increase in the summation of the pK_a values of the acids and the pK_a' of the amines (pK_a+pK_a'), reached a minimum at *ca.* 7, and then increased with an increase to values larger than 7. Further, as is shown in Fig. 8, the activity of aniline salts also showed the same tendency as that of the acetate or nitrate salts, that is, a folded line with a minimum point.

Just as in polymerization by the sodium salts or hydrochloride salts, the formation of the initiating species may be also the rate-determining step in this polymerization.

On the other hand, it is known that the hydrolysis

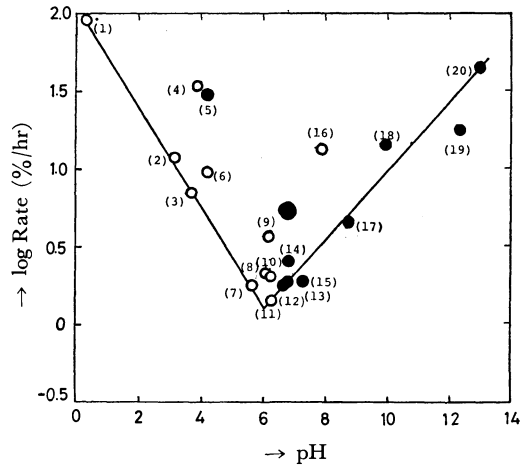

Fig. 9. Catalytic activity and pH of various salts: the condition of polymerization is the same as described in Fig. 1 the measurement of pH is carried out at 20°C with 0.1 mol/*l* aqueous (ethanol) solution.
(1) diphenylamine hydrochloride (2) aniline hydrochloride (3) aniline trichloroacetate (4) aniline sulfate (5) sodium dichloroacetate (6) triethylamine hydrochloride (7) aniline acetate (8) ammonium hydrochloride (9) triethanolamine hydrochloride (10) triethanolamine nitrate (11) ammonium nitrate (12) sodium chloride (13) tetraethylammonium iodide (14) sodium nitrate (15) tetraethylammonium bromide (16) ammonium acetate (17) sodium acetate (18) sodium borate (19) sodium ethylate (20) tetraethylammonium hydroxide

of the salt obtained from the weak acid (HB) with a weak base (NR_3) is in equilibrium:

$$R_3NHB + H_2O \rightleftharpoons R_3NHOH + HB$$

Therefore, it may be considered that this poly-

*5 The hydrolysis reaction of the salt obtained from a strong acid with various amines is:

$$R_3NHB + H_2O \rightleftharpoons H^+ + B^- + R_3NHOH$$

The concentration of the proton is expressed as $\sqrt{K_a'/C}$, where C is the concentration of the salt.

merization proceeds by means of the initiating species ($HOCH_2B$ or $HOCH_2OHNR_3$) produced by the reaction of the monomer with the proton or the hydroxy anion, and that the activities of the salts depend upon the quantity of protons or hydroxy anions produced by the reaction of the salt with the water present in the system.

The proton concentration is considered to be equal to the $K_{a(HX)}^{1/2} \cdot K_{a}'^{1/2}_{(NR_3)}$ value, and that of the hydroxy anion, to $K_w \cdot K_{a(HX)}^{-1/2} \cdot K_{a}'^{-1/2}_{(NR_3)}$. The reactions shown in Figs. 7 and 8 are in good accordance with these considerations.

The relationship between the activity and the pH[*6] in aqueous solutions of various salts are shown in Fig. 9. From this finding, it may be concluded that, in the range of pH values lower than 6, the polymerization proceeds by means of the initiating species ($HOCH_2B$) produced by the reaction of proton with the monomer, while in the range of pH values higher than 6, it proceeds by means the initiating species ($HOCH_2OHNR_3$) from the hydroxy anion and the monomer.

*6 The pH values were determined at 20°C by using 0.1 mol/l of an aqueous or ethanol solution of salts.

The authors are grateful to Professor Kenichi Fukui for his valuable suggestions and to Mr. Masatsune Kondō for his helpful discussions. They also wish to express their gratitude to Mr. Hiroshi Hatta for his technical assistance in carrying out the experiments.

The Mechanism of the Base-Promoted Rearrangement of *N,N*-Dichlorocyclohexylamine to 2-Aminocyclohexanone and the Deaminative Diazotization of 2-Aminocyclohexanone

Mamoru NAKAI,*1 Naomichi FURUKAWA and Shigeru OAE

Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sugimoto-cho, Sumiyoshi-ku, Osaka

(Received February 21, 1969)

N,N-Dichlorocyclohexylamine-1-^{14}C has been treated with sodium methoxide in methanol and then with hydrochloric acid to yield ^{14}C-labeled 2-aminocyclohexanone hydrochloride. Successive degradations have revealed that practically all the ^{14}C activity was found in the carbonyl carbon of the original aminoketone. From the ^{14}C distribution, it has been concluded that the reaction is essentially the same as that proposed for the Neber rearrangement. As a part of the degradation of 2-aminocyclohexanone, deaminative diazotization was employed to obtain cyclopentanecarboxylic acid together with other minor products. The ^{14}C tracer work revealed that the carbonyl group of the acid is originated from the carbonyl group of the 2-amino-ketone.

Baumgarten and his coworkers[1] reported that when *N,N*-dichlorocyclohexylamine is reacted with sodium methoxide and then treated with aqueous hydrochloric acid 2-aminocyclohexanone hydrochloride is formed, analogous to the Neber rearrangement of the corresponding oxime tosylate.[2,3] They have extended this reaction to other various *N,N*-dichloro-*s*-alkylamines.[4] A similar rearrangement of *N,N*-dichlorocyclohexylamine to 2-aminocyclohexanone hydrochloride has also been recently reported.[5] Meanwhile the rearrangement of *N,N*-dichlorodiphenylethylamine to desylamine was investigated by us using ^{14}C-labeled compound and revealed to proceed according to the mechanism similar to the Neber rearrangement as shown below[6] (Fig. 1).

Although the same mechanism may hold for the reaction of *N,N*-dichlorocyclohexylamine with sodium methoxide, the reaction could proceed *via* other mechanistic routes, since the Neber type rearrangement involves a very highly strained bicyclic azirine bearing a double bond at the bridge-head position, and other possibilities such as that involving the prior *gem*-dichlorination followed by hydrolysis could occur (Fig. 2). Thus

a similar ^{14}C tracer work is quite desirable. However, the same degradative procedure gave rather obscure results. Hence other better degradative methods have been tried. Among a few methods employed, a degradative diazotization of 2-aminocyclohexanone has been proved to be very promising since it gives the rearranged cyclopentanecarboxylic acid in yields always exceeding 35%. However, this degradative procedure must be examined at first, because it is not known whether or not this procedure changes the sequence of carbon skeleton, nor has it been clarified that the carbon dioxide formed during the rearrangement originates from the carbonyl carbon of 2-aminocyclohexanone.

We have accumulated data of the ^{14}C tracer experiments on these reactions. This paper will describe the results in detail.

N,N-dichlorocyclohexylamine-1-^{14}C has been synthesized, and a series of successive degradation has been carried out.

Both the synthetic and degradative procedures are shown below (Fig. 3).

Experimental

Preparation of *N,N*-Dichlorocyclohexylamine-1-^{14}C. Pimeric acid-1,7-^{14}C was obtained by the carbonation of pentamethylene magnesium bromide which was prepared from 0.9 g of magnesium and 4.0 g of pentamethylene dibromide, with $^{14}CO_2$ generated from 7.0 g (1 mCi) of barium carbonate. The crude product was recrystallized from benzene; yield 2.0 g (70%), mp 104°C.

A mixture of 1.8 g of pimeric acid-1,7-^{14}C and 0.1 g of barium carbonate was gradually heated in a metallic bath up to about 320°C and the distillate was collected. The crude cyclohexanone-1-^{14}C (0.9 g) was purified by distillation (bp 155°C).

The above cyclohexanone-1-^{14}C (2.5 g) was added to a solution containing 2.2 g of hydroxylamine hydrochloride in 5 m*l* of water, into which a solution containing 1.7 g of sodium carbonate in 5 m*l* of water was added. The mixture was filtered to collect the precipitate which was then washed with cold water and recrystallized from 50% ethanol. The yield of cyclohexanone oxime-1-^{14}C was 1.9 g in 75%; mp 91°C.

Strips of sodium (6 g) were added to a solution of cyclohexanone oxime-1-^{14}C (2.0 g) in 60 m*l* of absolute ethanol. From the reaction mixture, cyclohexylamine-1-^{14}C (1.3 g) was obtained in 75% yield; bp 132°C.

Cyclohexylamine-1-^{14}C (6.5 g) was chlorinated with 15 g of *t*-butyl hypochlorite in anhydrous benzene. *N,N*-Dichlorocyclohexylamine-1-^{14}C thus obtained was not isolated; the solution was used directly for the preparation of 2-aminocyclohexanone hydrochloride-*x*-^{14}C, as in the experiments of previous workers.[4]

Rearrangement of *N,N*-Dichlorocyclohexylamine-1-^{14}C. The rearrangement of *N,N*-dichlorocyclohexylamine-1-^{14}C was carried out by the following procedure used previously;[4] the benzene solution of *N,N*-dichlorocyclohexylamine-1-^{14}C prepared from 6.5 g of cyclohexylamine was treated with a methanolic sodium methoxide prepared from 4.8 g of sodium and 50 m*l* of methanol. The reaction mixture became very dark when the reaction ended. The aqueous acid extract was tan to red-brown, but most of the color could be removed by repeated treatments with active charcoal. The resulting, crude 2-amino-cyclohexanone hydrochloride-*x*-^{14}C was recrystallized from absolute methanol, then washed with a mixture of isopropanol and methanol to give a pure substance; yield 4.6 g (47%), nearly colorless crystals, mp 158°C.

Degradation of 2-Aminocyclohexanone Hydrochloride-*x*-^{14}C. Deamination of 2-aminocyclohexanone hydrochloride was reported by Edwards and Lesage,[7] who revealed that the reaction affords cyclopentanecarboxylic acid, bicyclo[3,1,0]hexane-2-one and 2-methyl-2-cyclopentene-1-one as the products from 2-aminocyclohexanone.

We also carried out the deaminative diazotization in a similar way. 2-Aminocyclohexanone hydrochloride-*x*-^{14}C (1.60 g) was dissolved in 9 m*l* of 6 N hydrochloric acid, and to this solution cooled in an ice-salt bath was

7) O. E. Edwards and M. Lesage, *Can. J. Chem.*, **41**, 1592 (1963).

added a solution of 3.6 g of sodium nitrite in 9 m*l* of water dropwise with stirring. The reaction mixture turned to blue. After the addition was complete the contents of the flask was stirred for 1 hr while keeping the temperature below 0°C, and then for 1 hr at room temperature, followed by heating for 1/2 hr at 50°C. It was then made alkaline with sodium carbonate and extracted with ether to remove neutral and acidic substances. The aqueous solution was acidified with hydrochloric acid and extracted with ether. This etheral solution was dried over anhydrous sodium sulfate and distilled, affording 0.8 g of acidic materials, *i. e.*, cyclopentanecarboxylic and adipic acids which were identified by comparing their infrared spectra with those of authentic samples. The latter acid was further confirmed by the mixed melting point determination with the authentic sample of adipic acid. Thus cyclopentanecarboxylic acid-*x*-^{14}C was obtained in about 35% yield based on the data of the isotopic dilution method; bp 103—105°C/8 mmHg.

The method of Loftfield was used to degradate cyclopentanecarboxylic acid-*x*-^{14}C[8]. This acid (2.3 g), bromine (1.1 m*l*) and phosphorus trichloride (0.15 m*l*) were heated to 100°C for one hour in a sealed tube. 1-Bromocyclopentanecarboxylic acid-*x*-^{14}C was dissolved in a mixture of 30 m*l* of acetone, 30 m*l* of water, 2.5 m*l* of acetic acid and 2 g of sodium acetate and then allowed to stand for 16 hr at room temperature. The resulting 1-hydroxycyclopentanecarboxylic acid-*x*-^{14}C (1.0 g) was obtained in 38% yield; mp 103°C.

In a distillation flask, a solution of 0.2 g of the hydroxy acid-*x*-^{14}C and 0.12 g of potassium permanganate in 30 m*l* of water was gradually heated to boiling. A stream of nitrogen was bubbled through the solution and the carbon dioxide released was introduced into a barium hydroxide trap. From the distillate (6.5 m*l*) was obtained cyclopentanone; the conversion was about 60%. One-third of this distillate was used to prepare cyclopentanone semicarbazone which was recrystallized from water; mp 207°C.

Measurement of the Activities. The activities of the samples were measured with a JRC Aloka 2π-gas flow G-M counter using Q gas. 1-Hydroxycyclopentanecarboxylic acid-*x*-^{14}C was used as the standard sample of the total activity. An aliquot of a sample was thoroughly oxidized by the Van Slyke-Folch Method, and all the carbon dioxide formed was converted to a barium carbonate tablet which was then subjected to ^{14}C counting.

The counting data obtained are shown in Table 1.

Table 1. The ^{14}C counting data

			 a)
Run 1	1240 cpm	278 cpm (100%)	7±3 cpm (~2.5%)
Run 2	17200 cpm	3650 cpm (100%)	63 cpm (1.7%)

a) Assayed as semicarbazone.

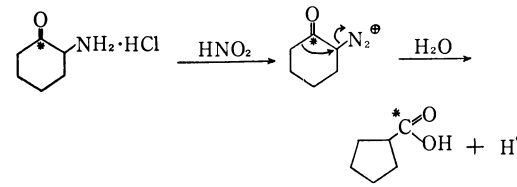
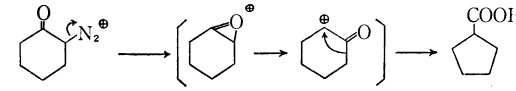
Results and Discussion

1-Hydroxycyclopentanecarboxylic acid was used as the standard sample of 2-aminocyclohexanone, and the ^{14}C total activities were counted. The value which substracts the ^{14}C activity of cyclopentanone from that of 1-hydroxycyclopentanecarboxylic acid may be regarded as the ^{14}C activity of carbonyl carbon of original 2-aminocyclohexanone. Thus semicarbazone of cyclopentanone obtained can be counted for the activity of all the positions except carbonyl carbon of aminoketone. As shown in Table 1, the ^{14}C activity (1.7%) of cyclopentanone carries only a very small portion of the original activity of 2-aminocyclohexanone. Therefore, carbonyl carbon of the original aminoketone carries essentially all the ^{14}C activity.

All the synthetic procedures used for the ^{14}C compounds are quite common ones that have often been tested in the past, and it is known that no rearrangement is involved in any step of the total synthesis of *N,N*-dichlorocyclohexylamine-1-^{14}C. Meanwhile the degradation of cyclopentanecarboxylic acid has also been carried out by a well-known procedure involving no skeletal rearrangement. A serious problem lies, however, in the step of deaminative diazotization of 2-aminocyclohexanone, since it involves the rearrangement of the carbon skeleton. However, since nearly all the carbon-14 activity was found to be concentrated at the resulting carboxyl group of cyclopentanecarboxylic acid, the formation of cyclopentanecarboxylic acid from 2-aminocyclohexanone appears to proceed through a simple Wagner-Meerwein type rearrangement as shown below.

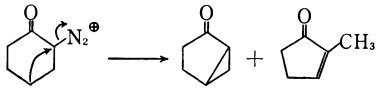


Thus, other possible routes such as that analogous to the one involved in the hydrolysis of α-halocyclohexanone,[9] shown below are excluded.



Although degradation was not performed for the other two products, namely 2-methyl-2-cyclopentene-1-one and bicyclo[3.1.0]hexane-2-one,[7] these are undoubtedly formed by the initial 1,2-shift from 4-position as shown below.

9) T. Masuike, N. Furukawa and S. Oae, unpublished.



The formation of a substantial amount of cyclopentanecarboxylic acid (35%) is interesting in connection with the highly energy-recoiled carbonium ion formed by the deaminative diazotization. Here again, the migration of the carbon-skeleton took place rather indiscriminately regardless of the electronic nature of β-methylene groups which undergo 1,2-shift.

The results of the degradation revealed that nearly all the ^{14}C activity originally placed at 1-position of *N,N*-dichlorocyclohexylamine was found in the carbonyl carbon of 2-aminocyclohexanone formed, similar to the previous case with *N,N*-dichlorodiphenylethylamine.

Therefore, the plausible mechanism for this reaction is that suggested previously by Banmgarten *et al.*; this is essentially the same as that proposed originally by Cram and Hatch for the Neber rearrangement.

The Reaction of Cobalt Hydrocarbonyl with Vinylacetate, Crotonate, Styrene, and Acrylates*[1]

Sohei SUGA, Hiromitsu MASADA and Haruki SUDA

Department of Industrial Chemistry, Faculty of Technology, Kanazawa University, Kanazawa

and Yoshihisa WATANABE and Yoshinobu TAKEGAMI

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Kyoto

(Received February 27, 1969)

Ethyl vinylacetate and ethyl crotonate reacted with cobalt hydrocarbonyl at 25°C to give three isomeric acylcobalt carbonyls, α- and γ-carbethoxy-butyrylcobalt carbonyls and β-carbethoxy-isobutyrylcobalt carbonyl. The distribution of these complexes depends greatly on the reaction time (0.5—20 hr). In both cases the β-isomer predominates at shorter reaction times (0.5—1.5 hr), while the γ-isomer predominates at longer reaction times. This shows that isomerization occurs among the complexes and that the equilibrium is very favorable to the γ-isomer. Acrylates and styrene react with cobalt hydrocarbonyl to give two isomeric acylcobalt carbonyls. The isomerization of the acylcobalt complex with a branched structure to that with a straight-chain structure is much promoted by the phenyl and ester groups. The promoting effect of the ester groups is the highest in benzyl, followed by allyl, and ethyl, isopropyl, butyl, and cyclohexyl. Such a promoting effect can reasonably be attributed to the $-I$ effect of these groups.

Some of the present authors have previously shown that acylcobalt carbonyls isomerize under relatively mild conditions.[1-4] In the reaction of cobalt hydrocarbonyl with ethyl acrylate, the α-carbon was selectively carbonylated to give α-carbethoxypropionylcobalt carbonyl.[2] This fact shows that the ester group in the acrylate has a significant effect on the addition of cobalt hydrocarbonyl to the carbon-carbon double bond of the acrylate. The α-isomer, however, isomerized to β-isomer much more readily in non-polar solvents. On the other hand, *n*- and isobutyrylcobalt carbonyls isomerized with difficulty in non-polar solvents. Thus, the ester group adjacent to the acylcobalt carbonyl group has a promoting effect on the isomerization.

The present study will be concerned with the reaction of cobalt hydrocarbonyl with ethyl crotonate, ethyl vinylacetate, and different acrylates. From the former two olefins, three isomeric acylcobalt carbonyls are possible as reaction products. The effects of the ester groups on the distribution of these complexes and on the isomerization of the

comlexes will be examined. The reaction behavior of different acrylates and styrene will also be examined and compared.

Experimental

Reaction Procedure. The reaction was carried out in the way described in a previous paper, using 50 m*l* of a 0.09 M cobalt hydrocarbonyl solution in hexane in each run.[2]

Analytical Procedure. The solution of crude products was treated with iodine and ethyl alcohol, and then the excess iodine was removed with crystalline sodium thiosulfate. After the solution had been concentrated, the products were gas-chromatographed on a column, three meters long, 3 mm in diameter, and filled with Apiezon L or Carbowax on Cerite, at 130—220 °C and at the carrier-gas (helium) flow rate of 70 ml/min. The infrared spectra were recorded on a Nippon Bunko Model DS-301 spectrophotometer.

Materials. The ethyl acrylate, ethyl crotonate, styrene, ethylmalonate, methylsuccinate, glutarate, succinates, α- and β-phenylpropionates, and methylmalonates were commercial products. The following acrylates were synthesized by the usual ester exchange method: benzyl, allyl, isopropyl, and cyclohexyl acrylates. They have been proved to be sufficiently pure by gas chromatography. The cobalt hydrocarbonyl was prepared in the way described previously.[1] The ethyl vinylacetate was prepared from allyl chloride.[5]

Results and Discussion

The Reaction of Ethyl Vinylacetate and Ethyl Crotonate with Cobalt Hydrocarbonyl. The results of the reaction are summarized in Table 1. All of the reactions were carried out in hexane under an atmosphere of carbon monoxide.

The vinylacetate reacted with cobalt hydrocarbonyl at 25°C, with a carbon monoxide absorption, to give three isomeric acylcobalt carbonyls, α- and γ-carbethoxybutyrylcobalt carbonyls and β-carbethoxy-isobutyrylcobalt carbonyl, which then gave the corresponding esters, diethyl ethylmalonate, diethyl methylsuccinate, and diethyl glutarate, upon treatment with an alcoholic iodine solution. The distribution of these complexes depended greatly on the reaction time (Exps. 1—5). When the reaction time was only 0.5 hr, the β-isomer, the methylsuccinate, was predominant (Exp. 1). The percentage of the β-isomer decreased with an increase in the reaction time, but that of the γ-isomer, the glutarate, increased reversely. When the reaction time was more than 1.5 hr, the γ-isomer was predominant and the percentage of the γ-isomer amounted to more than 90%. These facts show that the β-carbon of the vinylacetate is readily carbonylated with cobalt hydrocarbonyl to give the β-carbethoxy-isobutyrylcobalt carbonyl as the major product, then the β-isomer is readily isomerized to the γ-isomer under the conditions employed, and that the equilibrium among the complexes is very favorable to the γ-isomer. On the other hand, such 1-olefins as 1-pentene reacted with cobalt hydrocarbonyl to give *n*-caproylcobalt carbonyl as the major product and also α-methylvalerylcobalt carbonyl,[6] these complexes were isomerized with much difficulty under the conditions described above.[4] The results obtained here show that the ester group in the vinylacetate has a great

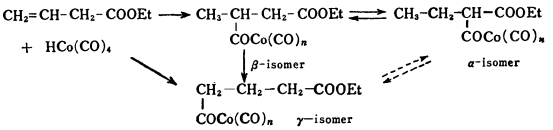
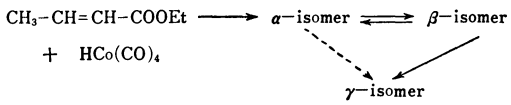
effect on the addition of cobalt hydrocarbonyl to the double bond and on the isomerization of the acylcobalt carbonyls: the ester group promotes the carbonylation of the carbon of the double bond more adjacent to the ester group, while on the contrary, the ester group promotes the isomerization of the acylcobalt carbonyls to that which has an acylcobalt group further from the ester group.

In this reaction, the α-isomer, the ethylmalonate, was obtained in a considerable yield. For the formation of this complex, two routes are possible: one from ethyl crotonate, and the other from the β-isomer. Under the conditions employed, the vinylacetate did not isomerize to ethylcrotonate. Thus, it is safe to conclude that the α-isomer is formed *via* the β-isomer by the isomerization.

On the basis of these results, the reaction seems to follow this reaction scheme:



Ethyl crotonate also gave the three isomeric acylcobalt carbonyls as the reaction products (Exps. 6—10). The distribution of the complexes depended on the reaction time. Longer reaction times were more favorable to the γ-isomer. The percentage of the α- and β-isomers decreased to less than 10%. When the reaction time was only 0.5 hr, the percentage of the α-isomer amounted to about 30%, indicating that, at the initial step of the reaction, the α-carbon of the crotonate was carbonylated relatively readily. The reaction of the crotonate was very slow. At 25°C, after even 20 hr, the yield of the products was only 0.2 mol/mol-$HCo(CO)_4$. On the contrary, the isomerization among the complexes, especially from the α-isomer to the β-isomer, appears to occur more readily. In the light of these results, the reaction of the crotonate may be considered to proceed typically as follows:



The Reaction of Cobalt Hydrocarbonyl with Styrene and Different Acrylates. The results of the reaction are summarized in Tables 2 and 3 and in Fig. 1. All of the reactions under an atmosphere of carbon monoxide were carried out in hexane in two stages: at first for 3 hr at 0°C, and then at 25°C for 0.5—6 hr. The gas absorption ceased completely within 3 hr at 0°C. As we have previously reported in detail, the rate of cobalt hydrocarbonyl consumption may be estimated by means of the rate of carbon monoxide absorption in the system.[2] At a low temperature

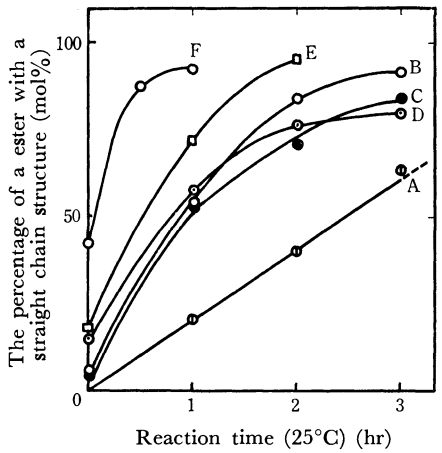


Fig. 1. The percentage of a ester with a straight chain structure *vs.* time plots for the reaction of cobalt hydrocarbonyl with styrene and acrylates.

