c) From II. To a solution of II (200 mg) in acetic acid (10 ml), zinc powder (0.4 g) was added in small portions. The reaction mixture was then warmed on a water bath for 30 min and filtered. The filtrate was diluted with water and made slightly alkaline with diluted ammonium hydroxide. The crystals precipitated were collected, washed with water, dried, and dissolved in chloroform. The solution was passed through a column of alumina and eluted with chloroform. From the effluent, VIII (90 mg) was obtained.

d) From III or IV. To a solution of III or IV (200 mg) in acetic acid (10 ml), zinc powder (0.5 g) was added. The mixture was treated as in the case of the reduction mentioned above to give VIII (100 mg).

2-Hydroxyphenazine (XI). A solution of VIII (200 mg) in 20% sulfuric acid (3 ml) was heated at 200°C for 8 hr in a sealed tube. After cooling, the reaction mixture was diluted with water, made slightly alkaline with diluted sodium hydroxide, and filtered by suction. The filtrate was acidified weakly with diluted acetic acid. The crystals thereby yielded were recrystallized from diluted ethanol to yield red needles (mp 248—250°C (decomp.); 70 mg), which were identified as XI[6] by a comparison of their infrared spectra.

9-Methyl-2-piperidinophenazine (XIII). *a) From XII. i)* A mixture of XII (1.4 g), piperidine (15 ml), and cuprous chloride (0.1 g) was refluxed for 50 hr and then poured into water (1 l). The crystals thereby formed were collected by filtration, washed with water, dried, and dissolved in benzene. The benzene solution was passed through a column of alumina and eluted with benzene. From the effluent, XII (0.5 g) was recovered. When the column was further eluted with chloroform, dark red crystals were obtained. Recrystallization from a mixture of cyclohexane and petroleum ether afforded XIII (mp 76—77°C; 190 mg) as fine, reddish-orange crystals.

Found: C, 77.95; H, 6.95; N, 15.32%. Calcd for $C_{18}H_{19}N_3$: C, 77.94; H, 6.91; N, 15.15%.

ii) A mixture of XII (1.4 g) and piperidine (15 ml) was treated as in the case of i) to give XIII (140 mg). XII (0.8 g) was also recovered.

b) From XV. To a solution of XV (200 mg) in acetic acid (6 ml), zinc powder (0.5 g) was added in small portions. The resulting mixture was treated as in the procedure c) used in the preparation of VIII to afford XIII (50 mg).

2-Chloro-9-methylphenazine-5-oxide (XIV). *a) By the Wohl-Aue Reaction.* To a solution of *p*-nitrochlorobenzene (45 g) and *o*-toluidine (25 g) in toluene (300 ml), powdered potassium hydroxide (60 g) was added, and the resulting mixture was refluxed gently for 5 hr. The toluene solution was filtered while hot and then steam-distilled. The crude product deposited in the remaining aqueous solution was collected, washed with water, dried, and dissolved in chloroform. The solution was then passed through a column of alumina and eluted with chloroform. From the effluent, crystals were obtained. These were recrystallized from benzene to afford XIV (mp 173—174°C; 5 g) as bright yellow needles.

Found: C, 63.59; H, 3.70; N, 11.40%. Calcd for $C_{13}H_9ClN_2O$: C, 63.81; H, 3.71; N, 11.45%.

A mixture of XIV (1 g) and zinc powder (1 g) in acetic acid (20 ml) was treated as in the case of the procedure c) used in the preparation of VIII to give crude crystals. Recrystallization from a mixture of benzene and ethanol afforded yellow needles (mp 152—153°C; 750 mg), which showed no depression of melting point upon admixture with XII.[7] The infrared spectrum was identical with that of XII.

b) By Oxidation. To a solution of XII (1 g) in acetic acid (50 ml), 30% hydrogen peroxide (5 ml) was added. The reaction mixture was warmed at 55°C for 3 hr and then poured into water (1 l). The crystals thus formed were collected by filtration and recrystallized from benzene to give XIV (850 mg).

9-Methyl-2-piperidinophenazine-5-oxide (XV). A mixture of XIV (2 g) and piperidine (10 ml) was refluxed for 16 hr and then poured into water (300 ml) and acetic acid (5 ml). The crystals thereby separated were collected, washed with water, and dried. The product was dissolved in benzene, and the solution was passed through a column of alumina and eluted with benzene. From the first effluent, XII (320 mg) was obtained, while XIV (620 mg) was recovered from the second effluent. When the column was then further eluted with chloroform, dark violet crystals were obtained from the effluent. The recrystallization of these from a mixture of benzene and methanol gave XV (mp 165—166°C; 750 mg) as reddish-violet needles.

Found: C, 73.54; H, 6.63; N, 14.03%. Calcd for $C_{18}H_{19}N_3O$: C, 73.69; H, 6.53; N, 14.33%.

7-Methoxy-2-piperidinophenazine (XVIII). *a)* A

mixture of XVI (1.5 g), piperidine (15 m*l*), and cuprous chloride (0.1 g) was refluxed for 50 hr and then treated as in the case of XV to give XVIII (mp 146—147°C; 160 mg) as bright reddish-orange needles (from a mixture of cyclohexane and benzene); XVI (0.9 g) was also recovered.

Found: C, 73.78; H, 6.45; N, 14.31%. Calcd for $C_{18}H_{19}N_3O$: C, 73.69; H, 6.53; N, 14.33%.

b) A mixture of XVI (1.5 g) and piperidine (15 m*l*) was refluxed for 100 hr; the resulting mixture gave XVIII (200 mg). XVI (1.1 g) was also recovered.

9-Methoxy-2-piperidinophenazine (XIX). A mixture of XVII (1.5 g), piperidine (15 m*l*), and cuprous chloride (0.2 g) was refluxed for 50 hr and then treated as in the case of XV to give dark orange crystals. Recrystallization from diluted methanol yielded XIX (mp 124—125°C; 310 mg) as deep reddish-orange needles. XVII (120 mg) was also recovered.

Found: C, 73.55; H, 6.38; N, 14.06%. Calcd for $C_{18}H_{19}N_3O$: C, 73.69; H, 6.53; N, 14.33%.

7-Methoxy-2-piperidinophenazine-5-oxide (XXI). *a*) A mixture of XX (1.5 g) and piperidine (15 m*l*) was refluxed for 25 hr and then poured into water (1 *l*). After the usual work-up, the crystals obtained were dissolved in benzene. The solution was passed through a column of alumina and eluted with benzene. From the first effluent, XVI (0.7 g) was obtained. XX (200 mg) was recovered from the second effluent. When the column was further eluted with chloroform, XVIII (55 mg) and dark red crystals were obtained. The recrystallization of the crystals from diluted methanol afforded XXI (mp 171—172°C; 150 mg) as fine, red crystals.

Found: C, 69.59; H, 6.14; N, 13.87%. Calcd for $C_{18}H_{19}N_3O_2$: C, 69.88; H, 6.19; N, 13.58%.

b) A mixture of XX (1.5 g) and piperidine (15 m*l*) was refluxed for 16 hr and then treated as in the case of a) above to give XVI (400 mg), XX (350 mg), and XXI (100 mg).

To a solution of XXI (200 mg) in acetic acid (10 m*l*), zinc powder (0.5 g) was added; the mixture was then treated as in the case of the procedure c) used in the preparation of VIII to afford XVIII (110 mg).

2-Chloro-9-methoxyphenazine-5-oxide (XXII). To a solution of XVII (1.4 g) in acetic acid (50 m*l*), 30% hydrogen peroxide (10 m*l*) was added. The resulting solution was warmed at 55°C for 3 hr and then poured into water (2 *l*). The deep yellow crystals which separated were collected and washed with water. The recrystallization of the crystals from a mixture of benzene and ligroin gave XXII (mp 217—218°C (decomp.); 1.2 g) as orange-yellow needles.

Found: C, 60.02; H, 3.49; N, 10.49%. Calcd for $C_{13}H_9ClN_2O_2$: C, 59.90; H, 3.48; N, 10.75%.

XXII was treated with zinc powder in acetic acid to give XVII.

9-Methoxy-2-piperidinophenazine-5-oxide (XXIII). A mixture of XXII (1.5 g) and piperidine (15 m*l*) was refluxed for 24 hr and then treated as in the case of the procedure a) used in the preparation of XXI to give XVII (450 mg), XIX (500 mg), and dark violet crystals. The crystals were recrystallized from diluted methanol to yield XXIII (mp 153—154°C; 250 mg) as deep reddish-violet micro-prisms.

Found: C, 69.73; H, 6.24; N, 13.26%. Calcd for $C_{18}H_{19}N_3O_2$: C, 69.88; H, 6.19; N, 13.58%.

To a solution of XXIII (100 mg) in acetic acid (5 m*l*), zinc powder (0.3 g) was added; the mixture was then treated as in the case of the procedure c) used in the preparation of VIII to afford XIX (50 mg).

1-Piperidinophenazine (XXV). *a*) To a solution of XXIV (1.5 g) in piperidine (15 m*l*), cuprous chloride or cupric chloride (0.2 g) was added. The mixture was refluxed for 70 hr and then poured into water (1 *l*). The resulting precipitate was washed with water, dried, and dissolved in benzene. The benzene solution was passed through a column of alumina and eluted with benzene. From the first effluent, XXIV (500 mg) was recovered, while crude crystals were obtained from the second effluent. Recrystallization from a mixture of cyclohexane and petroleum ether gave XXV (mp 130—131°C; 150 mg) as orange-red needles.

Found: C, 77.25; H, 6.60; N, 15.70%. Calcd for $C_{17}H_{17}N_3$: C, 77.53; H, 6.51; N, 15.96%.

b) A solution of XXIV (1.5 g) in piperidine (15 m*l*) was refluxed for 60 hr and then treated as in a) above to give XXV (50 mg). XXIV (0.9 g) was also recovered.

1-Piperidinophenazine-5-oxide (XXVII). *a*) A mixture of XXVI (1.5 g) and piperidine (15 m*l*) was refluxed for 25 hr and then treated as in the case of XXV to give XXIV (60 mg), XXV (50 mg), XXVI (50 mg), and dark red crystals (500 mg). The crystals were recrystallized from cyclohexane to afford XXVII (mp 161—162°C) as fine, reddish-violet needles.

Found: C, 72.98; H, 6.18; N, 14.90%. Calcd for $C_{17}H_{17}N_3O$: C, 73.09; H, 6.13; N, 15.04%.

b) A mixture of XXVI (1.0 g) and piperidine (10 m*l*) was refluxed for 10 hr and then treated as in the case of a) above to afford XXIV (50 mg), XXVI (650 mg), and XXVII (120 mg).

To a solution of XXVII (100 mg) in acetic acid (5 m*l*), zinc powder (0.3 g) was added; the mixture was then treated as in the case of the procedure c) used in the preparation of VIII to give XXV (25 mg).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 506—507 (1969)

Synthesis of 1- and 2-Morpholinophenazine Derivatives

Hideo Endo and Masao Tada

The Research Institute for Tuberculosis, Leprosy and Cancer, Tohoku University, Kitayoban-cho, Sendai

and Ken Katagiri

Shionogi Research Laboratory, Shionogi & Co., Ltd., Fukushima-ku, Osaka

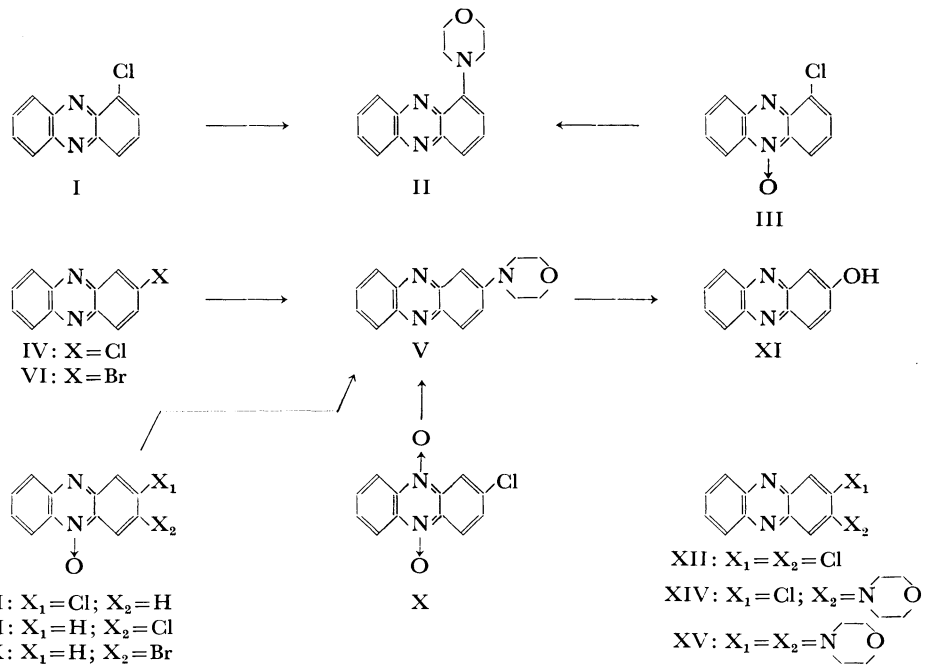
(Received June 19, 1968)

A number of new morpholinophenazines have been prepared by the reactions of various halogenophenazine derivatives with morpholine. It has been found that the replacement of the halogen atom of halogenophenazine-*N*-oxides with morpholine is accompanied by the removal of the oxide group and that no morpholinophenazine-*N*-oxides are formed in these reactions.

In a previous paper,[1] the reactions of halogenophenazine derivatives with piperidine were reported. The present paper will describe the synthesis of morpholinophenazines.

The reaction of morpholine with 1-chlorophenazine (I) in the presence of cuprous chloride or cupric chloride gave a 17% yield of 1-morpholinophenazine (II), which was also obtained from 1-chlorophenazine-5-oxide (III). The treatment of 2-chlorophenazine (IV) with morpholine gave a 59% yield of 2-morpholinophenazine (V), which was also derived from 2-bromophenazine (VI). Either 2-chlorophenazine-5-oxide (VII) or 3-chlorophenazine-5-oxide (VIII) was treated with morpholine to give V, which was also obtained from 3-bromophenazine-5-oxide (IX) or 2-chlorophenazine-5,10-dioxide (X). V was refluxed with diluted sulfuric acid or heated with diluted sulfuric acid at 200°C in a sealed tube to yield 2-hydroxyphenazine (XI), which had been reported by Vivian.[2]

The above series of reactions reveals that the replacement of the halogen atom with morpholine in halogenophenazine-*N*-oxides is accompanied by



1) H. Endo, M. Tada and K. Katagiri. This Bulletin, **42**, 502 (1969).

2) D. L. Vivian, *J. Am. Chem. Soc.*, **73**, 457 (1951).

the removal of the oxide group in these phenazine-*N*-oxides, as was found during substitution with piperidine by Landquist[3] and by us.[1] However, the present finding, that no *N*-oxides are produced, is in contrast with the corresponding reaction with piperidine.[1]

The reaction of 2,3-dichlorophenazine (XII)[4] or 2,3-dichlorophenazine-5-oxide (XIII)[4] with morpholine afforded both 2-chloro-3-morpholinophenazine (XIV) in a 44% yield and 2,3-dimorpholinophenazine (XV) in a 3% yield. XV was also obtained from XIV. Brackman *et al.* have reported that the reaction of 4,5-dimorpholino-*o*-benzoquinone with *o*-phenylenediamine gave XV.[5] The treatment of 2-chloro-9-methylphenazine (XVI) or 2-chloro-9-methylphenazine-5-oxide (XVII) with morpholine gave 9-methyl-2-morpholinophenazine (XVIII).

The growth-inhibitory activity of these reaction products against Crocker Sarcoma 180 will be reported on elsewhere.[6]

Experimental[7]

1-Morpholinophenazine (II). *a) From 1-Chlorophenazine (I).* A mixture of I (1.5 g) and cuprous chloride or cupric chloride (0.1 g) in morpholine (15 m*l*) was refluxed for 50 hr and then poured into water (300 m*l*). After the addition of acetic acid (8 m*l*), the resulting precipitate was collected, washed with water, sucked dry, and dissolved in benzene. The benzene solution was then passed through a column of alumina and eluted with benzene. From the effluent, I (0.95 g) was recovered. When the column was then further eluted with chloroform, dark orange crystals were obtained. Recrystallization from cyclohexane gave II (mp 165—166°C; 320 mg) as reddish-orange needles.

Found: C, 72.11; H, 5.74; N, 15.73%. Calcd for $C_{16}H_{15}N_3O$: C, 72.43; H, 5.70; N, 15.84%.

b) From 1-Chlorophenazine-5-oxide (III). A solution of III (1.5 g) in morpholine (15 m*l*) was refluxed for 24 hr and then treated as in the case of a) to give both I (1.1 g) and II (100 mg).

2-Morpholinophenazine (V) *a) From 2-Chlorophenazine (IV).* A solution of IV (1.5 g) in morpholine (15 m*l*) was refluxed for 70 hr and then treated as in the case of the procedure a) used in the preparation of II to give dark orange crystals (1.1 g). Recrystallization from benzene afforded V (mp 172—173°C) as yellowish orange needles. IV (0.1 g) was also recovered.

Found: C, 72.22; H, 5.68; N, 16.04%. Calcd for $C_{16}H_{15}N_3O$: C, 72.43; H, 5.70; N, 15.84%.

b) From 2-Bromophenazine (VI). A solution of VI (150 mg) in morpholine (5 m*l*) was refluxed for 50 hr and then treated as in the case of the a) used in the preparation of II to give V (80 mg). VI (20 mg) was also recovered.

c) From 2-Chlorophenazine-5-oxide (VII). A mixture of VII (1.5 g) and morpholine (15 m*l*) was refluxed for 12 hr and then treated as in the case of the a) used in the preparation of II to give both IV (600 mg) and V (450 mg).

d) From 5-Chlorophenazine-5-oxide (VIII). A mixture of VIII (1.5 g) and morpholine (15 m*l*) was refluxed for 12 hr and then treated as in the case of the a) used in the preparation of II to give both IV (150 mg) and V (500 mg).

e) From 3-Bromophenazine-5-oxide (IX). A mixture of IX (150 mg) and morpholine (5 m*l*) was refluxed for 12 hr and then treated as in the case of the a) used in the preparation of II to give V (40 mg).

f) From 2-Chlorophenazine-5,10-dioxide (X). *i)* A mixture of X (1.5 g) and morpholine (15 m*l*) was refluxed for 3 hr and then treated as in the case of the a) used in the preparation of II to give crude crystals (1.1 g), which contained IV (850 mg), V(20 mg), and a mixture (15 mg) of VII and VIII.

ii) A mixture of X (1.5 g) and morpholine (15 m*l*) was refluxed for 12 hr and then treated as in the case of the a) used in the preparation of II to give IV (530 mg) and V (580 mg).

The Reaction of 2,3-Dichlorophenazine (XII) or 2,3-Dichlorophenazine-5-oxide (XIII) with Morpholine. A mixture of XII or XIII (1.5 g), morpholine (15 m*l*), and cupric chloride (0.2 g) was refluxed for 70 hr and then poured into water (1.5 *l*). The crystals thereby separated were collected, washed with water, sucked dry, and dissolved in benzene. The solution was passed through a column of alumina and eluted with benzene. From the first effluent, yellow crystals were obtained. Recrystallization from ethanol gave 2-chloro-3-morpholinophenazine (XIV) (mp 131—132°C; 800 mg) as bright yellow needles.

Found: C, 64.08; H, 4.69; N, 13.87%. Calcd for $C_{16}H_{14}ClN_3O$: C, 64.11; H, 4.71; N, 14.02%.

From the second effluent, dark orange crystals (60mg) were obtained; they were recrystallized from ethanol to form yellow needles (mp 218—219°C; 35 mg), which showed no depression of melting point on admixture with 2,3-dimorpholinophenazine (XV).[5] The infrared spectrum was identical with that of XV. By refluxing XIV (100 mg) in morpholine (5 m*l*) for 70 hr, XV (10 mg) was also obtained.

9-Methyl-2-morpholinophenazine (XVIII). *a) From XVI.* A mixture of XVI (1.5 g), morpholine (15 m*l*), and cupric chloride (0.2 g) was refluxed for 70 hr and then treated as in the case of the a) used in the preparation of II to give orange crystals. Recrystallization from a mixture of benzene and cyclohexane afforded XVIII (mp 185—186°C; 650 mg) as brilliant yellowish-orange needles. XVI (250 mg) was also recovered.

Found: C, 73.00; H, 6.05; N, 15.01%. Calcd for $C_{17}H_{17}N_3O$: C, 73.09; H, 6.13; N, 15.04%.

b) From XVII. A mixture of XVII (1.5 g), morpholine (15 m*l*), and cupric chloride (0.2 g) was refluxed for 70 hr and then treated as in the case of the a) used in the preparation of II to give both XVI (110 mg) and XVIII (850 mg).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 508—512 (1969)

Syntheses and Reactions of Functional Polymers. XL. Enhanced Reactivity of Poly(vinyl chloride) by Neighboring-Group Participation of the *N*,*N*-Disubstituted Dithiocarbamate Function*1

Takeshi NAKAI, Hideo KAWAOKA*2 and Makoto OKAWARA

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received June 27, 1968)

In order to demonstrate that neighboring-group participation of the *N*,*N*-disubstituted dithiocarbamate function is involved in the substitution reaction of poly (vinyl chloride) (PVC) with the dithiocarbamate anion, the rates of reactions of PVC and the copolymer (vinyl chloride-*S*-vinyl *N*,*N*-diethyldithiocarbamate) with $^{-}$SCS-NEt$_2$ were compared under the same conditions. These polymer reactions were undertaken in dimethylformamide or tetrahydrofuran at 45°C. The rate enhancements with the copolymer were observed in both solvents. From these observations, it was concluded that the chloromethylene groups in PVC neighboring the dithiocarbamate function were activated toward the nucleophile *via* neighboring-group participation. This is the first time that neighboring-group participation involving the polymer main chain might be observed in the polymer reaction. The difference in reaction mechanism between the polymer reaction and the model reaction was discussed.

It is well-known that poly(vinyl chloride) (PVC) is more unsusceptible to nucleophilic substitution (S_N) reactions and more readily eliminates hydrogen chloride, as compared with alkyl chlorides. For that reason, chemical modifications of PVC have been subjected to restriction.

During the course of our studies on preparations of photosensitive polymers containing the dithiocarbamate function by polymer reactions, it was found that PVC reacted readily with dithiocarbamate anions in dimethylformamide (DMF) at 40—50°C without elimination of hydrogen chloride.[1] The remarkable reactivity of PVC under mild conditions might be due to three factors: (i) the enhanced electrophilicity of PVC by the solvation with DMF,[2] (ii) the large nucleophilicity of the dithiocarbamate anion[3] and (iii) enhancement of the nucleophilicity by DMF.[4]

On the other hand, we have reported that neighboring-group participation of the *N*,*N*-disubstituted dithiocarbamate function is involved through the intermediacy of the isolatable anchimeric cation*3 in the reactions of 1,2-dichloroethane[5] and 1,3-dichloropropane (a model compound for PVC)[6] with the dithiocarmate anion, *e. g.*, as shown in Scheme 1.

The present work was undertaken in order to prove that neighboring-group participation of the

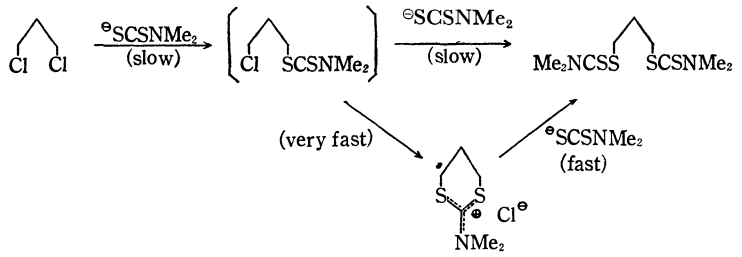
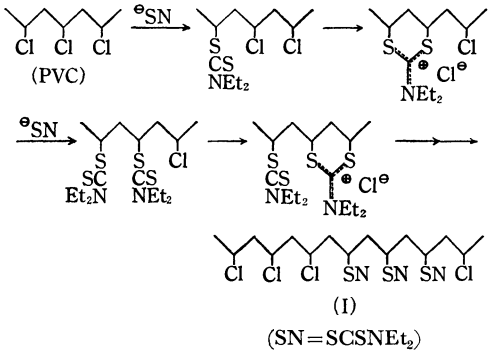


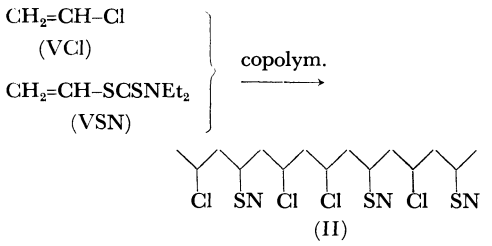
Scheme 1

dithiocarbamate function is certainly involved in the reaction of PVC with *N*,*N*-diethyldithiocarbamate anion ($^{-}$SN). Assuming that the concept of neighboring-group participation might be applied into the polymer reaction of PVC with $^{-}$SN, the reaction should proceed as shown in Scheme 2 to result in the formation of the polymer containing the block-type structure (I).



Scheme 2

On the other hand, the copolymer from vinyl chloride (VCl) and *S*-vinyl *N*,*N*-diethyldithiocarbamate (VSN) should be of the random structure as given by the formula (II).



Consequently, it can be said that the polymer (II) apparently contains more chloromethylene (-CHCl-) groups neighboring the dithiocarbamate function than the polymer (I) does. Thus, in order to demonstrate that the neighboring group participates in the polymer reaction, we attempted to compare the rate of reaction of the polymer (I) and $^{-}$SN with that of the polymer (II) under the same reaction conditions.

Results

Reactions of PVC with Sodium *N*,*N*-Diethyldithiocarbamate (NaSN). Reactions of PVC with NaSN (initial molar ratio 2 : 1) were carried out in DMF or tetrahydrofuran (THF) at 45°C. The reaction was followed by the sulfur analysis of the resulting polymer precipitated after a given interval. The results obtained are shown in Table 1. As shown in Fig. 1, the reaction fitted in a

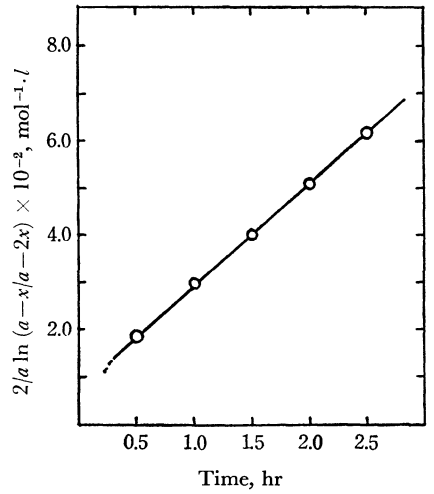


Fig. 1. Second-order rate plot for the reaction of PVC with NaSN in DMF at 45°C.

second-order rate equation (the rate constant= 2.78×10^{-6} mol$^{-1}\cdot l\cdot$sec^{-1}). It may be noted that the rate of reaction in DMF is much larger than that in THF. The fact indicates that the three factors described above have a serious influence on the rate of reaction.

Reactions of the Copolymer (VCl-VSN) with NaSN. *S*-Vinyl *N*,*N*-diethyldithiocarbamate (VSN) was prepared by the vacuum pyrolysis of ethylene bis(*N*,*N*-diethyldithiocarbamate).[7] The copolymerization of VCl with VSN was undertaken in bulk at 45°C using *a*,*a*'-azobisisobutyronitrile

Q=0.044, e=+0.20[8]; VSN Q=0.45, e=−1.54[7]). The ratio r_{VCl} and r_{VSN} obtained were 0.069 and 1.426, respectively, indicating that VCl is less reactive than VSN. Thus, in order to prepare the random copolymer such as the formula (II), VSN was copolymerized with VCl from a low range of feed compositions. All copolymers were obtained in the form of solid. The experimental data are shown in Table 2. Concentrations of VSN

8) L. J. Young, *J. Polymer Sci.*, **54**, 411 (1961).

in the copolymers were evaluated by sulfur analyses.

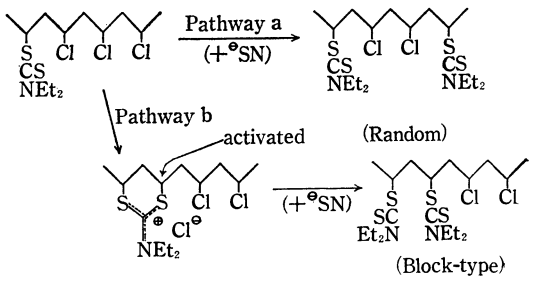
Next, reactions of these copolymers with NaSN were undertaken in DMF or THF under the same conditions as the reaction of PVC described above. Then, in order to compare exactly reactivities of the copolymer and PVC containing the same amount of VSN as the copolymer, the same molar amount of sodium chloride as that of VSN in the copolymer was added to the reactant mixture and the initial molar ratio (VCl in the copolymer+added NaCl)/(VSN in the copolymer+added NaSN) was adjusted to two in all cases. The VSN content of the resulting copolymer precipitated after a given interval was evaluated by the sulfur determination. The results obtained are given in Table 3. The plots of the VSN content in the resulting copolymers against the time are shown in Figs. 2 and 3, together with data for the reaction of PVC as references.

Discussion

Figure 2 shows important facts: (i) the rate enhancement*4 with the copolymer was clearly observed as compared with PVC containing the same concentration of VSN as the copolymer and (ii) the rate enhancement with the copolymer increased with the concentration of VSN in the copolymer. These facts lead substantially to the reasonable conclusion that participation of the neighboring dithiocarbamate function is no doubt involved in these polymer reactions, that is, the chloromethylene groups neighboring the dithiocarbamate function are activated toward the dithiocarbamate anion, as described in Scheme 2. These facts also indicate that the polymer from PVC and $^{-}$SN contains considerably the block-type structure such as the formula (I). This is the first time that neighboring-group participation involving the polymer main chain might be observed in the polymer reaction. The neighboring-group effects in polymer reactions reported so far all involve the polymer side chains. This method for activating PVC may further provide a possibility of a variety of chemical modifications of PVC *via* the S_N reaction with other nucleophiles which resist reaction with PVC itself. We are studying the reaction of the copolymer(VCl-VSN) with other nucleophiles.

Contrany to expectation the solvent effect on the rate enhancement with the copolymer was not particularly predominant (compare Figs. 2 and 3). This finding is in direct contrast to the observation that in the reaction of 1,2-dichloroethane with *N*,*N*-dimethyldithiocarbamate anion, neighboring-group participation of the dithiocarbamate function in THF is about two hundred times as large as that in DMF.[5] Taking it into consideration that the large solvent effect was observed on the rate of reaction of PVC with $^{-}$SN, this fact indicates that the normal S_N2 reaction involving no neighboring-group participation simultaneously occurs in the polymer reactions and that, in contrast to reactions of 1,2-dichloroethane and 1,3-dichloropropane described above, the intramolecular cyclization involving the neighboring dithiocarbamate function is slow for the polymer reaction.

In short, these polymer reactions consist of both the normal S_N2 reaction (pathway a) and the intramolecular cyclization followed by the S_N reaction (pathway b) giving a random polymer and block-type polymer respectively, as shown below.



Scheme 3. Copolymer or PVC containig the SN function.

In all cases kinetical observation leads to the conclusion that the S_N reaction involving neighboring-group participation (pathway b) certainly occurs in the polymer reaction.

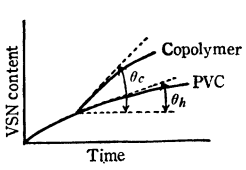
Experimental

Materials. Commercial NaSN was washed several times with chloroform and then dried *in vacuo*. This salt contains two molecules of coordinated water.[9] Commercial PVC (P=400) was purified by reprecipitating twice (DMF-MeOH). *S*-Vinyl *N*,*N*-diethyldithiocarbamate (VSN) was prepared by the vacuum pyrolysis of ethylene bis(*N*,*N*-diethyldithiocarbamate)[7] and then twice distilled at a reduced pressure (yield 95%); bp 93—94°C/1 mmHg, n_D 1.588 (27°C).

The solvents employed were purified by the usual methods.

Copolymerization Procedure. Commercial VCl was purified as follows: VCl was transferred into a flask cooled in a Dry Ice mixture from a cylinder through

*4 The rate enhancement with the copolymer is related to the ratio $\tan\theta_c/\tan\theta_h$ which was more than one, as illastrated below.



9) T. Nakai and M. Okawara, This Bulletin, **41**, 707 (1968).

a 10% aqueous solution of sodium hydroxide and a soda lime column. Using the usual vacuum system, VCl was further distilled through a soda lime column and then a given amount of purified VCl was condensed into a hard-glass tube of approximately 150 m*l* capacity containing given amounts of VSN and AIBN. The tube was carefully sealed and then immersed into a thermostat maintained at 45±0.5°C. After a given interval, the tube was removed from the thermostat and opened at −78°C. The reaction mixture was poured into a large amount of methanol giving a slightly yellowish precipitate. The copolymer was filtered and dried *in vacuo*. The copolymer was purified by reprecipitation (DMF-MeOH) and then completely dried *in vacuo*. The concentration of VSN in the copolymer was evaluated by sulfur determinations. The experimental results obtained are summarized in Table 2.

Polymer Reaction Procedure. The reaction of PVC with NaSN was undertaken as follows: a solution of 6.30 g (0.10 mol) of PVC and 8.60 g (0.05 mol) of NaSN in 100 m*l* of DMF was stirred in the thermostat maintained at 45±0.5°C. After a given interval, 25 m*l* of the reaction mixture was pippetted out and then poured into approximately 100 m*l* of methanol giving a white precipitate. The resulting polymer was purified by reprecipitation (DMF-MeOH) and dried *in vacuo*. The degree of substitution, that is, the concentration of VSN in the resulting polymer, was evaluated by two sulfur determinations. The experimental results obtained are summarized in Table 1. Infrared spectra of the resulting polymers exhibited no absorption bands due to the carbon-carbon double bond, indicating that no elimination of hydrogen chloride occurred during the reaction.

The reaction of the copolymer prepared above with NaSN was carried out under the same conditions as those of PVC. For example, a solution of 1.00 g of the copolymer (sulfur content 6.06%), 0.055 g of NaCl and 1.10 g of NaSN in 14.3 m*l* of DMF was stirred at 45°C. After a given interval, 7 m*l* of the reaction mixture was poured into methanol to give a slightly yellowish precipitate. The content of VSN in the resulting copolymer was evaluated by sulfur determinations. The results obtained are given in Table 3.

The authors are grateful to Mr. Yoshio Jo, the Nihon Zeon Co., for sulfur determinations.

The Cooxidation of Hydrocarbons in the Liquid Phase. V. Determination of the Reactivity Ratios

Etsuo NIKI, Yoshio KAMIYA and Nobuto OHTA

Department of Fuel Engineering, The University of Tokyo, Hongo, Tokyo

(Received June 28, 1968)

The cooxidations of cumene (C) and tetralin (T) and of styrene (S) and tetralin were studied in the presence of azobisisobutyronitrile; the reactivity ratios, r, were obtained as $r_C=0.21$ and $r_T=5.0$ for the cumene-tetralin system at 80°C and as $r_S=2.7$ and $r_T=0.49$ for the styrene-tetralin system at 70°C. A new method for the determination of r values from the rates of cooxidation has been developed. The merits and demerits of several methods for the determination of r values are discussed. In cases where a large curvature, preferably a rate minimum, is obtained by plotting the rates against the reactant compositions, the determination from the rates of cooxidation may be most suitable. In other cases, the use of the copolymerization equation may be preferable by product analyses. The hydroperoxide method may be valid for some systems.

In the liquid-phase autoxidation of hydrocarbons, the peroxy radicals play an important role as chain carriers, and the bimolecular reaction of the peroxy radical and the hydrocarbon is the rate-determining step. The reactivities of the hydrocarbons toward the peroxy radicals, however, are hard to ascertain, although much data have been presented on the reactivities of the hydrocarbons toward other free radicals and atoms.[1] The difficulty in obtaining the reactivities toward the peroxy radicals comes mostly from the fact that there are no appropriate sources for the peroxy radicals. The other oxy radical, alkoxy radicals, can be produced by the thermal or photochemical decomposition of dialkyl peroxides,[2] alkyl hypohalites,[3] peroxy oxalates,[4]

1) W. A. Pryor, "Free Radicals," McGraw-Hill Book Co., New York (1966), Chap. 12; K. U. Ingold, International Symposium on Free Radicals in Solution, Ann Arbor, Mich,. Aug., 1966.

or hyponitrites.[5]

The absolute rate constants for the propagation step in the autoxidation of hydrocarbons, k_p, can be determined by either the rotating sector method[6] or the thermocouple method.[7] However, the reactivities of the hydrocarbons toward the peroxy radicals obtained from the absolute rate constants ate those toward the peroxy radicals derived from the hydrocarbons themselves, and the reactivities of the various hydrocarbons toward a specific peroxy radical can not be obtained.

Recently, the cooxidation method has been used in order to get information on this subject. By performing the cooxidations of binary mixtures of standard hydrocarbon and various hydrocarbons, relative reactivities can be obtained from the values of the reactivity ratios. Furthermore, the reactivities and selectivities of the various peroxy radicals may also be obtained from the reactivity ratios together with the knowledge of the absolute k_p values.

Thus, the reactivity ratios are understood to be very important, and several workers have tried to determine them. However, the precise determination of the reactivity ratios is very hard, and some of the values thus far reported are suspect. This paper will present an improved method for the determination of the reactivity ratios from the rates of cooxidation and will discuss the several methods thus far reported.

Results

Cooxidation of Cumene and Tetralin. When this work was started, the reactivity ratios, r, in the cooxidation of cumene (C) and tetralin (T) had been reported to be $r_c=0.043$ and $r_T=16$ at 90°C by Russell,[8] $r_T=10$ at 60°C by Alagy *et al.*,[9] and $r_C=0$ and $r_T=2.5$ at 60°C in a benzene solution by Russell and Williamson.[10] These values seemed inconsistent, and so the cooxidation of this binary system was reinvestigated in order to obtain reliable r values from the rates of cooxidation.[11]

In the oxidation of the binary mixtures of cumene and tetralin, the following six propagation steps and three termination steps are involved:

$$\begin{aligned}
&\text{Propagation:}\quad C\cdot + O_2 \rightarrow CO_2\cdot\\
&\qquad\qquad T\cdot + O_2 \rightarrow TO_2\cdot\\
&\qquad\qquad CO_2\cdot + CH \rightarrow COOH + C\cdot \qquad k_{CC}\\
&\qquad\qquad CO_2\cdot + TH \rightarrow COOH + T\cdot \qquad k_{CT}\\
&\qquad\qquad TO_2\cdot + TH \rightarrow TOOH + T\cdot \qquad k_{TT}\\
&\qquad\qquad TO_2\cdot + CH \rightarrow TOOH + C\cdot \qquad k_{TC}\\
&\text{Termination:}\quad CO_2\cdot + CO_2\cdot \rightarrow \left.\begin{matrix}\\ \\ \end{matrix}\right\} \text{non-radical products} + O_2 \qquad k_{tCC}\\
&\qquad\qquad CO_2\cdot + TO_2\cdot \rightarrow \qquad\qquad\qquad\qquad\qquad\quad 2k_{tCT}\\
&\qquad\qquad TO_2\cdot + TO_2\cdot \rightarrow \qquad\qquad\qquad\qquad\qquad\quad k_{tTT}
\end{aligned}$$

The steady-state treatment gives the following rate equation:[14]

$$-\frac{dO_2}{dt}=\frac{(r_C[C]^2+2[C][T]+r_T[T]^2)R_i^{1/2}}{(r_C^2\delta_C^2[C]^2+2\phi r_C r_T\delta_C\delta_T[C][T]+r_T^2\delta_T^2[T]^2)^{1/2}} \tag{1}$$

where: $r_c = k_{CC}/k_{CT}$, $r_T = k_{TT}/k_{TC}$, $\delta_C = (2k_{tCC})^{1/2}/k_{CC}$, $\delta_T = (2k_{tTT})^{1/2}/k_{TT}$, $\phi = k_{tCT}/(k_{tCC}k_{tTT})^{1/2}$.

It was confirmed that the rates of the cooxidation of cumene and tetralin were independent of the oxygen pressure above 150 mmHg and were proportional to the square root of the initiator concentrations; this demonstrates that only peroxy radicals are involved in the termination reactions and that Eq. (1) is obeyed under the reaction conditions employed.

The reactivity ratios were determined from the rates of cooxidation. Equation (1) has three unknown factors, r_c, r_T and ϕ. The expression:

$$F(r_C, r_T, \phi) = Ar_C^2 + Br_Cr_T\phi + Cr_Cr_T + Dr_T^2 + Er_C + Fr_T + G = 0 \tag{2}$$

where: $A = V\delta_C^2[C]^2-[C]^4$, $B = 2V\delta_C\delta_T[C][T]$, $C = -2[C]^2[T]^2$, $D = V\delta_T^2[T]^2-[T]^4$, $E = -4[C]^3[T]$, $F = -4[C][T]^3$, $G = -4[C]^2[T]^2$, $V = (-dO_2/dt)^2/R_i$,

14) E. Niki, Y. Kamiya and N. Ohta, *Kogyo Kagaku Zasshi* (*J. Chem. Soc. Japan, Ind. Chem. Sect.*), **70**, 42, 1679 (1967). A statistical factor of 2 is included in the cross termination rate constant, k_{tCT}. The definition of $\phi=k_{tCT}/2(k_{tCC}k_{tTT})^{1/2}$ instead based on the treatment of Flory gives the same rate equation.

can be derived from Eq. (1). The runs performed with various initial mixture compositions all give Eq. (2) with various values for each coefficient, A to G. The three unknowns can be calculated from each combination of the three equations, F_1, F_2, and F_3. By eliminating the term $r_c r_T \phi$ and then the term r_T^2, r_T can be expressed with r_C (Eq. (3)):

$$r_T = (u_1 r_T^2 + u_2 r_T + u_3)/(u_4 r_T + u_5) \quad (3)$$

where: $u_1 = a(D_1B_3 - D_3B_1) - d(A_1B_3 - A_3B_1)$,

$u_2 = e(D_1B_3 - D_3B_1) - d(E_1B_3 - E_3B_1)$,

$u_3 = g(D_1B_3 - D_3B_1) - d(E_1B_3 - E_3B_1)$,

$u_4 = -c(D_1B_3 - D_3B_1) + d(C_1B_3 - C_3B_1)$,

$u_5 = -f(D_1B_3 - D_3B_1) + d(F_1B_3 - F_3B_1)$,

$a = A_1B_2 - A_2B_1$, $c = C_1B_2 - C_2B_1$,

$d = D_1B_2 - D_2B_1$, $e = E_1B_2 - E_2B_1$,

$f = F_1B_2 - F_2B_1$, $g = G_1B_2 - G_2B_1$.

The substitution of r_T thus obtained into the equation obtained by eliminating the term $r_C r_T \phi$ yields the fourth-degree equation of r_C (Eq. (4)), which can be solved by substitution or by Newton's method:

$$G(r_C) = v_1 r_C^4 + v_2 r_C^3 + v_3 r_C^2 + v_4 r_C + v_5 \quad (4)$$

where: $v_1 = au_4^2 + cu_1u_4 + du_1^2$,

$v_2 = 2au_4u_5 + cu_2u_4 + cu_1u_5 + 2du_1u_2 + eu_4^2 + fu_1u_4$,

$v_3 = au_5^2 + cu_3u_4 + cu_2u_5 + du_2^2 + 2du_1u_3 + 2eu_4u_5 + fu_2u_4 + fu_1u_5 + gu_4^2$,

$v_4 = cu_3u_5 + 2du_2u_3 + eu_5^2 + fu_3u_4 + fu_2u_5 + 2gu_4u_5$,

$v_5 = du_3^2 + fu_3u_5 + gu_5^2$.

The values of u_i and v_i are functions of [C], [T], δ_C, δ_T, R_i and the rates of oxygen absorption. The substitution of r_C obtained from Eq. (3) gives r_T. Thus, from each of the combination of the three runs performed, r_C and r_T are obtained. The values for r_C and r_T numbering, ${}_nC_3$, can be obtained by performing the cooxidations with n different compositions.[15]

The values of δ were calculated from the rate equation for the oxidation of neat hydrocarbon, RH (Eq. (5)):

$$-dO_2/dt = k_p(2k_t)^{-1/2}[RH]R_i^{1/2} + R_i(1/e - 1)/2 \quad (5)$$

The second term on the right hand of Eq. (5) is the correction for the nitrogen and oxygen evolved and is absorbed in the initiation and termination steps, e being the efficiency of the initiator. The values of 1.52×10^{-4} sec^{-1} and 0.65 were taken for k_t and e respectively at 80°C. The rates of the oxidation of pure cumene and tetralin at 80°C in the presence of 1.00×10^{-2} M of AIBN were 6.00×10^{-5} and 1.09×10^{-4} M/sec respectively, while values of 166 and 94.5 (M sec)$^{-1/2}$ were obtained for δ_C and δ_T respectively. The rates of the cooxidation of cumene and tetralin at 80°C are shown in Table 1.

TABLE 1. RATES OF COOXIDATIONS OF CUMENE AND TETRALIN[a]

Cumene M	Tetralin M	$-dO_2/dt \times 10^5$ M/sec	ϕ[b]
0.00	7.35	10.9	
2.40	4.90	7.72	4.12
3.60	3.68	6.13	4.38
4.80	2.45	4.69	4.39
6.00	1.23	3.49	4.40
6.55	0.668	3.17	4.41
7.20	0.00	6.00	

a) 80°C, [AIBN] = 1.00×10^{-2}M.
b) See text.

Examples of the solution of Eqs. (4) and (3) are shown in Fig. 1. Thus, the reactivity ratios were obtained as 0.21 ± 0.01 and 5.0 ± 0.1 for r_C

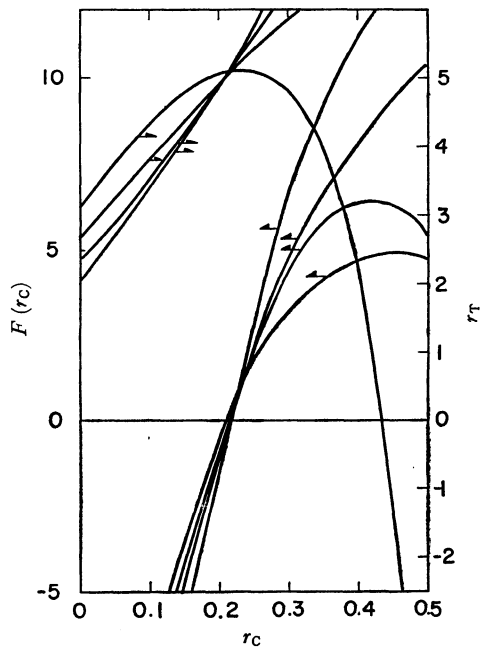

Fig. 1. Determination of r values in the cooxidation of cumene (C) and tetralin (T), 80°C.

15) Alagy *et al.*[9] determined r values from the rates of cooxidation for the first time. They eliminated the term $r_C r_T \phi$ alone to obtain a group of quadratic equations of r_C *vs.* r_T, whose positive intersections being the solution. However, the drawing of the conics is troublesome. On the contrary, in the procedures presented in this paper, the values of two reactivity ratios can be obtained directly from the computer, more easily and more accurately.

and r_T respectively. These values seem reasonable compared with those of Mayo *et al.*[12] and Howard *et al.*[13] reported recently. Equation (1) can be solved for ϕ from a knowledge of the values of r_C and r_T, the two hydrocarbon concentrations, the rate of initiation, and the rate of oxidation. The results are shown in Table 1. A weighed average of 4.3 was taken as the value of ϕ.[16]

Cooxidation of Styrene and Tetralin. The cooxidation of styrene (S) and tetralin (T) was performed at 70°C under an atmospheric pressure of oxygen. This system was employed in order to establish the validity of our rate method for determining the reactivity ratios. Styrene[17] and tetralin are useful hydrocarbons since both of them produce secondary peroxy radicals whose termination reactions are simple compared with those of tertiary peroxy radicals; moreover, as will be discussed below, this system is suitable for the determination of the reactivity ratios by means of product analyses.

Table 2. Rates of cooxidation of styrene and tetralin[a]

Styrene M	Tetralin M	$-dO_2/dt \times 10^5$ M/sec	Kinetic chain length	$(M\,sec)^{-1/2}$	ϕ[b]
8.75	0.00	14.0	272	44.8	
7.30	1.23	10.6	206		3.08
5.83	2.45	8.26	160		2.84
3.50	4.41	4.82	93.5		3.95
2.92	4.90	4.35	84.5		3.95
1.46	6.13	3.54	68.8		3.94
0.795	6.68	3.42	66.5		3.96
0.00	7.35	3.95	76.7	130	

a) 70°C, [AIBN] = 1.00×10^{-2}M.
b) Calculated assuming $r_S = 2.7$ and $r_T = 0.49$.

The rates of the cooxidations of styrene and tetralin are summarized in Table 2. A rate minimum is again observed in this system. The values of 2.7 and 0.49 were obtained for r_S and r_T respectively from the results in Table 2 by a treatment similar to that used for the system of cumene and tetralin. The value of ϕ was obtained as 3.9.

The reactivity ratios in this styrene-tetralin system were also determined by product analyses. In order to avoid high conversions of the oxidants, the oxygen uptake and the hydroperoxide formation were measured by the use of a gas buret and by the iodometric titration of the Wibaut method[18] respectively. The amount of styrene reacted was taken as the difference between the oxygen uptake and the hydroperoxide formed, the latter corre-

sponding to the disappearance of tetralin. The oxidation products of styrene are mostly styrene polyperoxide, plus small amounts of benzaldehyde and formaldehyde, under an atmospheric pressure of oxygen and with a long kinetic chain length.[17] The Wibaut method[18] gave little titer for polyperoxide, while the tetralyl hydroperoxide could be determined quantitatively (Table 3). This procedure was first employed by Mayo and his coworkers for the cooxidation of styrene and cumene.[12] The results are summarized in Table 3. The oxidations were performed up to a conversion of approximately 4% based on the oxygen uptake, where 2—7% of the initial hydrocarbons were oxidized. The results in Table 3 were treated by means of the Mayo-Lewis method[19] and the Fineman-Ross method,[20] which are shown in Figs. 2 and 3.

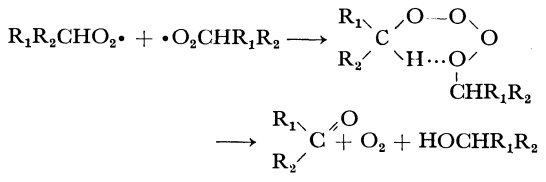
The r values obtained from the Mayo-Lewis method show considerable scatter. This must be mostly because the conversions of both hydrocarbons are very small where, as will be discussed later, a small error in the final concentrations of the hydrocarbons causes a large error in the r values. A Fineman-Ross plot gave the values of 3.3 and 0.49 for r_S and r_T respectively. These values are in reasonably good agreement with those obtained from the rates of cooxidation. Although the conversions were kept low, there still remains some possibility that some loss of precision is involved due to the complicated chain-transfer reaction of tetralyl hydroperoxide with the polystyrylperoxy radical.[21] On the other hand, the reactivity ratios can be determined from the rates of cooxidation at the initial stage of the oxidation.

Discussion

The merits and demerits of several methods for the determination of the reactivity ratios will be discussed in this section.

Determination from the Rates of Cooxidation. The merits of this method are, first, the rates of oxygen absorption can be measured quite easily and accurately, and secondly, they can be obtained at the initial stage of the oxidation. In the present work, the conversions of both hydrocarbons are about only 1% or less. These merits will become more obvious hereafter.

One of the difficulties comes from the complicated termination reactions. The chain termination reactions by secondary and primary peroxy radicals are now fairly well understood to proceed *via* the following cyclic transition state:[22]



The bimolecular interactions of tertiary peroxy radicals, lacking α-hydrogen, are complicated and have been studied intensively by many investigators recently.[23] As for the interaction between cumylperoxy radicals, it is assumed to produce oxygen and two cumyloxy radicals, a minor portion of which recombines in the cage to form dicumyl peroxide, while the rest undergoes cleavage reaction to give acetophenone and methyl radical. The methylperoxy radical produced from the methyl radical participates in the terminating reaction. This method of determining r values assumes that ϕ is a constant. However, as has been pointed out by Mayo,[12] the ϕ concept is an arbitrary one, and if the methylperoxy radical plays a significant part in the chain termination reaction, the three termination steps listed above may not be enough in themselves and so this method may be unreliable.

The absolute rate constants in the oxidations of cumene[7,13,23-26] and tetralin[27,28] have been de-

termined and the extrapolated values of $k_{CC}=1.4$, $k_{tCC}=2.8\times10^4$, $k_{TT}=41$, and $k_{tTT}=9.8\times10^6$ M^{-1} sec^{-1} are obtained at 80°C. The other rate constants in the cooxidation of cumene and tetralin can be calculated by the use of these absolute rate constants, the two reactivity ratios, and the ϕ value. They are $k_{CT}=6.7$, $k_{TC}=8.2$, and $k_{tCT}=2.3\times10^6$ M^{-1} sec^{-1}. From the four propagation rate constants, $k_{TC}/k_{CC}=5.9$ and $k_{TT}/k_{CT}=6.1$; this implies that the tetralylperoxy radical is approximately 6 times as reactive as the cumylperoxy radical toward cumene and tetralin.[29] The steady state concentrations of cumylperoxy and tetralylperoxy radicals can be calculated from Eqs. (6) and (7):

$$[CO_2\cdot] = k_{TC}[C]R_t^{1/2}/(2k_{tCC}k_{TC}^2[C]^2 + 4k_{tCT}k_{CT}k_{TC}[C][T] + 2k_{tTT}k_{CT}^2[T]^2)^{1/2} \quad (6)$$

$$[TO_2\cdot] = k_{CT}[T][CO_2\cdot]/k_{TC}[C] \quad (7)$$

In Fig. 4, the calculated concentrations are plotted against the hydrocarbon compositions, while Fig. 5 shows the rates of each of the four propagation steps. The rates of the individual termination reaction can be computed using the values of the peroxy radical concentrations and the absolute rate constants. The results are shown in Fig. 6. These figures show that the contribution of the bimolecular interaction of cumylperoxy radicals in the chain termination is small even when the concentration of the cumylperoxy radicals is much larger than that of the tetralylperoxy radical; for example, at the 0.90 molar fraction of cumene, the cumylperoxy radical is richer than the tetralylperoxy radical by a factor of 12, but the relative importance of the interaction of cumylperoxy radicals is only 5%, and 80% of the termination is performed by the reaction between cumylperoxy and tetralylperoxy radicals. The crossed interaction

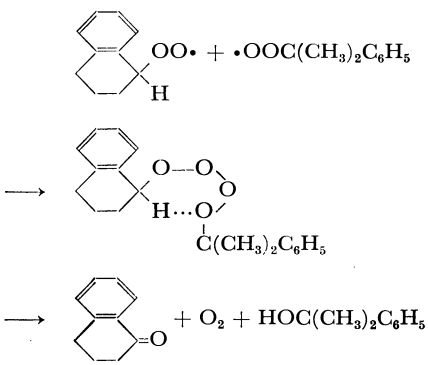
a: $[CO_2\cdot]$, b: $[TO_2\cdot]$, c: $[CO_2\cdot]+[TO_2\cdot]$

between cumylperoxy and tetralylperoxy radicals is assumed to proceed as follows to really terminate chains without any cleavage reaction to form the methyl radical.[31] Thus, the ϕ value may well be assumed to be constant when the concentration of tetralin is more than 10%.



The effects of error in the determination of the reactivity ratios from the rates of cooxidation were examined. Table 4 shows how a 10% error in r values affects the rates of cooxidation. It was confirmed that every group of the calculated rates of cooxidation in Table 4 gave the assumed r values. Since the plots of the oxygen uptake against the time gave an excellent straight line at the initial stage of the oxidation with satisfactory reproducibility, and since it is not difficult to obtain the rates of oxidation within an experimental error of 10%, accurate r values are expected to be obtained from the rates of cooxidation.

27) J. A. Howard and K. U. Ingold, *Can. J. Chem.*, **44**, 1119 (1966).
28) C. H. Bamford and M. J. S. Dewar, *Proc. Royal Soc.*, **A198**, 252 (1949).
29) If the reactivities of the peroxy radicals, ROO·, are independent of the structure of R, the product of two reactivity ratios is unity. However, it must be noteworthy that the product of two r values being unity does not always imply the identical reactivities of the peroxy radicals independent of their nature. Even if the reactivities are different, the product of two r values can be unity when the *relative* reactivities of the peroxy radicals are same toward the hydrocarbons. Ingold and his collaborators[27,30] suggest that the differences in the reactivities of the peroxy radicals are due to steric factors. But the difference in the electron affinity of the peroxy radicals may be responsible in part.
30) B. S. Middleton and K. U. Ingold, *Can. J. Chem.*, **45**, 191 (1967).
31) A large value of ϕ may also support this concept.

It was found, however, that when the curve obtained by plotting the rates of oxidation against the hydrocarbon compositions is uneven, a small error in the rate will produce a large error in the reactivity ratios. Figure 7 shows a plot obtained by assuming that Nos. 1,3, and 5 in Table 4 have −10%, +10% and −5% errors respectively in the rates of oxidation. The curve, as may be seen, is uneven. The calculation of the reactivity ratios from Eqs. (4) and (3) using these values gave poor results. For example, Nos. 1, 2 and 4 gave the values of 0.06 and 2.0 for r_C and r_T respectively, while Nos. 1, 3, and 4 gave 0.0 and 0.6. It was also found that the smaller the curvature of the plot, the larger the effects of error in the rate of oxidation on the reactivity ratios (see No. 5 in Table 4).

The above discussion suggests that the determination of the reactivity ratios from the rates of cooxidation is reliable and useful if a smooth plot is obtained between the rates of cooxidation and hydrocarbon compositions and if the curvature is

large, preferably when the rate minimum is observed.

Mayo-Lewis Method.[19] This method was derived from the copolymerization equation[32] and was first applied to the cooxidations of benzaldehydes by Walling and McElhill.[33] The initial and final concentrations of both hydrocarbons must be known. The two initial concentrations can be calculated, and the final concentrations are measured experimentally either by analyzing them directly by means, for example, of gas-liquid chromatography or by analyzing the products. Russell and Williamson[10] determined the reactivity ratios for many systems by making use of this method. However, in most cases employed, the reactivity ratios show considerable scatter. The best results were obtained for the system of cumene and *cis*-decalin. Table 5 shows their results and also some values calculated assuming that the errors indicated in the eighth column are involved. The solutions of the results in Table 5 by using the integrated form of the Mayo-Lewis method are shown in Fig. 8, which indicates that a small error

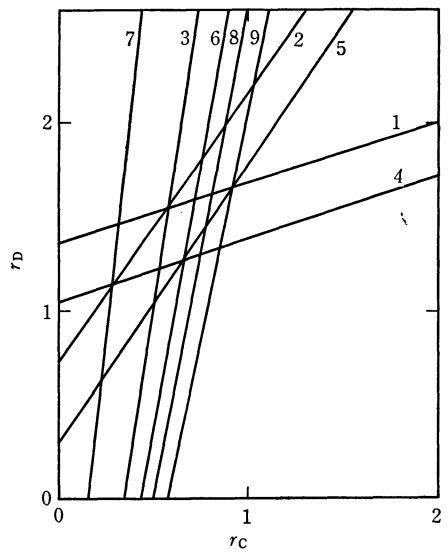

Fig. 8. Cooxidations of cumene (C) and *cis*-decalin (D), 60°C.

will produce a large error in r values. Experimentally, the values of $r_C=0.58$ and $r_D=1.56$ are obtained, but when one of the three concentrations contains an error of 5%, the values of r_C and r_D are 0.70 and 1.7 (Nos. 1, 2, 6); 0.69 and 1.4 (1, 3, 5); 0.48 and 1.3 (2, 3, 4), and 0.39 and 1.4 (1,2,7) respectively. Thus an error of only 5% in one of the three systems will produce a 10—30% error in the reactivity ratios. Furthermore, analyses by gas-liquid chromatography are usually apt to involve a greater error. When the conversions of the hydrocarbons are small, this analytical error may be more critical.

On the other hand, if the oxidation advances and hydroperoxides are built up considerably, the following cross induced decomposition of hydroperoxides by the peroxy radicals complicates the kinetic scheme. The work by Thomas and Tolman[25] and by Howard, Schwalm, and Ingold[13] indicates the possibilities of these reactions:

$$\mathrm{AOOH} + \mathrm{BOO\cdot} \longrightarrow \mathrm{AOO\cdot} + \mathrm{BOOH}$$
$$\mathrm{BOOH} + \mathrm{AOO\cdot} \longrightarrow \mathrm{BOO\cdot} + \mathrm{AOOH}$$

In order to reduce this difficulty, Hendry[34] devised a new technique in which the consumption of the more reactive hydrocarbon and the oxygen uptake are measured. This procedure is especially attractive in cases where reactants have large differences in reactivity. However, even in this procedure, the conversion of the more reactive hydrocarbon is more than 10%, generally between 20—25%.[34]

b) Assumed.

Fineman-Ross Method.[20] This method was also derived from the copolymerization equation. A limitation of this method is that this can be used only when the conversions of both oxidants are small enough so that the decrease in the concentrations is negligible compared with their initial concentrations. The determination of the variation in the reactants at the very initial stage is very difficult.

Hydroperoxide Method. Recently, Howard, Schwalm, and Ingold[13] proposed a new method for the determination of the reactivity ratios. They

32) F. R. Mayo and C. Walling, *Chem. Revs.*, **46**, 191 (1950).
33) C. Walling and E. A. McElhill, *J. Am. Chem. Soc.*, **73**, 2927 (1951).
34) D. G. Hendry, International Oxidation Symposium, San Francisco, Calif., Aug., 1967.

have oxidized one hydrocarbon in the presence of hydroperoxide derived from another hydrocarbon. In the oxidation of the system of AH plus BOOH, the following elementary steps are involved:[13]

$$\mathrm{AH} \longrightarrow \mathrm{A}\cdot \qquad R_i = \text{Rate of initiation}$$

$$\mathrm{A}\cdot + \mathrm{O_2} \longrightarrow \mathrm{AOO}\cdot$$

$$\mathrm{AOO}\cdot + \mathrm{BOOH} \longrightarrow \mathrm{AOOH} + \mathrm{BOO}\cdot \qquad k_{\mathrm{ABOOH}}$$

$$\mathrm{BOO}\cdot + \mathrm{AH} \longrightarrow \mathrm{BOOH} + \mathrm{A}\cdot \qquad k_{\mathrm{BA}} \ (\ll k_{\mathrm{ABOOH}})$$

$$2\,\mathrm{BOO}\cdot \longrightarrow \text{non-radical products} \qquad k_{t\mathrm{BB}}$$

A steady state treatment gives the following rate equation:

$$-\mathrm{d}O_2/\mathrm{d}t = k_{\mathrm{BA}}[\mathrm{AH}]R_i^{1/2}/(2k_{t\mathrm{BB}})^{1/2} \qquad (8)$$

Since [AH], R_i, and $k_{t\mathrm{BB}}$ are known, k_{BA} can be calculated by measuring the rate of oxidation. If k_{BA} is known, r_{B} can be calculated with the value of k_{BB}, which can be measured separately.

Howard *et al.*[13] assumed that the termination reaction is solely by the interaction of the peroxy radicals which were derived from the hydroperoxide. However, there remains some possibility that a cross termination reaction by AOO· and BOO· radicals as well as the bimolecular interaction of BOO· radicals may also be important, especially when the latter is much slower than the former. Actually, in a mixture of tetralin and cumyl hydroperoxide, the cross termination between cumylperoxy and tetralylperoxy radicals is calculated, from the concentrations of both peroxy radicals and the absolute rate constants, to compose up to 30% of the total. Another limitation is that this method is applicable only for the peroxy radicals whose incipient hydroperoxides can be isolated.

In conclusion, the method for the determination of the reactivity ratios must be carefully chosen depending on the systems. When the rates of cooxidation are plotted against the reactant compositions, three types of lines are obtained: a large curvature, a gently-sloping curve, and a straight line. In cases where a large curvature, preferably a rate minimum, is observed and a smooth line is obtained, the determination from the rates of cooxidation may be most suitable. In other cases, the use of the copolymerization equation may be preferable. A direct determination of the reactants by gas-liquid chromatography is not appropriate, and the measurements of the oxygen uptake and/or hydroperoxide formed, and the analyses of hydroperoxides are more suitable when the copolymerization equation is used. The hydroperoxide method may be valid for some systems.

Experimental

Cumene and tetralin were shaken successively with sulfuric acid, water, alkali, and water, dried with calcium chloride, and then distilled under reduced pressure of nitrogen. Styrene was washed with alkali and then with water, dried, and distilled under reduced pressure of nitrogen. All the hydrocarbons were passed down the activated alumina column immediately before use. Azobisisobutyronitrile was recrystallized from methanol several times. Oxygen was used without further purification.

The rate of oxygen absorption was measured by a manometer in a constant pressure closed system. Stirring was accomplished by means of a magnetic stirrer with a Teflon-coated stirring bar. The volume of oxygen absorbed was read periodically, every one or two minutes, depending on the rate, and was plotted against the time. In every run, more than fifteen points were plotted. No induction period was observed, and a straight line was obtained. The slope was read and was taken as the rate of oxidation. The cell was cleaned by washing successively with a solution of $K_2Cr_2O_7$ plus concentrated sulfuric acid, ammonia, water, acetone, and methanol, and then dried. Hydroperoxide was determined by iodometric titration, the Wibaut method,[18] where hydroperoxide was treated with KI in 80% acetic acid at room temperature.

The calculation was done at the Data Processing Center of the University of Tokyo using a OKITAC 5090 computer.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 521—527 (1969)

The Synthesis of Regular Copolymers of Glycine and Alanine

Sho TAKAHASHI*1

Department of Physics, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya

(Received July 8, 1968)

The synthesis of polypeptides with a repeating sequence of glycines and L-alanines, *i. e.*, poly-(L-Ala-Gly-Gly), poly-(L-Ala-L-Ala-Gly), and poly-(L-Ala-L-Ala-L-Ala-Gly), are reported. Polymerization was achieved by a self-condensation of *p*-nitrophenyl esters of the corresponding tri- or tetrapeptides.

In 1963, Gratzer and Doty[1] reported the remarkable stability of the α-helical conformation of poly-L-alanine. On the other hand, the simplest polyamino acid, poly-glycine, has the so-called β-conformation in the solid state, as is well known.[2] It seemed to us to be very much meaningful to study the conformation of a series of copolymers made from glycine and alanine, since the interactions between their side chains were the simplest to interpret theoretically. To analyze the problem unambiguously, the glycine-alanine copolymers must be sequential. (It has been shown by Nylund and Miller[3] that different monomer reactivity ratios are observed between the beginning and the close of the random copolymerization of glutamic acid- and leucine-*N*-carboxy anhydride). In this paper, we wish to report the synthesis of sequential polypeptides consisting of glycine and L-alanine.

Efforts to obtain sequential copolymers of glycine and alanine have been made by many workers, such as the attempt to get poly-(L-alanyl-glycyl-glycine) from methyl L-alanyl-glycyl-glycinate by Fischer[4] and those to get poly-(D,L-alanyl-glycyl-glycine) from the analogous tripeptide methylester or thiophenylester by Wilson and Pascu[5] and Schramm *et al.*[6] Other references are cited in the review by Katchalsky and Sela.[7] These polymers, however, had rather low molecular weights, and the reproducibility was poor. It was necessary to carry out self-condensation reactions at elevated temperatures because of the relatively low reactivity of peptide alkylesters.

In the past few years, several papers related to the synthesis of sequential polymers of other amino acids have appeared. The methods which have been reported may be classified into two categories: (a) the treatment of a free peptide in solution with a suitable condensing agent (dicyclohexylcarbodiimide,[8a-c] tetraethylpyrophosphite,[8c,9] pyrophosphoric acid,[10] and ethyl metaphosphate[11] have been used as condensing agents.) and (b) the self-condensation of peptide, one of whose terminals has been activated by an adequate substituent towards the attack of the other terminal of another molecule. Noguchi[12] developed the *N*-carbothiophenyl amino acid method and synthesized poly-(L-alanyl-glycine), which has also been synthesized recently by Australian workers.[13a] An active ester method has also been applied; the results are

satisfactory with peptide *p*-nitrophenyl esters[13b,14] or pentachlorophenyl esters.[15]

We selected the *p*-nitrophenyl ester method for the synthesis of sequential polymers of glycine and L-alanine. The principles of the synthesis of such regular polypeptides with high molecular weights are the following: (1) the number of amino acids which build up a polymerization unit must be three or more in order to exclude a primary intramolecular cyclization, since dipeptides may form six-membered ring compounds (diketopiperazine derivatives); (2) in order to avoid an intramolecular cyclization, a satisfactory concentrated solution of reactants must be used.

Results

Synthesis of Polymerizing Units. In order to avoid racemization yielding peptide bonds during the course of the condensation reaction, we always used the so-called azide method if L-alanine was present in a position where the reaction occurred. The azide method is one of the two methods which have been recommended for the coupling of amino acids without racemization[16] (the other one[17] is coupling through 1-hydroxy-piperidine esters). Figure 1 outlines the synthetic steps for the required derivatives of tri- and tetra-peptides.

L-Alanine was ethylated in ethanol saturated with hydrogen chloride, and then converted into the hydrazide of carbobenzoxyalanine according to the method described by Erlanger and Brand.[18] The azide coupling of II with ethyl glycyl-glycinate hydrochloride, which has been derived from the ethanolysis of diketopiperazine (IV) in the presence of hydrogen chloride,[19] gave the ethyl ester of carbobenzoxy-L-alanyl-glycyl-glycine (III). The compound III was also obtained from step-by-step synthesis through the compound VI[18,20] and compound VII. The compound III was hydrolyzed with a slight excess of sodium hydroxide in aqueous methanol; this afforded a free acid (VIII) which was then converted into *p*-nitrophenyl ester (IX) by the use of dicyclohexylcarbodiimide as the condensing agent. Recently, Kovacs[15] recommended the use of a pentachlorophenyl ester instead of a *p*-nitrophenyl ester as the active ester for polymerization, since a pentachlorophenyloxy group is probably a more electron-attracting group than a *p*-nitrophenyloxy group; these catalytic hydrogenation will be used in contrast to the case of a *p*-nitrophenyl ester. We also tried to synthesize a pentachlorophenyl ester of VIII from VIII and pentachlorophenol using dicyclohexylcarbodiimide, but the surprisingly low solubilities of the ester towards general solvents made it very difficult to purify the crude ester. The carbobenzoxy group of the compound IX was smoothly eliminated in the usual manner in acetic acid half-saturated with hydrogen bromide, and the resulting *p*-nitrophenyl-L-alanyl-glycyl-glycinate was recrystallized enough times to obtain a high-molecular-weight polymer.

p-Nitrophenyl L-alanyl-L-alanyl-glycinate hydrobromide and *p*-nitrophenyl (L-alanyl)$_3$-glycinate hydrobromide were synthesized in the same manner. Of the derivatives appearing in Fig. 1, mention should be made of the remarkable crystallizability of the compound XVI. It gave large needles very easily in the presence of a small amount of methanol, even if we started from crude, half-crystalline XV. Elementary analysis confirmed the presence of one mole of methanol as a methanol of crystallization.

Initially we tried to synthesize a *p*-nitrophenyl ester of carbobenzoxy-L-alanyl-(glycyl)$_3$ through a free acid, XXVIII, but the ethyl ester, XXII, showed a striking resistance towards hydrolysis under usual conditions, in great contrast with the other cases.[21] For instance, when treated with 1.3 molar sodium hydroxide in methanol, analogous ethyl esters, III, XIII, and XVIII, were hydrolyzed completely within 20 min. On the contrary, 90% or more of XXII was present even after 48 hr under the same conditions (as confirmed by an infrared spectral analysis). Also, the isobutyl ester, XXVII, was not hydrolyzed. In these cases, the prolonged treatment of the XXII or XXVII esters with alkali or treatment under more drastic conditions resulted in the simultaneous elimination of the carbobenzoxy group. The effort to obtain a *t*-butyl ester of XXVIII from VIII and *t*-butyl glycinate[22] failed; the oily crude material resisted further purification. A *p*-toluenesulfonic acid-catalyzed ester-interchange reaction between XXII or XXVII and a large excess of *p*-nitrophenol in

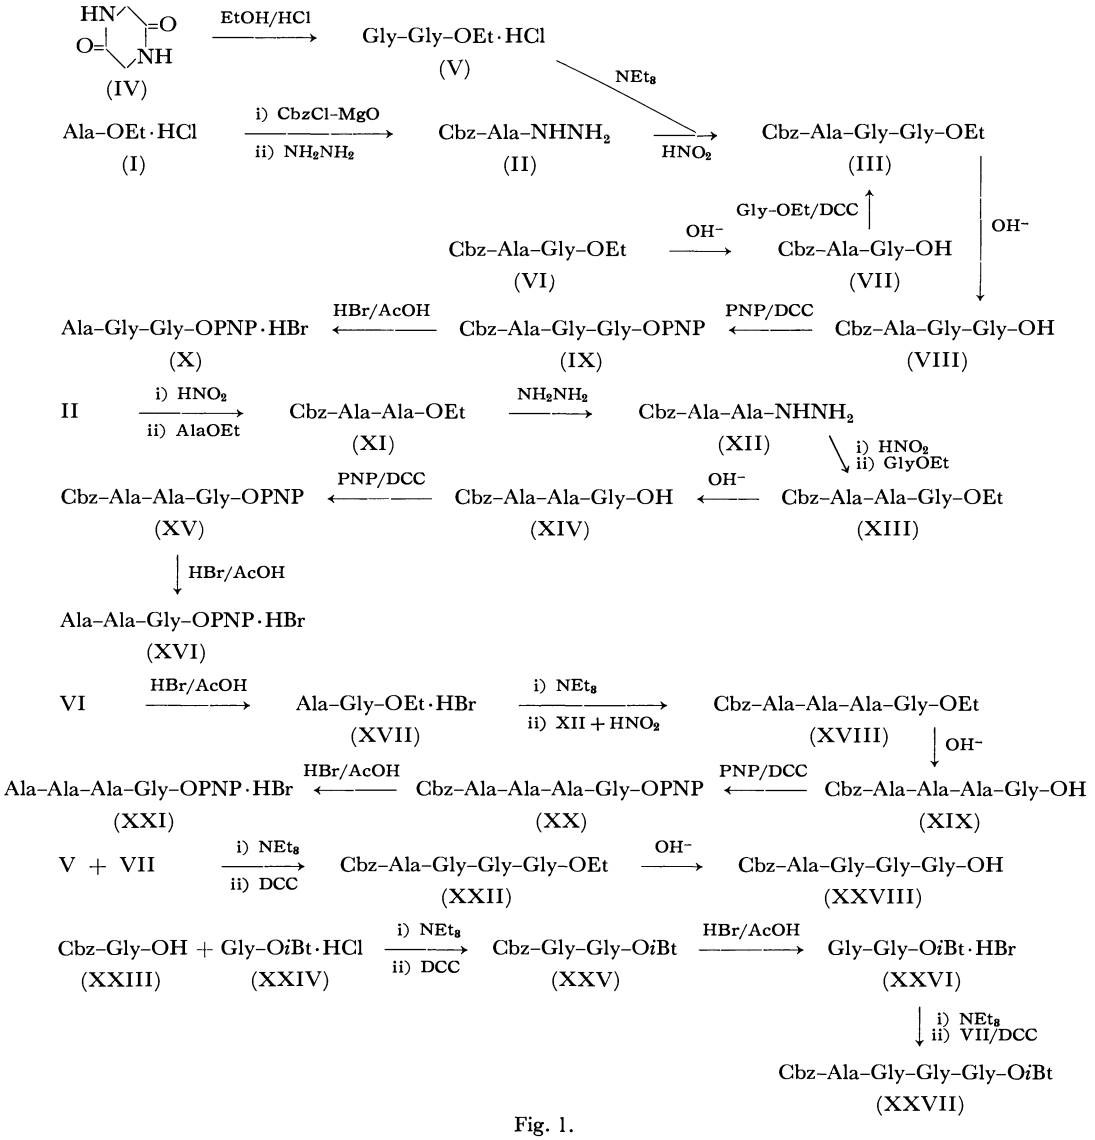

Fig. 1.

tetrahydrofuran also resulted in the accompanying destruction of the carbobenzoxy group.