All of the reaction were carried out in two stages: At 0°C for 3 hr and then at 25°C for 0.5—3 hr.

B: Ethyl acrylate
C: Isopropyl acrylate
D: Cyclohexyl acrylate
E: Allyl acrylate
F: Benzyl acrylate

the acylcobalt carbonyls with a branched-chain structure were almost selectively formed by the direct addition of cobalt hydrocarbonyl to the olefins, while higher temperatures promoted the isomerization of these complexes to those with a straight-chain structure. The complexes were finally converted to the corresponding esters upon treatment with an alcoholic iodine solution. The effects of the structures on the isomerization were examined by means of the distribution of the esters.

A large excess of the olefin was used in order that the cobalt hydrocarbonyl used might be consumed completely and in order that acyl cobalt carbonyls might not be converted to aldehydes. The amount of aldehydes formed was negligible.

Styrene. As Table 2 shows, styrene gave selectively, α-phenylpropionylcobalt carbonyl at 0°C, while at 25°C this isomerized gradually to β-phenylpropionylcobalt carbonyl. The isomerization was slower than that in the case of acrylates (*cf.* Fig. 1). These facts show that the phenyl group activates the α-carbon of the styrene for the carbonylation and that it also promotes the isomerization. On the other hand, in the case of 1-pentene, caproyl- and α-methylvalerylcobalt carbonyls were formed in a 3 : 1 ratio at 0—25°C in non-polar solvents; these complexes were isomerized with much difficulty under these conditions.[4,6] This apparent discrepancy is due to some difference between the effects of the phenyl and propyl groups (CH_2=CH–R, R=Ph and Pr). Two effects appear to operate here. The first,

and probably the most important, is an electronic effect. The electron-attracting effect, the $-I$ effect, of the phenyl group is stronger than that of the propyl, and the phenyl group also has a conjugation effect. A second effect concerns a steric factor. The steric effect of the phenyl, however, seems to be almost comparable to that of the propyl. Thus, the large difference in reaction behavior between these groups may be attributed to the electronic effect.

In the α-phenylpropionylcobalt carbonyl, the $-I$ effect of the phenyl group probably decreases the electron density on the cobalt atom; this, in turn, reduces the thermal stability of this complex. This consideration is strongly supported by the fact that acylcobalt carbonyls are safely separated as more stable triphenylphosphine derivatives,[6] in which a stronger basicity of the phosphine increases the electron density on the cobalt atom.[7]

7) E. R. Tucci, *Ind. Eng. Chem., Product Research and Development*, **7**, 32 (1968).

Accordingly, it is safe to conclude that the promoting effect of the phenyl on the isomerization of the α-phenylpropionylcobalt carbonyl to the β-isomer is due to the $-I$ effect.

Acrylates. As Table 3 shows, different acrylates were used. All of them behave similarly in this reaction. At first at 0°C, acylcobalt carbonyls with a branched-chain structure predominated, and then at 25°C they were isomerized readily to those with a straight-chain structure.

As Fig. 1 shows, the isomerization rate was the highest in benzyl acrylate, followed by allyl and by ethyl, isopropyl, and cyclohexyl acrylates. It is well known that the ester groups have the $-I$ effect. Thus, the promoting effect of the ester groups on the isomerization can be explained by the argument employed in the case of styrene. The fact that even α-carbethoxypropionylcobalt carbonyl triphenylphospine is too unstable to be separated[6] indicates that the ester group greatly reduces the thermal stability of this type of complex. Moreover, the largest promoting effect of the benzyl and allyl ester groups may be attributed to the larger $-I$ effect of the benzyl and allyl groups. The effects of such saturated alkyl groups as ethyl and isopropyl seem to be almost comparable (*cf.* Fig. 1).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 2924—2930 (1969)

Studies on *s*-Triazines. I. Cotrimerization of Trichloroacetonitrile with Other Nitriles*[1]

Ko WAKABAYASHI, Masaru TSUNODA and Yasushi SUZUKI

Research Laboratory, Mitsubishi Chemical Industries Ltd., Mizonokuchi, Kawasaki, Kanagawa

(Received March 7, 1969)

2-Substituted 4,6-bis(trichloromethyl)-*s*-triazines have been prepared by the cotrimerization of CCl_3CN with some nitriles. The reaction proceeds, in general, smoothly at ordinary pressure in the presence of hydrogen halide or Friedel-Crafts catalyst-hydrogen halide complex. An improved method was developed for the nitriles such as propionitrile with which CCl_3CN did not easily cotrimerize under above mentioned conditions.

2-Substituted 4,6-bis(trichloromethyl)-*s*-triazines and their derivatives, such as 2-substituted 4-amino-6-trichloromethyl-*s*-triazines, are highly effective as herbicides,[1,2] fungicides,[3,4] nitrification inhibitors,[5-10] in soil and antimalarials.[11]

Starting material, CCl_3CN, is easily obtained by the chlorination[12-16] of CH_3CN which is a by-product in SOHIO acrylonitrile process. This led us to investigate the cotrimerization of CCl_3CN with other nitriles.

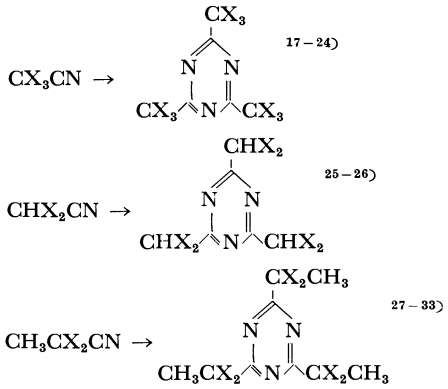
* Reaction condition; See Experimental A).

Several authors[17-33] observed the formation of the *s*-triazines from α-chlorinated nitriles.



Scheme 1. (X: halogen)

Trimerization of nitriles has been effected with both basic and acidic catalysts. The basic catalysts, such as sodium,[34,35] potassium methoxide,[36] diethylzinc,[37,38] sodium hydride[38] and *N*-sodium methylaniline[38] give, in general, dimers[39] or pyrimidines[36] as main products. Acid catalyzed trimerization of nitriles [17-21,23-33] affords *s*-triazines in good yields. The reaction [19-21] was carried out in a closed system. $AlBr_3$-HCl (Norton's catalyst) is so effective that it can afford excellent yield under ordinary pressure in trimerization of CCl_3CN.[21]

* Reaction condition; See experimental B-a).

naphthyl,[40] 2-chloroethyl[43] and 2-bromoethyl[43]), has also been reported, although the reaction is exceedingly slow.

We wish to report the results of reexamination and development of Norton's catalyst and also results of cotrimerization of CCl_3CN with other nitriles to give *s*-triazines.

Results and Discussion

Trimerization of CCl_3CN was undertaken to find out a new effective catalyst.

As shown in Table 1, it is clear that the use of combined catalysts to trimerize CCl_3CN (Friedel-Crafts catalysts-hydrogen halides) produces a good result, especially with $AlBr_3$-HCl, $AlBr_3$-HBr and BF_3 etherate-HCl. But the use of HCl only produces 1.6% yield of I.

Under a similar condition the use of combined catalysts to cotrimerize CCl_3CN with CH_3CN was investigated. These results are listed in Table 2. It is evident that the use of hydrogen halides only as well as that of the combined catalysts were effective, although the reaction was slow.

The parent peaks in mass spectrum of I and II are *m/e* 429(P_1) and *m/e* 327(P_2). Peaks at mass *m/e* 394(P_1-35), 292(P_2-35); 359($P_1-35\times2$), 257($P_2-35\times2$); 324($P_1-35\times3$), 222($P_2-35\times3$) are results from the loss of one, two and three chlorine atom(s) respectively. There are also large peaks at mass *m/e* 117($^+CCl_3$) and 108($^+CCl_2$-CN) in both spectra. Intensities of isotope peaks of I relative to the parent peak for chlorines (Cl_9) are as follows: P_1, 100% (100%), (Calcd (Found)); P_1+2, 287 (294); P_1+4, 366 (368); P_1+6, 273 (276); P_1+8, 130 (134); P_1+10, 42 (43). Similarly, intensities of isotope peaks of II relative to the parent peak for chlorines (Cl_6) are P_2, 100 (100); P_2+2, 190 (192); P_2+4, 153 (152); P_2+6, 65 (69).

The structure of all samples, (II), was identified by the consideration of Mass, IR, UV and NMR spectra with an authentic sample.[25,40]

The data in Table 2 indicate that the combined catalyst, $AlBr_3$-HCl, are most effective and economical.[44] This particular catalyst was used to investigate the distribution of the products by changing the molar ratio of CCl_3CN and CH_3CN. Table 3 shows the results.

We see that the best result was obtained in molar ratio, *n*: 1.5 or 2.0, in the cotrimerization of CCl_3CN with CH_3CN. GLC's relative R_t values are (I)=1.00, (II)=0.38 (based on (I)=1.00). These values were the same as those of authentic samples.

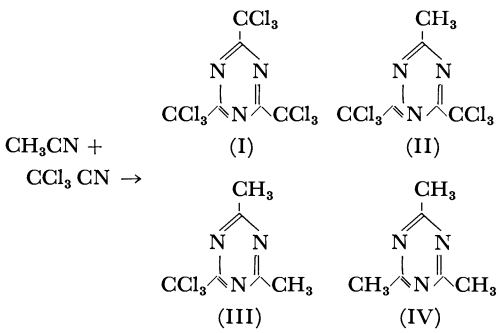
Table 3.* The effect of molar ratio for cotrimerization of CCl_3CN with CH_3CN

$n\,CCl_3CN + CH_3CN \rightarrow I + II$

CCl_3CN/CH_3CN Molar ratio (n)	Yield** of II (%)	Selectivity I	Selectivity II
1.0	97		100
1.5	97		100
2.0	95	0.5	99.5
3.0		23.5	76.5
4.0		38.8	61.2

* Experiment was carried out in the same reaction condition as Experimental B-a) in the presence of $AlBr_3$ (3g), using 41 g (1 mol) of CH_3CN.

** Based on CCl_3CN.



Scheme 2

Although the values of relative R_t of III and IV synthesized from another route were 0.16 and 0.08, no peak was found when the sample prepared from cotrimerization of CCl_3CN with CH_3CN was inspected.

Several other nitriles as well as CH_3CN were cotrimerized with CCl_3CN, using HCl-catalyst only. As shown in Table 4, several 2-substituted 4,6-bis(trichloromethyl)-*s*-triazines were obtained.

Some aliphatic nitriles which have more than 3 carbon atoms did not cotrimerize until a new improved method[45,46] was developed.

That is to say, 2-alkyl*2-4,6-bis(trichloromethyl)-*s*-triazines were prepared from cotrimerization of 2 mol CCl_3CN and 1 mol aliphatic nitriles in good yield when anhydrous HCl was introduced into the mixture and then heated strongly. The use of a combined catalyst also promoted this reaction. But it was not necessarily required, because the use of HCl only gave good results.

Table 5 shows the compounds obtained from the above mentioned method.

The following two experiments were carried out to observe some aspects of the mechanism about HCl-catalysed cotrimerization of CCl_3CN with CH_3CN. This mechanism may explain the cotrimerization of CCl_3CN with other nitriles also.

a) Addition of 1 mol CH_3CN to the adduct*3 of 2 mol of CCl_3CN and 1 mol HCl.

b) Addition of 1 mol CH_3CN that has already absorbed 1 mol HCl to the adduct of 2 mol of CCl_3CN and 1 mol HCl.

Like Grundmann *et al.*[25] we could hardly obtain the (co)trimerized product under the condition of a). However, the reaction proceeded readily to afford in a good yield under the condition of b).

† Reaction conditions; See Experimental B-b).

*1 Characteristic absorption of *s*-triazine system. *2 *s*, singlet; *d*, doublet; *t*, triplet; *q*, quartet; *qi*, quintet; *h*, heptet; *m*, multiplet. *3 H. G. Schmelzer *et al.*, German Pat. 1200314 (1965). *4 n_D^{28} 1.4746. *5 n_D^{28} 1.4850. *6 Z. H. Pazenko *et al.*, *Ukr. Khim. Zh.*, **29**, (11), 1192 (1963). It was reported that this compound was obtained without strong heating.

The mechanism may be explained as follows. The dimer (VII) (formed from 2 molecules CCl_3CN and 1 molecule HCl) and acetimidoyl chloride (VI) (formed from 1 molecule CH_3CN and 1 molecule HCl) may produce the adduct (VIII) by Diels-Alder type reaction. VIII may be changed into resonance-stabilised *s*-triazine, II, by the loss of 2 molecules HCl.

It may be explained that the intermediates (VIII) from the nitriles in Table 4 are converted smoothly into *s*-triazine by the loss of 2 molecules HCl at room temperature, but the intermediates (VIII) from the nitriles in Table 5 are not converted without strong heating.

Experimental

All the boiling points and melting points are uncorrected. Gas-liquid chromatography was performed with a Shimadzu GC-2C fitted with a flame ionization detecter, with 25 ml/min of nitrogen, using a 2 m×4 mm column containing 4% SE-30 on Gaschrom. P. IR spectra were obtained with a JASCO model IR-S spectrometer. UV spectra were obtained with a Perkin-Elmer model 202 spectrometer. NMR spectra were determined at 60 Mc with a Varian A-60 spectrometer, using TMS as the internal standard. Mass spectra were obtained with a Hitachi RMU-6C spectrometer.

Materials. *Nitriles.* CH_2ClCH_2CN[47] was prepared from acrylonitrile. CCl_3CN[12] was prepared by the chlorination of acetonitrile and CH_2ClCCl_2CN[48] by the chlorination of acrylonitrile. *i*-C_4H_9CN, *s*-C_4H_9CN, *t*-C_4H_9CN, *n*-$C_9H_{19}CN$, 2-ClC_6H_4CN, 3-ClC_6H_4CN, 4-BrC_6H_4CN, 2,4-$Cl_2C_6H_3CN$, 3,4-$Cl_2C_6H_3CN$ and 2,4,5-$Cl_3C_6H_2CN$ were prepared by the dehydration of corresponding amide with P_2O_5. Acetonitrile and acrylonitrile were supplied from Kasei Mizushima Ltd. Other nitriles were obtained from Tokyo Kasei Kogyo Co., Ltd.

Metal Halides. All reagents were obtained from Wako Pure Chemical Industries Ltd.

A) Trimerization of CCl_3CN. *2,4,6-Tris(trichloromethyl)-s-triazine (I).* 32 g (0.22 mol) of CCl_3CN and 0.5 g of a catalyst were placed into a 300 ml flask. The mixture was saturated with anhydrous HCl at −10—0°C with stirring. The reaction mixture was kept at room temperature for 12 hr to complete trimerization. The contents of the flask was melted by heating at 100—110°C and poured into a large quantity of water to wash out HCl and catalyst. The mixture was cooled to let the product solidify again. The solid product was filtered, dried in air and recrystallized from ethanol (Table 1). Analysis example; using $AlBr_3$-HCl as the catalyst.

Found: C, 16.60; N, 9.49; Cl, 73.90%. Calcd for $C_6N_3Cl_9$: C, 16.64; N, 9.70; Cl, 73.66%.

IR absorption; 1545, 1341 cm^{-1} (*s*-triazine ring).

UV absorption; $\lambda_{max}^{CH_3OH}$ 219 mμ (ε 2590); 287 mμ (ε 790).

B) Cotrimerization of CCl_3CN. *a) 2-Methyl-4,6-bis(trichloromethyl)-s-triazine (II).* 289 g (2 mol) of CCl_3CN and 50 g (1.2 mol) of CH_3CN and a catalyst were placed into a 500 ml flask. The mixture was saturated with anhydrous HCl at −20—0°C with stirring, which was continued at the same temperature for 2—3 hr. At the end of the reaction time the contents of the flask solidified. After the reaction mixture was kept at room temperature to complete cotrimerization, the product was melted by heating at 100—110°C and poured into a large quantity of water to wash out HCl and the catalyst. After being cooled to room temperature, the separated solid was collected, dried in air and then recrystallized from ethanol. (Table 2).

Analysis example; using $AlBr_3$-HCl as the catalyst.

Found: C, 21.99; H, 1.00; N, 12.69; Cl, 64.48%. Calcd for $C_6H_3N_3Cl_6$: C, 21.84; H, 0.92; N, 12.74; Cl, 64.49%.

IR absorption; 1543, 1339 cm^{-1} (*s*-triazine ring).

UV absorption; $\lambda_{max}^{CH_3OH}$ 219 mμ (ε 1920); 280 mμ (ε 950).

NMR spectrum ($CDCl_3$); τ 7.02 (CH_3).

b) 2-Alkyl[2]-4,6-bis(trichloromethyl)-s-triazine.* The mixed solution of 289 g (2 mol) of CCl_3CN and 1.2 mol of RCN was saturated with anhydrous HCl at −30—−15°C by cooling with dry ice-methanol bath for 2 hr with stirring, which was continued at −10—0°C for 2—3 hr. The reaction mixture was kept overnight at room temperature. Then HCl gas was removed under reduced pressure by a water pump, gradually heating the reaction mixture at 150—200°C to complete cotrimerization. The residue is fractionated under reduced pressure. Thus 2-alkyl-4,6-bis(trichloromethyl)-*s*-triazine was obtained (Table 5).

C) The Preparation of Authentic Samples. *a) 2,4-Dimethyl-6-trichloromethyl-s-triazine (III).* III was prepared from acetic anhydride and *N*-(acetimidoyl) trichloroacetamidine which was prepared from CCl_3CN and acetamidine.[49] Yield 55%. Mp 72—73°C (lit[49] mp 69—71°C).

IR absorption; 1540 cm^{-1} (*s*-triazine ring).

UV absorption; $\lambda_{max}^{CH_3OH}$ 234 mμ (ε 2020); 260 mμ (ε 890).

NMR spectrum ($CDCl_3$); τ 7.26 (CH_3).

b) 2,4,6-Trimethyl-s-triazine (IV). IV was prepared by the method of Schaefer[50] from ethyl acetimidate. Yield 90%. Mp 60°C. Bp 150—155°C (lit[50] bp 155°C).

IR absorption; 1536 cm^{-1} (*s*-triazine ring).

UV absorption; $\lambda_{max}^{CH_3OH}$ 228 mμ (ε 270); 257 mμ (ε 390).

NMR spectrum ($CDCl_3$); τ 7.42 (CH_3).

D) Experiments to Elucidate HCl-catalysed Cotrimerization of CCl_3CN with CH_3CN. *a) The Reaction of CH_3CN and the Adduct (VII) of CCl_3CN and HCl.* 18 g (0.5 mol) of anhydrous HCl was absorbed into 144.5 g (1 mol) of CCl_3CN at −10—0°C for 0.5 hr. Then 20.5 g (0.5 mol) of CH_3CN was added to this solution with stirring. The mixture was allowed to stand for 90 hr at room temperature. The product was distilled under reduced pressure by a water pump.

50) F. C. Schaefer and G. A. Peters, *J. Org. Chem.*, **26**, 2778 (1961).

The distillate was a mixture of CH_3CN and CCl_3CN. A small amount of residue was obtained. This compound was found out to be a mixture of II and unidentified substance by GLC and IR analyses.

b) The Reaction of the Adduct (VI) of CH_3CN and HCl, and the Adduct (VII) of CCl_3CN and HCl. 18 g (0.5 mol) of anhydrous HCl was absorbed into 144.5 g (1 mol) of CCl_3CN at −10—0°C for 0.5 hr. 18 g of anhydrous HCl was also absorbed into 20 .5g (0.5 mol) of CH_3CN under the same condition. Then two solutions were mixed at 0—10°C with stirring. The mixture was allowed to stand for 90 hr at room temperature. At the end of the reaction, the reaction mixture almost solidified which was then poured into water. The crude product was filtered and air-dried to yield 140 g (85%). Mp 90—93°C. This compound was identified II by GLC and IR analyses.

The authors are indebted to the Mitsubishi Chemical Industries Ltd. for their generous support of this publication. They also wish to express their thanks to Mr. Y. Takigawa for obtaining and interpreting the spectra which were of great assistance in this work and Mr. K. Suzuki for the microanalyses. Valuable technical assistance was also provided by Mr. M. Tsuda and Mr. M. Nakazawa.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 2931—2937 (1969)

Studies on *s*-Triazines. II. Cotrimerization of Trichloroacetonitrile with Thiocyanates[1),*1]

Ko WAKABAYASHI, Masaru TSUNODA and Yasushi SUZUKI

Research Laboratory, Mitsubishi Chemical Industries Ltd., Mizonokuchi, Kawasaki, Kanagawa

(Received April 11, 1969)

2-Substituted thio-4,6-bis(trichloromethyl)-*s*-triazines, a new class of *s*-triazine derivatives, were obtained by the cotrimerization of CCl_3CN with a wide variety of thiocyanates. Generally, the reaction proceeded smoothly at ordinary pressure in the presence of hydrogen chloride or the combined catalyst, Friedel-Crafts catalyst-hydrogen chloride.

Literature[2–4] has revealed that attempts to prepare 2-substituted thio-4,6-bis(trichloromethyl)-*s*-triazines have mostly met with failure.

Kober[5] reported that the reaction of 2,4,6-tris-(trichloromethyl)-*s*-triazine (I) with alcohols, in the presence of tertiary amines, led to the stepwise replacement of the CCl_3-groups with the alkoxyl groups, depending upon the reaction condition. Then Kober further attempted to determine whether the reaction of I with alkanethiols, instead of alcohols, would react in the presence of tertiary amines resulting in the formation of 2-alkylthio-4,6-bis(trichloromethyl)-*s*-triazines. His results, however, indicated that the reaction of I with

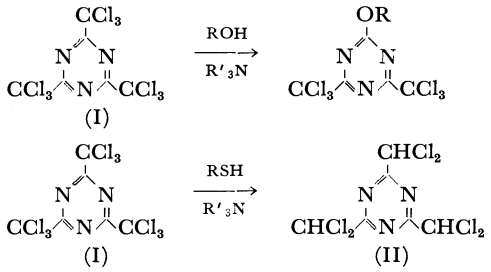
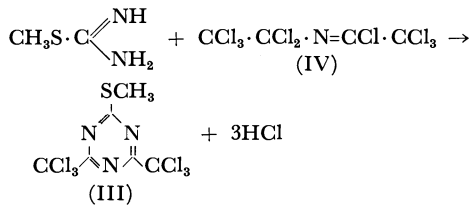
alkanethiols in the presence of tertiary amines took an entirely different course as compared with the reaction of I with alcohols. Instead of being replaced with the alkylthio groups, the CCl_3-groups were converted into $CHCl_2$-groups and resulted in 2,4,6-tris(dichloromethyl)-*s*-triazine (II).[2]



Scheme 1

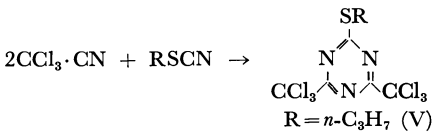
The only type of these *s*-triazines hitherto known, is 2-methylthio-4,6-bis(trichloromethyl)-*s*-triazine[3] (III) which was obtained from the reaction of *S*-methyl isothiourea with *N*-pentachloroethyl-trichloroacetimidoyl chloride (IV). The following Scheme 2 shows this method to be successful.



Scheme 2

While the *S*-methyl isothiourea is derived readily from thiourea,[6] IV has been only obtained by high temperature (250—300°C) chlorination reaction of $(C_2H_5)_2NH$[7] or of *N*-ethyl-trichloroacetimidoyl chloride[8] under UV irradiation. Many side reactions may occur, if the reaction is not carried out carefully in this chlorination process. Because of such conditions, the method mentioned above is not readily applicable to the preparation of the desired compounds.

The authors have also investigated the preparation of 2-substituted thio-4,6-bis(trichloromethyl)-*s*-triazines, in order to evaluate these *s*-triazines as fungicides[9] or nitrification inhibitors[10] in soil. Accordingly, the extention of the cotrimerization reaction[1] of CCl_3CN with other nitriles to that of CCl_3CN with RSCN, have been examined as a method in the preparation of these types of *s*-triazines. The results show that 2-substituted thio-4,6-bis(trichloromethyl)-*s*-triazines can be prepared in high yield by a less costly and moderate reaction condition involving the simple cotrimerization of CCl_3CN with RSCN at atmospheric pressure.



Scheme 3

Cotrimerization reaction was done by introducing HCl gas into the mixture of 2 mol of CCl_3CN and 1 mol of RSCN and a small amount of Friedel-Crafts catalyst.[11] The strong heating treatment was

11) H. G. Schmelzer and E. Degener, U. S. Pat. 3347859 (1967).

We came across this patent a few days after we carried out our experiment. $ZnCl_2$-HCl is used in the patented reaction instead of our combined catalyst, $AlBr_3$-HCl.

necessary to cotrimerize completely CCl_3CN with RSCN as well as the cotrimerization of CCl_3CN with aliphatic nitriles.[1] The reaction time was shortened by using Friedel-Crafts catalyst, which was not necessarily required to achieve this reaction.