Polymerization. Polymerization was achieved successfully in dimethyl sulfoxide as the solvent. 30—40% solutions of X, XVI and XXI were reacted with equimolar amounts of triethylamine. The yields of the polymers were in the range of 30—40% of the theory.

Molecular-weight Determinations. Since the polymers dissolved only in dichloroacetic acid or in trifluoroacetic acid, we met very great difficulty in determining the molecular weights of the polymers. Measurements using the ultracentrifuge were impossible because such solvents would corrode the cells.

If we assume the Doty's viscosity-molecular-weight relationships[23] which were obtained in the case of poly-benzyl-L-glutamate in dichloroacetic acid, to be valid in our case also, we can estimate the order of the molecular weights of our polymers by measuring the intrinsic viscosity in dichloroacetic acid. Such measurements give the values of 30000, 35000, and 20000 as the molecular weights for poly-Ala-Gly-Gly, poly-Ala-Ala-Gly, and poly-Ala-Ala-Ala-Gly respectively. There must be, of course, some slight modifications of the coefficient appearing in Doty's viscosity-molecular weights relationship, and the relationship remains to be established for other peptides, but the results obtained above will

23) P. Doty, J. H. Bradbury and A. M. Holtzer, *J. Am. Chem. Soc.*, **78**, 947 (1956).

be not so incredible as a first-order approximation if we remember that most polypeptides exist in the form of a random-coil conformation in dichloroacetic acid (except in the case of poly-L-leucine).[24] For instance, Kovacs calculated the molecular weight of his poly-Glu-Ala-Glu to be 25000 by the sedimentation velocity method using the ultracentrifuge. On the other hand, his sample showed an intrinsic viscosity of 0.3 dl/g in dichloroacetic acid, a value which corresponds to MW 40000 if we apply Doty's relationship. DeTar[14a] also showed that the values obtained by this relationship for the various polymers are at least roughly comparable with those obtained by the Archibald technique or by end-group assays using the DNP method.

Problem of Racemization. It is essential to know whether a racemization reaction has occurred or not. We measured the optical rotatory dispersion curves for the acid hydrolysates of polymers and compared them with that of L-alanine treated under the same hydrolytic conditions. The results showed that the racemization was less than 5%, if it occurred at all.

Experimental

The recorded melting points are determined on a microhotstage and are uncorrected. The infrared spectra were taken with a JASCO DS-402G grating-type spectrometer or with a JASCO IR-S spectrometer with a NaCl prism mounted. The measurements were made with KBr discs. The optical rotatory dispersion measurements were made with a JASCO ORD/UV 5 recording spectropolarimeter. The azide coupling reactions were carried out in a cold room (at 2—3°C). Viscosity measurements were made at 22°C with an Ostwald type viscometer whose flow time for solvent dichloroacetic acid was about 8 min. Elementary micro analysis was carried out at the Faculty of Agriculture in this university, and the mean values of two or three times analysis are reported. The amino acids analysis was carried out with a Beckman-Spinco amino acid autoanalyzer, Model 120, using a 90 cm column. Commercially available dimethyl sulfoxide was distilled under reduced pressure, 90—92°C fraction at 28 mm/Hg was used. L-Alanine was kindly gifted from Ajinomoto Co. Inc., by the courtesy of Professor Y. Hirata.

Ethyl Carbobenzoxy-L-alanyl-glycyl-glycinate (III). *a) Azide Method.* Five grams of carbobenzoxy-L-alanine hydrazide[18] was dissolved in the mixture of 10 m*l* of 5N hydrochloric acid and 100 m*l* of water and cooled to −10°C. A cold solution of sodium nitrite (1.65 g) was added to it, then the oily azide precipitated was extracted with diethyl ether. After washing the extracts with water and 3% sodium bicarbonate and drying over sodium sulfate for a short time, the cold solution of ethyl glycyl-glycinate, which was prepared from 4.2 g of ethyl glycyl-glycinate hydrochloride (V) and 2.75 g of triethylamine in 100 m*l* of diethyl ether and applied filtration of precipitated amine hydrochloride, was added to it. The reaction mixture was stood for overnight at 2—3°C, then washed with 0.5 N hydrochloric acid and 3% sodium bicarbonate solution. The solvent was removed *in vacuo* to leave white crystalline III, which was recrystallized from ethanol. Yield, 4.2 g mp 134—136°C.

Found: C, 56.06; H, 6.11; N, 11.63%. Calcd for $C_{17}H_{23}O_6N_3$: C, 55.88; H, 6.35; N, 11.50%.

IR: 1743 (ester), 1699 (carbobenzoxy) cm^{-1}.

The compound V was prepared by the restricted ethanolysis of diketopiperazine (IV) in the presence of hydrogen chloride.[19]

b) Dicyclohexylcarbodiimide Method. Ethyl carbobenzoxy-L-ananyl-glycinate[18,20] (30 g) was hydrolyzed in 20% aqueous methanol with 130 m*l* (1.2 eq.) of 0.95 N sodium hydroxide. 23 g of the free acid (VII) was obtained as white massive crystals, and recrystallized from methanol-water, mp 129—134°C. 3.8 g of the free acid VII was dissolved in the mixture of 1.9 g of ethyl glycinate hydrochloride and 1.75 g of triethylamine in 40 m*l* of dimethylformamide. 2.8 g of dicyclohexyl-carbodiimide in 5 m*l* of dimethylformamide was then added dropwise under stirring with external cooling. The solution was stirred for 1 day at room temperature. The dicyclohexylurea was filtered off and the solvent was removed at 1 mm/Hg. The resultant solid was washed with water and recrystallized from ethanol to give the tripeptide ester III, mp 133—135°C, which was undepressed on admixture with a sample prepared by method a).

Carbobenzoxy-L-alanyl-glycyl-glycine (VIII). Ethyl carbobenzoxy-L-alanyl-glycly-gylcinate III, 10 g, was hydrolyzed by 37.4 m*l* of 0.95 N sodium hydroxide in 100 m*l* of 90% aqueous methanol. The solution was stood for 20 min and filtered. Acidification of the filtrate with 5 N hydrochloric acid to pH 1 and concentration under reduced pressure gave a solid of free acid (VIII), which was recrystallized from water. An analytical sample showed mp 163°C.

Found: C, 53.43; H, 5.61; N, 12.54%. Calcd for $C_{15}H_{19}O_6N_3$: C, 53.40; H, 5.68; N, 12.46%.

1725 (COOH), 1680 (sh. carbobenzoxy) cm^{-1}.

***p*-Nitrophenyl Carbobenzoxy-L-alanyl-glycyl-glycinate (IX).** To a cooled mixture of carbobenzoxy-L-alanyl-glycyl-glycine (VIII, 5 g), *p*-nitrophenol (2.2 g), and dimethylformamide (90 m*l*), 3.7 g of dicyclohexylcarbodiimide in 10 m*l* of dimethylformamide was added dropwise with magnetically stirring. The stirring was continued at 0°C overnight. The dicyclohexylurea was filtered off and the solvent was removed at 1 mm/Hg. On addition of diethyl ether (50 m*l*) and storage in the refrigerator, *p*-nitrophenyl ester (IX) crystallized, 4 g, mp 147—150°C. The compound was crystallized from ethanol, mp 149—152°C.

Found: C, 55.03; H, 4.81; N, 12.26%. Calcd for $C_{21}H_{22}O_8N_4$: C, 55.02; H, 4.84; N, 12.22%.

Ethyl Carbobenzoxy-L-alanyl-L-alanyl-glycinate (XIII). Ethyl carbobenzoxy-L-alanyl-L-alaninate (XI) was derived from carbobenzoxy-L-alanine hydrazide (II) and ethyl L-alaninate hydrochloride (I) by an azide method, and recrystallized from ethyl acetate–*n*-hexane, mp 115—117°C (lit.[18,25] mp 116°C). The compound (XI) was reacted with hydrazine in ethanol to afford carbobenzoxy-L-alanyl-L-alanine hydrazide (XII), which was recrystallized from ethanol, mp 211—213°C (lit.[18] mp 209°C). 10 g of XII was dissolved in the mixture of 5 N hydrochloric acid (15.5 m*l*) and water (300 m*l*), and cooled to −10°C. A solution of 2.7 g of sodium nitrite in 10 m*l* of water was then added to it, and the resultant precipitate was extracted with chloroform (150 m*l* × 2). The combined extracts were washed with water and 3% sodium bicarbonate solution and reacted with ethyl glycinate which was prepared from 7 g of ethyl glycinate hydrochloride and 6.7 g of triethylamine in 100 m*l* of chloroform. After standing overnight at 2—3°C, the reaction mixture was washed thoroughly with 0.5 N hydrochloric acid and 3% sodium bicarbonate solution. The solvent was removed under reduced pressure to give a crystalline tripeptide ethyl ester (XIII), 9.2 g, mp 170°C. Recrystallization twice from ethanol raised the mp to 177—179°C.

Found: C, 57.03; H, 6.41; N, 11.13%. Calcd for $C_{18}H_{25}O_6N_3$: C, 56.98; H, 6.64; N, 11.08%.

IR: 1742 (ester), 1683 (carbobenzoxy) cm^{-1}.

Carbobenzoxy-L-alanyl-L-alanyl-glycine (XIV). Ethyl ester XIII was hydrolyzed in aqueous methanol with 1.3 equivalent of sodium hydroxide as described in the preparation of VIII. It was recrystallized from water or dimethylformamide-chloroform, mp 205—206°C. Yield was about 85%.

Found: C, 54.64; H, 6.05; N, 11.91%. Calcd for $C_{16}H_{21}O_6N_3$: C, 54.69; H, 6.02; N, 11.96%.

IR: 1730 (broad, COOH), 1670 (carbobenzoxy) cm^{-1}.

***p*-Nitrophenyl Carbobenzoxy-L-alanyl-L-alanyl-glycinate (XV).** Five grams of dicyclohexylcarbodiimide in 10 m*l* of chloroform was added dropwise to the mixture of 5 g of the compound XIV, 2.26 g of *p*-nitrophenol, and 90 m*l* of dimethylformamide with magnetically stirring at 0°C. The reaction mixture was stirred overnight at room temperature. A half milliliters of acetic acid was added to it to destroy an excess carbodiimide and stirring was continued for another 2 hr. Dicyclohexylurea was filtered off and the solvent dimethylformamide was removed at 1 mm/Hg until a few milliliters of dimethylformamide remained. On adding 20 m*l* of chloroform and standing for a few hours, the solution separated further amounts of dicyclohexylurea. This step was repeated several times to eliminate cyclohexylurea as possible. The syrup remained was dissolved in a few milliliters of chloroform and kept in the refrigerator to give crystalline XV. Yield, 6.0 g (90% of theory). Crude material was recrystallized from methanol, mp 192—193°C.

Found: C, 55.54; H, 5.15; N, 11.94%. Calcd for $C_{22}H_{24}O_8N_4$: C, 55.93; H, 5.12; N, 11.86%.

IR: 1760 (ester), 1685 (carbobenzoxy), 1345 (NO_2) cm^{-1}.

***p*-Nitrophenyl L-Alanyl-L-alanyl-glycinate Hydrobromide (XVI).** The compound XV was dissolved in 6 m*l* of acetic acid saturated with hydrogen bromide. After the reaction had proceeded for 2 hr, excess hydrogen bromide and acetic acid were removed under reduced pressure at 40°C. The gummy residue was washed thoroughly with dry diethyl ether to be free from the traces of acid. On addition of small amount of methanol, tripeptide ester hydrobromide XVI crystallized out soon, 1.3 g, mp 172—184°C with decomposition. For the polymerization, the material was recrystallized from methanol three times, mp 180—185°C with decomposition.

Found: C, 39.79; H, 4.71; N, 11.91%. Calcd for $C_{14}H_{18}O_6N_4 \cdot HBr \cdot CH_3OH$: C, 39.92; H, 5.14; N, 12.42%.

IR: 1764 (ester), 1492 and 1355 (NO_2) cm^{-1}.

Ethyl Carbobenzoxy-L-alanyl-L-alanyl-L-alanyl-glycinate (XVIII). Ten grams of carbobenzoxy-L-alanyl-L-alanine hydrazide XII was reacted with ethyl L-alanyl-glycinate in the same condition as mentioned in the synthesis of the compound XIII. Ethyl L-alanyl-glycinate was prepared from triethylamine (5.1 g) and XVII (13 g), which in turn was obtained by the deacylation of ethyl carbobenzoxy-L-alanyl-glycinate, VI, in acetic acid saturated with hydrogen bromide. After standing for 24 hr at room temperature, the reaction mixture separated the crystalline XVIII. Filtration and recrystallization from ethanol-water gave a pure product, 9.5 g, mp 235—237°C.

Found: C, 56.03; H, 6.88; N, 12.38%. Calcd for $C_{21}H_{30}O_7N_4$: C, 55.99; H, 6.71; N, 12.44%.

IR: 1748 (ester), 1695 (carbobenzoxy) cm^{-1}.

Carbobenzoxy-L-alanyl-L-alanyl-L-alanyl-glycine (XIX). Tripeptide ethyl ester (XVIII, 7 g) was hydrolyzed with 31 m*l* of 1 N sodium hydroxide in 40% aqueous methanol. On acidification with 7 m*l* of 5 N hydrochloric acid, free acid (XIX) crystallized out as fine needles, 2.6 g, mp 225°C. It was crystallized from ethanol-water, the sample for analysis had mp 232—234°C. The same pure sample was obtained by reprecipitation (after dissolving the material in 1 N sodium hydroxide, the required amount of 5 N hydrochloric acid was added).

Found: C, 54.01; H, 6.31; N, 13.29%. Calcd for $C_{19}H_{26}O_7N_4$: C, 54.02; H, 6.20; N, 13.26%.

IR: 1720 (COOH), 1697 (carbobenzoxy) cm^{-1}.

***p*-Nitrophenyl Carbobenzoxy-L-alanyl-L-alanyl-L-alanyl-glycinate (XX).** 2.1 g of the tetrapeptide free acid XIX was reacted with *p*-nitrophenol (0.85 g) and dicyclohexylcarbodiimide (1.25 g) in 30 m*l* of dimethylformamide. The *p*-nitrophenyl ester XX was crystallized from dioxane-water or ethanol-water. The material from dioxane-water showed slightly higher mp (240°C with decomposition), than that from ethanol-water (mp 236—237°C with decomposition).

25) W. H. Stein, S. Moore and M. Bergmann, *J. Biol. Chem.*, **154**, 191 (1944).

Found: C, 55.46; H, 5.00; N, 12.62%. Calcd for $C_{25}H_{29}O_9N_5$: C, 55.24; H, 5.38; N, 12.89%.

p-Nitrophenyl L-Alanyl-L-alanyl-L-alanyl-glycine Hydrobromide (XXI). The compound XX was deacylated in hydrogen bromide-saturated acetic acid as described in the case of XVI. The resulting oily product was crystallized and recrystallized from isopropyl alcohol and ethyl ether in about 70% yield, mp 153°C (decomposition). This material was highly hygroscopic and labile to light.

Found: C, 41.78; H, 5.91; N, 14.16%. Calcd for $C_{17}H_{23}O_7N_5 \cdot HBr$: C, 41.64; H, 4.93; N, 14.28%.

IR: 1680 (ester), 1360 (NO_2) cm^{-1}.

Ethyl Carbobenzoxy-L-alanyl-glycyl-glycyl-glycinate (XXII). Twenty-two grams of carbobenzoxy-L-alanyl-glycine was dissolved in the mixture of ethyl glycyl-glycinate hydrochloride (19 g), triethylamine (9.8 g), and dimethylformamide (200 m*l*). To this turbid solution, 18 g of dicyclohexylcarbodiimide in dimethylformamide (50 m*l*) was added portionwise under cooling. After stirring for 24 hr at room temperature, the product ester was obtained by the usual manner, and crystallized from ethanol, 21.5 g, mp 168—169°C. Analytical sample which was recrystallized twice from ethanol showed mp 173—175°C.

Found: C, 54.21; H, 6.13; N, 13.29%. Calcd for $C_{19}H_{26}O_7N_4$: C, 54.02; H, 6.20; N, 13.26.

IR: 1740 (ester) 1696 (carbobenzoxy) cm^{-1}.

Attempted Hydrolysis of Tetrapeptide Ester XXII. a) The peptide ester XXII was treated with 1.3 equivalent molar of sodium hydroxide in 50% aqueous methanol for 48 hr at room temperature. On acidifying and concentrating the reaction mixture, the resultant products contained 90% or more of the starting ester XXII (from an infrared spectra). Tetrahydrofuran, in place of methanol, was also used as solvent, but showed no significant effects.

b) The peptide ester XXII was boiled for 15 min under the same medium described as above. The infrared spectra of the products thus obtained showed a significant relative decrease of the peak 1695 cm^{-1} (carbonyl group of benzyloxycarbonyl moiety). Furthermore, the products was oily and resisted towards further attempts to purify them. The same destruction of benzyloxycarbonyl group was observed in the trial for ester interchange reaction. In that case, the peptide ester XXII was refluxed with large amount of *p*-nitrophenol in tetrahydrofuran in the presence of *p*-toluenesulfonic acid.

Isobutyl Glycyl-glycinate Hydrobromide (XXVI). Isobutyl glycinate hydrochloride (XXIV) was prepared in the usual manner from isobutyl alcohol, glycine, and hydrogen chloride. XXIV was coupled with carbobenzoxy-glycine using dicyclohexylcarbodiimide to afford isobutyl carbobenzoxy-glycyl-glycinate (XXV) in 91% yield.

Thirty five grams of XXV was dissolved in 50 m*l* of acetic acid saturated with hydrogen bromide. After 30 min, the separated crystalline hydrobromide XXVI was filtered. Filtrate gave further crop of XXVI on concentration under reduced pressure. The combined material was recrystallized from isobutyl alcohol, 24.2 g (83% of theory), mp 184—188°C.

Found: C, 35.67; H, 6.19; N, 9.99%. Calcd for $C_8H_{16}O_3N_2 \cdot HBr$: C, 35.69; H, 6.36; N, 10.41%.

IR: 1743(ester) cm^{-1}.

Isobutyl Carbobenzoxy-L-alanyl-glycyl-glycyl-glycinate (XXVII). To the cold suspension of carbobenzoxy-L-alanyl-glycine (VII, 10 g), isobutyl glycyl-glycinate hydrobromide (XXVI, 11.5 g) and triethylamine (4.33 g) in dimethylformamide (100 m*l*), 8.1 g of dicyclohexylcarbodiimide in 30 m*l* of dimethylformamide was added dropwise at 0°C with magnetically stirring. Stirring was continued for 24 hr at room temperature. Following filtration through Hyflo "Super-Cel", solvent was evaporated under reduced pressure at 45°C. Scratching and trituration with water induced crystallization. The product (XXVII) was filtered off and recrystallized from ethyl acetate or aqueous tetrahydrofuran. There were slight differences in the fingerprint region of infrared spectra between the product crystallized from ethyl acetate and that from tetrahydrofuran and water; the former had higher mp (141—145°C), the latter lower mp (122—128°C). Elementary analysis was taken with the product from ethyl acetate.

Found: N, 12.01%. Calcd for $C_{21}H_{30}O_7N_4$: N, 12.44%.

IR: 1719 (ester), 1699 (carbobenzoxy) cm^{-1}.

The isobutyl ester, XXVII, was not hydrolyzed under the condition shown above.

Polymerization of X, XVI and XXI. Each compound was dissolved in dimethyl sulfoxide to give a 30—40% solution. With vigorous stirring, an equimolar amount of triethylamine was added to it in a portion. Stirring was continued, but after about 30 min, the reaction mixture solidified. After 1 day, the completely solidified mixutre was crushed and washed with dimethyl sulfoxide (5 times, applying a centrifugation) and methanol. The resultant pale yellow powder was dissolved in a few milliliters of dichloroacetic acid, filtered with a glass-filter. Polymer was reprecipitated from this solution with methanol or chloroform. Amino acid analysis: (a) Poly-(L-Ala-Gly_2), Ala : Gly=0.99 : 2; (b) Poly-(L-Ala_2-Gly), Ala : Gly=2.01 : 1; (c) Poly-(L-Ala_3-Gly), Ala : Gly=2.98 : 1.

Elementary analysis: (a) Poly-(L-Ala-Gly_2). Found: C, 45.49; H, 5.79; N, 22.67%. Calcd for $(C_7H_{11}O_3N_3)_n$: C, 45.40; H, 5.99; N, 22.69%. (b) Poly-(L-Ala_2-Gly). Found: C, 47.21; H, 6.27; N, 19.98%. Calcd for $(C_8H_{13}O_3N_3)_n$: C, 48.23; H, 6.58; N, 21.10%. (b) Poly-(L-Ala_3-Gly). Found: C, 47.32; H, 6.80; N, 19.52%. Calcd for $(C_{11}H_{18}O_4N_4)_n$: C, 48.88; H, 6.71; N, 20.73%.

Viscosities in dichloroacetic acid: (a) Poly-(L-Ala-Gly_2); $\eta_{sp}/c=0.235$ ($c=1\%$), $[\eta]=0.22$. (b) Poly-(L-Ala_2-Gly); $\eta_{sp}/c=0.294$ ($c=1\%$), $[\eta]=0.26$. (c) Poly-(L-Ala_3-Gly); $\eta_{sp}/c=0.170$ ($c=1\%$), $[\eta]=0.15$.

Optical Purity. 0.5% solutions of polymers in 6 N hydrochloric acid were heated in refluxing xylene for 24 hr. Hydrolysates were evaporated to dryness in a vacuum desiccator in which potassium hydroxide was placed, and redissolved in 0.1 N hydrochloric acid to make 1% solutions. L-Alanine itself was also treated under the same condition. Optical rotatory dispersion curve was measured on each sample; the value of molecular rotation in the range of 240 mμ to 600 mμ were identical in each case within 5% error. These values are: 518° at 250 mμ, 135° at 300 mμ, 62° at 350 mμ, and 27° at 400 mμ.

The author wishes to express very much thanks to Professor Fumio Oosawa and the members of his laboratory for their encouragements and discussions. Thanks are also due to Professor Yoshimasa Hirata and Ajinomoto Co. Inc., for their interests and supports in this work. Mr. Natsuki Kato arranged the microanalysis, and it is the author's pleasure to acknowledge him.

Organic Syntheses by Means of Metal Complexes. II.[1] Oxo Reaction Catalyzed by Cyclopentadienyliron Dicarbonyl Dimer

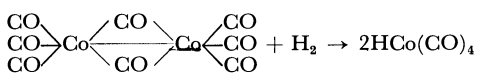
Jiro Tsuji and Yoichi Mori

Basic Research Laboratories, Toyo Rayon Co., Kamakura

(Received July 10, 1968)

It was found that cyclopentadienyliron dicarbonyl dimer is an active catalyst for oxo reaction and the characteristic features of the catalysis have been studied.

Carbonylation reactions of olefins are catalyzed by transition metal carbonyls, and iron, cobalt and nickel carbonyls are commonly used for the reactions. These metal carbonyls catalyze different types of the carbonylation reactions of olefins and acetylenes.[2,3] The relationship between the structure of the metal carbonyls and their catalytic activity seems to be an interesting problem. Metal carbonyls can be classified into mononuclear and polynuclear carbonyls as one way of the classification. Typical mononuclear carbonyls are nickel tetracarbonyl and iron pentacarbonyl. Dicobalt octacarbonyl (I) belongs to the latter and has a cobalt-cobalt bonding. The major difference of the catalytic activity of these two types of metal carbonyls can be explained in the following way from a mechanistic standpoint. It is known that the first step of the carbonylation reactions is the formation of a metal hydride bond in most cases. Dicobalt octacarbonyl forms cobalt tetracarbonyl hydride (II) by splitting the cobalt-cobalt bond by reacting with hydrogen as shown below.



$$+ H_2 \rightarrow 2HCo(CO)_4$$

I II

On the other hand, the carbonylation reaction catalyzed by nickel tetracarbonyl proceeds in the presence of hydrogen halide and the first step of the carbonylation is the oxidative addition of hydrogen halide to nickel tetracarbonyl to form halonickeldicarbonyl hydride (III).[4]

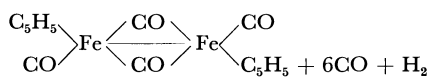
$$Ni(CO)_4 + HX \longrightarrow HNi(CO)_2X + 2CO$$

III

Once these metal hydrides are formed, then follows the insertion of olefin into the metal hydride bond in both cases.

It is possible to convert mononuclear carbonyls into dinuclear carbonyls by the coordination of cyclopentadienyl anion. For example, nickel, iron and molybdenum carbonyls can be converted into the dinuclear ones by reacting with dicyclopentadiene ($C_{10}H_{12}$).

$$2Fe(CO)_5 + C_{10}H_{12} \longrightarrow$$



$$+ 6CO + H_2$$

IV

On the other hand, dicobalt octacarbonyl can be converted into the mononuclear cyclopentadienyl cobalt dicarbonyl (V) by the reaction of cyclopentadiene as shown below.

$$Co_2(CO)_8 + 2C_5H_6 \rightarrow 2C_5H_5Co(CO)_2 + 4CO + H_2$$

I V

Thus it seems interesting to investigate the catalytic activity of these mono- and dinuclear carbonyls coordinated with cyclopentadienyl anion. So far no studies have been reported on the catalytic activity of these metal carbonyls coordinated with

cyclopentadienyl anion. In other words, this study was undertaken to find whether there is any similarity in the catalytic activity between dicobalt octacarbonyl (I) and cyclopentadienyliron dicarbonyl dimer (IV). In this paper the catalytic activity of the complex (IV) in oxo reaction is described.

The oxo reaction, namely the formation of aldehydes from olefins, carbon monoxide and hydrogen, is carried out most satisfactorily by the catalytic action of typical dinuclear carbonyls such as cobalt and rhodium carbonyls. So far, there is no report that any iron carbonyls are active for the oxo reaction. Now it was found that the oxo reaction can be carried out with the complex IV as the catalyst under certain conditions. The reaction of propylene with carbon monoxide and hydrogen to form butyraldehydes was studied under several different conditions.

$$CH_3CH{=}CH_2 + H_2 + CO \xrightarrow{IV} CH_3CH(CHO)CH_3 + CH_3CH_2CH_2CHO$$

Table 1. Effect of pressure[a]

Press. (atm) H_2	Press. (atm) CO	Ratio of iso/*n*-aldehyde	Yield (%)[b]	Higher aldehydes (g)
50	50	2.14	69.5	0.68
100	50	1.45	52.3	0.68
75	75	1.98	45.5	0.79

a) Reactions were carried out with the complex IV (0.7 g), propylene (10 ml), benzene (15 ml), and toluene (2 ml), at 150°C for 40 hr.
b) Total yield of C_4 aldehydes based on the charged propylene.

Table 2. Effect of reaction temperature and time[a]

Reaction Temp. (°C)	Reaction Time (hr)	Ratio of iso/*n*-aldehyde	Yield (%)	Higher aldehydes (g)
175	40	2.52	10.5	0.3
150	40	2.14	69.5	0.68
150	15	2.06	9.1	trace
125	40	—	trace	—

a) Reactions were carried out with the complex IV (0.7 g), propylene (10 ml), benzene (15 ml), hydrogen (50 atm) and carbon monoxide (50 atm).

In Tables 1 and 2, the effects of the reaction temperature, time and pressure on the reaction are shown. From these results, several characteristic features of the catalytic activity of the complex IV are apparent. One of them is that a larger amount of isobutyraldehyde was formed than *n*-butyraldehyde, and higher hydrogen pressure relative to that of carbon monoxide tends to favor the formation of the normal aldehyde. In the usual oxo reaction catalyzed by dicobalt octacarbonyl, several by-products are formed. For example, the hydrogenation of aldehydes to alcohols is observed in a considerable extent by hydrogenating activity of dicobalt octacarbonyl. Also aldol condensation of the aldehydes to form higher unsaturated aldehydes is another side reaction. A strongly acidic cobalt-tetracarbonyl hydride catalyzes the aldol condensation. These side reactions were almost negligible in the oxo reaction catalyzed by the complex IV and the products of the reaction were almost free of the alcohols and aldol condensation products. Therefore, it can be said that the acidic property and hydrogenating activity of the complex IV are weaker than those of dicobalt octacarbonyl.

Table 3. Oxo reaction of butenes[a]

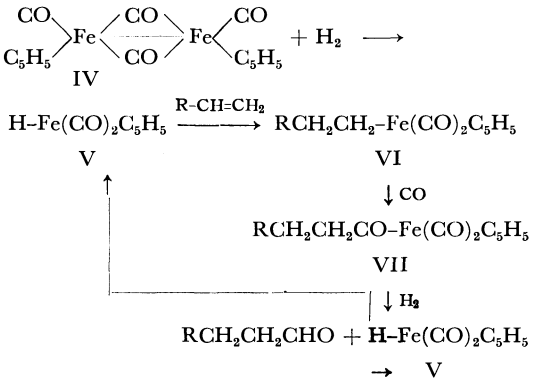
Butene	Ratio of 2-methylbutyraldehyde/*n*-valeraldehyde	Yield (%)[b]	Higher aldehydes (g)
1-Butene	2.03	53.8	0.18
cis-2-Butene	2.59	25.4	0.62
trans-2-Butene	3.02	16.8	0.57

a) Reactions were carried out with the complex IV (0.7 g), butene (10 ml), benzene (15 ml), hydrogen (50 atm), and carbon monoxide (50 atm) at 150°C for 40 hr.
b) Total yield of C_5 aldehydes based on the charged butenes.

Several solvents were tested in the reaction and it was found that ethanol and benzene were most satisfactory. When the reaction was carried out in ethanol, the product was aldehydes and no ester was formed. Then the carbonylation of 1-butene, *cis*- and *trans*-2-butenes was carried out and the results are shown in Table 3. It was observed that 1-olefin is more reactive than 2-olefins, and cis olefin is more reactive than trans olefin as expected. It should be noticed that *n*-valeraldehyde was formed in a considerable amount from 2-butenes and it is apparent that the complex IV catalyzes the isomerization of the inner olefins to the terminal olefins.

It can be said that the catalytic activity of the complex IV is somewhat lower than that of dicobalt octacarbonyl and longer reaction time is necessary. The range of optimum reaction temperature seems to be narrow, and best result was obtained at 150°C. After the reaction, it is possible to recover the catalyst intact by handling the reaction mixture under mild conditions and the recovered catalyst can be used again.

Finally the mechanism of the reaction is proposed in the following way. The first step of the reaction is the splitting of the iron-iron bond with hydrogen to form cyclopentadienylirondicarbonyl hydride (V). The successive insertions of olefin and carbon monoxide are followed to form alkyl (VI) and acyl complex (VII). Finally, the acyl complex (VII) is converted into the aldehyde with the regeneration of the hydride complex (V).



Experimental

Material. Cyclopentadienyliron dicarbonyl dimer was prepared by a known method from iron pentacarbonyl and dicyclopentadiene (red purple crystals, mp 194°C (decomp.).[5]

Oxo Reaction of Propylene. Only typical reaction is described. The complex IV (0.7 g), benzene (15 m*l*) and toluene (2 m*l*) were mixed in a glass vessel equipped with a gas inlet capillary, and the vessel was placed in an autoclave (100 m*l*). Liquid propylene (10 m*l*) was measured in a measuring glass tube and then distilled into the autoclave with cooling in a dry ice bath. Carbon monoxide and hydrogen (50 kg/cm² each) were introduced at room temperature. The reaction was carried out at 150°C for 40 hr with shaking. Pressure drop of 80 kg/cm² was observed during the reaction. The amounts of the aldehydes formed were determined gas chromatographically (squalene at 100°C) and the formation of *n*-butyraldehyde (2.3 g) and isobutyraldehyde (4.93 g) was confirmed. By distillation, 0.68 g of a higher boiling aldehyde was obtained.

Studies of Aminosugars. XXI. The Total Synthesis of Kanamycin C[1)]

Sumio UMEZAWA, Shinkiti KOTO, Kuniaki TATSUTA and Takayuki TSUMURA

Department of Applied Chemistry, Faculty of Engineering, Keio University, Koganei-shi, Tokyo

(Received July 16, 1968)

4-*O*-(3-*O*-Benzyl-2-carbobenzoxyamino-4,6-*O*-isopropylidene-2-deoxy-*α*-D-glucopyranosyl)-*N*,*N*′-dicarbobenzoxy-2-deoxystreptamine has been prepared from paromamine and condensed with 3-acetamido-2,4,6-tri-*O*-benzyl-3-deoxy-*α*-D-glucopyranosyl chloride by a modified Koenigs-Knorr reaction. The identity of the synthetic *α*,*α*-diglycoside with a substance of the same structure derived from natural kanamycin C was shown. Removal of the masking groups gave the product identical with natural kanamycin C.

In recent years, certain strains of *Streptomyces* have been found to produce aminoglycosidic antibiotics which are entirely carbohydrate in nature, for example, streptomycins, neomycins, kanamycins and paromomycins. Interest in the chemistry of aminoglycosides has recently become widespread and has received added impetus as the recognition of the great importance of the aminoglycosidic antibiotics in medicines and biology has grown. However, none of these carbohydrate-antibiotics has never been synthesized. In this paper we describe the total synthesis of kanamycin C, a member of kanamycin congeners, syntheses of other members, kanamycin A and B, being described in the following papers.

In a previous paper[2)] we prepared the *β*,*β*-

1) Part XXXVI of "Studies on Antibiotics and Related Substances" by Sumio Umezawa. This paper was read before the 21th Annual Meeting of the Chemical Society of Japan, Osaka, April, 1968. (See abstracts of papers of the Meeting, Vol. 3, p. 2212). A part of this work has been briefly communicated: S.Umezawa, S. Koto, K. Tatsuta and T. Tsumura *J. Antibiotics*, **21**, 162 (1968).

2) S. Koto, Y. Ito and S. Umezawa, This Bulletin, **38**, 1447 (1965).

diglycosides, which are kanamycin-analogues, from deoxystreptamine and 3-amino-3-deoxy-D-glucose or 6-amino-6-deoxy-D-glucose by way of the Koenigs-Knorr reaction and found that these compounds showed no antibiotic activity. These results underlined the fact that the approach to the synthesis of aminoglycosidic antibiotics found difficulty in the formation of α-glycosidic linkages. The preparation of α-glycopyranosides in high yields still remains the most important problem of carbohydrate chemistry, and in these circumstances we considered it advisable, as far as possible, to suitably mask 1-halogeno-sugars on one hand, and to partially mask aglycones on the other hand, considering the neighboring groups participation.

Kanamycin C was first discovered by Rothrock *et al.*,[3] and the structure (VIII) was elucidated by Murase.[4] Kanamycin C is composed of 3-amino-3-deoxy-D-glucose and paromamine[5] (I) which is a nonreducing fragment of paromomycin and is an α-glycoside of 2-amino-2-deoxy-D-glucose joined at C-1 to the C-4 of 2-deoxystreptamine. In this paper we described the synthesis of kanamycin C from paromamine. Since we[6] have previously synthesized paromamine, the combined achievements constitute the first synthesis of kanamycin C.

Paromamine was treated with carbobenzoxy chloride in the presence of sodium carbonate in aqueous acetone at about −10°C to give tri-*N*-carbobenzoxy-paromamine (II) in an 88% yield, which was acetonated with 2,2-dimethoxypropane in the presence of *p*-toluenesulfonic acid in *N*,*N*-dimethylformamide (DMF) at 110°C to give the diisopropylidene derivative (III), mp 243—245°C, $[\alpha]_D^{18}$ +71° (*c* 0.59, DMF), in a quantitative yield. According to the finding by Evans *et al.*[7] that the acetal exchange reaction of methyl α-D-glucopyranoside with 2,2-dimethoxypropane mainly gives methyl 4,6-*O*-isopropylidene-α-D-glucoside, the structure of III is considered to include an isopropylidene group attached to C-4 and C-6 in the glucosamine moiety.

Benzylation of III with benzyl bromide in the presence of barium oxide and barium hydroxide in DMF gave IV, mp 160—162°C, $[\alpha]_D^{18}$ +72° (*c* 0.60, DMF), in a 82% yield. Deacetonation of IV by treatment with 80% acetic acid gave quantitatively 4-*O*-(3-*O*-benzyl-2-carbobenzoxyamino-2-deoxy-α-D-glucopyranosyl)-*N*,*N*′-dicarbobenzoxy-2-deoxystreptamine (V), mp 270—271°C (decomp.), $[\alpha]_D^{18}$ +101° (*c* 0.52, DMF).

When V was caused to react with 2,2-dimethoxypropane at room temperature, partial acetonation of V was successful to give monoisopropylidene derivative (VI), mp 239—241°C, $[\alpha]_D^{18}$ +75° (*c* 0.63, DMF), in a 55% yield. It is worth mentioning that the hydroxyl groups of C-4 and C-6 in the glucosamine moiety were acetonated in preference to the hydroxyl groups in deoxystreptamine.

3-Acetamido-2,4,6-tri-*O*-benzyl-3-deoxy-α-D-glucopyranosyl chloride[8] was condensed with VI in the presence of mercuric cyanide and Drierite in benzene-dioxane at 100°C. The product was treated with acetic acid to remove the isopropylidene group, hydrogenated over palladium black in a mixture of dioxane-water-concentrated hydrochloric acid to remove carbobenzoxy and benzyl groups, and de-*N*-acetylated with barium hydroxide to give a ninhydrin-positive product. This was dinitrophenylated with 2,4-dinitrofluorobenzene in the presence of sodium bicarbonate in aqueous ethanol and then *O*-acetylated with acetic anhydride and anhydrous sodium acetate. The product, which showed about four spots with R_f-values of 0.56, 0.45, 0.35 and 0.27 on a thin-layer chromatogram (TLC) with a solvent system: toluene-MEK (2 : 1), was chromatographed on a silica-gel column with the same solvent system. The substance of R_f-value 0.35 was isolated to give synthetic hepta-*O*-acetyl-tetra-*N*-(2,4-dinitrophenyl)-kanamycin C (VII), mp 208—211°C (decomp.), $[\alpha]_D^{18}$ +285° (*c* 0.75, acetone), in a 15% overall yield from VI.

On the other hand, natural kanamycin C was dinitrophenylated and acetylated to give hepta-*O*-acetyl-tetra-*N*-(2,4-dinitrophenyl) derivative of kanamycin C, mp 208—211°C (decomp.), $[\alpha]_D^{18}$ +299° (*c* 0.64, acetone).

The identity of the synthetic VII with the above mentioned derivative of natural kanamycin C was established by elemental analyses, specific rotations, by their failure to depress the mixed melting point and identical mobilities on TLC and infrared spectra.

Hydrolysis of VII with methanolic ammonia followed by treatment with Dowex 1×2 (OH^-) resin gave a crystalline free base of synthetic kanamycin C (VIII), $[\alpha]_D^{18}$ +139° (*c* 0.50, water), which was identical with an authentic sample of the natural kanamycin C. Optical rotations were essentially equal and infrared spectra were superimposable. On descending paper chromatography the R_f-value of the synthetic VIII agreed with

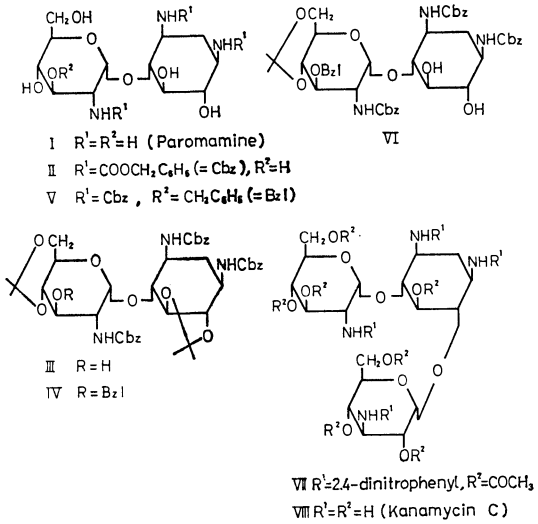
that of natural kanamycin C. The antibiotic spectra[9] and minimal inhibitory concentrations of the synthetic VIII against test organisms were in agreement with those of natural kanamycin C.



Experimental

General Procedures. Thin layer chromatography (TLC) was performed on "Silica-Rider for TLC" (Daiichi Pure Chemicals Co.) using the following solvent systems: (a) benzene - methyl ethyl ketone (MEK) (4 : 1), (b) benzene - MEK (1 : 1), and (c) toluene - MEK (2 : 1). The 2,4-dinitrophenyl (DNP) derivatives were visualized directly on an air-dried plate as yellow spots, while others were detected by spraying a dried chromatogram with 50% sulfuric acid and heating it at 110°C. Paper chromatography was performed on Toyo filter paper No. 51, using a solvent system: (d) *n*-butanol - pyridine - water - acetic acid (6 : 4 : 3 : 1); ninhydrin in pyridine (0.3%) was sprayed on. Infrared spectra were determined in potassium bromide pellets.

Tri-*N*-carbobenzoxyparomamine (II). To a mixture of paromamine (I) (5 g) and sodium carbonate (15 g) in water (50 m*l*) and acetone (150 m*l*) was added slowly carbobenzoxychloride in toluene (30%, 28 g) under stirring at −10—−5°C. After having been stirred for about 4 hr, the reaction mixture was set aside in a refrigerator overnight. The resulting white solid was shaken with a mixture of water (400 m*l*) and ether (20 m*l*), collected by filtration and pressed between filter papers to remove moisture and oily matters. The waxy product was triturated with 1 N hydrochloric acid (300 m*l*), filtered, washed with water and dried *in vacuo*. Recrystallization from dioxane (400 m*l*) gave a colorless solid, 6.7 g, mp 258°C (decomp.), $[\alpha]_D^{18}$ +64.5° (*c* 0.67, DMF). The mother liquor deposited a further crop, 3.1 g. Total yield 88%. IR spectrum: 3330, 1697 and 1542 cm^{-1} (NHCbz).

Found: C, 59.74; H, 6.28; N, 5.55%. Calcd for $C_{36}H_{43}N_3O_{13}$: C, 59.58; H, 5.97; N, 5.79%.

4-*O*-(2-Carbobenzoxyamino-4,6-*O*-isopropylidene-2-deoxy-*α*-D-glucopyranosyl)-*N*,*N*′-dicarbobenzoxy-5,6-*O*-isopropylidene-2-deoxystreptamine (III). To a solution of II (4.7 g) in anhydrous DMF (30 m*l*) was added *p*-toluenesulfonic acid monohydrate (0.06 g) and 2,2-dimethoxypropane (6.2 m*l*), and the solution was heated at 110°C for 4 hr with occasional stirring. The mixture was neutralized with Amberlite IRA-400 (OH type) washed with methanol before use and filtered. Concentration gave a residue, which solidified when triturated with water. Recrystallization from ethanol; colorless crystals, 5.2 g (98%), mp 243—245°C, $[\alpha]_D^{18}$ +71° (*c* 0.59, DMF), IR spectrum: 3340, 1698 and 1533 (NHCbz), 1167, 1137 and 1047 cm^{-1} (ketal).

Found: C, 62.63; H, 6.50; N, 5.39%. Calcd for $C_{42}H_{51}N_3O_{13}$: C, 62.60; H, 6.38; N, 5.21%.

4-*O*-(3-*O*-Benzyl-2-carbobenzoxyamino-4,6-*O*-isopropylidene-2-deoxy-*α*-D-glucopyranosyl)-*N*,*N*′-dicarbobenzoxy-5,6-*O*-isopropylidene-2-deoxystreptamine (IV). To a solution of III (5.1 g) in anhydrous DMF (80 m*l*) was added pulverized barium oxide (5.2 g) and barium hydroxide octahydrate (6.2 g) with stirring and the mixture was cooled to −10°C. Benzyl bromide (3.7 m*l*) was added drop by drop to the mixture under vigorous agitation. The reaction temperature was allowed to rise gradually to 0°C during 4 hr and then to room temperature during an additional 4 hr. The slightly colored mixture was further stirred continuously for 20 hr at room temperature. Chloroform (150 m*l*) was added and the mixture was filtered through a layer of Celite (thickness 20 mm). The filtrate was evaporated to give a sirup, which was chromatographed on a silica-gel column (400 g, 51 × 510 mm) with a solvent mixture (a). An eluate between 1400—2300 m*l* was evaporated to dryness. The residue was recrystallized from ethanol to give IV; yield 4.7 g (82%), mp 160—162°C, $[\alpha]_D^{18}$ +72.4° (*c* 0.61, DMF), IR spectrum: 3335, 1730—1700 and 1540—1520 cm^{-1} (NHCbz), 1172, 1132 and 1040 cm^{-1} (ketal).

Found: C, 65.47; H, 6.67; N, 4.80%. Calcd for $C_{49}H_{57}N_3O_{13}$: C, 65.68; H, 6.41; N, 4.69%.

4-*O*-(3-*O*-Benzyl-2-carbobenzoxyamino-2-deoxy-*α*-D-glucopyranosyl)-*N*,*N*′-dicarbobenzoxy-2-deoxystreptamine (V). A suspension of IV (3.0 g) in aqueous acetic acid (80%; 100 m*l*) was stirred at 50°C until the solution became clear and then kept at room temperature overnight. The resulting precipitate was collected, washed with water and dried *in vacuo*. Recrystallization from ethanol gave colorless needles of V; yield 2.7 g (98%), mp 270—271°C (decomp.), $[\alpha]_D^{18}$ +101° (*c* 0.52, DMF), IR spectrum: 3340, 1699 and 1538 (NHCbz) 1026 cm^{-1} (*O*-benzyl).

Found: C, 63.08; H, 6.13; N, 5.24%. Calcd for $C_{43}H_{49}N_3O_{13}$: C, 63.30; H, 6.05; N, 5.15%.

4-*O*-(3-*O*-Benzyl-2-carbobenzoxyamino-2-deoxy-4,6-*O*-isopropylidene-*α*-D-glucopyranosyl)-*N*,*N*′-dicarbobenzoxy-2-deoxystreptamine (VI). To a solution of V (2.2 g) in DMF (13 m*l*) was added *p*-toluenesulfonic acid (0.03 g) and 2,2-dimethoxypropane (0.8 m*l*), and the mixture was allowed to stand at room temperature overnight. After neutralization with Amberlite IRA-400 (OH type) washed with methanol before use, the solution was evaporated to give a residue, which showed two spots of R_f values 0.86 and 0.53 on TLC with the solvent system (b). The residue was chromatographed on a silica-gel column (200 g, 50 × 295 mm) with the solvent system (b), the effluent being cut into fractions of 15 m*l* each. The substance of

R_f 0.53 appeared in the fractions of tube Nos. 30—53, which afforded 1.3 g of VI (55%). Recrystallization from ethanol; mp 239—241°C, $[\alpha]_D^{18}$ +75.2° (*c* 0.63, DMF), IR spectrum: 3335, 1697 and 1535 (NHCbz), 1170, 1130 and 1035 (ketal), 1026 cm^{-1} (*O*-benzyl).

Found: C, 64.29; H, 6.11; N, 4.78%. Calcd for $C_{46}H_{53}N_3O_{13}$: C, 64.55; H, 6.24; N, 4.91%.

The diisopropylidene derivative IV (R_f 0.86) was also obtained from the fractions between tube Nos. 31—33 and weighed 0.5 g.

Proof for the Structure of VI. Monoisopropylidene derivative VI (13 mg) in DMF (1 m*l*) was benzylated in the above-mentioned manner with barium oxide (24 mg), barium hydroxide octahydrate (29 mg) and benzyl bromide (18 m*l*). The TLC of the oily product showed that VI completely vanished and a new spot appeared. The oily product was dissolved in hot aqueous acetic acid (80%) and allowed to stand at room temperature for 5 hr. The colorless solid separated was collected, yield 8 mg. The deacetonated product was hydrolyzed in a mixture of glacial acetic acid, methyl cellosolve, water and concentrated hydrochloric acid (10 : 5 : 3 : 2) by heating at 100°C for 10 hr under reflux to remove carbobenzoxy groups and to cleave the glycosidic linkage. On the other hand, a control experiment was carried out with II. The paper chromatogram of the hydrolyzates using the solvent system (d) and ninhydrin-coloration showed that the fully benzylated VI gave neither 2-amino-2-deoxy-D-glucose nor 2-deoxystreptamine, while II gave both of them, indicating that the isopropylidene and benzyl groups are present in the glucosamine moiety of VI.

Synthetic Hepta-*O*-acetyl-tetra-*N*-(2,4-dinitrophenyl)-kanamycin C (VII). A mixture of VI (1.13 g), dried powdery mercuric cyanide (0.46 g) and freshly activated Drierite (3.66 g) in a mixture of dioxane (5.5 m*l*) and benzene (11 m*l*) was heated to reflux for a few minutes under agitation. To the mixture, which was somewhat cooled, was added well dried 3-acetamido-2,4,6-tri-*O*-benzyl-3-deoxy-α-D-glucopyranosyl chloride[8] (1.3 g, 1.7 eq.) and the reaction mixture was stirred vigorously under reflux for 9 hr under anhydrous conditions. During the course of reaction the mixture turned gradually dark and somewhat pasty. The resulting mixture was filtered and thoroughly washed with dioxane and ethyl acetate. The filtrate combined with washings was evaporated to give a sirup, which was extracted with ethyl acetate (150 m*l*). The extract was washed with three 100 m*l* portions of 20% aqueous sodium chloride, dried over anhydrous sodium sulfate and evaporated to give an oily product (1.8 g). Aqueous acetic acid (80%; 20 m*l*) was added and the mixture was warmed to 50°C under stirring until the solution became clear. The solution was allowed to stand for 1 hr and evaporated to give the deacetonated product, which was then hydrogenated over palladium black (0.3 g) in a mixture of dioxane (21 m*l*), water (3.5 m*l*), ethanol (0.5 m*l*) and concentrated hydrochloric acid (2 m*l*), under 3 atm of hydrogen pressure at about 40°C with occasional addition of portions of water whose total volume was 35 m*l*. The hydrogenolysis took 48 hr for completion. After removal of the catalyst, the solution was evaporated at a temperature below 30°C to give a sirup (0.74 g). The ninhydrin-positive sirup was dissolved in 1 N aqueous barium hydroxide (40 m*l*) and heated over a boiling water bath for 2 hr. The mixture was acidified with 3 N sulfuric acid to pH 2 and the mixture was centrifuged to remove barium sulfate. The supernatant was neutralized with Dowex 1×2 (OH type) and evaporated to give a colorless sirup (0.6 g) of free base. Paper chromatography and bioautography of the product showed that the product mainly contained the substance whose R_f-value coincided with that of natural kanamycin C. The product was dinitrophenylated with 2,4-dinitrofluorobenzene (0.84 g) in the presence of sodium bicarbonate (0.4 g) in 50% aqueous ethanol (60 m*l*) at room temperature under stirring overnight. Precipitation of a yellow gummy substance was observed. The resulting mixture was neutralized with 0.1 N hydrochloric acid and followed by evaporation to give a sirup. This was acetylated with acetic anhydride (20 m*l*) and anhydrous sodium acetate (1 g) with stirring at 100°C. After evaporation, the residue was extracted with acetone and the extract was evaporated to give a yellow glass (1.8 g), which showed about four spots with R_f value of 0.56, 0.45, 0.35 and 0.27 on TLC with the solvent system (c). The product was chromatographed on a silica-gel column (150 g, 49×310 mm) with the same solvent system, being cut into fractions of 8 g each. The main product of R_f value 0.35 appeared in fractions of tube Nos. 34—48, which was evaporated and followed by recrystallization from the solvent system (c) to give yellow needles of VII (overall yield from VI, 15%); mp 208—211°C (decomp.), $[\alpha]_D^{18}$ +285° (*c* 0.75, acetone), IR spectrum: 3320, 1620, 1595, 1550, 1525, 1335, 835 and 745 (NHDNP), 1750, 1365 and 1220 cm^{-1} (OAc).

Found: C, 46.68; H, 4.34; N, 11.84%. Calcd for $C_{56}H_{58}N_{12}O_{34}$: C, 46.61; H, 4.05; N, 11.65%.

Synthetic Kanamycin C (VIII). A sample (47 mg) of VII was dissolved in 20 m*l* of methanol saturated with ammonia at 0°C and allowed to stand at room temperature for 4 hr to remove acetyl groups. Evaporation of the reaction mixture *in vacuo* gave a yellow glass (39 mg), which was treated with 0.5 m*l* of Dowex 1×2 (OH type) in moistened acetone (3 m*l*) at room temperature for 4 hr to remove dinitrophenyl groups. The resin was filtered off, and the filtrate was evaporated. The residue was passed through a small column of Dowex 1×2 (OH type) with water to give a colorless solution of pure free base. Evaporation followed by recrystallization from aqueous methanol containing small amount of ethanol gave VIII; $[\alpha]_D^{18}$ +139° (*c* 0.50, water).

Found: C, 44.40; H, 7.28; N, 11.80%. Calcd for $C_{18}H_{36}N_4O_{11}$: C, 44.62; H, 7.49; N, 11.56%.

The natural kanamycin A showed $[\alpha]_D^{18}$ +145° (*c* 0.58, water) [lit.[4] $[\alpha]_D^{18}$ +126° (*c* 1, water)]. On descending paper chromatography by ninhydrin-coloration using the solvent system (d), the R_f-value of the synthetic product (VIII) agreed with that of the natural kanamycin C. Infrared spectra of VIII and the natural specimen were superimposable. The antibiotic spectra[9] and minimal inhibitory concentrations of the synthetic product VIII against test organisms coincided with that of natural kanamycin C.

Natural Hepta-*O*-acetyl-tetra-*N*-(2,4-dinitrophenyl)-kanamycin C. To a solution of natural kanamycin C (50 mg) in water (0.5 m*l*) was added sodium bicarbonate (26 mg) and 2,4-dinitrofluorobenzene (58 mg) in ethanol (0.6 m*l*) and the mixture was vigorously stirred at room temperature for 3 hr. Water (1 m*l*) was

added and agitated overnight to precipitate a yellow solid, which was collected and washed thoroughly with water; yield 95 mg (82%). The *N*-dinitrophenyl derivative (95 mg) was acetylated with acetic anhydride (5 m*l*) and anhydrous sodium acetate (0.5 g) by heating at 110°C under stirring for 2 hr. The resulting mixture was concentrated under reduced pressure and followed by dilution with acetone and filtration. The filtrate was again evaporated and made free from acetic anhydride by co-evaporating with toluene three times to give a yellow glass (140 mg), which was purified by chromatography on a silica-gel column (10 g, 23×100 mm) with the solvent system (c) being cut into 3 m*l* each. The fraction Nos. 8—20 were collected and evaporated to give a yellow solid; 130 mg (89%). Crystallization from the solvent system (c) afforded yellow needles of hepta-*O*-acetyl-tetra-*N*-(2,4-dinitrophenyl)-kanamycin C; mp 208—211°C (decomp.), $[\alpha]_D^{18}$ +299° (*c* 0.64, acetone), IR spectrum: 3320, 1620, 1595, 1550, 1525, 1335, 835 and 745 (NHDNP), 1750, 1365 and 1220 cm^{-1} (OAc).

Found: C, 46.65; H, 4.24; N, 11.78%. Calcd for $C_{56}H_{58}N_{12}O_{34}$: C, 46.61; H, 4.05; N, 11.65%.

The authors are indebted to the Kawasaki-Factory of Meiji-Seika, Ltd., for supplying kanamycin C. Thanks are also due to Mr. Saburo Nakada for microanalyses and to Mr. Yoshio Nishimura and Mr. Hirokuni Hineno for technical assistance.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 533—537 (1969)

Studies of Aminosugars. XXII. The Total Synthesis of Kanamycin A[1]

Sumio UMEZAWA, Kuniaki TATSUTA and Shinkiti KOTO

Department of Applied Chemistry, Faculty of Engineering, Keio University, Koganei-shi, Tokyo

(Received July 16, 1968)

6-*O*-(3-Amino-3-deoxy-*α*-D-glucopyranosyl)-2-deoxystreptamine, which was previously synthesized, was masked with carbobenzoxy, isopropylidene and benzyl groups to give 6-*O*-(2-*O*-benzyl-3-carbobenzoxyamino-3-deoxy-4,6-*O*-isopropylidene-*α*-D-glucopyranosyl)-*N*,*N*′-dicarbobenzoxy-2-deoxystreptamine, with which 2,3,4-tri-*O*-benzyl-6-(*N*-benzylacetamido)-6-deoxy-*α*-D-glucopyranosyl chloride was condensed by a modified Koenigs-Knorr reaction, to give an *α*,*α*-diglycoside compound. The identity of the product with a substance of the same structure derived from natural kanamycin A was shown. Removal of the masking groups gave the synthetic kanamycin A, which was identical to the natural specimen.

Kanamycins[2] belong to a group of water-soluble, basic antibiotics that are entirely carbohydrate in nature and show broad-spectrum antibacterial activity. They were discovered by H. Umezawa *et al.* in cultures of *Streptomyces kanamyceticus* n. sp. Okami *et* Umezawa. Kanamycin A is the major component of kanamycin complex produced by the above-mentioned strain. Cleavage products of kanamycin A are 3-amino-3-deoxy-D-glucose (kanosamine), 6-amino-6-deoxy-D-glucose and 2-deoxystreptamine. The former two kinds of aminosugars had not previously been encountered in natural products. (3-Amino-3-deoxy-*α*-D-glucopyranosyl)-2-deoxy-streptamine[3] and (6-amino-6-deoxy-*α*-D-glucopyranosyl)-2-deoxy-streptamine[4] were also isolated from the partial hydrolysis product. The structure of kanamycin A[5-7] (VIII) was established as *O*-(6-amino-6-deoxy-*α*-D-glucopyranosyl)-(1→4)-*O*-[3-amino-3-deoxy-*α*-D-glucopyranosyl-(1→6)]-1,3-diamino-1,2,3-trideoxy-*myo*-inositol. Absolute configuration of kanamycins

were recently revealed.[8-10]

After having completed structural studies on kanamycin A, we turned to contemplation of its synthesis. There appeared to be two possible routes to kanamycin A, one of which was a route *via* a masked derivative of 6-*O*-(3-amino-3-deoxy-*α*-D-glucopyranosyl)-2-deoxystreptamine (I, 3AD) and the other was a route *via* a masked derivative of 4-*O*-(6-amino-6-deoxy-*α*-D-glucopyranosyl)-2-deoxystreptamine (6AD). We chose the former route, because 3AD is more readily obtainable than 6AD from the partially hydrolyzed product of kanamycin A in order to identify with the synthetic specimen. In the present paper, the total synthesis of kanamycin A and related compounds are described.[11]

The initial phase of the synthesis was thus concerned with the preparation of 3AD, which has very recently been reported.[12] The 3AD now had to be suitably masked. Treatment of 3AD with carbobenzoxychloride in aqueous sodium carbonate gave tri-*N*-carbobenzoxy derivative (II) in a 84% yield. Acetonation of II with 2,2-dimethoxypropane in the presence of *p*-toluenesulfonic acid in dimethylformamide (DMF) at 110°C afforded the diisopropylidene derivative (III), mp 234°C, $[\alpha]_D^{18}$ +53° (*c* 0.67, DMF), in a quantitative yield. Benzylation of III with benzyl bromide in the presence of barium oxide and barium hydroxide in DMF afforded the benzyl derivative (IV), mp 258°C, $[\alpha]_D^{18}$ +43° (*c* 0.67, DMF), which was deacetonated by treatment with 80% acetic acid to give 6-*O*-(2-*O*-benzyl-3-carbobenzoxyamino-3-deoxy-*α*-D-glucopyranosyl)-*N*,*N*′-dicarbobenzoxy-2-deoxystreptamine (V), mp 288°C, (decomp.), $[\alpha]_D^{18}$ +40° (*c* 0.67, DMF), quantitatively. Treatment of V with 2,2-dimethoxypropane at 5°C in the presence of *p*-toluenesulfonic acid in DMF successfully gave monoisopropylidene derivative (VI), mp 240°C, $[\alpha]_D^{18}$ +40° (*c* 0.67, DMF), in a 64% yield. It is worth mentioning that the hydroxyl groups at C-4 and C-6 in the 3-amino-3-deoxy-D-glucose moiety were acetonated in preference to the hydroxyl groups in the deoxystreptamine. This reaction is similar to that carried out in the preparation of the corresponding derivative of paromamine in the case of the total synthesis of kanamycin C in the foregoing report.

We could now proceed along the main synthetic pathway. In analogy to the foregoing studies on kanamycin C, the intermediate VI was condensed with 6-(*N*-benzylacetamido)-2,3,4-tri-*O*-benzyl-6-deoxy-*α*-D-glucopyranosyl chloride[13] in the presence of mercuric cyanide and Drierite in dioxane-benzene. The product was treated with aqueous acetic acid to remove the isopropylidene group, hydrogenated over palladium black to remove carbobenzoxy and *O*-benzyl groups, de-*N*-acetylated with barium hydroxide, and again hydrogenated to remove the *N*-benzyl group. The ninhydrin-positive product was dinitrophenylated with 2,4-dinitrofluorobenzene and then *O*-acetylated with acetic anhydride and anhydrous sodium acetate. The product, which showed about six spots with R_f-values of 0.54, 0.34, 0.30, 0.27 (main), 0.25 and 0.15 on a thin-layer chromatogram (TLC) with a solvent system (e): toluene-MEK (3 : 1), was chromatographed on a silica-gel column with the same solvent. The main product (VII) of the R_f-value 0.27 was isolated as yellow needles in an overall-yield 10.1% from VI.

On the other hand, kanamycin A was dinitrophenylated and acetylated to give hepta-*O*-acetyl-tetra-*N*-(2,4-dinitrophenyl)-kanamycin A.

The synthetic yellow needles (VII), mp 210—213°C (decomp.), $[\alpha]_D^{18}$ +50° (*c* 1.0, acetone), were proved to be identical to the above-mentioned derivative of natural kanamycin A by elemental analyses, specific rotations, by their failure to depress the mixed melting point, identical mobilities on TLC and infrared spectra.

13) This compound was reported by S. Umezawa *et al.* at the 20th Annual Meeting of the Chemical Society of Japan, Tokyo, Mar. 31, 1967. (See abstracts of the papers of the Meeting, Vol. III, p. 596). S. Koto, T. Tsumura, Y. Kato and S. Umezawa, This Bulletin, **41**, 2765 (1968).

Before dinitrophenylation of the ninhydrin-positive product, we made efforts to directly separate the synthetic kanamycin A from the crude product by chromatographic technique, but it was unsuccessful. We found that VII could be separated when the crude product was subjected to dinitrophenylation and acetylation.

Hydrolysis of VII with methanolic ammonia followed by treatment with an excess of Dowex 1×2 (OH^-) resin afforded a free base, which was purified by chromatography on a column of Dowex 1×2 (OH^-) resin and recrystallized from aqueous methanol - ethanol to afford the synthetic kanamycin A of $[\alpha]_D^{18}$ +149° (*c* 0.87, water). The natural kanamycin A showed $[\alpha]_D^{18}$ +151° (*c* 1.0, water). The identity of the synthetic kanamycin A with the natural specimen was further established by elemental analyses, identical mobilities on TLC, superimposable infrared spectra and by their failure to depress the mixed melting point. The antibiotic spectra and minimal inhibitory concentrations[1] of the synthetic kanamycin A against test organisms were in agreement with those of the natural kanamycin A.

Experimental

General Procedures. Thin layer chromatography (TLC) and paper chromatography were carried out similarly as described in the foregoing report, using solvent systems: (a) benzene-ethanol (4 : 1), (b) benzene-methyl ethyl ketone (MEK) (4 : 1), (c) benzene-methanol (4 : 1), (d) benzene-ethyl acetate (1 : 2), (e) toluene-MEK (3: 1), and (f) *n*-butanol - pyridine - water - acetic acid (6 : 4 : 3 : 1).

6-*O*-(3-Carbobenzoxyamino-3-deoxy-α-D-glucopyranosyl)-*N*,*N*′-dicarbobenzoxy-2-deoxystreptamine (II). To a solution of 6-*O*-(3-amino-3-deoxy-α-D-glucopyranosyl)-2-deoxystreptamine (I) (6.0 g) and sodium carbonate (18 g) in a mixture of water (60 m*l*) and acetone (180 m*l*) was added carbobenzoxychloride in toluene (30%, 32 g) under agitation at −10°C during an hour. Having been stirred for about 4 hr, the reaction mixture was set aside in a refrigerator overnight. The resulting solid was shaken with a mixture (600 m*l*) of water and ether (15: 1 v/v), collected and pressed between filter papers. The waxy product was triturated with 1 N hydrochloric acid (300 m*l*), filtered, washed with water and dried. Recrystallization from dioxane (900 m*l*) afforded colorless solid; 9.5 g. The mother liquor gave a second crop; 1.8 g. Total yield 84%; mp 280—282°C (decomp.), $[\alpha]_D^{18}$ +54° (*c* 0.67, DMF), IR spectrum: 3330, 1693 and 1547 cm^{-1} (NHCbz).

Found: C, 59.86; H, 6.25; N, 5.66%. Calcd for $C_{36}H_{43}N_3O_{13}$: C, 59.58; H, 5.97; N, 5.79%.

6-*O*-(3-Carbobenzoxyamino-3-deoxy-4,6-*O*-isopropylidene-α-D-glucopyranosyl)-*N*,*N*′-dicarbobenzoxy-4,5-*O*-isopropylidene-2-deoxystreptamine (III). To a solution of II (4.6 g) in anhydrous DMF (30 m*l*) was added *p*-toluenesulfonic acid monohydrate (0.06 g) and 2,2-dimethoxypropane (7.0 m*l*), and the solution was heated at 110°C for 4 hr with occasional stirring. The mixture was neutralized with Amberlite IRA-400 (OH type; 10 m*l*) washed with methanol before use, filtered and the solution was evaporated *in vacuo* to give a residue, which was solidified by treatment with water; yield 4.9 g (94%). An analytically pure sample was obtained by chromatography on a silica-gel column, using the solvent system (a); mp 233—234°C, $[\alpha]_D^{18}$ +53° (*c* 0.67, DMF), IR spectrum: 3350, 1700 and 1537 (NHCbz), 1175 and 1063 cm^{-1} (ketal).

Found: C, 62.67; H, 6.59; N, 5.35%. Calcd for $C_{42}H_{51}N_3O_{13}$: C, 62.60; H, 6.38; N, 5.21%.

6-*O*-(2-*O*-Benzyl-3-carbobenzoxyamino-3-deoxy-4,6-*O*-isopropylidene-α-D-glucopyranosyl)-*N*,*N*′-dicarbobenzoxy-4,5-*O*-isopropylidene-2-deoxystreptamine (IV). To a solution of III (4.9 g) in anhydrous DMF (80 m*l*) was added pulverized barium oxide (4.9 g) and barium hydroxide octahydrate (5.9 g) with stirring and the mixture was cooled to −15°C. Benzyl bromide (3.5 m*l*) was added dropwise to the mixture under agitation, and the reaction temperature was allowed to raise gradually to 0°C during 4 hr. The mixture was further stirred for 20 hr at room temperature and filtered through a thick layer of Celite. The filtrate and washings were combined and evaporated *in vacuo* to give a sirup, which was taken up into chloroform (200 m*l*) to precipitate a gelatinous mass. This product was transferred to the top of a thick layer of Hyflosupercel (60×60 mm) and washed with chloroform (300 m*l*) and then with hot chloroform (300 m*l*) to afford a fraction containing IV, which was evaporated *in vacuo* to give an analytically pure solid of IV; 4.1 g, mp 258°C; $[\alpha]_D^{18}$ +43° (*c* 0.67, DMF), IR spectrum: 3340, 1700 and 1538 (NHCbz), 1177 and 1066 cm^{-1} (ketal).

Found: C, 65.88; H, 6.66; N, 4.51%. Calcd for $C_{49}H_{57}N_3O_{13}$: C, 65.68; H, 6.41; N, 4.69%.

6-*O*-(2-*O*-Benzyl-3-carbobenzoxyamino-3-deoxy-α-D-glucopyranosyl)-*N*,*N*′-dicarbobenzoxy-2-deoxystreptamine (V). A suspension of IV (4.1 g) in 80% aqueous acetic acid (120 m*l*) was heated at 80°C for a while to give a clear solution, which was kept standing at room temperature overnight to separate a colorless precipitate. This was collected, washed with water and dried to afford a colorless powder of V, mp 286—288°C (decomp.), $[\alpha]_D^{18}$ +40° (*c* 0.67, DMF), IR spectrum: 1695 and 1547 (NHCbz), 1052 cm^{-1} (*O*-benzyl).

Found: C, 63.13; H, 6.32; N, 5.02%. Calcd for $C_{43}H_{49}N_3O_{13}$: C, 63.30; H, 6.05; N, 5.15%.

6-*O*-(2-*O*-Benzyl-3-carbobenzoxyamino-3-deoxy-4,6-*O*-isopropylidene-α-D-glucopyranosyl)-*N*,*N*′-dicarbobenzoxy-2-deoxystreptamine (VI). To a solution of V (2.8 g) in DMF (17 m*l*) was added *p*-toluenesulfonic acid monohydrate (0.03 g) and 2,2-dimethoxypropane (1.2 m*l*), and the mixture was allowed to stand at about 5°C for 16 hr. The mixture was neutralized with Amberlite IRA-400 (OH type; 8 m*l*) washed with methanol before use, and evaporated *in vacuo* to give a sirup, which was solidified by trituration with water. The crude product (2.9 g) was extracted with ethyl acetate (340 m*l*) and the extract was evaporated under reduced pressure. The residue was crystallized from ethanol; yield 1.9 g (64%). Examination of the product by TLC using the solvent system (d) indicated that the product was quite pure, mp 239—240°C, $[\alpha]_D^{18}$ +40° (*c* 0.67, DMF), IR spectrum: 3340, 1698 and 1540 (NHCbz), 1172 and 1063 cm^{-1} (ketal).

Found: C, 64.43; H, 6.09; N, 4.76%. Calcd for

$C_{46}H_{53}N_3O_{13}$: C, 64.55; H, 6.24; N, 4.91%.

Proof for the Structure of VI. The monoisopropylidene derivative VI (26 mg) was benzylated with benzyl bromide (0.036 ml) in the presence of barium oxide (47 mg) and barium hydroxide octahydrate (58 mg), similarly as described for the preparation of IV. TLC using the solvent system (b) showed that VI completely disappeared and a new spot appeared. An oily product (20 mg) was dissolved in a mixture of acetic acid (6.0 ml), methyl cellosolve (3.0 ml), water (1.6 ml) and concentrated hydrochloric acid (1.2 ml) and heated at 100°C for 10 hr. The paper chromatography of the hydrolyzate using the solvent mixture (f) and ninhydrin-coloration showed that hydrolysis of the fully benzylated VI gave neither 3-amino-3-deoxy-D-glucose nor 2-deoxystreptamine, while analogous hydrolysis of II (a control test) gave both of them.

Synthetic Hepta-*O*-acetyl-tetra-*N*-(2,4-dinitrophenyl)-kanamycin A (VII). A mixture of VI (1.65 g), finely pulverized mercuric cyanide (0.7 g) and freshly ignited Drierite (5.4 g) in anhydrous dioxane (10 ml) was heated to reflux for 15 min under stirring and then cooled to room temperature. To the mixture was added well dried 2,3,4-tri-*O*-benzyl-6-(*N*-benzylacetamido)-6-deoxy-α-D-glucopyranosyl chloride (2.2 g; 1.9 eq.) in anhydrous benzene (30 ml) and the mixture was stirred vigorously under reflux for 10 hr to give a brown viscous mixture. The mixture was passed through a bed of Celite and washed with dioxane (100 ml) and ethyl acetate (100 ml). The filtrate and washings were combined and evaporated. The brown residue (6.4 g) was extracted with ethyl acetate (120 ml) and the extract was washed with three 100 ml portions of 20% aqueous potassium bromide and 100 ml of water. After drying over anhydrous sodium sulfate, the solution was evaporated to give an oily product (5.8 g). To the product was added 80% aqueous acetic acid (40 ml) and the mixture was kept standing for 30 min with occasional stirring. Evaporation under reduced pressure afforded a colorless sirup (5.0 g). This deacetonated product was hydrogenated over palladium black (0.5 g) in a solvent mixture of dioxane (30 ml), water (2 ml) and concentrated hydrochloric acid (3 ml) under 3.5 atm of hydrogen pressure at about 40°C with occasional addition of small portions of water whose total volume was 30 ml. After 24 hr, the hydrogenation was completed and the catalyst was filtered off. The solution was evaporated under reduced pressure below 30°C and made free from hydrogen chloride by co-distillation with *n*-butanol to afford a colorless sirup (1.4 g). The product was heated with 1 N barium hydroxide (60 ml) at 100°C for 2.4 hr to remove the *N*-acetyl group. The hydrolyzate was neutralized with 3 N sulfuric acid to pH 2. Inorganic matter was removed by centrifuging and the supernatant was treated with Dowex 1×2 (OH type) to pH about 9.5. After removal of the resin, the solution was evaporated to give a colorless sirup (0.8 g). Finally, the *N*-benzyl blocking was removed by catalytic hydrogenation. The sirup (0.8 g) in water (10 ml) and concentrated hydrochloric acid (0.5 ml) was shaken over palladium black (0.3 g) under 3.5 atm of hydrogen pressure for 48 hr at about 40°C. After removal of the catalyst, the solution was evaporated under reduced pressure at 30°C and followed by co-distillation with *n*-butanol to afford a glassy product (0.9 g). The product was ninhydrin-positive and the major R_f value indicated that the product consisted of the hydrochloride of synthetic kanamycin A. However, attempts to isolate it were unsuccessful. Then the product was dinitrophenylated with 2,4-dinitrofluorobenzene (1.7 g) in 50% aqueous ethanol (60 ml) in the presence of sodium bicarbonate (0.63 g) at room temperature overnight under stirring, whereupon a gummy product separated. Addition of water (80 ml) to the mixture and further agitation made the gummy product powdery. The yellow powder (1.73 g) was acetylated with acetic anhydride (30 ml) in the presence of freshly fused sodium acetate (1.5 g) at 100°C for 10 hr with stirring. The resulting mixture was evaporated *in vacuo* and the residue was extracted with excess acetone. The extract was evaporated and made free from acetic anhydride by co-distillation with toluene to give a yellow glass (2.2 g), which showed a major spot of R_f 0.27 together with several minor spots on TLC using the solvent system (e). The product was chromatographed on a silica-gel column (200 g; 4.7×26 cm) with the same solvent system, the effluent being cut into 10 ml each. The main product having R_f value 0.27 appeared in fractions of Nos. 65—70. Evaporation gave yellow needles, 0.28 g (overall yield from VI 10%), recrystallization from the same solvent system gave VII; mp 210—213°C (decomp.), $[\alpha]_D^{18}$ +50° (*c* 1.0, acetone), IR spectrum: 3340, 1625, 1600, 1550, 1525, 1340, 835 and 745 (NHDNP), 1765, 1370 and 1220 cm^{-1} (OAc).

Found: C, 46.71; H, 4.22; N, 11.58%. Calcd for $C_{56}H_{58}N_{12}O_{34}$: C, 46.61; H, 4.05; N, 11.65%.

The melting point of VII was not depressed by admixture with the hepta-*O*-acetyl-tetra-*N*-(2,4-dinitrophenyl) derivative of natural kanamycin A described below. On TLC with the solvent system (e), the synthetic VII and the above-mentioned derivative of kanamycin A showed identical mobilities and their IR spectra were superimposable.

Synthetic Kanamycin A (VIII). A sample (50 mg) of VII was dissolved in methanol (8 ml) saturated with ammonia at 0°C and the solution was allowed to stand at room temperature for 4 hr. Concentration of the solution *in vacuo* gave a sirup, which was treated with Dowex 1×2 (OH type; *ca.* 2 ml of wet resin) in acetone (9 ml) at room temperature with stirring overnight. After removal of the resin, the solution was evaporated and followed by purification by passing through a small column of Dowex 1×2 (OH type; *ca.* 1 ml) to give a colorless glass, which was treated with aqueous methanol containing ethanol to afford the crystalline free base of synthetic kanamycin A (VIII); yield 47%, $[\alpha]_D^{18}$ +149° (*c* 0.87, water).