In several cases the authors did not use solvents. When RSCN was not dissolved completely in CCl_3CN, suitable solvents such as ether, chloroform, carbon tetrachloride, *etc.*, could be used.

The following information shows that the product from CCl_3CN and n-C_3H_7SCN was to be a 2 : 1 cotrimer of them. The product has a strong infrared absorption at 1550 and 1503 cm^{-1} (*s*-triazine ring). Figure 1 shows the result of mass spectrum analysis.

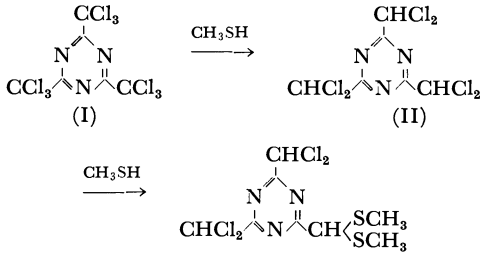
As shown in Fig. 1, the molecular peak (M^+), *m/e* 387, corresponds to the calculated molecular weight of 2-(*n*-propylthio)-4,6-bis(trichloromethyl)-*s*-triazine (V). *m/e* 352 and 317 register the exact weight of M^+-35(atomic weight of chlorine) and $M^+-2\times35$, respectively. Also as shown in Table 1, the isotope abundances are the same as those calculated, and the NMR spectrum of the product shows the existence of the n-C_3H_7 group.

Judging from these results, we can state that the product from CCl_3CN and n-C_3H_7SCN is the 2 : 1 cotrimer of them, V.

Table 2 shows 2-substituted thio-4,6-bis(trichloromethyl)-*s*-triazines obtained from the cotrimerization of CCl_3CN with RSCN.

The authors also attempted Kober's methods,[2] making I react with methanethiol in the presence of $(C_2H_5)_3N$, but could not obtain the desired III.

II and 2,4-bis(dichloromethyl)-6-bis(methylthio)-methyl-*s*-triazine were confirmed by IR and NMR to be the products in this reaction.



Scheme 4

Experimental

All boiling points and melting points are uncorrected. IR spectra were obtained with a JASCO model IR-S spectrometer. UV spectra were obtained with a Perkin-Elmer model 202 spectrometer. NMR spectra were determined at 60 Mc with a Varian A-60 spectrometer using TMS as the internal standard. Mass spectra were obtained with a Hitachi RMU-6C spectrometer.

Procedure of the Method. *2-Substituted Thio-4,6-bis(trichloromethyl)-s-triazine.* 290 g (2 mol) of CCl_3CN and thiocyanate*[2] (1 mol) and 3 g of $AlBr_3$ were placed in a 500 m*l* flask (if necessary, the solvent should be added). Anhydrous hydrogen chloride (*ca.* 150 g) was introduced into the mixed solution at −40—−20°C with stirring. The reaction mixture was kept at −10—0°C for 12 hr and then at room temperature for the next 24 hr. Hydrogen chloride gas was then removed under reduced pressure (20—30 mmHg) by use of a water pump from the reaction mixture, gradually heating it to 150—200°C to complete cotrimerization. The residue was fractionated under reduced pressure (Method A) or recrystallized from ethyl acetate (Method B). 2-Substituted thio-4,6-bis(trichloromethyl)-*s*-triazines obtained were shown in Table 2.

2,4,6-Tris(dichloromethyl)-s-triazine[2] (*II*). To the mixed solution of 21 g (0.2 mol) of $(C_2H_5)_3N$ and 96 g (2 mol) of CH_3SH was added 43.3 g (0.1 mol) of 2,4,6-tris-(trichloromethyl)-*s*-triazine by small portion at −20—−30°C with stirring. After adding, 200 m*l* of ether was added to this solution and the excess CH_3SH was removed below room temperature. The separated $(C_2H_5)_3N$-HCl salt was filtered and the filtrate was concentrated to remove ether and CH_3SSCH_3. The resulting oily residue was fractionated to give 24.7 g (75% yield) of 2,4,6-tris(dichloromethyl)-*s*-triazine, bp 150—60°C/0.5 mmHg, mp 62—65°C. Recrystallization from petroleum ether raised the melting point to 67—70°C. Found: C, 21.95; H, 1.03; N, 12.66; Cl, 64.52%. Calcd for $C_6H_3N_3Cl_6$: C, 21.84; H, 0.92; N, 12.74; Cl, 64.49%. IR absorption (KBr): 1552 cm^{-1} (characteristic absorption of *s*-triazine system). NMR spectrum ($CDCl_3$): τ 3.27 (singlet, $CHCl_2$).

2,4-Bis(dichloromethyl)-6-bis(methylthio)methyl-s-triazine. Using 50 g (0.5 mol) of $(C_2H_5)_3N$ and 96 g (2 mol) of CH_3SH and 43.3 g (0.1 mol) of 2,4,6-tris(trichloromethyl)-*s*-triazine, the reaction was carried out in the same way as in the preparation of II. The major product, 23 g (65% yield), bp 125—128°C/0.01 mmHg, n_D^{23} 1.5572, was 2,4-bis(dichloromethyl)-6-bis(methylthio)methyl-*s*-triazine.

Found: C, 27.35; H, 2.46; N, 12.01; Cl, 39.96; S, 18.34%. Calcd for $C_8H_9N_3Cl_4S_2$: C, 27.21; H, 2.57; N, 11.90; Cl, 40.16; S, 18.16%.

IR absorption (Film): 1548 cm^{-1} (characteristic absorption of *s*-triazine system).

NMR spectrum ($CDCl_3$): τ 7.73 (singlet, 6H, SCH_3); 6.12 (singlet, H, $-CH\langle^{S}_{S}$); 3.35 (singlet, 2H, $CHCl_2$).

The authors are indebted to the Mitsubishi Chemical Industries Ltd. for their generous support of this work. They also wish to thank Mr. Y. Takigawa for kindly assisting in interpreting the spectra. Valuable technical assistance was also provided by Mr. M. Tsuda and Mr. M. Nakazawa.

*2 Materials. Alkyl thiocyanates were prepared from KSCN and the corresponding alkyl halides and aryl thiocyanates from the corresponding anilines.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 2938—2944 (1969)

Reactions of Diazoketones in the Presence of Metal Chelates. II. Reactions with Olefinic Compounds*[1]

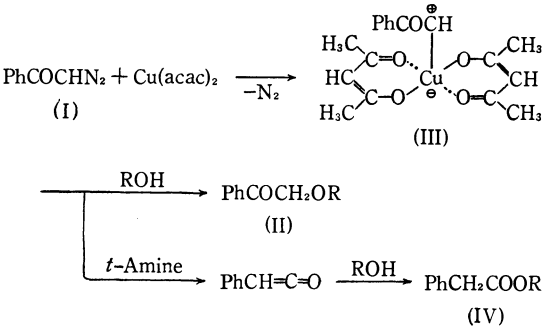
Matsuji TAKEBAYASHI, Toshikazu IBATA, Hideki KOHARA and Kozaburo UEDA

Department of Chemistry, College of General Education, Osaka University, Toyonaka, Osaka

(Received March 10, 1969)

The reaction of α-diazoacetophenone with olefinic compounds, such as vinyl acetate, *cis*- and *trans*-stilbenes and cyclohexene, has been studied in the presence of bis(acetylacetonato)copper-(II). The reaction gave the corresponding cyclopropane derivatives, the addition products of benzoylcarbene to the double bond of olefinic compounds in good yields, accompanied by *cis*- and *trans*-dibenzoylethylenes, dibenzoylethane or dilactone. Addition of carbene was found to be stereospecific in the cases of *cis*- and *trans*-stilbenes. A mechanism has been advanced in which a ketocarbene-metal chelate complex is included as an intermediate of the reaction.

In a previous paper[1] we reported that the reaction of α-diazoacetophenone (I) with alcohols in the presence of metal chelates, such as bis(acetylacetonato)copper(II) and bis(acetylacetonato)-nickel(II), gives the corresponding alkoxyacetophenones(II), and that the tertiary amines such as triethylamine, pyridine and quinoline, suppress the formation of the alkoxyacetophenones (II) and promote that of alkyl phenylacetates (IV) in proportion to the increase in the amount of amines added. The mechanism of the reaction has been explained as follows by assuming the intermediacy of a ketocarbene-metal chelate complex (III).



This paper deals with the reaction of the ketocarbene-metal complex with olefinic compounds. Stork and Ficini[2] have studied the copper-catalyzed decomposition of 1-diazo-6-hepten-2-one, and obtained bicyclo[4.1.0]heptanone-2 as an intramolecular cyclo-addition product of olefinic ketocarbene. Thereafter, the intramolecular cycloaddition of olefinic ketocarbenes has been utilized for the formation of strained bicyclo- and tricyclo-compounds.[3,4] On the other hand, studies of the intermolecular addition of ketocarbenes to carbon-carbon double bonds have recently been reported.[5,6]

We studied the reaction of α-diazoacetophenone with olefinic compounds in the presence of bis(acetylacetonato)copper(II) in order to gain further insight on the carbenoid mechanism of copper-chelate-catalyzed decomposition of diazoketones.[1]

Results and Discussion

Reaction of α-Diazoacetophenone with Vinyl Acetate. The bis(acetylacetonato)copper-catalyzed decomposition of α-diazoacetophenone (I) was carried out in a large excess of vinyl acetate under a homogeneous condition. Exothermic reaction took place and an evolution of almost theoretical amount of nitrogen was observed. The reaction product was separated into two fractions by vacuum distillation.

By means of elemental analyses and IR and NMR spectra, the lower boiling fraction was confirmed to be a mixture of *cis*- and *trans*-1-benzoyl-2-acetoxy-cyclopropanes (V) (1 : 6), the addition products of benzoylcarbene to vinyl acetate. The NMR spectra of the components are different from each other as shown in Figs. 1 and 2.

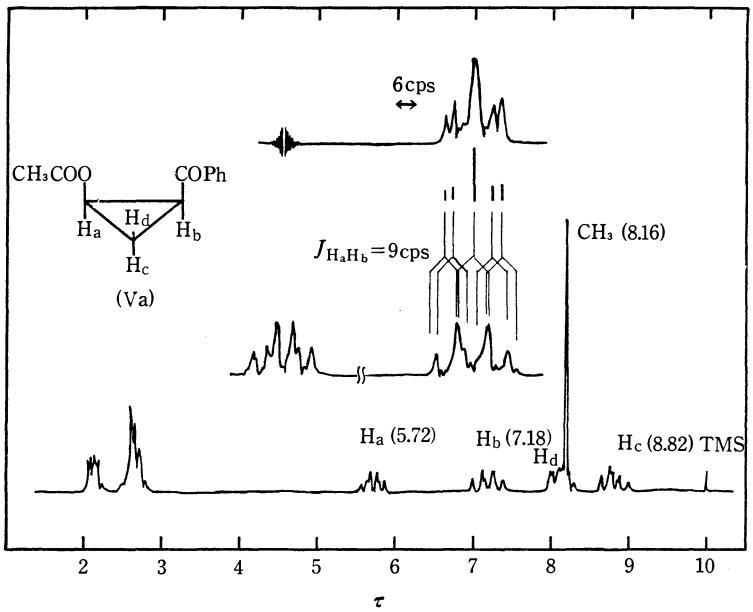

Fig. 1. NMR spectrum of Va.

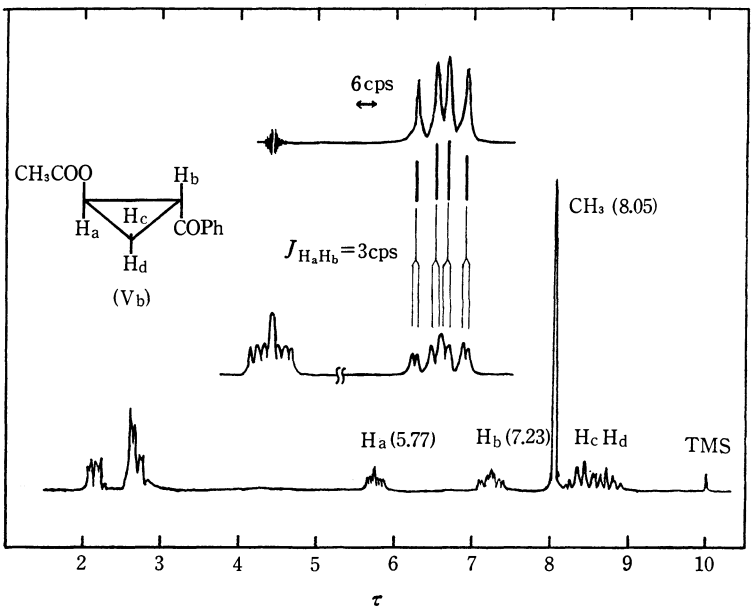

Fig. 2. NMR spectrum of Vb.

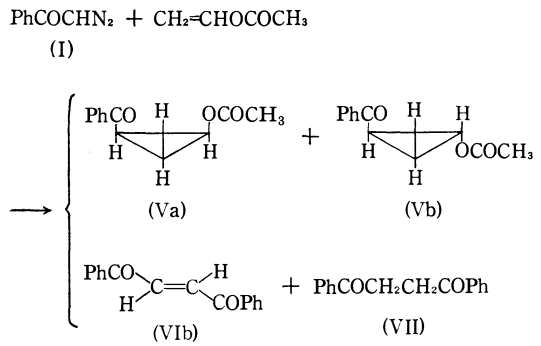
One component is identified as *cis*-1-benzoyl-2-acetoxy-cyclopropane (Va) and the other as *trans*-isomer (Vb) by the observation of their NMR spectra. The singlet signal of acetoxy proton of Va appears at higher field (8.16 τ) than that of Vb (8.05 τ), and the J_{HaHb} coupling constant of Va (9 cps) is larger than that of Vb (2.3 cps).*2 The

*2 The coupling constants were measured by the spin-decoupling method. The *cis*-coupling constant of vicinal protons of cyclopropane ring is generally larger than the *trans*-coupling constant. The *trans*-coupling constant (J_{HaHb}) of Vb was observed to be abnormally smaller than usual.[7] The other coupling constants between protons of Va and Vb will be reported elsewhere in detail.

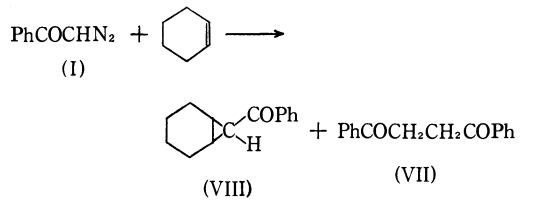
*3 Decomposition of I in a large excess of vinyl acetate in the presence of catalytic amount of nickelocene was carried out and the same results as shown in the case of $Cu(acac)_2$ were observed, affording a mixture of Va and Vb in 44% yield.

yield of this isomeric mixture was 58 per cent of the theoretical amount calculated from I.*3 The vpc analysis of the lower boiling fraction showed a very small peak at the retention time of 9.5 min, which became larger with the addition of authentic acetophenone. Further investigation of the presence of acetophenone in this fraction was not carried out.

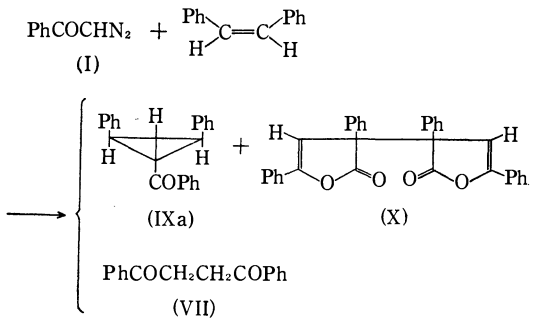
The higher boiling fraction was a mixture of *trans*-1,2-dibenzoylethylene (VIb)[8] (5% yield) and a trace of 1,2-dibenzoylethane (VII).[9] The structure of VIb and VII was confirmed by the comparison of the melting points and IR spectra with those of the authentic samples.



Reaction of α-Diazoacetophenone with Cyclohexene. The reaction of I with cyclohexene in the presence of copper-salts to give 7-benzoylnorcarane (VIII) has been reported by Cowan *et al.*[6] The decomposition of I in a large excess of cyclohexene at 75°C in the presence of $Cu(acac)_2$ gave a small amount (5%) of VII in addition to the main product VIII (51%). Product VIII was also found to be a mixture of *syn*- and *anti*-isomers by elemental analyses, melting point test and IR absorption spectra of their 2,4-dinitrophenylhydrazones, although Cowan *et al.* had reported only one hydrazone of VIII.[6]



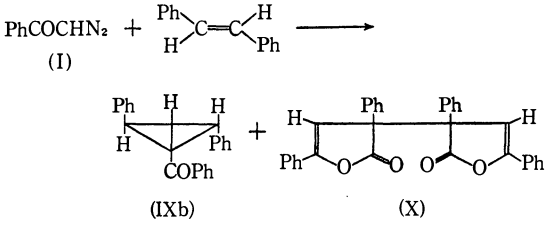
Reaction of α-Diazoacetophenone with Stilbene and Diphenylacetylene. In the cases of the reactions of I with *cis*- and *trans*-stilbenes and diphenylacetylene, the "dropwise addition method" was applied in order to avoid the formation of dimers of benzoylcarbene. In the case of *cis*-stilbene, the cyclopropane derivative (IXa) was obtained in 19% yield, accompanied with dilactone (X)[10] and VII in 3.2 and 2.4% yield, respectively. The structure of X was assigned by the comparison of IR spectrum with that of the authentic sample obtained by the photolysis of I in a benzene solution.[11]



The structural assignment of IXa was established by the IR and NMR spectra. The NMR spectrum of IXa has quasi-doublet signal of Ha at 6.74 τ and quasi-triplet signal of Hb at 6.48 τ in 2 : 1 area ratio as shown in Fig. 3.

This NMR pattern of cyclopropane ring protons agreed with that of calculated AB_2 type having coupling constant of 2.0 cps and chemical shift difference of 6.0 cps.[12] The coupling constant of cyclopropane ring protons Ha and Hb of IXa, J_{HaHb}=5 cps, has a normal value compared with those of usual *trans*-protons in cyclopropane derivatives.[9]

The reaction of I with *trans*-stilbene gave an adduct (IXb), in 5 per cent yield besides the recovered *trans*-stilbene and X (1.5%).



The structure of IXb was established by means of

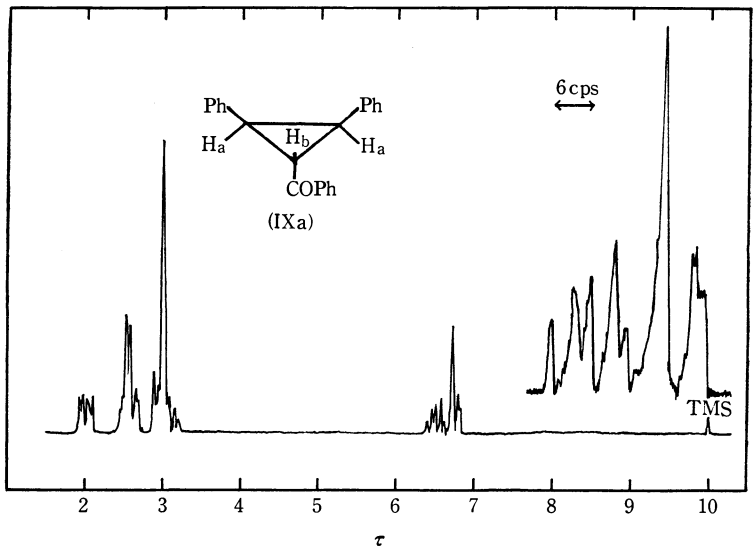

Fig. 3. NMR spectrum of IXa.

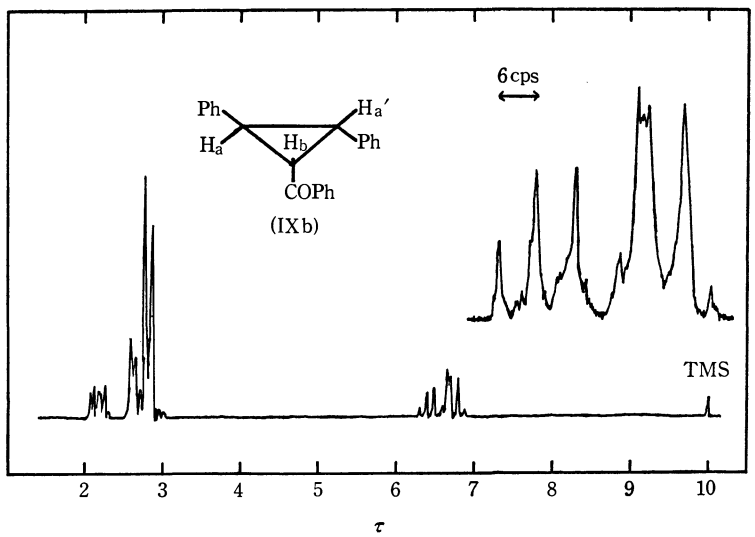

Fig. 4. NMR spectrum of IXb.

elemental analysis and IR and NMR spectra (Fig. 4).

The sharp melting points of IXa and IXb and their thin-layer chromatograms suggest that they are not contaminated with each other and are chemically pure. The NMR spectrum of IXa has a singlet signal at 3.00 τ corresponding to ten protons of two phenyl groups bonding directly to cyclopropane ring. On the other hand, the NMR spectrum of IXb has two singlet signals at 2.78 and 2.87 τ attributed to two phenyl groups which are in a different magnetic state, and quasitriplet of one proton at 6.42 τ and also quasi-doublet of two protons at 6.74 τ of ABB′ type. The *ortho*-proton signal of benzoyl group of IXb appears at higher field than that of IXa.

These results indicate that the addition of this carbene complex (III) to stilbene proceeds stereospecifically.

While the reaction of I with diphenylacetylene in a benzene solution gave no adduct of carbene to carbon-carbon triple bond, small amounts of VII and X (4.5%) were obtained.

Decomposition of α-Diazoacetophenone in Inert Solvents. When the catalytic decomposition of I was carried out by the "mixed method" in a benzene solution at 48°C, the adduct of carbene to benzene, *viz.*, a norcaradiene derivative, was not detected. However, *cis*- and *trans*-1,2-dibenzoylethylenes (VIa and VIb), the formal dimers of

benzoyl-carbene, were obtained in the yields of 11.3 and 13.6 per cent, respectively.

In a chloroform solution, I also gave VIa and VIb in the yields 13.0 and 0.06 per cent, respectively, contrary to the result of Grundmann and Trischmann[8] who obtained neither of these products.

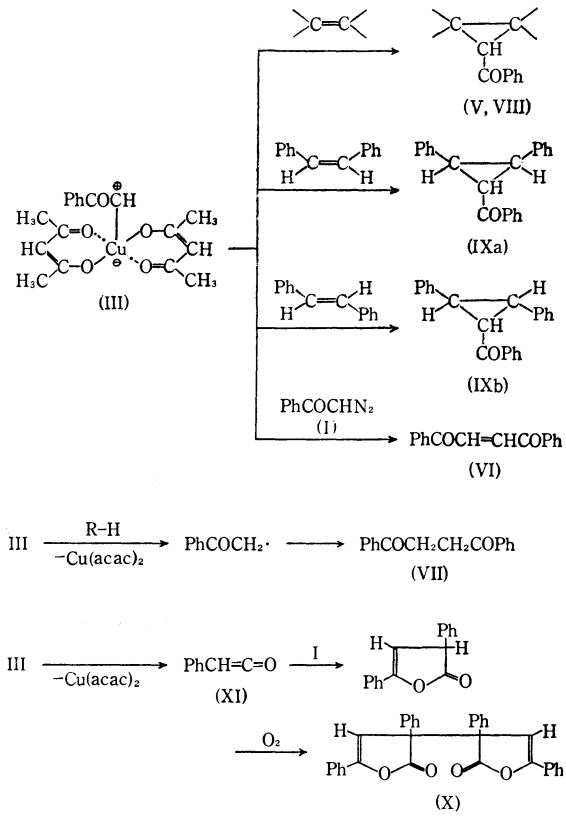
In methyl benzoate, 57.0 per cent yield of VIa and 2.9 per cent yield of VIb were obtained by the "mixed method," while only a polymer of benzoylcarbene was produced by the "dropwise addition method."[13]

Mechanism. From the results mentioned above, the catalytic reaction of α-diazoacetophenone with olefinic compound is also reasonably explained by assuming the copper-carbenoid intermediate (III) as well as the metal-chelate-catalyzed decomposition of I in alcohols.[1] Since no addition products to diphenylacetylene[14] and to benzene were obtained, the reactivity of this carbenoid intermediate seems to be not so large.

The *cis*- and *trans*-1,2-dibenzoylethylenes (VI) may be formed by the reaction of I with carbenoid (III) in the case of "mixed method" where no substrate having enough reactivity to the carbenoid is present except I in the reaction system. Grundmann and Trischmann[8] have reported that the copper-powder-catalyzed decomposition of I in various solvents gives *trans*-1,2-dibenzoylethylene (VIa). However, the isolation of *cis*-isomer has not been accomplished yet by the catalytic decomposition of α-diazoketones. The ratio of *cis*- and *trans*-isomers largely depends upon the nature of the solvents.