Found: C, 44.47; H, 7.69; N, 11.27%. Calcd for $C_{18}H_{36}N_4O_{11}$: C, 44.62; H, 7.49; N, 11.56%.

On descending paper chromatography by ninhydrin-coloration using the solvent system (f), the R_f value of the synthetic product VIII agreed with that of the natural kanamycin A. Infrared spectra of VIII and the natural specimen were superimposable. The antibiotic spectra and minimal inhibitory concentrations[14] of the synthetic product VIII against test organisms coincided with that of natural kanamycin A.

Natural Hepta-*O*-acetyl-tetra-*N*-(2,4-dinitrophenyl)-kanamycin A. To a solution of natural kanamycin

14) S. Umezawa, K. Tatsuta and S. Kto, *J. Antibiotics*, **21**, 367 (1968).

A (0.5 g) in water (5 m*l*) was added sodium bicarbonate (0.2 g) and 2,4-dinitrofluorobenzene (0.45 g) in ethanol (5 m*l*), and the mixture was agitated for 2 hr at room temperature to give a yellow gummy substance, which was rubbed by glass rod with water (15 m*l*) to give a yellow powdery solid; 0.9 g (75%).

The dinitrophenyl derivative was then fully acetylated with acetic anhydride (20 m*l*) in the presence of anhydrous sodium acetate (2 g) by heating at 100°C under stirring for 3 hr. The resulting mixture was evaporated *in vacuo* and followed by dilution with excess acetone. Insoluble matters were filtered off and the solution was evaporated and made free from acetic anhydride by co-evaporation with toluene to give a yellow glass, 1.95 g. The product was purified by silica-gel column chromatography (150 g; 3.5 × 35 cm) with a solvent mixture of benzene-MEK (2 : 1), the effluent being cut into 10 g each. The fraction Nos. 34—37 were combined and evaporated to afford *N*-dinitrophenyl-*O*-acetyl derivative of natural kanamycin A; 0.6 g (41% from the base). Recrystallization from the same solvent system gave yellow needles; mp 210—213°C (decomp.), $[\alpha]_D^{18}$ +52° (*c* 1.0, acetone), IR spectrum: 3340, 1625, 1600, 1550, 1525, 1340, 835 and 745 (NHDNP), 1765, 1370 and 1220 cm^{-1} (OAc).

Found: C, 46.74; H, 4.10; N, 11.69%. Calcd for $C_{56}H_{58}N_{12}O_{34}$: C, 46.61; H, 4.05; N, 11.65%.

We wish to thank Professor H. Umezawa for his helpful advice, Mr. S. Nakada for microanalyses and Mr. T. Tsumura for technical assistance. We also thank the Kawasaki-Factory of Meiji-Seika, Ltd., for supplying kanamycin A.

(Received July 16, 1968)

4-*O*-(3,4-Di-*O*-benzyl-2,6-dicarbobenzoxyamino-2,6-dideoxy-*α*-D-glucopyranosyl)-*N*,*N*′-dicarbobenzoxy-2-deoxystreptamine has been prepared from neamine and condensed with 3-acetamido-2,4,6-tri-*O*-benzyl-3-deoxy-*α*-D-glucopyranosyl chloride by a modified Koenigs-Knorr reaction to give an *α*,*α*-diglycoside. The identity of the product with a substance of the same structure derived from natural kanamycin B was shown. Removal of the masking groups from the product gave the synthetic kanamycin B, which was identical with natural kanamycin B.

Paper chromatography[2] and ion-exchange chromatography[3] of the kanamycin complex revealed the presence of two minor congeners, kanamycin B and C, in addition to kanamycin A. Kanamycin B was isolated by counter-current distribution of the salicylidene derivatives and by chromatography.[4,5] Kanamycin B is composed of 2-deoxystreptamine, 3-amino-3-deoxy-D-glucose and 2,6-diamino-2,6-dideoxy-D-glucose.[4,6] The structure of kanamycin B was established as *O*-(2,6-diamino-2,6-dideoxy-*α*-D-glucopyranosyl)-(1→4)-*O*-[3-amino-3-deoxy-*α*-D-glucopyranosyl-(1→6)]-1,3-diamino-1,2,3-trideoxy-*myo*-inositol.[6,7] In other words, kanamycin B is an *α*-glycoside of neamine[8] (I) and 3-

amino-3-deoxy-D-glucose. In this paper, we describe the synthesis of kanamycin B from neamine and 3-amino-3-deoxy-D-glucose. Since we[9] have synthesized neamine (I) from paromamine which was synthesized[10] from glucosamine and 2-deoxystreptamine, the combined achievements constitute the total synthesis of kanamycin B.

Neamine was converted into tetra-*N*-carbobenzoxy-neamine (II). Treatment of II with 2,2-dimethoxypropane in the presence of *p*-toluenesulfonic acid in *N*,*N*-dimethylformamide (DMF) at 110°C followed by chromatography on silica gel gave a mixture of monoisopropylidene derivatives (IIIa and IIIb) in a 41% yield. The mixture was benzylated with benzyl bromide in the presence of barium oxide and barium hydroxide in DMF and followed by chromatography on silica gel to afford 4-*O*-(3,4-di-*O*-benzyl-2,6-dicarbobenzoxy-amino-2,6-dideoxy-*α*-D-glucopyranosyl)-*N*,*N*′-dicarbobenzoxy-5,6-*O*-isopropylidene-2-deoxystreptamine (IVa) mp 185°C, $[\alpha]_D^{18}$ +57° (*c* 0.67, DMF) and 4-*O*-(2,6-dicarbobenzoxy-amino-2,6-dideoxy-3,4-*O*-isopropylidene-*α*-D-glucopyranosyl)-5,6-di-*O*-benzyl-*N*,*N*′-dicarbobenzoxy-2-deoxystreptamine (IVb) mp 230—231°C, $[\alpha]_D^{18}$ +33° (*c* 0.67, DMF) in 12% and 37% yield respectively.

Deacetonation of IVa by treatment with aqueous acetic acid gave 4-*O*-(3,4-di-*O*-benzyl-2,6-dicarbobenzoxyamino-2,6-dideoxy-*α*-D-glucopyranosyl)-*N*,*N*′-dicarbobenzoxy-2-deoxystreptamine (V) in an 86% yield, mp 221—222°C, $[\alpha]_D^{18}$ +58° (*c* 0.67, DMF).

The compound V was condensed with 3-acetamido-2,4,6-tri-*O*-benzyl-3-deoxy-*α*-D-glucopyranosyl chloride, which was already utilized for the synthesis of kanamycin C,[11] in the presence of mercuric cyanide and Drierite in benzene-dioxane. The condensation product was hydrogenated in a mixture of dioxane–water–concentrated hydrochloric acid over palladium black to remove the *O*-benzyl and *N*-carbobenzoxy groups, and de-*N*-acetylated with hot aqueous barium hydroxide to give a ninhydrin-positive product. Paper chromatography and bioautography of the product showed that the product mainly contained the substance whose R_f-value coincided with that of natural kanamycin B, however, attempts to isolate it were unsuccessful. Then the product was *N*-dinitrophenylated with 2,4-dinitrofluorobenzene in aqueous ethanol in the presence of sodium bicarbonate and then *O*-acetylated with acetic anhydride and sodium acetate. The product, which showed about four spots of R_f-values 0.40, 0.33, 0.13 and 0.08 on a thin layer chromatogram with a solvent system (c): toluene–methyl ethyl ketone (4 : 1), was chromatographed on a silica gel column with the same solvent system. The substance of R_f-value 0.08 was isolated and proved to be synthetic hexa-*O*-acetyl-penta-*N*-(2,4-dinitrophenyl)-kanamycin B (VI) mp 212—213°C (decomp.), $[\alpha]_D^{18}$ +220° (*c* 0.3, acetone), overall yield from V being 5%.

On the other hand, natural kanamycin B was dinitrophenylated and acetylated by the above-mentioned procedure to afford the hexa-*O*-acetyl-penta-*N*-(2,4-dinitrophenyl) derivative of kanamycin B, mp 217—218°C (decomp.), $[\alpha]_D^{18}$ +240° (*c* 0.4, acetone).

The identity of the synthetic VI to the above-mentioned derivative of natural kanamycin B was established by elemental analyses, specific rotations, by their failure to depress the mixed melting point and identical mobilities on thin layer chromatography and infrared spectra.

We have investigated the above-mentioned removal of *O*-benzyl and *N*-carbobenzoxy groups in some detail and found that treatment of the condensation product with sodium in liquid ammonia instead of catalytic hydrogenation with palladium black gave a better result and the overall yield of VI from V was raised to about 15%.

Finally, ammonolysis of the synthetic VI with methanolic ammonia followed by hydrolysis with excess of Dowex 1×2 (OH^-) resin afforded a free base, which was purified by chromatography on a column of the same resin. The free base melted at 178—182°C (decomp.), $[\alpha]_D^{18}$ +130° (*c* 0.5, water). The identity of the free base to the natural kanamycin B [mp 179—181°C (decomp.), $[\alpha]_D^{18}$ +128° (*c* 0.5, water)] was further established by their failure to depress the mixed melting point,

identical mobilities on thin layer chromatography and infrared spectra. The antibiotic spectra and minimal inhibitory concentrations[1] of the synthetic kanamycin B against test bacteria were identical with those of the natural kanamycin B.

Experimental

General Procedures. Thin layer chromatography (TLC) was carried out on "Silica-Rider for TLC" (Dai-ichi Pure Chemicals Co.) using three solvent systems: (a) benzene-ethanol (7 : 1), (b) benzene-methyl ethyl ketone (MEK) (4 : 1), and (c) toluene-MEK (4 : 1), as mobile phases. Paper chromatography was performed in the previously described fashion.

Tetra-*N*-carbobenzoxy-neamine (II). To a solution of neamine (I) (15 g) and sodium carbonate decahydrate (39 g) in water (150 m*l*) was added acetone (450 m*l*) under agitation and the mixture was cooled to −5 — −10°C. Carbobenzoxychloride in toluene (30%; 104 g) was added for one hour. After having been vigorously stirred for about 4 hr at −5— −10°C, the reaction mixture was set aside in a refrigerator overnight. The resulting colorless solid was collected by filtration and tightly pressed between filter papers to remove oily matter and moisture. The waxy product was pulverized with 1 N hydrochloric acid (600 m*l*), filtered and dried *in vacuo* to give a colorless powder; yield 43 g. The product was dissolved in a hot mixture of dioxane (850 m*l*) and water (6 m*l*) and insoluble matters were filtered off. When the filtrate was allowed to stand at room temperature overnight, a colorless gelatinous mass precipitated; yield 34 g. The mother liquor deposited a second crop, 1.2 g. Total yield 89%, mp 259°C (decomp.), $[\alpha]_D^{18}$ +44° (*c* 0.67, DMF), IR spectrum (KBr): 1698 and 1538 cm^{-1} (NHCbz).

Found: C, 61.59; H, 5.97; N, 6.64%. Calcd for $C_{44}H_{50}N_4O_{14}$: C, 61.54; H, 5.86; N, 6.52%.

4-*O*-(3,4-Di-*O*-benzyl-2,6-dicarbobenzoxyamino-2,6-dideoxy-α-D-glucopyranosyl)-*N*,*N*′-dicarbobenzoxy-5,6-*O*-isopropylidene-2-deoxystreptamine (IVa) and 4-*O*-(2,6-Dicarbobenzoxyamino-2,6-dideoxy-3,4-*O*-isopropylidene-α-D-glucopyranosyl)-5,6-di-*O*-benzyl-*N*,*N*′-dicarbobenzoxy-2-deoxystreptamine(IVb). A mixture of II (5.2 g), *p*-toluenesulfonic acid monohydrate (0.052 g) and 2,2-dimethoxypropane (1.4 m*l*) in anhydrous DMF (30 m*l*) was heated at 110°C for 4 hr. The resulting reddish-brown solution was cooled and neutralized with about 10 m*l* of Amberlite IRA-400 (OH type) washed with methanol before use. The resin was filtered off and the solution was evaporated. The residue was chromatographed on a silica-gel column (500 g; 47×680 mm) using the solvent system (a) to separate two fractions of R_f-values 0.65 and 0.55 on TLC with the solvent system (a). The fraction of R_f 0.55 appeared between 930 m*l* and 2100 m*l*. The fraction was still a mixture of two kinds of mono-*O*-isopropylidene derivatives (IIIa and IIIb); yield 3.37 g (63%), $[\alpha]_D^{18}$ +42° (*c* 0.67, DMF).

Found: C, 63.03; H, 6.31; N, 6.34. Calcd for $C_{47}H_{54}N_4O_{14}$: C, 62.80; H, 6.05; N, 6.23%.

The mixture (5.28 g) of monoisopropylidene derivatives was dissolved in anhydrous DMF (70 m*l*) and to the solution were added powdery barium oxide (5.04 g) and finely crushed barium hydroxide octahydrate (6.35 g). After being cooled to −10°C, benzyl bromide (5.1 m*l*) was added dropwise into the mixture, and vigorously stirred at 0°C for 4 hr and then at room temperature for an additional 20 hr. The slightly colored mixture was diluted with chloroform (140 m*l*) and the insoluble matters were filtered off. The filtrate was evaporated *in vacuo* and the residue was extracted with chloroform. Concentration of the extract gave an oily substance, which was chromatographed on a column of silica-gel (500 g, 50×695 mm), using the solvent system (b). Each 15 g fraction was examined by TLC. The fractions containing only a substance of an R_f-value 0.50 appeared in tube Nos. 20—29. Evaporation afforded IVa, yield 0.74 g (12%), mp 185°C, $[\alpha]_D^{18}$ +57° (*c* 0.67, DMF), IR spectrum (KBr): 3350, 1700 and 1536 (NHCbz), 1137 and 1060 cm^{-1} (ketal).

Found: C, 68.07; H, 6.32; N, 5.30%. Calcd for $C_{61}H_{66}N_4O_{14}$: C, 67.89; H, 6.16; N, 5.19%.

Fractions (850 m*l*) after tube No. 43 contained the substance of R_f 0.25. Evaporation gave IVb, yield 2.33 g (37%), mp 230—231°C, $[\alpha]_D^{18}$ +33° (*c* 0.67, DMF), IR spectrum (KBr): 3350, 1700 and 1535 (NHCbz), 1157, 1133, 1060 and 1020 cm^{-1} (ketal).

Found: C, 67.43; H, 6.37; N, 5.32%. Calcd for $C_{61}H_{66}N_4O_{14}$: C, 67.89; H, 6.16; N, 5.19%.

4-*O*-(3,4-Di-*O*-benzyl-2,6-dicarbobenzoxyamino-2,6-dideoxy-α-D-glucopyranosyl)-*N*,*N*′-dicarbobenzoxy2-deoxystreptamine (V). A sample (0.74 g) of IVa was dissolved in warm aqueous acetic acid (80%, 25 m*l*), and the solution was kept standing at room temperature overnight. The resulting solid was collected, washed well with water and dried *in vacuo* to give an analytically pure solid of V; yield 0.64 g (90%), mp 221—222°C, $[\alpha]_D^{18}$ +58° (*c* 0.67, DMF), IR spectrum (KBr): 3340, 1699 and 1540 (NHCbz), 1037 cm^{-1} (*O*-benzyl).

Found: C, 66.74; H, 6.41; N, 5.58%. Calcd for $C_{58}H_{62}N_4O_{14}$: C, 67.04; H, 6.01; N, 5.39%.

Proof for the Structure of V. Each sample (10 mg) of V and IVb was dissolved in a mixture of acetic acid (0.6 m*l*) and acetic anhydride (0.1 m*l*) and to the solution was added a mixture of acetic acid and sulfuric acid (5 : 1; 0.07 m*l*) at 0°C. The solutions were stirred at room temperature overnight and then poured onto cracked ices (about 3 g) to separate an oily substance, which was extracted with benzene (6 m*l*). Each extract was washed with aqueous 5% sodium bicarbonate solution and water. After drying over sodium sulfate, each benzene-solution was evaporated and the residue was de-*O*-acetylated by treatment with saturated methanolic ammonia (10 m*l*) in a refrigerator overnight. The mixture was evaporated *in vacuo* and to the residue was added 1 N aqueous barium hydroxide (8 m*l*). After heating at 100°C for 4 hr, each hydrolyzate was neutralized with 3 N sulfuric acid to pH 2 and insoluble matters were removed by centrifuge. Each supernatant was treated with Dowex 1×2 (OH type) to pH 8—9 and the resin was filtered off. Evaporation and drying *in vacuo* afforded a mixture of free bases. Each mixture was examined by paper chromatography with the solvent system of (d) by ninhydrin coloration. 2-Deoxystreptamine was present in the hydrolyzate from V, while IVb did not produce 2-deoxystreptamine.

Synthetic Hexa-*O*-acetyl-penta-*N*(2,4-dinitrophenyl)-kanamycin B (VI). A mixture of V (0.8 g), well pulverized mercuric cyanide (0.31 g) and freshly activated Drierite (3.3 g) in a mixed solvent of benzene (9 m*l*) and dioxane (3 m*l*) was heated to reflux with stirring under anhydrous conditions and then cooled to room temperature. To the mixture was added well dried 3-acetamido-2,4,6-tri-*O*-benzyl-3-deoxy-*α*-D-glucopyranosyl chloride (0.60 g; 1.7 eq.) at once and the mixture was vigorously stirred at reflux temperature for 20 hr. During the course of the reaction the mixture gradually became somewhat thick and brown. After removal of insoluble matters by filtration, the solution was evaporated. The dark brown residue was extracted with ethyl acetate (70 m*l*) and the extract was washed with five 20 m*l* portions of 20% aqueous potassium bromide and then three 20 m*l* portions of water. After being dried over anhydrous sodium sulfate, the ethyl acetate solution was evaporated to give a sirup, 0.75 g. The condensation product was hydrogenated over palladium black (0.3 g) in a mixture (24 m*l*) of dioxane, water, methanol and concentrated hydrochloric acid (20 : 1 : 2 : 1) at about 40°C under 3.5 atm of hydrogen pressure with occasional additions of small portions of water, whose total volume was 5 m*l*. After removal of the catalyst, the hydrogenated solution was evaporated to dryness *in vacuo*. The residue was again hydrogenated over fresh palladium black (0.15 g) in the same manner as mentioned above until the total volume of water reached 10 m*l*. The same hydrogenation procedure was further repeated twice. The total duration of hydrogenation took 150 hr. After removal of the catalyst, the solution was evaporated to give a ninhydrin-positive sirup, 0.55 g, which was hydrolyzed by heating with 1 N barium hydroxide (10 m*l*) on a boiling water water bath for 2.5 hr. After cooling to room temperature, the mixture was neutralized with 3 N sulfuric acid to pH 2 and the insoluble matter was removed by centrifuge. The solution was neutralized with Dowex 1×2 (OH type) to pH 7—8, and the resin was filtered. Evaporation of the filtrate afforded a sirup of a mixture of free bases, 0.51 g. All attempts to obtain kanamycin B from the product in a pure form have so far been unsuccessful.

The mixture (0.5 g) of free bases was dinitrophenylated with 2,4-dinitrofluorobenzene (1.2 g) in the presence of sodium bicarbonate (0.55 g) in a mixture (60 m*l*) of water and ethanol (1 : 1) under stirring at room temperature overnight. The resulting mixture was neutralized with 0.1 N hydrochloric acid and dried up *in vacuo* to give a yellowish-orange residue, from which excess 2,4-dinitrofluorobenzene was removed by co-distillation with *n*-butanol. The residue was fully acetylated by heating with acetic anhydride (20 m*l*) and anhydrous sodium acetate (1.1 g), at 110°C, stirring vigorously for 5 hr. The mixture was dried up *in vacuo* and extracted with acetone. The extract was again evaporated to afford a yellow sirup, 1.5 g, which showed about four spots of R_f-values 0.40, 0.33, 0.13 and 0.08, on TLC, developing with the solvent system (c). The sirup was chromatographed on a column of silica-gel (10 g, 22×55 mm) with the solvent system (c), each fraction of the effluent being 10 g. The substance of R_f-value 0.08 appeared in the fractions of Nos. 12—25, which was evaporated to give yellow needles of VI, 0.06 g (5% overall-yield from V). Recrystallization from the solvent system (c); mp 212—213°C (decomp.), $[\alpha]_D^{18}$ +220° (*c* 0.3, acetone), IR spectrum (KBr): 3350, 3120, 1625, 1600, 1530, 1340, 835 and 745 (NHDNP), 1760 and 1220 cm^{-1} (OAc).

Found: C, 46.16; H, 4.23; N, 12.96%. Calcd for $C_{60}H_{59}N_{15}O_{36}$: C, 46.01; H, 3.80; N, 13.42%.

On TLC the R_f-value of the synthetic VI agreed with that of the hexa-*O*-acetyl-penta-*N*-(2,4-dinitrophenyl) derivative of natural kanamycin B (see below). Infrared spectra of VI and the above derivative were superimposable. The melting point of VI was not depressed by admixture with the above derivative.

We have investigated the above-mentioned removal of *O*-benzyl and *N*-carbobenzoxy groups in some detail. Instead of hydrogenation with palladium black, the condensation product (a sirup 0.7 g) was dissolved in liquid ammonia (60 m*l*) and sodium (0.3 g) was added under cooling in a solid carbon dioxide - methanol bath (−80——85°C). The solution became blue and the reaction was continued for 2 hr with occasional stirring. To the solution was added ammonium chloride until the blue color disappeared. Evaporation of the solution at room temperature left a colorless residue, which was treated with water to precipitate insoluble matters. The mixture was filtered and the solution was evaporated. The resulting colorless, ninhydrin-positive residue was dissolved in 1 N aqueous barium hydroxide solution (50 m*l*) and refluxed at 100°C for 2 hr. After cooling to room temperature, the solution was acidified with 3 N sulfuric acid to pH 2 and the barium salt was removed by centrifuge. The solution was filtered and neutralized with Dowex 1×2 (OH type) to pH about 7. After removal of the resin, the solution was evaporated *in vacuo* to give a colorless sirup. Dinitrophenylation and acetylation followed by chromatography with silica gel were carried out by similar procedure as described above. The yield of VI was 0.18 g (15% overall yield from V).

Synthetic Kanamaycin B (VII). A sample (77 mg) of VI was dissolved in methanol (50 m*l*), saturated with dry ammonia gas at 0°C and the red solution was set aside at room temperature overnight. After evaporation under reduced pressure, the residual yellow sirup was taken up with acetone (5 m*l*) and treated with excess Dowex 1×2 (*ca.* 2 m*l* of wet OH type) at room temperature for 12 hr with stirring. After removal of resin, the solution was evaporated *in vacuo* to give a glassy residue (24 mg) of VII, which was purified by chromatography with a small column of Dowex 1×2 (6× 50 mm). Treatment of the product with ethanol containing a small amount of water gave an analytically pure VII; 17 mg (72%), mp 178—182°C (decomp.), $[\alpha]_D^{18}$ +130° (*c* 0.5, water).

Found: C, 44.90; H, 7.34; N, 14.51. Calcd for $C_{18}H_{37}N_5O_{10}$: C, 44.71; H, 7.71; N, 14.49%.

On a descending paper chromatogram the R_f-value of the synthetic VII was in agreement with that of natural kanamycin B, after developing for 72 hr at room temperature. The antibiotics spectra and minimal inhibitory concentrations[1] of synthetic VII against test organisms coincided with those of natural kanamycin B.

Hexa-*O*-acetyl-penta-*N*-(2,4-dinitrophenyl) Derivative of Natural Kanamycin B. Free base of natural kanamycin B (40 mg) was dinitrophenylated with 2,4-dinitrofluorobenzene (59 mg) in the presence

of sodium bicarbonate (26 mg) in a mixture of water (0.5 m*l*) and ethanol (0.5 m*l*) with vigorous agitation at room temperature overnight. The yellow precipitate was collected and washed thoroughly with water and ethanol; yield 77 mg.

The product (75 mg) was then fully *O*-acetylated by heating with acetic anhydride (7.5 m*l*) in the presence of anhydrous sodium acetate (750 mg) at 110°C for 4 hr under stirring. The mixture was dried up to give a residue, which was extracted with an excess of acetone. The extract was evaporated *in vacuo* to give a yellow product; 99.9 mg. The product was purified on a column of silica-gel (10 g; 22×55 mm) with toluene-MEK (2 : 1), the effluent being cut into 1 m*l* each. After the initial effluent of 24 m*l*, hexa-*O*-acetyl-penta-*N*-(2,4-dinitrophenyl) derivative of natural kanamycin B was eluted in tube Nos. 5—24; 77 mg (49.2%), mp 217—218°C (decomp.), $[\alpha]_D^{18}$ +240° (*c* 0.4, acetone), IR spectrum (KBr): 3350, 3120, 1625, 1600, 1530, 1340, 835 and 745 (NHDNP), 1760 and 1225 cm^{-1} (OAc).

Found: C, 46.31; H, 4.21; N, 13.38%. Calcd for $C_{60}H_{59}N_{51}O_{36}$: C, 46.01; H, 3.80; N, 13.42%.

The authors are indebted to the Kawasaki-Factory of Meiji-Seika Co. Ltd., for supplying kanamycin B. Thanks are also due to Professor Hamao Umezawa of Institute of Microbial Chemistry for helpful advice and to Mr. Saburo Nakada for microanalysis.

Gas Chromatographic Determination of Nitrogen in Metals by Means of Inert Gas Fusion Using Silicon

Jiro KASHIMA and Takuo YAMAZAKI

The Castings Research Laboratory, Waseda University, Totsuka-machi, Shinjuku-ku, Tokyo

(Received March 16, 1968)

Nitrogen in metals has been determined by means of chemical distillation which is a modification of the Kjeldahl method.[1,2] A vacuum fusion method and inert gas fusion method each making use of a platinum bath have also recently come into use. The results obtained by these methods agree with those obtained by the Kjeldahl method.[3,4]

This paper deals with the determination of nitrogen by means of inert gas fusion. We found that when a metal or alloy is melted in a graphite crucible in the presence of silicon, nitrogen and oxygen contained in the metal or alloy are completely set free. The molten product passes into the graphite crucible. Utilizing this fact a new method for the determination of nitrogen was worked out. This method is much simpler than the Kjeldahl method.

A tin capsule containing the sample (10—80 mg) and silicon (100—300 mg) was put in a graphite crucible. The graphite crucible was heated in a stream of argon up to 1900°C by means of a high frequency induction furnace. In less than a minute the molten product passed into the crucible. All of the gases contained in the sample were liberated. The gases were then passed through a column (length=70 cm, inner diameter=0.4 cm), filled with activated charcoal and kept at −20°C, for 3 min. The gases absorbed by activated charcoal were liberated by heating the column up to 140°C, and the amount of liberated gases was determined by means of gas chromatography. The amount of nitrogen was calculated by means of the formula

$$m = A\frac{a-b}{w} \times 100,$$

where m=nitrogen in wt %, A=constant, a=chromatographic area in cm^2, b=chromatographic area in blank test in cm^2, w=weight of sample in gram.

The constant A denotes the weight of nitrogen per square centimeter of chromatographic area. It has the value 1.5 μg per cm^2. The results are shown in Fig. 1. For the construction of the figure, the procedure given in a previous paper was used.[5] Linearity holds up to 5 μg of nitrogen. Deviation from linearity takes place for the values of nitrogen higher than this.

Degassed graphite crucibles were used in the experiment. Degassing was carried out by heating

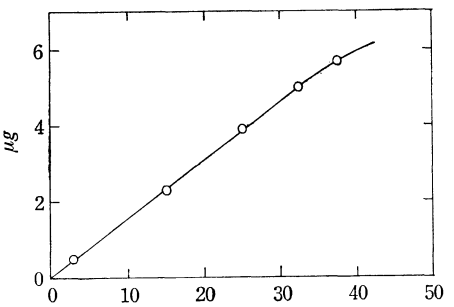

Fig. 1. Relation between the weight of nitrogen and gas chromatographic area.

Table 2. Nitrogen content of pure iron prepared by various methods

Preparation of iron	No. of determinations	Nitrogen, wt%		Standard deviations %
		Inert gas fusion	Kjeldahl method	
Iron, melted by arc, melted for the second time in a vacuum furnace	4	0.0008_8	0.0009	0.0001_0
Iron, melted by arc	4	0.0035_5	0.0035	0.00009_6
Iron, open hearth	5	0.0106_0	0.0106	0.0001_3

a crucible containing 100 mg of silicon at 1900°C for 3 min in a stream of argon. Most of the gases were eliminated by this treatment. The treatment was repeated. The amounts of nitrogen and oxygen liberated by the second treatment were determined by means of gas chromatography and were found to be negligibly small. A degassed graphite crucible could be use three times for the determination of nitrogen. The results are given in Table 1.

As an illustration, the results of the determination of nitrogen in pure iron are given in Table 2. The values obtained coincide with those obtained by means of the Kjeldahl method. The results obtained from other metals are summarized in Table 3.

Table 3. Nitrogen content in metals

Preparation of 2-Alkenonitrile by Means of the Pyrolysis of Diethyl 1-Cyanoalkyl Phosphate

Yoshiki OKAMOTO, Tsutomu NITTA and Hiroshi SAKURAI

The Institute of Scientific and Industrial Research, Osaka University, Yamada-kami, Suita-shi, Osaka

(Received April 25, 1968)

In previous papers, it has been reported that the long-chain aliphatic aldehydes and *α*-hydroxycarboxylic acids were prepared from diethyl acylphosphonates by treatment with sodium borohydride or potassium cyanide *via* the following scheme:

$$\mathrm{RCOPO(OC_2H_5)_2} \xrightarrow{\mathrm{NaBH_4}} \mathrm{RCH(OH)PO(OC_2H_5)_2} \xrightarrow{\mathrm{OH^-}} \mathrm{RCHO} + \mathrm{HPO(OC_2H_5)_2} \quad (1)^{1)}$$

$$\mathrm{RCOPO(OC_2H_5)_2} \xrightarrow[2)\ \mathrm{KCN}]{1)\ \mathrm{NaHSO_3}} \mathrm{RCH(OH)PO(OC_2H_5)_2} \xrightarrow{\mathrm{OH^-}} \mathrm{RCH(CN)OPO(OC_2H_5)_2} \xrightarrow[\mathrm{H_2O}]{\mathrm{H^+}} \mathrm{RCH(OH)COOH} \quad (2)^{2)}$$

It has also been reported that 2-butenonitrile was synthesized by the pyrolysis of 1-cyanopropyl acetate, itself prepared by the acetylation of propionaldehyde cyanhydrin.[3] In order to get long-chain 2-alkenonitriles, the corresponding long-chain aliphatic aldehydes were necessary. The preparation of long-chain aldehyde is, however, generally troublesome, and, in addition, the cyanhydrin could not be acetylated in a good yield.

In this note, a convenient method for the preparation of 2-alkenonitrile by means of the pyrolysis of diethyl 1-cyanoalkyl phosphate will be reported.

2) Y. Okamoto, T. Nitta and H. Sakurai, *ibid.*, **71**, 187 (1968).

3) D. L. Macpeek, P. S. Strarcher and B. P. Benjamin, *J. Am. Chem. Soc.*, **81**, 680 (1959).

$$RCH_2\dot{C}H(OPO(OC_2H_5)_2)\dot{C}N \longrightarrow RHC{=}CHCN + HPO(OC_2H_5)_2 \quad (3)$$

Diethyl acylphosphonates were easily prepared in good yields by the reaction of the corresponding acid chloride and triethyl phosphite.[2] The properties and the yields are summarized in Table 1.

Table 1. Preparation of diethyl acylphosphonates ($RCH_2COPO(OC_2H_5)_2$)

R	Yield (%)	Bp (°C/mmHg)	n_D^{25}
CH_3	85	66—67/0.5	1.4245
C_2H_5	90	75—76/1	1.4273
C_4H_9	89	85—86/0.5	1.4326
C_8H_{17}	87	125—126/0.5	1.4392
$C_{10}H_{21}$	88	155—156/1	1.4407

Diethyl 1-cyanoalkyl phosphates could be obtained from the corresponding diethyl acylphosphonate and potassium cyanide in an aqueous solution, but the yields were reduced by the hydrolysis reaction of some of the diethyl acylphosphonates.

$$RCOPO(OC_2H_5)_2 + H_2O \xrightarrow{OH^-} RCOOH + HPO(OC_2H_5)_2 \quad (4)$$

On the other hand, when the sodium bisulfite adduct of diethyl acylphosphonate, which had been prepared by the addition of diethyl acylphosphonate to the saturated aqueous solution of sodium bisulfite, was treated with an aqueous solution of potassium cyanide at pH 8, the corresponding cyanhydrin derivative was obtained as crystals in high yields. The yields and the properties are listed in Table 2. The infrared spectra showed the absortption peak of the hydroxyl group at 3170 cm^{-1}.

Diethyl 1-cyano-1-hydroxyalkylphosphonate isomerized rapidly into diethyl 1-cyanoalkyl phosphate in a large excess of a saturated aqueous solution of potassium cyanide (pH>12). The reaction occurred exothermically, and the diethyl 1-cyanoalkyl phosphate was almost quantitatively separated in an oily layer. After having been washed with water, the phosphate was used for the pyrolysis without further purification. The infrared spectra showed no absorption peak of the hydroxyl group.

Table 2. Preparation of diethyl 1-cyano-1-hydroxyalkylphosphonate ($RCH_2C(OH)(CN)PO(OC_2H_5)_2$)

R	Yield (%)	Mp (°C)		Anal. (%) P	N	C	H
CH_3	85	—	Found	14.01	6.31	43.22	7.11
			Calcd	14.00	6.33	43.88	7.29
C_2H_5	88	68—69	Found	13.00	5.97	46.00	7.79

			Calcd	11.77	5.32	50.19	8.42
C_8H_{17}	87	42—43	Found	10.21	4.41	56.00	9.70
			Calcd	10.01	4.53	55.01	9.76
$C_{10}H_{25}$	90	45—46	Found	8.86	3.93	58.58	10.05
			Calcd	8.92	4.03	58.77	10.03

The pyrolysis was carried out under reduced pressure (2—3 mmHg) in a stainless steel tube (ϕ 3 cm×60 cm) heated at 400—600°C in an electric furnace. The thermal decomposition of diethyl 1-cyanoalkyl phosphate occurred thoroughly above 300°C. The pure 2-alkenonitriles were obtained by the fractional distillation of the pyrolysis products. The yields and the properties of 2-alkenonitriles are listed in Table 3.

Table 3. Preparation of 2-alkenonitrile obtained from 1-cyanoalkyl phosphate (RCH=CHCN)

R	Yield (%)	Bp (°C/mmHg)	n_D^{20}
CH_3	71	103—105	1.4195
C_2H_5	53	44—45/17	1.4301
C_4H_9	52	71—74/22	1.4399
C_8H_{17}	52	86—89/1.5	1.4507
$C_{10}H_{21}$	51	105—109/3.5	1.4549

The purities of the 2-alkenonitriles were checked by gas chromatography (>98%). The infrared spectra indicated that the double bond (C=C) was only in the trans form (965 cm^{-1}).

The yield of 2-butenonitrile from diethyl 1-cyanopropyl phosphate was almost equal to that from 1-cyanopropyl acetate.

Diethyl 1-cyano-2-phenylethyl phosphate gave 3-phenylpropenonitrile in a 76% yield, but diethyl 1-cyanobenzyl phosphate did not give the corresponding 2-alkenonitrile, but rather benzalaldehyde in a 51% yield.

Experimental

Diethyl Acylphosphonate. The diethyl acylphosphonates were prepared by the reaction of the corresponding acyl chlorides with triethyl phosphite according to a procedure described earlier.[2]

Diethyl 1-Cyano-1-hydroxyalkylphosphonate and Diethyl 1-Cyanoalkyl Phosphate. One hundred grams of diethyl acylphosphonate were stirred, drop by drop, into 400 ml of a saturated aqueous solution of sodium bisulfite at 30°C. The reaction mixture came to be viscous; then a saturated aqueous solution of potassium cyanide was stirred in over a period of 1 hr, until the pH of the mixture rose to 8. The oily layer separated was extracted with ether. After the evaporation of the solvent, diethyl 1-cyano-1-hydroxyalkylphosphonate solidified on cooling. It was then recrystallized

from acetone (see Table 2).

Eighty grams of diethyl 1-cyano-1-hydroxyalkylphosphonate were added slowly to 200 m*l* of a saturated aqueous solution of potassium cyanide cooled with ice water. The isomerization reaction occurred exothermically. Then the reaction mixture was stirred for 30 min, and the product was extracted with ether. The ethereal extract was washed with water. After the removal of the solvent under a vacuum, the residue, diethyl 1-cyanoalkyl phosphate, was obtained; it was used for pyrolysis without any further purification.

Pyrolysis of Diethyl 1-Cyanoalkyl Phosphate. Typical Procedure. Thirty grams of diethyl 1-cyanoalkyl phosphate were charged continuously, at the rate of 1 m*l*/min, into the top of a 60 cm stainless steel tube (dia. 3 cm), which was inclined at twenty degrees from the horizontal; the tube was then heated at 600°C under reduced pressure (3—5 mmHg). The products were trapped as solid materials in a tube cooled with liquid nitrogen. Pure 2-alkenonitrile was obtained by fractional distillation in the presence of a catalytic amount of hydroquinone (see Table 3).

The Crystal Structure of Tetraallyldichromium, $Cr_2(C_3H_5)_4$

Takao Aoki, Akio Furusaki and Yujiro Tomiie†

Faculty of Science, Kwansei Gakuin University, Nishinomiya

and Katsuhiro Ono and Kenjiro Tanaka

Research Institute of Idemitsu Kosan Co., Ltd., Tokuyama

(Received May 6, 1968)

A product of the reaction of anhydrous chromium chloride with allylmagnesium chloride in an ether solution was found to be a potential component of a catalyst for the polymerization of olefins. The product can be recrystallized from hydrocarbon solutions in needle-like crystals, brownish-black in color and with a metallic luster. Though this compound is exceedingly inflamable when exposed to air, we have succeeded in determining its chemical composition by elementary analysis and its molecular weight by the cryoscopic method. From the results of infrared absorption, mass spectroscopic analysis, and nuclear magnetic resonance, it was concluded that the compound is tetraallyldichromium, corresponding to the molecular formula $Cr_2(C_3H_5)_4$, and that the reaction can be written as follows:

$$2CrCl_3+6C_3H_5MgCl \rightarrow Cr_2(C_3H_5)_4+C_6H_{10}+6MgCl_2.$$

The yield of the reaction reaches 90—95% if the temperature is controlled properly.

With a hope to look into the mechanism of the catalytic activity, we have undertaken an X-ray crystal analysis of tetraallyldichromium.

Samples sealed in glass capillary tubes filled with argon gas were used throughout the experiment because of their high sensitivity to air. The single crystals used were prisms elongated along the c-axis, with dimensions of (0.1—0.2)×(0.1—0.2)×(1.5—3.0)mm. The crystal data are as follows: the molecular weight is 268; the unit cell is tetragonal with $a=18.19\pm0.09$, $c=7.50\pm0.05$ Å, and contains eight molecules of $Cr_2(C_3H_5)_4$; the space group is $P\bar{4}2_1c$—D_{2d}^{4}; the density calculated is 1.44 g·cm^{-3}.

X-Ray intensities were visually estimated from multiple-film equi-inclination Weissenberg photographs taken from the zeroth to the fifth layer around the c-axis with Ni-filtered Cu$K\alpha$ radiation. Five oscillation photographs taken using the equi-inclination method were prepared in order to find the scale factors by comparing the structure factors of reflections appearing in each layer with those of the equatorial reflections. The relative intensities of all the six layer reflections put on the same scale were corrected for the Lorentz-polarization factor,

but not for the absorption effect. The relative values of the observed structure factors of 656 independent reflections were converted into an absolute scale by Wilson's method.

The positions of the chromium atoms were determined from a three dimensional Patterson function and refined by the least-squares method. Twelve carbon atoms were found on a Fourier map calculated using the phases of the heavy atoms alone. The fourteen positions thus obtained were refined by the least-squares method, taking into consideration the anisotropic thermal motions of all the atoms and the anomalous dispersion effect of chromium. The final R factor was 11.2%.

The atomic positions thus obtained are given in Table 1; the estimated maximum deviations are 0.06 Å for the carbon and 0.006 Å for the chromium atoms. The interatomic distances and bond angles are shown in Fig. 1. The configuration of the complex, $Cr_2(C_3H_5)_4$, and the packing arrangement in the unit cell are shown in Figs. 2 and 3 respectively. Four allyl ligands make a distorted tetrahedron around the two directly-coupled metal atoms. The Cr–Cr distance, 1.97Å, in the molecule is considerably smaller than that found in metallic chromium, 2.50 Å; it is indeed, the smallest metal-to-metal distance reported so far for organometallic compounds. The four ligands may be divided into two groups on the basis of the mode of coordination. The planes of the C11–C12–C13 and C31–C32–C33 groups are nearly parallel to the Cr–Cr axis and each of these groups is coordinated to both of the chromium atoms. On the other hand, the C21–C22–C23 and C41–C42–C43 groups are approximately perpendicular to the Cr–Cr axis and each is coordinated to one of the chromium atoms. The average bond length of the C–C bond is 1.45 Å, which is comparable with the mean value of the single and double bonds of the carbon atoms. None of the intermolecular interatomic distances are abnormally short, so the molecules are held together by the van der Waals interactions alone.

Because of the unexpected death of one of the present authors (Yujiro Tomiie), this work was completed in the laboratory of Professor Tokunosuké Watanabé, to whom the authors' thanks are also due for his helpful discussions about this manuscript. The authors would like also to thank Mr. K. Echigoya for his assistance in measuring the intensities.

The Formation of 1,4-Disubstituted Piperazines from 1-Substituted Aziridines

Itaru OKADA, Nobuhiro ITOH and Rokuro SUDO

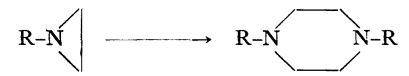
Laboratory of Organic Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received May 31, 1968)

The dimerization of aziridines to piperazines has received little attention.[1-5] Heine and his coworkers reported that 1-arylsulfonylaziridines and 1-phenylaziridine, on treatment with sodium iodide, were dimerized to the corresponding piperazines.[6] Recently, Dick found the reaction of certain 1-alkylaziridines with alkyl or alkenyl halides gave nearly quantitatively the corresponding 1,1,4-trialkylpiperazinium halides.[7]

In the course of our study we found that the treatment of 1-cyclohexylaziridine with four equivalents of phenylmagnesium bromide gave a 41% yield of 1,4-dicyclohexylpiperazine. The structure of this piperazine was established by a study of the melting point,[8] by its elemental analysis and by a study of its infrared spectrum. Similarly, 1-benzylaziridine was dimerized to the corresponding 1,4-disubstituted piperazine. Control runs in the absence of the Grignard reagent resulted in the recovery of aziridines. Using half an equivalent of magnesium bromide instead of the Grignard reagent, 1-substituted aziridines in refluxing methanol were dimerized to the corresponding 1,4-disubstituted piperazines in 50—70% yields. The dimerization of aziridines also occurred with a catalytic amount of other Lewis acids. These results are summarized in Table 1.

TABLE 1. REACTION OF 1-SUBSTITUTED AZIRIDINES WITH LEWIS ACIDS OR PHEYLMAGNESIUM BROMIDE



Reaction	Substituent	Catalyst	Yield %	Mp°C or Bp°C/mmHg

It is well known that the reaction of ethylene oxide with a Grignard reagent gives a primary alcohol. However, the reaction of aziridines with this reagent did not give secondary amines, but piperazines. The catalytic action of the Grignard

reagent seems to be the following: Initially, the magnesium of this reagent coordinates to the basic aziridine nitrogen; then the electrophilic ring carbon attacks not the carbon of the Grignard reagent, but another aziridine nitrogen, and a piperazine is formed. The reason for this seems to be that the nucleophilicity of the Grignard reagent is less strong than that of aziridine nitrogen. In view of this, it is obvious that Lewis acids are also more effective catalysts than the Grignard reagent.

Experimental

Reaction of 1-Substituted Aziridines with Phenylmagnesium Bromide. An 80 m*l* portion of a dry ether solution containing 0.16 mol of phenylmagnesium bromide was prepared, and to this solution there was added rapidly 0.04 mol of aziridine dissolved in 50 m*l* of dry ether. The mixture was then refluxed for 7 hr and allowed to stand at room temperature overnight. The solution was decomposed by pouring in 40 g of ammonium chloride and ice. The ether layer was washed with water and dried over anhydrous potassium carbonate. The solvent was evaporated and allowed to stand in a refrigerator overnight. The oily brown residue was treated with 10 m*l* of acetonitrile. A white precipitate was separated by filtration and recrystallized.

Reaction of 1-Substituted Aziridines with Magnesium Bromide. A mixture of 0.02 mol of the aziridine, 1.84 g of magnesium bromide, and 40 m*l* of methanol was refluxed for 7 hr. The solvent was evaporated, and the residue was treated with a slight excess of potassium hydroxide and water. The solution was extracted several times by ether. The ether layer was dried over anhydrous potassium carbonate and evaporated. The crude product was recrystallized or distilled. In the case of 1-benzylaziridine, a white crystal was obtained as a by-product; mp 141—142°C.

A Correlation between the Magnetic and Optical Properties of Some Cation Radical Salts

Yoichiro SATO, Minoru KINOSHITA, Mizuka SANO*1 and Hideo AKAMATU

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo

(Received June 5, 1968)

The paramagnetic susceptibilities of the cation radical salts formed by the oxidation of phenothiazine (PT), *N*-methylphenothiazine (MPT), and thianthrene (TA) with antimony pentachloride have been reported in a previous paper.[1] The variation in the susceptibilities for PT·$SbCl_4$ and PT·$SbCl_5$ with temperature has been explained in terms of the linear Ising model; thus, the spin-exchange coupling parameters (J) have been determined to be 0.034 and 0.0042 eV respectively. The susceptibilities for MPT·$SbCl_5$ and TA·$SbCl_5$, on the other hand, obeyed the Curie-Weiss law above 100°K. The Weiss constants (θ) for these salts were found to be -5 ± 10°K and 0 ± 4°K respectively.

In this paper we will report a finding of correlation between the values of the spin-exchange coupling parameter and the intensities of the absorption band in the near-infrared region of the solid cation radical salts. The static susceptibility of phenothiazine bromide (PT·Br), which was prepared by the procedure of Kehrmann and Diserens,[2] was also measured as a function of temperature with a Faraday-type magnetic balance. The absorption spectrum of a solid radical salt was obtained with a powder sample suspended in liquid paraffin.

Results and Discussion

Solid phenothiazine bromide was found to be diamagnetic at room temperature (-14.3×10^{-5} emu/mol). After corrections had been made for the diamagnetism and for a small paramagnetism due to impurities, the intrinsic paramagnetic susceptibility for the bromide was found to be 1.2×10^{-5} emu/mol at 296°K, and to decrease with a decrease in temperature. The change in the paramagnetic susceptibility with temperature was found to fit well the curve calculated from the linear Ising model, for which J was taken to be 0.12 eV.

The values of the spin-exchange coupling parameter for MPT·$SbCl_5$ and TA·$SbCl_5$ were not given explicitly in the previous paper. If we assume that the linear Ising model for which the relation

$J=-k\theta$ holds in the temperature region $T \gg J/k$, is applicable to the paramagnetism of the salts, the parameter can be estimated from the observed value of a Weiss constant. The values thus calculated are listed in Table 1.

TABLE 1. EXCHANGE COUPLING PARAMETER FOR THE SALTS STUDIED

Compound	J (eV)
TA·$SbCl_5$*	$\sim$ 0
MPT·$SbCl_5$*	$\sim 4.3 \times 10^{-4}$
PT·$SbCl_5$*	4.2×10^{-3}
PT·$SbCl_4$*	3.4×10^{-2}
PT·Br	$\sim 1.2 \times 10^{-1}$

* The paramagnetism of these salts originates entirely from the respective mono-positive organic molecules and antimony pentachloride is thought to be forming closed shell negative ions.[1]

The absorption spectra for solid TA·$SbCl_5$ and MPT·$SbCl_5$ were found to correspond well to the spectra of the respective solutions in dichloromethane, and no extra band could be observed in the spectra of the solids, as is shown in Fig. 1. This result reveals that the cation radicals in a solid are nearly as free as in a solution. The same conclusion has been derived from the magnetic susceptibility measurements, which have shown negligible values of the spin-exchange coupling parameter for these salts.

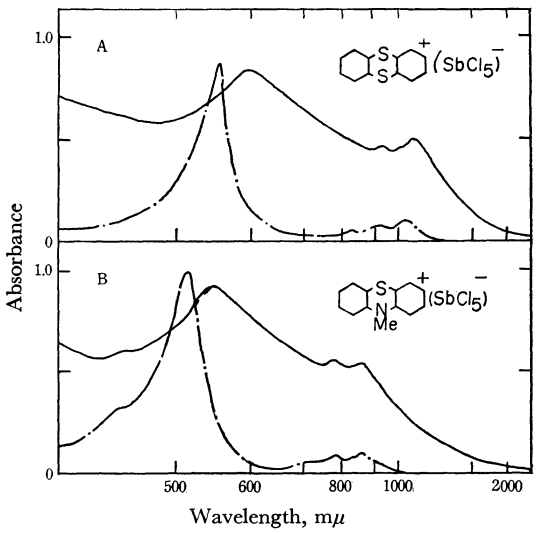

Fig. 1. A, The absorption spectra of thianthrene mono-positive ion. ———— Solid TA·$SbCl_5$, —·—·—·— dichloromethane solution; B, The absorption spectra of *N*-methylphenothiazine mono-positive ion. ———— Solid MPT·$SbCl_5$, ——·——·——·—— dichloromethane solution.

The spin-exchange coupling parameters for the three kinds of radical salts of phenothiazine, PT·Br, PT·$SbCl_4$, and PT·$SbCl_5$, were larger in value than those for MPT·$SbCl_5$ and TA·$SbCl_5$, and their values decreased in this sequence, as Table 1 shows. The solution spectra of all these phenothiazine salts showed the same pattern, a pattern which was also in agreement with that reported for a phenothiazine mono-positive ion by Shine and Mach.[3] When the salts were formed into a solid, they showed extra absorption bands in the near-infrared region, where no absorption was found in the solution spectra. As is shown in Fig. 2, PT·Br, PT·$SbCl_4$, and PT·$SbCl_5$ exhibited new absorption bands at 900, 1070, and 1000 mμ (shoulder) respectively. The band for PT·Br was found to be the strongest in intensity among the salts; this fact is consistent with the fact that the spin exchange coupling parameter for the salt is the largest in value. The absorption bands for the phenothiazine salts decreased in intensity in the same sequence as the spin-exchange coupling parameters, though little difference was found with respect to the position of the absorption band.

The new absorption band is regarded as arising

from charge-transfer interaction between phenothiazine cation radicals in the solid. When phenothiazine radicals are stacked in a face-to-face manner, forming chain-like arrays of molecules, as is known in the structure of some radical salts,[4] the charge-transfer absorption may be expressed as a transition of the type $\langle\cdots D^+D^+D^+D^+\cdots\rangle \rightarrow \langle\cdots D^+D^{2+}D^0D^+\cdots\rangle$, where D denotes a phenothiazine molecule. The excitation energy of the transition is not greatly influenced by a small change in the intermolecular distance or mutual orientation, for it is essentially determined by the difference between the ionization potential and the electron affinity of the phenothiazine *mono-positive ion* radical (D^+). This is in agreement with the observed insensitivity of the band positions in the three phenothiazine radical salts.

The spin-exchange coupling parameter and the intensity of a charge-transfer band are both thought to be approximately proportional to the square of an overlap integral between neighboring radicals. A relatively small change in the intermolecular distance or mutual orientation may cause a somewhat large change in the overlap integral; this change, in turn, results in the different intensity of the charge-transfer absorption and in the different value of the spin-exchange coupling parameter. This may be what has been observed with the three kinds of phenothiazine radical salts. The same interpretation can be given to the appearance of intense charge-transfer absorption bands with the radical salts, such as *p*-phenylenediamine bromide,[5] Würster's blue perchlorate at 77°K,[5-9] and alkali metal salts of 7,7,8,8-tetracyano-*p*-quinodimethan,[10,11] which exhibit strong antiferromagnetic spin-exchange coupling.

From the observed correlation between the magnetic and optical properties, it may be inferred that the spin-exchange coupling parameter, J, is determined mainly by the charge-transfer interaction in these salts. A qualitative explanation may be made by considering, for the sake of brevity, a particular pair of adjacent radicals in a chain. The pair of identical radicals gives rise to a singlet (non-magnetic) state and a triplet (magnetic) state, for which the relative positions are determined, to a first approximation, by an exchange integral between the paired radicals. The excited charge-transfer configuration specified above, which is usually singlet, will then interact with the ground state and stabilize its energy, while the triplet state remains unaffected, thus leading to a further separation of the singlet-triplet energy gap. This view of the situation, when extended to a linear array of radicals, implies that the charge-transfer configurational interactions also contribute to the determination of the relative energy levels of the magnetic and non-magnetic states. Therefore, it appears that the sign and magnitude of a spin-exchange coupling parameter are sensitively dependent on the relative energies of the exchange interaction and the charge-transfer configurational interaction effects. For the cation radical salts studied here, it is likely that the stabilization energy due to the latter effect is of primary importance rather than that due to the former.

Studies on the Coagulation of Silver Sol: Effect of Dialysis, Non-electrolytes and Ageing on the Constants of Bhattacharya's Equation

Mukhtar SINGH and O. P. BANSAL

Chemical Laboratories, Agra College, Agra, India

(Received April 20, 1968)

Bhattacharya *et al.*[1] established the relation between the electrolyte concentration, C, and the inverse of the corresponding time of coagulation, $1/t$, in the zone of slow coagulation and obtained hyperbolic curves in the majority of cases, although straight lines were obtained in some cases. The relation established by them is,

$$C = a + \frac{m \cdot 1/t}{n + 1/t} \qquad (1)$$

where a, m and n are constants. The equation on simplifying assumes the form:

$$1/(C - a) = (n/m)t + 1/m \qquad (2)$$

Accordingly, a verification of the equation can be made from the coagulation data if the plots between $1/(C-a)$ and t provide a straight line.

In this communication, an attempt has been made to study the variations of the constants, *i. e.*, a, m and n at different periods of dialysis of the sol. The values of the constants have also been evaluated in the presence of different non-electrolytes to throw light on the stabilising or sensitising power of the non-electrolytes used. The effect of ageing on the above constants for the dialysed silver sol using $NaNO_3$, $Ba(NO_3)_2$ and $Al(NO_3)_2$ as coagulating electrolytes, has also been incorporated in this paper.

Experimental

Silver sol was prepared by adding just sufficient ammonia to 20 m*l* of 5% silver nitrate solution to dissolve silver hydroxide formed; the solution was then made upto one litre. 2% solution of tannic acid was then added to the solution, drop by drop with constant stirring, until a dark brown sol was obtained. It was dialysed against running distilled water until free from electrolytes.

Three different samples of the sol were prepapred. One sample was used for the study of the effect of dialysis,the second for the effect of ageing and the third for the study of non-electrolyte effect.

Time of coagulation of the sol, using $NaNO_3$, $Ba(NO_3)_2$ and $Al(NO_3)_3$ as coagulating electrolytes was determined by light extinction method, using a Gallenkamp Photoelectric Colorimeter. For each concentration of the coagulating electrolyte, the extinction was plotted against the time (Fig. 1). Then a straight line parallel to the time axis was drawn so as to cut all the curves at different points, referring to the same state of aggregation in all the different cases.

The inverse of the coagulating time thus obtained were plotted against the electrolyte concentration, and the value of a was determined as the concentration extrapolated to $(1/t)\rightarrow 0$, as is shown in Fig. 2. Finally, $1/(C-a)$ was plotted against t; straight lines, as Figs. 3 and 4 show, were obtained, as was to be expected from Eq. (2). The values of m and n can be obtained from these straight lines.[2] The values of the constants obtained for the same stage of coagulation given by the same extinction value for the sol at the different stages of dialysis and ageing, and also in the presence of different amounts of various non-electrolytes have been recorded in Tables 1, 2 and 3.

Discussion

Bhattacharya's equation, in the form of Eq. (2), shows that the plots, $1/(C-a)$ against t should be a straight line and this has actually been observed in all cases of the present studies (Representative Figs. 3 and 4) confirming the applicability of the equation for the coagulation of the sol by electrolytes, in the partially dialysed state and also in the presence of non-electrolytes.

If $1/t$ is made large as compared to n, Eq. (1) takes up the form, $C=a+m$. This means that m is the excess of the electrolyte that should be added above the critical stability concentration, a, in order to cause the immediate coagulation of the sol. It may be said that at $C=a+m$, the region of slow coagulation merges into that of rapid coagulation. From Table 1 it is evident that the value of $(a+m)$ decreases with progressive dialysis of the sol indicating that the region of slow coagulation merges into that of rapid coagulation earlier in the dialysed sol. From this, it is evident that the sol becomes increasingly sensitive with progressive dialysis.

The values of the constants, a, $(a+m)$ and n show a decrease in the presence of ethanol, acetone and formamide but the presence of urea causes an increase. Ethanol, acetone and formamide sensities the sol against mono, di and tri-valent ions, since in the presence of these non-ionic substances the region of slow coagulation merges into that of rapid coagulation earlier as evidenced by the low values of $(a+m)$. Urea stabilises the sol. The extent of stabilisation or sensitisation increases with the increased non-ionic addition.

Ageing results in aggregation of particles which renders the sol unstable and since a, $(a+m)$ and n are connected with the stability, the values of these constants should decrease with the ageing of the sol, and this fact has also been confirmed experimentally.

On examining critically the variations in the values of a, it is found that the variations in the values of a with the valency of the precipitating ion support the law that the coagulating power of the ion increases with the increase in its valency. This law has been stated originally for the lowest electrolyte concentration, $(a+m)$ required for the rapid coagulation, but here the law is applied better to the maximum electrolyte concentration, a, at which even the slow coagulation is expected not to occur.

Thanks are due to Dr. A. K. Bhattacharya, D. Sc., F.R.I.C. (London), Prof. of Chemistry, University of Jammu and Kashmir and Dr. A. Kumar for their valuable suggestions in this work.

Zirconium Ethoxide: A New Method of Preparation

S. K. ANAND, J. J. SINGH, R. K. MULTANI and B. D. JAIN

Department of Chemistry, University of Delhi, Delhi-7, India

(Received May 10, 1968)

Meerwein and Bersin[1] could not obtain zirconium tetraethoxide by the interaction between zirconium tetrachloride and sodium ethoxide in anhydrous alcohol due to the formation of $NaH[Zr(OEt)_6]$ which in the presence of dry HCl gas however gave zirconium tetraethoxide. Bradley and Wardlaw,[2,3] prepared $Zr(OEt)_4$ by the action of dry ammonia on solutions of zirconium tetrachloride in appropriate alcohol. The above methods involve the use of anhydrous alcohol, the preparation of which is quite tedious.

It is well known that most of the alkyl esters of fatty acids react with ammonia and form corresponding alcohols and acid amides. This property of the esters has been utilised for the preparation of a number of metal alkoxides. The present communication deals with the preparation of zirconium tetraethoxide by the interaction of anhydrous zirconium tetrachloride in dry benzene with ethyl formate, ethyl acetate or diethyl oxalate in the presence of dry ammonia, whereby the alcohol which is formed in the above reaction is itself used in the formation of metal alkoxide.

Through benzene dried azeotropically, containing anhydrous zirconium chloride and ester-dried over anhydrous magnesium sulphate (quantities given in Table 1) placed in a two necked one litre quickfit flask fitted with a reflux condenser, dry ammonia was passed. As the reaction was exothermic in all cases, ice bath was used to prevent the loss of benzene and the lower esters. On the completion of the reaction and after the removal of dissolved ammonia under reduced pressure, zirconium tetraethoxide was obtained by distillation at 235°C/5.2 mmHg.

Zirconium in the alkoxide was estimated as ZrO_2 and ethoxy group was determined by the chromic acid method.[4,5]

From the analytical data (given in Table 1), the composition of the compound obtained in all the cases studied above corresponds to $Zr(OC_2H_5)_4$.

Although a large number of workers,[6,7] have prepared metal alkoxides by the ammonia method no definite information regarding the role of ammonia in the reaction has been reported and it is generally believed that it acts as a hydrogen chloride acceptor. Fowles and Pollard[8–10] who have studied in detail the behaviour of a number of transition metal halides towards ammonia have reported the formation of various ammoniates and amido chlorides of these metsls. In order to ascertain the role of ammonia in the above reactions the formation of the above intermediates during the preparation of zirconium tetraethoxide by the present method is also under investigation.

TABLE 1

Ester	Ester taken (g)	$ZrCl_4$ taken (g)	Benzene taken (g)	Yield %	Analysis of Zr-ethoxide found	
					%Zr	$\%OC_2H_5$
Ethyl formate	10.5	1.1	550	60—65	33.52	66.25
Ethyl acetate	16.0	1.5	500	54—57	33.65	66.18
Diethyl oxalate	10.0	0.9	400	49—51	33.55	66.25

Calcd for $Zr(OC_2H_5)_4$: Zr, 33.63; OC_2H_5, 66.37%.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 555 (1969)

Spectrophotometric Determination of a Trace Amount of Cobalt(II) in Nickel(II) Solution

Mutsuo KODAMA

Department of Chemistry, Ibaraki University, Mito, Ibaraki

(Received June 8, 1968)

Previously,[1,2] we studied the substitution reactions of Eriochrom Black T (BT) with cobalt(II)- and nickel(II)-EDTA chelates spectrophotometrically, and determined the reaction mechanism and rate constants.

The reaction of BT with cobalt(II)-EDTA chelate was found to proceed much faster than that with nickel(II)-EDTA chelate. In the mixture of nickel(II)- and coblat(II)-EDTA chelates, the reaction of BT may proceed through both nickel(II)- and cobalt(II)-EDTA chelates. Therefore, in nickel(II)-EDTA solution contaminated with a trace amount of cobalt(II)-EDTA chelate, the rate at which the concentration of BT decreases would be much greater than that in the pure nickel(II)-EDTA chelate solution. Hence, even a trace amount of cobalt(II) in the nickel(II)-EDTA solution may be estimated by determining the increase in the apparent rate at which the concentration of BT decreases.

As stated previously,[1,2] both reactions of BT with cobalt(II)- and nickel(II)-EDTA chelate are first-order in BT and first-order in metal(II)-EDTA chelate. Consequently, the initial rate of the substitution reaction, $-(\mathrm{d[BT]}/\mathrm{d}t)_0$, in the mixed solution of nickel(II)- and cobalt(II)-EDTA chelate containing uncomplexed EDTA can be expressed as,

$$-\left(\frac{\mathrm{d[BT]}}{\mathrm{d}t}\right)_0 = (k_{\mathrm{Ni}}\cdot[\mathrm{NiY^{2-}}] + k_{\mathrm{Co}}[\mathrm{CoY^{2-}}])\cdot[\mathrm{BT}]_0 \quad (1)$$

where k_{Ni} and k_{Co} are the conditional second-order rate constants of the reaction of BT with pure nickel(II)-EDTA chelate and that with pure cobalt(II)-EDTA chelate, respectively. Both k_{Ni} and k_{Co} values increase with increasing pH value of the solution.[1,2]

Alternatively, one can define the initial reaction rate as,

$$-\left(\frac{\mathrm{d[BT]}}{\mathrm{d}t}\right)_0 = k\cdot[\mathrm{MY^{2-}}]_t\cdot[\mathrm{BT}]_0 \quad (2)$$

where $[\mathrm{MY^{2-}}]_t = [\mathrm{NiY^{2-}}] + [\mathrm{CoY^{2-}}]$.

Combining the above two equations, one can derive the following relation.

$$[\mathrm{CoY^{2-}}] = \frac{k - k_{\mathrm{Ni}}}{k_{\mathrm{Co}} - k_{\mathrm{Ni}}}[\mathrm{MY^{2-}}]_t \quad (3)$$

This relation clearly shows that when the total concentration of cobalt(II)- and nickel(II)-EDTA chelates is known, the concentration of cobalt(II)-EDTA chelate in the nickel(II)-EDTA chelate solution, $[\mathrm{CoY^{2-}}]$, can be estimated from k, k_{Ni} and k_{Co} values determined experimentally. The concentration of cobalt(II) in the nickel(II)-EDTA solution was estimated with the aid of Eq. (3) using k, k_{Ni} and k_{Co} values determined at pH 9.60. Typical results are given in Table 1, which can be regarded as satisfactory. k_{Ni} and k's used in the calculation of $[\mathrm{CoY^{2-}}]$ were determined from the initial slope of absorbance *vs.* time curves, because the absorbance decreases almost linearly with time in the reaction of BT with pure nickel(II)-EDTA, and with nickel(II)-EDTA contaminated with a small amount of cobalt(II). On the other hand, k_{Co} was estimated from the slope of the linear relation between $\log(A_{\mathrm{D}}/(A-A_{\mathrm{CoD}}))$[1] and time t, because the reaction of BT with cobalt(II)-EDTA chelate proceeds so rapidly that the initial slope cannot be determined accurately.

Table 1. Calculation of $[\mathrm{CoY^{2-}}]$ with the aid of Eq. (3)

$\mu = 0.30$, 15°C
$\lambda = 630\,\mathrm{m}\mu$, pH = 9.60
$k_{\mathrm{Co}} = 1.74\times10^{1}$, $k_{\mathrm{Ni}} = 3.58\times10^{-2}$

k	$[\mathrm{MY^{-2}}]_t$ mM	$[\mathrm{CoY^{2-}}]$ mM

Studies on Heteroaromaticity. XXIX.[1] Synthesis and Reactions of 1-(5-Nitro-2-furoyl)aziridine Oxime

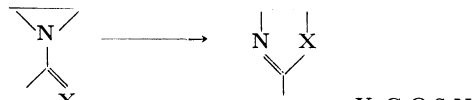
Tadashi SASAKI and Toshiyuki YOSHIOKA

Institute of Applied Organic Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya

(Received June 10, 1968)

In the previous papers,[2,3] we have reported the ring-opening reactions of β-(5-nitro-2-furyl)-acryloylaziridine and *N*-[β-(5-nitro-2-furyl)vinyl]-*N'*-ethyleneurea with acid, base or nucleophilic reagents affording oxazoline derivatives similar to general activated aziridine derivatives,[4] but in low yields.

This paper deals with the synthesis and reactions of 1-(5-nitro-2-furoyl)aziridine oxime (I), which was readily prepared from 5-nitro-2-furonitrile oxide[5] and aziridine in ether at 0°C in 80% yield. This structure was confirmed by the elemental analysis and the spectral data; an absorption at 3200 cm^{-1} in the infrared spectrum and a signal at 7.75 τ (singlet, 4H, $-CH_2-CH_2-$) in the NMR spectrum indicate the presence of an OH group and aziridine ring respectively. The aziridine ring in I was comparably stable and it did not react at all with aniline or *p*-toluidine even when it was refluxed in toluene for 8 hr. By addition of a catalytic amount of boron trifluoride etherate to a dry ethereal solution of I and aniline, however, I polymerized even at room temperature. Treatmet of I with acetic anhydride at room temperature, with phenyl isocyanate in refluxing benzene, or with benzoyl chloride in the presence of triethylamine at room temperature, gave the corresponding *O*-substituted oximates, II, III, and IV, in high yields respectively.



(V) (VI) X: C, O, S, N

Aziridines V possessing unsaturated substituents on the nitrogen are known to undergo ring expansion to yield 1-azacyclopentene derivatives VI.[6] It was of interest to determine whether or not the similar processes would occur in our aziridine oxime.

All attempts for ring-expansion of I by treating it in refluxing ethanol with organic acids like *p*-nitrobenzoic acid or 5-nitro-2-furoic acid were unsuccessful and only resulted in the cleavage of the aziridine ring to form products, VII and VIII, in low yields. The infrared spectra of VII and VIII showed common absorptions at 3500,

6) P. Scheider, *J. Org. Chem.*, **32**, 2628 (1967).

3400 (ν_{NH}), 1720, and 1715 (ν_{CO}) cm^{-1} and their ultraviolet absorption spectra manifested patterns similar to that of *N*-methyl-(5-nitro-2-furan)carbonamidoxime which is known to be a tautomeric mixture between its amino oxime and amino alcohol.[7] However, when I was treated with a mineral acid such as hydrochloric acid in acetone at room temperature for 1 day, an oily product was obtained, which was further treated with an aqueous sodium carbonate solution to afford 3-(5-nitro-2-furyl)-4,5-dihydro-6*H*-1,2,4-oxadiazine (IX), mp 195—197°C, in 51% yield; this structure was confirmed by the elemental analysis and the spectral data. The infrared spectrum showed absorptions at 3200 (sharp, ν_{NH}) and 1620 ($\nu_{C=N}$) cm^{-1} and the NMR signals appeared at around 2.6 τ (broad, 1H, NH), 6.10 (triplet, 2H, $-CH_2O-$) and 6.61 (multiplet, 2H, $-CH_2N-$), all supporting the presence of 4,5-dihydro-6*H*-1,2,4-oxadiazine ring in IX.

About the mechanism of the formation of IX from I, this reaction seems to proceed through two discrete steps; the first step is the cleavage of the ring by acid treatment and the second one is the ring closure by alkaline treatment, as have been reported by Rajagopalan and Talaty.[8]

All the results are summarized in the above scheme.

Experimental[9]

1-(5-Nitro-2-furoyl)aziridine Oxime (I). 5-Nitro-2-furohydroxamoyl chloride[7] (0.95 g) was dissolved in 20 m*l* of dry ether. To this solution was added a solution of 1.0 m*l* of aziridine in 5 m*l* of dry ether with stirring at 0—5°C. After 3 minutes' stirring at the same temperature, aziridine hydrochloride was filtered off and the filtrate was kept standing overnight in an ice box. The precipitates were collected, washed with ethanol and recrystallized from ethanol to afford 0.7 g (80%) of I as light yellow crystals, mp 172°C (decomp). IR (KBr) cm^{-1}: 3200 (broad, ν_{OH}), 1630 ($\nu_{C=N}$). UV λ_{max}^{EtOH} mμ (ε): 348 (11600), 250 (8000). NMR (DMSO-d_6) τ: −1.25 (singlet, 1 H, OH, disappeared on deuteration), 2.28 and 2.92 (each doublet, 1 H, J=3.8 cps, nitrofuran ring protons), 7.65 (singlet, 4 H, $-CH_2-CH_2-$).

Found: C, 42.82; H, 3.73; N, 20.82%. Calcd for $C_7H_7O_4N_3$: C, 42.64; H, 3.58; N, 21.32%.

1-(5-Nitro-2-furoyl)aziridine Oxime *O*-Acetylate (II). A solution of 0.4 g of I in 6 m*l* of acetic anhydride was allowed to stand at room temperature overnight. Removal of the unreacted acetic anhydride *in vacuo* afforded an oil. It was treated with 10 m*l* of water to give yellow precipitates, which were recrystallized from ethanol - petroleum ether to give 0.27 g (55%) of II, mp 129°C. IR (KBr) cm^{-1}: 1760 (ν_{CO}). UV λ_{max}^{EtOH} mμ (ε): 326 (16500), 250 (10200).

Found: C, 44.94; H, 3.69; N, 17.42%. Calcd for $C_9H_9O_5N_3$: C, 45.19; H, 3.79; N, 17.57%.

1-(5-Nitro-2-furoyl)aziridine Oxime *O*-Phenylcarbamate (III). A mixture of 0.23 g of I and 0.3 m*l* of phenyl isocyanate in 20 m*l* of dry benzene was refluxed for 4 hr. After removal of the solvent under reduced pressure, the residue was recrystallized from ethanol to give 0.27 g (71%) of III, mp 145°C. IR (KBr) cm^{-1}: 3360 (ν_{NH}), 1750 (ν_{CO}). UV λ_{max}^{EtOH} mμ (ε): 330 (15500), 237 (22000).

Found: C, 53.00; H, 3.84; N, 18.49%. Calcd for $C_{14}H_{12}O_5N_4$: C, 53.16; H, 3.82; N, 17.72%.

1-(5-Nitro-2-furoyl)aziridine Oxime *O*-Benzoate (IV). A mixture of 0.3 g of I and 4 m*l* of benzoyl chloride was dissolved in a mixture of 10 m*l* of tetrahydrofuran and 10 m*l* of dry ether. To this solution was added 0.4 m*l* of triethylamine in 5 m*l* of dry ether at room temperature with stirring. After stirring was continued for 3 hr, the solids which separated were filtered, washed with water and recrystallized from ethanol to give 0.76 g (80%) of IV as light yellow crystals, mp 166°C. IR (KBr) cm^{-1}: 1735 (ν_{CO}). UV λ_{max}^{EtOH} mμ (ε): 325 (15300), 254 (12100), 232 (14800).

Found: C, 56.05; H, 3.72; N, 13.94%. Calcd for $C_{14}H_{11}O_5N_3$: C, 55.81; H, 3.68; N, 13.95%

Reaction of I with Organic Acids. A solution of 0.4 g of I and 0.35 g of *p*-nitrobenzoic acid in 30 m*l* of ethanol was refluxed for 7 hr. The solvent was removed under reduced pressure and the oily residue was treated with 20 m*l* of ethanol - water (1 : 2). The solids which separated were filtered and recrystallized from ethanol - petroleum ether to give 0.36 g (50%) of VII as yellow crystals, mp 122°C. IR (KBr) cm^{-1}: 3500 (ν_{NH}), 3200 (ν_{OH}), 1720 (ν_{CO}). UV λ_{max}^{EtOH} mμ (ε): 360 (5900), 295 (9600), 254 (19200).

Found: C, 45.88; H, 3.29; N, 15.70%. Calcd for $C_{14}H_{12}O_8N_4$: C, 46.16; H, 3.32; N, 15.38%.

Similarly, 0.25 g (30%) of VIII, mp 134—136°C, was obtained from 0.4 g of I and 0.37 g of 5-nitro-2-furoic acid after 4 hr's refluxing in 15 m*l* of ethanol and worked up as above. IR (KBr) cm^{-1}: 3490 (ν_{NH}), 3400 (ν_{OH}), 1715 (ν_{CO}). UV λ_{max}^{EtOH} mμ (ε): 360 (6200), 294 (16500), 234 (10300).

Found: C, 40.91; H, 2.84; N, 15.92%. Calcd for $C_{12}H_{10}O_9N_4$: C, 40.68; H, 2.85; N, 15.82%.

3-(5-Nitro-2-furyl)-4,5-dihydro-6*H*-1,2,4-oxadiazine (IX). To a solution of 0.4 g of I in 8 m*l* of acetone was added a mixture of 2 m*l* of concentrated hydrochloric acid and 5 m*l* of acetone at 0—5°C for 0.5 hr with stirring. Stirring was continued at room temperature for 1 day. After a distillable fraction was removed under reduced pressure, an oily residue was dissolved in 10 m*l* of water and the solution was made alkaline with an aqueous sodium carbonate solution and then, stored overnight in an ice box. The precipitates were collected, washed with water and recrystallized from

9) All melting points were determined on a Yanagimoto electric micromelting point apparatus and uncorrected. All the infrared and ultraviolet spectra were recorded on a JASCO Model IR-S infrared spectrometer and on a Hitachi Model ESP-2 recording spectrometer respectively. The NMR spectra were taken on a Varian A-60 apparatus with tetramethylsilane as an internal standard and the chemical shifts are presented in terms of τ-values.

ethanol to give 0.24 g (51%) of IX as brown crystals, mp 197°C. IR (KBr) cm^{-1}: 3200 (sharp, ν_{NH}), 1620 ($\nu_{C=N}$). UV λ_{max}^{EtOH} $m\mu$ (ε): 348 (7300), 304 (7600), 240 (6800). NMR (DMSO-d_6) τ: 2.88 and 2.90 (each doublet, 1 H, J=3.8 cps, nitrofuran ring protons), 2.6 (broad, 1 H, NH, disappeared on deuteration), 6.10 (triplet, 2 H, J=4.0 cps, CH_2), 6.61 (multiplet, 2 H, CH_2).

Found: C, 42.65; H, 3.50; N, 21.15%. Calcd for $C_7H_7O_4N_3$: C, 42.64; H, 3.58; N, 21.32%.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 558—560 (1969)

Studies on Reactions of Isoprenoids. V.[1] 1,3-Dipolar Cycloaddition Adducts of Myrcene with Benzonitrile Oxide

Tadashi SASAKI, Shoji EGUCHI and Teruhiko ISHII

Institute of Applied Organic Chemistry, Faculty of Engineering, Nagoya University, Furo-cho, Chikusa-ku, Nagoya

(Received June 13, 1968)

In continuing our previous study on the diene reactivity of myrcene,[1] this paper deals with the reactivity of each double bond in myrcene with benzonitrile oxide. Although several 1,3-dipolar cycloaddition reactions with butadiene and its derivatives have been reported,[2,3] there seems no report concerning the 1,3-dipolar cycloaddition reactions with myrcene, 7-methyl-3-methylene-1,6-octadiene.

Results and Discussion

The 1,3-dipolarophilicity of myrcene toward several 1,3-dipoles such as diazomethane, diphenylnitrilimine, phenyl azide, tosyl azide, and benzonitrile oxide was examined, among which, however, only benzonitrile oxide showed enough reactivity to give the corresponding adducts. Myrcene was treated with benzonitrile oxide in refluxing ether and the reaction products were purified on a silica-gel column to give four products, I—IV as shown in Table 1.

As seen from this table, all of these products had the composition corresponding to 1 : 2-adducts. It is interesting that neither 1 : 1-adduct nor 1 : 3-adduct was obtained in the reaction using a 1 : 1-molar ratio[4] of myrcene to benzonitrile oxide, though some of the butadiene derivatives are known to give a 1 : 1-adduct with benzonitrile oxide.[3] This fact might suggest that the reactivity of the three double bonds in myrcene with benzonitrile oxide discriminates an isolated double bond from conjugated ones in the examined conditions as will be supported by the following structural

TABLE 1. 1,3-DIPOLAR CYCLOADDUCTS OF MYRCENE WITH BENZONITRILE OXIDE

Troshchenko, *Izv. Sib. Otd. Akad. Nauk SSSR, Ser. Khim. Nauk*, **1963**, 147; *Chem. Abstr.*, **59**, 13960h (1963).

4) No 1 : 3-adduct was obtained even in the reaction using a 1 : 2-molar ratio of myrcene to benzonitrile oxide.

elucidation of the four adducts.

The structure of I was assigned as A or B on the basis of its NMR spectrum which had the signals at τ 2.10—2.80 (10 H, m, two phenyl protons), 4.80 (1 H, broad s, C=CH), 5.02 (1 H, unsymmetrical t, J=8.0 Hz, O-C<u>H</u>CH_2- in an isoxazoline ring), 6.54 (2 H, d, J=8.0 Hz, O-$CHC\underline{H}_2$- in an isoxazoline ring), 6.58 (2 H, d, J=3.0 Hz, $-CH_2-$ in an isoxazoline ring),[5] 7.60—8.03 (4 H, complex m, $-CH_2CH_2-$), 8.28 and 8.35 (6 H, s, $C=C(CH_3)_2$).

The structure of II was assumed to be similar to that of I, since its infrared spectrum was superimposable with that of II and the R_f values of I and II on TLC[6] examinations were exactly the same value of 0.43.

The structure of III and IV were also assignable as A or B from their NMR data; III had the signals at τ 2.20—2.78 (10 H, m, two phenyl protons), 4.81 (1 H, broad s, C=CH), 5.04 (1 H, t, J=8.0 Hz, $OC\underline{H}CH_2$- in an isoxazoline ring), 6.56 (2 H, d, J=8.0 Hz, $OCHC\underline{H}_2$- in an isoxazoline ring), 6.64 (2 H, d, J=3.0 Hz, $-CH_2-$ in an isoxazoline ring), 7.65—8.10 (4 H, complex m, $-CH_2CH_2-$), 8.30 and 8.37 (6 H, s, $C=C(CH_3)_2$); IV had the signals at τ 2.10—2.70 (10 H, m, two phenyl protons), 4.85 (1 H, broad s, C=CH), 5.04 (1 H, unsymmetrical t, J=7.5 Hz, $OC\underline{H}CH_2$- in an isoxazoline ring), 6.57 (2 H, unsymmetrical d, J=7.5 Hz, $OCHC\underline{H}_2$- in an isoxazoline ring), 6.60 (2 H, s, $-CH_2-$ in an isoxazoline ring), 7.54—8.10 (4 H, complex m, $-CH_2CH_2-$), 8.27 and 8.35 (6 H, s, $C=C(CH_3)_2$).

The infrared spectra of I—IV were very similar one another, I and II exhibiting absorption bands at 1600, 1570, 1500, 920, 860, 763, and 691 cm^{-1}, and III and IV, at 1600, 1570, 1500, 940, 920, 900, 860, 764, and 693 cm^{-1}. From these data, I and II could be distinguishable from III and IV, since the former group had only one band at 920 cm^{-1} and the latter, three bands at 940, 920, and 900 cm^{-1} in fingerprint regions. On the other hand, the results of TLC[6] examinations of I—IV indicated also the same discrimination[7] in I—IV.

The two possible structure A and B for the isolated four 1 : 2-adducts could now be possibly

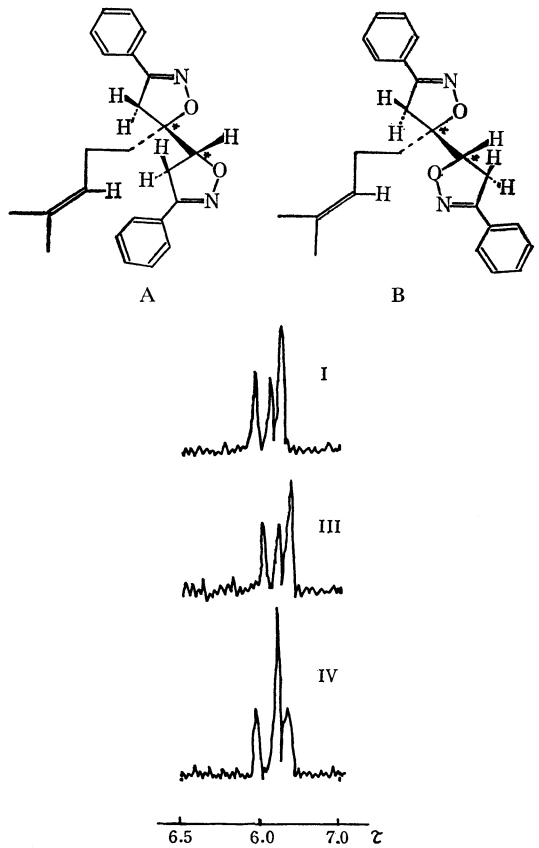

Fig. 1. NMR spectra of I, III, and IV in $CDCl_3$ at 60 Mc. Methylene protons signals of isoxazoline rings.

correlated with the presence of two groups, I and II, and III and IV, in these adducts. However, the observed subtle differences in their infrared and NMR spectra (Fig. 1), and R_f values on TLC were unsatisfactory to distinguish them.[8]

The isolation of the four 1 : 2-adducts could be explained by the presence of the two asymmetric

5) In a strict sense, this signal should be analyzed as an AB q, although both outer signals of an AB q of I at this region were very weak and they were almost hidden in noises as shown in Fig. 1. Only in the spectrum of I, the value of $J_{AB}/_{d\tau}$=0.86 for this q could be obtained.

6) TLC (Thin Layer Chromatography) was carried out by using silica-gel (Wakogel, B-5) plate, benzene as a developing solvent, and iodine as a developing reagent.

7) The R_f values of III and IV on TLC were same each other and 0.32 which was slightly smaller than those (0.43) of I and II.

8) A conjecture that I and II may correspond to an A structure and III and IV, to a B structure, will be favored by the facts that the combined yield of I and II was much lower than that of III and IV, and melting points of I and II were lower than those of III and IV, since A is assumed to be less stable than B because of the electrostatic repulsions of two oxygen atoms.

9) All melting points were determined on a Yanagimoto micro-melting point apparatus and are uncorrected. Microanalyses were carried out on a Yanagimoto C. H. N. Corder Model MT-1. The infrared spectra (KBr) were recorded on a JASCO Model IR-S infrared spectrophotometer and NMR spectra were obtained in $CDCl_3$ with a Hitachi high-resolution NMR spectrometer Model H-6013 at 60 Mc. All NMR data are reported in τ values relative to TMS as an internal standard, and singlet peaks are designated as s, doublet as d, triplet as t, and so on.

carbons in both A and B, which are responsible for diastereoisomers.

Experimental[9]

Reaction of Myrcene with Benzonitrile Oxide. A mixture of 1.50 g (0.011 mol) of myrcene and benzonitrile oxide prepared from 2.0 g (0.013 mol) of benzhydroxamoyl chloride[10] and 1.6 g (0.016 mol) of triethylamine, in 50 m*l* of ether was refluxed for 16 hrs and the crude products were obtained as a sticky residue after removal of the solvent. Purification of the crude products on a silica-gel (Wakogel, C-100-200) column eluted with benzene afforded three main fractions. From the first fraction, crude myrcene was recovered and the second fraction was a mixture of I, II, III, and IV. From the third fraction, a mixture of III and IV was obtained (*ca.* 0.30 g). Further purifications of the second fraction on a silica-gel column afforded *ca.* 0.2 g of a mixture of I and II, and 0.20 g of a mixture of III and IV. Fractional recrystallizations of the mixture of I and II, and the combined mixture of III and IV (0.5 g) from benzene - *n*-hexane afforded finally analytically pure samples of I (0.050 g) as needles, II (0.002 g) as needles, III (0.030 g) as needles, and IV (0.300 g) as needles. Their yields, melting points, and analyses are summarized in Table 1.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 560—561 (1969)

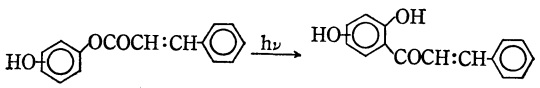
The Photo-Fries Rearrangement of Hydroxyphenyl Cinnamates*1

Heitaro OBARA, Hiroshi TAKAHASHI and Hiromichi HIRANO

Department of Applied Chemistry, Faculty of Engineering, Yamagata University, Yonezawa

(Received June 14, 1968)

Our recent investigation of the photochemical Fries rearrangement of phenyl cinnamate[1] has prompted the present authors to attempt the preparation of the corresponding hydroxychalcones (4, 5, and 6) by the photo-irradiation of *o*-, *m*- and *p*-hydroxyphenyl cinnamates (1, 2, and 3).



Hydroxyphenyl cinnamates		Dihydroxychalcones	
(1)	*o*-OH	(4)	2′,3′-di-OH
(2)	*m*-OH	(5)	2′,4′-di-OH
(3)	*p*-OH	(6)	2′,5′-di-OH

As we have described in a previous communication,[1] if these photo-Fries rearrangements are successful there may arise the possibility of a light-catalyzed synthesis of the corresponding polyhydroxychalcones from various polyhydroxyphenyl monocinnamates.

o-Hydroxyphenyl cinnamate (1), mp 137—138°C, *m*-hydroxyphenyl cinnamate (2), mp 112—113°C, and *p*-hydroxyphenyl cinnamate (3), mp 166—167°C, were isolated from the reaction mixture obtained by the acylation of catechol, resorcinol, and hydroquinone with cinnamoyl chloride in pyridine. The structures of these compounds were confirmed by the elemental analyses and by a study of their IR spectra.

The yields of these monocinnamates were generally low because there was some difficulty in separating them from the mixture of mono- and di-cinnamates.

The irradiation was carried out in a benzene solution under a nitrogen atmosphere at room temperature using a high-pressure 100 W mercury arc. After irradiation, the benzene was evaporated *in vacuo*, and the residue was chromatographed on a column of silica gel; the resulting chalcones were recrystallized from methanol or benzene.

2′,3′-Dihydroxychalcone (4)[2] was obtained from (1) in a 20% yield; this structure was identified by the elemental analysis, by a study of the IR spectrum, and, furthermore, by its conversion into 8-hydroxyflavanone (7).[2] Similarly, 2′,4′-dihydroxychalcone (5)[3] and 2′,5′-dihydroxychalcone (6)[4] were obtained in 5 and 16% yields respectively; these structures were identified by a comparison of the melting points and UV and IR spectra with those of authentic samples. The formation of 3,′4′-dihydroxychalcone and 2′,6′-dihydroxychalcone from (1) and (2) respectively was expected in these photochemical reactions, but no such chalcones could be isolated from the above irradiation products.

Experimental

All the melting points are uncorrected.

***o*-Hydroxyphenyl Cinnamate (1).** Into a solution of 8.8 g of catechol in 60 m*l* of pyridine, 13.6 g of cinnamoyl chloride was slowly stirred over a period of about 1 hr at 45°C. The reaction mixture was then poured into cold water and extracted with ether. After the removal of the ether-insoluble crystals, the ether layer was washed with a dilute aqueous sodium hydrogencarbonate solution, dilute hydrochloric acid, and then water. The ether solution was evaporated *in vacuo*, and the residual crystals were dissolved in warm ethanol. After the removal of the ethanol-insoluble crystals by filtration, the filtrate was evaporated *in vacuo*; the resulting white crystals were then recrystallized from benzene. Yield, 4.76 g (24.8%), mp 140—141°C. IR (KBr): 3380 (ν_{OH}) and 1708 cm^{-1} (ν_{CO}). UV: λ_{max}^{EtOH} 283 mμ (log ε=4.49).

Found: C, 75.15; H, 5.32%. Calcd for $C_{15}H_{12}O_3$: C, 74.99; H, 5.03%.

Catechol dicinnamate was obtained from the ether-insoluble part. Yield, 6.3 g (29.6%), mp 126—127°C (from ethanol). IR (KBr): 1730 and 1720 cm^{-1} (ν_{CO}).

Found: C, 77.99; H, 5.03%. Calcd for $C_{24}H_{18}O_4$: C, 77.82; H, 4.92%.

***m*-Hydroxyphenyl Cinnamate (2).** This compound was prepared in a 3.7% yield by the same method as in the case of (1). Mp 112—113°C (from benzene). IR (KBr): 3350 (ν_{OH}) and 1692 cm^{-1} (ν_{CO}). UV: λ_{max}^{EtOH} 284 mμ (log ε=4.42).

Found: C, 75.21; H, 5.21%. Calcd for $C_{15}H_{12}O_3$: C, 74.99; H, 5.03%.

Resorcinol dicinnamate, yield, 22.8%, mp 118—119°C (from ethanol). IR (KBr): 1728 cm^{-1} (ν_{CO}).

Found: C, 77.86; H, 5.11%. Calcd for $C_{24}H_{18}O_4$: C, 77.82; H, 4.92%.

***p*-Hydroxyphenyl Cinnamate (3).** To a stirred solution of 8.8 g of hydroquinone in 60 m*l* of pyridine, there was slowly added 13.6 g of cinnamoyl chloride over a period of about 1 hr at 45°C. The reaction mixture was then poured into cold water and extracted with ether, and the ether layer was washed with a dilute aqueous sodium hydrogencarbonate solution, dilute hydrochloric acid, and then water. The ether solution was evaporated *in vacuo*, and the residual white crystals were dissolved in warm methanol. After the removal of the methanol-insoluble crystals by filtration, the filtrate was evaporated *in vacuo*; the resulting white crystals were recrystallized from ethanol. Yield, 4.0 g (20.8%), mp 167—168°C. IR (KBr): 3389 (ν_{OH}) and 1695 cm^{-1} (ν_{CO}). UV: λ_{max}^{EtOH} 283 mμ (log ε=4.49).

Found: C, 75.04; H, 5.28%. Calcd for $C_{15}H_{12}O_3$: C, 74.99; H, 5.03%.

Hydroquinone dicinnamate was obtained from the above methanol-insoluble part. Yield, 3.3 g (11.0%), mp 186—188°C (from benzene). IR (KBr): 1735 cm^{-1} (ν_{CO}).

Found: C, 78.12; H, 5.19%. Calcd for $C_{24}H_{18}O_4$: C, 77.82; H, 4.92%.

Irradiation of *o*-Hydroxyphenyl Cinnamate (1). A solution of 500 mg of (1) in 300 m*l* of dry benzene was irradiated under a nitrogen atmosphere at room temperature by a high-pressure 100 W mercury arc for 30 hr. After irradiation, benzene was evaporated *in vacuo* and the resulting crude mixture was chromatographed on a 570×30 mm column of silica gel. 2′,3′-Dihydroxychalcone (4) was obtained as orange crystals from the first elution with ligroin-benzene-ethyl acetate (2 : 2 : 1). Yield, 100 mg (20%), mp 149—150°C (from methanol) (lit. mp 151°C[2]). IR (KBr): 3460 (ν_{OH}) and 1632 cm^{-1} (ν_{CO}). UV: λ_{max}^{EtOH} 232 (log ε=4.32), 322 mμ (4.63).

Found: C, 75.22; H, 5.27%. Calcd for $C_{15}H_{12}O_3$: C, 74.99; H, 5.03%.

This chalcone (4) was converted into 8-hydroxyflavanone, mp 191—192°C (lit. mp 192°C[2]), by refluxing it with methanolic hydrochloric acid for 10 hr.

Irradiation of *m*-Hydroxyphenyl Cinnamate (2). A solution of 1.0 g of (2) in 300 m*l* of benzene was irradiated for 30 hr as has been described above. Elution with benzene-ethyl acetate (2 : 1) gave 400 mg of white crystals, which were identified as the unchanged starting materials by a comparison of the IR spectrum with that of (2). The second fraction gave 50 mg of yellow crystals, which were identified as 2′,4′-dihydroxychalcone (5) by a comparison of the IR spectrum with that of an authentic sample. Mp 146—147°C (from benzene) (lit. 150—151°C[3]). The third fraction gave 110 mg of resorcinol, while the fourth fraction, which was eluted with methanol, gave 120 mg of brown, viscous polymeric products.

Irradiation of *p*-Hydroxyphenyl Cinnamate (3). A solution of 1.0 g of (3) in 500 m*l* of benzene was irradiated for 30 hr and then worked up as has been described above. Elution with chloroform-ethyl acetate (10 : 1) gave 160 mg of orange crystals, which were identified as 2′,5′-dihydroxychalcone (6) by a comparison of the IR spectrum with that of an authentic sample. Mp 172—173°C (from methanol) (lit. mp 173—173.5°C[4]). IR (KBr): 3280 (ν_{OH}) and 1637 cm^{-1} (ν_{CO}). UV: λ_{max}^{EtOH} 229 (log ε=4.12), 316 (4.37) and 408 mμ (3.69).

The authors wish to acknowledge the microanalyses of Mr. Jun-ichi Onodera, and the technical assistance of Mr. Norio Moriya.

The Preparation of Copper(I) Complex Containing Organic Halide*1

Keisuke WADA and Harukichi HASHIMOTO

Department of Synthetic Chemistry, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received June 14, 1968)

The copper ion catalysed reactions of organic halides have been extensively studied for their potent utilities in the field of organic synthetic chemistry. One important subject still remaining is the elucidation of the nature of the interaction between organic halide and copper ion. An approach to this problem is the preparation of a relatively stable complex of intermediate character of the reaction between organic halide and copper ion. Organocopper compound that involves copper-carbon bond is a fairly familiar one.[1] Only a little is known, however, about a compound that involves the direct interaction between copper and halogen atom in the organic halide. In 1914, Peters prepared the cuprous cyanide complex coordinated by methyl iodide.[2] Since then no remarkable study has been reported on this type of the compound.

During the course of studies on the redox ligand transfer reaction or organic halide with transition metal complex,[3] we discovered new complexes of general formula CuX (organic halide) $(P\phi_3)_2$. The complexes were obtained by the reaction of cuprous chloride, triphenylphosphine and organic halide in acetonitrile solutions under a nitrogen stream at reflux. The complexes were separated from reaction mixture as precipitates and after repeated washing with ethyl ether, were dried *in vacuo*. Typical of these complexes is that of benzyl iodide.

The same complex was obtained also by the reaction of tris(triphenylphosphine)-copper(I) chloride and benzyl iodide. The yield was nearly stoichiometric in this case.

$$CuCl(P\phi_3)_3 + C_6H_5CH_2I \longrightarrow CuCl(C_6H_5CH_2I)(P\phi_3)_2 + P\phi_3$$

Found: C, 61.98; H, 4.23; Cu, 7.52%. Calcd for $CuCl(C_6H_5CH_2I)(P\phi_3)_2$: C, 61.36; H, 4.43; Cu, 7.55%. The complex is white crystalline and rather sensitive to light but fairly stable against oxygen. The infrared spectrum of the complex gives a sharp strong band at 581 cm^{-1} and several other bands due to triphenylphosphine and benzyl iodide. The 581 cm^{-1} band is assigned to C–I stretching of benzyl iodide coordinated to copper atom, although there remains some uncertainty. The NMR spectrum of methylene proton at elevated temperature gives a signal at 5.08 ppm. The signal of free benzyl iodide at the same condition appears at 5.33 ppm. The ultraviolet spectrum shows a new band at 250 mμ.

The reaction of this complex and ethylenediamine in acetonitrile produces a trace of bibenzyl. The complex of this type may be the precursor of intermediate in the redox ligand transfer reaction of organic halide.[3]

Stochastic Model for Langmuir Isotherm

Kenji ISHIDA

Depatment of Applied Chemistry, Ibaraki University, Hitachi, Ibaraki

(Received June 17, 1968)

A monolayer adsorption isotherm was deduced theoretically by Langmuir on the basis of a kinetic interpretation of the adsorption of gas molecules on a solid surface.[1] On the same assumption as in the classical Langmuir theory, a stochastic model for the adsorption-desorption process in a closed system at constant temperature can be formulated as follows. Let us denote by $p(n)$ the probability of finding n adsorbed molecules in stationary state and by λ and μ the probabilities of adsorption and desorption for one molecule, respectively. The probability $p(n)$ then satisfies the set of difference equations,[2]

$$\lambda\{\gamma-(n-1)\}\{(\sigma-(n-1)\}p(n-1)-\{\lambda(\gamma-n)(\sigma-n)+\mu n\}p(n)+\mu(n+1)p(n+1)=0 \quad (0\leq n\leq\sigma) \tag{1}$$

where γ is the total number of molecules in the system under consideration, σ the number of sites on the surface and $\gamma>\sigma$ and $p(-1)=p(\sigma+1)=0$ have been assumed. The probability $p(n)$ is independent of the initial state of the system and $\sum_{n=0}^{\sigma}p(n)=1$ is satisfied. The set of difference equations, (1), may be solved recurrently. We then have the stationary probability distribution,

$$p(n)=r_n z^n/R_{\sigma,\gamma}(z) \tag{2}$$

where $z=\lambda/\mu$ and $r_n=\binom{\sigma}{n}(\gamma)_n=\binom{\sigma}{n}\gamma!/(\gamma-n)!$ and $R_{\sigma,\gamma}(z)=\sum_{n=0}^{\sigma}r_n z^n$ is called the rook polynomial.[3] The probability distributions for different values of z are illustrated in Fig. 1. It is to be noted, here, that the statistic-mechanical model leads also to the probability distribution,[4]

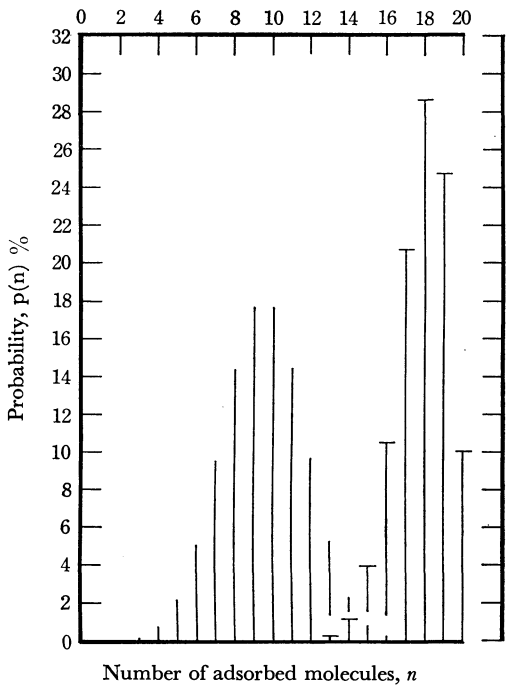

Fig. 1. Probability distribution.
$\gamma=100$, $\sigma=20$; —: $z=10^{-2}$, |—: $z=10^{-1}$

$$p_{\text{S.M.}}(n)=(1/Q)\frac{\sigma!}{n!(\sigma-n)!}q^n\frac{1}{(\gamma-n)!}q_G{}^{\gamma-n}=(q_G{}^{\gamma}/Q\gamma!)\binom{\sigma}{n}(\gamma)_n(q/q_G)^n \tag{3}$$

which is of the same form as (2). In this formula, the quantities q and q_G denote respectively the partition functions of adsorbed and gaseous molecules and the partition function for the whole system,

$$Q=(q_G{}^{\gamma}/\gamma!)\sum_{n=0}^{\sigma}\binom{\sigma}{n}(\gamma)_n(q/q_G)^n$$

1) I. Langmuir, *J. Am. Chem. Soc.*, **38**, 2221 (1916); **40**, 1361 (1918).

4) For proof, refer to T. L. Hill, "Introduction to Statistical Thermodynamics," Addison-Wesley Publishing Company, Reading, Massachusetts (1960), Section 10-3.

is regarded as the normalization factor.

It follows from (2) that the mean number of adsorbed molecules, $\langle n\rangle$, is given by

$$\langle n\rangle = z\frac{\mathrm{d}}{\mathrm{d}z}R_{\sigma,\gamma}(z)/R_{\sigma,\gamma}(z) \tag{4}$$

It is convenient to relate $R_{\sigma,\gamma}(z)$ to the confluent hypergeometric function[5] $\Phi(\gamma+1, \gamma-\sigma+1; 1/z)$ by the formula,

$$R_{\sigma,\gamma}(z) = (\gamma)_\sigma z^\sigma \mathrm{e}^{-1/z}\Phi(\gamma+1, \gamma-\sigma+1; 1/z) \tag{5}$$

Substituting (5) into (4) and using the differential relation,

$$z\frac{\mathrm{d}}{\mathrm{d}z}\Phi(\gamma+1, \gamma-\sigma+1; 1/z) = \sigma\Phi(\gamma, \gamma-\sigma+1; 1/z) - (\sigma+1/z)\,\Phi(\gamma+1, \gamma-\sigma+1; 1/z)$$

we obtain

$$\langle n\rangle = \sigma\Phi(\gamma, \gamma-\sigma+1; 1/z)/\Phi(\gamma+1, \gamma-\sigma+1; 1/z) \tag{6}$$

Therefore, the mean number of gas molecules, $\langle n_G\rangle = \gamma - \langle n\rangle$, is given by

$$\langle n_G\rangle = (\gamma-\sigma)\Phi(\gamma, \gamma-\sigma; 1/z)/\Phi(\gamma+1, \gamma-\sigma+1; 1/z) \tag{7}$$

where we have used the recurrence relation,

$$\gamma\Phi(\gamma+1, \gamma-\sigma+1; 1/z) - \sigma\Phi(\gamma, \gamma-\sigma+1; 1/z) = (\gamma-\sigma)\,\Phi(\gamma, \gamma-\sigma; 1/z)$$

It follows from (6) and (7) that the stochastic Langmuir isotherm may be written in the form,

$$\langle n\rangle = \sigma\frac{z\langle n_G\rangle}{1+z\langle n_G\rangle - z(\gamma-\sigma)\Delta} \tag{8}$$

where for brevity we have introduced a quantity Δ defined by

$$\Delta = \Phi(\gamma, \gamma-\sigma; 1/z)/\Phi(\gamma+1, \gamma-\sigma+1; 1/z) - \Phi(\gamma-1, \gamma-\sigma; 1/z)/\Phi(\gamma, \gamma-\sigma+1; 1/z)$$

In deriving (8), we have also used the recurrence relation,

$$(1/z)\,\Phi(\gamma, \gamma-\sigma+1; 1/z) = (\gamma-\sigma)\{\Phi(\gamma,\gamma-\sigma; 1/z) - \Phi(\gamma-1, \gamma-\sigma; 1/z)\}$$

It is possible, however, to connect the quantity Δ with the variance (fluctuation),

$$\langle n^2\rangle - \langle n\rangle^2 = \langle n\rangle + z^2\frac{\mathrm{d}^2}{\mathrm{d}z^2}R_{\sigma,\gamma}(z)/R_{\sigma,\gamma}(z) - \left(z\frac{\mathrm{d}}{\mathrm{d}z}R_{\sigma,\gamma}(z)/R_{\sigma,\gamma}(z)\right)^2$$

Applying (5) to this equation, we obtain, after rather long but straightforward algebra,

$$\langle n^2\rangle - \langle n\rangle^2 = \langle n\rangle(\gamma-\sigma)\Delta \tag{9}$$

where $\Delta > 0$ in the case of $\gamma > \sigma$. By combining (9) with (8), we obtain

$$\langle n\rangle = \sigma\frac{z\langle n_G\rangle}{1+z\langle n_G\rangle}\left\{1+\frac{\langle n^2\rangle - \langle n\rangle^2}{\sigma\langle n_G\rangle}\right\} \tag{10}$$

which can be also deduced directly from (1). Since the inequality $\langle n^2\rangle - \langle n\rangle^2 \ll \sigma\langle n_G\rangle$ holds for ordinary statistical thermodynamic systems, (10) becomes

$$\langle n\rangle \simeq \sigma\frac{z\langle n_G\rangle}{1+z\langle n_G\rangle}$$

which is, in the mean, consistent with the classical Langmuir isotherm. The variance (9), however, may not be negligible in small systems.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 564—565 (1969)

Stochastic Model for Autocatalytic Reaction

Kenji ISHIDA

Department of Applied Chemistry, Ibaraki University, Hitachi, Ibaraki

(Received June 17, 1968)

In the autocatalytic reaction A→B, the rate of production of B is not only proportional to the concentration of reactant A, but also to the concentration of product B; in other words the reaction catalyzes itself. Hence, this reaction may be regarded as a second-order reaction.

To construct a stochastic model for the autocatalytic reaction, let the random variable $X(t)$ represent the number of molecules of the product B at time t, and let us denote the probability of finding x molecules of B in the reaction system at time t by $P(x\,;t)=\mathrm{Prob}\{X(t)=x\}$, $x=b,\ b+1,\cdots,\ b+a$, where $X(0)=b(\geq 1)$ and $a(\geq b)$ is the total number of molecules of reactant A. If, then, the

transition probability that one B-molecule will be produced in the interval $(t,\ t+\Delta t)$ is given by $k\{a-(x-b)\}x\Delta t+o(\Delta t)$, it follows from the stochastic theory of second-order reaction kinetics[1-3] that the probability $P(x\,;t)$ satisfies the set of differential-difference equations

$$\frac{\mathrm{d}}{\mathrm{d}t}P(x;t) = k\{a-[(x-1)-b]\}(x-1)P(x-1;t) - k\{a-(x-b)\}xP(x;t) \qquad (1)$$
$$(b \leq x \leq b+a)$$

where k is the rate constant and $P(b-1\,;t)=0$ has been assumed for all $t \geq 0$. This is to be solved with the initial conditions

$$P(x;0) = 1 \quad \text{for } x = b$$
$$= 0 \quad \text{otherwise.}$$

We then have the probability distribution, for $b \geq x \geq (a+b)/2$ $(a+b,$ even) or $b \geq x \geq (a+b-1)/2$ $(a+b,$ odd),

$$P(x;t) = \frac{a!(x-1)!}{(a+b-x)!(b-1)!}\sum_{i=b}^{x}(-1)^{i-b}(a+b-2i) \times \frac{(a+b-x-i-1)}{(a-i)!(i-b)!(x-i)!}\exp\{-k(a+b-i)it\}$$
$$= \frac{a!(x-1)!}{(a+b-x)!(b-1)!}\sum_{j=0}^{x-b}(-1)^{j}(a-b-2j) \times \frac{(a-x-j-1)!}{(a-b-j)!j!(x-b-j)!} \times \exp\{-k(a-j)(b+j)t\} \qquad (2)$$

which has been derived by the method of Laplace transform.

The restriction $b \geq x \geq (a+b)/2$ or $b \geq x \geq (a+b-1)/2$ has been assumed for the study of the initial stage of reaction. In this stage, it follows that the approximations

$$\frac{a!}{(a+b-x)!} = a^{x-b}\prod_{i=1}^{x-b-1}\left(1-\frac{i}{a}\right) \simeq a^{x-b}$$

and

$$(a-b-2j)\frac{(a-x-j-1)!}{(a-b-j)!} = a\left(1-\frac{b+2j}{a}\right)\Big/a^{x-b+1}\prod_{i=0}^{x-b}\left(1-\frac{b+j+i}{a}\right) \simeq a^{-(x-b)}$$

hold for sufficiently large $a(\gg b)$. Moreover, we assume that

$$k(a-j)(b+j) = ka\left(1-\frac{j}{a}\right)(b+j) \simeq \lambda(b+j)$$

where ka has been replaced by the new constant λ. By introducing these approximations into (2), we obtain

$$P(x;t) = \frac{(x-1)!}{(x-b)!(b-1)!}\exp(-\lambda bt) \times \sum_{j=0}^{x-b}\frac{(x-b)}{j!(x-b-j)!}\{-\exp(-\lambda t)\}^{j} = \binom{x-1}{x-b}\exp(-\lambda bt)\{1-\exp(-\lambda t)\}^{x-b} \qquad (3)$$

in agreement with Delbrück's treatment.[4] He proposed the differential-difference equation (4) describing the statistical fluctuation of a simple autocatalytic reaction mechanism. We thus see that the probability distribution (3) satisfies the equation,

$$\frac{\mathrm{d}}{\mathrm{d}t}P(x;t) = \lambda(x-1)P(x-1;t) - \lambda xP(x;t) \qquad (4)$$
$$(x=b,\ b+1,\ \cdots)$$

on the assumption that the number of molecules of reactant A is so large that it remains constant through the course of reaction. As long as the initial number of molecules, a, is sufficiently large but finite, (3) is an approximation of (2) and holds only for the initial stage of the autocatalytic reaction. This will become still more clear by comparing the following two rate equations for the means $\langle x \rangle$,

$$\frac{\mathrm{d}}{\mathrm{d}t}\langle x\rangle = k\{a-(\langle x\rangle - b)\}\langle x\rangle - k(\langle x^2\rangle - \langle x^2\rangle)$$

and

$$\frac{\mathrm{d}}{\mathrm{d}t}\langle x\rangle = \lambda\langle x\rangle$$

which can be derived from (1) and (4), respectively.

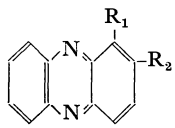
and Ken KATAGIRI

Shionogi Research Laboratory, Shionogi & Co., Ltd., Fukushima-ku, Osaka

(Received June 19, 1968)

In previous papers,[1,2] the reactions of halogenophenazine derivatives with piperidine and morpholine were reported. In this paper, the reactions of various halogenophenazine derivatives with mercaptoacetic acid will be reported.

Landquist has reported that the reaction of 2-chlorophenazine-5,10-dioxide (I) with sodium mercaptoacetate gave 2-carboxymethylthiophenazine (II).[3] By a modification of this method, we could obtain II from 2-chlorophenazine (III), 2-bromophenazine (IV), 2-chlorophenazine-5-oxide (V), 3-chlorophenazine-5-oxide (VI), and 3-bromophenazine-5-oxide (VII). The reaction of either 1-chlorophenazine (VIII) or 1-chlorophenazine-5-oxide (IX) with sodium mercaptoacetate gave 1-carboxymethylthiophenazine (X). In this case, 1-chlorophenazine was shown to be less reactive toward the reagent than 2-chloro compounds.



II: R_1=H; R_2=SCH_2CO_2H
X: R_1=SCH_2CO_2H; R_2=H

The enhancement of the reactivity of halogen by the oxide groups in halogenophenazine oxides was also observed in the present experiments.

The growth-inhibitory activity of II and X against Crocker Sarcoma 180 has also been investigated and will be reported on elsewhere.[4]

Experimental[5]

2-Carboxymethyl thiophenazine (II). *a) From III.* To a solution of III (1.7 g) in ethanol (40 m*l*), a sodium mercaptoacetate solution prepared from mercaptoacetic acid (1.5 g) and a 10% sodium hydroxide aqueous solution (14 m*l*) was added. The mixture was refluxed for 17 hr and then poured into water (0.5 *l*). The aqueous solution was filtered, and the filtrate was slightly acidified with diluted hydrochloric acid. The crystals (1.9 g) thereby separated were collected, washed with water, and dried. Recrystallization from ethanol afforded fine, brownish-yellow prisms (mp 255—256°C (decomp.)), which were identified as II[3] by a comparison of their infrared spectra.

b) From IV. To a solution of IV (0.2 g) in ethanol (4 m*l*), a solution of mercaptoacetic acid (150 mg) in 10% sodium hydroxide (1.4 m*l*) was added; the mixture was then treated as in the case of a) to give II (140 mg).

c) From V. To a solution of V (1.9 g) in ethanol (40 m*l*), a solution of mercaptoacetic acid (1.5 g) in 10% sodium hydroxide (14 m*l*) was added; The mixture was then refluxed for 5.5 hr and treated as in the case of a) to give II (1.7 g).

d) From VI. To a solution of VI (1.9 g) in ethanol (40 m*l*), a solution of mercaptoacetic acid (1.5 g) in 10% sodium hydroxide (14 m*l*) was added. The mixture was then refluxed for 5 hr and treated as in the case of a) to afford II (1.8 g).

e) From VII. To a solution of VII (0.2 g) in ethanol (4 m*l*), a solution of mercaptoacetic acid (150 mg) in 10% sodium hydroxide (1.4 m*l*) was added. The mixture was then refluxed for 4.5 hr and treated as in the case of a) to give II (140 mg).

1-Carboxymethylthiophenazine (X). *a) From VIII.* To a solution of VIII (1.7 g) in ethanol (40 m*l*), a solution of mercaptoacetic acid (1.5 g) in 10% sodium hydroxide aqueous solution (14 m*l*) was added. The mixture was refluxed for 20 hr and then poured into water (0.5 *l*). The crystals which separated were filtered and recrystallized from methanol to recover VIII (1.2 g). The filtrate was slightly acidified with diluted hydrochloric acid to give crystals (530 mg). Recrystallization from ethanol afforded X (mp 240—241°C (decomp.)) as fine, brownish-yellow crystals.

Found: C, 62.19; H, 3.96; N, 10.08%. Calcd for $C_{14}H_{10}N_2O_2S$: C, 62.21; H, 3.73; N, 10.36%.

b) From IX. To a solution of IX (1.9 g) in ethanol (40 m*l*), a solution of mercaptoacetic acid (1.5 g) in 10% sodium hydroxide (14 m*l*) was added. The resultant mixture was refluxed for 10 hr and treated as in the case of a) above to yield both X (550 mg) and VIII (1.2 g).

Protonation of Allene. Evidence for the Formation of 1,1-Diphenyl-3,3-dibromoprop-1-ene

Fumio TODA, Masahiro HIGASHI and Katsuhiko AKAGI

Department of Industrial Chemistry, Faculty of Engineering, Ehime University, Matsuyama

(Received June 21, 1968)

It has been reported[1] that the action of phosphorus tribromide on 1,1-diphenylprop-2-yn-1-ol (I) in acetic acid affords 1,1-diphenyl-3,3-dibromoprop-1-ene (VIII) (mp 82°C) and that the reaction proceeds *via* the bromoallene intermediate II, as is shown in Scheme 1. Recently, Martinet and Doupeux[2] have reported the formation of 1,1-diphenyl-1,3-dibromoprop-2-ene (IX) (mp 81—82°C) by the reaction of hydrogen bromide and 1,1-diphenyl-3-bromopropa-1,2-diene (II), which had been isolated by the action of phosphorus tribromide on I in hexane.

Our treatment of II with hydrogen bromide afforded crystals (mp 82°C) which were identical with those obtained previously.[2] However, some physical data (mp, infrared and NMR spectra) reported[2] for IX were identical with those of VIII. These ambiguous results prompted us to reinvestigate the structure of the dibromide and then the protonation of bromoallene II.

An evidence that the dibromide is allylic *gem*-dibromide (VIII) but not 1,3-dibromide (IX) was obtained by the following cross-addition reactions. 1,1-Diphenyl-3-bromo-3-chloroprop-1-ene (IV) (mp 50—52°C), derived from II and hydrogen chloride, was identical with that obtained from the chloro-analog of II (III) and hydrogen bromide, as is shown in Scheme 1. Since the treatment of II with a large excess of hydrogen bromide or of hydrogen chloride afforded VIII or dichloro-analog V, phosphorus trihalide in acetic acid was used as the source of hydrogen halide in order to avoid the presence of excess hydrogen halide. The bromochloro compound, IV, thus obtained was different from the dichloro-analog, V (mp 23.5—24°C), prepared by the addition of hydrogen chloride to III. The infrared spectra of IV and V were almost identical with that of VIII. The acid- or base-catalysed hydrolysis of IV and V gave 1,1-diphenylprop-1-en-3-al (VI), as in the case of VIII.[1] Finally, the structure of the dibromide reported in two previous articles[1,2] may be identified as allylic *gem*-dibromide VIII.

The above results led us to the following speculation. The cation in which the plus charge is located on C-3, $>C{=}CH{-}\overset{+}{C}HBr$, may be more stable than that in which the charge is on C-1, $>\overset{+}{C}{-}CH{=}CHBr$. The stability of the former may be due to a longer conjugate system for the delocalization of the positive charge.

The ultraviolet spectrum[1] of VIII, 242 (10200), 266 (14700), and 273 mμ (ε, 16500), shows the presence of a conjugate system corresponding to 1,1-diphenylethylene and supports the structure VIII. Martinet and Doupeux have assigned the structure IX to the dibromide on the basis of the infrared and NMR spectra, but not the ultraviolet spectrum. We have tried to identify the infrared and NMR spectral bands of VIII, by which they were misled to determine the structure of the dibromide to be IX.

The infrared spectrum of VIII showed a strong band at 880 cm^{-1}, as is shown in Fig. 1. In order to identify this band, VIII-2-d was prepared by the addition of deuterium bromide to II. In VIII-2-d, the 880 cm^{-1} band shifted to 735 cm^{-1}. Therefore, the band may be assigned to the out-of-plane deformation of $\overset{2}{C}{-}H$. This assignment is reasonable

2) P. Martinet and H. Doupeux, *Compt. rend.*, **261**, 2498 (1965).

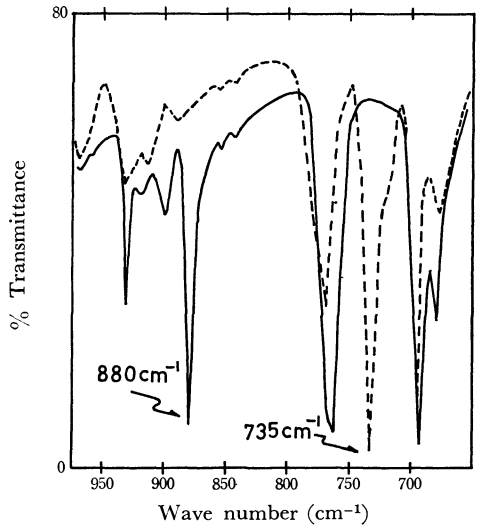

Fig. 1. The infrared spectra of VIII (——) and VIII-2-d (------).

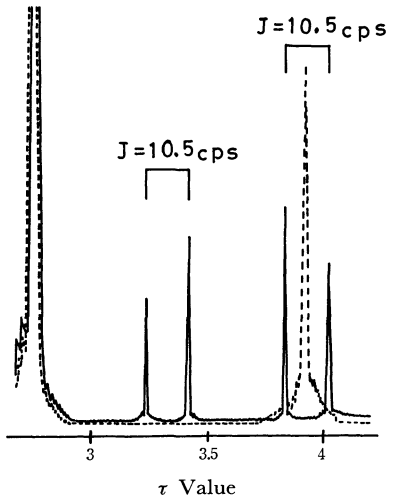

Fig. 2. The NMR spectra of VIII (——) and VIII-2-d (------).

since it is well known[3] that the general frequency for the CH out-of-plane deformation of trisubstituted ethylene, 840—800 cm^{-1}, varies with the change in substituents.

As is shown in Fig. 2, the NMR spectrum of VIII showed a multiplet (centered at 2.70, phenyl) and two doublets (centered at 3.35, $J=10.5$ cps and centered at 3.95τ, $J=10.5$ cps) in the integrated ratio of 10 : 1 : 1. Martient and Doupeux have identified the two doublets as two vinyl hydrogens of IX. However, since the structure VIII instead of IX was confirmed to be correct, the two doublets may be assinged to vinyl and allylic hydrogens. The doublet at the lower field, which disappeared in the spectrum of VIII-2-d (Fig. 2), may be attributed to the vinyl hydrogen. The remaining signal may be due to the allylic hydrogen. The observed value, 3.95τ, of the allylic methine hydrogen agrees fairly well with that calculated, 3.78τ, according to Shoolery's equation[4] using 2.33 and 1.32 ppm as the effective shielding constants of bromine and diphenylethylene respectively.

Experimental[5]

Instrumental Analyses. The infrared spectra were recorded in Nujol mull on a grating spectrophotometer, IR-G, of Japan Spectroscopic Co. The NMR spectra were recorded in carbon tetrachloride on a Japan Electron Optics Laboratory C-60 spectrometer, using TMS as the internal standard.

1,1-Diphenyl-3-bromopropadiene (II) and 1,1-Diphenyl-3-chloropropadiene (III). A solution of I (3.0 g, 15 mmol) in hexane (40 m*l*) was cooled to *ca.* −25°C with a dry ice-methanol bath. Into the solution, phosphorus tribromide (4.0 g, 15 mmol) was stirred over a 20-min period. The stirring was then continued for a further 2 hr at *ca.* −25°C. The crystalline solid recrystallized from hexane afforded II as colorless needles, 3.0 g (74%), mp 74.5—75°C (lit.[2] mp 67—69°C). IR: 1926 cm^{-1} ($\nu_{C=C=C}$).

Found: C, 66.07; H, 3.89%. Calcd for $C_{15}H_{11}Br$: C, 66.38; H, 4.06%.

The treatment of I with phosphorus trichloride in hexane under the conditions employed for the preparation of II afforded III as colorless needles in a 59% yield after recrystallization from hexane, mp 46.5—48.5°C. IR: 1930 cm^{-1} ($\nu_{C=C=C}$).

Found: C, 78.72; H, 4.58%. Calcd for $C_{15}H_{11}Cl$: C, 79.43; H, 4.91%.

1,1-Diphenyl-3,3-dibromoprop-1-ene (VIII) and 1,1-Diphenyl-3,3-dibromoprop-1-ene-2-d (VIII-2-d). The dibromide VIII was prepared by the reaction of I and phosphorus tribromide in acetic acid[1] or by that of II and hydrogen bromide in hexane,[2] mp 82°C (lit.[1] 82°C: lit.[2] 81—82°C). The mixed melting point of the dibromides prepared according to the methods of those two articles showed no depression.

The deuterated dibromide, VIII-2-d, was obtained by the reaction of II and deuterium bromide[6] in hexane; it consisted of colorless prisms, mp 82°C. IR: 2500 ($\nu_{=C-D}$) and 735 cm^{-1} ($\delta_{=C-D}$). NMR: 2.70 (multiplet, phenyl, 10 H) and 3.95τ (singlet, methine, 1H). The acid- or base-catalyzed hydrolysis of VIII-2-d afforded VI-2-d in a quantitative yield. For VI-2-d, the CH out-of-plane deformation of trisubstituted ethylene of VI, 880 cm^{-1}, was shifted to 755 cm^{-1}.

1,1-Diphenyl-3-bromo-3-chloroprop-1-ene (IV). *A*)

3) L. J. Bellamy, "The Infra-red Spectra of Complex Molecules," Methuen, London (1958), p. 31.

4) B. P. Dailey and J. N. Shoolery, *J. Am. Chem. Soc.*, **77**, 3977 (1955).

5) All melting points are corrected.

6) Deuterium bromide was prepared by the reaction of phosphorus tribromide and deuterium oxide, according to the reported procedure: H. Kwart and J. L. Nyce, *J. Am. Chem. Soc.*, **86**, 2601 (1964).

Into an ice-cooled mixture of II (2.58 g, 9 mmol) and acetic acid (5 m*l*), phosphorus trichloride (1.5 g, 10 mmol) was stirred over a 5-min period. The stirring was continued for a further 30 min, and the reaction mixture was decomposed with water and extracted with ether. The ether layer was washed with water and dried over sodium sulfate, and the solvent was evaporated to dryness to leave IV as colorless leaflets, 0.9 g (37%), mp 50—52°C,. IR: 875 cm^{-1} ($\delta_{=C-H}$).

Found:*1 C, 56.96; H, 3.70%. Calcd for $C_{15}H_{12}BrCl$: C, 58.54; H, 3.90%.

B) Into an ice-cooled mixture of III (1.7 g, 7.5 mmol) and acetic acid (5 m*l*), phosphorus tribromide (1.0 g, 3.5 mmol)*2 was stirred over a 5-min period. Crystalline solid 1.3 g (56%), mp 50—52°C. A mixed-melting-point determination with crystals obtained by the procedure A showed no depression. The infrared spectrum was identical with that of crystals obtained by the procedure A. The acid- or base-catalyzed hydrolysis of IV afforded VI in a quantitative yield, mp 44°C. A mixed-melting-point determination with an authentic specimen (lit.[7] mp 44.5—45.5°C) showed no depression.

1,1-Diphenyl-3,3-dichloroprop-1-ene (V). Into an ice-cooled solution of I (3.0 g, 15 mmol) in acetic acid (5 m*l*), phosphorus trichloride (4.0 g, 30 mmol) was stirred over a 5-min period. After 2 days, the reaction mixture was decomposed with water and extracted with ether. The ether layer was washed with water and dried over sodium sulfate. The crude oil remaining after the evaporation of the solvent was distilled to afford V, 2.3 g (65%), bp 134°C/2 mmHg, mp 23.5—24°C. IR: 1617 ($\nu_{C=C}$) and 876 cm^{-1} ($\delta_{=C-H}$). The spectrum was similar to those of VIII and IV.

Found: C, 68.28; H, 4.31%. Calcd for $C_{15}H_{12}Cl_2$: C, 68.44; H, 4.56%.

The acid or base-catalyzed hydrolysis of V afforded VI in a quantitative yield, mp 44°C. A mixed-melting-point determination with an authentic sample (lit.[7] mp 44.5—45.5°C) showed no depression.

The treatment of III with hydrogen chloride in hexane also afforded V in a quantitative yield.

*1 Since the bromochloride IV was converted into dibromide VIII and dichloride V gradually by repeated recrystallizations from hexane, it was difficult to purify it further.

*2 When a large excess of phosphorus tribromide was used, dibromide VIII was isolated as the sole product.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 569—570 (1969)

Synthesis of Pipataline

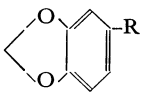
Yoshimori OMOTE, Hinako TAZAWA, Yoshimori FUJINUMA and Noboru SUGIYAMA

Department of Chemistry, Tokyo Kyoiku University, Otsuka, Tokyo

(Received June 27, 1968)

Atal *et al.*[1] have recently reported the isolation of pipataline from *Piper peepuloides* Roxb. and proposed that its structure is 1-(3,4-methylenedioxyphenyl)-1-dodecene (I). In connection with our studies[2-4] of melanin precursors we have synthesized pipataline (I) as a model catechol melanin precursor. The synthesis of pipataline consists of the addition of *n*-undecyl magnesium iodide to piperonal and the removal of the water.

Heating *n*-undecyl magnesiumiodide and piperonal under reflux for one hour gave an alcohol (II) as a colorless liquid, bp 200—220°C/10^{-3}—10^{-4} mmHg, this alcohol was then dehydrated, by aluminum oxide at 200°C for 30 min. The product (I) was extracted with ether and recrystallized from petroleum ether - ethanol to afford colorless crystals, mp 37°C. The spectral data of UV, IR and NMR, are in good agreement with those of natural pipataline.[1]



I, R= $CH{=}CH(CH_2)_9CH_3$
II, R= $CH(OH)CH_2(CH_2)_9CH_3$

Experimental

***n*-Undecyl Iodide.** A mixture of *n*-undecyl alcohol (6 g), iodine (5.4 g), and red phosphorus (0.6 g) was heated at 110—120°C for 6 hr and then kept overnight at room temperature. The ethereal extract from the reaction mixture was washed with a 10% aqueous sodium thiosulfate solution and dried over anhydrous sodium sulfate. The removal of the solvent gave *n*-undecyl iodide (6.2 g), which was then distilled at

1) C. K. Atal, K. L. Dhar and A. Pelter, *Chem. & Ind.*, **1967**, 2173.

2) Y. Omote, U. Kurabayashi, A. Momose and N. Sugiyama, *Nippon Kagaku Zasshi* (*J. Chem. Soc. Japan, Pure Chem. Sect.*), **88**, 80 (1967).

104—110°C/2 mmHg (lit.[5] 125°C/3 mmHg).

1-(3,4-methylenedioxyphenyl)-1-dodecanol (II). Piperonal (2.1 g) dissolved in ether (20 m*l*) was added to *n*-undecyl magnesiumiodide, prepared from magnesium (0.5 g) and *n*-undecyl iodide (3 g) in ether (25 m*l*), under cooling with ice water. The mixture was heated with stirring under reflux for one hour. To the mixture there was then added 3 N hydrochloric acid under cooling. The etheral layer from the acidified mixture was washed with a 40% aqueous sodium bisulfite and then with an aqueous sodium bicarbonate solution. After drying over anhydrous sodium sulfate, the solvent was evaporated, and to the residue there was added ethanol. Then the undissolved precipitates were filtered off and the ethanol solution was evaporated to give the alcohol (II) (0.7 g), which was distilled at 200—220°C/10^{-3}—10^{-4} mmHg in a molecular still. Found: C, 75.54; H, 9.85%. Calcd for $C_{19}H_{30}O_3$: C, 74.47; H, 9.87%. IR ν (liq. film) 3400, 2925, 1610, 1245 and 1043 cm^{-1}. UV λ_{max}^{EtOH} nm 234, 288.

From the insoluble precipitates described above there was obtained a hydrocarbon (0.3 g), mp 43—44°C, mol wt (Rast)=341, IR ν^{KBr} 2900, 2840, 1470 and 718 cm^{-1}. This seems to be docosane (mp 47°C), probably resulting from the reaction of *n*-undecyl magnesiumiodide with *n*-undecyl iodide.

Pipataline (I). The alcohol (II) (0.35 g) was dehydrated by activated aluminum oxide (0.18 g) under a nitrogen atmosphere at 180—200°C for 30 min. The reaction mixture was then extracted with ether. The removal of the solvent and recrystallization from petroleum ether - ethanol gave pipataline as colorless crystals (50 mg), mp 37°C (lit.[1] 38°C). Found: C, 78.62; H, 9.78%. Calcd for $C_{19}H_{28}O_2$: C, 79.12; H, 9.79%. IR ν^{KBr} 2920, 2850, 1605, 1248 and 1040 $cm.^{-1}$ UV λ_{max}^{EtOH} nm (ε) 262 (12700), 269 (12400) and 307 (6100). NMR τ ($CDCl_3$) 3.12(1H), 3.23 (2H, aromatic), 3.40 (1H,d,J=15 cps, olefinic), 3.7—4.1 (complex pattern, olefinic), 4.05 (methylendioxy), 7.6—8.0 (allylic), 8.2—8.9 (methylene), 8.95—9.3 (methyl).

Infrared Spectra and Molecular Conformations of Poly-γ-methyl-DL-glutamate

Yukio MASUDA

Department of Chemistry, Japan Women's University, Bunkyo-ku, Tokyo

and Tatsuo MIYAZAWA

Institute for Protein Research, Osaka University, Kita-ku, Osaka

(Received June 27, 1968)

Polyamino acids are known to take various conformations, namely the α helix, β-form or disordered form. For conformation diagnoses, the amide I and II bands in the infrared spectra[1] are extensively used. In our previous study, the amide V bands arising from the N–H out-of-plane bending mode were also found useful for conformation studies.[2] With the observed amide bands, the conformations of racemic polyamino acids were analysed in the present study.

Poly-γ-methyl-DL-glutamate (PMDLG) were synthesized by the Leuchs method. Racemic γ-methyl-DL-glutamate (mp 185°C) was converted to *N*-carboxyamino acid anhydride [A] (mp 72°C), which was polymerized in dioxane, with the initiator [I] of sodium methoxide or *n*-hexylamine. The polymer was precipitated by pouring the reaction mixture into diethyl ether, filtered, washed, and dried. The molecular weight of the polymers were estimated by viscosity measurements in dichloroacetic acid.[3] Infrared absorption spectra were observed with solid films cast from chloroform solution or with potassium bromide discs. Hitachi 225 or EPI-L spectrophotometers were used for the infrared measurements.

Fig. 1A shows the infrared spectrum of PMDLG ($A/I=100$). The amide I bands at 1685 and 1625 cm^{-1} indicate the existence of the β-form. However, the strong amide I band at 1655 cm^{-1}, amide II band at 1540 cm^{-1}, and the strong amide V band at 635 cm^{-1} indicate that the predominant conformation of this polymer is the α helix. This observation is similar to the case of copoly-γ-

methyl-D,L-glutamate (D : L=1 : 1, A/I=200) which exhibits a strong amide V band at 630 cm^{-1}. In the far infrared region, the characteristic band[4] of α-helical polyglutamate esters is also observed at 410 cm^{-1} for PMDLG.

For the low-molecular-weight PMDLG with A/I=20 or 8, the amide I bands were observed at 1690 and 1630 cm^{-1}, amide II bands at 1525 cm^{-1}, and the amide V band at 700 cm^{-1}. Accordingly, these molecules are predominantly in the β-form. On the other hand, Fig. 1B shows the infrared spectrum of PMDLG with A/I=4. The amide I bands at 1695, 1660, and 1633 cm^{-1}, the amide II bands at 1545 and 1530 cm^{-1}, and the amide V bands at about 700 and 670 cm^{-1} indicate that there are some fractions of the disordered form together with the β-form. This conformation of PMDLG (A/I=4) makes contrast with the case of PMLG (A/I=4) which is predominantly in the β-form. Thus infrared observations are useful especially for conformation diagnoses of DL-polypeptides which do not exhibit optical rotatory dispersion.

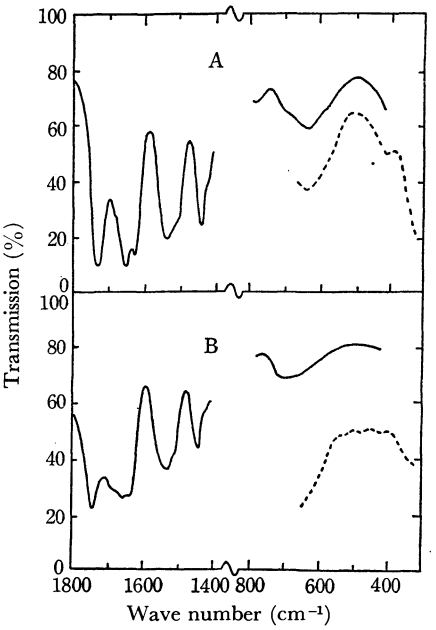

Fig. 1. Infrared Spectra of Poly-γ-methyl-DL-glutamate, A/I=100 (A) and A/I=4 (B); measured with Hitachi 225 (solid line) or EPI-L (broken line).

The Cobalt Carbonyl-catalyzed Hydroesterification of Methyl Acrylate with Carbon Monoxide and Methanol

Akio MATSUDA

Government Chemical Industrial Research Institute, Tokyo, Mita, Meguro-ku, Tokyo

(Received July 2, 1968)

In a previous paper it was reported that the cobalt carbonyl-catalyzed hydroesterification of acrylonitrile with carbon monoxide and methanol occurred in the presence of a small amount of hydrogen and a limited amount of pyridine, and that the amount of methyl α-cyanopropionate produced was larger than that of methyl β-cyanopropionate.[1] The present report is concerned with the results obtained when methyl acrylate was used in this reaction instead of acrylonitrile. The reaction procedure and the method of analyses were essentially the same as have been described in the previous report.[1]

Standard samples for the gas chromatographic analyses were obtained as follows. Dimethyl succinate was obtained commercially. Dimethyl methylmalonate was synthesized by the action of methanol and 86% sulfuric acid on methyl α-cyanopropionate, which was the main product of the hydroesterification of acrylonitrile and which had already been identified.[1] Dimethyl γ-ketopimelate was separated by distillation from the reaction product and was purified by recrystallization from cyclohexane.

Identification of Dimethyl γ-Ketopimelate. Mp 53°C. IR spectrum: C=O (ester) 1748 cm^{-1}, C=O (ketone) 1725 cm^{-1}. NMR spectrum at 60 Mc (in carbon tetrachloride, with tetramethyl-

silane as the internal standard): α-CH_2 τ 7.42 (triplet), β-CH_2 τ 7.35 (triplet), OCH_3 τ 6.39 (singlet).

Found: C, 53.50; H, 6.96%. Calcd for $C_9H_{14}O_5$: C, 53.46; H, 6.98%.

Results

The hydroesterification of methyl acrylate occurred in the presence of a small amount of hydrogen and pyridine, resulting in a high yield of dimethyl succinate and a very small yield of dimethyl methylmalonate. This exclusive formation of β-methoxycarbonylated product is in contrast to the case of the hydroesterification of acrylonitrile, where α-methoxycarbonylation predominates.[1] Dimethyl γ-ketopimelate was found as a by-product.

The effect of the reaction temperature is shown in Table 1.[2] The reaction rate is almost independent of the temperature in the 120—160°C range. The yield of dimethyl succinate decreases as the temperature increases, whereas the yield of dimethyl γ-ketopimelate increases with the temperature. The α/β ratio, contrary to the case of acrylonitrile,[1] increases along with the temperature.

Table 1. The effect of reaction temperature

1/2 mol methyl acrylate, 2 mol methanol, 4 mmol $Co_2(CO)_8$, 30 mmol pyridine; total pressure 200 kg/cm²; reaction time 1 hr; hydrogen content of the gas used, 5%.

Reaction temp. °C	Rate const. k min^{-1}	Conversion mol %	Products yields (mol %) DM	DS	DK[a]	α/β[b]
120	10×10^{-2}	100	1.9	82	2.3	0.023
140	13×10^{-2}	100	2.0	78	5.5	0.026
160	12×10^{-2}	100	1.9	67	7.8	0.029

a) Abbreviations DM, DS, and DK stand for dimethyl esters of methylmalonic acid, succinic acid, and γ-ketopimelic acid.
b) α/β stands for the mole ratio DM/DS.

The effect of the amount of pyridine is shown in Table 2; the rate constant and the selectivity toward each product are plotted against the amount of pyridine in Fig. 1.[3] The rate constant, k, increases almost in proportion to the amount of pyridine; this indicates that the reaction rate is first order with respect to the pyridine concentration. The selectivity toward dimethyl succinate increases with the amount of pyridine, whereas the selectivity toward dimethyl methylmalonate decreases slightly. The α/β ratio remarkably decreases as the amount of pyridine increases; this trend is again opposite to the case of acrylonitrile, where the methyl α-cyanopropionate/methyl β-cyanopropionate mole ratio increases along with the amount of pyridine.[1] The selectivity toward methyl γ-ketopimelate becomes larger as the amount of pyridine is reduced.

A more detailed study aimed at obtaining enough information to explain the above differences between the results of the hydroesterification of methyl acrylate and that of acrylonitrile will be reported in the future.

Table 2. The effect of the amount pyridine

1/2 mol methyl acrylate, 1/2 mol methanol, 4 mmol $Co_2(CO)_8$; reaction temperature 110°C, total pressure 160 kg/cm²; hydrogen content of the gas used, 7%.

Pyridine mmol	Rate const. k min^{-1}	Reaction time min	Conversion mol %	Products yields (mol %) DM	DS	DK	α/β

3	2.3×10^{-2}	120	100	3.2	75	13	0.043
10	8.8×10^{-2}	25	90	2.0	73	7.0	0.027

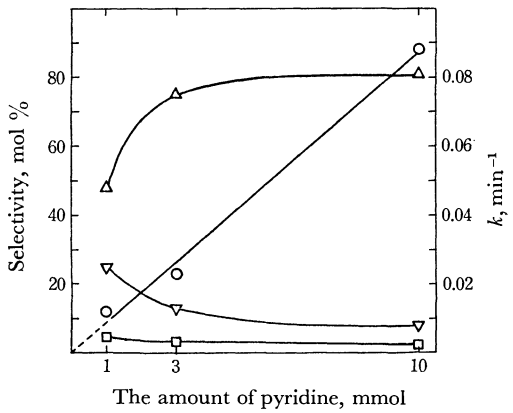

Fig. 1. The plot of k and the selectivity against the amount of pyridine.
-○-: k (min^{-1}).
-△-: Dimethyl succinate (mol %).
-▽-: Dimethyl γ-ketopimelate (mol %).
-□-: Dimethyl methylmalonate (mol %).

2) The overall first-order rate constant, k, was roughly estimated from the amount of gas supplied during the early stages of the reaction. The conversion was also roughly estimated from the total amount of gas supplied during the reaction. Although the product contained small amounts of acetal and methyl propionate resulting from the hydroformylation and hydrogenation of methyl acrylate, their yields are not listed in the table because of the lack of data.

3) The selectivity was calculated from Table 2 by dividing the yield by the conversion.

The Stability of Fused Rings in Metal Chelates. V. Copper(II) Chelates of the Schiff Base Derived from Pyruvic Acid and *n*-Propanolamine

Akitsugu NAKAHARA, Isao MIYACHI and Toshihiko KOHNO

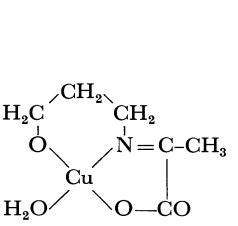
Institute of Chemistry, College of General Education, Osaka University, Toyonaka, Osaka

(Received July 10, 1968)

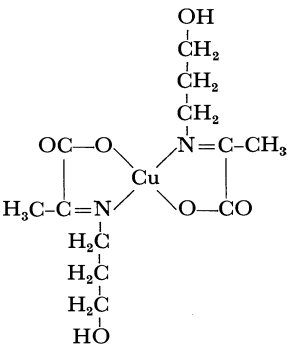
Although ethanolamine molecule is provided with two donor groups for chelation, it cannot always be coordinated as a bidentate ligand around a metal ion. The Schiff base derived from salicylaldehyde and ethanolamine is, for instance, coordinated around copper(II) to produce not only the one-to-one type copper(II)-Schiff base complex but also the one-to-two type complex,[1] in which the hydroxyl groups of the ethanolamine moieties are free from coordination. In addition to that, the Schiff base derived from pyruvic acid and ethanolamine reacts with copper(II) to form exclusively the one-to-two type copper(II)-Schiff base complex; consequently the corresponding one-to-one type complex is hardly obtained regardless of the molar ratio of copper(II) to Schiff base employed in the preparation.[2]

These findings are explainable by taking into account the rather weak binding ability of alcohol oxygen in one hand, and the low stability of the 5-5[3] fused-chelate-ring structure on the other hand.[4] If this interpretation is valid, it may well be suggested that the successful preparation of the one-to-one type copper(II)-Schiff base complex of this kind will become easier by adopting *n*-propanolamine instead of ethanolamine moiety, because of its more stable 5-6 fused-chelate-ring structure as indicated in I. On the basis of this consideration, we have recently succeeded in preparing the one-to-one type copper(II) complex of the Schiff base derived from pyruvic acid and *n*-propanolamine, I, as well as the corresponding one-to-two type chelate, II.

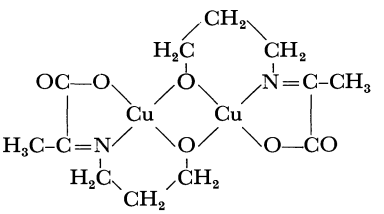
The freshly prepared one-to-one type complex is a blue lath-shaped crystal, and is described by the



(I)



(II)



(III)

formula, $[Cu(pyv=propam)(H_2O)]\cdot 4H_2O$, where pyv=propam represents the Schiff base derived from pyruvic acid and propanolamine. However, the complex undergoes a gradual dehydration of itself in atmosphere, resulting a purple crystalline powder, to which a binuclear structure as illustrated in III is easily assigned on the basis of its extremely subnormal magnetic moment (0.7 B. M. for copper atom) and magnitude of molcular weight (428.7) in chloroform. The formation of this binuclear complex is even more accelerated by heating *in vacuo*.

Although we do not have any decisive proof for the particular binuclear structure III, the other possible structure, in which two copper(II) atoms are bridged by carboxylate-oxygen, would be less plausible in some respects. For example, there is a fact that similar type complex of *N*-ethanolsalicylaldimine does not give the corresponding binuclear complex,[1] whereas that of *N*-*n*-propanolsalicylaldimine does to produce a brownish

2) Y. Komiyama and A. Nakahara, to be submitted. The title of paper will be "The Crystal and Molecular Structure of Bis(β-hydroxyethyliminopyruvato)copper-(II) Tetrahydrate."

3) A fused-chelate-ring consisting of two five-membered rings is abbreviated as 5-5 in this paper.

4) A. Nakahara, Y. Yamamoto and Y. Matsumoto, This Bulletin, **37**, 1137 (1964).

Table 1. Magnetic susceptibilities per gram and magnetic moments of copper (II) complexes of γ-hydroxypropyliminopyruvate

Complex	Temp. °C	$10^6\chi_g$	μ(B.M.)
[Cu(pyv=propam$_2$)]·2H$_2$O	16	3.55	1.9
[Cu$_2$(pyv=propam)$_2$]	18	0.45	0.7

purple binuclear complex.[5,6] In other words, the propanol-oxygen seems to take an important role in the formation of binuclear complexes.

The one-to-two type copper(II)-Schiff base complex is a light blue plate, and shows a normal magnetic moment (1.9 B. M. for copper atom). The two alcohol-oxygen atoms must, of course, be free from coordination in the light of the molecular structure of the corresponding chelate with β-hydroxyethyliminopyruvate, determined by X-ray analysis.

Of interest is comparison of the tendency for the formation of binuclear complexes: (1) the one-to-one type complex with salicylideneiminoethanol does not form binuclear complex, (2) the same type complex with salicylideneiminopropanol cannot even be isolated because of high stability of the binuclear complex, (3) similar complex with γ-hydroxypropyliminopyruvate is appropriately stable and, for this reason, complexes of both monomer and dimer structure can be isolated in crystalline state.

Experimental

The Preparation of Copper(II) Complexes of Schiff Base derived from Pyruvic Acid and *n*-Propanolamine. *The One-to-One Type Copper(II)-Schiff Base Complex, I,* [Cu(pyv=propam)(H$_2$O)]·4H$_2$O. A mixture of 1.76 g (0.02 mol) of pyruvic acid and 1.50 g (0.02 mol) of ethanolamine were dissolved in 200 m*l* of aqueous ethanol (50 vol %). To this was added 1.60 g (0.04 mol) of sodium hydroxide and 4 g (0.02 mol) of copper(II) acetate monohydrate. The mixture was stirred and heated at about 70°C for 1.5 hr; hereupon a blue-green solution was obtained. After it had been filtered, the solution was concentrated until the volume of the solution became one third of the initial state. The resulting solution was allowed to stand overnight in a refrigerator. A large amout of blue-green crystals was obtained, which was recrystallized from a small quantity of water. Found: C, 24.06; H, 6.28; N, 4.84. Calcd for [Cu(pyv=propam)(H$_2$O)]·4H$_2$O: C, 24.28; H, 6.45; N, 4.72%. Since the compound readily underwent a dehydration in atmosphere, the elemental analysis had to be performed by uisng freshly deposited crystals.

The One-to-Two Type Copper(II)-Schiff Base Complex, II, [Cu(pyv=propam)$_2$]·2H$_2$O. The almost same procedure as that employed in the above preparation was adopted, but the molar ratio of the reagents was 1 : 2 : 1 copper(II): Schiff base : sodium hydroxide instead of 1 : 1 : 2. mp 188—192°C (decomp). Found: C, 36.51; H, 6.32; N, 7.24%. Calcd for [Cu(pyv=propam)$_2$]·2H$_2$O: C, 37.16; H, 6.24; N, 7.22%.

The Binuclear form of the One-to-One Type Copper(II)-Schiff Base Complex, III. The complex, I, was dehydrated at 80°C *in vacuo* for several hours until the weight became constant. Found: C, 34.69; H, 4.30; N, 6.79%. Calcd for [Cu$_2$(pyv=propam)$_2$]: C, 34.87; H, 4.39; N, 6.78%. Molecular weight in chloroform: 428.9. Calcd for the above formula: 413.4.

Magnetic Measurements. The magnetic susceptibility was determined at room temperature by using a Gouy magnetic apparatus. The results are shown in Table 1. From the observed susceptibilities, the magnetic moments were evaluated per copper atom. The results are shown in Table 1.

The Molecular Weight of the Complex, III, was determined with a Hitachi Model-115 osmometer by using chloroform solution.

The authors thank the Ministry of Education for the financial support granted for this research.

Gel Filtration of Mixtures of Surfactants on Sephadex. II. Estimation of Micellar Molecular Weights of Mixed Surfactants

Fumikatsu TOKIWA, Kenji OHKI and Isao KOKUBO

Research Laboratories, Kao Soap Company, Minato-Yakushubata, Wakayama-shi

(Received July 10, 1968)

It has been shown in previous works[1,2] that gel filtration is useful as a research tool for studying the micellar properties of surfactants and that it also furnishes a simple means of estimating the micellar molecular weight (MMW) of a single surfactant from the retention volume of the micelle (V_M).

In the present work, the gel filtration of mixtures of two surfactants at different mixing ratios has been studied, together with the determination of the MMW's of the mixtures, in order to establish the relation between V_M and MMW. The surfactants used were sodium dodecyl sulfate (SDS), $C_{12}H_{25}OSO_3Na$, and dodecyl polyoxyethylene ether (DPE), $C_{12}H_{25}O(CH_2CH_2O)_pH$, with a p value of 12.[3]

TABLE 1. MICELLAR PROPERTIES OF THE MIXTURES OF SDS AND DPE

Mixing ratio in mole SDS/DPE	in 0.10 M NaCl				in water	
	V_M/V_0	$D_M \times 10^7$, cm²/sec	ϕ, ml/g	MWM[a] $\times 10^{-4}$	V_M/V_0	MMW[b] $\times 10^{-4}$
100/0	1.90	10.1	1.30	2.65	2.30	1.75
80/20	1.77	9.36	1.44	3.00	2.24	1.90
60/40	1.65	8.02	1.68	4.10	2.29	1.85
40/60	1.53	7.26	1.83	5.08	2.21	1.95
20/80	1.35	6.59	1.94	6.14	1.95	2.70
0/100	1.25	6.42	2.01	6.50	1.30	6.20

a) Calculated from diffusion and viscosity data.
b) Estimated from the log MMW *vs.* V_M/V_0 curve.

Table 1 gives the relative retention volumes of the micelles, V_M/V_0, at different SDS/DPE ratios in the absence and in the presence of 0.10 M NaCl, where V_0 is the void volume of the column used. These values were obtained on Sephadex G-100 by a method previously described.[1] Sephadex G-100 was chosen by taking into account its fractionation range of molecular weight (1×10^3—1×10^5). The V_M/V_0 value in 0.10 M NaCl decreases gradually with a decrease in the amount of SDS, while the value in water is almost constant, independently of the SDS/DPE ratio, in the region from 100/0 to 40/60, and then it decreases steeply with an increase in the amount of DPE. The V_M/V_0 values in the presence of sodium chloride are, in general, smaller than those in water. It has been found in a previous work that there is a linear relation between log MMW and V_M/V_0 for various types of single surfactants, but not for surfactants with a heterocyclic structure.[1] Now, it is of interest and importance to learn whether the linear relation would also be found in the present mixed systems.