On the other hand, dilactone (X) was observed in the reaction of I with *cis*- and *trans*-stilbenes and diphenylacetylene, which have no large reactivity toward III. In these cases, the concentration of substrate reacting with III is so small that a part of carbenoid (III) releases benzoylcarbene, which leads to phenylketene (XI) by concerted phenyl migration. The phenylketene reacts with I and finally affords dilactone as reported in the case of photolysis of I.[11] The release of benzoylcarbene from carbenoid (III) seems to be rather slow, since the yield of X is small (1.5—4%). This may be supported by the fact that the formation of esters, produced from phenylketene, is accelerated in alcohols by the addition of tertiary amines.[1] The formation of 1,2-dibenzoylethane (VII) is explained by the dimerization of relatively stable phenacyl radical, which is formed by the hydrogen abstraction of the carbenoid from the solvents or substrates.

The mechanism of the formation of products obtained is summarized as follows:



Experimental

All melting and boiling points described in this paper were not corrected. The IR spectra were determined in potassium bromide disks for crystals or in liquid film for liquid samples, respectively, on a Hitachi Infrared Spectrophotometer, model EPI-S2. The NMR spectra were recorded at 60 Mc with a Hitachi High Resolution NMR Spectrometer, model R-20, using tetramethylsilane as an internal standard.

Materials. *α-Diazoacetophenone* was prepared from benzoyl chloride and diazomethane according to the method of Newman and Beal,[15] and recrystallized several times from *n*-hexane, mp 47.5—48.0°C.

Bis(acetylacetonato)copper(II) was prepared according to published directions.[16]

cis-Stilbene was prepared by the decarboxylation[17] of α-phenylcinnamic acid in the presence of copper chromite in a quinoline solution, and purified by distillation, bp 108—110°C/5 mmHg.

trans-Stilbene was obtained by the reduction of benzoin[18] by zinc amalgam and hydrochloric acid, and was recrystallized from 95% ethanol, mp 123.5—124.0°C.

Diphenylacetylene was prepared by the oxidation of

benzil dihydrazone using yellow mercuric oxide,[19] mp 60—61°C.

Cyclohexene was obtained by dehydration of cyclohexanol in the presence of catalytic amount of sulfuric acid,[20] and dried over calcium chloride and purified by distillation before use.

Vinyl Acetate, Benzene and Chloroform. Commercial products were purified by distillation before use.

vinyl acetate	bp 71.5—72.0°C
benzene	bp 79.5—80.0°C
chloroform	bp 61.0—61.2°C

Reaction of α-Diazoacetophenone (I) with Vinyl Acetate in the Presence of Cu(acac)$_2$. A solution of 5.0 g (0.034 mol) of I and 0.1 g (3.8×10^{-4} mol) of Cu(acac)$_2$ in 150 m*l* of vinyl acetate was warmed gradually under an atmosphere of nitrogen. The evolution of nitrogen was observed at 48°C, and then the temperature rose to 55—56°C by exothermic reaction. Within 20 min an almost theoretical amount of nitrogen was evolved and the color of the mixture turned to dark-green with the evolution of nitrogen. After leaving the reaction mixture to stand for two hours more at 50°C, unreacted vinyl acetate was removed by distillation under ordinary pressure. The residue was fractionally distilled under reduced pressure and two fractions were obtained; bp 115—125°C/1 mmHg, and bp 160—172°C/1 mmHg.

The lower boiling fraction was further purified by distillation, bp 114—116°C/1 mmHg.

Found: C, 70.63; H, 6.09%. Calcd for $C_{12}H_{12}O_3$: C, 70.57; H, 5.92%.

IR (neat); 3050, 1750(ester), 1665(benzoyl), 1450 and 1230 cm^{-1}.

The gas chromatogram*4 of this fraction showed two main peaks of retention time 17.5 and 22.5 min in the area ratio of about 1 : 6. The former indicates *cis*-isomer (Va) and the latter *trans*-isomer (Vb).

The higher boiling fraction crystallized on standing at room temperature. The fractional recrystallization from light petroleum gave two substance. One was 0.24 g (5%) of yellow crystals and the other was a trace of colorless crystals. The yellow compound of melting point 107—109°C was identified as *trans*-1,2-dibenzoylethylene (VIb) in good agreement with the IR spectrum and the melting point (mp 110°C) with the authentic sample[8] prepared by the copper-bronze catalyzed decomposition of I.[11] The colorless crystalline compound, mp 147—148°C (from ethanol), was identified as 1,2-dibenzoylethane (VII) in agreement with elemental analysis data with $C_{16}H_{14}O_2$, and IR (KBr disk); 3025, 2900, 1675, 1590, 1220, 990, 775, 740 and 695 cm^{-1}.

Reaction of I with Cyclohexene in the Presence of Cu(acac)$_2$. A solution of 5.0 g (0.34 mol) of I in 150 m*l* of cyclohexene was decomposed at 75°C until nitrogen evolution was complete in the presence of 0.1 g (3.8×10^{-4} mol) of Cu(acac)$_2$ by the method described above. The reaction mixture was distilled under reduced pressure after removal of cyclohexene, and 3.5 g of distillates was obtained, bp 124—140°C/1 mmHg. The elemental analysis data of this compound agreed with the calculated one for 7-benzoylnorcarane, $C_{14}H_{16}O$, after further distillation. IR (neat); 3050, 3020, 1450, 760, 700 cm^{-1} (phenyl), 2940 2860, 1420 cm^{-1} (aliphatic C-H) and 1675 cm^{-1} (C=O). NMR (in CCl_4); 2.05—2.17 τ, (m), 2H, *o*-H in phenyl group: 2.5—2.75 τ, (m), 3H, *m*- and *p*-H in phenyl group: 7.55—7.70 τ, (m), 1H, methyne-H adjacent to benzoyl group: 7.9—8.4 τ, (broad d), 6H: 8.55—8.80 τ, (broad s), 4H.

The IR and NMR spectra showed no olefinic absorption bands. From these results this compound was identified as VIII. The 2,4-dinitrophenylhydrazone of VIII was derived from 1.0 g of VIII and 1.1 g of 2,4-dinitrophenylhydrazine in the presence of sulfuric acid in aqueous alcoholic solution. The hydrazone obtained was fractionally recrystallized from ethyl acetate and two hydrazones were obtained; one was cubic orange crystals, mp 210—211°C. Found: C, 63.25; H, 5.21; N, 14.87%. Calcd for $C_{20}H_{20}N_4O_4$: C, 63.15; H, 5.30; N, 14.73%. The other was orange needles, mp 188.5—189.0°C (easily soluble in ethyl acetate). Found: C, 63.34; H, 5.16; N, 14.40%.

The distillation residue was further distilled at higher temperature, and 0.20 g (5%) of 1,2-dibenzoylethane was obtained mp 147.0—148.0°C (from ethanol).

Reaction of I with *cis*-Stilbene in the Presence of Cu(acac)$_2$ (by Dropwise Addition Method). The 50 m*l* of benzene solution of 5.0 g (0.034 mol) of I was added drop by drop to the 100 m*l* of benzene solution of 6.2 g (0.036 mol) of *cis*-stilbene and 0.1 g (3.8×10^{-4} mol) of Cu(acac)$_2$ at 80°C under stirring. After the evolution of nitrogen was observed and the reaction was complete, the reaction mixture was allowed to stand for one hour at 80°C and then overnight at room temperature. The white substance precipitated was separated by filtration, and washed several times by a small amount of benzene. This precipitate did not dissolve in the usual organic solvents at room temperature. It melted at 250—255°C (lit[6] 290—292°C) but its IR spectrum was completely superimposable with that of dilactone (X) prepared by the photolysis of I in a benzene solution.[11] The yield of X was 0.12 g (3.2%). Benzene was removed by distillation from the filtrate and the residue was distilled under reduced pressure. Unreacted *cis*-stilbene was removed by distillation at 108°C/1 mmHg, 5.0 g (80%). The fraction boiling at 150—170°C/1 mmHg crystallized at room temperature, and was left to recrystallize four times from ethanol and twice from light petroleum, mp 93.0—94.5°C.

Found: C, 88.80; H, 6.15%. Calcd for $C_{22}H_{18}O$: C, 88.56; H, 6.08%. IR (KBr disk); 3050, 1655, 750 and 700 cm^{-1}.

From the distillation residue, 0.10 g (2.4%) of VII was isolated by the distillation at higher temperature and recrystallized from ethanol, mp 147—148°C (lit[8] 140°C).

Reaction of I with *trans*-Stilbene (by Dropwise Addition Method). The reaction of 3.3 g (0.023 mol) of I and 4.0 g (0.022 mol) of *trans*-stilbene was carried out by the "dropwise addition method" at the reflux temperature of benzene in the presence of 0.1 g of Cu(acac)$_2$. 0.06 g (1.5%) of X was obtained as an insoluble precipitate. A part of the residue crystallized

19) *Ibid.*, Coll. Vol. 4, p. 377 (1963).
20) *Ibid.*, Coll. Vol. 2, p. 14 (1950).

*4 Gas chromatographic measurement was carried out with a Yanagimoto Gas Chromatograph, model GCG-3DH, using a 3 m column packed with Apiezon Grease M. Temp. : 195°C; carrier gas: H_2, 80 cc/min.

by the removal of benzene under reduced pressure. The crystals, 2.6 g (65%), were identified as the recovered *trans*-stilbene by comparison of IR spectrum with that of the authentic sample, and by the mixed melting point test, mp 127—128°C. The liquid part crystallized on standing in the refrigerator for several days, and was purified by repeated recrystallization from *n*-hexane, mp 155.5—156.5°C.

Found: C, 88.84; H, 5.95%. Calcd for $C_{22}H_{18}O$: C, 88.56; H, 6.08%.

Reaction of I with Diphenylacetylene. The reaction of I (5.0 g, 0.034 mol) and diphenylacetylene (6.1 g, 0.034 mol) was carried out by the "dropwise addition method" in benzene at 80°C in the presence of $Cu(acac)_2$ (0.1 g). By a similar treatment of the reaction mixture, 0.2 g (4.5%) of X and a trace of VII (mp 143—145°C) were obtained besides the recovered diphenylacetylene. No other detectable compound was isolated.

Reaction of I in Inert Solvents. The $Cu(acac)_2$ catalyzed decomposition of I (5.0 g, 0.034 mol) was performed in benzene or chloroform by "mixed method" at 48—80°C. Solvent was removed *in vacuo* from the reaction mixture, and residue was fractionally recrystallized into two compounds from *n*-hexane. One was identified as *trans*-1,2-dibenzoylethylene. The other was identified as *cis*-1,2-dibenzoylethylene by elemental analyses and IR and NMR spectra, white needles from *n*-hexane, mp 135.5—136.5°C (Found: C, 81.43; H, 5.37%).

NMR (in $CDCl_3$); 2.89 τ, (s), 2H, olefinic-H: 2.4—2.7 τ, (m), 6H, *m*- and *p*-H in phenyl: 1.95—2.25 τ, (m), 4H, *o*-H in phenyl.

The authors express their cordial thanks to Dr. Takashi Ando and Mr. Yoshio Takai of Osaka University for their suggestion on the assignment of NMR spectra, and also to the Ministry of Education for a grant-in-aid for Scientific Research.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 2944—2947 (1969)

Conformation and S=O Stretching Absorptions of Simple Sulfoxides

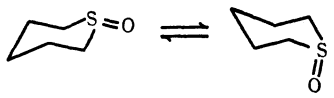
Michinori Ōki, Isao Oka and Katsushiro Sakaguchi

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received March 12, 1969)

The infrared S=O stretching absorptions of several simple sulfoxides have been measured. Some sulfoxides show one absorption maximum, whereas others show two. These results may be attributed to the rotational isomerism about the S–C axis. Convincing evidence for this conclusion has been obtained by the measurement of the spectra of methyl isopropyl sulfoxide at various temperatures.

The conformation of thian oxide has been discussed on the basis of various pieces of evidence. An X-ray diffraction study of *trans*-1,4-dithian 1,4-dioxide has led to the conclusion that the S=O axial conformation is present in the crystals.[1] The nuclear magnetic resonance spectrum of the same compound also supports the idea that the stable conformation is the S=O axial form.[2] On the other hand, it has been claimed from the thermal equilibration of thian 1-oxide that the stable form of the compound is the S=O axial chair (2).[3] Since the axially-substituted isomer of cyclohexane is well known to be less stable than the equatorial, there must be some force operating to stabilize the axial form of the thian oxide or to destabilize the equatorial form.[1] Their stereochemical interest in the thian oxide derivatives has led the present authors to examine the infrared spectra of several simple sulfoxides.



(1) (2)

During the course of this study, Cairns *et al.* reported that the multiplicity of the S=O stretching absorption of sulfoxides could be explained by the Fermi resonance.[4] The data accumulated in this laboratory agree with those obtained by Cairns and his co-workers in the sense that sulfoxides sometimes give multiple absorption bands in the region of 1100—1000 cm^{-1}, but not on the origin of this phenomenon. The purpose of this communication is to present the basis upon which the authors would like to ascribe the phenomenon to

the presence of the rotamers about the C–S bonds.

Experimental

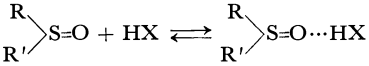
The infrared spectra were measured on a Perkin-Elmer 112 G grating spectrophotometer (slit width: 1.6 cm^{-1}) and a Japan Optics Co., Ltd., 402 G spectrometer. In every case the agreement of the data of the two instruments was good. The samples were dissolved in carbon disulfide or carbon tetrachloride to make up *ca.* 0.05 mol/*l* solution unless otherwise mentioned. The temperature dependence of the spectra was determined using liquid cells consisting of a Hg-Sn amalgam spacer and KBr discs at 0.03 mol/*l* concentration in carbon disulfide.

The spectra were scanned in the region of 1100—1000 cm^{-1} and were compared with those of the parent sulfide in order to eliminate absorptions due to skeletal vibrations. This technique, together with the operation to form an intermolecular hydrogen bond, removed the difficulty in assigning the S=O stretching absorption band.

Materials were prepared and purified according to the literature, and the physical constants were measured in order to check the purity. Special care was taken to avoid moisture during the handling of the lower homologs.

Results and Discussion

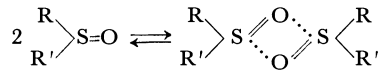
Some of the sulfoxides show single absorption bands and others, doublet absorption bands. In order to clarify the origin of these bands, two techniques were used. One was the comparison of the spectra measured in carbon tetrachloride or carbon disulfide with those obtained in chloroform. The other was the comparison of the spectra of the sulfoxide obtained in carbon tetrachloride with those obtained by adding phenol to carbon tetrachloride. In every case, the bands observed in a carbon tetrachloride solution diminish in intensity when measured in chloroform or when phenol is added, and new bands are observed at *ca.* 1020 cm^{-1} and at a frequency lower than the original by *ca.* 20 cm^{-1}. Although it was not possible to erase completely the bands at 1070—1040 cm^{-1} by these techniques, the results mentioned above are good evidence that there is an equilibrium, such as is shown by Eq. (1), because the reduced intensity corresponds to the decreased population of the free sulfoxide and the new band



(1)

at a lower frequency is an indication of the formation of the hydrogen bond. Thus, one or two bands of sulfoxide in the 1070—1040 cm^{-1} region can be assigned to S=O stretching vibrations. These facts, together with the findings that some symmetrical sulfoxides have only one absorption, whereas the unsymmetrical sulfoxides usually have two, are not in agreement with the postulation by Cairns *et al.*[4]

Other possible causes for the appearance of multiple absorptions for the S=O stretching vibration are: 1) solute-solvent interactions, 2) solute-solute interactions, 3) the coupling of vibrations, and 4) equilibrium among rotational isomers. The possibility of 1) can be disregarded because multiple absorption is observed even in carbon tetrachloride and carbon disulfide solutions, in which no significant solute-solvent interactions are to be expected. There is a possibility that monomer-dimer equilibrium (Eq. (2)) is a cause of the doublet nature of the bands, but the dependency of the absorption upon the concentration of the solute (to be discussed below), together with the fact that this possibility cannot be the reason why some sulfoxides give one band while others give two, are good indications that it is not really the case.



(2)

The S=O stretching absorptions of dimethyl sulfoxide and methyl isopropyl sulfoxide in carbon disulfide were measured in solutions from 3 to 0.0003 mol/*l*. The results indicate that when the concentration is higher than *ca.* 0.5 mol/*l* the shape of the spectra changes, but it does not in solutions of less than 0.1 mol/*l* concentration. Thus, Beer's law is applicable to the absorption when the concentration is less than 0.1 mol/*l*.*1

With the above discussions in mind, it seems attractive to consider that the origin of the multiplicity of the S=O stretching bands is the rotational isomerism. Two C–S bonds must be considered when one discusses the isomerism of sulfoxides. Projection through one of the C–S axes may be given as I—III.*2 I is the conformation in which S=O oxygen staggers between two hydrogens.

*1 The authors prefer, in this connection, to say that the association of sulfoxide occurs according to Eq. (2) when the concentration is higher than 0.5 mol/*l*. This opinion conflicts with the report[5] by Mislow *et al.* that a sulfoxide forms a dimer in the concentration range of 0.02—0.06 mol/*l*, but it is almost unbelievable that the dimer survives even at the concentration of 0.0003 mol/*l*, where no change of spectra was observed. The matter is still to be explored. However, the following discussions are not affected whether the sulfoxide is a monomer or a dimer unless significant populations of monomers and dimers are present due to equilibration.

5) K. Mislow, M. G. Green, P. Laur and D. R. Chisholm, *J. Am. Chem. Soc.*, **87**, 665 (1965); see also R. F. Watson and J. F. Eastham, *ibid.*, **87**, 664 (1965).

*2 The present authors adopt this classification mainly because of the success of similar classification in alcohols; primary, secondary, and tertiary alcohols were shown to possess O–H stretching absorptions according to their classes.[6]

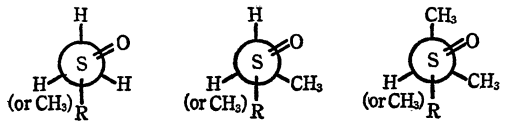
$(CH_3)_3C$	$(CH_3)_3C$	III+III	1040	412

[a] The numbers in parentheses involve considerable uncertainty because these bands are observed as shoulders.

Similarly, S=O oxygen staggers between methyl and hydrogen and between two methyls in the II and III conformations respectively.



(I) (II) (III)

Looking at the results listed in Table 1, it is rather striking that the data fit in well with the idea of rotational isomerism. Thus, dimethyl sulfoxide can assume only one conformation (a combination of I and I; *i.e.*, Newman projections written through two C–S axes can be presented by I) whatever potential minima are taken, as long as the ethane-like potentials are postulated; indeed, it has only one absorption. Likewise, di-*t*-butyl sulfoxide (a combination of III and III) and methyl *t*-butyl sulfoxide (a combination of I and III) can take only one stable conformation and give only one absorption band. Column 3 of Table 1 lists all the possible conformations of sulfoxides. It is noticeable that some are able to take more conformations than the number of absorption bands, but no compound has more absorption bands than the number of conformations possible for the sulfoxides. The exact reason for the apparent lack of conformity between the number of conformations and that of absorptions is not known, but, it may be attributed to the scarce population of certain rotamers due to steric and/or thermodynamical reasons or to the poor resolution of the instrument.

It is tempting, from the data, to postulate that a conformation gives rise to a characteristic absorption in a certain range; the classification may be summarized as is shown in Table 2. The reason

Table 2. Correlation between the conformations of sulfoxide and S=O stretching absorptions

Conformation (combination of)	$\nu_{S=O}$ (cm^{-1})
I and I	1069
I and II	1065
I and III II and II	1058—1054
II and III	1051—1045
III and III	1040

for the effect of alkyl branching (the shift to a lower frequency) is not quite understood at present, but it may be either the inductive effect of the alkyl group and/or a possible interaction between C–H and S=O groups, as will be discussed later.

Simpler examples are alkyl aryl sulfoxides, whose S=O stretching absorption data and their conformations are given in Table 3. In these cases the rotation about the C_{Ar}–S bond can be neglected, because a single conformation is so favored that its contribution is overwhelming as long as the phenyl ring is substituted symmetrically.*3

It will be noted that *p*-tolyl methyl sulfoxide gives only one band because only one conformation is possible. The same reason can be given for the

*3 In this respect, it is interesting to note that *o*-tolyl methyl sulfoxide gives three bands in the S=O stretching region, 1073, 1060 and 1040 cm^{-1}, all of which are diminished in intensity when dissolved in chloroform; after a dissolution, also, a new band is observed at 1032 cm^{-1}.

TABLE 3. S=O STRETCHING ABSORPTION DATA OF ALKYL ARYL SULFOXIDES IN CARBON DISULFIDE (ArSOR)

(IV) (V) (VI)

presence of one band in phenyl t-butyl sulfoxide. Phenyl isopropyl sulfoxide and phenyl ethyl sulfoxide can have two stable conformations and possess two S=O stretching absorptions. Thus, it may be said that the IV conformation gives rise to a band at 1065—1055 cm^{-1}. Similarly, the V and VI conformations give bands at 1055—1050 and 1048 cm^{-1} respectively.

The possibility of a coupling of vibrations can not be ruled out completely because the lower frequency region has not been extensively studied, but the possibility of rotational isomerism is so great, as has been discussed above, that the coupling is less likely.

The most convincing evidence for the idea that the multiplicity of the S=O stretching absorptions is attributable to the rotational isomerism is obtained by measuring the spectra at various temperatures. Methyl isopropyl sulfoxide was selected as an example to study the temperature dependence of the spectra because this compound shows a distinctly two-peaked band and possesses only two possible classes of rotational isomers. The results are shown in Fig. 1.

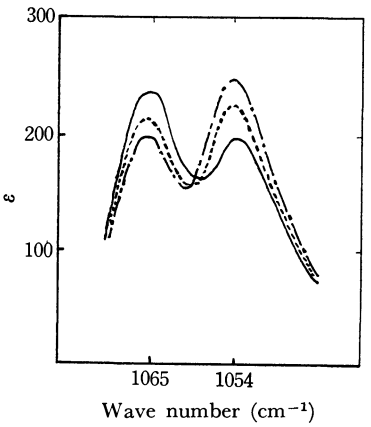

Fig. 1. Temperature dependence of S=O stretching absorptions of methyl isopropyl sulfoxide: room temperature (——), −10——20°C (·····), and −50——80°C (—·—).

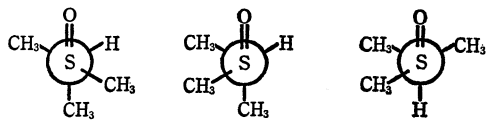
It is apparent that the intensity at the lower frequency increases at the expense of the other band when the temperature is lowered, the results lending firm support to the idea of rotational isomerism.

It is not thermodynamically possible for a stable isomer to be less populated at any temperature. Therefore, if it is assumed that the absorption intensity per molecule is the same for any kind of rotamer, the observed change in intensity seems to contradict the thermodynamical considerations. The apparent contradiction can, however, be overcome when the statistical factor is considered; namely, there are two conformations (VII and VIII) which give rise to the absorption at a higher frequency, whereas there is only one conformation which corresponds to the absorption at a lower frequency (IX).*4



(VII) (VIII) (IX)

These considerations inevitably lead to the conclusion that the IX conformation is more stable than VII and VIII. No convincing evidence accounting for the stability of IX has yet been obtained, but two items are worthy of note. The first is the assumption that the steric bulkiness of the oxygen atom in sulfoxide is less than that of the lone-pair electrons, and the second is the possibility of the existence of a hydrogen bond between the methyl group and the oxygen atom of sulfoxide. The first possibility arises in connection with the fact that the S=O axial form is more stable than the equatorial in thian 1-oxide, but the same reasoning may also be used in favor of the second possibility. Work is now in progress attempting to distinguish these possibilities.

*4 The mirror images of rotamers, VII, VIII, and IX, are neglected in these discussions, because each enantiomer should exist in an equal quantity.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 2948—2951 (1969)

A Partial Asymmetric Synthesis *via* a Cyclic Oxyphosphorane[1)]

Motoo Muroi, Yuzo Inouye[2)] and Minoru Ohno

Institute for Chemical Research, Kyoto University, Uji, Kyoto

(Received March 14, 1969)

A partial asymmetric synthesis was achieved in the carbon-carbon condensation which involved the reaction of (−)-menthyl pyruvate with trimethyl phosphite, followed by alkaline hydrolysis of the intermediate cyclic oxyphosphorane to yield (−)-(S:S)-2,3-dimethyltartaric acid. With knowledge of absolute configurations of both the chiral center and the predominant enantiomer of the product, an *ex post facto* interpretation of the steric course was made on the basis of relative steric stability of transition state conformations of the addition step of III to I.

It has been known that a dicarbonyl compound reacts with trialkyl phosphite to give a cyclic oxyphosphorane (1 : 1 adduct), which can further react with another molecule of the same or of other dicarbonyl compound to yield diastereomeric forms of saturated oxyphosphorane (2:1 adduct).[3)]

In the case of methyl pyruvate and trimethyl phosphite,[3c)] the intermediate 1 : 1 adduct was not an isolable 2,2,2-trimethoxy-1,3,2-dioxaphospholene (II) containing new P–O bonds but exclusively an open dipolar species (III) presumably in a rapid equilibrium with a 1 : 1 adduct having a P–C bond (IV), and the quite reactive dipolar intermediate underwent nucleophilic addition to a second molecule of pyruvate with formation of a mixture of stable diastereomeric 1,3,2-dioxaphospholanes (V). Upon alkaline hydrolysis, the resulting cyclic oxyphosphoranes yielded a mixture of *meso* and racemic 2,3-dimethyltartaric acids (VI).

The new carbon-carbon condensation of this type seems to be interesting from the viewpoint of asymmetric synthesis. Should asymmetric synthesis be obtained by this process, two asymmetric carbon atoms would be simultaneously created in the *threo*-form, and furthermore, this might provide the means of preparing optically active hydroxy-acids of biochemical interest and of assigning absolute configurations thereof. Since pyruvic acid has both a suitably activated prochiral carbonyl function (reaction center) and an adequate "handle" (carboxyl group) through which a chiral reagent (asymmetric center) may be properly accommodated, the present system fulfils the requirements for practice of asymmetric synthesis.

As expected, the asymmetric reaction of (−)-menthyl pyruvate with trimethyl phosphite followed by alkaline hydrolysis of the resulting diastereomeric oxyphosphorane mixture gave 2,3-dimethyltartaric acid of a levorotation. The present asymmetric system produced exclusively the *racemic* form of 2,3-dimethyltartaric acid, in contrast to the corresponding non-dissymmetric reaction.[3c)] This may be attributed to the bulkiness effect of carbomenthoxy groups in the intermediate oxyphosphoranes.

The geometry of the two possible optically inactive forms of 2,3-dimethyltartaric acid was determined by the unambiguous stereospecific routes of synthesis: dimethylfumaric acid[4)] was oxidized with hydrogen peroxide in the presence of WO_3 to give the corresponding dihydroxy-acid, mp 178—180°C. As generally accepted,[5)] the WO_3-catalyzed hydroxylation proceeds in a *trans*-fashion, so that the *trans*-addition of hydroxyl groups to *trans*-olefin should lead to *meso*-modification. Thus, the *meso*-configuration can be safely assigned to this form. In a similar way, the hydroxylation of dimethyl dimethylfumarate with permanganate in ethanol at −40°C gave another isomer melting at 186—186.5°C. The *racemic* configuration can be deduced to this form, for the permanganate hydroxylation is a well-established *cis*-addition.[5)] This deduction is in agreement with that from optical resolvability criterion[6)] and from the IR-spectral study of calcium and barium salts of the two optically inactive modifications.[7)]

R=CH_3- or (−)-menthyl

Scheme 1

The absolute configuration of the chiral form of this acid has not yet been established, without the knowledge of which the steric course of the present asymmetric reaction can not be successfully elucidated. It is hazardous to compare the optical activities of homologous α-hydroxy-acids such as lactic, malic, tartaric and mandelic acids of the well-defined configurations and to extrapolate the correlation as such to the present acid, since the steric environment of the α-carbon atom is substantially changed by replacement of a hydrogen atom with a methyl group. This replacement changes neither configurational series of the conventional DL-system nor notation of configuration based on the RS-system since the sequence of ligands on the chiral α-carbon is not inverted by this process. However, the order of bulkiness of the ligands does alter as one traverses from hydrogen to methyl, the latter being obviously bulkier than hydroxyl. Thus, the characterization of absolute configuration based on both the RS- and DL-systems does not allow unequivocal correlation with sign of the optical activities. Citramalic acid whose absolute configuration has been determined[8] seems to be adequate for configurational correlation with 2,3-dimethyltartaric acid. The stereochemical environments of the α-carbon atom in both acids are closely similar, since the order of priority (sequence rule) parallels that of bulkiness of ligands. The Cotton effect in 200—230 mμ region due to the optically active carboxyl chromophore was observed with both chiral acids. It was found that (+)-(S)-citramalic acid and (−)-2,3-dimethyltartaric acid exhibited a negative Cotton effect in this region, so that the (S:S)-configuration may be tentatively assigned to (−)-2,3-dimethyltartaric acid. The Brewster atomic asymmetry rule[9] also predicts a levorotation for the (S:S)-configuration of this acid.*1

We can now discuss the steric course of the present asymmetric synthesis, having the necessary information on absolute configuration of both the asymmetric center and the final product. The stereochemical-determining step in the present system is the nucleophilic addition of the open dipolar species (III) to a second molecule of (−)-menthyl pyruvate (I) leading to diastereomeric dioxaphospholanes (V). Since it has been shown that, under those conditions (20°C), the condensation is irreversible and there is no detectable equilibration among diastereomers once they are formed[3d], this step must be kinetically controlled. The conformation of the open dipolar **III** may well be assumed to be coplanar as implicit in the figure, since the lateral overlap of 3d-p-p-p(-p)-p orbitals of $\overset{+}{P}$–O–C–$\overset{-}{C}$(=O)–O concerned may be maximal in this conformation and stabilize the system. The transoidal coplanar topology may reasonably be

*1 Other experimental evidence for this assignment will be presented in a future publication.

postulated also for (−)-menthyl pyruvate (I) because this conformation with the minimum dipole-dipole and steric interactions has been invoked by Prelog with some measure of success in his asymmetric reactions involving the nucleophilic addition of Grignard reagent to α-keto esters of chiral alcohols.

A priori, the prime consideration being that all nonbonded repulsive interactions should be minimized in the transition state, the nucleophilic addition of III to I should take place in staggered orientations of substituents of both prochiral carbons and with the carbonyl-oxygen (in I) oriented closer to the phosphorus atom (in II) so as to permit a concerted process in which a new P–O bond concomitantly forms as the new C–C bond does. Under these propositions, four transition state conformations may be possible, if one takes into consideration the diastereotopic faces of both prochiral sp^2-carbanionic carbon in III and carbonyl carbon in I. Of the four, the *re-si* and *si-re* combinations *i.e.* the nucleophilic attack of III with its front side to the rear side of I and the reverse, equally lead to the same and identical transition state conformation, which eventually should afford the *meso*- end product. As can be seen, accumulated *gauche* (*cis*) interactions between substituents, in particular between the two bulkier carbomenthoxy groupings, would make this transition state kinetically unfavorable and this may account for the lack of the *meso*-form in the reaction product. In contrast, the two bulkier carbomenthoxy groups in the *re-re* and *si-si* transition state conformations, which would lead to R:R and S:S enantiomers respectively, are disposed to be *anti* to each other. These transition states are sterically more favored and are thus expected to be energetically more stable than the *meso*-counterpart. Inspection of the scale models reveals that, of these two, the *si-si* transition state conformation is sterically more favored than the *re-re* competitor, since the former is less crowded with respect to the two chiral moieties than the latter. The chemical consequence of this situation is the predominant formation of the (−)-(S : S)-2,3-dimethyltartaric acid in the present asymmetric synthesis. The above-mentioned argument on the steric course combined with its reaction mechanism of the present asymmetric system is in good agreement with what has been found experimentally. This furnishes another example of "double induction"—the discrimination between diastereotopic faces of a chiral compound by another chiral reagent.

Experimental

Asymmetric Synthesis of Dimethyl 2,3-Dimethyltartrate. (−)-Menthyl pyruvate (bp 106—108°C/4 mmHg, n_D^{15} 1.4522, $[\alpha]_D^{25}$ −75.3° (*c* 20.2, methanol);

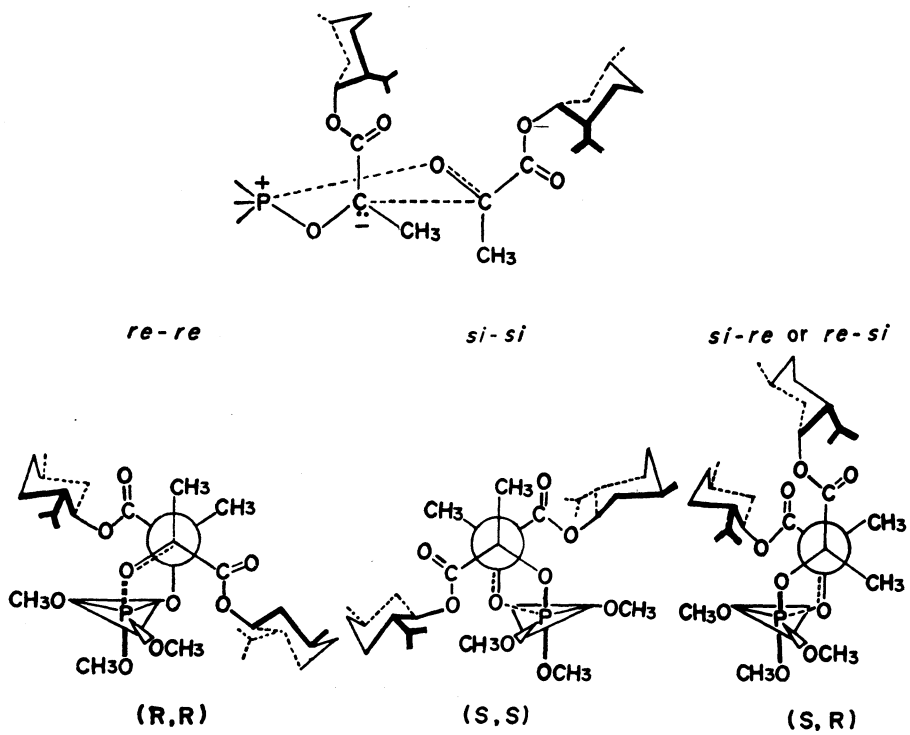

Fig. 1

22.6 g, 0.1 mol) was slowly added to trimethyl phosphite (12.4 g, 0.1 mol) with stirring and external cooling. The mixture was kept at 0°C for 1 hr and at 20°C for 8 hr. The excess of phosphite was removed *in vacuo*, the residue (26.3 g) was poured into water (11 m*l*) and the strongly acidic solution was treated with one equivalent of 2 N NaOH solution. The solution was refluxed for 7 hr and was neutralized with 2 N NaOH and extracted with ether. After removal of ether, the residue (13.8 g) was saponified with an excess of KOH in aqueous methanol for 40 hr. Methanol was evaporated and the liberated menthol was thoroughly extracted with ether. The resulting solution was acidified with dil. sulfuric acid and evaporated to dryness. Ethereal solution of diazomethane was added to the residue and the organic layer was distilled under reduced pressure to give dimethyl 2,3-dimethyltartrate, bp 80—85°C/0.09 mmHg, n_D^{15} 1.4510. The IR-spectrum was identical in every respect with that of the authentic dimethyl (+)-2,3-dimethyltartrate. Yield 2.2 g (35.1%). $[\alpha]_D^{15}$ −1.39° (*c* 9.46, methanol), optical yield 7.06% based on the maximum rotation 19.7° (*vide infra*).

***meso*-2,3-Dimethyltartaric Acid.** Tungstic oxide (150 mg) was dissolved in 30% hydrogen peroxide (10 m*l*) and water (15 m*l*) and to this solution was added dimethylfumaric acid[4] (4.8 g). The mixture was stirred at 70°C for 5 hr and then dried up to give a crystalline product (0.7 g), which was recrystallized from nitromethane to yield *meso*-2,3-dimethyltartaric acid, mp 179—180°C.[6,7] Yield 0.2 g (3.4%).

***racemic* 2,3-Dimethyltartaric Acid.** To a chilled (−40°C) solution of dimethyl dimethylfumarate (5.5 g) in ethanol (180 m*l*) was added a solution of potassium permanganate (5 g) and magnesium sulfate heptahydrate (4.5 g) in water (150 m*l*) during 6 hr. The mixture was set aside at room temperature for 12 hr and then filtered. The combined filtrate and washings were concentrated under reduced pressure to about 30 m*l*-volume and was thoroughly extracted with chloroform. The extract was distilled to give dimethyl 2,3-dimethyltartrate boiling at 91—93°C/0.2 mmHg (3.1 g). The dimethyl ester was saponified with KOH (1.3 g) in boiling methanol and the solvent was removed, acidified with 2 N HCl and extracted with ethyl acetate. Removal of ethyl acetate yielded a crystalline product (2.1 g), which was recrystallized from nitromethane to give *racemic* 2,3-dimethyltartaric acid, mp 185—186°C. Found: C, 40.60; H, 5.64%. Calcd for $C_6H_{10}O_6$: C, C, 40.45; H, 5.66%. Yield 1.2 g (18.2%).

Resolution of *racemic* 2,3-Dimethyltartaric Acid. The racemic acid (7 g) and (−)-ephedrine (6.5 g) were dissolved in hot ethyl acetate (300 m*l*) and the solution was allowed to stand overnight at room temperature, when the ephedrine salt (10.5 g) crystallized out. After triangular fractional recrystallization from acetone, the salt was decomposed with ammonia to afford, after acidification and usual work-up, the optically active acid of the constant rotation (0.7 g). Mp 161—162°C, $[\alpha]_D^{25}$ 13.6° (*c* 0.99, water).

The active acid was converted by the standard method with diazomethane into the dimethyl ester. bp 81—83°C/0.1 mmHg, n_D^{25} 1.4485, $[\alpha]_D^{25}$ 19.7° (*c* 2.65, methanol).

Synthesis and Resolution of Citramalic Acid. According to the method in literature,[11] (±)-citramalic acid, mp 116—117°C, was prepared and resolved through the brucine salt to afford optically pure (+)-acid, mp 112°C, $[\alpha]_D^{25}$ 23.6° (*c* 3.0, water).

Optical rotatory dispersion curves were measured on a Yanagimoto Model ORD-185A recording spectropolarimeter using a 0.5 cm cell at 20°C in 0.1 N HCl solution.

(+)-Dimethyltartaric acid $[\phi]_{589}$ +24.2° (*c* 1.53): ORD (*c* 0.055) $[\phi]_{350}$ +120°, $[\phi]_{229}$ +3170° (1st extremum), $[\phi]_{218}$ 0°, $[\phi]_{208}$ −4530°! (shoulder). (*a*) +77!.

(+)-Citramalic acid $[\phi]_{589}$ +35.8° (*c* 2.31): ORD (*c* 0.196) $[\phi]_{350}$ +94°, $[\phi]_{240}$ 0°, $[\phi]_{228}$ −197° (1st extremum), $[\phi]_{222}$ 0°, $[\phi]_{212}$ +1290°! (shoulder). (*a*) −14!.

Base-catalyzed Condensation of *o*-Nitroacetophenone. IV. Structure of Dehydro-derivative of Compound A, a Condensation Product

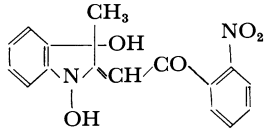
Takeo SAKAN, Kousuke KUSUDA[1] and Toshio MIWA

Faculty of Science, Osaka City University, Sumiyoshi-ku, Osaka

(Received March 22, 1969)

The alkaline hydrogen peroxide oxidation of compound A, $C_{17}H_{14}O_5N_2$, a base-catalyzed condensation product of *o*-nitroacetophenone, gave a dehydro compound, $C_{17}H_{12}O_5N_2$. The structure of the dehydro compound was deduced from the spectral data of its derivatives to be a (*o*-nitrobenzoyl)-1-hydroxycarbostyril. The forced hydrogenation of the dehydro compound gave 3-(*o*-aminobenzoyl)-4-methylcarbostyril, which was synthesized by the condensation of *o*-aminoacetophenone and ethyl *o*-nitrobenzoylacetate followed by reduction. Therefore, the dehydro compound proved to be 1-hydroxy-4-methyl-3-(*o*-nitrobenzoyl)carbostyril. On the other hand, the alkaline hydrogen peroxide oxidation of compound A methyl ether gave *o*-nitrobenzoic acid and 1-methoxy-3-methyldioxindole along with *o*-nitroacetophenone. These facts are explained by assuming a transition state which would be controlled by the presence of a hydrogen bonding.

In the first paper of this series,[2] the alkaline hydrogen peroxide oxidation of compound A(I),[3] $C_{17}H_{14}O_5N_2$, a base-catalyzed condensation product of *o*-nitroacetophenone, was reported to give dehydro-compound A, $C_{17}H_{12}O_5N_2$, with a loss of two atoms of hydrogen. A striking change of the ultraviolet absorption of compound A by the dehydrogenation implied that the compound had undergone a major reaction during the transformation.



I

Dehydro-compound A is a weak acid similar to compound A and has a broad band at 3145 cm^{-1} in its infrared spectrum. In contrast to the latter, the dehydro compound shows carbonyl stretching absorptions at 1675 and 1600 cm^{-1}.

Methylation of dehydro-compound A with dimethyl sulfate and potassium carbonate gave a methyl ether, which lost both acidity and the 3145 cm^{-1} band of the original compound. The 1600 cm^{-1} carbonyl band of dehydro-compound A was shifted to 1647 cm^{-1} during methylation.

On hydrogenation over palladium-on-carbon, dehydro compound A methyl ether absorbed three moles of hydrogen to yield a yellow amine, $C_{18}H_{16}O_3N_2$, melting at 220—222°C. This amine has a C-methyl group and a methoxyl group. Its ultraviolet spectrum has a new band at 384 mμ. Acetylation of the amine with acetic anhydride led to a monoacetyl derivative, $C_{20}H_{18}O_4N_2$, mp 202—203°C. In the ultraviolet spectrum of this compound, the 380 mμ band of the amine shifted by 40 mμ to a shorter wavelength (Fig. 1). Such a characteristic hypsochromic shift indicates that the original amine contains an *o*-aminobenzoyl

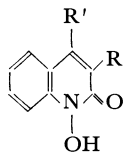
group;[4] therefore, dehydro-compound A should be an o-nitrophenyl ketone.

Reduction of the acetamido derivative with sodium borohydride gave a compound decomposing at 141—143°C. This compound was difficult to purify, but its infrared spectrum showed that the keto function of the o-acetamidobenzoyl group was reduced. All the compounds derived from dehydro-compound A have a set of triple absorption maxima (near 230, 280 and 340 mμ) as shown in Fig. 1. The spectral feature is characteristic of the carbostyril derivative;[5] consequently, dehydro-compound A was assumed to be an α-quinolone derivative. The carbonyl band (1647 cm^{-1}) of its methyl ether is in good accord with those (1661—1650 cm^{-1}) of α-quinolones.[5,6]

Providing that the carbostyril system still possesses a hydroxyl group on the nitrogen atom as proposed for compound A (I), dehydro-compound A would be a cyclic hydroxamic acid; the weak acidity as well as the carbonyl band (1600 cm^{-1}) of longer wavelength than those of usual α-quinolones may be attributed to the hydroxamic function.

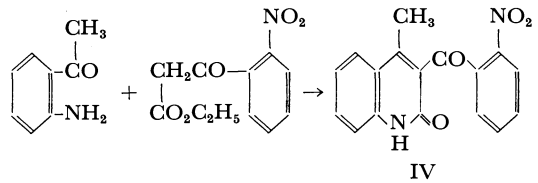
These facts suggest structure II or III for dehydro-compound A. Of these structures, the former appears to be more plausible, if the carbostyril ring is formed by the C_α-C_β ring fission of the indoline nucleus[7] with a β-methyl group in compound A (I).



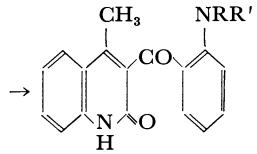
II: R=o-Nitrobenzoyl, R'=CH_3
III: R=CH_3, R'=o-Nitrobenzoyl

In order to derive dehydro-compound A to a readily available compound, attempts were made to remove the hydroxyl group attached to the cyclic nitrogen atom. The methoxyl group of an *N*-methoxycarbostyril was reported to be removed by reduction with zinc and hydrochloric acid.[8] No reduction was carried out with the yellow amine, $C_{18}H_{16}O_3N_2$, derived from dehydro-compound A methyl ether. Catalytic hydrogenation over Raney nickel seemed promising, because such a hydrogenolysis of a 1-methoxyoxindole led to an oxindole;[3] however, this also failed with dehydro-compound A methyl ether. Forced hydrogenation of dehydro-compound A over Raney nickel at a hydrogen pressure of 80 atm and at a temperature of 115°C yielded a deoxy compound. Being difficult to purify, the product was acetylated immediately to produce a monoacetyl derivative, $C_{19}H_{16}O_3N_2$, mp 279—280°C, and a diacetyl derivative, $C_{21}H_{18}O_4N_2$, mp 218—220°C. Both of the acetyl derivatives on hydrolysis gave the same bright yellow amine, $C_{17}H_{14}O_2N_2$, decomposing at 277—279°C. Thus ultraviolet absorption spectra of the amine and its acetyl derivatives indicate the survival of the o-aminobenzoyl system through the hydrogenation process. The amine would be represented by formula V on the basis of the assumed preferential structure II for dehydro-compound A. This was proved to be the fact by the following synthesis of the amine.

Heating o-aminoacetophenone with ethyl o-nitrobenzoylacetate afforded 4-methyl-3-(o-nitrobenzoyl)carbostyril IV, which in turn was hydrogenated to the corresponding amine V. This amine was spectroscopically identical with the amine obtained by the high-pressure hydrogenation of dehydro-compound A. Acetylation of V gave a monoacetyl derivative VI, which was identified with the monoacetyl compound, $C_{19}H_{16}O_3N_2$, by a mixed melting point determination; consequently, the diacetyl compound, $C_{21}H_{18}O_4N_2$, was assumed to have the structure VII because of the absence of the amide II band in its infrared spectrum.



IV



V : R, R'=H
VI : R=H, R'=$COCH_3$
VII: R, R'=$COCH_3$

The establishment of the structure of amine V excluded structure III for dehydro-compound A and evidently confirmed that dehydro-compound A is 1-hydroxy-4-methyl-3-(o-nitrobenzoyl)-2-quinolone. As a corollary, the C_{18}-amine derived from dehydro-compound A methyl ether, its acetyl derivative, and the sodium borohydride reduction product of the latter were assigned structures VIII,

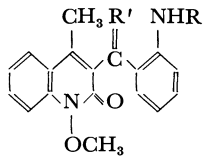
IX, and X, respectively.



VIII: R=H, R'=O
IX : R=Ac, R'=O
X : R=Ac, R'=H, OH

Formation of the dehydro compound from compound A may be explained as shown in Chart 1.

The oxidation of α,β-unsaturated ketones with alkaline hydrogen peroxide is a familiar reaction leading to epoxy ketones.[9] The reaction was proposed to be stereoselective and to proceed through a transition state controlled by the overlap of the pi-orbitals of the enolate anion.[10] In this case, the transition state is presumed to involve the overlap of p (or pi)-orbital on the α-carbon atom with the vacant orbital which is developing in the S_N2 reaction on the peroxide oxygen atom.[11] The hydrogen bondings shown in XII would force the transition state to assume a conformation where the overlap required for the formation of the epoxide ring is apparently impossible (Fig. 2-a). Therefore, another alternative nucleophilic substitution shown in XII may occur at the β-carbon atom of the indoline nucleus, if we assume a transition state shown in Fig. 2-b which leads to the formation of a cyclopropane ring in XIII.

The importance of the hydrogen bonding in the above rearrangement was substantiated by the alkaline hydrogen peroxide oxidation of the methyl

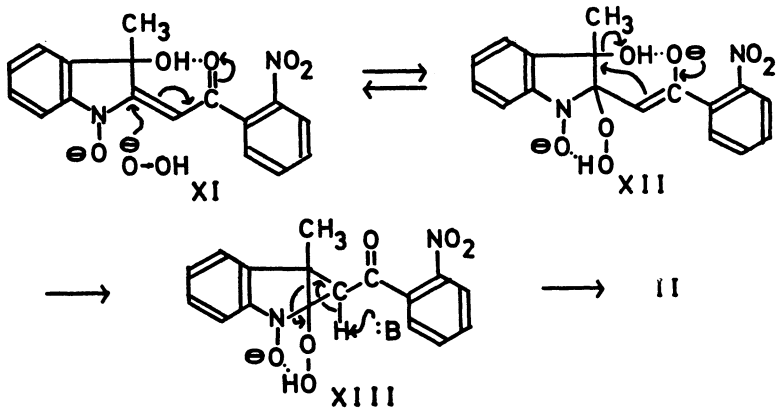


Chart 1

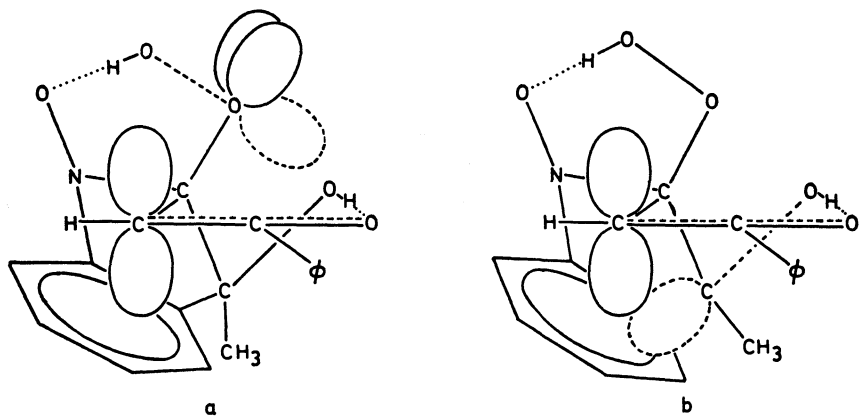

Fig. 2. Transition state for the reaction of XII. Overlapping of the orbitals is inhibited (a) or allowed (b).