The MMW values for the mixed micelles of SDS and DPE at various SDS/DPE ratios are given in Table 1; these values were calculated from the diffusion and viscosity data by the following equation, on the assumption that the micelle is a spherical and rigid particle:[5,6]

$$\mathrm{MMW} = \frac{4\pi r^3}{3} \cdot \frac{N}{\phi}$$

where:

$$r = kT/6\pi\eta D_M$$

Here, r is the radius of the micelle; η, the viscosity of the solvent; D_M, the diffusion coefficient of the micelle, and ϕ, the effective specific volume of the micelle, while N, R, and T have the conventional meanings. The values of ϕ and D_M are given in Table 1. The ϕ was obtained from the relative viscosity of the solution in terms of the Guth-Simha equation[5,7]; in the present case, it was independent of the concentration of the mixture at relatively high concentrations. The MMW value obtained from ϕ and D_M by Eq. (1) for SDS or DPE alone is in agreement with the

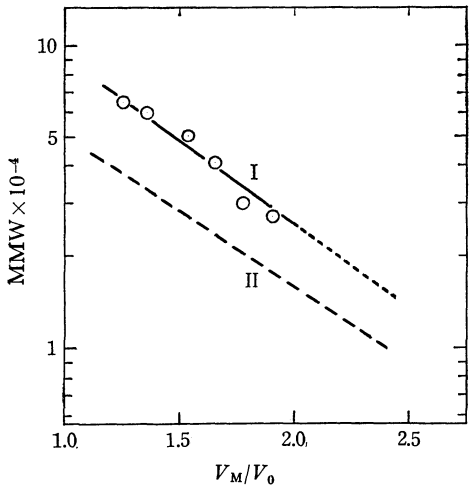

Fig. 1. The relation between log MMW and V_M/V_0 for the mixed micelles of SDS and DPE at various mixing ratios using the Sephadex G-100 column at 25°C (I). For reference, the relation for the various types of single surfactants on Sephadex G-75 is also shown by the broken line II.

published value.[8,9]

The MMW values thus obtained at various SDS/DPE ratios are plotted against V_M/V_0 in Fig. 1. A linear relation is seen between log MMW and V_M/V_0 although the points are somewhat scattered. For reference, the relation for various types of single surfactants obtained in a previous work[1] using Sephadex G-75 is also shown in Fig. 1. From the data presented above, it may be concluded that the gel filtration on Sephadex is a convenient way of roughly estimating the micellar molecular weights of mixed surfactants as well as of single surfactants. The MMW values of the mixed micelles of SDS and DPE in water, estimated from the log MMW *vs.* V_M/V_0 curve (I), are given in Table 1.

Experimental

The gel filtration measurements were performed on Sephadex G-100 by a method previously described, (*cf.* Fig. 1 in Ref. 1). The diffusion coefficients of the micelles were determined by the Schlieren method using a Neurath-type cell with the usual precautions.[4] The calculation of the diffusion coefficients was based on the moment method.[10,11] The viscosities of solutions were measured using a Cannon-Fenske-type viscometer with a flow time of 269 sec for pure water. All the experiments were carried out at 25°C.

The authors wish to express their thanks to Dr. H. Kita, Director of the Research Laboratories, for his encouragement and for the permission to publish this paper.

Magnetic Moments of Copper(II) Diethyldithiocarbamate and Related Compounds

Ken-ichi HARA, Wasuke MORI, Motomichi INOUE, Michihiko KISHITA, and Masaji KUBO

Department of Chemistry, Nagoya University, Chikusa, Nagoya

(Received July 13, 1968)

The X-ray crystal analysis of copper(II) diethyldithiocarbamate[1] and di-*n*-propyldithiocarbamate[2] has shown that the crystals are formed with a binuclear structure having the Cu-Cu distance equal to 3.38—3.59 Å as a unit. Each copper atom has a distorted tetragonal-pyramidal coordination involving four sulfur atoms from two diethyldithiocarbamate groups at the corners of a square and the fifth surfur atom belonging to the other monomeric unit at the apex of the tetragonal pyramid. At room temperature, copper(II) dialkyldithiocarbamates[3] show magnetic moments of 1.75—1.76 B. M., which are smaller than about 1.9 B.M. normally observed for magnetically dilute

TABLE 1. EFFECTIVE MAGNETIC MOMENTS, μ_{eff}, WEISS CONSTANTS, θ, MAGNETIC MOMENTS, μ_C, CALCULATED FROM CURIE CONSTANTS, C, MAGNETIC MOMENTS IN CHLOROFORM, μ_{sol}, AND MAGNETIC MOMENTS, μ_{calc}, CALCULATED FROM SPECTROSCOPIC DATA, Δ_1, OF COPPER (II) DIETHYLDITHIOCARBAMATE AND RELATED COMPOUNDS

Compounds	μ_{eff}, B.M.	θ, °K	C, emu/mol	μ_C, B.M.	μ_{sol}, B.M.	Δ_1, $10^4\,cm^{-1}$	μ_{calc}, B.M.
$Cu[(CH_3)_2NCS_2]_2$	1.75 (23°C)	−4	0.387	1.76	—	2.30	1.79
$Cu[(C_2H_5)_2NCS_2]_2$	1.75 (21°C)	+1	0.380	1.74	1.72	2.28	1.79
$Cu[(n\text{-}C_3H_7)_2NCS_2]_2$	1.76 (21°C)	−1	0.390	1.77	1.74	2.28	1.79

copper(II) compounds. In view of the binuclear structure and the low effective magnetic moments, one would expect the presence of spin coupling within a pair of copper atoms. However, electron spin resonance studies[4,5] yielded $g_\parallel=2.1085$ and $g_\perp=2.0236$, which are smaller than those of a majority of copper(II) complexes. This fact suggests that the low magnetic moments are due to a strong crystal field leading to the quenching of orbital contribution. In order to clarify this point, we have determined the magnetic susceptibilities of copper(II) dimethyldithiocarbamate, diethyldithiocarbamate, and di-*n*-propyldithiocarbamate in the solid state by the Gouy method[6,7] in a temperature range of 80—300°K and also the magnetic moments of these compounds of chloroform solutions.

The materials were prepared from commercial samples of sodium dialkyldithiocarbamates and copper(II) acetate. They were recrystallized from chloroform by adding methanol. The X-ray powder patterns of copper(II) diethyldithiocarbamate and di-*n*-propyldithiocarbamate showed agreement with the data of the complete X-ray crystal analysis.[1,2]

The magnetic susceptibilities of the compounds obey the Curie-Weiss law in the whole range of temperature studied. The Weiss constant and the Curie constant are listed in Table 1. The observed susceptibilities of the solutions of copper(II) diethyldithiocarbamate and di-*n*-propyldithiocarbamate in chloroform at 20°C show a linear relation to the concentration over the range of 0.3—1.2% and 0.4—2.4% by weight, respectively. The magnetic moments of the copper(II) complexes in chloroform were calculated from the slope of the susceptibility *versus* concentration plot and are shown in Table 1. Copper(II) dimethyldithiocarbamate could not be investigated in solutions, because it is sparingly soluble in common solvents.

The very small values for Weiss constants indicate that spin interaction is negligible in spite of the binuclear structure and the low effective magnetic moments. The magnetic moments, $\mu_C=1.74$—1.76 B.M., calculated from the Curie constants are smaller than about 1.9 B.M. for common copper(II) compounds. Since an unpaired electron in the $d_{x^2-y^2}$ orbital gives rise to magnetic polarization, the g-factor is given by

$$g_\parallel = 2\left(1-\frac{4\lambda}{\Delta_1}\right)$$
$$g_\perp = 2\left(1-\frac{\lambda}{\Delta_2}\right) \qquad (1)$$

for a copper(II) ion in a crystal field having D_{4h} symmetry.[8] Here, λ is the spin-orbit coupling constant, and Δ_1 and Δ_2 are energy separations between b_{2g} and b_{1g} states and between e_g and b_{1g} states, respectively. For copper(II) complexes,[9] λ is negative, and its absolute value is 625 cm^{-1}. Since Δ_2 is much greater than Δ_1, the magnetic moments of copper(II) compounds are given by

$$\mu = \left[\frac{1}{3}(g_\parallel{}^2+2g_\perp{}^2)S(S+1)\right]^{1/2}\beta$$
$$= 3^{1/2}\left(1-\frac{4\lambda}{3\Delta_1}\right)\beta \qquad (2)$$

where S is the total spin of a copper(II) ion equal to 1/2 and β denotes the Bohr magneton. Although the crystal field has C_{4v} symmetry in these copper(II) complexes, it can be approximated by D_{4h} symmetry because of a long distance of the apical sulfur atom from the central copper atom. In fact, the magnetic moments of copper(II) diethyldithiocarbamate and di-*n*-propyldithiocarbamate in chloroform agree excellently with those in the solid state as shown in Table 1. We have taken the visible and ultraviolet spectra of the compounds in chloroform and estimated Δ_1 in order to evaluate the magnetic moments by Eq. (2). The good agreement between the observed and calculated magnetic moments indicates that the low magnetic moments are due to the effect of a strong crystal field rather than to spin interaction between copper atoms in the binuclear structure.

SHORT COMMUNICATIONS

Studies on Photo-polarography. IV. Solvent Effect on Photocurrents

Hideo IMAI and Kazuo YAMASHITA

Department of Chemistry, Faculty of General Education, Hiroshima University, Hiroshima

(Received November 20, 1968)

The photoelectric effect at a metal-electrolyte interface has recently attracted attention in relation to the formation of the solvated electron and its reaction with the scavenger.[1-3] The solvent effect on this process, however, has not yet been reported. The authors have investigated the solvent effect on the photocurrent of nitrate in aqueous-organic solvent solutions containing 0.2 M KCl. The dropping mercury electrode was irradiated by the polychromatic light from a xenon lamp (250—350 mμ with a Toshiba UV-D25 filter), and the photocurrent was produced by the reaction of e_{aq}^- with NO_3^- to form NO_3^{2-} as the intermediate.[4]

The quadratic relationship[2] of the field effect on the photocurrent was proved in the potential region from -1.0 to -1.6 V *vs.* SCE. At a given potential the photocurrent was proportional to the square root of the nitrate concentration (0.1—10 mM) in good accordance with Barker's theory.[1]

According to the Barker model of the process, the photoelectrically emitted electrons are thermalized at around a distance, δ, away from the electrode surface, and are then hydrated (*cf.* Fig. 1). At the distance, δ, the coulombic energy (image force) is in balance with the thermal energy of the electron, *i. e.*,

$$\frac{e^2}{\varepsilon\delta} = kT \qquad (1)$$

where ε is the static dielectric constant of the medium and the other symbols are of their usual significance. It is noteworthy that in Eq. (1) δ is inversely proportional to ε. Our experimental evidence shows that log i_p (i_p, the photocurrent) is proportional to $1/\varepsilon$ as is shown in Fig. 2, *i. e.*,

$$\log i_p = K_1\left(\frac{1}{\varepsilon}\right) + K_2 \qquad (2)$$

where K_1 and K_2 are the constants. Assuming the exponential distribution of emitted electrons along the r axis, equation (3) can be derived as follows;

$$i_p \propto \int_\delta^\infty e^{-r}dr = -e^{-\delta} = -e^{-\frac{e^2}{\varepsilon kT}} \qquad (3)$$

Detailed investigation is now in progress in our laboratory.

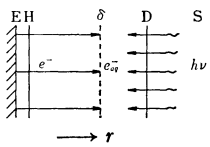

Fig. 1. Schematic representation of irradiated electrode surface.
E: Electrode D: Diffuse double layer
H: Helmholtz plane S: Solution
δ: Deposition plane

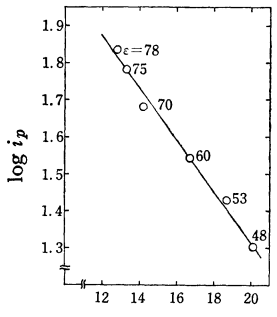

Fig. 2. Variation of log i_p with $1/\varepsilon$.
Solution; ethanol-water mixture containing 0.2 M KCl.
Scavenger of e_{aq}^-; 5 mM NO_3^-.
Applied potential; -1.6 V *vs.* SCE.
The measurements were carried out without altering at all the optical alignment. The values of ε were not corrected for the effect of the electric field and electrolyte.

A Thiocyanato Cobalt(III) Complex: $[Co(SCN)_2dip_2]ClO_4 \cdot 2H_2O$*

Nobufumi MAKI and Shukichi SAKURABA

Department of Chemistry, Faculty of Engineering, Shizuoka University, Johoku, Hamamatsu

(Received November 11, 1968)

As far as the cobalt(III) complexes are concerned, the rhodanato-ligand has been well known to be bound to the central cobalt(III) atom by the nitrogen atom; ideed, the isothiocyanato-cobalt(III) complexes have been more familiar than the thiocyanato-ones, in which the ligand(SCN^-) is bound by the sulfur atom.

Several years ago, the pentacyanocobaltate(III) complex, $K_3[Co(CN)_5SCN]$, was described as belonging to the group of the thiocyanato-complexes.[2] Recently, Stotz *et al.*[2] have reported the synthesis of the isothiocyanato complex, $K_3[Co(CN)_5NCS]$.

In the present communication, the dithiocyanatobis(2,2′-dipyridyl)cobalt(III) complex (a new complex) has been prepared and has been ascertained to be bound by the sulfur atom on the evidence of the absorption spectrum in the visible and infrared regions.

Preparation of $[Co(SCN)_2dip_2]ClO_4 \cdot 2H_2O$. A water solution (100 m*l*) containing 0.46 g of KNCS was stirred, drop by drop, into 300 m*l* of a water solution of *trans*-$[CoCl_2dip_2]Cl$[3] (1.0 g). First, a green precipitate separated from the solution, and then, it turned dark brown. The product was filtered and washed with water several times. The crude complex was twice recrystallized from a hot 60% ethanol-water mixture. Ruby-like red crystals were thus obtained. Found: Co, 9.81; C, 46.90; N, 16.62; H, 3.70%. Calcd for $[Co(SCN)_2dip_2]NCS \cdot 5/2H_2O$: Co, 9.98, C, 46.78; N, 16.60; H, 3.58%.

The perchlorate of the complex was obtained by treating the thiocyanate with 10% $HClO_4$ at 40°C. Found: Co, 9.28; C, 42.30; N, 13.53; H, 3.48%. Calcd for $[Co(SCN)_2dip_2]ClO_4 \cdot 2H_2O$: Co, 9.46; C, 42.42; N, 13.49; H, 3.24%.

The complex is insoluble in water but soluble in ethanol.

Figure 1 shows the absorption spectra of the dithiocyanato-cobalt(III) and its related complexes with 2,2′-dipyridyl. The absorptivity of the first spin-allowed band for the $[Co(SCN)_2dip_2]^+$ ion is seen to be considerably larger than those of the other complexes of the $[CoN_6]$ type. This fact may well be interpreted as being due to the hyperchromic effect of the sulfur-bonded ligand, SCN^-.

The infrared evidence is summarized in Table 1. The values of the C–S stretching-vibration fall within the 690—720 cm^{-1} range characteristic of sulfur-bonded thiocyanato-complexes, while the values for the usual isothiocyanato-ammine and -amine complexes come within the 780—860 cm^{-1} range characteristic of nitrogen-bonded isothiocyanato-complexes.[4]

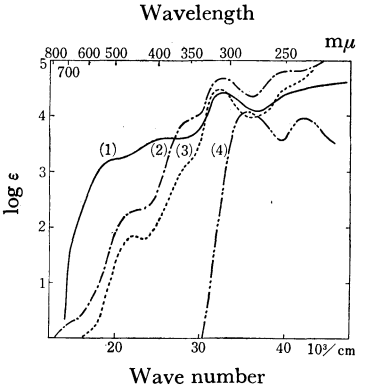

Fig. 1. The absorption spectra of the cobalt(III) complexes with 2,2′-dipyridyl:
(1) —— $[Co(SCN)_2dip_2]ClO_4 \cdot 2H_2O$; (2) –·– $[Co(NO_2)_2dip_2]Cl \cdot 5H_2O$; (3) ------ $[Co\,dip_3](ClO_4)_3 \cdot 3H_2O$; (4) ·–·– 2,2-dipyridyl.

Reversible Oxygenation of Cobalt(II) Complexes on Polyvinylpyridine

Akira MISONO, Seiichiro KODA and Yasuzo UCHIDA

Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Tokyo

(Received November 26, 1968)

Several kinds of oxygen complexes have been found recently[1] which are interesting from the point of view of oxidation catalysts and biochemical reactions. Among them, some *bis*- salicylaldehyde-imine-cobalt(II) complexes are well-known oxygen carrier chelates,[2] but the details of the oxygenation and the deoxygenation processes of these complexes and the technological designs of these complexes as solid-state oxidizing catalysts have not yet been fully studied.

The present authors found that an ESR signal appeared when a mixture of *bis*-salicylaldehyde-ethylenediimine cobalt(II) (A: prepared according to Ref. 3, recry. from methanol; the complex thus prepared is, as it stands, stable under air.) and *poly*-4-vinylpyridine (PVP: prepared according to Ref. 4) was exposed to oxygen, while, the signal disappeared when the mixture was placed in a vacuum. Several cycles were tried successfully. The same situation existed with the mixture of *bis*(salicylaldiminato)cobalt(II) (B: prepared according to Ref. 5; stable under air as it stands. The complex thus prepared is, however, suspected

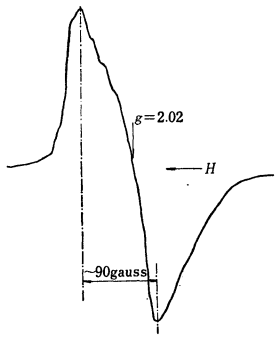

Fig. 1. The ESR signal on the mixture of the complex A and PVP under oxygen (at room temperature).

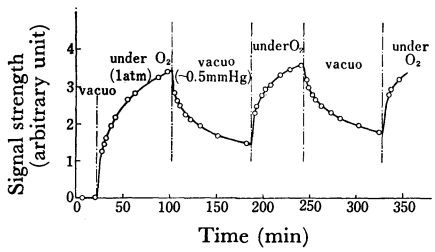

Fig. 2. The reversible cycles of the oxygenation and the deoxygenation of the complex A on PVP (at room temperature).

not to be pure *bis*(salicylaldiminato)cobalt(II) according to Ref. 6; this question remains to be solved in the future). These mixtures were made by mixing one of the complexes with PVP in methanol (for example, at the mole ratio (pyridine ring in the polymer/the complex) of about 50) and by then evaporating the solvent methanol.

Figure 1 shows the ESR signal of a mixture of the A complex and PVP under oxygen (1 atm). The ESR signal of the mixture of the B complex and PVP is almost the same.

The rate of the appearance and the disappearance of the signal may be rather well controlled by the diffusion of oxygen in the polymer film.

The presence of carbon monoxide (examined in the case of the mixture of the A complex and PVP) and that of ethylene (examined in the case of the mixture of the B complex and PVP) had no observable effect on the appearance or disappearance of the signal. When nitric oxide was introduced (examined in the case of the mixture of the B complex and PVP), the signal rapidly disappeared.

The signal cannot be identified exactly, but it may be caused by cobalt(II) coordinated with oxygen (for example, $Co^{II}-O_2 \leftrightarrow Co^{III}-O_2^{\ominus}$).

The oxygen adsorption on these mixtures should be compared with those on metal oxides and haemoglobins.

Some other complexes, such as copper(II) complexes mixed with PVP, are, in parallel, investigated by means of ESR in order to make clear the coordination structure of metal chelates on PVP.

Photoreaction of 3,4-Diphenyl-1,2,5-oxadiazole[1]

Toshio MUKAI, Toyonari OINE and Akira MATSUBARA

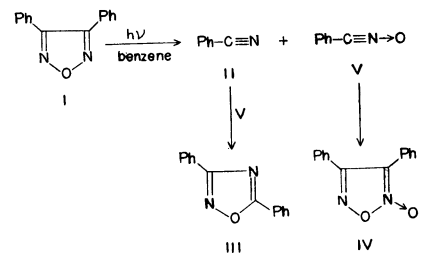
Department of Chemistry, Faculty of Science, Tohoku University, Sendai

(Received December 4, 1968)

Recent progress in the photochemistry of five-membered heterocycles[2] and our studies of the photochemistry of *α*-dioximes[3] have led us to investigate the photoreaction of 3,4-diphenyl-1,2,5-oxadiazole (I). Because very recently Cantrell and Haller reported an extensive study of the photochemistry of I and its related compounds[4], we intend to report our results, although our study has not yet been completed.

The irradiation of I in *benzene* (0.17%) in a Pyrex vessel with a high-pressure mercury lamp afforded benzonitrile (II) (50%), 3,5-diphenyl-1,2,4-oxadiazole (III), mp 106—108°C[5] (10%), and diphenylfuroxan (IV), mp 113—115°C, (14%), in addition to I (25%). Although Cantrell and Haller did not observe the formation of III and IV, the formation of all the photoproducts can be explained by the double-fragmentation process proposed by them.[4] That is, III can be derived by the recombination of II and benzonitrile oxide (V),[6] both of which are fragments from I, while IV is formed by the recombination of two moelcules of V.[7] However, the formation of III can also be explained by the ring contraction-expansion process as was first proposed by Ullman and Singh.[2a]

In order to distinguish between these two pathways, the irradiation of I was carried out in the presence of an excess of benzonitrile (5 equiv. to I). The finding that the formation of III increased very much compared to that of IV (III : IV is *ca.* 3.5 : 1) may suggest that the double fragmentation is the correct path for the formation of III.



On electron impact, I exhibits the following peaks (m^+/e): 222 (M^+, 95%), 192 ($M-NO^+$, 85%), 151 (17%), 119 ($Ph-C{\equiv}N{\rightarrow}O^+$ and $Ph-N{=}C{=}O^+$, 86%), 103 ($PhCN^+$, 10%), 91 (PhN^+, 34%) and 89 (PhC^+, 100%). Thus, it was made clear that the double fragmentation of I was observed not only in photolysis and thermolysis,[8] but also in electron impact.

On the other hand, the irradiation of I in *methanol* (0.17%) gave methyl benzoate (6%), phenacyl alcohol, mp 84—86°C, (3%), 3,5-diphenyl-1,2,4-oxadiazole (3%), and/or benzamide (2%), in addition to benzonitrile (64%). The formation of these minor products will be discussed elsewhere, because our study is still in progress.

A New Approach to the Study of the Reactions of Nitrogen Atoms with Hydrocarbons

Takefumi OKA and Shin SATO

Department of Applied Physics, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received December 10, 1968)

The reactions of nitrogen atoms with various hydrocarbons have been extensively investigated by many investigators using the discharge of nitrogen gas at low pressures.[1-4] The main product observed in their experiments was hydrogen cyanide. Other products, such as ammonia and methyl cyanide, were always found in minor amounts.

Recently, a few groups, including that of our laboratory, used high-energy radiations to produce nitrogen atoms in the gas phase at higher pressures.[5] However, nitrogen-containing product observed was again only hydrogen cyanide, and the reaction mechanism was very much complicated by the participation of nitrogen molecule ions in the reactions.

We have studied the γ-radiolysis of a liquid nitrogen containing small amounts of various hydrocarbons. This short communication will report the preliminary results obtained; these results are quite different from the results obtained in the gas phase.[5]

When a 3-m*l* portion of liquid nitrogen containing 4×10^{-2} mol% of propylene was irradiated at 77°K by γ-rays for three hours at the dose rate of 10^6 R/hr, the products observed were methyl cyanide (0.80 μmol), propane (0.55 μmol), and small amounts of ethane, ethylene, isobutane, 4-methylpentene-1 and ammonia. The absence of hydrogen cyanide was noticeable.

Table 1 summarizes the results for nitrogen-containing products obtained when various hydrocarbons were used. With the hydrocarbons of group 1, various nitrogen-containing products were observed, while with those of group 2 practically no such products were observed. At first sight, this appears to indicate that nitrogen atoms have less reactivity to the hydrocarbons in the group 2.

Table 1. Nitrogen containing products and their approximate *G*-values[a]

Hydrocarbon[b]	Products (*G*-values)	Mp °C
	Group I	
Ethylene	HCN (0.2), CH_3CN (0.1), NH_3 (small)[c]	−169.2
Propane	CH_3CN (0.08)	−189.9
Propylene	CH_3CN (0.13), NH_3 (small)[c]	−185.2
Allene	HCN (small), CH_3CN (0.05), CH_2=CHCN (0.05)	−136.0
Butene-1	HCN (small), CH_3CN (0.05), C_2H_5CN (0.05)	−185.4
	Group II	
Acetylene	no HCN	−81.8
trans-Butene-2	no HCN, no nitril compounds	−105.6
1,3-Butadiene	HCN (small), no nitril compounds	−108.9

a) Estimations are based on the energy absorbed by liquid nitrogen.
b) Mole fraction of each hydrocarbon is in the order of 10^{-4}.
c) After treated with Nessler reagent, analyzed spectrophotometrically at 430 mμ.

However, it may be expected from the melting points listed in the table that the hydrocarbons of the group 1 are more soluble in liquid nitrogen than are those of the group 2. This may be the reason why the hydrocarbons of the group 2 give few nitrogen-containing products.

Experimental. A certain amount of hydrocarbon was frozen in a sample tube at 77°K. When compressed nitrogen gas (1.5 atm) was then introduced into the tube at 77°K, nitrogen was gradually liquefied at the bottom of the tube. This was continued until a required volume of the liquid was obtained. Then the cock of the tube was closed and the tube was removed from the vacuum line. The sample was then vigorously shaken in order to mix its contents. After irradiation, the volatile components were pumped off from the mixture at 77°K and the residue was analyzed by gas chromatography (a 5-m column packed with Carbowax 20 M and a 2-m column of dioctyl phthalate), mass spectrometry, and infrared spectroscopy.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 583—593 (1969)

Study of Wall Effect on the Flow of Polyvinylpyrrolidone Solutions in Capillary*1

Takehiko WATANABE, Takeshi MINESHITA and Sôzaburo ONO

Laboratory of Biophysical Chemistry, College of Agriculture, University of Osaka Prefecture, Sakai, Osaka

(Received June 3, 1968)

Dependence of the viscosity of the polyvinylpyrrolidone ($\bar{M}_v = 4.0 \times 10^4$ and 9.0×10^5) solutions on the bore-size of capillary viscometer has been studied at 35°C, in pure water, in dimethyl sulfoxide (DMSO), in water-DMSO, and in aqueous solution with various cosolutes, at various concentrations (0.5—5.0 g/100 m*l*). Viscosity measurements were carried out with a Maron-Belner type low shear capillary viscometer with various capillary radii (0.0190—0.0761 cm) within the shear stress range of 0.2—20 dyn/cm^2 at the capillary wall. The solutions showed a behavior of non-Newtonian flow and dependence on the size of the capillary. The viscosity of the polymer solutions in DMSO, and in water-DMSO decreased with the decrease in the capillary bore-size within the range of shear stress studied, and that in pure water, although similar phenomena as above were observed in higher shear stress, increased with the decrease in the capillary bore-size at the range of the lower shear stress, and this capillary bore-size dependence could not be observed with the aqueous solutions with cosolutes. The difference in the characteristics of the capillary bore-size dependence of the viscosity may be attributed to the difference in the behavior of the polymer molecules existing near the wall at which the thermal motion of the polymer molecules will be hindered by the existence of the capillary wall. The results were represented by the modified Ree-Eyring generalized flow formula for a flow system containing one Newtonian flow unit and one non-Newtonian one which included the additional terms dependent on the capillary bore-size. The viscosity equation suitable for analysing the dependence of the viscosity on the capillary bore-size at entire ranges of the rate of shear, was derived by assuming the wall layer composed of the double layers (of thickness d_o and $d_i - d_o$) in the flowing liquid in the capillary tube, and by combining this equation with the modified Ree-Eyring equation, the values of d_o and d_i were calculated.

Many papers[1-9] have been published concerning the phenomena that the viscosity of many suspensions, including blood, when measured with the capillary viscometer, decreases with decreasing capillary bore-size. For a similar phenomenon observed with polymer solution, experimental and theoretical treatments[10-11] were made by Oldroyd and Toms. However, as stated in the previous paper,[12] the results obtained with polyvinylpyrrolidone or PVP, solutions, could not be explained satisfactorily with their treatments. The capillary bore-size dependence of the viscosity of PVP in various solvents at the infinite high rate of shear, was treated by assuming the existence of the wall layer (of thickness d_i) in the flowing liquid.

In the present paper, the analysis of the capillary bore-size dependence of the viscosity at entire ranges of rate of shear was attempted.

Experimental

PVP used was a commercial product, Luviskol K-90 and K-30 were obtained from Badische Anilin und Soda Fabrik A. G. Other materials were commercial chemicals.

As to the viscosity measurements, a Maron-Belner low shear capillary viscometer with continuous varying pressure head was used.[13-14] The instrumental dimensions of the viscometers are shown in Table 1. Details on viscosity measurements are the same as described in the previous paper.[15]

TABLE 1. THE DIMENSIONS OF THE VISCOMETER

Radius of capillary $R\times10^2$ (cm)	Radius of bulb R_b (cm)	Length of capillary L (cm)	Radius of manometer $R_m\times10$* (cm)
7.61	1.095	27.7	3.99
5.02	1.260	28.7	4.00
3.08	1.245	28.7	1.40
3.02	1.270	28.9	1.44
2.73	1.300	29.4	0.97
2.38	1.250	28.6	1.08
2.28	1.261	28.8	1.44
1.90	1.260	29.0	1.00

* The R_m values of the corresponding viscometer listed in Table 1 of Ref. 15 and in Table 2 of Ref. 12 should read the values listed in this table.

The measurements of extinction angle were carried out by using a Rao Flow Birefringence Viscometer Model No. B-23.

The spectrophotometric measurements were carried out with the use of a Hitachi EPS-3 Recording Spectrophotometer.

Results and Discussion

The plots of viscosity *vs.* rate of shear for K-30 aqueous solution (adjusted to pH=10.4 with KOH) and the aqueous solution with cosolute, *i. e.*, serine, aspartic acid, tryptophan, benzoic acid, and lactic acid, and K-90 aqueous solution with benzoic acid or tryptophan, in various capillaries are shown in Figs. 1(a), 1(b), 1(c), and 1(d). These substances used as cosolutes are known as the agents which induce the change in the dissolved state of the PVP molecules in various ways.[16] The viscosity of the PVP aqueous solution without cosolute shows marked dependence on the capillary bore-sizes, in the same manner as stated in the previous papers.[12,15] However, the viscosity of the aqueous solution with cosolute did not show the observable dependence on the capillary bore-size, in spite of the fact that non-Newtonian nature of the aqueous solution with cosolute, *i. e.*, serine, aspartic acid, and tryptophan, is more enhanced than that in the case without cosolute. The results show that the flow of the non-Newtonian fluids does not always

show the capillary bore-size dependence of the viscosity. The other typical plots of viscosity *vs.* shear stress for K-90 solutions at various concentrations in DMSO in various capillaries are shown in Fig. 2.

Non-Newtonian flow behavior is observed, and the viscosity decreases with the decrease of capillary bore-size in all ranges of shear stress studied. Similar results are obtained with the solutions in water-DMSO mixture and also in *n*-propanol and in water - *n*-propanol mixture as reported in the previous paper.[15]

The experimental results were represented by the modified Ree-Eyring generalized flow formula for a flow system containing one Newtonian flow unit and one non-Newtonian one which includes the additional terms dependent on the capillary bore-size (radius: R) as follows:[15]

$$\eta = \left(\eta_1' - \frac{\sigma_1}{R}\right) + \left(\frac{1}{b_2'} + \frac{\sigma_2}{R}\right)\left(\frac{1}{a_2}\right)\left(\frac{a_2}{G}\right)\sinh^{-1}\left(\frac{G}{a_2}\right) \tag{1}$$

where,

$$\eta_1' - \frac{\sigma_1}{R} = \eta_1, \quad \frac{1}{b_2'} + \frac{\sigma_2}{R} = \frac{1}{b_2},$$

$$\eta_1 = \frac{x_1\beta_1}{\alpha_1}, \quad a_2 = \frac{1}{\beta_2}, \quad b_2 = \frac{a_2}{x_2},$$

and

$$\eta_0 = \eta_1 + \frac{1}{a_2 b_2} = \left(\eta_1' - \frac{\sigma_1}{R}\right) + \left(\frac{1}{a_2}\right)\left(\frac{1}{b_2'} + \frac{\sigma_2}{R}\right)$$

$$= \left(\eta_1' + \frac{1}{a_2 b_2'}\right) - \frac{\left(\sigma_1 - \frac{\sigma_2}{a_2}\right)}{R} = \eta_0' - \frac{\left(\sigma_1 - \frac{\sigma_2}{a_2}\right)}{R} \quad (3)$$

In the above equations the values of η_∞, η_0, η_1, η_1', $1/b_2$, and $1/b_2'$ must be positive; however, as stated in the previous paper,[15] the values of $1/b_2'$ obtained with K-90 aqueous solution and those of $MgCl_2$ solution obtained by the extrapolation of the line representing the linear relationship between $1/b_2$ *vs.* $1/R$ at the range of relatively larger values of $1/R$ are negative. Moreover, as shown in Fig. 3 the results obtained with 2.0% K-90 aqueous solution show that the slope of the plots of $1/b_2$ *vs.* $1/R$ changes at a certain radius (R_i). This result shows that Eq. (1) holds strictly in the same manner as in the case of other systems, for the flow of K-90 solutions in water and in $MgCl_2$ solution in the capillary having the radius larger than R_i above which the values of $1/b_2'$ are positive. Therefore, with K-90 solution in water and $MgCl_2$ solution reported in the previous paper[15] the σ_2 values with the slope having a positive $1/b_2'$ will also be expected if the experiment is carried out using the viscometers having much larger capillary radius than those used in the previous study.[15]

As shown in the previous papers,[12,15] the dependence of $\eta_\infty(=\eta_1)$ of the polymer solutions on the value of R will be explained as such a result of the decrease in the relaxation time of the solvent molecules near the wall compared with that of the bulk, because the rotational redistribution of the oriented PVP molecules in the preferred direction under the streamline of the flow may be geometrically hindered by the capillary wall and the resistance of the PVP molecules against the flow of the solvent molecules under the shear stress will become weaker near the wall than that in the bulk. From the above consideration, it may be expected that when the dissolved polymer molecules take a spherical form and have no tendency to orient under the streamline of the flow, the

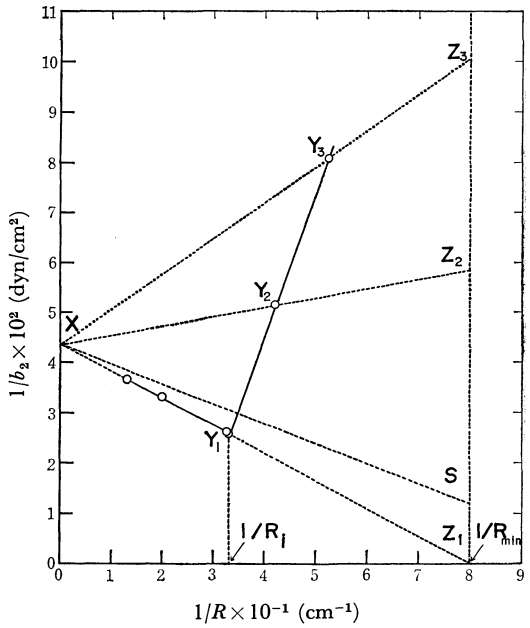

Fig. 3. Plots of $1/b_2$ *versus* $1/R$ for K-90 (2%) in water.

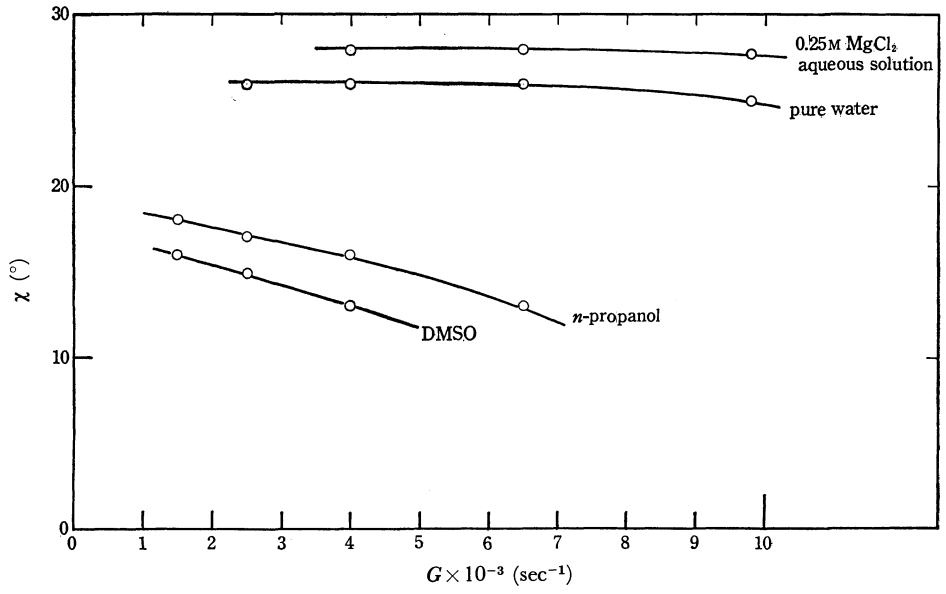

Fig. 4. Plots of extinction angle *versus* rate of shear for K-90 (1%) in various solvents.

observed viscosity would not change with the bore-size of the capillary.

The dependence of the extinction angle on the rate of shear for K-90 (1%) in various solvents is shown in Fig. 4. The PVP molecules in *n*-propanol, and in DMSO, in water and in 0.25M $MgCl_2$ aqueous solution show the tendency to orient under the streamline of flow. On the other hand, in the case of the solutions with the cosolute, the position of the arms of the cross of isocline could not be detected, *i. e.* extinction angle is equal to 45° in all rates of shear, and the orientation under the streamline of flow could not be observed. From these results, the PVP molecules may be expected to interact with the cosolute and to take spherical form in solution, because the degradation of the PVP molecules with the interaction with the cosolute could not be expected. Therefore, it may be concluded that the orientation of the polymer molecules under the streamline of flow is one of the necessary conditions for the appearance of the capillary size dependence of the viscosity.

For the viscosity at a finite rate of shear, the contribution of the non-Newtonian term of Eq. (1) must be considered. The geometric hindrance of the capillary wall to the free rotation of PVP molecules described above, would control the nature of the flow pattern of the polymer solution in the capillary tube independently of the magnitude of the pressure of the streamline. When the contribution of the non-Newtonian term to the solution viscosity depends solely on a compromise between the thermal motion of the PVP molecules and the orienting effect of the streamline, the value of σ_2, will take a value satisfying the following relation

$$-\frac{\sigma_1}{\eta_1'} = \frac{\sigma_2/a_2}{1/a^2b_2'}$$

or

$$\sigma_2 = -\sigma_1(1/b_2')/\eta_1' \qquad (4)$$

When the observed value of σ_2 is more positive than the one expected from Eq. (4), some additional structural formation of the PVP molecules near the wall will be expected to occur and on the contrary when more negative, the slippage of PVP molecules at the wall will occur. The formation of the above structure at the wall will be facilitated by the same geometric hindrance stated above to the thermal motion of the PVP molecules near the wall, because the interaction will be promoted between the wall surface and polymer molecules, *e. g.*, the adsorption of polymers on the wall *etc.*, thus, favoring the subsequent formation of some structure in the neighborhood of the wall.

The adsorption and the subsequent formation of some structure at the wall will be studied by the measurement of the change in concentration of the solution before and after the filtration through the fine sintered glass filter under gravity. The concentration of the PVP was determined by the spectroscopic measurement in the range of the wavelength between 220 and 240 mμ.*2 The first 1 m*l* of the filtrate of the 0.02 g/*l* solutions of PVP in water, in 0.25M $MgCl_2$ aqueous solution and in *n*-propanol showed the decrease in concentration of the magnitude of 5−10% compared with that of the original solution. But in the case of 0.01 g/*l* aqueous solution of PVP with 2.5×10^{-4}M tryptophan or 1.25×10^{-4}M benzoic acid, no appreciable change in the concentration was observed. Therefore, the occurrence of the adsorption of the PVP molecules on the glass wall will be one of the factors which determine the behavior of the flow of the polymer solution in capillary tube.

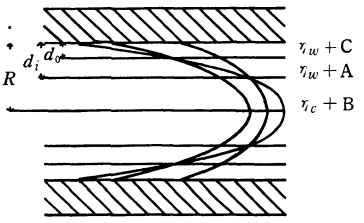

Fig. 5. Schematic model of the flow in the presence of wall layer.

Considering the above stated wall effect of the viscosity of the solutions, the flow model was proposed as shown in Fig. 5. The flowing liquid was assumed to be composed of a liquid layer near the wall (wall layer thickness d_i) and the bulk liquid. The former is divided into two layers at the distance of d_o ($d_o<d_i$) from the wall, one of which is situated on the near side of the wall, having the viscosity of η_w+C, and the other on the far-side, having the viscosity of η_w+A. The latter has the viscosity of η_c+B, to which the influence of the existence of the wall could not reach. The flow of these liquid layers may be represented by Poiseuille's law. Then the flow volume V of the liquid flowing through the tube in the interval of time t (sec) is

$$V=\frac{\pi Pt}{2L}\left[\frac{1}{\eta_w+C}\int_{R-d_o}^{R}(R^2-r^2)r\cdot dr+\frac{1}{\eta_w+A}\int_{R-d_i}^{R-d_o}(R^2-r^2)r\cdot dr+\frac{1}{\eta_c+B}\int_{0}^{R-d_i}(R^2-r^2)r\cdot dr\right.$$

*2 The PVP has the broad absorption peak with high intensity below 210 mμ, however, this range of wavelength could not be used for the concentration determination, because the $MgCl_2$ aqueous solution and *n*-propanol have also the intense absorption peaks in the same range of wavelength.

$$+ (R-d_o)^2\left\{\frac{1}{2(\eta_w+C)}[R^2-(R-d_o)^2] - \frac{1}{2(\eta_w+A)}[R^2-(R-d_o)^2]\right\} + (R-d_i)^2\left\{\frac{1}{2(\eta_w+A)}[R^2-(R-d_i)^2]\right.$$
$$\left. - \frac{1}{2(\eta_c+B)}[R^2-(R-d_i)^2]\right\}\Bigg] \quad (5)$$

where, P: driving pressure and r: distance from the center of tube.
The experimental value of the volume of flow is expressed as follows:

$$V = \pi PtR^4/8L\eta_{exp} \quad (6)$$

where η_{exp} is the viscosity determined experimentally. The values of V of both Eqs. (5) and (6) should be equal. Hence,

$$\eta_{exp} = \frac{(\eta_w+C)(\eta_w+A)(\eta_c+B)}{(\eta_w+C)(\eta_w+A) + (A-C)(\eta_c+B)D_0 + (\eta_c-\eta_w)(\eta_w+C)D_i + (B-A)(\eta_w+C)D_i} \quad (7)$$

where,
$$D_i = 4(d_i/R) - 6(d_i/R)^2 + 4(d_i/R)^3 - (d_i/R)^4$$
$$D_0 = 4(d_o/R) - 6(d_o/R)^2 + 4(d_o/R)^3 - (d_o/R)^4$$

Comparing Eq. (7) with Eq. (3)

$$\frac{\sigma_1 - \frac{\sigma_2}{a_2}}{R} = \frac{(\eta_c+B)\{(A-C)(\eta_c+B)D_0 + (\eta_c-\eta_w)(\eta_w+C)D_i + (B-A)(\eta_w+C)D_i\}}{(\eta_w+C)(\eta_w+A) + (A-C)(\eta_c+B)D_0 + (\eta_c-\eta_w)(\eta_w+C)D_i + (B-A)(\eta_w+C)D_i}$$

when $G \to 0$, $\eta_{exp} = \eta_1 + \frac{1}{a_2 b_2} = \eta_0$, and $\eta_c + B = \eta_1' + \frac{1}{a_2 b_2'} = \eta_0'$ (8)

When $(G/a_2)\to\infty$, the values of A, B, C, in above flow model are zero, *i. e.*, A, B, $C=0$, therefore, the flow model will be reduced to simpler one composed of the wall layer (thickness: d_i) having the viscosity of η_w and the bulk liquid of viscosity η_c as follows.[12]

$$\eta_{exp} = \eta_c[1-\{(\eta_c-\eta_w)D_i\}/\{\eta_w+(\eta_c-\eta_w)D_i\}] \quad (9)$$

where $\eta_c \geq \eta_{exp} \geq \eta_w$, since the values of $\eta_\infty(\eta_1)$ decrease with the decrease of capillary radii. Comparing the Newtonian term of Eq. (1) or Eq. (2) with Eq. (9),

$$\sigma_1 = \eta_c(\eta_c-\eta_w)D_iR/\{\eta_w+(\eta_c-\eta_w)D_i\},$$
$$\eta_{exp} = \eta_\infty = \eta_1 \quad \text{and} \quad \eta_c = \eta_1' \quad (10)$$

Comparing Eq. (10) with Eq. (8)

$$B = 1/a_2 b_2' \quad (11)$$

Under the conditions of $(G/a_2)\to 0$ and $\eta_0 \geq \eta_\infty$, the relations of A, B, $C>0$ and $d_o \leq d_i$ must be satisfied.

For the calculation of the value of d_i and d_o, the value of η_w must be determined. However, there is no satisfactory way, either experimentally or theoretically, of determining the value of η_w. Whenever the polymer molecules near the wall are oriented completely by the geometric hindrance of the capillary wall under the pressure of the streamline at G/a_2 or $G\to\infty$, the expected viscosity value of flowing polymer solution near the wall, could not be lower than that of the solvent or that calculated by the Einstein equation. In the following calculation, the value of the viscosity expected from the Einstein equation was arbitrarily taken as the value of η_w.

Moreover, when the line of the plot of experimental $1/b_2$ *vs.* $1/R$, taking a more negative slope than the one expected from Eq. (4), intersects the $1/R$ axis at a point (where $1/b_2=0$) having a smaller value of $1/R$ than the one corresponding to the η_w value on η_1 *vs.* $1/R$ plots, the value of viscosity corresponding to the $1/R$ where $1/b_2=0$ on the line of η_1 *vs.* $1/R$ plots must be taken as the value of η_w in order to satisfy the condition of $\eta_0 \geq \eta_1\ (\eta_\infty) \geq \eta_w$.

Applying the value of η_w to Eq. (9) with the aid of Eq.(10), values of d_i corresponding to each R will be calculated. The value of $1/R$ corresponding to the η_w above stated, on the line of η_1 *vs.* $1/R$ relation gives the maximum value of $1/R\,(=1/R_{\min})$ where Eq. (1) could hold. Therefore the value of $R_{\min}$ is the minimum radius below which the capillary bore-size dependence of the viscosity could not be observed.

In calculating the value of d_o, the values of A and C must be determined. The value of A is given by the product of $1/a_2$ times the value of $1/b_2$ (*e. g.* point S in Fig. 3) corresponding to the $1/R_{\min}$ on the line drawn from $1/b'_2$ (point X) with a slope of σ_2 satisfied by the Eq. (4). The value of C is obtained from the value of $1/b_2$ corresponding to $1/R_{\min}$ on the slope of experimental $1/b_2$ *vs.* $1/R$ relation. Applying these values of A and C with the value of B obtained with Eq. (11) and the values of η_c, η_w and d_i already obtained, to Eq. (7), the values of d_o corresponding to each R will be calculated.

The relationships between d_o or d_i and R obtained with 2% K-90 in water and 1% K-90 in DMSO are shown in Figs. 6 and 7. In the case of 2% K-90 in water as shown in Fig. 3, where the relation $1/b_2$ *vs.* $1/R$ has been represented by two straight lines crossing at a point of a certain

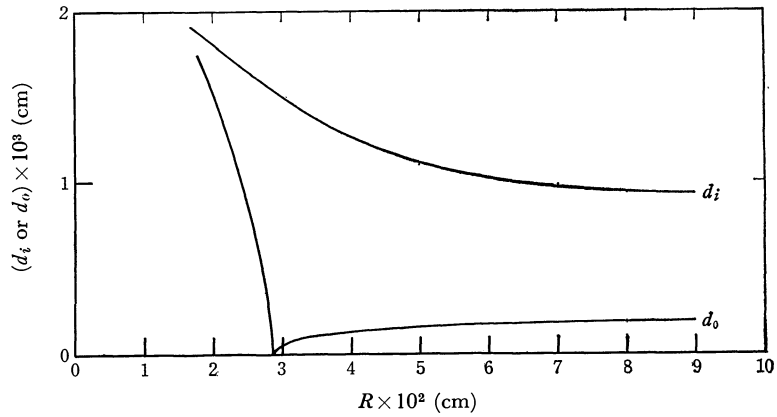

Fig. 6. Relation between d_i or d_o, and R, calculated from Eq. (7) and Eq. (9), with polymer K-90 (2%) in water, where $\eta_w=14.0\times10^{-3}$ (poise), $\eta_c=53.0\times10^{-3}$ (poise), $A=5.8\times10^{-3}$ (poise), $B=22.0\times10^{-3}$ (poise), $C=0$ (where $R > 0.0302$ (cm)) and $C=30\times10^{-3}$ (poise) (at $R=0.0238$ (cm)) and so on.

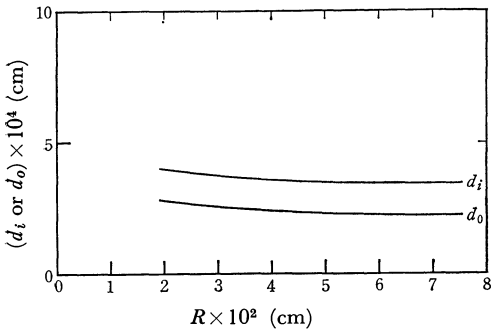

Fig. 7. Relationship between d_i or d_o and R, calculated from Eq.(7) and Eq. (9), with polymer K-90 (1%) in DMSO, where $\eta_w=1.00\times10^{-2}$ (poise), $\eta_c=42.4\times10^{-3}$ (poise), $A=1.63\times10^{-3}$ (poise) $B=6.9\times10^{-3}$ (poise), $C=11.1\times10^{-3}$ (poise).

radius (R_t), the value of C for the range of $1/R$ smaller than the value of $1/R_t$, is given by the product of $1/a_2$ times the value of $1/b_2$ (point Z_1 in Fig. 3) obtained on the extrapolated line from the experimental $1/b_2$ *vs.* $1/R$ relationship (line XY_1) of the corresponding range of $1/R$ as stated above. In the range of $1/R$ above the $1/R_t$, the value of C is obtained from the value of $1/b_2$ (point Z_2 or Z_3) corresponding to $1/R_{min}$ on the straight line drawn from $1/b_2'$ (point X) through the experimental $1/b_2$ (point Y_2 or Y_3); therefore, in this range not only the values of d_o changes with R but also the values of C changes with R. The results obtained with K-90 2.0% aqueous solution show that in a larger capillary bore the nature of capillary dependence of the viscosity of the solution at $G/a_2\rightarrow0$ may be predominantly determined by the slippage of the PVP molecules at the wall, and in a smaller capillary bore it may be determined by the existence of the some structure formed at the wall.

The abnormal phenomenon observed with K-90 in water, may be expected to occur under the conditions as follows. As shown in Figs. 3 and 8, the experimental results that the relation $1/b_2$ *vs.* $1/R$ or η_0 *vs.* $1/R$ must be represented by two straight lines, were obtained with K-90 aqueous solutions in the concentration range of 0.5—2.0%; however, in the case of K-30 aqueous solution, such a result was obtained only with the solution of such a high concentration as 5.6%. On the other hand, the tendency of the increase of η_0 with the decrease of capillary radius is always observed with the aqueous solution of PVP irrespective of molecular weight; therefore, this tendency may be said to be the general character of the flow of the PVP aqueous solution in a capillary and may be brought about

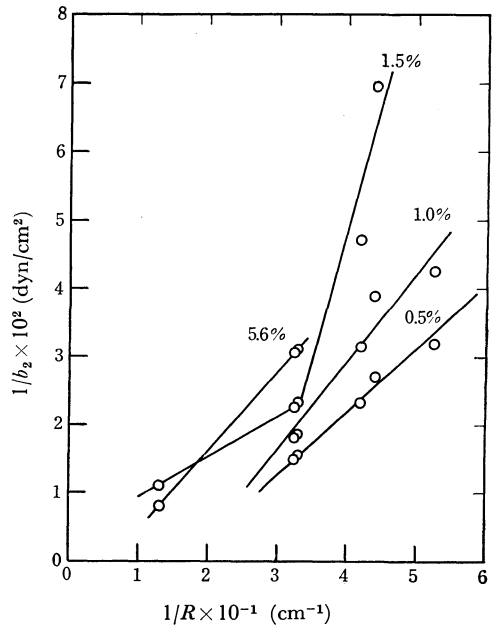

Fig. 8. Plots of $1/b_2$ *versus* $1/R$ for K-90 (1.5%, 1.0%, 0.5%) and K-30 (5.6%) in water.

by the poor nature of water as solvent. In water, compared with the case of good solvent, the adsorption of PVP molecules on the wall surface occurs more easily and subsequent formation of a rather stiff structure is facilitated by the more frequent contacts and the stronger entanglement of PVP molecules under the geometric hindrance of the wall to the thermal motion of the PVP molecules. Such a sturcture at the wall may be formed more easily in a narrower tube than in a wider one, because the geometric hindrance of the wall to the thermal motion of the PVP molecules will be more enhanced in the narrower capillary tube in which the hindrance for the rotational motion of the PVP molecules in the shear surface will occur more frequently than in the case in a wider tube. The flow behavior of the solution in the capillary tube of radius $R_{\min}$ is determined by the structure at the wall as stated above.

On the other hand, when the concentration of PVP in the solution becomes higher or the molecular weight becomes larger, the more frequent contacts and stronger entanglements of PVP molecules in the solution will assist the formation of a certain structure throughout the solution and the PVP molecules near the wall will be forced to move with the adjacent molecules existing at the far-side of the wall, that is, the slippage of the PVP molecules at the wall will occur. Such a slippage will occur in the case of the flow of the solution in the capillary tube of radius larger than R_i.

In the solution flowing through the capillary tube of radius between R_i and $R_{\min}$ the actual behavior of the PVP molecules at the wall will be determined by a compromise between the two effects stated above on the PVP molecules near the wall. A similar situation will also hold with the solution of PVP in $MgCl_2$ aqueous solution.

As shown in Fig. 9, when the value of η_0 is larger than that of η_0', the calculated value of d_o (this distance is designated as d_c) becomes larger than that of d_i and this does not satisfy the prerequisite of $d_o < d_i$. The change of d_i and d_c with R is shown in Fig. 10. This result may be brought about under circumstances where the formation of the structure near the wall extends from the wall to the central bulk liquid beyond the region of the wall layer. The result also shows the development of the very viscous layer (thickness; $d_c - d_i$, viscosity $= (\eta_w + A) + (\eta_w + C) + (\eta_c + B)$) on the far-side of the wall and in contact with the wall layer (thickness; d_i, viscosity $= \eta_w + C$) with the disappearance of the layer of viscosity of $(\eta_w + A)$. Referring to the observation made by Segré and Silberberg[17] with the dilute suspension of macroscopic spherical particles of polymethyl methacrylate in a liquid of high viscosity that the collection of the particles occurs in a thin annular region within the flowing liquid through a tube, such a development of high viscous layer as stated above is not an unrealizable phenomenon. Furthermore by the application of the present treatment to the analysis of the capillary bore-size dependence of the viscosity of blood,[18] which shows a similar characteristics as shown in Fig. 9, a possible mechanism for the above phenomenon will be obtained.

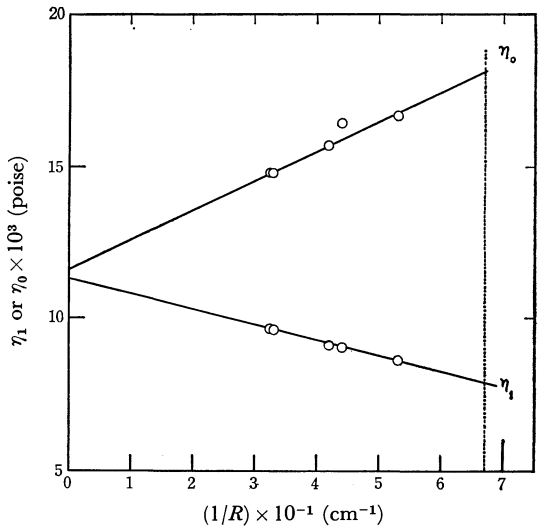

Fig. 9. Plots of η_1 *versus* $1/R$, and η_0 *versus* $1/R$, for K-30 (1%) 0.25 M $MgCl_2$ aqueous solution, where $\eta_w = 7.9 \times 10^{-3}$ (poise), $\eta_c = 11.3 \times 10^{-3}$ (poise), $A = 0.21 \times 10^{-3}$ (poise), $B = 0.3 \times 10^{-3}$ (poise), $C = 10.2 \times 10^{-3}$ (poise).

The Flow Properties of γ-Polyglutamic Acid Solutions in Capillary*1

Takeshi MINESHITA, Shigeru MATSUMURA, Hiromi ONO, Takehiko WATANABE and Sôzaburo ONO

Laboratory of Biophysical Chemistry, College of Agriculture, University of Osaka Prefecture, Sakai, Osaka

(Received June 3, 1968)

Dependence of the viscosity of the solution of γ-polyglutamic acid in eater at various pH's on the bore-size of the capillary viscometer has been studied at 25°C at various concentrations (0.01—0.05 g/100 m*l*). Measurements were carried out with a Maron-Belner type low shear capillary viscometer with various capillary radii (1.9×10^{-2}—7.6×10^{-2} cm) within the shear stress range 0.2—20 dyn/cm^2 at the capillary wall. The polymer solutions showed a non-Newtonian flow behavior and a capillary bore-size dependence and both of these properties were diminished with the decreasing of pH. This capillary bore-size dependence may be attributed to the geometric hindrance of the capillary wall to the thermal motion of the polymer molecules near the wall. The dissolved state of the polymer molecules in solutions of various pH's has been studied by means of optical rotatory dispersions, flow birefringence and intrinsic viscosity. The dissolved state of the polymer solution as well as the capillary bore-size dependence were sensitive to pH. The polymer molecule in neutral and alkaline media may be in the form of a highly expanded chain and in acid medium in a contracted form having a some ordered chain conformation.

In the previous papers,[1-3] the dependence of the viscosity of polyvinylpyrrolidone solutions on the bore-size of capillary viscometer was reported and the flow of the polymer solution through the capillary was treated by assuming the existence of the double wall layer which is owing to the geometric hindrance of the capillary wall to the thermal motion of the polymer molecules near the wall in the flowing liquid.

In this paper, the similar treatments as stated above, were attempted to the solution of γ-polyglutamic acid, as an example of polyelectrolytes, and also the study on the dissolved state of γ-polyglutamic acid was made concerning the appearance of the capillary bore-size dependence of the viscosity.

Experimental

Materials. γ-Polyglutamic acid, or γ-PGA is a polymer of glutamic acid linked through the γ-carboxyl and α-amino group and was supplied by Dr. Sawao Murao, Laboratory of Fermentational Chemistry of University of Osaka Prefecture. This polymer is produced by the *Bacillus subtlis uar. polyglutamicum* from glucose and urea and composed of about 60% D-glutamic acid and 40% L-anomer. Molecular weight of the polymer is estimated as more than 1000000. More details for the polymer will be presented by Murao in elsewhere.[4]

Measurements. A Maron-Belner type capillary viscometer[5] suitable for the study of the flow of non-Newtonian fluids at the low shear stress of 0.2 to 20 dyn/cm^2 was used. Details on viscosity measurements was the same as described in the previous paper.[1]

Viscometers used for the determination of intrinsic viscosity were the Ubbelohde dilution type having the efflux time of about 180 sec for water at 25°C at which temperature the measurements were made.

The extinction angle, χ, and the birefringence, Δn, were measured with a Rao Flow Birefringence Viscometer Model No. B-23 over the gradient range from 50 to 5000 sec^{-1} at 25±0.01°C.

Optical rotatory dispersion (ORD) measurements were carried out with a Yanagimoto ORD-185. All measurements were made in quartz cells with an optical path of 0.10, 0.20, or 0.50 cm at 25±0.01°C.

Results and Discussion

The plots of viscosity *vs.* rate of shear of γ-PGA solution (0.05%) at pH 2.2 are shown in Fig. 1(a). Non-Newtonian flow behavior and capillary bore-size dependence were observed in all ranges of

rate of shear studied for the solution of higher concentration, while in lower concentration, the flow property approaches to one of Newtonian character and the capillary bore-size dependence becomes slight. The other examples of the plots of viscosity *vs.* rate of shear of γ-PGA solution (0.01%) at pH 7.1 in various capillaries are shown in Fig. 1(b). It is obviously shown that both

the non-Newtonian nature and the capillary bore-size dependence of the viscosity were more enhanced in an neutral solution, especially in lower ranges of shear stress.

The experimental results were expressed by the modified formula of the generalized Ree-Eyring equation[1,6,7] for a flow system containing one Newtonian flow unit and one non-Newtonian unit which includes the additional terms dependent on the capillary bore-size as follows.

$$\eta = \left(\eta_1' - \frac{\sigma_1}{R}\right) + \left(\frac{1}{b_2'} + \frac{\sigma_2}{R}\right)\left(\frac{1}{a_2}\right)\left(\frac{a_2}{G}\right) \sinh^{-1}\left(\frac{G}{a_2}\right) \tag{1}$$

where $\eta_1 = \eta_1' - \frac{\sigma_1}{R}$ and $\frac{1}{b_2} = \frac{1}{b_2'} + \frac{\sigma_2}{R}$,

$\sigma_1 = -\mathrm{d}(\eta_1)/\mathrm{d}\left(\frac{1}{R}\right)$,

$\sigma_2 = \mathrm{d}\left(\frac{1}{b_2}\right)\Big/\mathrm{d}\left(\frac{1}{R}\right)$, $\eta_1 = x_1\beta_1/\alpha_1$,

$a_2 = 1/\beta_2$, and $b_2 = a_2/x_2$,

and x is the fractional area on a shear surface occupied by the flow unit, β is the relaxation time of the flow unit, and α is the ratio of shear volume to twice the average kinetic energy of the flow unit; the subscripts 1 and 2 of the parameters refer to the Newtonian and non-Newtonian flow units, respectively and R is the radius of the capillary tube.

The flow represented by Eq. (1) becomes Newtonian under the condition of $(G/a_2)\to\infty$, and $(G/a_2)\to 0$, and the values of viscosity, η_∞ (at $G/a_2\to\infty$) and η_0 (at $G/a_2\to 0$) are reduced to

$$\eta_\infty = \eta_1 = \eta_1' - \frac{\sigma_1}{R} \tag{2}$$

and

$$\eta_0 = \eta_1 + \frac{1}{a_2 b_2} = \left(\eta_1' - \frac{\sigma_1}{R}\right) + \left(\frac{1}{a_2}\right)\left(\frac{1}{b_2'} + \frac{\sigma_2}{R}\right)$$

$$= \left(\eta_1' + \frac{1}{a_2 b_2'}\right) - \left(\frac{\sigma_1 - \frac{\sigma_2}{a_2}}{R}\right) = \eta_0' - \frac{\left(\sigma_1 - \frac{\sigma_2}{a_2}\right)}{R} \tag{3}$$

The values of η_1, a_2, b_2 and $\eta_0\left(=\eta_1 + \frac{1}{a_2 b_2}\right)$ obtained with Eq. (1) are shown in Table 1.

The relationships between $\eta_1(=\eta_\infty)$ and $1/R$ for γ-PGA solutions at various pHs are shown in Fig. 2. For comparing this relation for γ-PGA with that for PVP solution, one of the typical one obtained with PVP (K-90 0.5%) 0.25M $MgCl_2$ aqueous solution, is also shown in Fig. 2

Plots of η_1 *vs.* $1/R$ show approximately linear relation with negative slope of σ_1 in all examples. Therefore, also in the case of γ-PGA solutions, this dependence of η_1 of the polymer solution on R may be treated as the similar dependence as presented in preceding paper[1] for PVP in various

solvents. This dependence will be due to the decrease in relaxation time of the solvent molecules near the wall compared with that of the bulk, because of the geometric hindrance of the capillary wall to the thermal motion of the polymer molecules oriented in the preferred direction under the streamline of the flow near the wall. And the resistance of the polymer molecules against the flow of the solvent molecules under the shear stress will become weaker near the wall than that in the bulk; this wall effect on the orientation of the polymer molecules will extend a certain distance from the wall into the central part of the solution in a capillary. Thus, as shown in preceding paper,[1] the viscosity of the solution in the narrower capillary will decrease compared with that in the wider one.

The relationships between $1/b_2$ and $1/R$ for γ-PGA solutions at various pHs are shown in

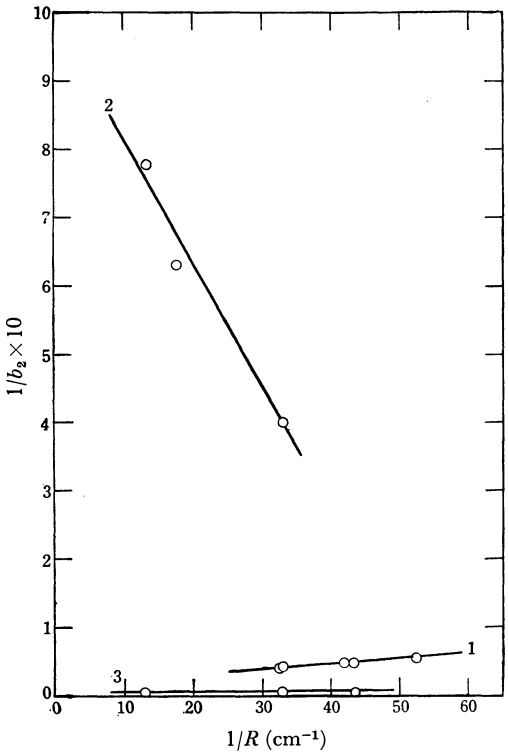

Fig. 3. Plots of $1/b_2$ *versus* $1/R$ for γ-PGA and PVP solutions.
(1) K-90 (1.5%) in *n*-propanol
(2) γ-PGA (0.01%) aqueous solution (pH=7.1)
(3) γ-PGA (0.05%) aqueous solution (pH=2.2)

Fig. 3. A typical plot of PVP obtained with K-90 (1.5%) *n*-propanol solution is compared with that of γ-PGA solution. Plots of $1/b_2$ *vs.* $1/R$ for PVP solution in *n*-propanol show the linear relation, of which slope σ_2 takes a positive value, while the one for γ-PGA solution at pH 7.1 shows a negative one, and $1/b_2$ decreases with the increase of $1/R$.

When no additional effect of the wall on the flow of the polymer solution will occur with the decrease of rate of shear except the one considered in the case of η_∞ (G/a_2 or $G\to\infty$), the following relationship must be held between σ_1 and σ_2.

$$-\frac{\sigma_1}{\eta_1'}=\left(\frac{\sigma_2}{a_2}\right)\Big/\left(\frac{1}{a_2b_2'}\right)$$

or

$$\sigma_2=-\sigma_1\left(\frac{1}{b_2'}\right)\Big/\eta_1' \qquad (4)$$

The experimental value of σ_2 obtained with γ-PGA solutions at pH 7.1 is more negative than the calculated one by Eq.(4). This result suggests the occurence of the slippage of the γ-PGA molecules at the wall because of the existence of the

repulsive force between the negatively charged glass surface and negatively charged γ-PGA molecules owing to the ionization of the carboxyl group of the polymer.

According to the flow equation based on the double wall layer model presented in the previous paper[3] experimental value of viscosity(η_{exp}) is represented as follows;

$$\eta_{exp} = \frac{(\eta_w+C)(\eta_w+A)(\eta_c+B)}{(\eta_w+C)(\eta_w+A) + (A-C)(\eta_c+B)D_o + (\eta_c-\eta_w)(\eta_w+C)D_i + (B-A)(\eta_w+C)D_i} \quad (5)$$

where $D_i=4(d_i/R)-6(d_i/R)^2+4(d_i/R)^3-(d_i/R)^4$ and $D_0=4(d_o/R)-6(d_o/R)^2+4(d_o/R)^3-(d_o/R)^4$

Where $(G/a_2)\to\infty$, the values of A, B, C in above flow equation are zero, *i. e.*, A, B, $C=0$. Therefore, the flow model will reduced to simpler one composing of the wall layer (thickness: d_i) having the viscosity of η_w and the bulk liquid of viscosity η_c, and under the conditions of $(G/a_2)\to 0$, where $\eta_0\geq\eta_\infty$, the relations, A, B, $C\geq 0$ and $d_o\leq d_i$ are held.

Combining Eq. (1) with Eq. (5) as the same manner as stated in the previous paper,[3] the values of d_o and d_i corresponding to each R were calculated as shown in Fig. 4.

With the solution at pH 2.2, the following relationship holds among the viscosity of the each layer $\eta_c+B>\eta_w+C>\eta_w+A$ as in the case of PVP in *n*-propanol and this fact suggests the some structural formation at the wall in the flowing liquid in capillary tube. On the contrary, with the solution at pH 7.1, where $\eta_c+B>\eta_w+A>\eta_w+C$, the slippage of the polymer molecules will occur at the wall surface.

The structural formation at the wall was ascertained by the measurement of the concentration change of the solution between the one before and after the filtration through the glass filter as the same manner as stated in the previous paper.[3]

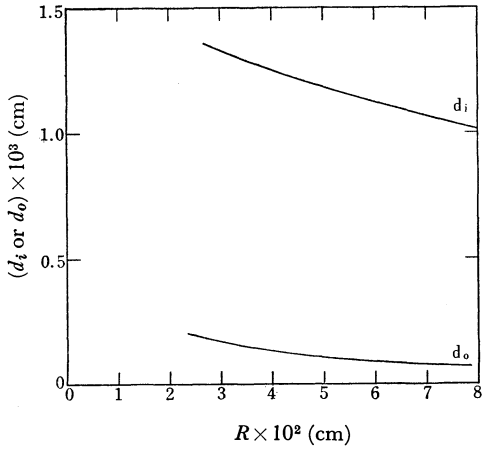

Fig. 4(b). Plots of d_i or d_o *versus* R for γ-PGA (0.01 %) aqueous solution (pH=7.1), where $\eta_w=12.0\times 10^{-3}$ (poise), $\eta_c=18.0\times 10^{-3}$ (poise), $A=125\times 10^{-3}$ (poise), $B=187\times 10^{-3}$ (poise), and $C=0$.

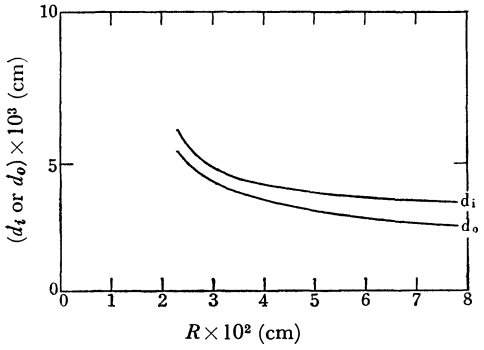

Fig. 4(a). Plots of d_i or d_o *versus* R for γ-PGA (0.05%) aqueous solution (pH=2.2), where $\eta_w=8.0\times 10^{-3}$ (poise), $\eta_c=12.5\times 10^{-3}$ (poise), $A=0.64\times 10^{-3}$ (poise), $B=1.0\times 10^{-3}$ (poise), $C=1.0\times 10^{-3}$ (poise).

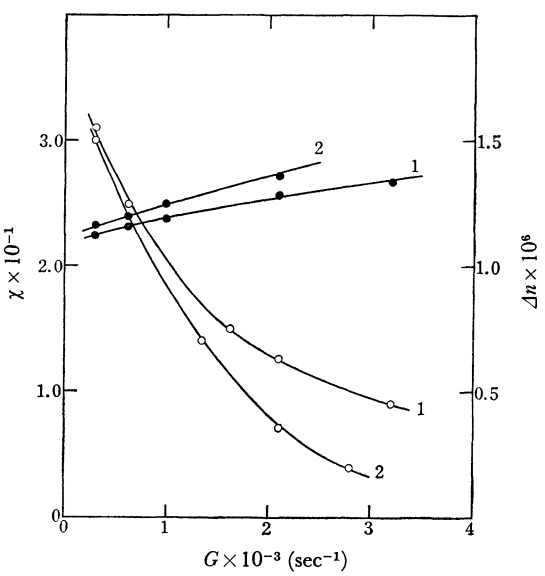

Fig. 5. Relationship between χ and Δn for γ-PGA solutions (○) extinction angle (χ); (●) birefringence (Δn), 1, γ-PGA (0.01%) in water (pH=7.0); 2, γ-PGA (0.01%) in water (pH=11.2).

With neutral solution no appreciable change in concentration was observed in spite of the very high

value of intrinsic viscosity as stated below. Whereas in acid solution the decrease in concentration of γ-PGA by the filtration was observed and this fact will support the above assumption of the some structural formation at the wall in acid medium.

For the interpretation on the cause of the marked difference in flow of the two kinds of solutions (at low pH and neutral or higher pH) the experiments have been made as follows. The plots of extinction angle and the birefringence of the polymer solution against the rate of shear are shown in Fig. 5. The lower extinction angle and higher flow birefringence was observed with the increase of rate of shear for the polymer solution of neutral or higher pH and it obviously shows that the polymer molecules would orient remarkably. However, at lower pH, the position of the arms of the cross of isocline could not be detected in all rates of shear, and the orientation under the streamline of the flow could not be observed. It may be assumed that the γ-PGA molecules in acid medium will actually orient under the streamline of the flow because if the molecules did not show the tendency to orient, the capillary bore-size dependence of the viscosity must disappear as the case of the PVP aqueous solution with cosolute as stated in the previous paper.[3] The change in the degree of the orientation of the polymer molecules at each pH may be due to the change in the dissolved states of the polymer in each solvents.

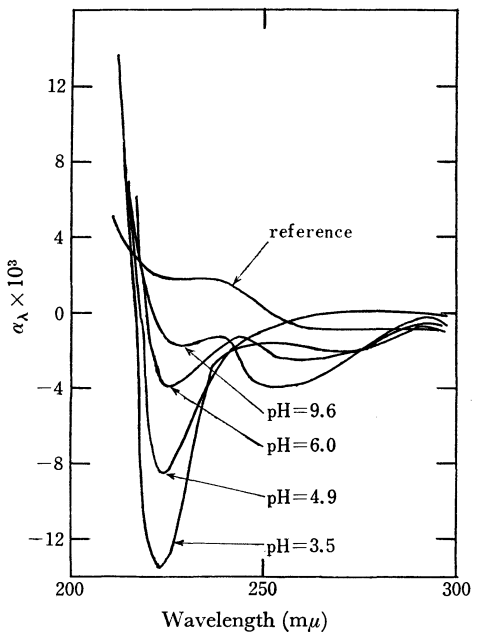

Fig. 6. Optical rotatory dispersion curves for γ-PGA (0.012%) in water.

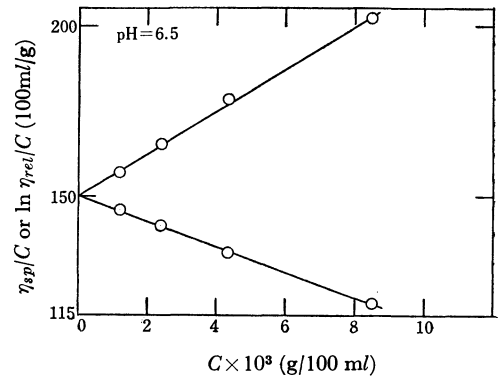
The change in the conformation of the polymer molecules at various pH's, will be reflected in ORD curves in ultraviolet zone. The curves are shown in Fig. 6. The curves, at the lower pH show a negative Cotton effect with a trough at 225 mμ and the depth of the trough becomes deeper with decreasing in pH. Dependence of the ORD curves on pH values shows obviously the conformation change of the polymer molecules, from the disordered conformation at higher pH to the more ordered one with the decrease of the pH values.