11) In the nucleophilic substitution of the peroxide, the nucleophile is assumed to approach the peroxides along the line formed by the two peroxide oxygens. (J. O. Edwards, "Peroxide Reaction Mechanisms," ed. by J. O. Edwards, Interscience Publishers, New York (1962), p. 69).

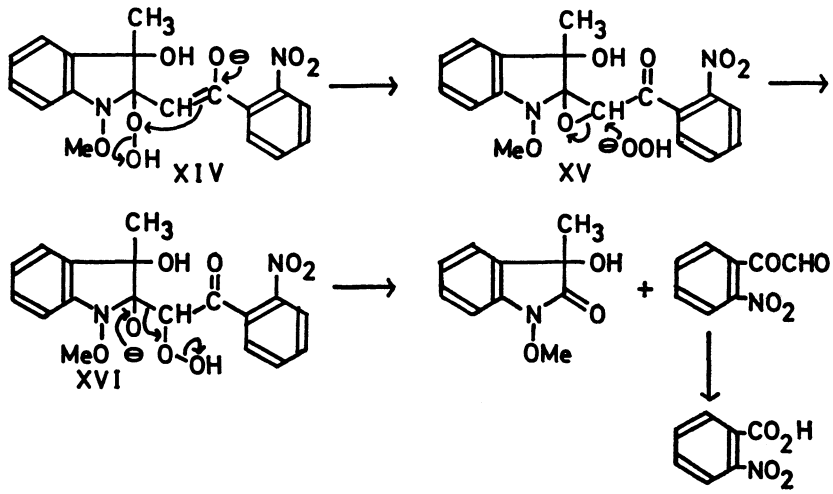

Chart 2

ether of compound A. The reaction of compound A methyl ether with alkaline hydrogen peroxide in dioxane followed quite a different course from that of compound A, leading to 1-methoxy-3-methyldioxindole, which was previously obtained by the ozonolysis of the methyl ether,[3] and *o*-nitrobenzoic acid, along with a small amount of *o*-nitroacetophenone. The difference is not due to the solvent effect since the oxidation of compound A under the same condition as the methyl ether gave dehydro-compound A as a sole product. A mechanism shown in Chart 2 may be proposed for the oxidation of the methyl ether.

In the transition state of the oxidation of the methyl ether, however, the hydrogen bond would be too weak to prevent the overlap of the p-orbital of the α-carbon atom with the vacant orbital on the oxygen atom in the peroxide group. The epoxide may be attacked by another hydroperoxide ion at the electron-defficient site to produce an open-chain alkoxide ion XVI, which will give the dioxindole and *o*-nitrophenylglyoxal, the latter being further oxidized into *o*-nitrobenzoic acid.

o-Nitroacetophenone was formed apparently by the oxidation of the dioxindole, because it was formed in some quantity even when *o*-nitrobenzoic acid was formed almost quantitatively.

Experimental

Hydrogenation of Dehydro-compound A Methyl Ether. 3-(*o*-Aminobenzoyl)-1-methoxy-4-methyl-2-quinolone (VIII). A solution of 2.8 g of dehydro-compound A methyl ether in 80 cc of ethanol was hydrogenated at atmospheric pressure using 1.4 g of 5% palladium-on-carbon to absorb 530 cc (20°C) of hydrogen. During the hydrogenation greenish yellow crystals separated. The catalyst was removed by filtration from the hot solution and washed well with hot ethanol. Evaporation of the ethanol left 2.5 g of yellow amine, which, after recrystallization from ethanol, melted at 220—222°C. λ_{max}^{EtOH} mμ (log ε): 230 (4.68), 266—270 (4.14), 336 (3.98), 384 (4.00). λ_{max}^{Nujol} cm^{-1}: 3425, 3310 (NH), 1645, 1613 (C=O).

Found: C, 70.15; H, 5.69; N, 9.20%. C-Methyl group (Kuhn-Roth):[12] 0.52. Calcd for $C_{18}H_{16}O_3N_2$: C, 70.11; H, 5.23; N, 9.09%. C-Methyl group: 1.00.

***N*-Acetyl Derivative (IX)** was obtained by treatment of 0.7 g of the amine with 10.5 cc of boiling acetic anhydride for 5 min. Excess of the anhydride was decomposed with water and the product was recrystallized from methanol, mp 202—203°C. λ_{max}^{EtOH} mμ (log ε): 232 (4.74), 275 (4.27), 340 (4.13). ν_{max}^{Nujol} cm^{-1}: 3290 (NH), 1698, 1650, 1634 (C=O), 1520 (amide II).

Found: C, 68.63; H, 5.26; N, 8.32%. Calcd for $C_{20}H_{18}O_4N_2$: C, 68.56; H, 5.18; N, 8.00%.

Sodium Borohydride Reduction of the *N*-Acetyl Derivative was effected in methanol at room temperature. After being allowed to stand overnight, the reduction mixture was diluted with water and evaporated to remove methanol. Extraction with benzene gave crystals, which, after recrystallization from benzene-ligroin, decomposed at 141—143°C. λ_{max}^{EtOH} mμ (log ε): 230 (4.77), 276 (3.86), 331 (3.76). λ_{max}^{Nujol} cm^{-1}: 3345 (OH and NH), 1695, 1637 (C=O), 1522 (amide II).

High Pressure Hydrogenation of Dehydro-compound A. 3-(*o*-Aminobenzoyl)-4-methyl-2-quinolone (V). Hydrogenation of 1.4 g of dehydro-compound A was effected in ethanol over 0.8 g of Raney nickel at a hydrogen pressure of 80 atm and at a temperature of 115°C for 16 hr. Without removal of the catalyst, the solvent was distilled off under reduced pressure. The resulting residue was heated with acetic anhydride under reflux for one hour. After removal of the catalyst, work-up in usual way gave crystals, which were recrystallized repeatedly from methanol. From the less soluble fraction, the monoacetyl derivative VI was obtained as leaflets, mp 274—276°C.

12) E. J. Eisenbraun, S. M. McElvain and B. F. Aycock, *J. Am. Chem. Soc.*, **76**, 607 (1954).

λ_{max}^{EtOH} mμ (log ε): 230 (4.68), 270 (4.28), 328—332 (4.08). ν_{max}^{Nujol} cm^{-1}: 3248 (NH), 1692, 1658, 1631 (C=O), 1520 (amide II).

Found: C, 70.56; H, 5.08; N, 8.93%. Calcd for $C_{19}H_{16}O_3N_2$: C, 71.24; H, 5.03; N, 8.75%.

The monoacetyl derivative was identified with the independently synthesized amide VI (see below) by a mixed melting point determination.

The more soluble fraction gave the diacetyl derivative VII as leaflets melting at 218—220°C. λ_{max}^{EtOH}: 328 mμ (log ε 3.82). ν_{max}^{Nujol} cm^{-1}: 1706, 1672, 1637 (C=O).

Found: C, 69.84; H, 5.16; N, 8.02%. Calcd for $C_{21}H_{18}O_4N_2$: C, 69.60; H, 5.00; N, 7.73%.

A mixture of 35 mg of the monoacetyl derivative and 1 cc of concentrated hydrochloric acid was heated on a water bath for 3 hr. Evaporation of the hydrochloric acid *in vacuo* followed by recrystallization from 90% acetic acid gave bright yellow prisms decomposing at 272—275°C. Hydrolysis of the diacetyl derivative in a similar way afforded a base decomposing at 277—279°C, which showed no depression by a mixed melting point determination with the product from the monoacetyl derivative. λ_{max}^{EtOH} mμ (log ε): 229—230 (4.62), 270 (4.08), 335 (3.87), 350 (3.88), 378—382 (3.89). ν_{max}^{Nujol} cm^{-1}: 3400, 3290 (NH), 1647, 1626 (C=O).

Found: C, 73.10; H, 5.26; N, 9.97%. Calcd for $C_{17}H_{14}O_2N_2$: C, 73.36; H, 5.07; N, 10.07%.

The amine was identified with the authentic specimen (see below) by ultraviolet and infrared spectroscopy.

4-Methyl-3-(*o*-nitrobenzoyl)-2-quinolone (IV). A mixture of 0.55 g of *o*-aminoacetophenone and 0.95 g of ethyl *o*-nitrobenzoylacetate was heated in a sealed tube at 170—200°C for 4 hr. The mixture was treated with benzene and the resulting precipitate was recrystallized from methanol to give leaflets, mp 238—240°C. λ_{max}^{EtOH} mμ (log ε): 231 (4.51), 284 (3.95), 351 (3.75). ν_{max}^{Nujol} cm^{-1}: 1681, 1621 (C=O), 1531, 1351, 860 (NO_2).

Found: C, 66.42; H, 4.13; N, 9.20%. Calcd for $C_{17}H_{12}O_4N_2$: C, 66.23; H, 3.92; N, 9.09%.

3-(*o*-Aminobenzoyl)-4-methyl-2-quinolone (V). A solution of 48 mg of the nitro compound IV in 1 cc of ethanol was hydrogenated in the presence of 40 mg of 5% palladium-on-carbon to give amine V decomposing at 275—277°C.

3-(*o*-Acetamidobenzoyl)-4-methyl-2-quinolone (VI). Acetylation was accomplished by heating 36 mg of the amine IV in 3 cc of acetic anhydride under reflux. Work-up in the usual way and recrystallization from methanol gave 31 mg of crystals melting at 282—284°C.

Alkaline Hydrogen Peroxide Oxidation of Compound A Methyl Ether. To a solution of 690 mg of compound A methyl ether in 5 cc of dioxane was added 2 cc of 10% methanolic potassium hydroxide, followed by the addition of 5 cc of 30% hydrogen peroxide with cooling. After removal of half of the solvent under reduced pressure, the residue was made acidic with 20% hydrochloric acid. The resulting mixture was extracted with a mixture of benzene and ether, and the extract was washed with aqueous sodium hydrogencarbonate solution. Acidification of the aqueous solution gave 329 mg (96.5%) of *o*-nitrobenzoic acid. The neutral fraction (190 mg) was chromatographed on active alumina "Wako" as a benzene solution. The first band was eluted with benzene to give 48 mg of an oil; it was characterized as a 2,4-dinitrophenylhydrazone, mp 170—174°C, which was identified with that of *o*-nitroacetophenone by infrared spectroscopy. The second band, eluted with a mixture of 300 cc of benzene and 5 drops of ethanol gave 130 mg of crystals, which, after recrystallization from benzene-ligroin, melted at 134—135°C, and which was identified with 1-methoxy-3-methyldioxindole[3] by infrared spectroscopy.

Alkaline Hydrogen Peroxide Oxidation of Compound A in Dioxane. A solution of 347 mg of compound A in 3 cc of dioxane was treated with 1.5 cc of 10% methanolic potassium hydroxide and 1.5 cc of 30% hydrogen peroxide. After being stirred overnight, the mixture was acidified with saturated sulfur dioxide solution. Concentration of the mixture, followed by filtration of the resulting precipitate gave 258 mg of crude dehydro-compound A, which, after recrystallization from methanol, was identified with the authentic sample[2] by infrared spectroscopy.

Asymmetric Reactions. III. Stereoselectivity Difference between Grignard and Alkyllithium Reactions with 2,3-*O*-Substituted-D-glyceraldehydes

Yoshiaki OHGO, Juji YOSHIMURA, Masami KONO and Tetsuo SATO

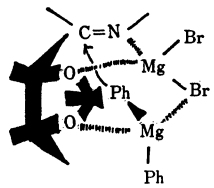
Laboratory of Organic Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received March 24, 1969)

Stereoselectivity has been investigated in addition reactions of 2,3-*O*-isopropylidene-D-glyceraldehyde (I) or 2,3-di-*O*-benzyl-D-glyceraldehyde (II) with phenylmagnesium bromide or phenyllithium. Stereoselectivity difference between the Grignard and phenyllithium reactions occurred in the case of compound (I): the phenyllithium reaction gives *threo* and the Grignard reaction *erythro* products predominantly. On the other hand, no difference in stereoselectivity has been observed between the reactions with 2,3-di-*O*-benzyl-D-glyceraldehyde (II): both reactions gave *threo* product predominantly.

In a previous paper,[1] it has been reported that the asymmetric induction of *N*-substituted 2,3-*O*-isopropylidene-D-glyceraldimines with alkyllithium produced *threo* compound, and that with the Grignard reagent gave *erythro* product predominantly.

The steric direction of the alkyllithium reaction can be explained by Cram's rigid model.[2] Stereoselectivity of the Grignard reaction which was incompatible with the Cram's model was explained by assuming a coordinative interaction between C_3-oxygen and magnesium.



A

This paper reports that the same steric difference was observed in the reaction with 2,3-*O*-isopropylidene-D-glyceraldehyde and the fixation of oxygen atoms at 2- and 3-position by ketal ring is an essential factor for the occurrence of the stereoselectivity difference between the Grignard and alkyllithium reactions.

Materials

2,3-*O*-Isopropylidene-D-glyceraldehyde was prepared according to the method established by Baer and Fisher.[3] Freshly distilled material was used in each experiment.

2,3-*O*-Benzyl-D-glyceraldehyde was synthesized as follows.

Benzylation of 3,4-*O*-isopropylidene-D-mannitol with benzyl chloride and sodium hydride in dimethyl sulfoxide afforded 1,2;5,6-tetrabenzyl-3,4-*O*-isopropylidene-D-mannitol which was subjected to acid hydrolysis to give 1,2;5,6-tetra-*O*-benzyl-D-mannitol. Oxidative scission of the tetrabenzyl derivative with lead tetraacetate in benzene solution gave 2,3-di-*O*-benzyl-D-glyceraldehyde (bp 143—144°C/0.004 mmHg, $[\alpha]_{578}=+52°$) in a comparatively high yield (see experimental part). The structure was confirmed by means of IR data and microanalysis.

---- Process carried out in order to establish stereochemical correlation.

Results and Discussion

2,3-*O*-Isopropylidene-D-glyceraldehyde (I)[3] or 2,3-di-*O*-benzyl-D-glyceraldehyde (II) was treated with 3 mol of phenyllithium or phenylmagnesium bromide in ether. The reaction mixture was decomposed with ice water, and from the ether layer a diastereomeric mixture of the corresponding addition products was obtained (IIIa, IIIb or IVa, IVb).

III and IV were respectively converted to a diastereomeric mixture of crystalline 1-*C*-phenyl-1,2,3-tri-*O*-benzoyl-glycerols (VIa and b) by acid hydrolysis of III or by catalytic hydrogenation of IV followed by benzoylation. The optical rotations and analytical results of the mixture are shown in Table 1. From the diastereomeric mixture two crystalline compounds were obtained by fractional crystallization, *i. e.*, mp 145.5—146°C, $[\alpha]_{578}$ −70.5°; mp 139.5°C, $[\alpha]_{578}$ +36.5°.

The isomer with mp 145.5—146°C has been reported by Tiffeneau and Neuberg.[4] However, no assignment of configuration was made.

The above diastereomers should have D-*threo* or D-*erythro* configuration. The configuration will be assigned as follows.

The de-acetonated product (Va+Vb) was distilled at 150—153°C/0.09 mmHg. It crystallized partially and the crystals with mp 103—105°C (Va) were separated from syrup (Vb). On the other hand, IIIa and IIIb were derived from Va and Vb by acetonation, respectively. The configuration of IIIa, IIIb, Va and Vb was presumed from comparison of optical rotational strength and sign with those of analogous compounds 1-*C*-phenyl-glycitols and their isopropylidene derivatives.[5,6]

The isomer bearing oxygen right in the Fischer Projection seems to have more positive rotation than the one bearing oxygen left. The analgous relation has been observed in the case of α-aminonitrile and 1-*C*-phenyl-1-alkylamino-1-deoxy-D-glycerols.[7,1a] Since Va and IIIa have positive values (+18° and +10.2°) [Vb and IIIb have negative (−24° and −24.7°)], it can be inferred that Va and IIIa have D-*erythro* configuration, and Vb and IIIb D-*threo*.

Their configurations are also deduced from comparison of the IR spectra of dilute solution of IIIa and IIIb (which were derived from Va and Vb by acetonation). The ratio of the bonded and free hydroxy stretching frequency (at 3630—3580 region) of IIIb is much greater than that of IIIa in dilute solution (see experimental). This implies that IIIb has *threo* configuration whose hydrogen bonding is stable.[8] The same conclusion may be derived from NMR spectra. Stable conformation of the *erythro* and the *threo* compound (IIIa,b)

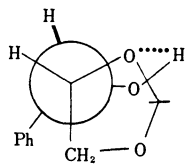
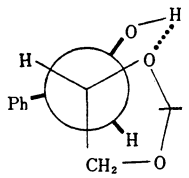
will be regulated by the balance of attractive force due to O_1H–O_2 hydrogen bonding and the repulsion between non-bonded groups. Most stable conformations of the *erythro* and *threo* may be represented by B and C respectively in which phenyl group



B



C

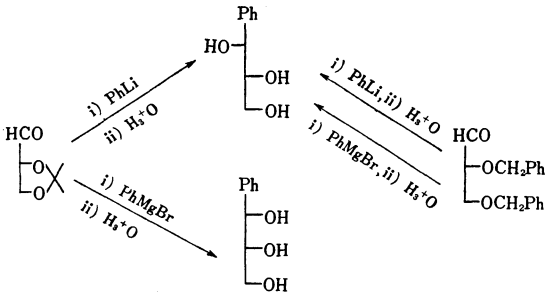
is located in such a way that the non-bonded interaction may be minimized within the range making hydrogen bonding possible. If so, it can be expected from Karplus equations[9] that $J_{H_1H_2}$ of *threo* is larger than that of the *erythro* compound. In the case of IIIa, signal at 5.15 due to H_1 splits in quartet (J=5 cps and 2.5 cps). By addition of H^+ the quartet changes to doublet with J=5 cps which is ascribed to $J_{H_1H_2}$. The coupling constant ($J_{H_1H_2}$) of IIIb is 8 cps. This fact is consistent with the above assumption.

On the other hand, Va was correlated with VIa (mp 145.5°C) by benzoylation of the former. In consequence, series a (IIIa, Va, VIa) belongs to D-erythro type, and series b (IIIb, Vb, VIb) to D-threo type.[10]

The produced diastereomer ratio was calculated from optical rotations of *erythro* (VIa), *threo* (VIb) and the diastereomeric mixture produced in the reaction. The results are shown in Table 1.

As expected, the difference in stereoselectivity between the Grignard and phenyllithium reactions occurred with 2,3-*O*-isopropylidene-D-glyceraldehyde; the phenyllithium reaction gives *threo* and Grignard reaction *erythro* products predominantly.

On the other hand, the same reaction with 2,3-di-*O*-benzyl-D-glyceraldehyde gives no difference in stereoselectivity between the two reactions; *threo* product is predominant in both reactions. This may imply that C_3–O must be fixed in a certain steric position suitable to interaction with the reagent for the Grignard reaction to give *erythro* product.



Scheme 3

Experimental

The NMR spectrum was taken in deuteriochloroform solution with a JNM-4H-100 Spectrometer (Japan Electron Optics Laboratory Co., Ltd.) at 100 Mc/sec, using tetramethylsilane as an internal standard.

The hydrogen bonding measurements were performed in dilute CCl_4 solution on a Perkin-Elmer 125

Table 1

Run	Substrate	Reagent	Products: Optical rotation $[\alpha]_{546}$	Optical rotation $[\alpha]_{578}$	Analysis C	Analysis H	Ratio *threo*	Ratio *erythro*
1	I	PhLi	−3.0	−3.6	74.99	5.25	63	37

* During the course of preparation of our article, a similar study was reported by M. H. Delton and G. U. Yuen [*J. Org. Chem.*, **33**, 2473 (1968)]. According to their report, the Grignard reaction gives *threo* products in 58% and *erythro* in 42% yield. The difference between their results and ours may be due to the difference in experimental methods, particularly in measurements. Delton and Yuen determined the diastereomeric ratio by gas chromatography, while we carried it out by optical rotation. In view of this, further experiments are now in progress and the results will be published later.

9) M. Karplus, *J. Chem. Phys.*, **30**, 11 (1959).

10) This assignment was confirmed by preliminary experiment deriving IIIa and IIIb to L(+) and D(−)-1-methoxyphenylacetaldehyde[5] respectively. More precise experiments are under investigation and will be published later.

grating spectrophotometer. The optical rotations were measured on a Carl Zeis Photoelectric Precision Polarimeter (0.005°).

Addition Reaction of 2,3-*O*-Isopropylidene-D-glyceraldehyde with Phenylmagnesium Bromide. A solution of 14 g of 2,3-*O*-isopropylidene-D-glyceraldehyde in 20 m*l* of ether was slowly added to a well-stirred solution of phenylmagnesium bromide prepared from 51 g (0.32 mol) of bromobenzene and 7.93 g. of magnesium in 170 m*l* of ether. The mixture was stirred for 1 hr at 0—5°C and for four hours at reflux-temperature of the ether solution. The reaction mixture was poured into ice-water containing ammonium chloride. The ether layer was separated, and washed with water. The solution was dried and concentrated under reduced pressure to give a syrup (16.5 g, yield 74%, $[\alpha]_{578}$ −4.77). The syrup was dissolved in 300 m*l* of ethanol and to the solution was added 4.4 m*l* of concentrated hydrochloric acid and 142 m*l* of water. The mixture was refluxed for 2 hr. The reaction mixture was neutralized by potassium carbonate solution and concentrated under reduced pressure. The residue was extracted twice with 100 m*l* of ethyl acetate. The combined ethyl acetate solution was concentrated *in vacuo* to give 6.5 g of syrup (yield 49%).

The diastereomeric mixture (5 g) of 1-*C*-phenyl-D-*threo*- and D-*erythro*-glycerol was treated with benzoyl chloride (14.2 g) and pyridine (8 g) in chloroform (40 m*l*) at room temperature. The mixture was allowed to stand overnight and then poured into ice-water. The chloroform layer was separated and washed with water repeatedly until the layer became neutral. The chloroform layer was dried and concentrated under about 15 mmHg and then under 0.001 mmHg at 80—100°C for 5 hr to give colorless crystals (14 g, yield 98%). Analytical data agreed with those of the 1,2,3-tri-*O*-benzoyl-1-*C*-phenyl-D-glycerol (see Table 1). Optical rotation was measured ($c=2.00$, $l=0.5$, benzene). Fractional crystallization from an ethanol-benzene mixture gave two diastereomers; VIa (1,2,3-tri-*O*-benzoyl-1-*C*-phenyl-*erythro*-D-glycerol) mp 145.5—146°C; $[\alpha]_{578}$ −70.5, $[\alpha]_{546}$ −81 ($c=2.00$, $l=0.5$, benzene); VIb (1,2,3-tri-*O*-benzoyl-1-*C*-phenyl-*threo*-D-glycerol) mp 139.5°C, $[\alpha]_{578}$ +36.5 ($c=2.028$, $l=0.5$, benzene), $[\alpha]_{546}$ +41.5. Found: C, 74.57; H, 5.08%. Calcd for $C_{30}H_{24}O_6$: C, 74.99; H, 5.03%.

Addition Reaction of I with Phenyllithium. A solution of 14 g of 2,3-*O*-isopropylidene-D-glyceraldehyde in 20 m*l* of ether was slowly added to a well-stirred solution of phenyllithium prepared from 51 g (0.32 mol) of bromobenzene and 4.48 g of lithium in 170 m*l* of ether. The same procedure as in the Grignard reaction gave a diastereomeric mixture of 1,2,3-tri-*O*-benzoyl-1-*C*-phenyl-*threo*-D- and *erythro*-D-glycerols in total yield of about 50%.

1-*C*-Phenyl-2,3-*O*-isopropylidene-*erythro*-D-glycerol (IIIa). 1-*C*-Phenyl-*erythro*-D-glycerol (Va) (12 g) was treated with 250 m*l* of acetone containing 19.3 g of zinc chloride at room temperature for 2 days. The reaction mixture was poured with stirring into a solution of K_2CO_3 (26 g) in 26 m*l* of water covered with 300 m*l* of ether. The acetone-ether solution was dried over potassium carbonate and then concentrated *in vacuo* to give 16 g of syrup. The syrup was distilled at 175—176°C/30 mmHg. Yield, 10 g, (67%). $[\alpha]_{578}$ +10.7, $[\alpha]_{546}$ +12.2 ($c=2.052$, ethanol).