The change in the hydrodynamic volume of the polymer molecules in solution may be estimated by the change in the value of the intrinsic viscosity



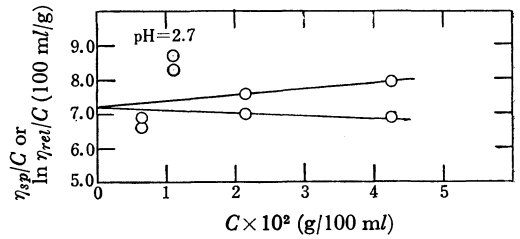


Fig. 7. Plots of η_{sp}/C or ln η_{rel}/C *versus* C for γ-PGA solutions.

between the solutions at pH 2.7 and 6.5. The results are shown in Fig. 7. The intrinsic viscosity at higher pH is very larger compared with that of the lower one: at pH 6.5 about 150 (100 ml/g) and at pH 2.7 about 7.0 (100 ml/g). This fact shows that the polymer molecules in higher pH solution will be dissolved as the more expanded form than that in the lower one.

Thus, from the results of flow birefringence, optical rotatory dispersion, and intrinsic viscosity, the polymer molecule in neutral and alkaline media will be in highly expanded chain conformation while that in the acid medium in contracted form having a some ordered conformation. Therefore, the polymer molecule in neutral and alkaline media will be as the form readily to orient under the

streamline of the flow, while that in the acid medium will be in the contracted form of which the tendency to orient under the streamline of the flow could not be obviously observed by the flow birefringence measurement because the length of the dissolved molecules becomes shorter than the minimum length necessary for the observation with the apparatus. Therefore, it may be said that the measurement of the capillary bore-size dependence of the polymer solution is a sensitive method for the estimation of the anisotropy of the shape of the dissolved polymer molecules.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 599—607 (1969)

Kinetics and Mechanism of Oxidation of D-Glucose and D-Fructose by Potassium Ferricyanide in the Presence of Ammonia

K. C. GUPTA

Chemistry Department, University of Lucknow, India

and M. P. SINGH

Chemistry Department, University of Allahabad, India

(Received January 20, 1968)

The reaction rate is independent of the concentration of ferricyanide ion and directly proportional to both the reducing sugar and ammonia concentration. The reaction is of general basic catalysis in nature. The reaction rate is decreased with the addition of ammonium chloride due to common ion effect. The catalytic constants k_{OH^-} and k_{NH_3} have been calculated graphically. The reaction rate is, also, decreased with the gradual decrease in dielectric constant of the solvent and increased with the gradual increase in ionic strength. The rate expression obtained is as:

$$-\frac{d[Fe\,y^{3-}]}{dt} = k_1[NH_3]\,[\text{Reducing Sugar}]$$

Conant, Aston and Tonberg[1] have studied the oxidation quantitatively of four aldehydes and D-glucose, D-fructose and D-arabinose by alkaline molybdicyanide, tungsticyanide and ferricyanide potentiometrically. They found that more alkaline the solution the more rapid was the reaction. They have also considered that the initial stage of the oxidation of an organic substance by an electron abstracting agent might be fast, reversible and pH dependent. Speakman and Waters,[2] Hinshelwood and Shorter,[3] Drummond and Waters[4] have also reported the enolization to be necessary prior to oxidation of aldehydes and ketones. The most systematic study of the kinetics of oxidation of reducing sugars in alkaline medium by bivalent copper by Singh, Krishna and Ghosh[5] in the presence of complexing agents, Singh and Singh[6] in absence of complexing agents and by alkaline hexacyanoferrate(III) by Nath and Singh[7] has been done. They have reported the reaction rate to be independent of oxidizing agent and directly proportional to reducing sugar and alkali concentration. The similar results have been obtained by Srivastava, Nath and Singh[8a,8b] in the oxidation of aldopentoses and disaccharides.

The present study deals with the kinetics of

oxidation of D-glucose and D-fructose by potassium ferricyanide in the presence of weak base ammonia. The effect of solvent (dielectric constant) and ionic strength on the reaction rate has also been studied.

Experimental

The course of the reaction has been followed by estimating unreduced potassium ferricyanide at different intervals of time iodometrically. The reactions were started by mixing the fresh solution of reducing sugar with potassium ferricyanide and ammonia kept in a bottle in an electrically maintained thermostat at constant temperature which has an accuracy of ± 0.1°C.

Potassium ferricyanide, sulphuric acid, sodium thiosulphate, potassium ferrocyanide and D-glucose used were of B.D.H. (Analar) grade. Ammonia, Ammonium chloride B.D.H. (L.R.) and E. Merck sample of potassium iodide and D-fructose were also used. The values for the dielectric constant of alcohol-water mixture were obtained with a cell of 1.68$\mu\mu$f capacity by a dielectrometer (Dielkometer Type TBK No. 53015) working on the principle of heterodyne beat method.

Results and Discussion

The kinetics of oxidation of D-glucose[9] has been done by us. The next series of experiments have been performed by following the kinetics of oxidation of D-fructose by potassium ferricyanide in the presence of ammonia. The results obtained are similar to that of D-glucose except that the D-fructose has a higher rate (4.8 times) of oxidation.

Order of Reaction with Respect to Ferricyanide Ion. The order of the reaction with respect to ferricyanide ion has been determined by keeping the concentration of D-fructose high. The standard zero-order velocity constant (k_s) has been calculated by multiplying k_0 ($\Delta x/\Delta t$) by the strength (s) of sodium thiosulphate used divided by aliquot (v) sucked *i. e.* $k_s = k_0 \times s/v$. The following Tables 1 and 2 and the summarized Table 3 show the same k_s values at increasing concentration of potassium ferricyanide at constant concentration of other reactants. This indicates that the reaction rate is independent of ferricyanide ion. Also, the results of Table 1 have been shown graphically in Fig. A, in which the molar concentration of remaining ferricyanide ion has been plotted against time t. A straight line after slight induction period is obtained. From the slope the k_s value comes out to be 6.66×10^{-5} mol $l^{-1} \cdot min^{-1}$ which is identical to the value of k_s calculated in Table 1. This further confirms that reaction rate is independent of ferricyanide ion.

Table 4 shows the effect of variation of potassium ferrocyanide on the reaction rate at constant concentration of other reactants. Practically the same k_s values indicate that the reaction rate is not affected by the concentration of the ferrocyanide ion. The slight increase in k_s value at its higher concentration is due to increase in ionic strength.

Order of Reaction with Respect to D-Fructose. In order to determine the order of the reaction with respect to D-fructose, its concentration has been varied keeping the concentration of other reactants constant. The results have been given in summarized form in Table 5. It is observed that zero order velocity constant increases proportionately with the increase in concentration of D-fructose. In the third column, the k_s/[D-fructose] value has been calculated which is fairly uniform. This indicates that the reaction rate is directly proportional to D-fructose concentration.

Table 6 shows the effect of increasing concentrations of ammonia on the reaction rate under identical condition of other reactants at two different temperatures, *i. e.*, 40°C and 35°C. It is observed that k_s value gradually increases with the increasing concentrations of ammonia. Also, the k_s values have been calculated for normal concentration of ammonia. These values gradually decrease with the increase in concentration of ammonia and decrease in hydroxyl ion concentration.

Further, these results have been shown graphically (Fig. 1) by plotting k_s against the concentration of ammonia. It is observed that at lower con-

centration of ammonia, there is direct proportionality; but at higher concentration there is deviation due to the decrease in dissociation of ammonia.

Common Ion Effect and Catalytic Constants. For reactions involving catalysis by bases there is a secondary salt effect which has to do with the effect of ionic strength on the dissociation of weak bases. Thus the actual degree of dissociation of a weak base such as ammonia can be changed by changing the concentration of salts in solution. Since the rate of reaction depends on the concentration of hydroxyl ions obtained from ammonia, it is clear that the rate of reaction will depend on the salt concentration. Table 7 shows the results at increasing concentrations of ammonium chloride on the reaction rate at constant concentration of other reactants. Due to common ion effect the hydroxyl ion concentration decreases with the increase in ammonium chloride concentration; which

leads to gradual decrease in zero order velocity cononstant.

The reaction between ferricyanide ion and D-glucose (*loc. cit.*) and D-fructose is of general basis catalysis in nature. In order to confirm this the following experiments have been performed at varying concentrations of ammonia and ammonium chloride by keeping their ratio constant. The results have been given in summarized form in Tables 8 and 9.

results are at constant pOH because pOH of the system is related by the following equation.

$$\text{pOH} = \text{p}K_b + \log \frac{[\text{salt}]}{[\text{base}]} \qquad (1)$$

where $pK_b = \log 1/K_b$, K_b being dissociation constant of the base which is related with the equilibria

$$NH_3 + H_2O \rightleftharpoons NH_4^+ + OH^-$$

From the above equation it is clear that the increase in k_s values is only due to the increase in

TABLE 10.

undissociated ammonia. This shows that the reaction is of general basic catalysis in nature and in these experiments the total rate (k_s) is governed by the following equation.

$$k_s = kOH^-\cdot[OH^-]+k_{NH_3}\cdot[NH_3] \qquad (2)$$

where k_{OH^-} and k_{NH_3} are the catalytic constants of OH^- and NH_3 respectively. In order to show the validity of Eq. (2) the results of these Tables have been shown graphically in Figs. 2, 3, 4 and 5 by plotting k_s against ammonia concentration and the catalytic constant of OH^- (k_{OH^-}) has been calculated from the value of the intercept of the ordinate and the value of k_{NH_3} has been calculated from the slope of the straight line. The values obtained are given in Table 10.

From the graph it is clear that linearity is obtained only at lower concentrations of the base and the electrolyte. The deviation at higher concentrations is due to the fact that Eq. (2) is valid only at low ionic strength.

Effect of Dielectric Constant and Ionic Strength. In the reaction between ion-dipolar molecule the logarithm of the velocity constant is a linear function of ionic strength (μ) instead of square root of μ as in the case of reaction between ion-ion. This is only valid when there is a large variation in ionic strength, because under such conditions Debye-Hückel term disappears and only the Hückel term ($b\mu$) becomes prominent. On the other hand, the activity of the hydroxyl ion can be increased by the addition of the neutral salt, and thus the catalytic influence of the hydroxyl ion becomes a function of the concentration of the salt. This is also called a secondary salt effect. In order to show the validity of the above conclusion the effect of varying dielectric constant (by adding ethanol or methanol by volume) and ionic strength on the reaction rate has been studied. The results have been given in the Tables 11, 12

and 13. In the case of ammonia the reaction rate decreases with the decrease in dielectric constant, but in the case of strong base sodium hydroxide enhanced reaction rates with the decrease in dielectric constant are obtained. On the other hand when neutral salt (KCl) is added at particular dielectric constant the reaction rate increases with the gradual increase in ionic strength.

In the case of ion-ion reactions, the effect of ionic strength and dielectric constant on the reaction rate is expressed by Brönsted-Christiansen-Scatcherd[10] equation. A similar relationship is expressed by Amis and Joffé[11] and Laidler and Eyring[12] in the case of reaction between ion-dipolar molecule. Both the above equations show that logarithm of velocity constant varies as ionic strength instead of square root of ionic strength as in the case of ion-ion reactions. In order to show the validity of the data the log k_s has been plotted against μ (Fig. 6). A straight line with slight deviation at low ionic strength (due to complication of secondary salt effect) is obtained. Further, ln k_0' varies as $1/D$, where k_0' is the velocity constant at zero ionic strength and D is the dielectric constant of the solution. These two equations lead to contradictory results[13] which have been described in the following lines.

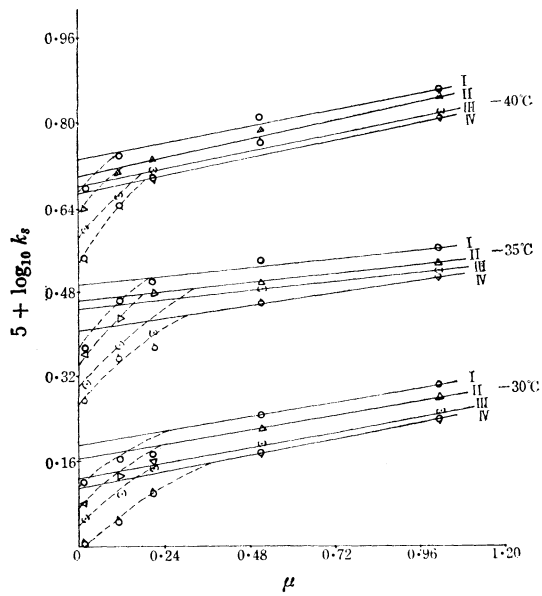

Fig. 6

Variation of ionic strength
$[K_3Fe(CN)_6] = 2.50 \times 10^{-3}$ M
$[NH_3] = 1.00 \times 10^{-1}$ N
[D-Glucose] $= 5.00 \times 10^{-2}$ M

10) Edawrd S. Amis, "Kinetics of Chemical Change in Solution," The Macmillan Company, N. Y. (1949), p. 77.

11) Edward S. Amis and H. H. Jaffé, *J. Chem. Phys.*, **10**, 598 (1942).

12) K. J. Laidler and H. Eyring, *Ann. New York Acad. Sci.*, **39**, 299 (1940).

	For positive ion effect of increasing		For negative ion effectof increasing	
	dielectric constant	ionic strength	dielectric constant	ionic sterngth
Author	decrease	increase	increase	decrease
Amis and Jaffé				
Laidler and Eyring	decrease	increase	decrease	increase

From the above results it is clear that both the equations predict the same results in the case of reaction between positive ion and dipolar molecule, but there is difference in the case of reaction between negative ion and dipolar molecule. Now in the present reaction between negative ion and dipolar molecule (reducing sugar) in presence of ammonia the effect of variation of ionic strength on the reaction rate is in agreement with the result predicted by Laidler and Eyring. Now, when the dielectric constant has been decreased, an increase in the reaction rate is observed in the presence of sodium hydroxide and decrease in the presence of ammonia. Thus the results obtained in the case of sodium hydroxide are again in agreement with Eyring's equation. The contradictory result obtained in the presence of ammonia is due to the fact that the decrease in the dielectric constant of the medium results in the decrease in hydroxyl ion and increase in NH_3 concentration. This has been shown graphically in Fig. 7 by plotting log k_s against $1/D$. A straight line with relative slope

is obtained. This fact is supported by Harned.[14] He has reported in the case of acetic acid that logarithm of ionization constant varies as $1/D$. Thus in our case there would have been an increase with the decrease in dielectric constant as observed in the case of sodium hydroxide (Fig. 8) and the decrease in the reaction rate observed is only due to decrease in dissociation constant.

Mechanism of the Reaction

A careful study of the oxidation of reducing sugars (D-glucose and D-fructose) indicates that the rate expression is of the form:

$$-\frac{d[Fe\ y^{3-}]}{dt}=k[NH_3][s] \qquad (1)$$

where [s] represents the concentration of reducing sugar and [Fe y^{3-}] the ferricyanide ion. The above equation indicates that the reaction velocity is independent of the concentration of ferricyanide ion and directly proportional to both the ammonia and reducing sugar concentration. For any given concentration of alkali, if the concentration of reducing sugar is comparatively larger than ferricyanide ion, the rate expression takes the form

$$-\frac{d[Fe\ y^{3-}]}{dt}=k_s=\frac{\Delta x}{\Delta t}$$

where

$$k_s=k[NH_3][s] \qquad (2)$$

where k_s is the standard zero velocity constant and k the specific rate constant.

From the results it appears that first step involves the action of alkali on the reducing sugar (*loc. cit.*)

14) H. S. Harned, *J. Phys. Chem.*, **43**, 275 (1939).

forming an intermediate 1,2-enediol, which is subsequently oxidized by the ferricyanide ion. The latter being a comparatively faster process, so that the reaction becomes independent of ferricyanide ion concentration.

Thus

$$[S] + [NH_3] \underset{k_{-1}}{\overset{k_1\,(slow)}{\rightleftharpoons}} \underset{R}{\overset{H}{\overset{|}{C}}}\!\!-\!\!OH \;\; \underset{|}{C}\!\!-\!\!OH \qquad \text{(1st step)}$$

1,2-enediol (en)

$$[en] + [Fe\ y^{3-}] \xrightarrow{k_2\,(fast)} [FeOY^{4-}] + \text{other reaction products} \qquad \text{(2nd step)}$$

considering the stationary state for enediol and $k_2 \gg k_{-1}$ the final rate expression comes out to be

$$-\frac{d[Fe\ y^{3-}]}{dt} = k_1[NH_3][S] \qquad (3)$$

where k_1 is identical with k of Eq. (1). Equation (3) confirms our experimental findings. Further, this leads to the conclusion that the rate of enolization is the rate of oxidation of the reducing sugar.

One of the authors (K. C. Gupta) is thankful to C.S.I.R., Government of India for financial assistance and to the Head of the Chemistry Department, University of Allahabad for providing the necessary facilities to carry out the research work.

Measurement of Negative Ions Formed by Electron Impact. I. Negative Ion Mass Spectra of Nitroalkanes

Satoru TSUDA, Akira YOKOHATA and Michihiro KAWAI

Department of Chemistry, Faculty of Engineering, Hiroshima University, Senda-machi, Hiroshima

(Received June 17, 1968)

The negative ion mass spectra of nitroalkanes (nitromethane, nitroethane, 1-nitropropane and 2-nitropropane) have been mesaured with a mass spectrometer under electron energies of 80 eV, 40 eV, 9.5 eV and 4.5 eV in the range of pressure used for usual analysis. The spectral intensities of negative ions were compared with those of positive ions. In 80 or 40 eV electron impact experiments, *m/e* 16 (O^-), 46 (NO_2^-), 26 (probably, CN^-) and 42 (probably, CNO^- or $C_2H_4N^-$) ions were commonly found. Their yields showed good linearity against pressure under the present experimental conditions. The peaks of *m/e* 61 (parent ion; $CH_3NO_2^-$) in nitromethane, of *m/e* 25 (C_2H^-) in nitroethane, 1-nitropropane and 2-nitropropane, and a relatively strong peak of *m/e* 60 ($CH_2NO_2^-$) in 1-nitropropane were characteristic. For lower electron energies, the strong dependency of the yield of negative ions on the electron energy was confirmed. The yield of negative ions as compared with positive ions for 80 eV and 40 eV of electron energy was lower by a factor of $\sim 10^4$. On the other hand, the comparison of the yield of positive ions for 15 eV electrons with that of negative ions for 9.5 eV electrons gave the value of ~ 0.2. In addition, of the role these negative ions in radiolysis has been briefly discussed.

In the last few years studies involving positive ion mass spectra have been carried out with a great variety of organic compounds. However, only a few papers have been published with respect to negative ion mass spectrometry. Also, discrepancies are seen between the published experimental results, which demonstrate the need for further work. In general, the mechanisms for formation of negative ions by electron impact can be classified into the following processes:[1] (a) The radiative capture of a free electron by a neutral atom ($e + A \rightarrow A^- + h\nu$). (b) Capture of a free electron by an atom with a third body taking up the excess energy ($e + A + B \rightarrow A^- + B +$ kinetic energy). (c) Capture of a free electron by a molecule, with the vibrational excitation of the molecular ion and its subsequent stabilization by a collision with another molecule ($e + XY \rightarrow (XY)^{-*}$; $(XY)^{-*} + A \rightarrow XY^- + A +$ kinetic energy). (d) Dissociative attachment: capture of a free electron by a mol-

1) E. W. McDaniel, "Collision Phenomena in Ionized Gases," John Wiley & Sons, Inc., New York (1964), p. 368.

ecule, the excess energy going into dissociation of the molecule ($e + XY \rightarrow (XY)^{-*} \rightarrow X + Y^-$). (e) Ion-pair production: noncapture dissociation of a molecule into positive and negative ions ($e + XY \rightarrow e + X^+ + Y^-$). (f) Transfer of one or more electrons to a neutral structure or a positive ion in a collision with another particle ($A + B \rightarrow A^- + B^+$; or $C^+ + D \rightarrow C^- + D^{2+}$).

Under ordinary laboratory conditions, and excluding charge-changing collisions, processes (b), (c) and (d) would be the most probable. For electron with energies in excess of about 7—20 eV, (e) will also become important.

As these processes are pressure dependent in different ways,[2] the relative intensities of negative ion mass spectra can be expected to change with sample pressure. A further complication is the low yield of negative ions as compared with positive ions in the range of 50 eV to 70 eV of electron energy. However, the recent developements of detection method and apparatus have overcome considerably these difficulties.

Moruzzi *et al.*[3] have surveyed the negative-ion species produced in oxygen and some gases containing oxygen for various pressures and E/P conditions*1 using an rf mass spectrometer coupled to an electron drift tube operating at pressures up to 5 mmHg. Compton *et al.*[4] have studied the non-dissociative electron capture in complex molecules and negative-ion lifetimes with a modified Bendix mass spectrometer. Melton *et al.*[5] have published the results of measurement for individual and total cross sections for the production of positive ions, negative ions and free radicals by using the modified dual electron beam method. Also, Christophorou and Compton[6] have reviewed the electron swarm and electron beam techniques under the subject of interaction of low energy electrons with polyatomic molecules.

On the other hand, the role of negative ions has recently drawn increasing attention in the field of radiation chemistry. Cundall *et al.*[7] have pointed out the importance of negative ions in the radiolysis of nitroalkanes. Warman[8] has elucidated the occurrence of the ion-molecule reactions of negative oxygen atom ions with the additives such as carbon dioxide and acetone in the radiolysis of alkane-nitrous oxide systems.

Also, in the silent discharge reactions in the gas phase with which a part of our recent works are concerned, the role of negative ions has been suggested to be important.[9]

At the present stage when the negative ion mass spectra were only measured for limited compounds, further work on negative ions is strongly required. The present work deals with the negative ion mass spectra of nitroalkanes,*2 especially in relation to the electron energy effect.

Experimental

This investigation was carried out using a standard Hitachi RMU-6D mass spectrometer equipped with a T-2M ion source having a straight line rhenium filament. The ion detection circuit consisted of a ten stage electron multiplier having Ag-Mg dynode and a Faraday collector. All the spectra were measured with an ionizing current of 80 μA and a constant accelerating voltage of 1.8 kV, under the ionizing energies of 80 eV, 40 eV, 9.5 eV and 4.5 eV.

The electron energy was calibrated by the vanishing current method as compared to the ionization potential of argon[10] or the appearance potential[11] of m/e 16 (O^-) from carbon monoxide.

The polarity of the collector ion lens was reversed for negative ion measurement. The electron multiplier was always operated at 1.4 kV.

The research grade nitroalkanes (nitromethane, nitroethane, 1-nitropropane and 2-nitropropane) were used without further purification. Data for each of the compounds were taken at a pressure of $\sim 10^{-6}$ mmHg in the source.

Results and Discussion

Nitromethane. In 80 eV electron impact experiments, negative ions of m/e 16 (O^-), 46 (NO_2^-), 26 (CN^-) and 42 (CNO^-) have mainly been observed (Fig. 1a). The result was consistent with that of Aplin *et al.*,[12] except that the relative intensity of m/e 16 (O^-) ion to m/e 26 (CN^-) ion was reversed.

It is probable that differences in the source

pressure and in the geometry of the ion source are responsible for this discrepancy, which emphasizes the much greater sensibility of negative ion mass spectrometry toward the change in experimental conditions as compared with positive ion mass spectrometry.

As in alcohols[2] the most intense peak was the *m/e* 16 (O^-) ion. Also, it might be mentioned that it is one of the characteristics found frequently in the compounds containing oxygen atoms. When the yield of O^- ion was compared with that of positive ion of *m/e* 30 (NO^+) (the most intense peak among the positive ions), NO^+/O^- was $\sim 0.5 \times 10^4$.

For 40 eV electrons (Fig. 1b), the pattern of the negative ions did not differ so much from that for 80 eV electrons except the decrement in the intensity of *m/e* 26 (CN^-) ion, and the ratio of $CH_3NO_2^+$ to O^- was $\sim 1 \times 10^4$.

The comparison of the yield of *m/e* 46 (NO_2^-) ion obtained with 9.5 eV electrons with that of positive ion of *m/e* 30 (NO^+) obtained with 15 eV electrons*3 (Fig. 1c; C condition) gave a value

of ~0.2 for NO^+/NO_2^-. It should be noted that under this condition the yield of NO_2^- is somewhat higher than NO^+.

For 4.5 eV electrons (Fig. 1d) *m/e* 46 (NO_2^-) ions predominated over other negative ions.

Table 1 shows the yields of the minor negative ions for 80 eV, 9.5 eV and 4.5 eV. For 80 eV, a relatively high yield of *m/e* 13 (CH^-) among the negative ions arising from the methyl group is consistent with that in methyl alcohol.[2] It is also of interest that the *m/e* 61 ($CH_3NO_2^-$) ion has been observed.

Nitroethane. For the impact of 80 eV electrons (Fig. 2a) negative ions of *m/e* 16 (O^-), 46 (NO_2^-), 26 (probably, CN^-), 25 (C_2H^-), 24 (C_2^-) and 42 (probably, CNO^- or $C_2H_4N^-$) have been observed. The peak of parent ion ($C_2H_5NO_2^-$) has not been found. When the yield of O^- ion was compared with that of $C_2H_5^+$ (the most intense peak among the positive ions), $C_2H_5^+/O^-$ was $\sim 1.3 \times 10^4$. A relatively large peak of *m/e* 25 (C_2H^-) among the negative ions arising from the ethyl group is quite similar to the situations in ethane or ethyl alcohol.[2]

TABLE 2. MINOR NEGATIVE IONS FROM $C_2H_5NO_2$

** Normalized to NO_2^- (yield=100)

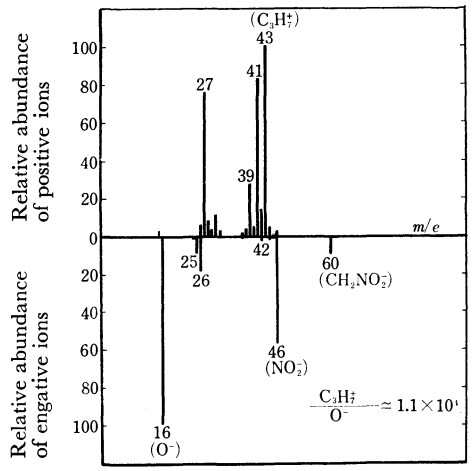

Fig. 3a

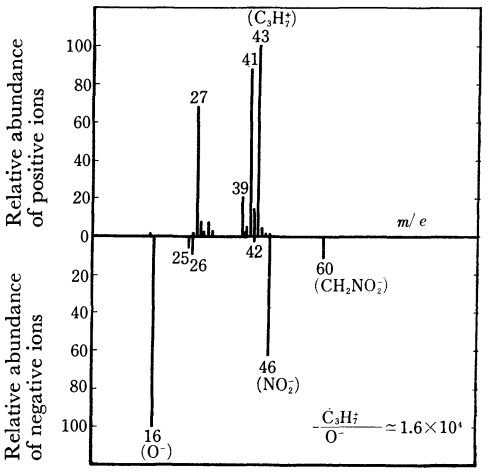

Fig. 3b

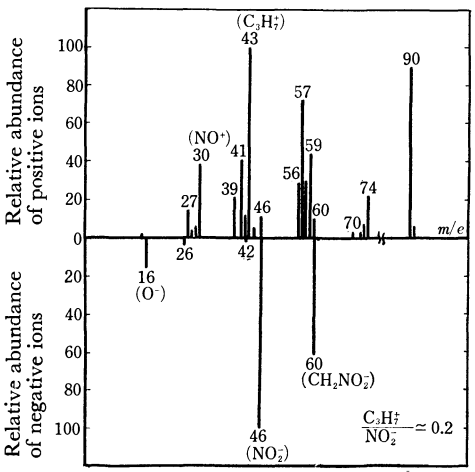

Fig. 3c

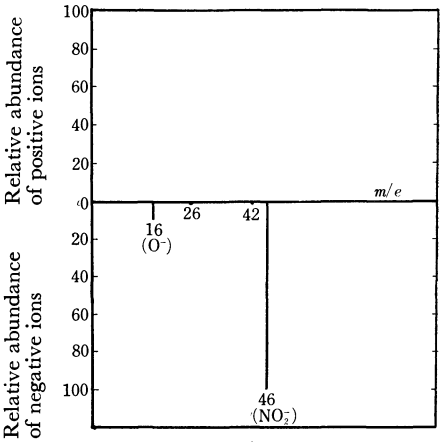

Fig. 3d.

Fig. 3. Positive and negative ion mass spectra of 1-nitropropane (source pressure: $\sim 10^{-6}$ mmHg).
a 80 eV b 40 eV c 15 eV for positive ions, 9.5 eV for negative ions d 4.5 eV

Mass spectra for 40 eV (Fig. 2b) were not so different from those of 80 eV except the decrement of peaks of *m/e* 26 (CN^-), 25 (C_2H^-) and 24 (C_2^-) ions. The ratio $C_2H_5^+/O^-$ was $\sim 1.5\times 10^4$.

For 9.5 eV and 4.5 eV (Figs. 2c and 2d), the *m/e* 46 (NO_2^-) ion predominated over other negative ions. Under C condition NO^+/NO_2^- was $\sim$0.1.

Table 2 shows the yields of the minor negative ions in relation to the electron energy. It can be seen that the ions formed extend over the range of *m/e* 25 to 48 and their variety is relatively small in both cases of 80 eV and 4.5 eV.

1-Nitropropane and 2-Nitropropane. For the impact of 80 eV and 40 eV electrons (Figs. 3a, 4a and 3b, 4b), 1-nitropropane and 2-nitropropane gave almost the same negative ions; *m/e* 16 (O^-), 46 (NO_2^-), 26 (CN^-) and 25 (C_2H^-), except for the appearance of *m/e* 60 ($CH_2NO_2^-$) in 1-nitropropane.

It is of great interest that in 1-nitropropane a relatively strong peak of *m/e* 25 (C_2H^-) ion has been observed as one of negative ions arising from the propyl group. This was consistent with the situation in *n*-propyl alcohol.[2)]

The comparison of the yield of O^- ion with that of $C_3H_7^+$ (the most intense peak among the positive ions) gave the following values for $C_3H_7^+/O^-$; $\sim 1.1\times 10^4$ at 80 eV and 1.6×10^4 at 40 eV for 1-nitropropane, $\sim 1.0\times 10^4$ and $\sim 1.4\times 10^4$ for 2-nitropropane, respectively.

Patterns obtained for 9.5 eV and for 4.5 eV (Figs. 3c, 4c and 3d, 4d) were similar respectively for the two samples, except a large peak of *m/e* 60 ($CH_2NO_2^-$) for electron impact of 9.5 eV on 1-nitropropane.

The ratio of the yield of $C_3H_7^+$ to O^- under the C condition; $C_3H_7^+/O^-$ were $\sim$0.2 for 1-nitropropane and $\sim$0.3 for 2-nitropropane.

** Normalized to NO_2^- (yield=100)

Tables 3 and 4 show the yields of minor negative ions for 1-nitropropane and 2-nitropropane respectively in relation to the electron energy.

Effect of Pressure. Figure 5 shows the relation between yields of *m/e* 46 (NO_2^-), 16 (O^-), 26 probably CN^-) and 42 (probably, CNO^- or $C_2H_4N^-$) ions and the pressure for each sample (5a for *m/e* 46 ion, 5b for *m/e* 16 ion, 5c for *m/e* 26 ion and 5d for *m/e* 42 ion) under the electron energy of 80 eV.

All the results showed good linearity against the pressure under a given experimental condition. Also, this linear relationship was independent of the electron energy as shown in Fig. 6 where the yields of *m/e* 46 (NO_2^-) ion from nitromethane are shown as an example. A similar linear relationship had been reported for *m/e* 1 (H^-) ion produced from hydrogen[13] under the electron energies of 6.8 eV, 10.0 eV and 14.2 eV in the range of pressure

14) T. Sugiura, T. Seguchi and K. Arakawa, This Bulletin, **40**, 2992 (1967).

present work, however, such a study was not made because of instrumental difficulties.

Role of Negative Ions in Radiolysis. The results obtained in this work suggest clearly the importance of the role of negative ions in the radiolysis of these compounds, at least in the primary process.

Indeed, in the radiolysis of nitromethane, the importance of the following reactions has been pointed out.[7]

$$CH_3NO_2 + e \longrightarrow CH_3 + NO_2^- \quad (1)$$
$$\longrightarrow CH_3^- + NO_2 \quad (2)$$
$$\longrightarrow CH_3NO + O^- \quad (3)$$
$$\longrightarrow CH_3NO^- + O \quad (4)$$

The finding that neither CH_3^- nor CH_3NO^- ions can be found, however, shows that the reactions (2) and (4) are to be rejected. Instead, the reaction (5) is to be taken into consideration, as presumed from the measurement of appearance potential of O^- ion from nitromethane.*4

$$CH_3NO_2 + e \longrightarrow CH_3N + O + O^- \quad (5)$$

Besides the above reactions, the reactions (6) and (7) accompanied with the formation of CN^- and CNO^- should be also added.*5

$$CH_3NO_2 + e \longrightarrow H_2O + OH + CN^- \quad (6)$$
$$CH_3NO_2 + e \longrightarrow H_2O + H + CNO^- \quad (7)$$

Furthermore, in 1-nitropropane the reaction (8) accompanied with the formation of $CH_2NO_2^-$ ion appears to be significant.*4

$$C_3H_7NO_2 + e \longrightarrow H + C_2H_4 + CH_2NO_2^- \quad (8)$$

Also, a relatively strong peak of $CH_2NO_2^-$ ion might provide an useful method for the identification of 1-nitropropane.

*4 to be discussed in the 2nd report of this series.
*5 to be published.

Measurement of Negative Ions Formed by Electron Impact. II. The Ionization Efficiency Curves of Negative Nitro, Oxygen Atom and Nitromethylene Ions from Nitroalkanes

Satoru TSUDA, Akira YOKOHATA and Michihiro KAWAI

Department of Chemistry, Faculty of Engineering, Hiroshima University, Senda-machi, Hiroshima

(Received June 17, 1968)

The ionization efficiency (IE) curves of NO_2^-, O^- and $CH_2NO_2^-$ ions from nitroalkanes (nitromethane, nitroethane, 1-nitropropane and 2-nitropropane) have been measured with a Hitachi RMU-6D mass spectrometer. Based on each authorized value of *IP*(CH_3, C_2H_5, C_3H_7, O and H), *D*(C–NO_2, C–H, C–C, NO–O and N–O), *EA*(NO_2 and O) and the excitation energy of CH_3, the respective onsets observed for the electron energies above ~3 eV on the IE curves were suggested to be interpreted as appearance potentials of the following reactions. For NO_2^- ions, $RNO_2+e\rightarrow R^*+NO_2^-$, $RNO_2+e\rightarrow R^++NO_2^-+e$; for O^- ions, $RNO_2+e\rightarrow RNO+O^-$, $RNO_2+e\rightarrow RN+O+O^-$, $RNO_2+e\rightarrow RN^++O+O^-+e$; for $CH_2NO_2^-$ ions, $CH_3NO_2+e\rightarrow H^+ CH_2NO_2^-+e$, $RNO_2+e\rightarrow H+R_1+CH_2NO_2^-$. On the other hand, the strong peak of NO_2^- ions due to the dissociative electron capture process ($RNO_2+e\rightarrow R+NO_2^-$) was observed at the lower electoron energy. Furthermore, a value of *EA*(CH_2NO_2) was presented to be ~0.5 eV.

Recently, several studies have been reported on the measurement of negative ion mass spectra by the electron impact method.[1-5] However, they have only been made for the limited kinds of compounds. Furthermore, the data of the ionization efficiency (IE) curves of negative ions are very limited. On the other hand, the role of negative ions is attracting increasing attention in the field of radiation chemistry.[6] Especially, the compounds containing nitrogen and oxygen atoms are of

interest.

The present work provides information on the IE curves of negative nitro, oxygen atom and nitromethylene ions (NO_2^-, O^- and $CH_2NO_2^-$) from nitroalkanes for which, as far as the authors know, few reports have been published.

Experimental

The investigation was carried out using a Hitachi RMU-6D mass spectrometer equipped with a T-2M ion source having a straight line rhenium filament. The ion detection circuit consisted of an electron multiplier and of a Faraday collector.

All experiments were made with an ionizing current of 80 μA down to the electron energy of ~3 eV, though it decreased considerably in intensity at lower energies. The accerelating voltage used was always 1.8 kV and the electron multiplier was operated at 1.4 kV. The energy scale was corrected by using the values (9.4 eV and 20.9 eV) of appearance potential of O^- ions from carbon monoxide[7] and those (4.4 eV and 17.3 eV) of O^- ions from oxygen.[8] The reliability of this work, however, is restricted to electron energies above ~3 eV, because of instrumental difficulties.

The research grade nitroalkanes (nitromethane, nitroethane, 1-nitropropane and 2-nitropropane) were used without further purification. Measurements for each of the compounds were made at a pressure of about 1×10^{-6} mmHg in the source and a pressure of about 2×10^{-7} mmHg in the analyzer tube.

Results and Discussion

Formation of NO_2^- Ion. Figures 1A-a, 1B-a, 1C-a and 1D-a show respectively the IE curves of NO_2^- ions produced from nitromethane, nitroethane, 1-nitropropane and 2-nitropropane. Figures 1A-b, 1B-b, 1C-b and 1D-b show the same curves, respectively, in the range of electron energy from 3 eV to 15 eV on an expanded scale.

Through all the samples, three resonance peaks were commonly found. In addition, for nitromethane a small peak at 12 eV was found. The first resonance peak lies at a considerably lower electron energy, the second at 4.6 eV for nitromethane, 5.4 eV for nitroethane, 5.5 eV for 1-nitropropane and 5.5 eV for 2-nitropropane, and the last at 8.5 eV, 9.7 eV, 9.8 eV and 9.9 eV, respectively.

These facts show clearly that three processes contribute to the formation of NO_2^- ions. The first process can be easily understood as the dissociative electron capture. Because $D<EA$ (D:

dissociation energy of C–N bond, *EA*: electron affinity of NO_2), the dissociative electron capture is energetically possible even with thermal electrons. The appearance potential of NO_2^- ions due to this process can be expected to be below zero, *e. g.*, for nitromethane, -1.4—-1.6 eV.*1

The second process which can be expected to appear at 4.0 eV is not well known. Following Schulz's interpretation made for the formation of H^- ions from hydrogen,[9] however, it seems to correspond to the process of $R^*+NO_2^-$ (R^*: excited state of radical). If a value of 4.0 eV in nitromethane is taken as the value of appearance potential of $CH_3^*+NO_2^-$, the excitation energy of methyl radical can be estimated to be 5.4—5.6 eV. The agreement with the value (5.7 eV) reported by Herzberg *et al.*[10] is relatively good. Of course, this interpretation is a tentative one which demonstrates the need for further work.*2

The third process seems to correspond to that of an ion pair formation $[R^+ + NO_2^-]$. Each value marked by B, C and D in Fig. 1 coincides well with the corresponding value[11] obtained by one of the authors except for nitromethane. Thus, the third process can be concluded as the ion pair formation. For nitromethane an ion pair seems to appear at ~7.9 eV (the value marked by A in Fig. 1) which is not inconsistent with the value (8.2 eV) estimated by taking $D(C\text{–}NO_2)=2.3$ eV, $IP(CH_3)=9.8$ eV and $EA(NO_2)=3.9$ eV. A small change in negative ion current around 8 eV, however, suggests that the cross section for ion pair formation is very small compared with that of other nitroalkanes.

The present work confirms also that the IE curve for 2-nitropropane is the same as that for 1-nitropropane. It is of interest that the peak due to the ion pair formation process has been found in ~8.5 eV for nitromethane and ~9.8 eV for other three compounds irrespective of the change of alkyl group. These results indicate that the cross section for ion pair formation $[R^+ + NO_2^-]$ varies strongly with the electron energy and has a maximum value around 8.5 eV or 9.8 eV.

The relative intensity of NO_2^- ions produced from each compound is shown in Table 1. The peak height of the third process in nitromethane was almost the same as that of negative oxygen atom ions (O^-)*3 produced from carbon monoxide under the same experimental condition. Therefore, the cross section for negative nitro ion formation due to the first process should be very large.

TABLE 1. RELATIVE INTENSITY OF NO_2^- IONS PRODUCED FROM NITROALKANES

Compound \ Process	Relative intensity of peak by each process*		
	1st process	2nd rpocess	3rd process
CH_3NO_2	(> 240)	~ 3	~ 3.5
$C_2H_5NO_2$	(> 130)	1	~ 6
$1\text{-}C_3H_7NO_2$	(> 150)	~ 1	~ 8
$2\text{-}C_3H_7NO_2$	(> 200)	~ 1.5	~ 8.5

* Normalized to the peak of 2 nd process in IE curve of NO_2^- from $C_2H_5NO_2$ (yield=1).

Formation of O^- Ion. Figures 2A, 2B, 2C and 2D show respectively the IE curves of O^- ions from nitromethane, nitroethane, 1-nitropropane and 2-nitropropane. Although the negative ions of *m/e* 16 may be assigned to the species (*e. g.* NH_2^-) other than O^- ion, their possibility might be ruled out in the range of low electron energy because the complicated rearrangement is necessary for its formation.

All of the results show the possibility of three processes. The first process appears at ~3.1 eV and peaks at ~ 6.6 eV irrespective of the compounds. Thus, this process seems to be the dissociative electron capture for which the reaction (1) or (2) can be expected.

$$RNO_2 + e \longrightarrow RNO + O^- \quad (1)$$
$$\longrightarrow RN + O + O^- \quad (2)$$

However, the reaction (2) would require much higher energy than ~3.1 eV, because the values of D(RNO–O) and D(RN–O) are expected to be higher than D(NO–O) and D(N–O)[12] respectively, as pointed out by Kandel.[13] At this stage we would prefer the reaction (1), although this problem is not fully resolved.

The second process seems to appear at ~8.3 eV for nitromethane, at ~8.6 eV for other three compounds and peaks at 9.5 eV and ~10.1 eV respectively. Possibly, this corresponds to the reaction (2). Then, the values of $D(CH_3NO_2 \rightarrow CH_3N+O+O)$ and $D(RNO_2 \rightarrow RN+O+O)$ are estimated to be ~9.8 eV and ~10.1 eV respectively.

*1 $D(CH_3\text{–}NO_2) \simeq 2.5$—2.3 eV (R. I. Reed, "Ion Production by Electron Impact," Academic Press, London (1962), p. 35). $EA(NO_2) \simeq 3.9$ eV (See Ref. 11).

A CH_3NO_2 B $C_2H_5NO_2$
C $1\text{-}C_3H_7NO_2$ D $2\text{-}C_3H_7NO_2$

The third process appears to ~16.4 eV irrespective of the compounds. The following ion pair formation might be considered.

$$RNO_2 + e \longrightarrow RN^+ + O + O^- + e \qquad (3)$$

For nitromethane the appearnace potential of the reaction (3) can be etimated to be ~16 eV, taking $\Delta H_f(CH_3N^+) \simeq 11.4$ eV,[14] $\Delta H_f(CH_3NO_2) \simeq -0.8$ eV,[13] $\Delta H_f(O) \simeq 2.6$ eV[15] and $EA(O) = 1.45$ eV.[16] It agrees approximately with 16.3 eV observed for nitromethane.

Table 2 shows the relative intensity of the peaks of O^- ions produced from each compound.

Formation of $CH_2NO_2^-$ (m/e 60) Ion. Figures 3(A), 3(B), 3(C) and 3(D) show respectively the IE curves of $CH_2NO_2^-$ ions*4 from nitromethane, nitroethane, 1-nitropropane and 2-nitropropane. All of the results except for nitromethane showed a broad resonance peak in the range of electron energy from 7.3 eV to ~16 eV. The peaks were respectively at 9.7 eV for nitroethane, at 9.7 eV for 1-nitropropane, and at 9.8 eV for 2-nitropropane.

A relatively high value of appearance potential (~7.3 eV) rules out the possibility of the dissociative electron capture process; $R+CH_2NO_2^-$ (R: radical).

In the discussion on IE curves of NO_2^- ions, the authors pointed out the possibility of ion pair formation in the range of electron energy from 6.8 eV to 15 eV. If the process of ion pair formation corresponds also to a value of ~7.3 eV, the electron affinity of CH_2NO_2 radical can be estimated to be 4.5 eV from the reaction (4) by using the values of $D(C_2H_5\text{–}CH_3)=3.5$ eV[12] and $IP(C_2H_5)=8.3$ eV[17]

$$1\text{-}C_3H_7NO_2 + e \longrightarrow C_2H_5^+ + CH_2NO_2^- + e \quad (4)$$

On the other hand, the reaction (5)[17] gives the value of 6.1 eV.

$$C_2H_5NO_2 + e \longrightarrow CH_3^+ + CH_2NO_2^- + e \quad (5)$$

In addition to their high values, their inconsistency rules out the possibility of the ion pair formation. Then, the possibility of reaction (6) or (7) is expected.*5

$$RNO_2 + e \longrightarrow H + R_1 + CH_2NO_2^- \quad (6)$$
$$RNO_2 + e \longrightarrow CH_3 + CH_2 + CH_2NO_2^- \quad (7)$$

However, the same value*6 of onset suggests the possibility of the reaction (6).

For 1-nitropropane in which the formation of $CH_2NO_2^-$ ions was successively observed for the electron energies higher than ~17 eV, the onset of ion pair formation might be expected in this range. Because of a very slow slope of IE curve (Fig. 3 C-b), however, it was very difficult to determine the value of onset.

On the other hand, a high onset value (17.5 eV) in nitromethane suggests strongly the possibility of the following ion pair formation.

$$CH_3NO_2 + e \longrightarrow H^+ + CH_2NO_2^- + e \quad (8)$$

Then, the electron affinity of CH_2NO_2 radical can be estimated to be 0.5 eV, by using $D(C\text{–}H)=4.4$ eV and $IP(H)=13.6$ eV. This value is also consistent with the value (0.6 eV) estimated from reaction (6), by taking $D(C\text{–}H)=4.4$ eV, $D(C\text{–}C)=3.5$ eV. However, because of a very small yield of $CH_2NO_2^-$ ion the reliability of this value is not so high.

TABLE 3. RELATIVE INTENSITY OF THE PEAKS OF $CH_2NO_2^-$ IONS

Compound	Relative intensity*
$C_2H_5NO_2$	~0.05
$1\text{-}C_3H_7NO_2$	~5
$2\text{-}C_3H_7NO_2$	~0.12

* Normalized to the peak of 2nd process in IE curve of NO_2^- from $C_2H_5NO_2$ (yield=1).

Table 3 shows the relative intensity of the peaks of $CH_2NO_2^-$ ion from each compound.*7 It should be emphasized that the intensity of $CH_2NO_2^-$ from 1-nitropropane is much stronger (about 100—40 times) than that from nitroethane and 2-nitropropane. This might be useful for the identification of 1-nitropropane.

The authors are indebted to Professor William H. Hamill, Radiation Laboratory, University of Notre Dame, Indiana, U. S. A. for helpful suggestions and discussions.

*4 The possibility of $C_2H_4O_2$ ion may be ruled out, because (1) in spite of the complicated rearrangement required for the formation of $C_2H_4O_2^-$ from $1\text{-}C_3H_7NO_2$, a relatively large peak of m/e 60 ion was found, and (2) the appearance potential observed cannot be explained with the formation of this ion.

17) C. E. Melton and W. H. Hamill, *J. Chem. Phys.*, **41**, 3464 (1964).

*5 The $CH_2NO_2^-$ ion from 2-nitropropane is considered to be the rearrangement ion.

*6 The appearance potential of the reaction (6) is shown as follows.

$AP=D(C\text{–}H)+D(C\text{–}C)-EA(CH_2NO_2)$

where the excess kinetic energy of fragment ions is ignored.

*7 The relative intensity of $CH_2NO_2^-$ ion from CH_3NO_2 was very samll (~0.02) in the range of electron energy from 20 eV to 23 eV.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 619—624 (1969)

Infrared Spectra of Acylureas and *NN'*-Deuterated Acylureas

Toyozo Uno, Katsunosuke Machida, Kazuhiko Hanai and Yutaka Saito

Faculty of Pharmaceutical Sciences, Kyoto University, Sakyo-ku, Kyoto

(Received July 3, 1968)

The infrared spectra of seven monoacylureas and their *NN'*-deuterated compounds have been measured in the region between 3600 and 450 cm^{-1}. A number of characteristic absorption bands of the $-CONHCONH_2$ and $-CONDCOND_2$ groups have been found and assigned by referring to the infrared spectra of related compounds and the isotopic frequency shifts. Partial deuteration by mixtures of water and heavy water has been made to distinguish the absorptions due to the NH and NH_2 groups from each other. The features of infrared spectra of monoacylureas can be explained by regarding them as composite spectra of aliphatic imides and urea. From the effect of the alkyl frame-work vibrations for the imide III frequency, it is suggested that the RCONH– group of monoacylureas takes the *trans* conformation.

The infrared spectra of monosubstituted amides and related compounds have been the subject of a large number of systematic investigation.[1] The coupling between the CN stretching vibration and the NH in-plane deformation vibration of monosubstituted amides has been proved to be related closely to the conformation of the –CONH– group. The amide II and III bands arising from this coupling are observed only for the *trans* conformation.[2] A similar effect of the structure on the vibrational coupling has been reported for the aliphatic imides in which two C=O bonds are connected to a NH bond.[3] It is desirable to extend the analysis of the amide type vibrational coupling to more complicated combinations of the C=O and NH bonds, since they are involved in many biologically important compounds.

The present paper deals with the infrared spectra of seven monoacylureas, $RCONHCONH_2$ [R = CH_3, C_2H_5, *n*-C_3H_7, *i*-C_3H_7, *n*-C_4H_9, *i*-C_4H_9, $(C_2H_5)_2CH$] and their *NN'*-deuterated derivatives. The assignment of the characteristic frequencies of the $-CONHCONH_2$ and $-CONDCOND_2$ groups was given on the basis of the spectral change on deuteration and comparison with related compounds such as urea,[4] monosubstituted amides[5] and aliphatic imides.[6]

Experimental

Acetylurea[7] and propionylurea[8] were prepared by heating a mixture of corresponding acid, acid anhydride, urea and trace sulfuric acid. The usual method of acylation with acyl chloride in dry benzene was used for preparing *n*-butyryl, *i*-butyryl-, *n*-valeryl, *i*-valeryl and diethylacetyl ureas.[8] These acylureas were recrystallized several times from ethyl alcohol. The *NN'*-deuterated compounds were prepared by recrystallization from a mixture of dioxane and heavy water, and partially deuterated compounds from a mixture of dioxane, water and heavy water.

The infrared spectra were recorded on a Koken DS 301 infrared spectrophotometer equipped with NaCl (4000—700 cm^{-1}) and KBr (700—450 cm^{-1}) prisms. The samples were subjected to the measurement in the form of solid dispersed in Nujol and H. C. B. (hexachlorobutadiene). The absorption frequencies are listed in Tables 1 and 2.

Results and Discussion

The Region above 2000cm^{-1}. Acylureas have both the NH_2 and NH groups, and three absorption bands due to the stretching vibrations of these groups are observed near 3430, 3320 and 3230 cm^{-1}. Watson *et al.* assigned the bands near 3420 and 3320 cm^{-1} to the NH_2 antisymmetric and symmetric stretching vibrations, respectively, and the band near 3230 cm^{-1} to the NH stretching vibration.[9]

We investigated the infrared spectra of partially deuterated samples obtained by exchange reaction with the mixture of water and heavy water in various proportions, and interchanged Watson *et al.*'s assignments of the bands near 3320 and 3230 cm^{-1} on the basis of the intensity change of these bands on the progress of deuteration. One may assume that the isotopic change on the NH_2 and NH groups hardly affects the vibrational frequencies of each other, and that the intensities of the NH_2 and the NH stretching bands are determined by the total concentration of the molecules involving the corresponding group. The concentration of the NH_2 group in the partially deuterated samples decreases more steeply than that of the NH group as the concentration of heavy water in the mixed solvent increases, since the former has two exchangeable protons while the latter has one. Such difference in the rate of concentration changes is expected to give rise to the difference in the rate of intensity changes between the NH_2 and the NH stretching bands, although one must be careful in taking account of the interference of bands due to the NHD group.

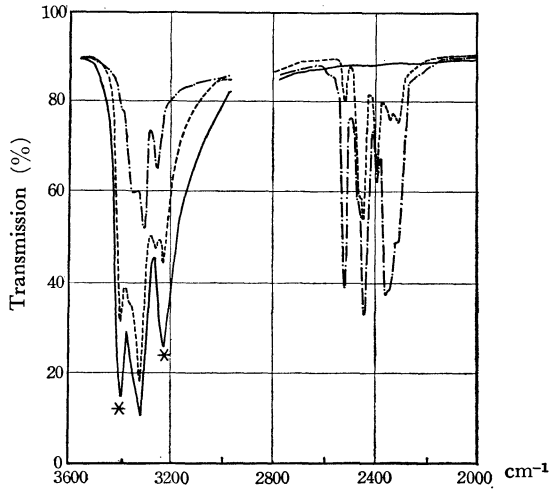

Fig. 1. Infrared spectra of propionylurea (———), partially deuterated propionylurea from 25% D_2O (--------) and partially dueterated propionylurea from 75% D_2O (– – – –).
* the band due to the NH_2 species.

In Fig. 1, the infrared spectra of partially deuterated propionylureas between 3800 and 2200 cm^{-1} are shown. The intensities of the bands at 3424 and 3252 cm^{-1} (labeled*) decrease more rapidly than the intensity of the band at 3342 cm^{-1} on the progress of deuteration. This result suggests that the bands at 3424 and 3252 cm^{-1} are due to the NH_2 antisymmetric and symmetric stretching vibrations, respectively, and that the band at 3342 cm^{-1} is due to the NH stretching vibration. Similarly, for the deuterated compounds the bands at 2550 and 2390 cm^{-1} are assigned to the ND_2 antisymmetric and symmetric stretching vibrations, respectively, and the band at 2466 cm^{-1} to the ND stretching vibration. The intensity changes of these bands on successive deuteration are just what are expected from the concentration changes of the ND_2 and the ND groups. The bands at 3370 and 3278 cm^{-1} are observed only for the partially deuterated samples. They are attributed to the NH stretching vibrations of the NHD group, and their contributions to the peak intensities of the NH_2 and the NH stretching bands are estimated to be small. The presence of two NH stretching bands of the NHD group may be due to the presence of the NH bonds in *trans* and *cis* conformations against the C=O bond. The partially deuterated samples show also the ND stretching bands of the NHD group at 2475 and 2413 cm^{-1}.

The Region between 2000 and 1500 cm^{-1}. Figures 2—8 show the representative infrared spectra of seven monoacylureas and their *NN'*-deuterated compounds in the region between 1900 and 400 cm^{-1}. The infrared spectra between 1800 and 1500 cm^{-1} of the presently investigated acylureas may be classified into two types distinguishable from each other by the feature of the C=O stretching and the NH_2 bending absorptions. The type I spectra are shown by acetyl-, propionyl-, *i*-butyryl- and diethylacetylureas, and the type II spectra by *n*-valeryl-, *n*-butyryl- and *i*-valerylureas.

In the type II spectra, the C=O stretching absorptions, observed as a sharp and strong band near 1690 cm^{-1} and its shoulder near 1705 cm^{-1}, are separated clearly from the NH_2 bending absorption near 1590 cm^{-1} which disappears on *NN'*-deuteration. In the type I spectra, on the other hand, the C=O stretching and the NH_2 bending absorptions overlap with each other and give rise to a strong composite band with three peaks near 1710, 1680 and 1620 cm^{-1}. The spectral change on *NN'*-deuteration gives no definite clue to identify the absorption due to the NH_2 bending vibration. We tentatively assigned the 1620 cm^{-1} peak to this vibration from analogy to the type II spectra. The difference between the type I and II spectra may result from the difference in the scheme of hydrogen bonds involving the C=O and the NH_2 groups. Although this spectral difference is rather empirical at the present stage, it should be noted that a preliminary survey of infrared spectra of a number of α-brominated acylureas has also shown the presence of the two types I and II. The C=O stretching absorption of the *NN'*-deuterated acylureas splits mostly into two distinct peaks, around 1680 and 1640 cm^{-1} for the type I and around 1690 and 1665 for the type II. Only diethylacetylurea shows a single peak at 1681 cm^{-1}.

The Region between 1500 and 850 cm^{-1}. The spectral change on *NN'*-deuteration is complicated in this region since many deformation vibrations of the NH_2, NH, ND_2 and ND groups show their frequencies in this region and they couple often with other vibrations. Acetylurea shows a medium band at 1485 cm^{-1} and two sharp and fairly strong bands at 1260 and 1098 cm^{-1}, all of which disappear on *NN'*-deuteration. The 1485 cm^{-1} and the 1098 cm^{-1} bands persist in the spectra of other acylureas, but the 1260 cm^{-1} band is replaced by a similar band near 1200 cm^{-1} on the change of the acyl group from acetyl to the others. In some cases involving large acyl groups, the presence of the 1480 cm^{-1} is obscured by the overlap of the CH_3 and CH_2 deformation absorptions, and is confirmed only by the comparison with the corresponding *NN'*-deuterated compounds. Instead of these bands, the *NN'*-deuterated acylureas show commonly four weak to medium bands around 1330, 1170, 1050 and 900 cm^{-1}. We assigned the 1100 cm^{-1} band of the undeuterated compounds to the NH_2 rocking vibration from analogy to acetamide,[10] urea[4] and biuret,[11] and the 1170 cm^{-1} band and the 900 cm^{-1} band of *NN'*-deuterated compounds to the ND_2 bending and ND_2 rocking vibrations, respectively, from analogy to

acetamide-d_2[10] and urea-d_4.[4] The remaining deuteration sensitive absorption frequencies are quite analogous to those reported for aliphatic acylic imides, RCONHCOR′ (R, R′=alkyl), and their *N*-deuterated derivatives.[6] The imide II band near 1500 cm^{-1} and the imide III band between 1240 and 1180 cm^{-1} of aliphatic acylic imides are replaced on deuteration by the imide II′ band near 1330 cm^{-1} and the imide III′ band near 1000 cm^{-1}. By the normal coordinate analysis of diacetamide,[3] it has been confirmed that the imide II and III bands arise from the coupling between the NH in-plane deformation vibration and the CN stretching vibrations of the –CONHCO– group, just as in the well known case of the amide II and III bands of monosubstituted amides. The imide II′ band of the deuterated acylic imides is mainly due to the CN stretching vibration and the imide III′ band due to the ND in-plane deformation vibration. From the structural analogy between acylureas and acylic imides, the 1480 cm^{-1} band of the presently investigated acylureas is identified immediately as the imide II band and the 1260 cm^{-1} of acetylurea and the 1200 cm^{-1} band of the other acylureas as the imide III band. The 1330 cm^{-1} and the 1050 cm^{-1} bands of the *NN′*-deuterated acylureas correspond probably to the imide II′ and III′ bands, respectively. These empirical assignmengs of the deuteration sensitive bands of acylureas are given support to by the infrared spectra of the partially deuterated samples. On the increase of the relative amount of heavy water in the solvent for the exchange reaction, the 1100 cm^{-1} band shows faster intensity decrease than the 1480 cm^{-1} band and the 1200 cm^{-1} band (1280 cm^{-1} for acetylurea), whereas the 1170 cm^{-1} and the 900 cm^{-1} bands show slower intensity increase than the 1330 cm^{-1} and the 1050 cm^{-1} bands. The partially deuterated samples show only a few additional absorptions appearing as satellite peaks of the above mentioned bands, although these samples are mixtures of many isotopic molecules with respect to the number and positions of deuterium atoms.

For aliphatic acylic imides it has been reported that the vibrations of alkyl groups contribute to the imide III band through the coupling with the CN stretching vibrations, and this coupling gives rise to the low frequency shift of the imide III frequency of aliphatic acylic imides from 1240 cm^{-1} to 1180 cm^{-1} on the change of alkyl frameworks from methyl to ethyl and larger alkyl groups. Similarly, the effect of the alkyl framework on the imide III frequency of acylureas presently observed indicates that the CN stretching vibration of the RCONH– group of acylureas couples with the NH in-plane deformation vibration as well as with the vibrations of the alkyl framework. It is well known that the coupling between the CN stretching and the NH in-plane deformation vibrations occurs only for the trans –CONH– group.[2] Accordingly, the RCONH– group of acylureas is probably in the trans conformation.

Besides the CN stretching vibration of RCONH– group participating in the imide II and III bands, acylureas have two more degrees of freedom for those arising from the $-NHCONH_2$ group. We assigned the weak or medium band near 950 cm^{-1} observed commonly for the presently investigated acylureas and their *NN′*-deuterated compounds to one of these two CN stertching vibrations. This absorption frequency is comparable with the CN symmetric stretching frequency of urea itself at 1000 cm^{-1}.[4] The remaining CN stretching band is then supposed to appear around 1450 cm^{-1} by analogy with the CN antisymmetric stretching frequency of urea (1660 cm^{-1}).[4] The interference of the CH deformation bands of alkyl groups makes it difficult, however, to identify this band. The strong bands near 1410 cm^{-1} for acylureas and near 1440 cm^{-1} for the *NN′*-deuterated compounds were tentatively assigned to this CN stretching vibration.

The Region between 850 and 450 cm^{-1}. For the undeuterated acylureas, four bands around 810, 700, 680 and 570 cm^{-1} are commonly observed between 850 and 450 cm^{-1}. Referring to the C=O out-of-plane deformation frequency of urea, we assigned the slightly broad band near 810 cm^{-1} of undeuterated acylureas to the corresponding vibration of the $-NHCONH_2$ group. On *NN′*-deuteration, this band is replaced by the sharp band at 770 cm^{-1}, the frequency being almost independent of the alkyl group. The broad bands around 700 and 680 cm^{-1} of acylureas disappear on deuteration and are assigned to the NH_2 wagging and the NH out-of-plane deformation, vibration respectively, from analogy with urea and aliphatic imides. For the *NN′*-deuterated compounds, the corresponding ND_2 wagging and the ND out-of-plane deformation bands are found near 550 and 500 cm^{-1}, respectively. These assignments were given support to again by the change in the relative intensities on partial *NN′*-deuteration.

The group frequencies so far left unassigned in this region are the C=O in-plane and out-of-plane deformation vibrations of the RCONH– group and the C=O in-plane deformation vibration of the $-NHCONH_2$ group. By comparison with the available data for monosubstituted amides,[5] imides[6] and urea,[4] these vibrations are expected to have their frequencies around 600 cm^{-1}. The strong band near 570 cm^{-1} of acylureas may therefore be taken as an overlapped absorption contributed by these vibrations. The corresponding band for *NN′*-deuterated compounds is observed around 530 cm^{-1}.

Photochemistry of Acridine and Acridan. Two Isomeric Forms of Acridine Semiquinone

Akira KIRA

(Received July 11, 1968)

A transient species characterized by the absorption peaks at 350 mμ and 560 mμ has been found in the flash photolysis of acridan in both benzene and methanol solutions. This species has been proved to be different from the acridine semiquinone reported already, but has been identified as another acridine semiquinone radical on the basis of its direct conversion to acridine and also from its low reactivity to oxygen which denies the possibility of being triplet acridan. Thus it is concluded that two isomeric forms of acridine semiquinone exist. From the result of the flash photolysis of biacridan, the one reported previously has been identified definitely with a radical having a hydrogen atom attached to the nitrogen atom of acridine. Therefore, the newly discovered one is most likely a radical with a hydrogen atom attached on the 9 carbon atom of acridine.

In previous papers,[1,2] acridine semiquinone with the absorption maxima at 278 mμ and ~520 mμ has been found in flash photolysis studies of acridine in alcohols. Judging from the results of steady-illumination studies,[3] the formation of semiquinone was also expected in the photoreduction of acridine by acridan (dihydroacridine) in inert solvents, but the transient species in this case showed some difference against the semiquinone described above both in its spectral and in kinetic features.[4] Under such circumstances, it is most desirable to study further the transient absorption spectra observed in the photoreduction of acridine in various conditions, and in particular, in the photodehydrogenation of acridan.

In the present work, the photoreaction of acridan was studied with the flash method in a non-polar solvent, benzene and also in a polar solvent, methanol, both of which had been used in the previous investigations. In addition, the transient species produced photochemically in benzene solutions of acridine and acridan was investigated in more detail. It has been found that the results are interpreted satisfactorily by regarding a new transient band from acridan as an isomer of the acridine semiquinone. Furthermore, the structure of the semiquinone found in the photoreduction of acridine was determined by comparing its spectrum with the transient spectrum in the photolysis of biacridan.

Experimental

Apparatus. A flash photolysis apparatus used in the present work was constructed recently at the Institute of Physical and Chemical Research.

The excitation source consisting of two U-shaped xenon flash lamps connected in series were fired with the electric charge stored in two or three 1 μF-capacitors at 6 to 10 kV. A half-intensity duration was 15 μs at 9 kV and 3 μF. A quartz cylinder 10 cm in length and with an inner diameter of 8 mm, was used as a sample cell. Liquid or solution filters were set between the lamps and the cell; filter cells were of quartz with a size of $106 \times 52 \times 8$ mm^3. Details of the apparatus are described elsewhere.[5]

Illumination Conditions. Samples were illuminated by the 64 to 94 J flash through filters. Methanol solutions were excited through a plastic filter with a ~250 mμ cut off. For benzene solutions of acridan, a liquid benzene filter was employed to eliminate the photo-excitation of the solvent. In the solutions of acridine and acridan, only the former was excited by using a Toshiba UV-D2 filter. Biacridan dissolved in dimethylsulfoxide (DMSO) was illuminated through the plastic filter described above. Although the solvent, DMSO, absorbs considerably under this condition, the excitation of the solvent did not disturb the observation of the transient spectra.

Samples. Acridan was prepared by reducing acridine with sodium amalgam and recrystallized three times from a methanol-water mixture after removing insoluble

precipitates. Acridine was recrystallized three times from an ethanol-water mixture.

Biacridan was photochemically prepared and recrystallized from dimethylsulfoxide.[6]

Benzene fractionally distilled from a guaranteed reagent of Wako Pure Chemicals Co. was used throughout the present work; it gave slower decays of the transient species in the photolysis of acridan than a Dotite "Primasol" benzene without further purification.

A G. R. methanol submitted to the fractional distillation was used; a "spectral" methanol which we purchased was found to contain some amines as a stabilizing agent.

Dimethylsulfoxide was twice fractionally crystallized from a Wako reagent grade reagent.

Solutions were degassed by the usual freeze-pump-thaw method. The procedure was repeated at least three times. When the distillation of a soluent between two traps was made as the method of degassging, some acridan was converted to acridine in the case of methanol.

Results and Discussion

Comparison of the Transient Spectra in Various Systems.

Transient absorption spectra for acridan are shown in Figs. 1 and 2. The peaks are situated at 352 and 557 mμ in a benzene solution and at 350 and 564 mμ in a methanol solution. Hereafter, we will call them the 350 mμ- and the 560 mμ-band respectively. These two bands decay similarly in the second order, as will be described later, and it appears that they are ascribed mainly to the one same species. They were also observed in the aerated solutions, though the intensities were somewhat reduced. The decay of the transient absorption in aerated solutions had duration times of the order of 10^{-4} sec. This suggests that a species giving rise to these bands has low reactivity to oxygen, because, if it were to react with oxygen with the diffusion-controlled rate constant, 10^{10} M^{-1} sec^{-1}, the duration time in aerated solutions containing $\sim 2\times 10^{-3}$M oxygen (for both solvents) would be of the order of 10^{-7} sec. The predominant final product was identified with acridine from its absorption spectra; an example for benzene solution is shown in Fig. 3. Furthermore, in methanol which is transparent in the near UV region, an intense maximum at 250 mμ characteristic of acridine was also observed. As shown in Fig. 4, the formation of acridine was found to proceed in parallel with the fade-out of the transient absorption at 560 mμ, in both deaerated and aerated methanol solutions.

According to previous papers,[1,2] the spectra of acridine semiquinone obtained in the photoreduction of acridine in deareated alcohol solutions have the maxima at ~480 and ~520 mμ in the visible

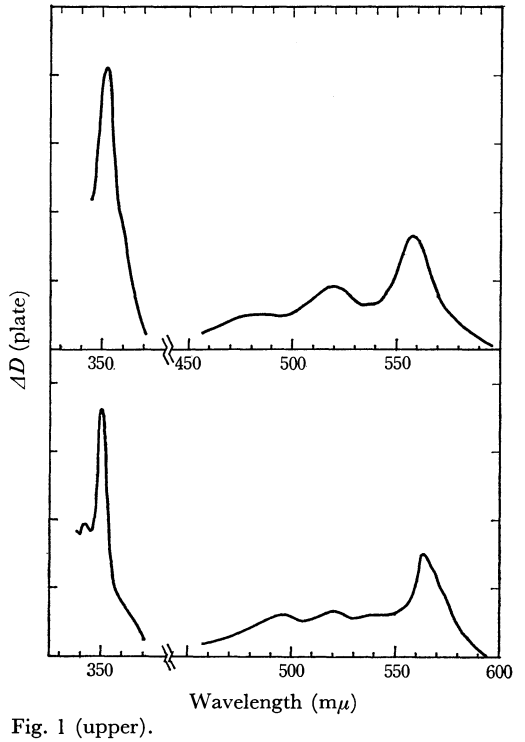

Fig. 1 (upper).
A transient spectrum observed in a deaerated benzene solution of 1×10^{-4} M acridan (t: 50 μsec), and
Fig. 2 (lower).
One observed in a deaerated methanol solution of 5×10^{-5} M acridan (t: 50 μsec). Both spectra were photographed on the same plate. The wavelength response of the plate (Fuji, Neopan.) is not corrected (also for Figs. 5 and 6).

region, but no appreciable band near 560 mμ. This semiquinone is so sensitive to oxygen that its spectrum completely vanishes in aerated solutions. Thus, the predominant transient species with 350 and 560 mμ bands found in the present investigation is quite distinguished from the acridine semiquinone previously reported.

As seen in Fig. 1, a weak maximum is perceived at 520 mμ in deaerated benzene solutions. Upon aeration, the intensity at 520 mμ was reduced to one eighth of the deaerated one, while the intensity at 560 mμ to one fourth. This suggests that the 520 mμ band in the present system is partially ascribed to the transient species reported in the previous paper. A maximum at 520 mμ was not observed clearly in a methanol solution.

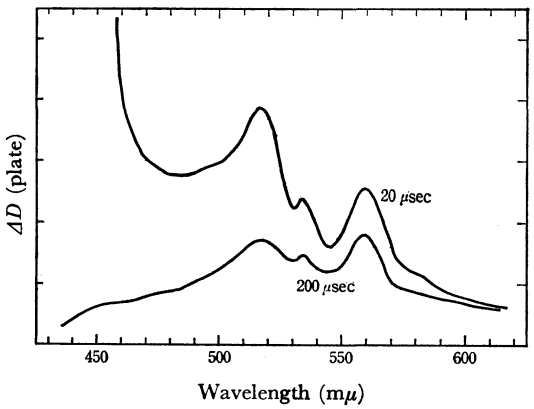

Fig. 5. Transient spectra in the photoreaction of acridine with acridan in deaerated benzene solution.

It was reported, in another previous paper,[4] that when acridine was excited by a flash in the benzene solutions containing acridan, a band with a maximum near 560 mμ as well as the 520 mμ band appeared. In that paper, however, both 520 and 560 mμ bands were attributed, tentatively or rather implicitly, to a single transient species. Hence the transient spectra in this system were examined in more detail under the condition that acridine was selectively excited. The spectra in the deaerated solutions given in Fig. 5 reconfirm the previous result. Thus the short-lived transient absorption is the T-T absorption of acridine with an intense peak at 440 mμ,[4] and the long-lived one consists of the 520 and 560 mμ bands. However, in view of the findings already described, a more reasonable interpretation is that the transient species consist of two components, the oxygen-sensitive and the oxygen-insensitive ones. This has actually been proved in the following way. The intensity ratio of the 520 mμ band to the 560 mμ band was examined in various oxygen concentrations. The results are given in Table 1, which shows definitely that oxygen attacks the 520 mμ band more efficiently.

Biacridan (Compound III in Fig. 7), which is hardly soluble in methanol and benzene, was dissolved in DMSO and its transient spectrum

Table 1. The dependence of the transient absorption intensity on the oxygen concentration

1×10^{-4}M Acridine and 1×10^{-4}M acridan in benzene solutions

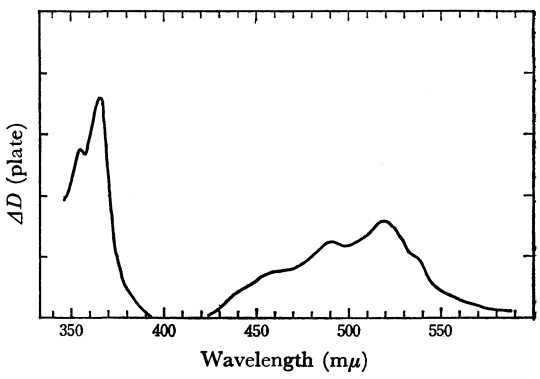
1.3×10^{-4}	0.095	0.100	0.95
2.2×10^{-4}	0.044	0.052	0.85

D is the optical density for 10 cm path and the superscript denotes the wavelength (mμ).

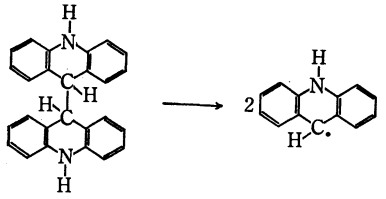


Fg. 6. A transient spectrum from biacridan in a deaerated DMSO solution (t: 200 μsec).

obtained upon flashing was examined. As Fig. 6 shows, the spectrum lacking the 560 mμ band, agrees with that obtained in the photoreduction of acridine in alcohols. The two bands located at ~520 mμ and at 350 mμ decay in a similar way and may be attributed to the same species. The bands in Fig. 6 were not observed in aerated solutions. The main final product was identified with acridine from the absorption spectrum. The yield of acridine was found to increase by a factor of two by the aeration. This is similar to the previous observation made in the photoreduction of acridine in alcohols. These findings substantiate the conclusion that the same transient species are produced in the photolysis of biacridan and in the photoreduction of acridine in alcohols.

Assignment of the Two Species. It is clear from the above experimental facts, that there are two kinds of long-lived species other than T-states, that is, the one without the 560 mμ band and the other with the 560 mμ band. Only the former is produced in the photolysis of biacridan and in the photoreduction of acridine in alcohols, while in benzene solutions both are produced in the reaction of excited acridine and acridan and, in the photolysis of acridan the latter is the main species.

Since there is no other type of dissociation conceivable for biacridan than the following one,



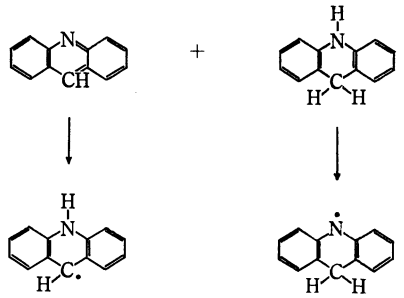
Biacridan (III) C-radical (I)

Fig. 7

the above results unambiguously lead to the assignment that the transient species without 560 mμ band is the radical with an unpaired electron on 9-carbon atom (C-radical).

Hitherto most workers[6-8] have considered, perhaps from chemical intuition, that the acridine semiquinone is the C-radical. In fact, the production of biacridan has been ascertained[6,9-11] in the photoreduction of acridine in hydrogen donating solvents and this may be regarded to support the formation of the C-radical as an intermediate. But the first confirmative evidence that only the C-radical is produced in the photoreduction of acridine in alcohols has been afforded in the present work.

As for the other transient species, it is most reasonable to assign it as an isomeric semiquinone with an unpaired electron on nitrogen atom (N-radical), because it is produced accompanied with the C-radical in the course of the photochemical reaction between acridine and acridan in inert solvents; the C-radical, in analogy with the photoreduction of acridine in alcohols, may be produced from acridine through a hydrogen atom transfer from acridan to acridine. This hydrogen atom is the one located either in 9-carbon or nitrogen atom in acridan and one may say, to be consistent with the experimental result, that the latter is more easily detached than the former. The main reaction may then be written as follows.