Found: C, 69.22; H, 7.89%. Calcd for $C_{12}H_{16}O_3$: C, 69.21; H, 7.74%.

The infrared measurement was carried out in 0.013 molar carbon tetrachloride solution. The infrared spectrum shows free and bonded OH stretching vibrations at 3619 cm^{-1} and 3578 cm^{-1} respectively. The ratio of bonded OH to free OH absorption is about 2—2.5. NMR spectrum: CH_3, 8.55, 8.66; OH, 7.35 (doublet, $J=2.5$ cps, this doublet disappeared on addition of trifluoroacetic acid); H_3 and H_3', 6.15τ (multiplet); H_2, 5.72τ (multiplet); H_1, 5.15τ (quartet, $J_{H_1H_2}=5$ cps, $J_{H_1OH}=2.5$ cps); phenyl, 2.65τ.

1-*C*-Phenyl-2,3-*O*-isopropylidene-*threo*-D-glycerol (IIIb). Vb was converted to IIIb by the same procedure as above (Va to IIIa) (yield; 56%). $[\alpha]_{578}=-24.7$ ($c=1.06$, $l=0.5$, ethanol), $[\alpha]_{546}=-27.5$ ($c=1.06$, $l=0.5$, ethanol).

Found: C, 68.85; H, 7.89%. Calcd for $C_{12}H_{16}O_3$: C, 69.21; H, 7.74%.

The infrared measurement was carried out in 0.0125 M carbon tetrachloride solution. The infrared spectrum shows bonded OH stretching vibration at 3600 cm^{-1} but no substantial absorption at higher frequency region. NMR spectrum: CH_3, 8.5 and 8.46τ; H_3 and H_3', 6.2τ (unresolved multiplet); H_2, 5.75τ (multiplet); H_1, 5.5τ (doublet, $J_{H_1H_2}=8$ cps).

1-*C*-Phenyl-*erythro* and *threo*-D-glycerols (Va and Vb). The reaction of phenylmagnesium bromide (prepared from 17 g of magnesium and 7.35 m*l* of bromobenzene) in ether (350 m*l*) with an ether solution of 2,3-*O*-isopropylidene-D-glyceraldehyde followed by acid hydrolysis [with a mixture of ethanol (560 m*l*), water (270 m*l*) and 12 N HCl (20 m*l*)] gave a syrup (30 g) of a diastereomeric mixture of 1-*C*-phenyl-*erythro* and *threo*-D-glycerols. From the syrup 9.4 g of a crystalline compound was obtained: mp 103—105°C, $[\alpha]_{587}$ +18, $[\alpha]_{546}$ +20 ($c=2$, $l=0.5$, ethanol).

When the residual syrup was distilled at 150—153°C/0.09 mmHg and left standing at room temperature additional crystals (3 g) were obtained. Total yield of crystalline isomer is 12.4 g. The residual syrup weighed 12.7 g. The rotation of the residual syrup; $[\alpha]_{578}$ −24, $[\alpha]_{546}$ −28 ($c=1.01$, $l=0.5$, ethanol).

Addition Reaction of 2,3-Di-*O*-benzyl-D-glyceraldehyde with Phenylmagnesium Bromide. A solution of 10 g (0.037 mol) of 2,3-di-*O*-benzyl-D-glyceraldehyde in 20 m*l* ether was added slowly into a stirred solution of phenylmagnesium bromide prepared from 17.5 g (0.11 mol) of bromobenzene and 2.7 g of magnesium in 100 m*l* ether at 0—5°C.

The same procedure as in the case of addition reaction of I with organometallic reagents gave 11.5 g of syrup (yield 89%) of addition products. The syrup (7.2 g) obtained above was hydrogenated with 10 g of palladium-barium sulfate catalyst in 260 m*l* of ethanol containing concd. hydrochloric acid (2.6 m*l*). The reaction mixture was neutralized with a 2 N sodium hydroxide solution and concentrated under reduced pressure. The residue was extracted with ethyl acetate. The ethyl acetate solution was concentrated to a syrup (3.7 g). 3.7 g of the diastereomeric mixture of 1-*C*-phenyl-D-glycerols was benzoylated with the same procedure as described before to give 10 g of the tribenzoate (100%). Fractional crystallization from a mixture of ethanol and benzene afforded two crystalline compounds of mp 145—146°C and mp 138—139°C. These com-

pounds were identified with VIa and VIb (mixed melting point).

Addition Reaction of 2,3-Di-*O*-benzyl-D-glyceraldehyde (II) with Phenyllithium. A solution of 10 g of II in 20 m*l* ether was added slowly to a well-stirred solution of phenyllithium prepared from 17.5 g of bromobenzene and 1.54 g of lithium at 0—5°C. The same procedure as in the Grignard reaction gave a diastereomeric mixture of 1,2,3-tri-*O*-benzoyl-1-*C*-phenyl-D-*threo* and D-*erythro* glycerol. Analytical results and optical rotations of diastereomeric mixtures are shown in Table 1.

2,3-Di-*O*-benzyl-D-glyceraldehyde. To a solution of 40 g of 3,4-*O*-isopropylidene-D-mannitol in 400 m*l* of dimethyl sulfoxide was slowly added 50 g of 50% sodium hydride and then 220 m*l* of benzyl chloride with vigorous stirring. The mixture was heated on a water bath for 30 min and left standing overnight. The reaction mixture was poured into ice-water, extracted with benzene, benzene layer was washed with water, dried over sodium sulfate and concentrated *in vacuo*. Last traces of benzyl chloride and dimethyl sulfoxide were removed in a high vacuum. The syrup thus obtained has no absorption due to OH stretching vibration. Yield; 90 g.

A suspension of 90 g of 1,2;5,6-tetra-*O*-benzyl-3,4-*O*-isopropylidene-D-mannitol in 200 m*l* of ethanol, 70 m*l* of water and 36 m*l* of concentrated hydrochloric acid was refluxed for 2 hr, and concentrated under reduced pressure to about 100 m*l* and extracted with benzene (400 m*l*). The benzene layer was washed first with a potassium carbonate solution and then water. The benzene layer was concentrated to a syrup. The syrup was washed with petroleum ether and dried *in vacuo*. Yield, 67 g (70%).

To a vigorously stirred solution of 40 g of 1,2;5,6-tetra-*O*-benzyl-D-mannitol in 500 m*l* of benzene was added 34 g of lead tetraacetate. The reaction mixture was stirred at room temperature for 3 hr. The resulting precipitate was filtered off. The mother liquor was dried over sodium sulfate and concentrated under reduced pressure to give a syrup. The syrup was distilled at 143—144°C/0.003 mmHg. $[\alpha]_{578}$ +52, $[\alpha]_{546}$ +58 (c=2.00, l=0.5, benzene). Yield, 20 g.

Found: C, 75.59; H, 7.04%. Calcd for $C_{17}H_{18}O_3$: C, 75.53; H, 6.71%.

The distillate has no substantial absorption in the OH region but has a remarkable absorption at about 1715 cm^{-1} which is due to aldehydic carbonyl stretching vibration.

The authors express their cordial thanks to Mr. K. Fukukawa for measurements of NMR spectra.

Synthetic Studies of Cobalt Carbonyl by Noble Metal Catalysts. I.*[1] The Effects of the Form of Cobalt Feed and Noble Metal Catalysts

Seiji USAMI, Takayoshi KONDO, Kotaro NISHIMURA and Yuzo KOGA

Central Research Laboratory, Toa Nenryo K. K., Oi-cho, Iruma-gun, Saitama

(Received March 24, 1969)

A novel method of synthesizing cobalt carbonyl was investigated by using noble metal catalysts. It has been observed that the materials containing palladium, *i. e.*, palladium black, palladium chloride, palladium acetylacetonate, bistriphenylphosphine dichloropalladium, and palladium-on-carriers, have a catalytic effect on the cobalt carbonylation reaction, and that palladium-on-carbon (Pd-C) is the most active catalyst. The reactivity of cobalt compounds in the cobalt carbonylation reaction catalyzed by noble metals increases in this order: $CoSO_4 \ll CoO \lesssim Co(OAc)_2 \lesssim$ Co-oleate $< Co(OH)_2$. When the Pd-C catalyst is used, cobalt hydroxide reacts with synthesis gas of 150 kg/cm^2 to give cobalt carbonyl almost quantitatively, even at from 50 to 55°C. The catalytic activities of noble metals were shown to be, in the order of decreasing activity: Pd > Au > Pt $\gg$ Ag. The effect of the catalyst concentration and the activity of noble-metal catalysts were also compared with those in the case of dicobalt octacarbonyl, as an auto-catalyst.

Cobalt carbonyl has been used in various organic synthetic reactions, *e. g.*, in hydroformylation, oligomerization, and the synthesis of acetic acid from methanol, and as a metal source for the synthesis of many organo-metal complexes. Many methods of synthesizing cobalt carbonyl have been proposed.

Making a general classification, the methods of synthesizing cobalt carbonyl may be divided into

*1 Presented partly at the 21st Annual Meeting of the Chemical Society of Japan, Osaka, April, 1968.

main methods, *i. e.*, with or without an autocatalyst. In the method without an autocatalyst, the cobalt carbonyl is prepared from inorganic cobalt salt and carbon monoxide in the presence of an alkaline substance,[1] or from cobaltous salts of weak acids under a high pressure of carbon monoxide[2] or synthesis gas.[3] On the other hand, the cobalt carbonyl is also prepared by using dicobalt octacarbonyl as an autocatalyst.[4] However, no synthetic method using any catalyst other than the autocatalyst has ever been reported.

In the present investigation, the promoting ability of several noble metals, *i. e.*, palladium, platinum, gold, and silver, which have been known to form the corresponding simple metal carbonyls only with difficulty, has been studied in connection with the cobalt carbonylation reaction.

Experimental

Reaction Procedures. The experimental method will be explained in terms of a typical run. An autoclave (500 m*l*), made of stainless steel and equipped with a magnetic stirrer, was used. *n*-Butyl alcohol (190 m*l*), 0.241 mol of a cobaltous compound, and 2.36 atom% of palladium-on-cobalt were placed in the autoclave. After the air in the autoclave had been replaced with synthesis gas ($H_2/CO=1.2$), the synthesis gas was introduced up to 150 kg/cm^2.

The autoclave was heated rapidly until 40°C and then at a rate of 0.6°C per minute until the gauge pressure began to decline. The temperature when the pressure began to drop was defined as the initiation temperature of the reaction, as is illustrated in Fig. 1, and the initiation temperature was used as one of the scales for measuring the reaction activity of cobalt salts and the promoting ability of the materials added. The autoclave was then kept at the initiation temperature for 60 min. Thereafter, the autoclave was rapidly cooled and depressured, and the cobalt carbonyl produced was taken out and analyzed.

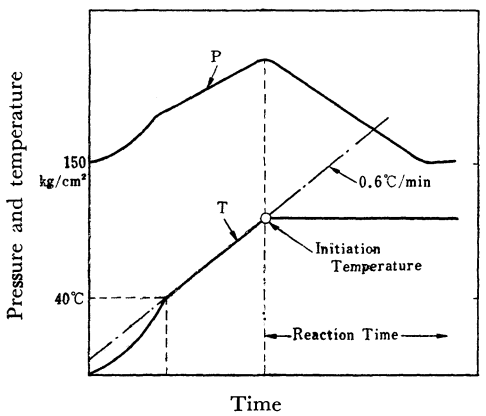

Fig. 1. Definition of the initiation temperature of reaction.

Analytical Procedures. The gasometric method reported by Wender *et al.*[5] was employed to determine the content of cobalt carbonyl in the carbonylation products. The crystals obtained from the products were identified as dicobalt octacarbonyl by the gasometric method, by infrared spectrometry, and by cobalt-metal analysis.

The cobalt and palladium were analyzed by the flame-photometric method.

Materials. The cobalt compounds and solvents were commercially available and were proved to be sufficiently pure. Materials containing palladium, *e. g.*, palladium chloride, palladium acetylacetonate, and palladium black, were purchased, but bis-triphenylphosphine dichloropalladium was prepared according to the method of Chatt.[6] The palladium-, platinum-, gold-, silver-, and copper-on-carbon (300 mesh up) containing 5 wt% metal were also commercially-available materials.

Results and Discussion

The Promoting Abilities of Materials Containing Palladium. The promoting abilities of various materials containing palladium were investigated in connection with the cobalt-carbonylation reaction. The results are summarized in Table 1. As Table 1 shows, in the absence of palladium, there was an induction period of about 10 min before the initiation of the cobalt carbonylation reaction even at high temperatures, from 213 to 220°C. However, the reaction occurred without any induction period even at extremely low temperatures when a catalytic amount of palladium was present. When the amount of palladium added was fixed at 2 atom%, the initiation temperatures were 155, 103, and 50—55°C for palladium black, palladium chloride, and palladium-on-carbon respectively.

The palladium complexes containing organic ligands, *i. e.*, palladium acetylacetonate and bis-triphenylphosphine dichloropalladium, were less active than the above palladium compounds. These findings seem to indicate that the most efficient form of materials containing palladium is the metal supported on a carrier.

When we compare the activity of dicobalt octacarbonyl as an autocatalyst with the materials containing palladium, we find that the autocatalyst is remarkably inferior to palladium-on-carbon.

4	$CoSO_4 \cdot 7H_2O$	*n*-butyl alcohol	220	no reaction
5	$Co(OH)_2$	*n*-butyl alcohol	50—55	62.2
6	$Co(OH)_2$	mixed solvent*3	60	97.0

*1 Reaction conditions: Feed, 0.241 mol (No. 1 to 5), 0.059 mol (No. 6); Pd on carbon (Pd content 5 wt%), 2.36 atom% on feed (No. 1 to 5), 2.41 atom% (No. 6); Solvent, 190 m*l*. Synthesis gas (H_2/CO 1.2) 150 kg/cm^2; Reaction time, 60 min. No carbon monoxide was supplied after the initiation of the reactions in the runs No. 1 to No. 5 but the reaction in No. 6 was carried out under a constant pressure by supplying carbon monoxide.
*2 Commercially-available material: cobalt content 96.5 wt%, CoO 15.86%.
3* 100 m*l* of *n*-butyl alcohol and 90 m*l* of toluene.

This fact is important in considering the reaction mechanism of cobalt carbonylation in the presence of palladium.

The Effect of the Carrier. The effect of the carrier of the materials containing palladium on the initiation temperature was also examined.

As Table 2 shows, the carrier remarkably affects the activity of the materials containing palladium. The palladium supported on a carrier is relatively more active than palladium black, which includes no carrier, palladium-on-carbon is the most active material among the palladiums supported on carriers. These results indicate the specific incorporation of palladium and carrier. The relation between the activity of the palladium-on-carrier and the physical properties, *i. e.*, the surface area and the particle size, was also investigated. However, the reactivity seems to be due to key factors other than those properties.

The Reactivities of Various Cobalt Compounds. The reactivities of various cobalt compounds in the cobalt-carbonylation reaction were examined in the presence of palladium-on-carbon; the results are shown in Table 3.

When commercially-available cobalt metal powder (300 mesh up) containing 96.5 per cent of cobalt was used, the carbonylation reaction was initiated at 78°C. Afterwards, it was revealed by X-ray analysis that the remarkable activity of cobalt metal powder was due to the cobalt monoxide which was formed on the surface of the cobalt metal powder rather than to the cobalt metal itself. Cobalt acetate and oleate showed similar initiation temperatures of from 75 to 76°C, while cobalt hydroxide showed much lower initiation temperatures between 50 and 55°C. The reactions

of those cobalt compounds were carried out at each initiation temperature for 60 min, the yields of cobalt carbonyl were about 60 to 70 mole per cent in each case.

These reaction conditions were unfit for determining the yield at complete conversion because of the following reasons. First, no excess of carbon monoxide was supplied. Second, the accurate analysis of the product was difficult, because large amounts of crystalline dicobalt octacarbonyl were precipitated from the reaction mixture and mingled with the powdery palladium-on-carbon. To determine accurately the yield at complete conversion for the reaction system using cobalt hydroxide, palladium-on-carbon, and butyl alcohol as solvents, the reaction with a lower concentration in cobalt hydroxide by supplying carbon monoxide was carried out in a solvent mixture of butyl alcohol and toluene, which is a good solvent system for the dicobalt octacarbonyl. Cobalt carbonyl was thus obtained in a 97% yield when these was a reaction at 60°C for 60 min, as is shown in Table 3. Moreover, no crystalline cobalt carbonyl was found in the reaction product. In the case of using cobalt sulfate, no reaction occurred until 220°C. These results may be understood easily by considering that the following equilibrium between the formation and the decomposition of cobalt carbonyl is partial to the left side:

$$2CoSO_4 + 8CO + 2H_2 \rightleftarrows Co_2(CO)_8 + 2H_2SO_4$$

The Effect of the Palladium Concentration. The effect of the palladium concentration in the reaction zone on the initiation temperature was investigated by using *n*-butyl alcohol as the solvent. The results are shown in Fig. 2.

The plot of the initiation temperature against the ratio of the promoter metal to the cobalt concentration indicates that the initiation temperature significantly decreases, with only a small increase (less than 1 atom percent on cobalt) in the concentration of palladium, and that less than 5 per cent of the palladium concentration gives rise to an adequate efficiency.

By comparing the effect of the palladium concentration on the initiation temperature with that of dicobalt octacarbonyl as an autocatalyst, as is shown in Fig. 2, the strong promoting activity of palladium-on-carbon is easily evaluated. In addition, no dissolved palladium was detected in the solution of the reaction product by careful analysis using a "Plane Grating Spectrograph Model GE 340." The behavior of palladium in the reaction mentioned above may be considered to suggest that palladium operates catalytically in the cobalt carbonylation reaction.

Catalytic Activity of Other Noble Metals. The other metals which are found in the neighborhood of palladium in the periodic table and which are generally considered to form simple metal carbonyls by themselves only with difficulty have also been investigated to see if they promote the cobalt carbonylation reaction.

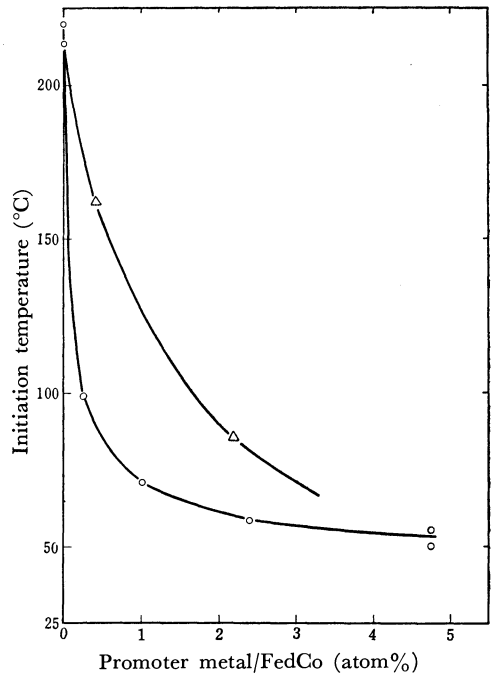

Fig. 2. Effects of the concentrations of promoters on the initiation temperature.
$Co(OH)_2$ 0.241 mol, Synthesis gas (H_2 : CO= 1.2 : 1) 150 kg/cm², *n*-BuOH 190 ml
⊙ Pd-C (H_2O (7.9 volume% on *n*-BuOH) was added in this series.)
△ $Co_2(CO)_8$

The experiments with the palladium catalyst showed that metal-on-carbon was the most active form. Platinum, gold, silver, and copper were tested as the metal-on-carbon for each metal. The results are shown in Fig. 3.

The initiation temperature in the reaction using the platinum-on-carbon catalyst fell sharply to 100°C when the concentration of platinum was increased to 0.723 atom%. However, little additional effect occurred over 1 atom%.

On the other hand, with gold-on-carbon, the initiation temperature fell gradually along the curve with the platinum catalyst in the low-concentration region, but over 1 atom% it fell dramatically, as was the case with palladium. At the Au/Co ratio of 4.5 atom%, gold-on-carbon can initiate the reaction at temperatures as low as 55°C. Silver-on-carbon showed only a poor activity, and copper-on-carbon had practically no effect on the cobalt-carbonylation reaction.

Thus, the relative activities of carbon-supported metals in the cobalt carbonylation are as follows: Pd> Au> Pt≫Ag≫Cu.

It is clear from the available data that platinum- and gold-on-carbon are excellent alternative cata-

lysts, and that palladium-on-carbon is still the best among the five materials examined here.

Summary

Cobalt carbonyl synthesis with noble metals as promoters has been investigated by using the initiation temperature of the reaction as a measure. The results of this study are as follows.

(1) It has been observed that materials containing palladium, platinum, gold, and silver have promoting effects on the cobalt-carbonylation reaction. The form of the materials containing metal significantly affects the promoting activity. Metal supported on active carbon exhibits an activity superior to that of the corresponding salts or complexes. The promoting activities of the noble metals supported on carbon examined here are in the order of: $Pd > Au > Pt \gg Ag$.

(2) From the plots of the promoter concentration against the initiation temperature, it has been revealed that by adding a small amount of noble metal promoters the initiation temperature of the reaction is markedly lowered; with an increase in the concentration, Pd and Au serve to lower the initiation temperature whereas Pt gives a constant initiation temperature above a certain concentration. Dicobalt octacarbonyl as an autocatalyst shows a concentration effect similar to those of Pd and Au, but the activity is much inferior to theirs.

(3) A cobalt-carbonylation reaction with a Pd-C promoter is also affected by the kind of cobalt compound as in the conventional case. The reactivities are in the order: $Co(OH)_2 >$ Co oleate $\simeq Co(oAc)_2 \simeq CoO \gg CoSO_4$.

Cobalt hydroxide, then, reacts at temperatures as low as from 50 to 55°C.

(4) It has been shown by a careful analysis that no dissolved palladium is present in the product solution. This and other data suggest that noble-metal promoters operate catalytically in the cobalt-carbonylation reaction.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 2966—2970 (1969)

Synthetic Studies of Cobalt Carbonyl by Noble Metal Catalysts. II.*1 The Investigation of Reaction Conditions

Seiji USAMI, Kotaro NISHIMURA, Takeo KOYAMA and Saburo FUKUSHI

Central Research Laboratory, Toa Nenryo Kogyo K. K., Tsurugaoka, Oi-cho, Iruma-gun, Saitama

(Received March 24, 1969)

The reaction conditions of cobalt carbonylation catalyzed by palladium have been investigated. Polar solvents have, with some exceptions, been shown to be superior to nonpolar solvents. The fact that the total pressure of synthesis gas and the partial pressure of hydrogen, especially the latter, have a great effect on the initiation temperature of reaction suggests that the presence of hydrogen is very important in the present reaction. The low reactivity and poor yield in the reactions of Raney cobalt indicate that a low-valency intermediate in the course of the cobalt-carbonylation reaction of cobaltous compounds may be somewhat different from the Raney-type Co(0). The initial step of the reaction seems to be affected only a little by various additives *e. g.*, water, triphenyl phosphine, lead naphthenate, and sodium hydroxide. The data previously available suggest that a palladium catalyst may primarily promote the reduction of Co(II) to Co(0) by activating hydrogen. The test of the lifetime of a palladium-on-carbon catalyst for a month indicates that there is no apparent decrease in the catalytic activity within this period.

Previous work[1] in our laboratory has shown that material containing palladium, platinum, gold, or silver, especially metals supported on active carbon, catalytically promotes the cobalt-carbonylation reaction.

In the present program, the effects of solvent, pressure, and additives on cobalt-carbonylation reactions catalyzed by palladium have been investigated.

Furthermore, in order to elucidate the behavior of palladium-on-carbon catalysts, the reaction of Raney cobalt has been studied. On the basis of these data, the role of the palladium catalyst will be briefly discussed.

Experimental

General Procedures. The experiments and the analysis of the reaction products were carried out in the way described in a previous paper.[1] The initiation temperature of the reaction, which was defined in the previous paper,[1] was also used here as one of scales measuring the reactivities of cobalt compounds and of the materials added.

Materials. Cobalt compounds, solvents, and other chemicals which were proved to be sufficiently pure were commercially available materials and were used without further purification. Palladium-on-carbon (300 mesh up) containing 5 wt% of palladium metal was purchased from the Kawaken Fine Chemicals Co., Ltd.

Raney Cobalt Feed. Thirty grams of Al-Co (1 : 1) alloy were added, drop by drop, to a 10% excess of an aqueous sodium hydroxide solution in open air or in a nitrogen atmosphere. After the addition has been completed, the developed Raney cobalt was decanted, washed with distilled water, and exchanged by acetone and finally by 190 m*l* of *n*-butanol. The freshly prepared suspension was used for the carbonylation reaction. After the reaction, the insoluble materials, *i. e.*, unreacted Raney cobalt and the catalyst, were filtered out and the cobalt carbonyl in the filtrate was analyzed as usual. The yield of cobalt carbonyl was calculated on the basis of the filtered solution of the reaction mixture in order to avoid any overestimation of the yield caused by adsorption gas on the surface of the Raney cobalt and the Pd-on-carbon.