C-radical N-radical (II)

Fig. 8

This interpretation is also supported by the type of hydrogen abstraction in the photolysis of acridan in which the species with 560 mμ band seems to be the principal intermediate. The view that the 560 mμ band is ascribed to an isomeric semiquinone is also supported by the fact that, in the photolysis of acridan, the formation of acridine proceeds in parallel with the fade-out of the 560 mμ band.

More direct proof for the above assignment of the N-radical analogous to the proof for the C-radical was attempted but was unsuccessful, since appropriate compounds which may give rise to the N-radical, for example, *N,N'*-biacridan or *N*-halogenated acridan were not available. Attempts for preparing the N-radical by the radiolysis method are now in progress.

Although there is scarcely any doubt that the 560 mμ band is due to the N-radical, it might be added that all other conceivable assignments can be rejected from the experimental facts. These will be described below briefly.

Firstly, this species can not be assigned as the triplet acridan, because in the photoreaction of acridine with acridan, the triplet energy transfer,[12]

$$A^T + AH_2 \longrightarrow A + AH_2^T$$

where a superscript T represents the triplet state, is, in all probabilities, not possible, since the energy levels of the triplet state are for acridine[13] and acridan[14] respectively 14800 cm^{-1} and 24200 cm^{-1}. In addition, the poor reactivity of this species to oxygen, does not agree with the generally accepted properties of the triplet state of organic molecules.

The second conceivable possibility is the formation of radical cation from acridan; but the absorption spectrum of acridan cation produced by a radiolysis method was found to be quite different.[15]

The final possibility is the formation of a certain molecular complex of the C-radical with acridine or acridan or alternatively dimerization of the C-radical. These possibilities are, however, safely denied from the concentration effect of certain substances on the relative intensity ratio of 560- to 520 mμ-band. For example, values of this ratio were 0.7 in the direct excitation of a benzene solution of 1×10^{-4}M acridan and 1.6 in the acridine excitation of a benzene solution containing 1×10^{-4}M acridine and 1×10^{-4}M acridan. In these experiments, the initial optical densities at 520 mμ were 0.40 and 0.15 respectively. These results preclude the possibility of the 560 mμ species being the radical dimer, because if it were the case, the dimer concentration should be proportional to the square of the monomer concentration in contradiction to the above data.

Some Aspects of the Kinetic Behaviors of the Two Semiquinones. Acridine-Acridan in Benzene. In the previous paper,[4] the second order rate constant for the decay of acridine semiquinone in the deaerated condition was estimated by analyzing the change in the optical density at 520, 560 and 350 mμ. The rate constant was interpreted to be related with Processes

$$2AH \longrightarrow (AH)_2$$
$$2AH \longrightarrow A + AH_2$$

The semiquinone treated in the previous paper, however, was the species produced by the reaction between acridine and acridan in benzene solutions and it has been proved by the present work that the species is not a single species but consists of the C-radical (AH) and N-radical (AH'). Hence the rate constants reported in that paper should be considered to be a kind of averaged one for the following processes,

$$AH + AH \longrightarrow AH_2 + A$$
$$\longrightarrow (AH)_2$$
$$AH + AH' \longrightarrow A + AH_2$$
$$AH' + AH' \longrightarrow A + AH_2$$
$$(\longrightarrow (AH')_2?) \quad etc.$$

Some of the ε-values are also concerned with both AH and AH'. It is impossible to analyze the data according to the above scheme.

As for the aerated solution, an attempt to evaluate the rate constant for $AH+O_2\rightarrow A+HO_2$ was unsuccessful in the previous paper. This was attributed to the complicated nature of the reaction. For instance, Reaction $AH+O_2\rightarrow A+HO_2$ and Reaction $AH_2+O_2^*\rightarrow AH+HO_2$, where O_2^* is the singlet oxygen, occur simultaneously. Besides the real situations are even more complicated because there are two radical species AH and AH'. It will practically be impossible to evaluate the rate constants for $AH+O_2\rightarrow A+HO_2$ and $AH'+O_2\rightarrow A+HO_2$ separately as long as the acridine-acridan system is concerned.

Acridan in Benzene. In Figs. 9 and 10 some of the typical decay curves of the transient absorption in benzene solutions of acridan are shown. The decay curves are drawn in terms of $D-D_{A\infty}$, where D is the observed optical density and $D_{A\infty}$, the one of acridine produced by one flash (at $t=\infty$), since the following relation holds where ε_R and ε_A

$$D - D_{A\infty} = l(\varepsilon_R - \varepsilon_A)[R]$$

are respectively the molar extinction coefficient of a radical and acridine.*1 It is evident that the decay obeys the second order satisfactorily. The rate constants at 560 mμ and at 356 mμ can be compared from the slopes in Fig. 10 and the values of D_i and D_A; it was found that the value at the former wavelength was always larger by about several ten %. This suggests that the C-radical, which also absorbs at 356 mμ, might be somewhat more stable than the N-radical in the deaerated condition. It is interesting that the above result eliminates the quick conversion of the type $AH \rightleftarrows AH'$ in this case. Because, if for instance, AH' converts to AH by the following reaction with a high rate,

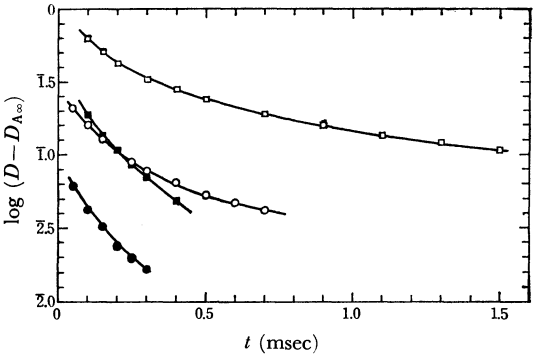

Fig. 9. Decay curves of the transient absorption in a benzene solution of acridan.
□, 356 mμ and ○, 560 mμ in deaerated solution,
■, 356 mμ and ●, 560 mμ in aerated solution.

14) H. Kokubun and K. Kikuchi, private communication.
15) T. Shida and A. Kira, to be published.

*1 At 560 mμ, both $D_{A\infty}$ and ε_A are zero, since acridine does not absorb.

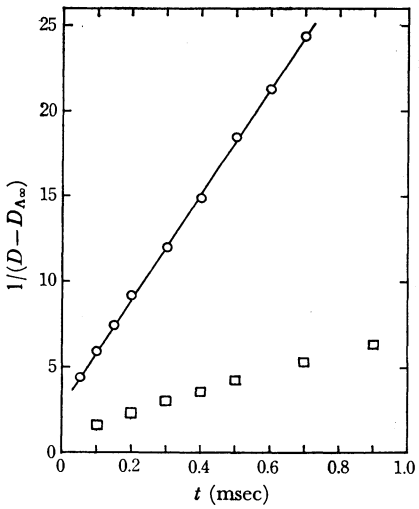

Fig. 10. The second-order plots for the decay curves given in Fig. 9. The symbols are the same as those in Fig. 9.

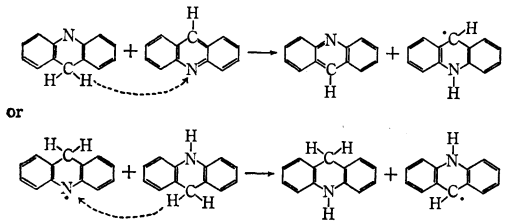

the apparent decay at 560 mμ should not obey a simple second order.

The true second order rate constant can be evaluated if one assumes that AH′ disappears according to the reaction

$$AH' + AH' \longrightarrow A + AH_2 \qquad (1)$$

If this is correct, ε^{560} (AH′) can be estimated from the value of D_∞^{356} (for acridine). The result was $1.3\times10^4 M^{-1}cm^{-1}$ and the rate constant for Reaction (1) was found to be $k_1\sim4\times10^9 M^{-1}sec^{-1}$. However there is no assurance that all AH′ disappears according to Reaction (1); on the contrary, it is more likely that a certain radical species produced by the reaction of hydrogen atoms with the solvent molecules participates in the reaction. In fact the k-value found for the methanol solution was different and appreciably larger than for the benzene solution. Therefore, it is also doubtful whether the above rate constant is concerned with only Reaction (1).

In the aerated solution, such a complication is supposed to be largely eliminated, because oxygen is likely to attack such radical species, and the disappearance of AH′ may perhaps occur mainly through Reaction $AH'+O_2\rightarrow A+HO_2$ (2) and Reaction (1). In fact, the decay curves under the aerated condition was found to be practically the same in benzene and in methanol. From the above reasoning, it may be allowed to put the rate formula as follows,

$$-\frac{dD}{dt}=\frac{2k_1}{\varepsilon_R l}D^2+k_2[O_2]D \qquad (3)$$

where k_1 and k_2 are the rate constants of Reactions (1) and (2) respectively. Dividing Eq. (3) by D, one gets

$$-\frac{d\log D}{dt}=\frac{2k_1}{\varepsilon_R l}D+k_2[O_2] \qquad (4)$$

Hence the plot of the gradient in Fig. 9 against the optical density gives $k_2[O_2]$ as an intercept on the ordinate. The value of k_2 thus obtained is $2\times10^5 M^{-1}sec^{-1}$ for both benzene and methanol solutions. According to the previous paper,[1] the corresponding value for the C-radical in ethanol is $1.2\times10^9 M^{-1}sec^{-1}$. The value of k_2 for the N-radical is not very reliable, and yet it is quite certain that the reactivity of C- and N-radical against oxygen is profoundly different.

The authors are grateful to Dr. Masashi Imamura for generous support and helpful discussions, and to Dr. Tadamasa Shida for useful suggestions.

Note Added after the Preparation of This Paper. We have found in a newly arrived Zeit. für physik. Chem. N. F., a paper of Zanker *et al.*[16] They gave some evidence for the photochemical formation of N-radical of some acridan derivatives in the rigid ethanol at low temperatures. For example, the transient band with the 575 mμ max for 9-C_2H_5 and 9-CH_3 acridan corresponds most likely to the 560 mμ band of our N-radical of acridine and also to the 570 mμ band in alcohols at low temperatures, reported by Niizuma and Koizumi.[17]

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 631—634 (1969)

Polymerization of *N*-Vinylcarbazole in the Presence of β-Cyanoacrolein

Hiroshi SUMITOMO and Ichiro TAKEMURA

Faculty of Agriculture, Nagoya University, Chikusa, Nagoya

(Received July 15, 1968)

It was found that *N*-vinylcarbazole (VCZ) initiated the polymerization in the presence of β-cyanoacrolein (CAL) even in air at room temperature. The polymerization of VCZ induced by CAL was investigated in benzene at 60°C. Polymer formed was found to be VCZ homopolymer. The rate of polymerization attains to a maximum at the mole fraction of CAL of about 0.65 in the monomer mixture. The products obtained from the terpolymerization in the system of CAL-VCZ-Styrene in benzene at 60°C contain no CAL unit and exclusively consist of the VCZ component. The composition curve of the copolymer is contrasted with that of a radical initiated copolymer. In view of these results, as well as the *Q-e* values of both CAL and VCZ, it seems possible that the cationic polymerization of VCZ is induced by some donor-acceptor type interaction between VCZ and CAL.

Since the publication of papers by Scott *et al.* and Ellinger (1963) it has often been shown that the polymerization of *N*-vinylcarbazole (VCZ) is easily induced by electron acceptors, although the mechanism of the initiation is still a matter of controversy.[1)]

We have observed that VCZ starts the polymerization immediately after mixing with β-cyanoacrolein (NC–CH=CH–CHO, CAL) even in air at room temperature. In the present note it is elucidated that the polymerization of VCZ is initiated cationically by some kind of interaction between a donor (VCZ) and an acceptor (CAL).

Experimental

Materials. CAL was prepared by dehydrogenation of β-cyanopropionaldehyde (CPA).[2),3)] VCZ (B.A.S.F. Chemicals Ltd.) was recrystallized from methanol (mp 65.5—66°C) after distillation under a reduced pressure (bp 142—142.5°C/2 mmHg). Styrene (St) was washed with an aqueous solution of sodium thiosulfate, water, 5% aqueous solution of potassium hydroxide and then water, drying on anhydrous sodium sulfate, before distillation at reduced pressure. Bp 46.7—47.0°C/22 mmHg. Azobisisobutyronitrile(AIBN) was recrystallized from ethanol. Benzene was distilled after drying with sodium.

Polymerization. The polymerization at different compositions of VCZ and CAL was investigated in air at 60°C. Terpolymerization of VCZ, CAL and St was also carried out at different molar ratios of VCZ to St, at the constant molar ratio, VCZ : CAL, of unity, and at the total monomer concentration of 4 mol/*l* in benzene, in air and at 60°C. Resulting polymer was precipitated into a larger amount of methanol, purified by the reprecipitation in the system of benzene (solvent) - methanol (precipitant), and then dried at room temperature under vacuum.

Determination of Polymer Composition. Infrared absorption spectra were measured for polymerization products, which were compared with those for parent monomers and their homopolymers. No St homopolymer was extracted with use of carbon tetrachloride from the product of the terpolymerization.

Polymer compositions were determined from nitrogen contents by the Kjeldahl method for the products in VCZ-CAL system and by an elementary analysis using C.H.N. Corder (Yanagimoto Co., Ltd.) for those in VCZ-CAL-St system. There is a good agreement between the results obtained in the nitrogen analysis by these different methods.

Viscometry. Viscosity numbers, η_{sp}/c, of polymers were measured at the concentration of 0.3 g/100 m*l* in benzene at 25±0.05°C with use of an Ostwald viscometer.

Results and Discussion

The results of the preliminary test are shown in Table 1.

VCZ alone gives no polymer in the present conditions, but the addition of CAL results in the formation of the polymer in higher yield even in air at room temperature. There appears no influence of the presence of a radical initiator. The nitrogen contents of the products show the agreement with the value calculated for VCZ homopolymer (PVCZ). An agreement between the infrared spectra (KBr disk), as shown in Fig. 1, of the product and of PVCZ which was obtained by AIBN initiated polymerization, also indicates

that no CAL unit was detectably incorporated into the polymer chain.

Figure 2 summarizes the results of the polymerization of VCZ in the presence of different mole fractions of CAL at the constant total monomer concentration of 0.4 mol/*l* in benzene at 60°C.

The polymerization starts without any induction period. The rate of polymerization seems to attain to a maximum at the mole fraction of CAL of about 0.65. Similar behaviors can be seen in Table 2 in which the polymerization is investigated at the total monomer concentration of 2 mol/*l*. All of the solution viscosity numbers, η_{sp}/c, of polymer are much lower than those of a radical polymer.

In Fig. 3 are plotted the rate as well as the viscosity numbers against the mole fraction of CAL in monomers to show the remarkable tendencies in graphical form. It is conceivable from these facts that there may be some donor-acceptor type of interaction between VCZ and CAL.

Table 3 includes the results of terpolymerization in the system of CAL-VCZ-St at the constant mole ratio of CAL to VCZ of unity in the total monomer concentration of 4 mol/*l* in benzene at 60°C.

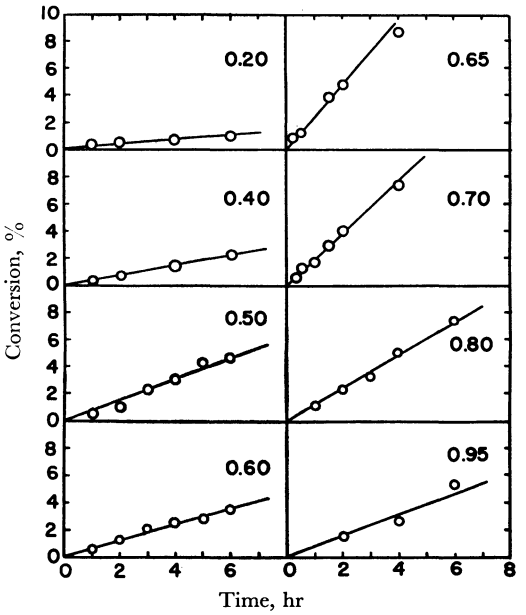

Fig. 2. Polymerization of VCZ in the presence of CAL.
Effect of composition in monomer mixture (numbers in figures show mole fraction of CAL).
[CAL]+[VCZ]=0.4 mol/*l*, benzene, 60°C, in air.

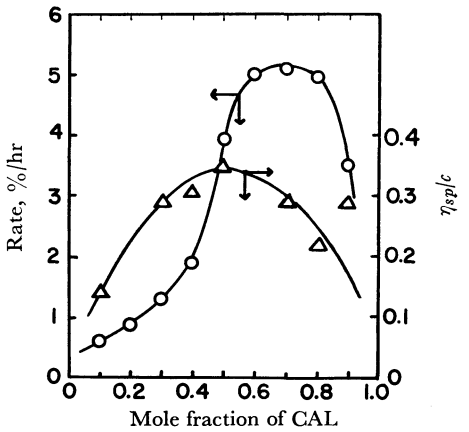

Fig. 3. Polymerization of VCZ in the presence of CAL.
Effect of composition in monomer mixture.
[VCZ]+[CAL]=2 mol/*l*, benzene, 60°C, in air.

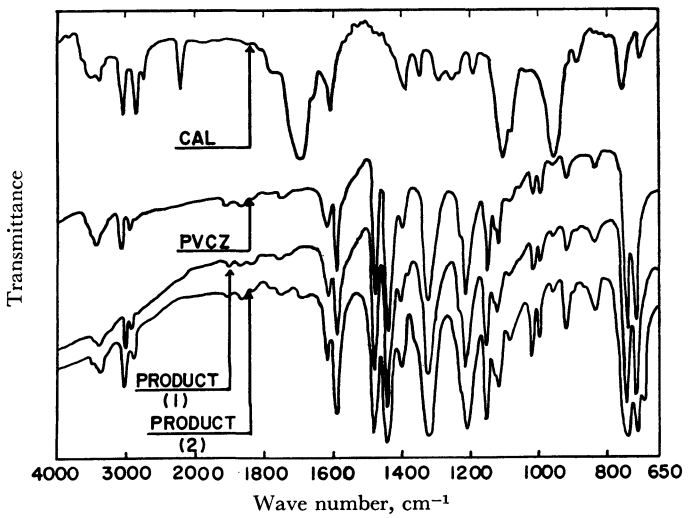

Fig. 4. Infrared absorption spectra of CAL monomer, PVCZ, a product (1) obtained from the experiments other than Expt. No. 513 and the product (2) obtained from Expt. No. 513.

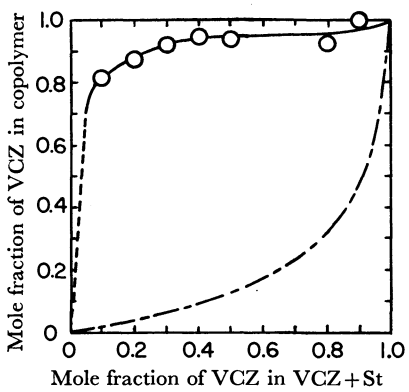

Fig. 5. Composition of copolymer as a function of monomer composition in CAL-VCZ-St system. [CAL]+[VCZ]+[St]=4 mol/*l*, [VCZ]/[CAL]=1, Benzene, 60°C, in air. ——: radical copolymerization of VCZ with St (R. Hart (1961)).

The infrared spectra of the Product 1, starting from the mole fraction of VCZ higher than 0.1 in the total amount of VCZ and St (any product excepting expt. No. 513), and of the Product 2 from that of 0.1, are compared with those of PVCZ and of CAL monomer in Fig. 4.

The spectra of both products are not different from that of PVCZ, excepting that an absorption by styrene appears slightly at 700 cm^{-1} in the spectrum of product 2, and do not represent any absorption peak of CAL.

In Fig. 4 the compositions of the copolymers obtained here are plotted against the monomer compositions. From the fact that the copolymers consist exclusively of the VCZ component and also that the curve is contrasted with that for the radical copolymer given by Hart,[4] it may be suggested that the copolymerization in the present system takes place cationically.

Q-e values of CAL are determined to be $Q=0.53$ and $e=2.07$[5] and those of VCZ are presented to be $Q=0.41$ and $e=-1.40$.[6] It seems possible, therefore, that there may exist some donor-acceptor type interaction between CAL and VCZ inducing the cationic polymerization of VCZ.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 634—636 (1969)

Copolymerization of β-Cyanoacrolein with Acrylonitrile

Ichiro TAKEMURA and Hiroshi SUMITOMO

Faculty of Agriculture, Nagoya University, Chikusa, Nagoya

(Received July 15, 1968)

Radical initiated copolymerization of β-cyanoacrolein (CAL, M_2) with acrylonitrile (M_1) in benzene at 60°C was investigated. The monomer reactivity ratios were determined to be $r_1=3.2$ and $r_2=0$. The copolymerization behavior is discussed in comparison with that in the system of styrene and CAL previously described. The Q and e values of CAL were also estimated to be 0.53 and 2.07, respectively, which were compared with those of other polar monomers.

In preceding papers,[1,2] the radical copolymerization of the new monomer, β-cyanoacrolein (CAL), with styrene (St) was investigated to give monomer reactivity ratios and to demonstrate the existence of a penultimate effect. It was also described that CAL induced the polymerization of *N*-vinylcarbazole even in air at room temperature and that there may be some donor-acceptor type interaction between *N*-vinylcarbazole and CAL in solution leading to initiate the cationic polymerization of *N*-vinylcarbazole.[2] The purpose of the present study is to determine the monomer reactivity ratios and *Q-e* values in the radical copolymerization of CAL with acrylonitrile (AN).

Experimental

Materials. CAL was prepared according to the same method as that previously described.[1] Commercial AN was twice distilled in a stream of nitrogen after drying over potassium carbonate. Bp 77.0—77.3°C.

a) In benzene at 60°C. The weight ratio of benzene to monomer, 2.
b) 0.5 mol% to monomer.
c) Determined by nitrogen contents by the Kjeldahl method.

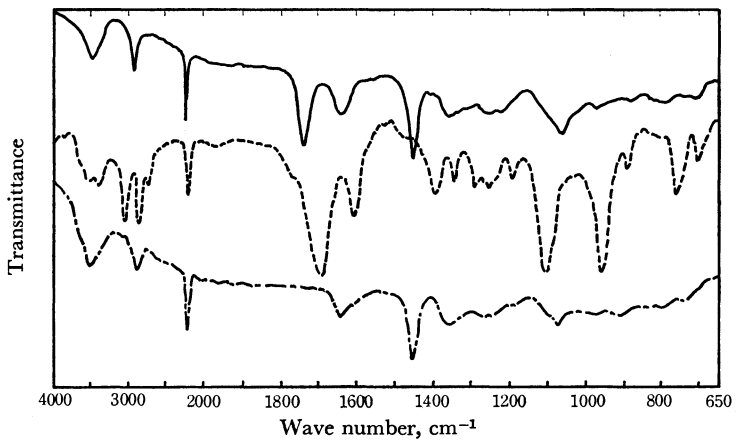

Fig. 1. Infrared absorption spectra of β-cyanoacrolein-acrylonitrile copolymer (solid curve), β-cyanoacrolein monomer (broken curve) and polyacrylonitrile (dot-dash-curve).

Azobisisobutyronitrile (AIBN) was recrystallized from ethanol. Benzoyl peroxide (Bz_2O_2) was purified by the reprecipitation from its chloroform solution into methanol. Benzene and dimethyl formamide (DMF) were purified in the usual way.

Polymerization. In a glass tube were placed initiator, CAL, AN and solvent in this order. The tube was sealed under vacuum after repeating freezing and thawing. Polymerization was conducted at 60± 0.1°C. The resulting copolymer was precipitated in a larger amount of methanol and then purified by the reprecipitation in the system of DMF-methanol.

Copolymer Composition. The compositions of copolymers were determined from nitrogen contents by the Kjeldahl method.

Results and Discussion

The results of the copolymerization of AN (M_1) with CAL (M_2) are summarized in Table 1. Figure 1 shows the infrared absorption spectra of the copolymer, AN homopolymer and the CAL monomer.

In Fig. 2 are plotted the compositions of the initial copolymers against the initial monomer compositions. No homopolymerization of CAL was experimentally found to occur in the present condition. Hence the monomer reactivity ratio r_2 can be estimated at 0. The solid curve shown in Fig. 2 are drawn adopting values of $r_1=3.2$ and $r_2=0$ to the conventional Lewis-Mayo equation and it agrees very closely with the experimental data. Included in Fig. 2 for comparison is the data obtained in the previous St (M_1)-CAL (M_2) system.[1]

There is a remarkable difference between the monomer reactivity ratios obtained in these copolymerization systems. The value of r_1 is larger than

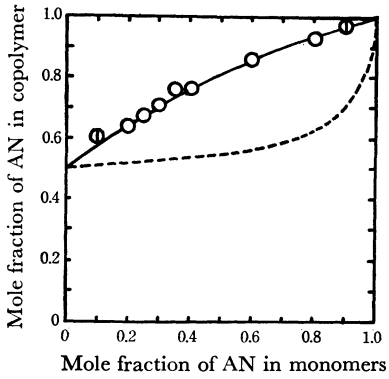

Fig. 2. Composition curve of St(M_1)-CAL(M_2) copolymerization ○, Bz_2O_2; ①, AIBN.
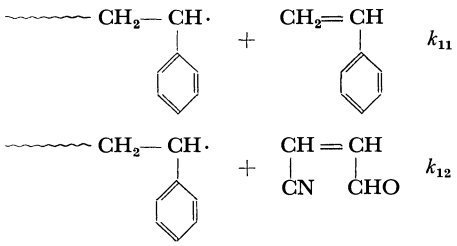
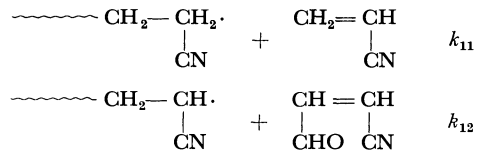
Solid curve, calculated by using $r_1=3.2$, $r_2=0$.
Broken curve shows St(M_1)-CAL(M_2) system ($r_1=0.09$; $r_1'=0.27$; $r_2=r_2'=0$).[1)]

unity in the AN (M_1)-CAL (M_2) system, whereas $r_1<1$ in the system of St (M_1)-CAL (M_2).

It has also been noticed in our experiments that, for example, the mixture of equal moles of St and CAL gives the copolymer at 5.7% conversion in 5.2 hr at 60°C, even in air without any other initiator. It is conceivable that there may be some donor-acceptor type interaction between St and CAL.



In the present copolymerization system, it may be suggested from the r_1 value that there exists stronger repulsion being attributed to the polar substituted groups between the growing AN radical and the coming CAL monomer rather than the AN monomer.



The values of Q and e for CAL calculated from the copolymerization data are shown in Table 2. Table 2 also includes the Q-e values for the related polar monomers.

TABLE 2. THE Q-e VALUES OF POLAR MONOMERS

Monomers		Q	e	Ref.
Maleic anhydride		0.23	2.25	3)
CAL	NC–CH=CH–CHO	0.53	2.07	This paper
Fumaronitrile	NC–CH=CH–CN	0.80	1.96	3)
Acrylonitrile	CH_2=CH–CN	0.60	1.20	3)
Acrolein	CH_2=CH–CHO	0.85	0.73	3)

It can be seen from the e values in Table 2 that the polar effect of substituted groups in CAL is comparable with that in fumaronitrile, larger than that in AN and acrolein, and smaller than that in maleic anhydride.

Electronic Spectra of Crystalline TCNQ Anion Radical Salts. II. Complex Salts*1

Yôichi IIDA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo

(Received July 17, 1968)

The present paper deals with crystalline TCNQ anion radical "complex" salts of $(M^+)_2(TCNQ)_3^{-\cdot}$ and $M^+(TCNQ)_2^{-\cdot}$ composed of the formally-neutral TCNQ and its anion radical $TCNQ^{-\cdot}$. Their crystalline electronic spectra were measured in the range between 4.0 and 30.8 kK by diffuse reflectance and in the 0.65—4.0 kK range by transmittance. None of their spectra except those of the (2 : 3) compounds were found to bear any resemblance to those in the simple salts. Although the spectra of the (2 : 3) compounds are similar to those of the simple salts with low conductivities, the former exhibit an additional weak absorption in the range lower than 6 kK. The (1 : 2) compounds with intermediate conductivities show a strong band around 3 kK, and those with high conductivities, around 2.0—2.5 kK. Their spectra are discussed on the basis of the interaction among unpaired electrons in connection with their electrical and magnetic properties. The difference in the interaction modes of the ion radicals between "simple" and "complex" salts is also speculated upon.

Our primary interest is in studying the interactions among unpaired electrons in the solid state of ion radical salts. Along this line, we have investigated the crystalline electronic spectra of Würster's cation radical salts[1] and 7,7,8,8-tetracyanoquinodimethane (TCNQ) anion radical simple salts.[2] It has been concluded that their crystalline spectra arise from charge-transfer interaction between ion radicals. Furthermore, the spectra have been proved to have a close correlation with their electrical and magnetic properties. In TCNQ simple salts, the charge-transfer bands have been observed around 9 kK in low-conductivity compounds and at 4.3 kK in high-conductivity compounds. On the other hand, TCNQ forms new classes of complex salts of $(M^+)_2(TCNQ)_3^{-\cdot}$ and $M^+(TCNQ)_2^{-\cdot}$ as well as simple salts of $M^+TCNQ^{-\cdot}$, where M^+ represents a diamagnetic counter cation.[3,4] Thus, the complex salts include the formally-neutral TCNQ besides the anion radical $TCNQ^{-\cdot}$. The complex salts range from semimetal-like substances with a temperature-independent paramagnetism to intermediate-conductivity compounds with triplet-exciton systems.[3-8] The purpose of the present paper is to study the electronic states of the complex salts in the solid state by means of their crystalline electronic spectra. This study also involves the effects of the introduction of neutral TCNQ molecules on the modes of the interaction among unpaired electrons previously investigated in the simple salts.[2]

Experimental

Materials. The TCNQ complex salts under investigation are classified below.

The (2 : 3) Compounds. $(Cs^+)_2(TCNQ)_3^{-\cdot}$ and $(Morpholinium^+)_2(TCNQ)_3^{-\cdot}$.

The (1 : 2) Compounds with Intermediate Conductivity. Methyltriphenylphosphonium$^+$(TCNQ)$_2^{-\cdot}$, Methyltriphenylarsonium$^+$(TCNQ)$_2^{-\cdot}$, Ethyltriphenylphosphonium$^+$(TCNQ)$_2^{-\cdot}$, Ethyltriphenylarsonium$^+$(TCNQ)$_2^{-\cdot}$, Trimethylphenylammonium$^+$(TCNQ)$_2^{-\cdot}$, Triethylammonium$^+$(TCNQ)$_2^{-\cdot}$, Triethylphenylammonium$^+$(TCNQ)$_2^{-\cdot}$, Tetraethylammonium$^+$(TCNQ)$_2^{-\cdot}$, Ethyltri-*n*-propylammonium$^+$(TCNQ)$_2^{-\cdot}$, and Tetra-*n*-propylammonium$^+$(TCNQ)$_2^{-\cdot}$.

The (1 : 2) Compounds with High Conductivity. Quinolinium$^+$(TCNQ)$_2^{-\cdot}$, *N*-Methylquinolinium$^+$(TCNQ)$_2^{-\cdot}$, *N*-Ethylquinolinium$^+$(TCNQ)$_2^{-\cdot}$, *N*-(*n*-Propyl)quinolinium$^+$

$(TCNQ)_2^-$, *N*-Methylisoquinolinium$^+(TCNQ)_2^-$, *N*-Ethylisoquinolinium$^+(TCNQ)_2^-$, Quinaldinium$^+(TCNQ)_2^-$, *N*-Methylquinaldinium$^+(TCNQ)_2^-$, *N*-Ethylquinaldinium$^+(TCNQ)_2^-$, Lepidinium$^+(TCNQ)_2^-$, *N*-Methyllepidinium$^+(TCNQ)_2^-$, *N*-Ethyl-2,6-dimethylquinolinium$^+(TCNQ)_2^-$, and *N*-Methylacridinium$^+(TCNQ)_2^-$.

These compounds were prepared by a direct reaction between TCNQ and the iodides in acetonitrile.[3] The compositions of the compounds, which have not yet appeared in the literature, were determined on the basis of the intensity-ratios of some absorption bands measured in acetonitrile.[3]

Measurements. The measurements of the absorption spectra in acetonitrile were carried out under the conditions presented in a previous paper.[2] The crystalline electronic spectra were measured in the range between 4.0 and 30.8 kK by means of diffuse reflectance and were plotted using the Kubelka-Munk equation $f(R)=(1-R)^2/2R$, where R is the reflectance. The details were the same as in previous papers.[1,2] The absorption spectra in the solid state were recorded in the range between 0.65 and 4.0 kK as Nujol mulls.

Results and Discussion

The absorption spectra of neutral TCNQ and anion radical $TCNQ^-$ in acetonitrile have been illustrated in a previous paper.[2] As for the complex salts in acetonitrile, the components have been found to be completely dissociated, thus giving a spectra consisting of those of independent TCNQ and $TCNQ^-$ molecules. However, in the solid state, TCNQ molecules form "supermolecules" composed of their unique groups.[4-9]

These complex salts may be divided into (2 : 3) and (1 : 2) salts on the basis of the ratio of cations to TCNQ molecules. It is further possible to divide the (1 : 2) salts into intermediate- and high-conductivity compounds on the basis of their electrical properties.[4] These classifications allow correlation with the optical and magnetic properties in the complex salts to be discussed below.

The (2 : 3) Compounds. They are restricted to $(Cs^+)_2(TCNQ)_3^{--}$ and (Morpholinium$^+)_2$-$(TCNQ)_3^{--}$, which were obtained in the form of large blue-black crystals. They have conductivities of the order of 10^{-3}—$10^{-5}\Omega^{-1}\,cm^{-1}$ or less and activation energies as high as 0.3 eV.[3,4]

$(Cs^+)_2(TCNQ)_3^{--}$. According to Fritchie and Arthur,[9] this salt crystallizes with the symmetry of the space group $P2_1/c(C_{2h}^5)$ and with two formula units per cell. TCNQ molecules pack face-to-face to form somewhat irregular columns parallel to the b-axis, with a unique grouping of charge-transfer-bonded triads. The inter-planar spacing is 3.22 Å within a triad and 3.26 Å between triads.

The absorption spectrum of the salt in acetonitrile is shown in Fig. 1, curve a. The crystalline spectrum illustrated in Fig. 1, curve b, is found to resemble that of the $TCNQ^-$ dimer in an aqueous solution[10] or those of the simple salts with low-conductivities.[2] The crystalline spectrum of the Cs salt comprises peaks at 10.1, 16.2 and 27.5 kK, a weak band in the region less than 6 kK and extending to 4 kK, and a slight shoulder around 23 kK. These three peaks almost correspond to those at 8.5, 16.4, and 27.8 kK respectively in the simple potassium salt.[2] The high-energy peaks at 16.2 and 27.5 kK in the Cs salt may also well be compared with those at 15.6 and 27.0 kK respectively in the dimer.[10] Neutral TCNQ in acetonitrile has a band peak at 25.3 kK with a molar extinction coefficient as high as 65000,[2] therefore, if this band makes some contribution to the band at 27.5 kK in the Cs salt, the appearance of a shoulder or a remarkable increase in the intensity relative to that at 16.2 kK may be expected. However, the spectrum of the Cs salt shows that this appears not to be the case. The shoulder around 23 kK is too slight to be the expected one; it is probably due to a non-interacting TCNQ or $TCNQ^-$ monomer in some kind of defects. Thus, the band due to TCNQ may be regarded as appreciably blue-shifted, thus making only a small contribution to the band at 27.5 kK. Therefore, for the same reason as with the simple salts,[2] the bands at 16.2 and 27.5 kK in the Cs salt should mainly be assigned to the shifted bands of the $TCNQ^-$ monomer, while the band at 10.1 kK must be the charge-transfer band between $TCNQ^-$ molecules (*cf.* Ref. 11). Finally, the weak low-energy band characteristic of the (2 : 3) salts may be regarded as due to charge-transfer interaction between $TCNQ^-$ and

TCNQ, for it appears only upon the introduction of TCNQ.

The finding that the crystalline spectrum is due almost entirely to the pair-by-pair interaction between unpaired electrons in the Cs salt is probably associated with its magnetic properties. According to Chesnut and Arthur,[7] its paramagnetism is to be attributed to a triplet-exciton state lying 0.16 eV above a singlet state.[8] Understandably, the pair-by-pair interaction leads to the singlet-triplet energy separation. However, the addition of neutral TCNQ to the $TCNQ^-$ dimer may contribute to a reduction of the localized triplet character, producing a triplet exciton in the crystal. The reason for this is as follows. With respect to the unpaired electrons, the dimer in the (2 : 3) salt corresponds to the doubly-charged TCNQ triad. The interacting distance between two unpaired electrons in the triplet state of the triad may be longer than that in the dimer without neutral TCNQ, because the lowest-triplet configuration is not mixed with the charge-transfer configuration and, consequently, the two electrons in the triplet state may be regarded as mutually repulsive.[2,11] Thus, the introduction of neutral TCNQ should decrease the intra-dimer interaction and increase the inter-dimer interaction in the triplet state, at least to some extent, thus resulting in the triplet exciton. On the other hand, the electronic transitions conceived here occur among singlet states, where the mixing of the lowest singlet configuration with the charge-transfer configuration in the triad is quite significant. Therefore, the pair-by-pair interaction may be regarded as strong in the singlet states, giving rise to the spectral resemblance to the dimer without neutral TCNQ. At any rate, the presence of additional TCNQ to this salt seems to perturb weakly the pair-by-pair interaction of ion radicals. This effect may make a small contribution to the increase in electrical conductivity. The conductivity of the complex Cs salt ($1\times10^{-5}\,\Omega^{-1}\,cm^{-1}$ at 23°C, compaction measurement) should be compared with that of the simple salt with the same cation (5×10^{-4}).[4]

(Morpholinium$^+$)$_2$(TCNQ)$_3^{-}$. The crystalline spectrum (Fig. 1, curve c) consists of peaks at 10.0, 16.3, and 27.6 kK, and a weak band in the region from less than 6 kK to 4 kK. These bands agree well with the corresponding bands in the Cs salt. Furthermore, the spectrum of the complex morpholinium salt bears a close resemblance, except the weak low-energy band, to that in the simple salt with the same cation,[2] which has peaks at 9.5, 16.3, and 27.7 kK. The band at 9.5 kK in the simple salt has been ascribed to the inter-radical charge-transfer transition, to which the band at 10.0 kK in the complex salt is also regarded as due. Again, in these morpholinium salts, the weak low-energy band is also characteristic of the complex salt. Although the electrical conductivity of the complex salt ($2\times10^{-4}\,\Omega^{-1}cm^{-1}$, single-crystal measurement)[3] is larger than that of the simple salt (1×10^{-9}),[4] the former is classified as part of the group with intermediate conductivity. Accordingly, the perturbation due to the introduction of TCNQ is certainly weak. There are many reasons to believe that the complex morpholinium salt possesses a crystal structure similar to that of the Cs salt and exhibits magnetic properties based on a triplet exciton.[6]

The (1 : 2) Intermediate-Conductivity Compounds. The counter cations of these compounds, such as methyltriphenylphosphonium (Ph_3PCH_3) or methyltriphenylarsonium (Ph_3AsCH_3), usually have a nearly spherical form and a relatively large size. These salts are obtained in the form of well-developed blue-black crystals. They have conductivities of the order of $10^{-2}\,\Omega^{-1}\,cm^{-1}$ or less, and activation energies as high as 0.3 eV.[3,4] In the following paragraphs, the results of some representative samples will be discussed in detail.

(Ph_3XCH_3)$^+$(TCNQ)$_2^-$ (X=P or As). These salts have almost identical electronic properties except for the occurrence of a phase transition in the phosphonium salt at 40°C.*2 The crystal structures of these salts have not yet been ascertained. The absorption spectrum of the phosphonium salt in acetonitrile and its crystalline spectrum are given

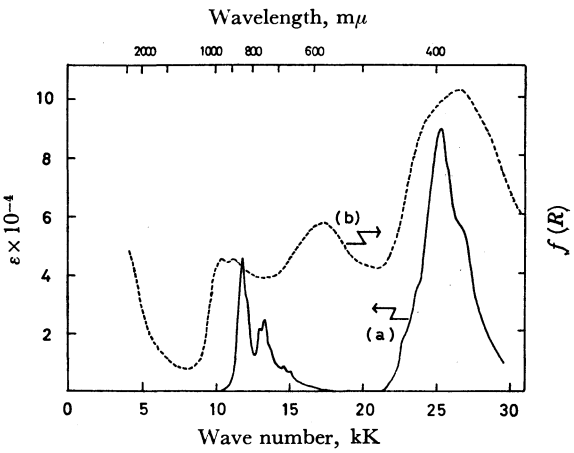

Fig. 2. Electronic spectra of $(Ph_3PCH_3)^+(TCNQ)_2^-$ in acetonitrile solution (a) and in the solid state (b).

*2 In the phosphonium salt, a phase transition occurs at 40°C, where an abrupt and reversible change in ESR intensity and electrical conductivity has been observed. The measurement of the thermal analysis has also been carried out. See Y. Iida, M. Kinoshita, M. Sano and H. Akamatu, This Bulletin, **37**, 428 (1964); Y. Iida, M. Kinoshita, A. Kawamori and K. Suzuki, *ibid.*, **37**, 764 (1964).

in Fig. 2 by curve a and curve b respectively. Quite similar electronic spectra in acetonitrile and in the solid state were obtained in the arsonium salt. The crystalline spectrum of the phosphonium or the arsonium salt, on the other hand, bears no resemblance to the dimer spectrum, consisting of peaks at 10.4, 11.4, 17.2, and 26.3 kK, and an intense band with its peak in the region less than 4 kK. Although the locations of the bands at 17.2 and 26.3 kK nearly correspond to those at 15.6 and 27.0 kK respectively in the dimer,[10] the band at 26.3 kK should comprise not only that due to the dimer but also that due to neutral TCNQ, because the band at 26.3 kK has an appreciably larger intensity than that at 17.2 kK and even has its shoulder around 24 kK. There has been no contribution of the band due to TCNQ in the (2 : 3) salts. The pair-by-pair interaction as to the unpaired electrons in the phosphonium or the arsonium salt is decreased compared to that in the (2 : 3) salts, but it still remains, because the peak at 17.2 kK almost certainly to be ascribed to the dimer spectrum[10] is relatively diffused and continuously overlaps with other bands. The decrease is probably caused by the presence of more TCNQ in the (1 : 2) salt than in the (2 : 3) salt. Whether the doublet bands at 10.4 and 11.4 kK are due to two different electronic transitions or to one with vibrational structures is not clear. Furthermore, it is difficult to decide whether they are shifted bands of the $TCNQ^-$ monomer or charge-transfer bands between $TCNQ^-$ molecules. However, it can be said that, although the charge-transfer band is expected to appear around 10 kK, the band splitting may make the latter possibility improbable. On the other hand, the location of the band peak in the range less than 4 kK was not determined by the diffuse reflectance spectrum. Therefore, we examined the infrared absorption spectrum, which indicates that this intense electronic band partially screens the vibrational spectrum and has its peak around 2.9—3.3 kK. It is not clear whether this band is to be ascribed to the charge-transfer band between $TCNQ^-$ and TCNQ, or to the direct transition from the valence state to the electrical conduction state. Possible support for the former possibility is that similar low-energy bands, although weak in intensity, have been observed in the (2 : 3) salts and that, here, they are remarkably increased in intensity by the further introduction of TCNQ. However, they appear in the compounds with relatively high electrical conductivities. Therefore, we believe that they are closely correlated with their high conductivities.

The paramagnetism of the phosphonium or the arsonium salt is based on a triplet-exciton state lying 0.062 eV above the singlet state.[6] Therefore, the mode of interaction among the ion radicals is certainly by pairs. However, the delocalization of the triplet exciton in these salts is increased (*i. e.*, there is an increase in the triplet-exciton band width) and its singlet-triplet energy separation is decreased, compared with the values in the Cs salt.[12] This change can probably be said to be caused, by an extension of the reason mentioned above for the Cs salt, by the presence of the additional TCNQ. However, in these (1 : 2) salts, the presence of this TCNQ still appreciably modifies the crystalline electronic spectrum with a pair-by-pair character. Such was not the case with the (2 : 3) salts, where the change is relatively slight. Furthermore, the presence of neutral TCNQ in the (1 : 2) salts causes a remarkable increase in the electrical conductivity. For example, the complex phosphonium salt has $2\times10^{-2}\ \Omega^{-1}\,cm^{-1}$ at 23°C (single-crystal measurement), a value which is markedly larger than the 2×10^{-11} of the simple salt with the same cation.[4] The former should also be compared with the 1×10^{-3} value of the complex Cs salt (single-crystal measurement),[4] where, on the contrary, the effect has been regarded as weak.

It may be concluded that, in the phosphonium or the arsonium salt, the perturbation due to the introduction of TCNQ is relatively strong. Nonetheless, one can still picture the TCNQ molecules as existing in unique groups of four (*i. e.*, two $TCNQ^-$ and two TCNQ molecules) along a one-dimensional column in the solid state.

The Other Compounds. All of the other compounds belonging to this group bear, more or less, an optical resemblance to those of the phosphonium or the arsonium salt. The band peaks of their crystalline spectra are designated as shown in Fig. 3, which also gives an example of the spectrum of

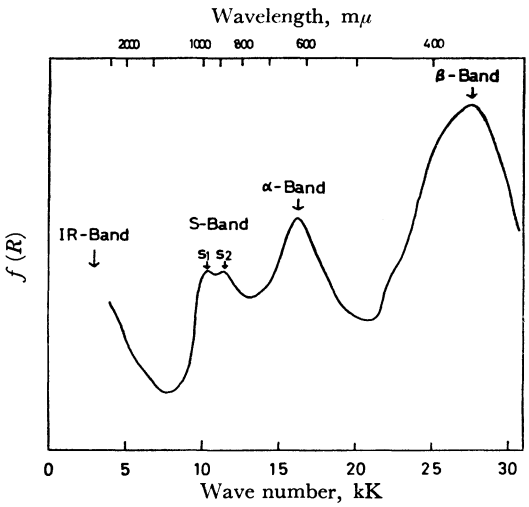

Fig. 3. Electronic spectrum of Triethylammonium$^+$-$(TCNQ)_2^-$ in the solid state, together with the designation of its band peaks.

the triethylammonium salt. The features of the low-energy band (IR-band), the splitting (~1 kK) of the doublet S_1- and S_2-bands, and the rather sharp α-band relative to the (1 : 2) high-conductivity compounds (see below) should be noted. The locations of the IR-bands in these intermediate-conductivity compounds are estimated to be in the same range as in the phosphonium salt (*i. e.*, 2.9—3.3 kK). The other peaks are listed in Table 1. Evidently, the corresponding band peaks are

shifted slightly by the change in the cations; on this change, however, depends the sharpness of the α-bands related to the degree of pair-by-pair interaction of ion radicals. The triethylammonium salt is found to have an especially sharp and strong α-band, exhibiting, on the other hand, magnetic properties based on a triplet exciton.*3

In all events, in the (1 : 2) intermediate-conductivity compounds, the pair-by-pair interaction of ion radicals is relatively decreased by the further introduction of TCNQ. However, we believe that that interaction mode will still not be changed.

The (1:2) High-Conductivity Compounds. The counter cations of these compounds are aromatic or heterocyclic cations such as quinolinium. These compounds come out of the solution in the form of small blue-black needles. The quinolinium salt, for example, exhibits an electrical conductivity as high as 100 Ω^{-1} cm^{-1} and an activation energy as low as 0.03 eV (single-crystal measurement).[4] In the following paragraphs, the results of the crystalline spectra in some representative samples will be discussed in detail.

Quinolinium$^+(TCNQ)_2^-$. The crystal structure of this salt has not yet been ascertained. The absorption spectrum in acetonitrile, shown by curve a of Fig. 4, is essentially the same as those of the (1 : 2) intermediate-conductivity compounds. Al-

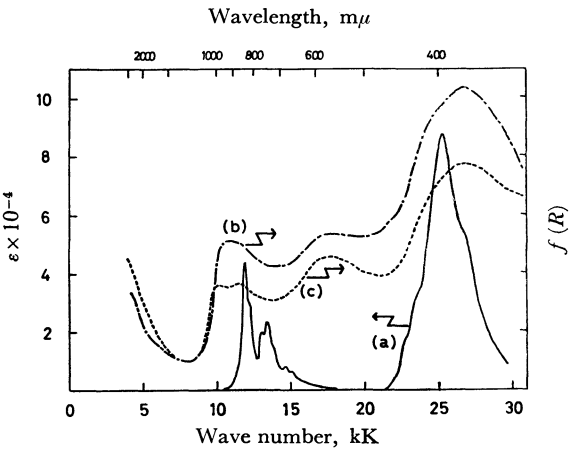

Fig. 4. Electronic spectra of Quinolinium$^+$ $(TCNQ)_2^-$ in acetonitrile solution (a), Quinolinium$^+$ $(TCNQ)_2^-$ in the solid state (b) and *N*-(*n*-Propyl)quinolinium$^+$ $(TCNQ)_2^-$ in the solid state (c).

though the crystalline spectrum illustrated by curve b of Fig. 4 bears a rough resemblance to those of the intermediate-conductivity compounds, some differences may be noted. The crystalline spectrum of the quinolinium salt has peaks at 10.5, 17.4, and 26.7 kK, and an intense band with its peak in the range less than 4 kK. The last band peak was not determined by means of the diffuse reflectance, so we have also examined the absorption spectrum, which shows, in this case, that the vibrational spectrum is completely screened by this intense electronic transition. The location of the peak is thus estimated to be around 2.0—2.5 kK. This band may be connected with that observed in the far infrared region by Kondow *et al.*[13] It should also be mentioned that this band is not exactly the same as the IR-band in the intermediate-conductivity compounds, which is around 2.9—3.3 kK. In connection with the contrast of their conductivities, this difference in their lowest-energy bands implies a difference in the interaction modes of unpaired electrons between high- and intermediate-conductivity compounds (see below). Furthermore, there is reason to believe that these bands in both the groups may arise from a transition from the valence band to the electrical conduction band.[13]

*3 In explaining the temperature dependence of the magnetic susceptibility of the triethylammonium salt, Soos and Hughes' theory (see Ref. 12) has supported the model of a weakly alternating antiferromagnet rather than that of almost isolated triplets. However, in the crystalline spectrum presented here, the especially sharp and strong α-band may imply a strongly pair-by-pair interaction of ion radicals in this salt.

TABLE 2. THE DATA FOR THE BAND PEAKS EXCEPT THE LOWEST-ENERGY BAND IN THE CRYSTALLINE ELECTRONIC SPECTRA OF THE (1 : 2) HIGH-CONDUCTIVITY TCNQ COMPLEX SALTS. THE DESIGNATION OF THE BANDS NEARLY CORRESPONDS TO THAT IN Fig. 3

Cation	S-Band (kK)		α-Band (kK)	β-Band (kK)

The quinolinium salt has one band, around 10.5 kK, corresponding to the S_1- and S_2-bands in the intermediate-conductivity compounds. Usually, the spectra of the compounds with high conductivities are found to comprise one band with no such splitting, whereas the splitting tends to appear with a decrease in the conductivity. Accordingly, the nature of the band at 10.5 kK depends on its conductivity. However, its origin is not clear. The band at 17.4 kK, probably related to the pair-by-pair interaction of ion radicals, is more diffused than the α-band in the intermediate-conductivity compounds and is remarkably overlapped with other bands. These findings imply that the pair-by-pair interaction would almost vanish in the quinolinium salt. On the other hand, the band around 26.7 kK rather resembles the β-band in the intermediate-conductivity compounds. These observations provide us with some reasons for the more-than-pair-by-pair interaction of ion radicals in this salt. As in the cases with some TCNQ salts,[7,9,14,15] the TCNQ molecules in the quinolinium salt should form a one-dimensional column, so each unpaired electron should interact equally and strongly with two neighbors. In this respect, the (1 : 2) high-conductivity compounds are different from the (1 : 2) intermediate-conductivity compounds. The more-than-pair-by-pair interaction of the ion radicals in the quinolinium salt causes the delocalization of the unpaired electrons, which, in turn, brings about its high electrical conductivity and the low activation energy. Also, in this case, the presence of neutral TCNQ makes some contribution to the delocalization. The mode of the interaction is, except for the exclusion of the neutral molecules, similar to those of some Würster's salts with a more-than-pair-by-pair and strong interaction[1] or that of the high-conductivity TCNQ simple salt of *N*-methylphenazinium.[2] In view of these facts, we believe that the magnetic property of the quinolinium salt with an almost temperature-independent paramagnetism ($\chi = 4.3 \pm 0.2 \times 10^{-7}$ emu/g)[5] may be based on a non-alternating linear chain antiferromagnet. However, we hesitate to accept the idea of a complete Heisenberg antiferromagnet because of the delocalization of the unpaired electrons.

The Other Compounds. All the other compounds belonging to this group show crystalline spectra essentially like that of the quinolinium salt. However, it is noteworthy that a splitting of the doublet bands around 10 kK appears, and that the sharpness of the band around 17 kK is increased, with a decrease in their electrical conductivities. The band peaks of their crystalline spectra, nearly corresponding to S-, α-, and β-bands in the intermediate-conductivity compounds, are listed in Table 2. The spectrum of the *N*-(*n*-propyl)quinolinium salt, as an example, is illustrated by curve c of Fig. 4. The decrease in the conductivities depends largely on the size and the shape of the cations. For example, the introduction of a substituent as bulky as *n*-propyl to the quinolinium cation decreases 100 Ω^{-1} cm^{-1} at 23°C of the quinolinium salt[4] to 2 of the *N*-(*n*-propyl)quinolinium salt.[3] Therefore, the introduction of bulky substituents to the flat cations (*e. g.*, aromatic or heterocyclic) leads to intermediate conductivities,

and the doublet bands around 10 kK and a rather sharp and strong α-band come to be clearly observed. Accordingly, it may be concluded that those introductions of substituents contribute, to varying degrees, to the change of the more-than-pair-by-pair interaction of ion radicals into the pair-by-pair interaction. It is expected that this change in the interaction modes will greatly affect their magnetic properties, again producing triplet excitons.

The author wishes to express his thanks to Professor Yoshio Matsunaga for his generous support to this work and to Mr. Nobuhiko Miyajima for his technical assistance.

The Etherification Reactions of Allyl Alcohol Catalyzed by the Copper(I) Chloride Complex*1

Tetsuya OGURA, Nobuo FURUNO*2 and Shinichi KAWAGUCHI

Department of Chemistry, Faculty of Science, Osaka City University, Sumiyoshi-ku, Osaka

(Received July 17, 1968)

Diallyl ether was produced exclusively when an allyl alcohol solution containing copper(I) chloride and ammonium chloride was heated in the absence of air. A mixture of allyl and ethyl alcohols gave diallyl and ethyl allyl ethers, but no trace of diethyl ether. The tracer experiment employing ^{18}O-enriched allyl alcohol showed that the C–O bond in allyl alcohol was ruptured in the ethyl allyl ether formation. The kinetic study of these etherification reactions showed that the rate determining step would include the nucleophilic attack of an allyl or ethyl alcohol molecule on the catalyst-substrate complex. A novel allyl alcohol complex, $(NH_4)_2Cu_2Cl_4(C_3H_6O)_2$, was isolated and characterized, but the active catalyst species was assumed to be $(NH_4)_2Cu_4Cl_6$. Methyl derivatives of allyl alcohol were also allowed to react in the presence of the same catalyst and the possible mechanism of etherification was discussed.

Copper(I) chloride was found by Berthelot[1] to enhance the solubilities of olefins such as ethylene and propylene in aqueous solutions. This fact suggests the specific interaction between copper(I) and the olefinic double bond. Gilliland *et al.*[2] succeeded later in synthesizing these complexes under pressure of olefins.

In our laboratory syntheses and reactions of metal complexes of substituted olefins have been studied, and crystalline complexes of copper(I) chloride with acrolein,[3] allyl alcohol[4] and allylamine[5] were prepared by direct reactions. This paper reports the catalytic action of copper(I) chloride complex for the etherification reactions of allyl alcohol, and a possible reaction mechanism is presented based on the kinetic and tracer experiments.

Experimental

Materials. Copper(II) chloride dihydrate was mixed with excess copper powder and heated to 110°C under reduced pressure. After the dehydration, the mixture was heated to 500°C resulting in liquid copper(I) chloride, which was cooled to room temperature. The crude product was crushed and purified by distillation at 500°C *in vacuo*. The highly pure specimens of copper(I) chloride for the kinetic experiments were prepared by distilling more than three times. Ammonium chloride of analytical grade was further purified by sublimation. Allyl alcohol was dried with molecular sieves, Type 3A (Linde Co.) and distilled through a 30 cm Widmer column. Commercial methylallyl alcohols were used

without further purification. Ethyl alcohol was dried employing magnesium ribbon.

Stoichiometry Determination of the Etherification Reactions. Into an ampoule containing 0.1—1 g of copper(I) chloride and 0.05—0.5 g of ammonium chloride was distilled 5 g of allyl alcohol or a mixture of allyl and ethyl alcohols *in vacuo*. The ampoule was sealed off, put into an autoclave together with water whose vapor pressure is very similar to that of allyl alcohol, and heated to 160—180°C.

Volatile reaction products were collected in a trap by vacuum distillation and separated by vapor phase chromatography (abbreviated as VPC) using a 1 m column packed with 30% triethanolamine on Chamelite CS of Kishida Chemicals, Ltd. (60°C, H_2 flow of 80 m*l*/min). The water content was determined by the Karl Fischer method.

Preparation and Reaction of Allyl Alcohol Enriched with ^{18}O. Twenty five grams of silver perchlorate was dissolved in 20 m*l* of ^{18}O-enriched (2%) water, to which 8 g of allyl chloride was added gradually under vigorous agitation in an ice bath. An exothermic reaction occurred separating out silver chloride. In order to neutralize perchloric acid produced, sodium hydrogen carbonate was added occasionally until yellow silver carbonate began to appear. The reaction mixture was kept standing for two days at room temperature. Volatile products were collected by distillation under reduced pressure and dried with anhydrous copper(II) sulfate. Allyl alcohol was separated from the by-product, diallyl ether, by means of VPC.

A mixture of labeled allyl alcohol (0.4 g), unlabeled ethyl alcohol (1.6 g), copper(I) chloride (0.05 g) and ammonium chloride (0.02 g) was allowed to react in an ampoule at 160—180°C. Calcium chloride was added to the product mixture to separate the ether layer. Ethyl allyl ether was fractionated through the VPC column and submitted to the mass spectrometric analysis.

Kinetic Studies. Since the reaction system containing copper(I) chloride is very sensitive to air, the whole procedure was performed under rigorous exclusion of air. A desired number of ampoules containing a reaction mixture of the same composition were prepared using the apparatus depicted in Fig. 1. The reaction mixture (30—40 m*l*) was made up by vacuum distillation of allyl alcohol into a large ampoule (A) containing a mixture of copper(I) chloride and ammonium chloride. The ampoule (A) was attached to the vacuum line in an inverse fashion. A small portion (about 2 m*l*) of the solution was transfered to each small ampoule (C) evacuated in advance through the tap (B). The ampoule (C) was then fused off at D. Many ampoules thus prepared were immersed in a liquid paraffin bath and maintained at a constant temperature between 120—180°C. Each ampoule was picked up at appropriate time intervals and quenched. The extent of reaction was determined by measuring the water content by means of the Karl Fischer method.

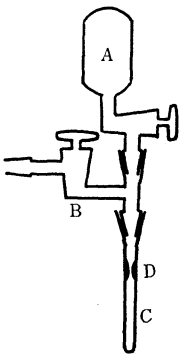

Fig. 1. The apparatus for preparing ampoules containing the reaction mixture of the same composition.

When a mixture of allyl and ethyl alcohols was allowed to react in the presence of copper(I) chloride and ammonium chloride, the produced ethers were separated through the VPC column. Diallyl and ethyl allyl ethers were identified, but no trace of diethyl ether was found. Preliminary calibration experiments revealed that the mole ratios of diallyl ether to allyl alcohol and ethyl allyl ether to ethyl alcohol in their mixture are proportional in the region below 0.05 to the respective peak height ratios on a vapor phase chromatogram (Fig. 2.) Many ampoules containing allyl and ethyl alcohols in various ratios together with copper(I) chloride and ammonium chloride were kept at a constant temperature of 148.1°C. The reaction was quenched at 0.01—2% conversion in either case, and amounts of diallyl and ethyl allyl ethers were determined by means of Fig. 2.

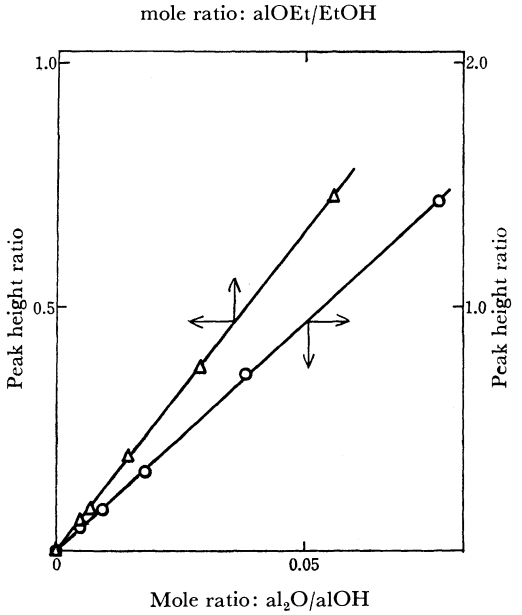

Fig. 2. Calibration lines between the mole ratio and the peak height ratio on a gas chromatogram of diallyl ether to allyl alcohol and ethyl allyl ether to ethyl alcohol.

Etherification of α-, β- and γ-Methylallyl Alcohols. To promote the elucidation of the reaction mechanism, the etherification reaction of substituted allyl alcohols were performed and the products distribution was measured in each case. In 3 m*l* of a methylallyl alcohol, 30 mg of copper(I) chloride and 10 mg of

ammonium chloride were dissolved and allowed to react at 92°C for 2.5—16 hr to attain 1—7% conversion. Reaction products were fractionated through a VPC column containing polyethylene glycol (1 m) and triethanolamine (1 m) at 96°C using hydrogen gas flow of 40 ml/min. The nature of each fraction was identified by means of its infrared and proton magnetic resonance spectra. Table 1 summarizes reaction products from each methylallyl alcohol and their relative rates of formation.

Table 1. Reaction products from methyl-substituted allyl alcohols in the presence of copper(I) chloride catalyst*

Substrate	Products	Relative rates of formation
α OH	γ OH	< 0.1
	α ₂O	1.2
	α O γ	1
β OH	β ₂O	1
γ OH	α OH	1
	α O γ	1
	γ ₂O	~0.03

* α, β and γ denote α-methylallyl (CH_2=CH–CH(CH_3)–), β-methylallyl (CH_2=C(CH_3)–CH_2–) and γ-methylallyl (CH(CH_3)=CH–CH_2–) radicals, raspectively.

Synthesis of the Crystalline Complex $(NH_4)_2Cu_2Cl_4(C_3H_6O)_2$. An allyl alcohol solution (30 ml) containing copper(I) chloride (0.531 g, 5.36 mmol) and ammonium chloride (0.287 g, 5.37 mmol) was heated at 80°C for 3 hr, and most of excess alcohol was distilled off. White crystals resulted were dried completely by distillation of the remaining solvent *in vacuo* at the temperature difference between 5 and 0°C for 3 days.

Found: Cu, 29.9; Cl, 33.4; C_3H_6O, 28.2%; Calcd for $(NH_4)_2Cu_2Cl_4(C_3H_6O)_2$: Cu, 30.1; Cl, 33.6; C_3H_6O, 27.6%.

Measurements. Copper was determined by the electrolysis, chloride gravimetrically as the silver salt, and allyl alcohol by the brominating method.[4] The infrared spectra were measured in Nujol with a Hitachi infrared spectrophotometer EPI-2, and NMR spectra with a 60 MC spectrophotometer, model JNM 3H60 of Japan Electron Optics Laboratory, Ltd. The mass analysis was performed with a Hitachi mass spectrometer RMU-6.

Results

The Stoichiometry of Diallyl Ether Formation. When allyl alcohol containing copper(I) chloride and ammonium chloride was heated for several hours at 160—180°C, the mixture separated into two liquid layers. The upper layer consisted of dially ether containing a small amount of copper(I) chloride, and the lower aqueous layer included copper(I) chloride, ammonium chloride and remaining allyl alcohol. In an experiment at 180°C for 24 hr, 93% of allyl alcohol employed (90.2 mmol) was converted to diallyl ether (42.1 mmol) and water (42.0 mmol), and no side reaction occurred. The mass balance can thus be represented by Eq. (1).

$$2CH_2{=}CH{-}CH_2OH \longrightarrow (CH_2{=}CH{-}CH_2)_2O + H_2O \quad (1)$$

When allyl alcohol containing highly pure copper(I) chloride alone was heated under the same conditions, no allyl ether was produced. Ammonium chloride alone does not work either. The effective catalyst must be composed of copper(I) chloride and a certain amount of chloride ions since calcium chloride works as well as ammonium chloride and lithium chloride is also effective though to a lesser extent. Silver perchlorate and nitrate were examined. Diallyl ether was produced in these cases, too, but some side reactions also proceeded depositing metallic silver.

Kinetics of the Diallyl Ether Formation. With any catalyst composition a first order linear plot was obtained before the extent of reaction attained to 25% (Fig. 3). The reaction rate is

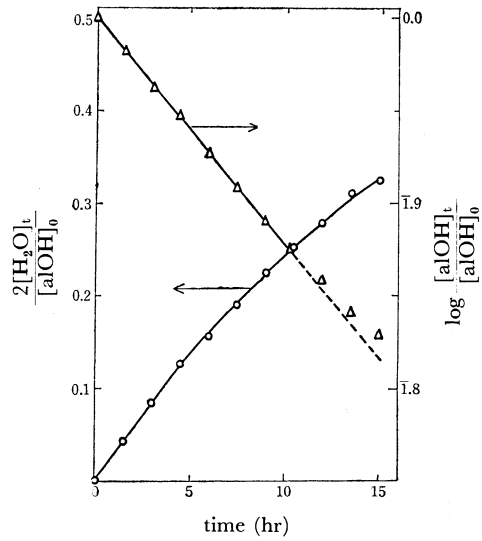

Fig. 3. The pseudo first order plot of the etherification reaction of allyl alcohol at 144.8°C. $[Cu_2Cl_2]_0$=0.0630, $[NH_4Cl]_0$=0.0581 mol/kg solvent

thus represented by Eq. (2). At a higher extent of the reaction the mixture separated into two layers

$$\frac{d[H_2O]}{dt} = -\frac{1}{2}\frac{d[C_3H_5OH]}{dt} = k_1[C_3H_5OH] \quad (2)$$

and the first order rate law did not hold any more.

The pseudo first order rate constant k_1 changed with concentrations of both copper(I) chloride and ammonium chloride. When the concentration of ammonium chloride was kept constant and that

of copper(I) chloride increased, the recation rate increased linearly as shown in Fig. 4. It should be noticed that the straight line intersects the abscissa. On the other hand the dependence of k_1 upon the concentration of ammonium chloride was rather complicated as illustrated in Fig. 5. A maximum appeared at a concentration of ammonium chloride about half that of copper(I) chloride in the monomer unit.

Adduct Formation of Copper(I) Chloride with Ammonium Chloride in Allyl Alcohol. The solubility of copper(I) chloride in water is very low, but is much enhanced by the coexistence of ammonium chloride and the formation of adducts, $CuCl \cdot NH_4Cl$ and $2CuCl \cdot NH_4Cl$ was reported.[6] On the other hand the solubility of ammonium chloride in allyl alcohol is very low (0.246 g in 100 g solvent at 20°C), but is enhanced by the presence of copper(I) chloride. For instance 0.685 g of ammonium chloride dissolves in 100 g of allyl alcohol at 10°C containing 1.26 g of copper(I) chloride. The mole ratio of the two solutes is close to unity suggesting the formation of 1 : 1 adduct in allyl alcohol.

The state of aggregation of copper(I) chloride by itself and also in the coexistence of ammonium chloride was investigated by measuring the boiling point elevation of allyl alcohol in nitrogen atmosphere with the modified Cotrell apparatus.[7] The molal elevation constant of boiling point of allyl alcohol was determined to be 1.615°C employing naphthalene as a reference solute. (Value of the constant calculated using 10.1 kcal/mol as the molar heat of vaporization[8] is 1.57°C.) Table 2 summarizes the results obtained. In each case the molality of solution found is nearly half of that employed, revealing that copper(I) chloride exists as a dimer in boiling allyl alcohol.[9] It should be noticed that

TABLE 2. DEGREE OF DIMERIZATION OF COPPER(I) CHLORIDE IN ALLYL ALCOHOL IN THE ABSENCE AND PRESENCE OF AMMONIUM CHLORIDE DETERMINED BY THE BOILING POINT ELEVATION

9) The report in a previous paper (Ref. 4) that copper(I) chloride exists as a monomer in boiling allyl alcohol was in error.

the degree of dimerization of copper(I) chloride is not affected by the presence of ammonium chloride up to the equimolar amount. This fact indicates that the equilibrium constant of the adduct formation (Eq. (3)) is very large and also that this adduct is not ionized appreciably in boiling allyl alcohol.

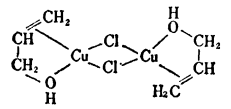
$$Cu_2Cl_2 \cdot xC_3H_6O + 2NH_4Cl \rightleftarrows (NH_4)_2Cu_2Cl_4 \cdot xC_3H_6O \quad (3)$$

The crystalline adduct $(NH_4)_2Cu_2Cl_4 \cdot (C_3H_6O)_2$ was in fact isolated as described in the Experimental Section. The characteristic infrared absorption bands of this complex are listed in Table 3 together

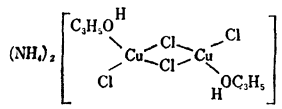
Table 3. Characteristic infrared absorption bands in Nujol (cm^{-1})

$(NH_4)_2Cu_2Cl_4 \cdot (C_3H_6O)_2$	1630	1010	~3400	1700
$Cu_2Cl_2 \cdot (C_3H_6O)_2$	1550	1015	3340	——
C_3H_6O	1645	1030	3340	——
Assignment	ν(C=C)	ν(C–O)	ν(O–H)	$\delta(NH_4)$

with those for dimeric copper(I) chloride complex with allyl alcohol.[4] In the latter complex coordination of the double bond of allyl alcohol is evidenced by the large shift of C=C stretching frequency to the lower frequency side. The coordination of OH group was also concluded by a slight shift of C–O stretching frequency in comparison with the allyl alcohol complex of calcium chloride,[4] and the dimeric structure of I was assigned to this complex. On the other hand the infrared absorption data in Table 3 indicate that in the present complex containing ammonium chloride, allyl alcohol is linked to copper as a unidentate ligand solely *via* the oxygen atom as shown by II.



I



II

In the aqueous solution of copper(I) chloride together with ammonium chloride, the water molecule may take the position of allyl alcohol, and the reported complex[10] $KCuCl_2 \cdot H_2O$ may be considered to have a dimeric structure like II.

Etherification Reactions in the Mixture of Allyl and Ethyl Alcohols. The rates of formation of diallyl and ethyl allyl ethers were calculated assuming the pseudo first order kinetics, and data thus obtained were plotted against each alcohol concentration. Straight lines were obtained as shown in Fig. 6 indicating that these reactions obey the following rate equations:

$$\frac{d[al_2O]}{dt} = k_1[alOH] = (k_a'[Cu_2Cl_2]_0[NH_4Cl]_0)\,[alOH] \quad (4)$$

$$\frac{d[EtOal]}{dt} = k_2[EtOH] = (k_e'[Cu_2Cl_2]_0[NH_4Cl]_0)\,[EtOH] \quad (5)$$

Here alOH denotes allyl alcohol. Figure 6 also indicates that the rate of formation of ethyl allyl ether is somewhat larger than that of diallyl ether: $k'_a = 17.9$, $k'_e = 29.2$ (kg·solvent)^2/mol^2·hr.

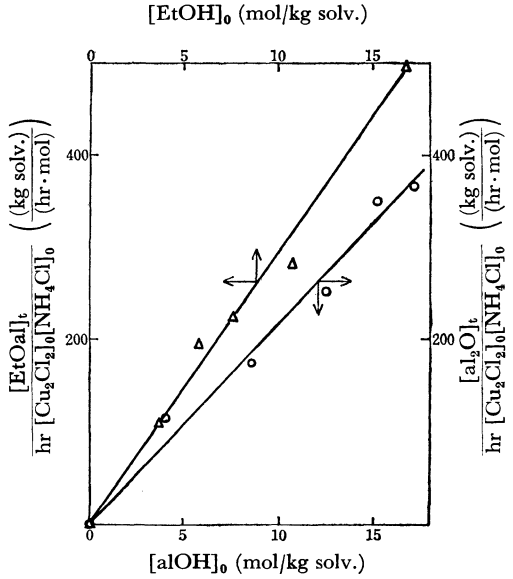


Fig. 6. Dependences of rates of diallyl and ethyl allyl ether formations upon the composition of mixtures of allyl and ethyl alcohols at 148.1°C.

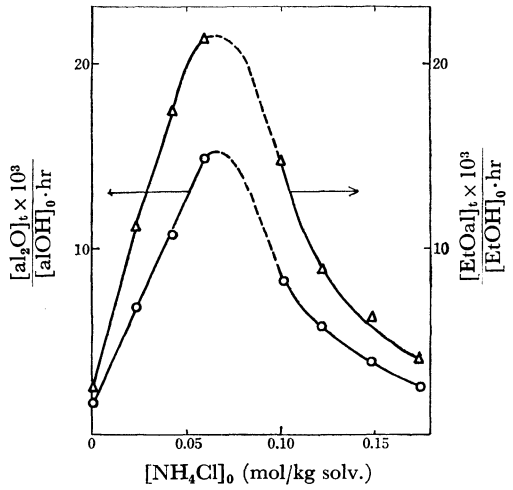

Fig. 7. Dependences of the pseudo first order rate constants of diallyl and ethyl allyl ether formations upon the concentration of ammonium chloride at 148.1°C.
$[Cu_2Cl_2]_0 = 0.0654$ mol/kg solvent

10) J. J. P. Valeton and W. Frömel, *Z. anorg. u. allg. Chem.*, **137**, 91 (1924).

Data plotted in Fig. 6 were obtained in the region of low concentrations of ammonium chloride, and Eqs. (4) and (5) hold only at these conditions. If the concentration of copper(I) chloride is kept constant and that of ammonium chloride is changed, the pseudo first order rate constants k_1 and k_2 change in the fashion shown in Fig. 7. Again, maximum rates are attained when the concentration of ammonium chloride is about half as large as that of copper(I) chloride in the monomer unit. These are the same features as that observed in the case of allyl alcohol alone (Fig. 5).