Results and Discussion

The Effects of Solvents. The effects of solvents on the initiation temperature in the cobalt-carbonylation reaction promoted by palladium-on-carbon were studied, they are summarized in Table 1. The reaction was initiated at lower temperatures in such polar solvents as *n*-butanol, diethyl ether, isobutyraldehyde, and pyridine than in the nonpolar solvent, *n*-hexane. With isobutyraldehyde, however, the initiation temperature was somewhat higher compared to those of the polar solvents examined. Such a superior property of polar solvents has also been found in conventional cobalt-carbonylation reactions.[2,3] In any case, since the reaction catalyzed by palla-

Solvent 190 m*l*, Synthesis gas (H_2/CO 1.2) 150 kg/cm²

dium proceeds smoothly at low temperatures in either solvent, it is possible to select a solvent according to whether the desired form of cobalt carbonyl is crystalline dicobalt octacarbonyl or another. However, care must be taken to use such solvents as pyridine or isobutyraldehyde, because the following reactions occur in these solvents to form the complex (I) or the trimer (II).

The isobutyraldehyde trimer (II) was identified by means of its molecular weight, elemental analysis, its melting point, and its IR spectra.

$$Co^{2+} + \text{Pyridine} \longrightarrow Co(Py)_6[Co(CO)_4]_2 \quad \text{(I)}$$

$$3(CH_3)_2CHCHO \xrightarrow{HCo(CO)_4} \text{2,4,6-triisopropyl-1,3,5-trioxane} \quad \text{(II)}$$

For experimental convenience, *n*-butanol was used as the solvent in the subsequent experimental runs unless otherwise noted.

The Effect of the Total Pressure. The influence of the total pressure of the synthesis gas on the initiation temperature was examined at a fixed ratio (1 : 3) of hydrogen to carbon monoxide. As Table 2 shows, the initiation temperature becomes higher with a decrease in the total pressure.

In these runs, the partial pressures of carbon monoxide were larger than the equilibrium pressures

Table 2. Effect of total pressure

Total press (kg/cm²)	Partial press (kg/cm²) H_2	Partial press (kg/cm²) CO	Equil. press P_{CO}* (kg/cm²)	Initiation temp. (°C)
142	77.5	64.5	0.7	50—55
72	39.3	32.7	1.7	72
26	14.8	11.2	2.8	82

* Calculated from Rudkovskii's equation.

of carbon monoxide at each temperature, while dicobalt octacarbonyl began to decompose thermally. The equilibrium pressure was calculated from the following equation, proposed by Rudkovskii:[4]

$$Co_2(CO)_8 \rightleftarrows 2Co + 8CO$$

$$\log P_{CO} = 7.94 - 2660/T$$

where P_{CO} and T are the partial pressure of CO (kg/cm²) and the absolute temperature (°K) respectively. From this and other data to be presented in the next section, it seems more likely that the upward tendency of the initiation temperature with a decrease in the total pressure is to be attributed to the effective concentration of gases, particularly hydrogen, in the liquid phase rather than to the equilibrium pressure of carbon monoxide.

In order to ascertain the yield of cobalt carbonyl in the reaction under a low pressure, the experiments were carried out with 58 mmol of cobalt hydroxide and 2.45 atom% of a palladium catalyst on cobalt in 190 m*l* of *n*-butanol. The results are shown in Table 3.

The pressure was kept at 80 kg/cm² by adding carbon monoxide; two experimental runs were carried out, one at 80°C for 100 min and one at 100°C for 60 min. Under those sets of conditions cobalt carbonyl was obtained in 79 and 88% yields, respectively. However, these yields were considered to be minimum values because of the analytical difficulty caused by the precipitation of crystalline $Co_2(CO)_8$. For comparison, the results at 150 kg/cm² of synthesis gas are also shown in the table, within the range of experimental error, a quantitative yield of cobalt carbonyl was attained even at temperatures as low as 60°C.

Table 3. Cobalt carbonyl synthesis under low pressure

$Co(OH)_2$ 0.241 mol, Pd/Co 2.36 atom% *n*-BuOH 190 m*l*, Synthesis Gas. 150 kg/cm²

The Effect of the Partial Pressure. Reactions were conducted at a fixed total pressure of 150 kg/cm² but with various ratios of hydrogen to carbon monoxide. The results are shown in Fig. 1 as a plot of the ratio of hydrogen to carbon monoxide against the initiation temperature. In the absence of hydrogen, no decline in the gauge pressure was found until 220°C. However, after the reactor has been cooled, the gauge pressure became a little lower than the initial pressure, and about 10% of cobalt carbonyl was formed.

These facts suggest that the reaction rate under the above conditions is too slow for the pressure decline to be detected. It was interesting that, in the reaction under a carbon monoxide atmosphere, a dehydrogenation reaction of the solvent, *n*-butanol, occurred. Small amounts of *n*-butyraldehyde, 1,1-dibutoxy-*n*-butane, 2-ethylhex-2-en-1-al, and 2-ethylhexanol-1 were detected by gas chromatography. When *n*-butanol was treated with palladium-on-carbon under carbon monoxide pressure at 170°C for 7 hr, no dehydrogenation product was detected.

Therefore, hydrogen appears to be abstracted from *n*-butanol by cobalt. However, the above data are insufficient for us to conclude which is the immediate acceptor of hydrogen, cobalt or palladium, at 220°C, or how the hydrogen thus abstracted acts in the reaction. On the contrary, the cobalt-carbonylation reaction occurred at much lower temperatures when hydrogen was added. With a total pressure of 150 kg/cm² and otherwise identical conditions except that the partial pressures of hydrogen were 5.8, 28.0, and 81.8 kg/cm², the initiation temperatures were 170, 65, and 55°C respectively. These marked effects of added hydrogen on the initiation temperature are of great importance in considering the role of palladium catalysts.

Cobalt Carbonylation of Raney Cobalt. Experiments were carried out to see whether palladium catalysts participate on the step of the addition of carbon monoxide to a low-valent cobalt intermediate in the course of the cobalt-carbonylation reaction. Raney cobalt was selected on the assumption that the intermediate has zero valence and was very similar to Raney cobalt. The results are summarized in Table 4.

Table 4. Cobalt carbonylation of Raney cobalt

Pd/Co (atom %)	H_2/CO (V/V)	Atmosphere for develop. of Al-Co alloy	Reaction initiation temp. (°C)	Co carbonyl yield (mol%)
0	0	Air	200<	3.2
0	1	Air	185	1.2
2.22	0	Air	200<	6.3
2.22	1	Air	163	2.2
0	0	N_2	200<	2.8
0	1	N_2	183	1.4
2.22	0	N_2	200<	3.2
2.22	1	N_2	178	1.7

Raney Co 15.0 g, *n*-BuOH 190 m*l*, Total press. 150 kg/cm² Pd-C (5 wt% Pd; 300 mesh up), Reaction time 60 min.

With 150 kg/cm² of carbon monoxide, no decline in the pressure was observed up to 200°C even in the presence of a palladium catalyst. On the other hand, a slow but apparent decline of the pressure was observed from 170 to 185°C in the reaction under 150 kg/cm² of synthesis gas, irrespective of the presence of a palladium catalyst. However, equally poor yields of cobalt carbonyl were obtained in both reactions under carbon monoxide and in the pressure of synthesis gas. A similar low yield in the conventional cobalt carbonylation with Raney cobalt has also been disclosed in the literature.[5]

According to a German patent,[6] cobalt carbonylation with reduced cobalt is strongly inhibited by a small amount of oxygen. In the present study, however, this factor may be excluded because the reactions of Raney cobalt developed in nitrogen and in an open atmosphere give very similar results. The results obtained here indicate that the reaction rate with Raney cobalt is much slower than that with cobalt hydroxide. In conclusion, it

seems reasonable to consider that the low-valent intermediate in the course of the cobalt carbonylation of a cobaltous compound, cobalt hydroxide, for example, is somewhat different from the Raney-type cobalt, Co(0), Therefore, the role of the palladium catalyst in this step is still obscure.

The Effects of Additives. In order to characterize the reaction in more detail, various materials, *i. e.*, dicobalt octacarbonyl, water, triphenyl phosphine, pyridine, dihexyl sulfide, lead naphthenate, and sodium hydroxide, were added to the reaction system. The results are listed in Table 5. The

Table 5. Effect of various additives

Additive	Additive/Pd (mol%)	H_2O/*n*BuOH (wt%)	Reaction initiation temp. (°C)
$Co_2(CO)_8$	26.0	—	51
none	—	—	50—55
none	—	7.9	58
Ph_3P	10.8	7.9	58
Pyridine	38.2	7.9	64
$(C_6H_{13})_2S$	10.8	—	55
Pb-Naph.	10.8	—	63
NaOH	10.8	—	61

reaction where dicobalt octacarbonyl coexisted with a palladium catalyst gave essentially the same initiation temperature as the case without dicobalt octacarbonyl as an additive. Such organic ligands as triphenyl phosphine and pyridine also had little effect on the initiation temperature. These results may be understood from the consideration that the examined materials probably react with cobalt carbonyl once formed and do not participiate in the step of cobalt-carbonyl formation. The addition of sulfur compounds such as dihexyl sulfide and heavy metals such as lead naphthenate, which are regarded as strong poisons for a usual hydrogenation reaction, showed no significant retarding effect. Sodium hydroxide, which seems to be a retarder of autocatalysis by cobalt hydrocarbonyl, also exerted the same retardation as lead soap. It is noteworthy that the initial step of cobalt carbonylation catalyzed by palladium-on-carbon is affected only a little by various additives. This phenomenon is considered to be very closely related to the characteristic mode of cobalt carbonylation where cobalt is reduced by hydrogen, even in the presence of such a strong poison as carbon monoxide in the general hydrogenation reaction.

The Role of the Palladium-on-carbon Catalyst. The reaction of cobalt carbonylation is schematically shown in Fig. 2. The first step (I) is the reduction of cobaltous cobalt to a low-valent intermediate; the second (II), is the coordination of carbon monoxide to the reduced cobalt intermediate, and the final step (III) is the reaction of the dicobalt octacarbonyl thus formed with hydrogen to produce cobalt hydrocarbonyl.

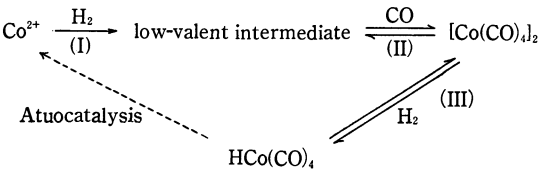

Fig. 2. Schematic reaction path of cobalt carbonylation.

Of these three steps, the contribution of hydrogen must be considered in I and III. If neither dicobalt octacarbonyl nor cobalt hydrocarbonyl is initially added as an autocatalyst, the contribution of hydrogen in III can be disregarded, at least at the beginning of the reaction. The following facts have been pointed out above:

1) The cobalt-carbonylation reaction is very slow under the pressure of only carbon monoxide, even in the presence of a palladium catalyst.

2) Even in the presence of hydrogen, when no palladium-on-carbon catalyst is used, a high initiation temperature is needed.

3) The reaction is promoted very much by the coexistence of hydrogen and a palladium catalyst.

In view of the above facts, the most reasonable conclusion to be drawn from the available data is that the role of a palladium-on-carbon catalyst consists in reducing Co(II) to a low-valent intermediate by activating hydrogen in I. From the observed difficulty in the cobalt carbonylation of Raney cobalt compared with that of cobalt hydroxide, a low-valent intermediate may be somewhat different from the Raney-type Co(0).

According to the equation presented by Rudkovskii,[4b] the equilibrium constant of Step III is calculated to be 3.37×10^{-5} at 52.5°C.

On the other hand, Iwanaga[7] has reported that the rate of (III) at 100°C under 100 to 200 kg/cm² of synthesis gas (H_2/CO; 1) is 1.7 mol%/min. Judging from these data, the contribution of an autocatalyst to the cobalt-carbonylation reaction with a palladium catalyst at a low temperature (55—55°C) is suspected to be very small.

Test of Catalyst Life. In order to ascertain the lifetime of a palladium-on-carbon catalyst, a flow test run was conducted for one month by using cobalt oleate at 120°C under a synthesis-gas (H_2/CO; 1.2) pressure of 200 kg/cm². No tendency of the catalytic activity to decrease could be observed within that period.

Summary

Following the preceding experiment, the reaction conditions of cobalt carbonylation catalyzed by palladium-on-carbon have been investigated. The experimental results obtained here indicate the following:

1) Such polar solvents as *n*-butanol, diethyl ether, isobutyraldehyde, and pyridine show excellent properties compared with the nonpolar solvent, *n*-hexane. In an ether solvent, the reaction proceeds smoothly at lower temperatures. Isobutyraldehyde and pyridine are not suitable for simple cobalt-carbonyl synthesis, since they easily react under the present reaction conditions.

2) With a decrease in the total pressure below 100 kg/cm^2, the initiation temperature of the reaction becomes higher. On the other hand, a marked lowering of the initiation temperature upon the addition of a small volume of hydrogen to the carbon monoxide atmosphere was observed. These data indicate that the presence of hydrogen is very important for the reaction.

A high yield of cobalt carbonyl can be obtained even at low pressure by adding carbon monoxide.

3) It is difficult for Raney cobalt to give cobalt carbonyl under a synthesis gas even in the presence of a palladium catalyst. Therefore, the low-valency intermediate in the course of cobalt carbonylation from a cobaltous compound may be somewhat different from the Raney-type Co(0).

4) The initiation temperature of the reaction is not affected significantly by such additives as water, dicobalt octacarbonyl, triphenyl phosphine, pyridine, dihexyl sulfide, lead naphthenate, and NaOH. This fact indicates that at least the initial step of the reaction is affected only a little by the above additives.

5) The available data suggest that the role of a palladium catalyst consists in reducing Co(II) to Co(0) by activating hydrogen.

6) The test of lifetime of a palladium-on-carbon catalyst for a one-month period gives no proof of a decrease in catalytic activity.

Photoinduced Reactions. XXXIII. Photochemical Reaction of a *para*-Quinone Methide[1]

Teruo MATSUURA and Katsuyuki OGURA

Department of Synthetic Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received March 28, 1969)

The photochemistry of a quinone methide (Ia) was investigated. Ia was unchanged on photolysis of an alcoholic solution (0.0064 M) with a high-pressure mercury lamp (Pyrex filter). However irradiation of a highly dilute solution of Ia or a sensitized reaction (acetophenone) gave an alcohol adduct (IIe in methanol and IIf in isopropyl alcohol) which might be formed *via* triplet excited state(s) of Ia. The methanol adduct IIe was also formed by the irradiation of Ia in methanol with a low-pressure mercury lamp through quartz. In this case the formation of IIe appears to be initiated by photochemical decomposition of methanol.

Photolysis of quinone methides is of interest in connection with the photochemical discoloration of xanthene dyes and the photorearrangement of 2,5-cyclohexadienones. We investigated the photochemistry of a quinone methide (Ia). During the course of our study, two papers on the photochemical reaction of quinone methides have appeared. Becker[2] found the quinone methide Ia to convert a phenol (IIa) by the photolysis of a highly dilute solution in isopropyl alcohol or by the acetophenone-sensitized photolysis. Recently, Krull and Schuster[3] showed that a quinone methide (Ib) in ethyl ether or cyclohexadiene afforded photochemically the corresponding solvent-adduct IIb or IIc, respectively, together with a small amount of a reduction product (IId). These papers prompted us to report the results obtained in our investigation on photolysis of the quinone methide Ia.

On photolysis of a methanol solution (0.0064 M) with a high-pressure mercury lamp (Pyrex filter) Ia was entirely unchanged. However, a methanol adduct IIe and a reduction product IIa were formed in the presence of acetophenone in 74 and 7% yields,

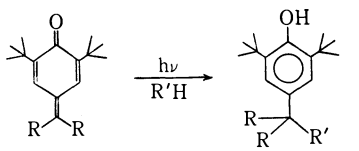
respectively. The structure of the adduct IIe was assigned from the NMR spectra of the adduct and of its acetate (see Experimental Section). The methanol adduct IIe was also formed as a main product in 50% yield by irradiation of a dilute methanol solution of Ia. The formation of IIe in the photolysis of a highly dilute solution of Ia or a sensitized reaction was perfectly quenched by air-bubbling. Therefore, it should be reasonable to presume that the adduct IIe was formed *via* the triplet excited state(s) of Ia. On the other hand, photolysis of a highly dilute solution of Ia in isopropyl alcohol with a high-pressure mercury lamp afforded not only the reduction product IIa (63% yield), as reported by Becker,[2] but also an isopropyl alcohol adduct (IIf) in 11% yield. The structure of the isopropyl alcohol adduct IIf was also deduced from its NMR spectrum.

It should be noted that the adduct IIe (44% yield) was also formed by the irradiation of Ia in methanol with a low-pressure mercury lamp (quartz filter) under bubbling nitrogen. On the other hand, in isopropyl alcohol the reduction product IIa was formed in 54% yield in addition to the adduct IIf (11%). In contrast to the photolysis of Ia with a high-pressure mercury lamp, the adduct IIe was also obtained in the presence of air, although in a low yield (14%), and 2,6-di-*t*-butyl-*p*-benzoquinone was obtained in 16% yield. When a low-pressure lamp with a Vycor filter was used for the photolysis of Ia in methanol, the formation of the adduct IIe was completely depressed. This is obviously due to the fact that a Vycor filter cuts off the 185-mμ line responsible for the photodecomposition of methanol to the hydroxymethyl radical as reported by Yang *et al.*[4] In fact, methanol was photochemically decomposed to afford ethylene glycol (80 mg per hour) with the low-pressure mercury lamp (quartz filer). These facts confirm that the formation of the adduct IIe in the photolysis of Ia with a low-pressure mercury lamp using a quartz filter resulted from the addition of the hydroxymethyl radicals, formed by the photochemical decomposition of methanol, to the quinone methide Ia as shown in Scheme I, rather than the excitation of Ia. The formation of IIe at high dilution or in the acetophenone-sensitized photolysis may be initiated by hydrogen abstraction of the triplet state(s) of Ia as described in Scheme II.



Ia R=Ph
Ib R=H

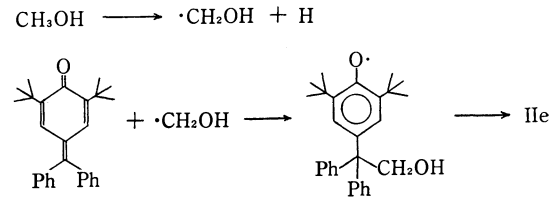
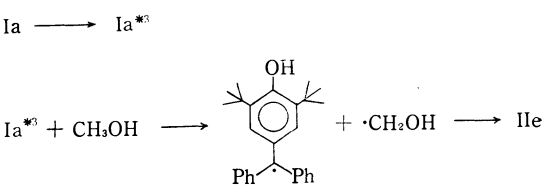


Scheme I



Scheme II

Experimental

Photolysis of Ia in Methanol. *(a) With a Low-pressure Mercury Arc Lamp.* A solution containing 1.00 g of the quinone methide Ia in 720 m*l* of methanol was irradiated for 15.5 hr with a 40 W low-pressure mercury arc lamp surrounded by a quartz filter under bubbling nitrogen. After removal of the solvent under reduced pressure, the residue was chromatographed on 40 g of silica gel. Elution with 75 m*l* of benzene yielded 120 mg of a yellow oil which was shown by a tlc analysis to contain a small amount of IIa. Further elution with 160 m*l* of benzene gave 482 mg of pale yellow crystals which were recrystallized from petroleum ether to afford the adduct IIe as colorless crystals, mp 119—120°C. NMR (in $CDCl_3$); τ 2.78 (10H, singlet, 2C_6H_5), 3.08 (2H, singlet, two aromatic protons), 4.88 (1H, singlet, a phenolic OH), 5.42 (2H, singlet, CH_2O-), 8.41 (1H, singlet, OH), and 8.66 (18H, singlet, two *t*-butyl groups).

Found: C, 83.30; H, 8.58%. Calcd for $C_{28}H_{34}O_2$: C, 83.54; H, 8.51%.

The acetate of the adduct IIe was prepared as usual (acetic anhydride and pyridine). Recrystallization from methanol gave colorless crystals, mp 124—126°C. NMR (in $CDCl_3$): τ 2.78 (10 H, a difused singlet, two phenyl). 3.11 (2H, singlet, two aromatic protons), 4.88 (1H, singlet, a phenolic OH), 4.92 (2H, singlet, CH_2O-), 8.12 (3H, singlet, CH_3COO), and 8.67 (18H, singlet, two *t*-butyl groups).

Found: C, 81.22; H, 8.32%. Calcd for $C_{30}H_{36}O_3$: C, 81.04; H, 8.16%.

(b) With a Low-pressure Mercury Arc Lamp under Air. A solution containing 500 mg of Ia in 250 m*l* of meth-

anol was irradiated for 16.5 hr with a 40 W low-pressure mercury arc lamp (quartz filter) under bubbling air. After removal of the solvent under reduced pressure, the residue was chromatographed on 40 g of silica gel. Elution with 200 m*l* of petroleum ether-benzene (1 : 1) gave 31 mg of a yellow oil which was shown by a vpc analysis to contain a trace of benzophenone. Further elution with 170 m*l* of the same solvent yielded 46 mg of yellow crystals, mp 59—60°C, which were identified as 2,6-di-*t*-butyl-*p*-benzoquinone (by infrared spectrum and mixture mp). Elution with 200 m*l* of benzene afforded 11mg of yellow oil which was not further investigated. Elution with 100 m*l* of benzene gave 84 mg of yellow crystals which were identified as the adduct IIe (by infrared spectrum).

(c) A Sensitized Reaction. A solution containing 500 mg of Ia and 6.67 g of acetophenone in 90 m*l* of methanol was irradiated for 17 hr with 100-W a high-pressure mercury arc lamp (Ushio UM 102) surrounded by a Pyrex cooling jacket under bubbling nitrogen. After the solvent had been removed under reduced pressure, the residue was chromatographed on 200 g of silica gel. Elution with 5 m*l* of benzene yielded 33 mg of yellow crystals. Recrystallization from methanol afforded 14 mg of pale yellow crystals which were identified as IIa (by infrared spectrum). Further elution with 20 m*l* of benzene gave 60 mg of a yellow oil which was not further investigated. Elution with 110 m*l* of benzene yielded 400 mg of yellow crystals. Recrystallization from petroleum ether gave 206 mg of colorless crystals, mp 118—120°C, which were identified as IIe (by infrared spectrum and mixture mp).

(d) With High Dilution. A solution containing *ca.* 15 mg of Ia in 1000 m*l* of methanol was irradiated with a 450-W high-pressure mercury arc lamp (Ushio UM 450) surrounded by a Pyrex cooling jacket under bubbling nitrogen until the yellow color discolored (50 min). Further *ca.* 15 mg of Ia was added and irradiated. This operation was repeated eight times and the total amount of the quinone methide Ia irradiated was 125 mg. After removal of the solvent under reduced pressure, the residue was chromatographed on 5 g of silica gel. Elution with 10 m*l* of benzene yielded 45 mg of a yellow oil which was shown by a tlc analysis to contain Ia and IIa. Further elution with 40 m*l* of benzene gave 68 mg of pale yellow crystals. Recrystallization from petroleum ether afforded pale yellow crystals, mp 119—120°C, which were identified as the adduct IIe (by infrared spectrum and mixture mp).

Photolysis of Ia in Isopropyl Alcohol. *(a) With a Low-pressure Mercury Arc Lamp.* A solution containing 500 mg of Ia in 200 m*l* of isopropanol was irradiated for 6 hr with a 40-W low-pressure mercury arc lamp surrounded a quartz filter under bubbling nitrogen. After removal of the solvent under reduced pressure, the residue was crystallized from petroleum ether to give 87 mg of pale yellow crystals, which were identified as IIa (by infrared spectrum). The mother liquor was chromatographed on 20 g of silica gel. Elution with 25 m*l* of petroleum ether - benzene (1 : 1) afforded 184 mg of pale yellow crystals, which were identified as IIa (by infrared spectrum). Further elution with 165 m*l* of petroleum ether - benzene (1 : 1) yielded 44 mg of a yellow oil which was not further investigated. Elution with 150 m*l* of petroleum ether - benzene (1 : 1) gave 66 mg of pale yellow crystals, which, on recrystallization from petroleum ether, afforded the adduct as chloroless crystals, mp 155.5—156.5°C. NMR (in $CDCl_3$); τ 2.81 (12H, a difiused singlet, two phenyl and two aromatic protons), 4.93 (1H, singlet, a phenolic OH), 8.44 (1H, singlet, OH), and 8.52 (6H, difused singlet, 2 CH_3), and 8.69 (18 H, singlet, two *t*-butyl groups).

Found: C, 83.71; H, 9.19%. Calcd for $C_{30}H_{38}O_2$: C, 83.67; H, 8.90%.