Tracer Experiments. In the etherification reaction between allyl and ethyl alcohols one molecule of water is eliminated. In order to elucidate the reaction mechanism, it is very important to find out from which alcohol the oxygen atom of water molecule originates. Allyl alcohol containing 1.83 atom % of ^{18}O was allowed to react with natural ethyl alcohol and ethyl allyl ether produced was submitted to the mass analysis. If the ether molecule has oxygen atom from allyl alcohol, the peak height ratio of mass 88 to mass 86 should be 18.8×10^{-3}. On the other hand if the oxygen atom in the ether molecule originated from ethyl alcohol, the ratio is expected to be 4.5×10^{-3}. Natural isotopic abundances of carbon, hydrogen and oxygen were taken into account in these calculations. Ethyl allyl ether produced in the reaction between natural allyl and ethyl alcohols showed the value of 4.4×10^{-3} as this ratio. The reaction product from the ^{18}O-enriched allyl alcohol and natural ethyl alcohol gave the ratio value of 4.6×10^{-3}, clearly indicating the following reaction.

$$C_3H_5{}^{18}OH + C_2H_5OH = C_3H_5OC_2H_5 + H_2{}^{18}O \quad (6)$$

Discussion

Effective Catalyst Species. It should be concluded that the complex I does not catalyze the reaction since highly pure copper(I) chloride alone was found to be ineffective. The points lying on the ordinates in Figs. 5 and 7 were brought about by copper(I) chloride which had been exposed to air for a while. Partial oxidation of copper(I) might have occurred resulting in a a mixture of copper(II) chloride and oxide playing a role of the chloride source. Figures 5 and 7 suggest that the most effective catalyst may have the composition of $Cu_2Cl_2\cdot NH_4Cl$. In Fig. 5 an appreciable activity is observed at the catalyst composition of $Cu_2Cl_2\cdot 2NH_4Cl$. This may be due either to the true activity of the complex II, or to a small amount of the above catalyst $Cu_2Cl_2\cdot NH_4Cl$ existing in equilibrium with the ineffective complex II. The rate profiles of diallyl ether formation in Figs. 5 and 7 were determined at different conditions, but calculations utilizing the dependences of rate upon temperature and the catalyst composition show that the maximum rates are nearly equal in both cases, indicating absence of the appreciable solvent effect upon the rate process. On the other hand, the rate of diallyl ether formation at the catalyst composition of $Cu_2Cl_2\cdot 2NH_4Cl$ in a mixture of allyl and ethyl alcohols (Fig. 7) is much lower than that at the corresponding conditions in allyl alcohol alone (Fig. 5). This fact might suggest that the complex II may not be appreciably effective, but the equilibrium forming the true catalyst $Cu_2Cl_2\cdot NH_4Cl$ may be unfavorable in the mixed solvent.

Now we assume that the following two equilibria are attained in allyl alcohol or in a mixture of allyl and ethyl alcohols.

$$Cu_2Cl_2 + 2NH_4Cl \overset{K_1}{\rightleftarrows} (NH_4)_2Cu_2Cl_4 \quad (7)$$

$$(NH_4)_2Cu_2Cl_4 + Cu_2Cl_2 \overset{K_2}{\rightleftarrows} (NH_4)_2Cu_4Cl_6 \quad (8)$$

Allyl alcohol molecules in the coordination sphere of copper(I) are omitted in these formulas. Equilibrium quotients are represented by

$$K_1 = \frac{y}{(a-2x-y)(b-2x-2y)^2} \quad (9)$$

$$K_2 = \frac{x}{y(a-2x-y)} \quad (10)$$

where $a=[Cu_2Cl_2]_0$, $b=[NH_4Cl]_0$, $x=[(NH_4)_2Cu_4Cl_6]$, and $y=[(NH_4)_2Cu_2Cl_4]$. If the active catalyst species is presumed to be $(NH_4)_2Cu_4Cl_6$, that is

$$k_1 = k_a x \quad (11)$$

the optimum activity should be shown when the maximum value of x is attained at appropriate b. Differentiating Eq. (10) with b,

$$\left(\frac{1}{K_2}+2y\right)\frac{dx}{db} = (a-2x-2y)\frac{dy}{db}$$

Here $dy/db\neq0$ and the maximum of x is realized when

$$a - 2x - 2y = 0 \quad (12)$$

From Eqs. (9) and (12)

$$|a-b| = \frac{1}{\sqrt{K_1}} \quad (13)$$

As is evidenced by the data in Table 2 and the fact that the complex $(NH_4)_2Cu_2Cl_4(C_3H_6O)_2$ was isolated as crystals, K_1 must be very large and hence Eq. (13) indicates that the maximum rate will be observed at $[NH_4Cl]_0$ near $[Cu_2Cl_2]_0$. This feature was in fact observed in Figs. 5 and 7.

From Eqs. (10) and (11)

$$k_1 = k_a K_2 y(a-2x-y)$$

If $K_1 \gg 1$, then $y \fallingdotseq b/2$ and if $K_2 \ll 1$, then $a-y \gg 2x$, and hence

$$k_1 \fallingdotseq k_a K_2 \frac{b}{2}\left(a-\frac{b}{2}\right)$$
$$= k_a K_2([NH_4Cl]_0/2)([Cu_2Cl_2]_0-[NH_4Cl]_0/2) \quad (14)$$

This relation is reconciled with the observed results in Fig. 4. The straight line really intersects the abscissa at $[Cu_2Cl_2]_0 \fallingdotseq [NH_4Cl]_0/2$. When $[Cu_2Cl_2]_0 \gg [NH_4Cl]_0/2$ Eq. (14) may be approximated by Eq. (4). The facts that the formation of ethyl allyl ether shows a similar rate profile with respect to the ammonium chloride concentration (Fig. 7) and obeys a similar rate law (Eq. (5)) suggest that this reaction also is promoted by the same catalyst species and goes through the same pathways as the diallyl ether formation.

The temperature dependence of k_aK_2 was measured and the apparent activation energy of 19.9 kcal/mol was obtained from the Arrhenius plot in Fig. 8. However the activation energy referring

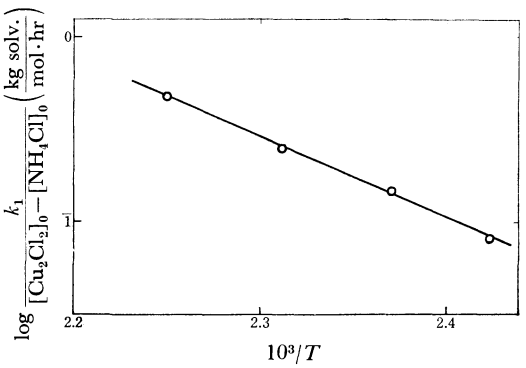

Fig. 8. The Arrhenius plot of the composite rate constant k_aK_2 (Eq. (14)) at a fixed concentration of ammonium chloride, 0.00916 mol/kg solvent.

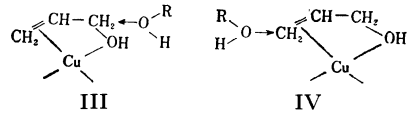
to k_a can not be determined since the heat of formation of the catalyst-substrate complex is unknown.

The effective substrate-catalyst complex here assumed, $(NH_4)_2Cu_4Cl_6 \cdot x(C_3H_6O)$ looks like a tetrameric species. Unfortunately this complex has not been isolated due to its low stability, or may be due to far larger stability of $(NH_4)_2Cu_2Cl_4(C_3H_6O)_2$. However, several examples of tetrameric copper(I) chloride complexes have been reported so far. Wilkins and Burkin[11] synthesized copper(I) halide complexes with long-chain aliphatic amines such as n-$C_{18}H_{37}NH_2$, n-$C_{12}H_{25}NH_2$ and n-$C_8H_{17}NH_2$. Monoamine complexes $CuX(RNH_2)$, where X=Cl, Br, I, were all tetrameric and substituted by pyridine to form $[CuXpy]_4$. The molecular weight of copper(I) chloride in diethylamine was determined by Clifton and Yoke to be tetrameric.[12] Furthermore the molecular structure of tetrameric copper(I) chloride complex of norbornadiene was determined with X-ray by Baenziger, Haight and Doyle to contain an eight-membered ring composed of copper and chlorine atoms.[13]

The reason is not clear at present why copper(I) chloride alone is not effective, but a little excess amount of chloride (Cu : Cl=2 : 3) is needed to realize the highest activity, and more excess amount of chloride is retarding. Chloride ions coordinated to copper(I) atom might modify the electronic state of the metal very delicately. Further comparative studies using fluoride, bromide or other ligands are needed.

Reaction Pathways. The etherification of alcohols is usually catalyzed by protonic acids and is believed to proceed *via* carbonium ions.[14] This view is supported by the fact that other Lewis acids such as zinc chloride, boron trifluoride and aluminum chloride also convert alcohols to ethers. However it is quite certain that the present copper(I) chloride catalyst is not playing the same role as these simple Lewis acids, but is activating the double bond mainly since diethyl ether was not produced at all. Tracer experiments employing ^{18}O-enriched allyl alcohol clarified that the C–O bond in allyl alcohol was ruptured in the etherification with ethyl alcohol. Furthermore the observed kinetics was interpreted to be first order with respect to the copper(I) complex of allyl alcohol and also first order concerning allyl or ethyl alcohol.

There still remain two possibilities whether the alkoxy group adds to the α-carbon III, or attacks the γ-carbon from the back side IV. In order to obtain a clue to this question allyl alcohol derivatives containing a methyl substituent at each carbon atom were used as substrates.



In the etherification of γ-methylallyl alcohol, α-methylallyl γ-methylallyl ether was produced exclusively, bis(γ-methylallyl) ether being a very minor product (Table 1). This result strongly supports the supposition that the nucleophilic attack of the alcohol molecule occurred on the γ-carbon accompanying migration of the double bond (S_N2') and cleavage of the C–O bond. On the contrary α-methylallyl alcohol produced both bis(α-allylmethyl) ether and α-methylallyl γ-methylallyl ether in nearly equal amounts.

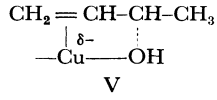
been studied very extensively.[15] The data on solvent effects indicate that the solvolysis of allyl chloride is closest to the bimolecular end of the mechanistic range, and that the mechanism shifts toward limiting S_N1 in the sequence $CH_2=CHCH_2Cl$, $CH_2=C(CH_3)CH_2Cl$, $CH_3CH=CHCH_2Cl$, $CH_3CHClCH=CH_2$, ------$(CH_3)_2CClCH=CH_2$. Thus, γ-methylallyl chloride is solvolyzed mainly *via* S_N2 path in ethanol resulting in γ-methylallyl alcohol in 91% yield. The electronic effect of γ-substituent is interpreted to greatly favor the normal S_N2 pathway. It is very interesting that quite the opposite result was obtained in the present etherification reaction. The ligation of the double bond to copper atom might decrease the electron density around γ-carbon so much as to favor the S_N2' pathway. The fact that the etherification of either methylallyl alcohol is about a hundred times faster than that of allyl alcohol suggests the specific character of the copper(I) catalysis.

In the case of allyl alcohol itself almost extreme S_N2' mechanism might be realized. The partial labeling of hydrogen atoms in allyl alcohol and NMR assays of the product ether will answer this question. On the other hand α-methylallyl chloride lies at the righthand side than γ-methylallyl chloride in the above mechanistic sequence from S_N2 to S_N1, and the products composition in Table 1 suggests that α-methylallyl alcohol may follow an intermediate mechanism between S_N2' and S_N1 and the polarized structure V of the copper complex may accept the nucleophilic atttack of the alcohol molecule on both α-and γ-carbon atoms.



V

The isomerization of methylallyl alcohol proceeds remarkably in the case of γ-methylallyl alcohol. The mechanism is not yet certain at all, but the trend agrees with the previous finding[15] that α-, β- and γ-methyl substituents on the allylic system increase the rate of isomerization of allylic alcohols by factors of 10^2, 10^1 and 10^3, respectively.

The authors are grateful to Professor Nobukazu Okazaki of the Nara Women's University for his kind gift of ^{18}O-enriched water. They also wish to thank Dr. Yoshio Hirose, Director of the Institute of Food Chemistry, for the mass spectrometric measurements.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 650—657 (1969)

Electron Spin Resonance Study of Radicals Formed by Abstracting Hydrogen from Amides*1

Teijiro YONEZAWA, Isao NODA and Takashi KAWAMURA

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received July 25, 1968)

Electron spin resonance (ESR) studies were made on various radicals formed from formamide, acetamide, *N*-methylformamide, *N*-methylacetamide, *N*,*N*-dimethylformamide and propionamide by hydrogen abstraction with hydroxyl radicals produced by the reaction of hydrogen peroxide and titanium trichloride in aqueous solution, using a rapid flow technique. In each case, except for formamide, various π-electron radicals were found. For formamide, *N*-methylformamide, and *N*,*N*-dimethylformamide, carbamoyl and its methyl substituted σ electron radicals were detected. The g factor of the σ electron radical is qualitatively discussed.

It is well known that acyl type radicals, thought to be σ electron radicals, are formed as intermediate species in radical reactions of aldehydes or formamides.[1] In the reaction of aldehydes with a hydroxyl radical in aqueous solution, the expected acyl type radicals were not detected with electron

*1 This work was presented at the Sixth Symposium on ESR Spectroscopy, Kyoto, Oct., 1967.

1) C. Walling, "Free Radicals in Solutions," John Wiley & Sons, Inc., N. Y. (1957).

spin resonance (ESR) spectroscopy. Buley and Norman[2] have proposed a reaction mechanism, in which the hydrated aldehyde R–CH$(OH)_2$ behaves as a reactant.[3] It is expected that acyl radicals will be observed when formamides, which barely exist in the form of hydrates NRR′–CH$(OH)_2$ in aqueous solution, react with a hydroxyl radical. An ESR study on intermediate radicals in the oxidation of simple amides with hydroxyl radical at room temperature was carried out using a rapid flow technique with a hydrogen peroxide and titanium trichloride redox system in aqueous solution. In each case, except for formamide, various π electron radicals formed by hydrogen abstraction were found, and for formamide and its *N*-methyl derivatives, ESR spectra attributed to acyl type σ electron radicals (carbamoyl radicals, CONRR′) were observed. It is our purpose here to investigate the properties of intermediate radicals, especially carbamoyl radicals. Recently, Livingston and Zeldes[4] reported an ESR study of free radicals formed from ultraviolet irradiation of a solution of an amide containing either hydrogen peroxide or acetone. A comparative discussion with their results is made in the present paper.

Experimental

The ESR spectrometer employed was a JEOL JES-3BSX instrument operating at a nominal frequency of 9.4 GHz with a 100 kHz field modulation with a TE_{011} cylindrical mode cavity. The static magnetic field was generated by a JES electromagnet with a nominal homogeneity of 1×10^{-6}/sample volume. For measurement of the *g* factor and hyperfine couplings, a glass capillary was attached to the sample tube. The capillary was filled with a reference compound, an aqueous solution of potassium peroxylamine disulfonate. The *g* factor and the hyperfine coupling constant of ^{14}N of the reference compound is 2.00559 ± 0.00001 and 13.07 ± 0.05 gauss, respectively. Estimated error limits are ±0.00002 and ±0.1 gauss for measured *g* factors and hyperfine coupling constants, respectively; otherwise probable errors are cited.

The rapid flow system consists of a JES-SM-1 mixing chamber and a JES-LC-0l capillary sample tube for aqueous solutions. The reagent solutions used were: (A) Acidified (0.1 M H_2SO_4) aqueous titanous chloride solution (0.02M); (B) aqueous hydrogen peroxide (0.2M). The substrate was added to solution (A) and its concentration varied within the range 0.3—3M, so as to obtain a sufficiently intense absorption.

Results and Discussion

The results obtained for each amide are presented separately and discussed. Hyperfine couplings are designated by the letter *a* with a superscript to indicate the magnetic nucleus and a subscript only where ambiguity would otherwise result. In the case of σ electron radicals, *g* factors are useful for the identification of radical structures, and are discussed later.

1. Formamide. The ESR spectrum of the radical formed by the reaction of formamide with hydroxyl radical is shown in Fig. 1. Parameters of this radical are summarized in Table 1. It has

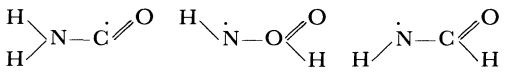
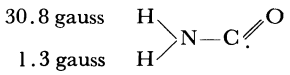
expected to be a σ electron radical. Possible structures for the σ electron radical with two nonequivalent protons and one nitrogen nucleus formed from formamide is I, II or III.



I II III

As shown later, σ electron radicals which have g factors and ^{14}N couplings with values approximately the same as those in Table 1 are formed from *N*-methylformamide and *N,N*-dimethylformamide. From the former, methylcarbamoyl radical (derivative of I) and the radical formed by N–H hydrogen abstraction (derivative of II or III) are possible. The only σ electron radical possible by abstracting hydrogen from *N,N*-dimethylformamide is dimethylcarbamoyl radical (dimethyl derivative of I), which shows that the σ electron radical formed from formamide should be the carbamoyl radical (I). This assignment of the radical formed from formamide is consistent with that of Livingston and Zeldes,[4] who have concluded that a hydroxyl radical formed through UV irradiation abstracts hydrogen bonded to the carbon atom of formamide resulting in a "non $-\pi$" radical. This identification also coincides with the theoretical conclusion of the present authors.[8]

On the other hand, Smith and Wood[9] perfomed an experiment similar to the present one and remarked that the radical of Table 1 is HCONH, formed by abstraction of hydrogen bonded to nitrogen. However, both experimental[4] and theoretical[8] evidence, together with the discussion given above, show that the radical of Table 1 is a carbamoyl σ electron radical. Referring to the calculated results,[8] the proton splitting constants are assigned as



This assignment is reasonable in comparison with those of vinyl[10] and iminoxy[11] radicals.

Fessenden[12] has reported the ^{13}C coupling constant of the β-carbon in a vinyl radical to be ± 8.55 gauss. When the spin density on the 2s atomic orbital is unity, ^{13}C and ^{14}N isotropic splitting constants are calculated to be 1110 gauss and 549 gauss, respectively.[13] The observed ^{14}N isotropic coupling constant of 21.8 gauss in the carbamoyl radical seems somewhat large when compared with the ^{13}C splitting constant of the vinyl radical if both radicals are considered to be planar.[14] The large ^{14}N coupling constant of the carbamoyl may be explained in the following way. When the CNH_2 group in the carbamoyl radical is a shallow pyramid[15] or the amino group is somewhat twisted around the N–C bond from the CNO plane, thus forming a non-planar structure of carbamoyl radical, the odd electron may delocalize into a lone pair orbital on the nitrogen. The odd electron density of the lone pair orbital of the nitrogen will induce a positive spin density at the nitrogen nucleus through spin polarization as well as through the s-nature of the lone pair orbital, resulting in a large isotropic ^{14}N hyperfine coupling constant. From the above, it is thought that the carbamoyl radical does not have a planar structure.

2. *N*-Methylformamide. Radicals formed by the reaction of *N*-methylformamide, $TiCl_3$ and H_2O_2 gave an asymmetric spectrum as shown in Fig. 2a. It is clear that more than one radical

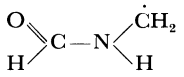
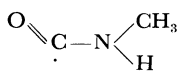
is present. This spectrum can be analyzed as two superimposed spectra shown in Figs. 2b and 2c, constructed with the parameters given in Tables 2 and 3. The radical of Table 2 (*i. e.* Fig. 2b) can be assigned to a π electron radical $HCONH(\dot{C}H_2)$. Livingston and Zeldes[4] have observed essentially the same spectrum as in Fig. 2b during photolysis of a 30% aqueous solution of *N*-methylformamide containing 1% H_2O_2, and identified the radical as $HCONH(\dot{C}H_2)$, with the possible structure



IV

The radical of Table 3 (*i. e.* Fig. 2c), which was not observed in the ESR-photolysis-study of Livingston and Zeldes,[4] is identified as a methyl carbamoyl σ electron radical with the configuration

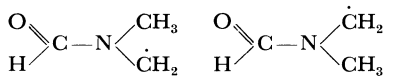


V

This assignment is based on following results: (1) the g factor of this radical (2.00182) is smaller than the spin-only value (2.00232) and resembles that of the carbamoyl radical formed from formamide (Table 1); (2) the ^{14}N coupling constant is nearly equal to that of the carbamoyl radical: (3) this radical should have a configuration with the NH bond *cis* to the odd electron σ orbital, otherwise the value of a^{H}_{NH} should be of the same order as $a^{H}_{NH,t}$= 30.8 gauss of the carbomoyl radical; (4) in the case of σ electron radicals, it is reasonable that the coupling constant of the methyl proton decreases from 30.8 gauss ($a^{H}_{NH,t}$ of the carbamoyl radical, Table 1) to 1.0 gauss ($a^{H}_{CH_3}$ of the methylcarbamoyl radical, Table 3) when the hydrogen in the amino group is substituted by a methyl group.

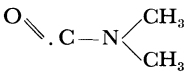
The NMR and IR studies[16] showed that *N*-methylformamide has its formyl hydrogen *trans* to the NCH_3. It is interesting that the abstraction of formyl hydrogen from *N*-methylformamide by a hydroxyl radical does not change the conformation of the skelton of O=C–N–C.

3. *N,N*-Dimethylformamide. Radicals formed from the reaction between *N,N*-dimethylformamide and hydroxyl radicals prepared by the redox reaction of $TiCl_3$ and H_2O_2 give a very complex ESR spectrum, as shown in Fig. 3a. The spectrum consists of three clusters of lines. All three clusters of lines were measured in considerable detail, and it was clear that three radical species resulting from abstraction of a hydrogen atom from a methyl or formyl groups were present. The spectrum of Fig. 3a consists of three spectra, Figs. 3b, 3c and 3d, constructed with the parameters listed in Tables 4, 5 and 6, respectively. The radicals in Table 4 and 5 (*i. e.* Figs. 3b and 3c) are easily identified as geometrically isomeric π radicals, $HCON(\dot{C}H_3)(\dot{C}H_2)$, formed by the abstraction of methyl hydrogen. A comparison of the parameters of Tables 2, 4 and 5 suggests that the radical of Table 5 has the same coformation as the radical from *N*-methylformamide. Assuming that $HCONH(\dot{C}H_2)$ has the conformation of IV in the preceding section, the radicals of Tables 4 and 5 may have the conformations VI and VII shown below, respectively.



VI VII

The radical of Table 6 with a small g factor is identified as dimethylcarbamoyl σ electron radical VIII.



VIII

The proton coupling constant of 0.7 gauss is assigned to the protons of the methyl group *trans* to the odd electron orbital in comparison with *N*-methylcarbamoyl radical formed from *N*-methylformamide. The proton coupling of the methyl group *cis* to the odd electron orbital is small and not resolved.

4. Acetamide. The radical obtained from acetamide gave a well-resolved spectrum, as Fig. 4. The ESR spectrum of this radical formed by abstraction of a hydrogen atom by OH radical has been reported by Livingston and Zeldes (OH radical prepared by photolysis of H_2O_2)[4] and by Smith and Wood (OH radical prepared from the redox reaction between $TiCl_3$ and H_2O_2).[9] This radical is $\dot{C}H_2CONH_2$ π electron radical and its parameters are summarised in Table 7.

Two amino-group protons of this radical are not equivalent, as seen in Table 7. It is interesting that the difference between the coupling constants of these two protons are very large relative to their magnitude (about 16% of their mean value). This difference may be interpreted as follows; (1) polarizabilities of two NH σ bonds are not equal mainly because of the difference in NH bond lengths;[17] thus, the σ-π exchange interaction

17) Two NH bond lengths of formamide are 1.002 Å and 1.014 Å, respectively (Ref. 15).

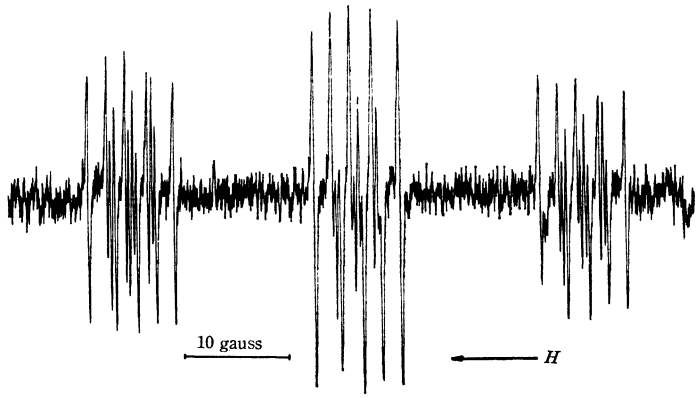

Fig. 4. The ESR spectrum of $\dot{C}H_2CONH_2$ formed by a hydrogen abstruction from acetamide.

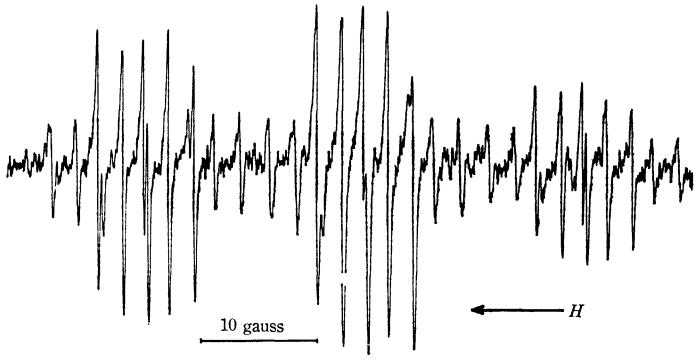

Fig. 5. The ESR spectrum of the radical formed by abstracting hydrogen from *N*-methylacetamide.

induces, at positions of amino-protons, different spin densities and/or (2) amino protons are out of the molecular plane with different angles,[18] then, the odd electron which delocalizes into the two NH σ bonds causes unequal spin densities at the amino-proton positions.

5. *N*-Methylacetamide. Figure 5 shows the spectrum of the radical obtained from *N*-methylacetamide. The ESR parameters are listed in Table 8 along with the parameters reported by Livingston and Zeldes.[4]

The radical was formed by abstraction of a hydrogen atom from a methyl group; there is ambiguity as to which methyl group lost the hydrogen, the choices are $OC(CH_3)NH(\dot{C}H_2)$ and $OC(\dot{C}H_2)NH(CH_3)$. A comparison of parameters of Table 8 with those for π electron radicals from methyl substituted formamides (Tables 2, 4 and 5) and acetamide (Table 7) gives some preference for $OC(CH_3)NH(\dot{C}H_2)$. Friedman and Shechter[19]

18) In the case of formamide, $\angle$(H'NC plane)(NCO plane)$=7\pm5°$ and $\angle$(H''NC plane)(NCO plane)$=12\pm5°$, where H' and H'' designate proton in the NH_2 group. Ref. 15.

reported that radical-dimerization of *N*-methylacetamide by *t*-butyl peroxide yields *N*,*N*′-diacetylethylenediamine (71% yield). This implies that the hydrogen atom in the *N*-methyl group is more easily abstracted than the hydrogen in the acetyl group by radical reactions. Therefore, the radical from *N*-methylacetamide is identified as $OC(CH_3)$-$NH(\dot{C}H_2)$, which agrees with the identification proposed by Livingston and Zeldes.[4]

6. Propionamide. Radicals formed by the reaction of propionamide with hydroxyl radicals gave the spectrum in Fig. 6a. The spectrum contains three triplets as in Fig. 6b, constructed from the parameters given in Table 9. The radical of Table 9 can be assigned to the radical $\dot{C}H_2CH_2$-$CONH_2$. The remaining lines can not be analyzed because of their low intensity.

$a^{H}_{\text{-}CH_2\text{-}}$ a)	25.6

a) In unit of gauss.

7. *g* Factor of σ Electron Radical. Stone[20] has derived the following expression for one of the diagonal components of the *g* tensor;

$$g^{zz} = g_e + \Delta g^{zz}, \tag{1}$$

where g_e is the free electron *g* factor, 2.00232, and Δg^{zz} is given by

$$\Delta g^{zz} = 2\sum_{n\neq p} \frac{\sum_k \sum_{\mu,\nu} C^{(p)}_{k\mu} C^{(n)}_{k\nu} < \chi_{k\mu}|l^z_k|\chi_{k\nu} > \sum_{k'} \sum_{\mu'\nu'} C^{(n)}_{k'\mu'} C^{(p)}_{k'\nu'} < \chi_{k'\mu'}|l^z_{k'}|\chi_{k'\nu'} > \zeta_{k'}}{\varepsilon_p - \varepsilon_n} \tag{2}$$

Here, l_k is the angular momentum about the *k*-th nucleus, ε_p and ε_n are the energies of molecular orbitals $\varphi^{(p)}$ and $\varphi^{(n)}$ and ζ_k is the spin-orbit coupling constant for the *k*th atom. Molecular orbitals $\varphi^{(p)}$ (half-occupied MO) and $\varphi^{(n)}$ (vacant or doubly occupied MOs) are expessed as linear combinations of the μth atomic orbital of the *k*th atom, $\chi_{k\mu}$, as

$$\varphi^{(p)} = \sum_k \sum_\mu C^{(p)}_{k\mu} \chi_{k\mu} \quad \text{and} \quad \varphi^{(n)} = \sum_k \sum_\mu C^{(n)}_{k\mu} \chi_{k\mu}. \tag{3}$$

Similar expressions give the other diagonal components. The *g* factor of a radical in solution is given as the arithmetic mean of the three diagonal elements of the *g* tensor,

$$g = g_e + \Delta g \tag{4}$$

$$\Delta g = \frac{1}{3}(\Delta g^{xx} + \Delta g^{yy} + \Delta g^{zz}). \tag{5}$$

In the case of σ electron radicals, MO's with π symmetry give large contributions to Δg, since the value of $\varepsilon_p - \varepsilon_n$, which appears in Eq. (2), is small. The odd electron orbital of σ radicals are generally localized on one atom. Therefore, the numerator of Eq. (2) often has a positive value, and the sign of Δg of Eq. (5) is, with some exceptions, determined by the energy differences between the half-occupied and lower vacant orbitals, and between the half-occupied and higher doubly occupied orbitals. When the former is smaller than the latter, Δg becomes negative and *vice versa*. Therefore it is expected that for the σ electron radical, which has an odd electron localized mainly on the less electronegative atom in that radical and has a higher half-occupied orbital energy, the *g* factor is expected to be smaller than the spin-only value (2.00232). Experimental *g* factors of such σ electron radicals as discussed above are summarized in Table 10. On the other hand, iminoxy radicals have been reported[11,21] to have *g* factors ranging from 2.005 to 2.008, which are much larger than the free-spin *g* factor. The odd electron of the iminoxy radical is mainly localized on the electronegative atoms (oxygen and nitrogen)

of the radical, and the energy level of the odd electron orbital is expected to be low.

Although the above discussions are highly qualitative, they are sometimes useful for the identification of σ electron radicals. It is noteworthy that the substitution of a methyl group into vinyl and carbamoyl radicals enlarges their g factors, as seen in Table 10. Substitution of a methyl group into these radicals elevates energy levels of π orbitals. On the other hand, the energy level of the odd electron σ orbital might be scarcely affected by a methyl substitution. The energy difference between the vacant π and the half-occupied σ orbitals of methyl substituted carbamoyl (or vinyl) radical is larger than that of the carbamoyl (or vinyl) radical. Differences between orbital energies of the half-occupied σ and doubly occupied π orbitals of methyl substituted carbamoyl (or vinyl) radicals are smaller than those of carbamoyl (or vinyl) radical. Both effects enlarge g factors of methyl substituted carbamoyl and vinyl radicals. These explanations for the g factors of carbamoyl, methylcarbamoyl and dimethlcarbamoyl radicals also confirm the present identification of σ electron radicals formed from formamide and its *N*-methyl and *N*,*N*-dimethyl derivatives.

Solvated Electron Formed in Water by the Silent Electric Discharge in Argon Atmosphere

Akira YOKOHATA

Department of Chemistry, Faculty of Engineering, Hiroshima University, Senda-machi, Hiroshima

(Received July 25, 1968)

Based on radiation chemistry of water a study on the chemical changes resulting from the silent electric discharge of aqueous solution under argon atmosphere was made for the purpose of elucidating the nature of the reducing species formed. In the neutral aqueous $ClCH_2COOH$ system the effects of such additives as CH_3OH and NO_3^- on the yield of Cl^- and in the system containing NO_3^- the yield of NO_2^- were investigated. Moreover, in the alkaline aqueous $K_3Fe(CN)_6$ system emphasis was placed on the yield of aquocomplex. In view of the non-dependence of the yield of Cl^- on the concentration of additive NO_3^- and of the low yields of NO_2^- and $Fe(CN)_5OH_2^{3-}$ produced, it was concluded that in the silent electric discharge the yield of solvated electrons which react with solutes in the bulk of water is very small ($G \lesssim 0.06$). Reasons for the low yield of solvated electrons are briefly described.

The chemical effects of silent electric discharge and those of high energy radiations have been demonstrated to be identical in many respects.[1-4] Silent electric discharge may be considered to be a peculiar particle-accelerator of low energy having the following characteristics.

(1) The electrons at one atmospheric pressure have an energy distribution from just above zero to a value slightly higher than the ionization potential of the gas in which the discharge occurs.[5,6]

(2) Relatively low voltages (10—15 kV) result in the high currents (~1 mA). From the point of view of total power, the dose rate can be expected to be considerably high.

Consistent with theoretical considerations, our recent studies[4] have proved that most of the reactions of aqueous solutions induced by the silent electric discharge in the inert gas atmospheres can be well interpreted with an indirect effect of the slow electrons to water molecules, the primary one being the radiolysis of water to give the intermediates, reducing radical or hydroxyl radical.

The apparent dose rate under our experimental conditions was 7.2×10^6 R/hr as reported previously[4] and each primary G value of radicals was estimated as follows:

$$^sG(\mathrm{Red}) = 0.6, \quad ^sG(\mathrm{OH}) = 0.7 \qquad (1)^{*1}$$

They were almost independent of pH within the experimental error. The content of $^sG(\mathrm{Red})=0.6$, however, is yet unknown. The present investigation was undertaken to estimate the yield of solvated electrons. Neutral aqueous monochloroacetic acid and alkaline aqueous potassium ferricyanide solutions were both selected as the reaction systems suitable for this purpose.

Experimental

The discharge tube and the electrical circuit used were identical with those previously described.[4] A discharge tube of the ozonizer type (Fig. 1) was composed of two coaxial hard-glass tubes; the tin foil wrapped

around the outer was used as one electrode (f) and dilute sulfuric acid in the inner tube (g) as the other electrode (the high-tension side). After pouring the sample solution into the discharge tube, discharge was made by applying high tension to these two electrodes with argon flowing through the gas space of the discharge tube at a velocity of about 120 ml/min.

All experiments were made at a constant solution volume of 10 ml, at room temperature after removing the dissolved oxygen from the solution by bubbling argon gas into the solution, and at a constant discharge current of I=1 mA.

The discharge tube was washed with a mixture of methylalcohol and a saturated aqueous solution of sodium hydroxide besides the usual cleaning solution, and dried by evacuation.

Gamma-ray irradiations were carried out using a 260 curie ^{60}Co source. The dose rate (1.57×10^5R/hr) was determined by the Fricke dosimeter, taking $G(Fe^{3+})$ =15.5.

Materials. Reagents used were of the reagent grade. Argon gas (pyrity: 99.998%) was used without further procedure. Triply-distilled water was used in all the runs.

Analysis. Microquantities of chloride were determined by the turbidimetric method.[7] The turbidity was measured at 350 mμ with a spectrophotometer. Nitrite ions were determined colorimetrically at 540 mμ.[8]

The aquopentacyanide ion, $Fe(CN)_5OH_2^{3-}$, was determined spectrophotometrically by the method using NaN_3.[9,10] A calibration curve was obtained by the following procedure: $Na_3Fe(CN)_5OH_2$ was prepared according to the method of Hofmann[11] and was purified by passing through an alumina chromatographic column and eluting with water. Its content in the eluted solution was determined by the ceric titration. An aliquot (2 ml) of the solution containing the various amounts of $Na_3Fe(CN)_5OH_2$ was pipetted in a 10 ml-volumetric flask to which 0.3 M CH_3COOH-0.3 M NaN_3 was added, and after 15—20 min the optical density at 560 mμ was measured. The molecular extinction coefficient thus obtained was 1.4×10^3 M^{-1} cm^{-1} at pH 4—6. The presence of $Fe(CN)_6^{4-}$ and $Fe(CN)_6^{3-}$ did not interfere with this measurement.

Results and Discussion

Neutral Monochloroacetic Acid Solution. It is well known[12] that in the field of γ-radiolysis the formation of inorganic chloride on irradiation of deaerated solution of $ClCH_2COOH$ is a result of reaction of the reducing species (mainly e_{aq}^-) with the solute. The reaction of OH radicals has been believed to result in dehydrogenation rather than dechlorination. The H-radicals among the reducing species induce principally the hydrogen abstraction reaction with a small possibility of dechlorination.[13] The reaction mechanism is shown as follows.

$$e_{aq}^- + ClCH_2COO^- \longrightarrow Cl^- + CH_2COO^- \quad (2)$$
$$H + ClCH_2COO^- \longrightarrow H_2 + ClCHCOO^- \quad (3)$$
$$\searrow Cl^- + H^+ + CH_2COO^- \quad (4)$$
$$OH + ClCH_2COO^- \longrightarrow H_2O + ClCHCOO^- \quad (5)$$

The silent electric discharge also leads to the formation of inorganic chloride. Figure 2 shows the relationship between the yield and the duration of discharge, in which a good linear correlation can be seen. The yield of Cl^- was independent of the solute concentration in the range from 1×10^{-3} to 1×10^{-2}M (pH=6.5).

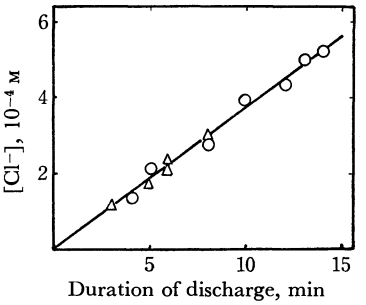

Fig. 2. Silent electric discharge of neutral aqueous solution of $ClCH_2COOH$.
○, 0.01 M $ClCH_2COOH$
△, 0.001 M $ClCH_2COOH$

If the above-mentioned mechanism can be accepted and reaction (4) can be ignored because $k_4=0.09\ k_3$,[13] the yield of e_{aq}^- should equal the yield of Cl^-. Our recent work, however, showed the formation of inorganic chloride in a considerable amount even under the experimental conditions in which reaction (2) could not be expected to

occur.*2 This finding is noteworthy in that the possibility of dechlorination reaction due to OH is suggested. Thus, a more detailed experiment was undertaken.

Figure 3 shows the effect of additive CH_3OH on the yield of Cl^- obtained by the silent electric discharge with discharge current at 1 mA and duration at 10 min. It is of great interest that there was a strong suppressive effect of CH_3OH.

When $[CH_3OH]/[ClCH_2COOH]<2$, CH_3OH cannot compete with the $ClCH_2COO^-$ for e_{aq}^-, because the rate constant of reaction of e_{aq}^- with $ClCH_2COO^-$, $k_2=3.8\times10^9 M^{-1}\,sec^{-1}$,[14] is much larger than that with CH_3OH, $k_{e_{aq}^-+CH_3OH}<10^7\ M^{-1}\,sec^{-1}$.[15] These findings lead to the possibility that in the case of silent electric discharge the radicals (*i. e.* OH, H) to be scavenged by CH_3OH play an important role in the formation of Cl^-. Thus, the competition of (6) with (7) and of (4) with (8) should be expected.

$$OH + ClCH_2COO^- \longrightarrow Cl^- + X \quad (6)$$
$$OH + CH_3OH \longrightarrow CH_2OH + H_2O \quad (7)$$
$$H + CH_3OH \longrightarrow CH_2OH + H_2 \quad (8)$$

where X means the reaction product. However, since the yield of Cl^- observed ($^sG(Cl^-)=0.3$) is much larger than the yield expected ($^sG(Cl^-)=0.06$) to be produced *via* reaction (4) on the basis of $^sG(Red)=0.6$ and $k_4=0.09\ k_3$ the contribution of hydrogen atom may not be considered to be significant. Thus, the possibility of (6) is strongly suggested.

If the occurrence of reaction (6) is possible, the considerable yield of Cl^- should be expected even by the addition of electron scavengers such as NO_3^-. Indeed, as shown later, experiments of γ-ray irradiation came up to our expectation. This residual amount is too much to be expected from H atoms and can be suppressed almost completely by the addition of 0.1 M CH_3OH. These findings tend to confirm the possibility of the occurrence of reaction (6).

Our study provides further evidence that Cl^- can be formed by the reaction of the Fenton reagent with $ClCH_2COOH$ but also be suppressed by the addition of CH_3OH.

In the absence of electron scavenger, however, there was hardly any effect of additive CH_3OH on the γ-radiolysis. This suggests that reaction (6) is important only in little or no presence of e_{aq}^-. In the present stage, the reaction scheme must await further study.*3 In any event, the main point here is that most of Cl^- produced by the silent electric discharge is due to the reaction of the active species (mainly OH) other than e_{aq}^- with $ClCH_2COO^-$.

Effect of Nitrate Ions Added in the $ClCH_2COOH$ System. Figure 4 shows the effect of NO_3^- on the yield of Cl^- and NO_2^- in the γ-irradiated solution of 0.01 M $ClCH_2COOH$ (deaerated, pH 6.5). The increment in NO_2^- yield and the decrement in Cl^- yield with an increasing NO_3^- concentration suggest the competition of (2) with (9), followed by (10) and (11).[16]

$$e_{aq}^- + NO_3^- \longrightarrow NO_3^{2-} \quad (9)$$
$$NO_3^{2-} + H^+ \longrightarrow NO_2 + OH^- \quad (10)$$
$$2NO_2 + H_2O \longrightarrow NO_2^- + NO_3^- + 2H^+ \quad (11)$$

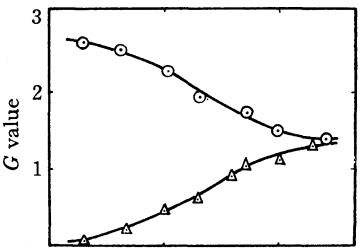

Fig. 4. Effect of KNO_3 on G (Cl^-) and G (NO_2^-) in γ-radiolysis of neutral aqueous solution of $ClCH_2COOH$ (1×10^{-2} M).
⊙, G (Cl^-) △, G (NO_2^-)

If above mechanism is accepted, Eq. (12) can be derived in the presence of sufficient amount of NO_3^- to scavenge all of e_{aq}^-.

$$G(NO_2^-) = 0.5\,G(e_{aq}^-) \quad (12)$$

Reaction (13) might be also expected, since $k_{H+NO_3^-}\approx10^7 M^{-1}\,sec^{-1}$ [17] and $k_{H+ClCH_2COO^-}=1.9\times10^6 M^{-1}sec^{-1}$ [18].

$$H + NO_3^- \longrightarrow HNO_3^- \quad (13)$$

However, as the yield of NO_2^- below pH 3 where a considerable amount of H could be expected by the reaction of e_{aq}^- with H^+ was negligibly small, HNO_3^- disappears probably through the reactions with solute or intermediates to yield products other than NO_2^-.

If, as discussed above, NO_2^- is produced *via* reactions (9)—(11), a simple competition of (2) with (9) leads to Eq. (14).

$$\frac{1}{G(NO_2^-)} = \frac{2}{G(e_{aq}^-)} + \frac{2}{G(e_{aq}^-)}\,\frac{k_2[ClCH_2COO^-]}{k_9[NO_3^-]} \quad (14)$$

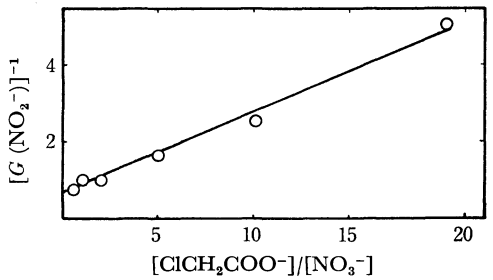

Fig. 5. A plot of $1/G(NO_2^-)$ against $[ClCH_2COO^-]/[NO_3^-]$ (Eq. (14)).

In Fig. 5 $1/G(NO_2^-)$ is plotted against $[ClCH_2COO^-]/[NO_3^-]$. A straight line in Fig. 5 supports the validity of the simple competition mentioned above. Thus, $k_2/k_9=0.15$ can be estimated by using a value of $G(e_{aq}^-)=2.8$. $K_9=1.1\times10^{10}$ M^{-1} sec^{-1} [19] gives $k_2=1.7\times10^9$ M^{-1} sec^{-1}, which is almost consistent with other workers (3.8 or 1.2×10^9 M^{-1} sec^{-1}).[14,20]

On the other hand, nitrite ion was also formed in the silent electric discharge. Figure 6 shows the relationship between the yield of NO_2^- and duration of discharge for aqueous solution of 0.01M $ClCH_2COO^-$+0.1M NO_3^- (pH=6.5). Figure 7 shows the dependence of the yield of Cl^- and NO_2^- on

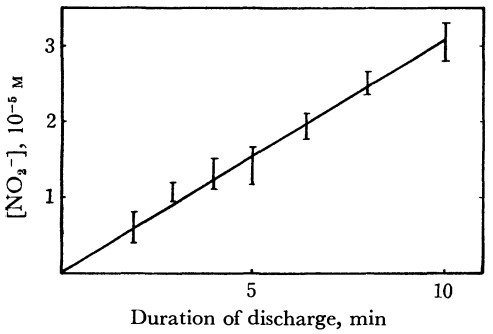

Fig. 6. Silent electric discharge of neutral aqueous solution of 0.01 M $ClCH_2COOH$+0.1 M KNO_3.

the NO_3^- concentration. A linear curve in Fig. 6 gives ${}^sG(NO_2^-)\approx0.03$, which is very small when compared with ${}^sG(\text{Red})=0.6$. Because $k_2/k_9=0.15$, most of the e_{aq}^- should react with NO_3^- to yield NO_2^- in the experimental conditions where $[ClCH_2COO^-]/[NO_3^-]<0.1$. Of course, H atoms may make a small contribution to this yield. Thus ${}^sG(e_{aq}^-)$ estimated by Eq. (12) gives the maximum value.

$$ {}^sG(e_{aq}^-) \lesssim 0.06 \qquad (15) $$

Non-dependence of the yield of Cl^- on the additive NO_3^- known as a strong electron scavenger (Fig. 7) is of interest. It is one of other evidences

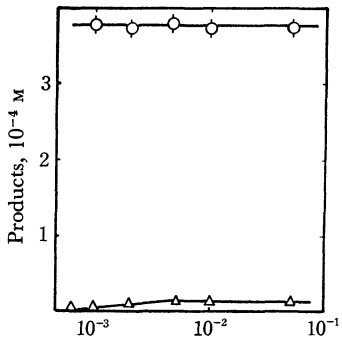

Fig. 7. Dependency of yields of Cl^- and NO_2^- on $[NO_3^-]$ in the silent electric discharge.
Initial concentration of $ClCH_2COOH$, 1×10^{-2} M (pH=6.5)
○, Cl^- △, NO_2^-

that in the silent electric discharge the yield of the solvated electrons can be concluded to be very small.

Alkaline Aqueous Solution of Potassium Ferricyanide. In order to secure a further evidence on the yield of solvated electrons, a study was extended to another system, $K_3Fe(CN)_6^{3-}$-0.1N NaOH solution. In this system the attention was directed toward the reaction of e_{aq}^- to $Fe(CN)_6^{3-}$.

It has been recently reported by Haïssinsky *et al.*[21] that aquopentacyanide is formed *via* following competitive reaction.

$$ e_{aq}^- + Fe(CN)_6^{3-} \longrightarrow Fe(CN)_6^{4-} \qquad (16) $$
$$ \searrow Fe(CN)_5OH_2^{3-} + CN^- \qquad (17) $$
$$ H + Fe(CN)_6^{3-} \longrightarrow Fe(CN)_6^{4-} + H^+ \qquad (18) $$
$$ \searrow Fe(CN)_5OH_2^{3-} + CN^- + H^+ \qquad (19) $$

More recently, Burchill *et al.*[22] reported that the product which gives a colored complex with nitrosobenzene ($Fe(CN)_5PhNO^{3-}$) is diminished by the presence of oxygen or N_2O, and therefore the product may be formed by Eq. (17). On the other hand, the formation of aquopentacyanide was also confirmed[23] by using NaN_3 instead of nitrosobenzene.

In the present work, the NaN_3 method was applied for the determination of the solvated electrons formed by the silent electric discharge.

In the silent electric discharge,*4 the product which gives a colored complex with NaN_3 was also found. Figure 8 shows that the relation of the yield of product to the duration of discharge is linear

23) S. Ohno and G. Tsuchihashi, *Radioisotopes (Japan)*, **16**, 434 (1967).
*4 The disappearance of ferricyanide ions has been reported[4] to be ${}^sG(-Fe(CN_6^{3-})=2.8$.

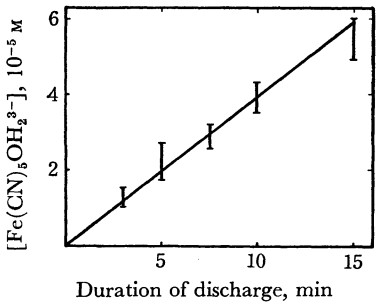

Fig. 8. Silent electric discharge of alkaline aqueous solution of 5×10^{-3} M $Fe(CN)_6^{3-}$ (0.1N NaOH).

and that the yield is independent of the concentration in the range from 5×10^{-3} M to 1×10^{-2} M $Fe(CN)_6^{3-}$ within the experimental error. Then the ${}^sG$ value of the product can be estimated to be about 0.03.

In clarifying the relation between $G(e_{aq}^-)$ and the G value of the product, the γ-ray experiment of the deaerated system was done in the same concentration range. The yield of the product ($G(Fe(CN)_5OH_2^{3-})=1.4$) was almost independent of the concentration in the range from 5×10^{-3} M to 1×10^{-2} M $Fe(CN)_6^{3-}$ and larger than the yield in lower concentration.*5

On the other hand, the strong suppressive effect of N_2O on the yield of the product was also confirmed in this experiment (Fig. 9). Thus, there seems to be no doubt that the product originates mostly from the reaction of e_{aq}^- with $Fe(CN)_6^{3-}$.

Therefore, in the range from 5×10^{-3} M to 1×10^{-2} M $Fe(CN)_6^{3-}$, Eq. (20) can be obtained by using a value of $G(e_{aq}^-)=2.8$.

$$G(e_{aq}^-)\approx 2G(Fe(CN)_5OH_2^{3-}) \qquad (20)$$

By applying the yield of the product obtained in the silent electric discharge (${}^sG(Fe(CN)_5OH_2^{3-})=0.03$) to Eq. (20), ${}^sG(e_{aq}^-)$ can be estimated to be about 0.06. A part of the yield, however, might be due to the H atom. Thus, this gives a maximum value.

$${}^sG(e_{aq}^-)\lesssim 0.06 \qquad (21)$$

General Discussion. In the case of the silent electric discharge clusters of intermediates will be formed densely on the surface of water by the impact of low energy particles (mainly e^-). In the clusters, the primary main product will be an excited water molecule since the energy of the electron is most probably less than the ionization

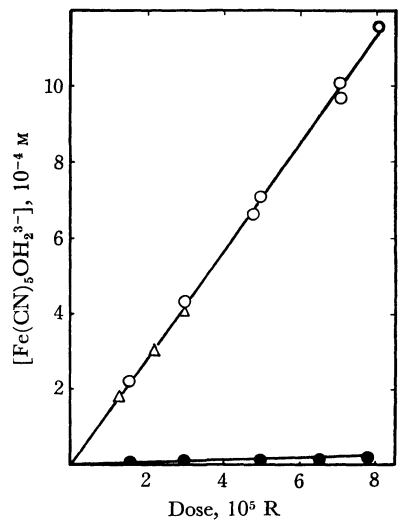

Fig. 9. γ-Ray radiolysis of alkaline aqueous solution of $K_3Fe(CN)_6$ (0.1 N NaOH).
○, 5×10^{-3} M $Fe(CN)_6^{3-}$
△, 1×10^{-2} M $Fe(CN)_6^{3-}$
●, 5×10^{-3} M $Fe(CN)_6^{3-}+2\times10^{-2}$ M N_2O

potential of water molecule. Thus the main reducing species produced from radiolysis by the silent electric discharge can be considered to be hydrogen atom formed mainly through the excitation of water molecule:

$$e_p^- + H_2O \longrightarrow H_2O^* + e_s^- \qquad (22)$$

(e_p^-: primary electron, e_s^-: secondary electron)

$$H_2O^* \longrightarrow H + OH \qquad (23)$$

In addition, the formation of negative ions would be also naturally expected[24] although they (H^- and O^-) would disappear *via* reactions (27) and (28).

$$e^- + H_2O \longrightarrow H + OH^- \qquad (24)$$
$$e^- + H_2O \longrightarrow H^- + OH \qquad (25)$$
$$e^- + H_2O \longrightarrow O^- + 2H \qquad (26)$$
$$H^- + H_2O \longrightarrow H_2 + OH^- \qquad (27)$$
$$O^- + H_2O \longrightarrow OH + OH^- \qquad (28)$$

A part of the primary or secondary electrons might also probably disappear *via* neutralization reaction with the positive ions M^+ (Ar^+, *etc.*) on the surface of water:

$$e_s^-(\text{ or } e_p^-) + M^+ \longrightarrow M \qquad (29)$$

Of course, a part of them might be also solvated to give e_{aq}^-, but most of the solvated electrons produced are expected to combine *via* reaction (30) before they escape from the clusters of intermediates to react with the solute in the bulk.

$$e_{aq}^- + e_{aq}^- \longrightarrow H_2 + 2OH^- \qquad (30)$$

The foregoing, although speculative, may provide an adequate explanation for the small yield of

*5 We confirmed that at a relatively low concentration of $Fe(CN)_6^{3-}$(*e. g.* 5×10^{-4}M), the yield of the product which gives a coloured complex with NaN_3 ($G(Fe(CN)_5OH_2^{3-})=0.5$) is approximately consistent with that[22] of nitrosobenzene method, and that the product has a dependency on the concentration of $Fe(CN)_6^{3-}$ as pointed out by Haïssinsky.

24) M. Burton, "Comparative Effect of Radiation," John Wiley & Sons, New York (1960), p. 152.

the solvated electron in the bulk of water.

In the present stage, however, it is very difficult to discuss quantitatively the fate of slow electrons.

It is our conclusion that in the silent electric discharge the yield of solvated electrons which react with solutes in bulk of water is very small ($^{s}G \lesssim 0.06$).

The author wishes to thank Professor S. Tsuda, Faculty of Engineering of Hiroshima Univ., for many helpful discussions and suggestions during this work. Thanks are also due to Professor M. Miura, Faculty of Science of Hiroshima Univ., for his continuing interest and encouragement.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 663—666 (1969)

The Microwave Spectrum, Structure, and Dipole Moment of Ethylene Episulfoxide

Shuji SAITO

Sagami Chemical Research Center, Sagamihara, Kanagawa

(Received August 1, 1968)

The microwave spectra of the normal species as well as the ^{13}C and ^{34}S isotopic molecules of ethylene episulfoxide have been observed. The rotational constants thus obtained lead to the following structural parameters: S–O=1.483±0.003 Å, C–S=1.822±0.003Å, ∠OSC=111°1′±10′, ∠CSC=48°46′±10′, on the assumption that the C–H distance and the ∠HCH and ∠H_2CC angles are the same as those of ethylene sulfide. From the Stark shifts, the dipole moment has been determined to be μ_a=3.61±0.04 D, μ_c=0.89±0.01 D and μ_{total}=3.72±0.04 D. The bond nature of S–O and C–S has then been discussed on the basis of these data.

Ethylene episulfoxide, a three-membered ring compound, was initially prepared by Hartzell and Paige[1] by the direct oxidation of ethylene sulfide with sodium metaperiodate. They reported that ethylene episulfoxide undergoes dethionylation to yield ethylene and sulfur monoxide at a temperature near 100°C.[1] Dodson and Sauers carried out the thermal decomposition of ethylene episulfoxide in the presence of dienes and obtained cyclic sulfoxides.[2] Among the several sulfoxides reported,[1-5] dimethyl sulfoxide is well-known as a useful reactant for the oxidation of various functional groups to carbonyl compounds,[6] and as an excellent solvent for various organic and inorganic compounds. Compared with dimethyl sulfoxide, ethylene episulfoxide is far too unstable and more reactive even under mild conditions.

As ethylene episulfoxide is one of the simplest alkyl sulfoxides, it would be interesting to determine its molecular structure. The accumulated data on the structures of alkyl sulfoxides give a way of understanding the stability and reactivity of these compounds. Accurate r_e structures of the SO[7] and SO_2[8] molecules were obtained from the microwave spectra in the vibrationally-excited states. Pierce and Hayashi[9a] and Dreizler and Rudolph[9b] determined the r_s structure of dimethyl sulfide by analyzing the rotational spectra of various isotopic species. The r_0 structures of dimethyl sulfoxide[10] and ethylene sulfide[11] were obtained

by microwave spectroscopy. The purpose of this research is to determine the structure and the dipole moment of ethylene episulfoxide from its microwave spectrum.

Experimental

The sample of ethylene episulfoxide, prepared by the oxidation of ethylene sulfide using perbenzoic acid, was kindly provided by Fukuyama and Sato.[12] The microwave spectrum of ethylene episulfoxide was studied in the region from 8000 MHz to 36000 MHz with a conventional sinusoidal Stark-modulated spectrograph. Most of the measurements were carried out with a 3-m absorption cell at room temperature.

Microwave Spectrum

A tentative molecular model was first drawn by inference from analogous compounds, such as dimethyl sulfoxide[10] and ethylene sulfide.[11] The model was found to be a nearly prolate symmetric top with a dipole moment whose a and c components are about four and one Debyes respectively. Thus, strong a-type R branch transitions would be observed near every 11000 MHz, and weak c-type Q branch transitions would cover the whole region. The Stark effects should be rather large.

Table 1. Observed microwave transition frequencies of ethylene episulfoxide (C_2H_4SO) in the ground state (MHz)

Transition	f_{obs}	Δf[a]
a-type		
$1_{01} \leftarrow 0_{00}$	10519.30[b]	0.00

12) A. Negishi, K. Sato, S. Saito and M. Fukuyama, Preprints for the 21st Annual Meeting of the Chemical Society of Japan, Suita (April, 1968).

A search was made, using an oscilloscope, in the 10—12 GHz region, where the $1_{01} \leftarrow 0_{00}$ transitions were expected to occur on the basis of the molecular model described above. A good absorption candidate was located at 10519 MHz; this absorption showed a typical $J=1 \leftarrow 0$ Stark effect. The assignment of this line to the $1_{01} \leftarrow 0_{00}$ transition was confirmed by the observation at about 21 GHz of three $J=2 \leftarrow 1$ transitions which showed Stark patterns characteristic of the $J=2 \leftarrow 1$ transitions. From the a-type transitions thus assigned, the c-type transitions were predicted and searched for by means of a strip-chart recorder. The observed frequencies are given in Table 1. Subsequent measurements were made on the a-type transitions of the S-34 and C-13 species in natural abundance; the results are shown in Table 2.

Table 2. Observed microwave transition frequencies of $C_2H_4{}^{34}SO$ and $^{13}CCH_4SO$ (MHz)

Transition	f_{obs}	Δf[a]
$C_2H_4{}^{34}SO$		
$2_{11} \leftarrow 1_{10}$	21135.38[b]	0.00
$2_{02} \leftarrow 1_{01}$	20936.94[b]	0.00

a) $\Delta f = f_{obs} - f_{calc}$. b) Accuracy ± 0.1 MHz.

Table 3. Rotational constants and centrifugal distortion constants of ethylene episulfoxide (MHz)

C_2H_4SO	
A	= 14107.86 ± 0.30
B	= 5369.99 ± 0.10
C	= 5149.37 ± 0.10
D_J	= 0.015 ± 0.010
D_{JK}	= 0.006 ± 0.015
$C_2H_4{}^{34}SO$	
B	= 5332.74 ± 0.10
C	= 5137.66 ± 0.10
$^{13}CCH_4SO$	
B	= 5290.14 ± 0.10
C	= 5050.44 ± 0.10

The rotational constants for the normal species were obtained by using three low-J transitions. In the analysis of the spectra, the centrifugal distortion effect was calculated by the following symmetric-top expression:

$$W(J,K_1,K_1) = E(J,K_{-1},K_1) - D_J J^2(J+1)^2 - D_{JK} J(J+1) K_{-}^2 - D_K K_{-}^4$$

where $W(J,K_{-1},K_1)$ denoted the rotational energy including centrifugal effects; $E(J,K_{-1},K_1)$ the rigid rotor rotational energy, and the other terms the usual centrifugal terms. This treatment is possible because the ethylene episulfoxide molecule is very close to a prolate symmetric top: $b_p=-0.01247$. The rotational spectra for the S-34 and C-13 species were analyzed in a similar way, using the centrifugal distortion corrections determined from the analysis of the normal species. The rotational constants and the centrifugal distortion constants are listed in Table 3.

Dipole Moment

Stark effect coefficients were measured for the $M=0$, $1_{01}\leftarrow 0_{00}$ transition and for the $M=1$ and 0 components of the $2_{02}\leftarrow 1_{01}$ transition. The Stark displacements were compared with those of the OCS molecule, for which the dipole moment was taken to be 0.7124 D.[13] The observed Stark coefficients and the comparison with the calculated values are shown in Table 4. μ_a was determined

Table 4. Stark coefficients and dipole moment of ethylene episulfoxide

Transition		$\Delta\nu/E^2$(MHz)/(V/cm)$^2\times 10^4$ obs	obs-calc
$1_{01}\leftarrow 0_{00}$	$M=0$	1.696	0.000
$2_{02}\leftarrow 1_{01}$	$M=0$	−0.463	0.000
	$M=1$	0.437	0.001
$\mu_a=3.61\pm0.04$ D		$\mu_c=0.89\pm0.01$ D	
$\mu_{total}=3.72\pm0.04$ D			

to be 3.61±0.04 D and μ_c, to be 0.89±0.01 D. They yield a value of 3.72±0.04 D for the total dipole moment, which makes an angle of 13°51′ with *a* principal axis. The orientation of the dipole moment relative to the molecular framework was not uniquely determined. The structural calculation described in the next section indicates that the S–O bond axis makes an angle of 42°2′ with the *a* axis, and the plane containing the C_2S ring, an angle of 24°46′ with the *a* axis, so that there are two possibilities, 28°11′ and 55°53′, for the angle between the S–O bond and the total dipole moment. In view of the fact that the dipole moment of ethylene episulfoxide is composed mainly of one S–O and two C–S bond moments, the former possibility, 28°11′, seems preferable to the latter. Figure 1 thus shows only the former configuration.

Molecular Structure

Seven structural parameters are necessary for specifying the molecular structure of ethylene episulfoxide. Fortunately, seven rotational constants have been obtained: three for the normal, two for the S-34, and two for the C-13 species. It seems inadequate to use the rotational constants, *B* and *C*, of the S-34 species for the determination of the structure, because the sulfur atom is so near the center of gravity that the structure derived from the rotational constants of the S-34 species is apt to be affected by zero-point vibrations.

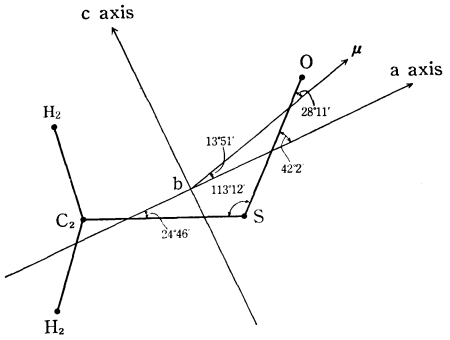

Fig. 1. Structure of ethylene episulfoxide.

Among the seven structural parameters, the most interesting ones are those which describe the episulfoxide part of the molecule. It can be expected that the ethylene part of ethylene episulfoxide is almost the same as that of ethylene sulfide. This prediction is understandable in view of the structures of dimethyl sulfide[9] and dimethyl sulfoxide[10] studied by microwave spectroscopy. Moreover, as a result of the small mass of the hydrogen atom, the moments of inertia depend only slightly on any assumption concerning the configuration of the ethylene part. Hence, we assume that the ethylene part of ethylene episulfoxide is the same as that of ethylene sulfide, that is, that C–H=1.078 Å, ∠HCH=116°0′, and $\angle H_2CC=151°43'$.[11] The four remaining parameters, the S–O and C–S distances, and the ∠OSC and ∠CSC angles are determined to give the five observed rotational constants for the normal

Table 5. r_0 structure of ethylene episulfoxide

r(S–O)	1.483 ± 0.003 Å
r(C–S)	1.822 ± 0.003 Å
∠OSC	110° 1′ ± 10′
∠CSC	48°46′ ± 10′
r(C–C)[a]	1.504 ± 0.003 Å
assumed parameters	
r(C–H)	1.078 Å
∠HCH	116° 0′
$\angle H_2CC$	151°43′

a) r(C–C) distance is not independent of the other parameters listed above.

and C-13 species. The structure thus obtained is given in Table 5.

Discussion

The molecular structure of ethylene episulfoxide determined above gives some clue for understanding the properties of alkyl sulfoxides, which have rarely been discussed. The S–O and C–S bond distances of the related compounds previously reported are compared in Table 6 with those of ethylene episulfoxide obtained in this work. The S–O and C–S bond moments of ethylene episulfoxide can be evaluated from the values of the total dipole moment given in Table 4 if the C–H bond moments are disregarded. These results are also listed in Table 6, along with the bond moments

TABLE 6. S–O and C–S BOND DISTANCES AND BOND MOMENTS IN VARIOUS COMPOUNDS

Molecule		r(S–O)	μ(S–O)	r(C–S)	μ(C–S)
$(CH_2)_2SO$[a]	r_0	1.483 Å	2.53 D	1.822 Å	1.06 D

of related compounds, which were calculated in a similar way. It may be seen that the S–O bond length of ethylene episulfoxide is longer than those of SO_2 and S_2O, and almost equal to that of SO. As was expected prior to the measurements, ethylene episulfoxide has nearly the same S–O bond distance as dimethyl sulfoxide. The C–S bond length of ethylene episulfoxide is a little longer than those of dimethyl sulfide, dimethyl disulfide, and dimethyl sulfoxide, and is almost equal to that of ethylene sulfide. This comparison indicates that the S–O bond of ethylene episulfoxide is almost a double bond, while the C–S bond is almost a single bond.

On the other hand, the C–S bond moment of ethylene episulfoxide is quite normal and is nearly the same as that of ethylene sulfide within the limits of experimental error, whereas the S–O bond moment is considerably larger than those of SO, SO_2, and S_2O. The unusual polarity of the S–O bond can be understood by means of the molecular orbital calculations made by Moffitt.[14] Using the self-consistent LCAO method, he calculated the bond order and the formal charge distribution in the SO, SO_2, SO_3, R_2SO, and R_2SO_2 molecules. He predicted that the dipole moments for alkyl sulfoxides would be about 3.5 D; according to the difference between the electronegativities of the alkyl groups and the sulfur atom, the positive charge moves considerably farther from the negatively-charged oxygen atom, and the C–S bonds of alkyl sulfoxides are weaker than those in alkyl sulfones and alkyl sulfides because the former has hardly any 3*s* electrons of the sulfur atom.

The weakness of the C–S bond has been demonstrated by the experimental finding that ethylene episulfoxide decomposes near 100°C.[1] This has also been confirmed by microwave spectroscopy detecting the rotational lines of sulfur monoxide in the ground state. The thermal decomposition of ethylene episulfoxide will be reported in a separate paper.

The author would like to express his hearty thanks to Professor Yonezo Morino for his encouragement and for the valuable advice given throughout this work. He also wishes to thank Dr. M. Fukuyama and Mr. K. Sato for providing a sample of ethylene episulfoxide.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 667—670 (1969)

Detection of Sulfur Monoxide in the Pyrolysis of Ethylene Episulfoxide by Microwave Spectroscopy

Shuji SAITO

Sagami Chemical Research Center, Sagamihara, Kanagawa

(Received August 8, 1968)

Microwave spectroscopy has been applied to the study of the pyrolysis of ethylene episulfoxide in the vapor phase. The rotational lines of SO in the electronic ground state, $^3\sum^-$, were observed with a good signal-to-noise ratio. The pyrolyzed sample of ethylene episulfoxide was analyzed semi-quantitatively by the use of the microwave spectra. It turned out that ethylene episulfoxide really decomposed into ethylene and sulfur monoxide. The mechanism of the thermal decomposition is discussed in detail.

Alkyl sulfoxides are interesting and important molecules, but only a few examples have been reported, for they are unstable.[1-7] Hartzell and Paige[3] and Negishi, Sato, Saito, and Fukuyama[7] synthesized ethylene episulfoxide by the direct oxidation of ethylene sulfide. Hartzell and Paige[3] observed, by means of mass spectrometry and differential thermal analysis, that it decomposed into ethylene and sulfur monoxide near 100°C. Dodson and Sauers[4] carried out the controlled thermal decomposition of ethylene episulfoxide in the presence of dienes and thus obtained cyclic sulfoxides. They suggested that the sulfur monoxide generated in the pyrolysis might be in the $^1\sum^+$ state or even in the $^1\Delta$ state. By observing and analyzing the rotational spectra of ethylene episulfoxide, Saito[8] determined the molecular structure and discussed the S–O and C–S bonds.

The microwave spectroscopy of free radicals has made considerable progress in recent years following a long pause after Dousmanis, Sanders, and Townes reported the OH radical.[9] Powell and Lide,[10] and Winnewisser, Sastry, Cook and Gordy[11] observed SO. Amano, Hirota and Morino[12] determined the r_e structure of SO. ClO[13] and SN[14] have also recently been studied by means of microwave spectroscopy.

The present work is concerned with the study of the pyrolysis of ethylene episulfoxide. The main purpose is to confirm the existence of SO in the pyrolyzed sample by means of microwave spectroscopy and, moreover, to ascertain the state in which the sulfur monoxide is generated in order to understand the mechanism of the thermal decomposition.

Experimental

The reaction vessel and the Stark absorption cell used are shown in Fig. 1. The reaction vessel was made of a quarz tube 15 mm in diameter and 300 mm long; the temperature of the vessel was controlled by varying the voltage applied to the heater. The temperature of the vessel was measured at the outer surface of the tube by a chromel-alumel thermometer. The vessel was connected by a Teflon coupler 8 mm in inner diameter with the Stark absorption cell of the microwave spectrograph. The absorption cell was made of an X-band waveguide 800 mm long; this waveguide was split in two in the centers of the narrow sides. The two pieces of the split waveguide were separated and fixed by Teflon spacers of the **H** form so as to serve as Stark electrodes. The inner dimensions of the electrodes were made equal to those of the X-band waveguide.

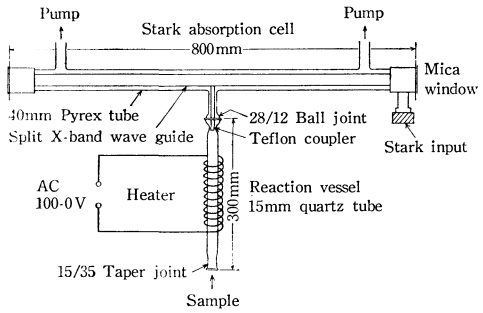

Fig. 1. Schematic diagram of reaction vessel and Stark absorption cell.

To prevent the decomposition and reaction of unstable molecules and radicals on the surface of the electrodes, the inner sides of the electrodes were coated with *"corning K"* coat.[10] The whole electrodes were then fixed in a Pyrex tube 40 mm in diameter by means of Teflon holders. The microweave spectrograph used was a conventional one with 110 kHz sinusoidal Stark modulation.[8] After passing through the absorption cell, the sample gas was led to a trap cooled to the temperature of liquid nitrogen, and then pumped by a rotary pump at the rate of 150 *l*/min.

The sample of ethylene episulfoxide, prepared by the oxidation of ethylene episulfide using perbenzoic acid, was kindly provided by Fukuyama, Sato and Makino.

Pyrolysis

The pyrolysis was done in the range from room temperature to 780°C and at pressures of from 0.01 to 0.1 mmHg. When the temperature of the reaction tube was raised gradually, at about 185°C the rotational line of sulfur monoxide in the electronic ground state, $^3\sum^-$, $J,K=1,0\leftarrow 0,1$ at 30001.58 MHz,[10] was observed by the use of a strip-chart recorder, as is shown in Fig. 2. With a further rise in the temperature, the absorption line of the SO became stronger, until above 250°C it was observable on a CRO. Above 560°C, the intensity of the line remained stationary. The variation in the intensity with the temperature is presented in Fig. 3. Under similar conditions of pyrolysis, the intensity of the transition of ethylene episulfoxide, $3_{03}\leftarrow 2_{02}$, at 31540.36 MHz[8] was followed. The temperature variation in the intensity is also shown in Fig. 3. It is clear that, above 560°C, ethylene episulfoxide decomposed by about 100%. The maximum signal-to-noise ratio of the absorption line of SO was about 5000, at 580°C and at 0.05 mmHg; this value was about twice as large as that of the SO generated in the reaction of atomic oxygen and OCS.[10,11]

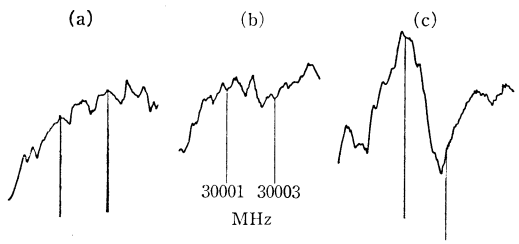

Fig. 2. Recorder tracings of the $J,K = 1,0 \leftarrow 0,1$ transition of the SO molecule in the $^3\sum^-$ state, generated in the pyrolysis of ethylene episulfoxide.
Frequency ≒ 30002 MHz
Stark DC bias = 500 V/cm
Stark mod. = 300 V/cm
Pressure = 0.02 mmHg
(a) At 180°C, the line of SO is not observed.
(b) At 187°C, the line is detected with the S/N of about one to two.
(c) At 200°C, the line has the S/N of about seven.

Experimental Results

The sample pyrolyzed at 580°C and 0.02 mmHg was analyzed semi-quantitatively by the use of the microwave spectra. The absorption lines of $(CH_2)_2SO$, SO, SO_2, and H_2CO were measured on a CRO, and those of $(CH_2)_2S$ and $(CH_2)_2O$, on a strip-chart recorder. The concentrations of the stable molecules, such as $(CH_2)_2SO$, SO_2, H_2CO, $(CH_2)_2S$, and $(CH_2)_2O$, were determined by comparison with the corresponding standard samples.[15] The concentrations of the unstable

molecules, SO[10] and S_2O,[16] were estimated by calculating the absorption intensity using the reported values of the microwave spectra. The results are listed in Table 1.

The final products of the pyrolysis were collected with a trap cooled at the temperature of liquid nitrogen; after vaporization, they were analyzed by the use of their infrared and microwave spectra. The main components of the products were ethylene and SO_2. The mole ratio between ethylene and SO_2 turned out to be about two.

Mechanism of Thermal Decomposition

It is interesting to consider the mechanism of the thermal decomposition of ethylene episulfoxide. The concentrations of ethylene sulfide and ethylene oxide were found to be less than 0.3% and 0.04% respectively, as is shown in Table 1. Thus, the abscission reaction of the S–O bond, which gives theatomicoxygen:

$$(CH_2)_2SO \longrightarrow (CH_2)_2S + O \qquad (1)$$

is probably not the main one in the thermal decomposition.

Prior to discussing the other mechanisms in detail, it is necessary to know the energy levels of ethylene and SO, and the heat of the decomposition. According to Evans,[17] Mulliken,[18] and Kuppermann and Raff,[19] the lowest triplet state of planar ethylene, $^3B_{3u}$, is about 4.6 eV ($\fallingdotseq$37100 cm^{-1}) above the ground state, ^1A_g. Rabinovitch, Douglas, and Looney[20] obtained the energy value of the lowest singlet state of perpendicular ethylene as the activation energy of the *cis-trans* isomerization of 1,2-di-deutero-ethylene. The $^1B_1$ state is located 2.66 eV ($\fallingdotseq$21500 cm^{-1}) above the ground state of the planar ethylene. There has been no observation of the lowest triplet state of the perpendicular ethylene, but the calculations for the electronic states of ethylene by various MO methods[21] suggest that the lowest triplet state, $^3A_2$, is below the singlet state, $^1B_1$, by from 0.1 to 0.3 eV. Hence, it is reasonable to assume that the $^3A_2$ state is located somewhere between 2.36 and 2.56 eV ($\fallingdotseq$19100 and 20700 cm^{-1}) above the ^1A_g state.

Unfortunately, there is no reliable data on the electronic states of SO. On the basis of the discussions made by Carrington *et al.*,[22] and on the basis of the energy levels of the oxygen molecule,[23–25] it is plausible to estimate that the $^1\Delta$ state of SO is located near, or less than 8000 cm^{-1} above, the ground state, $^3\Sigma^-$.

On the other hand, the heat of the decomposition of ethylene episulfoxide to ethylene and SO in the vapor phase can be calculated by the use of the heat of the formation of dimethyl sulfoxide on the assumption that the heat of the formation of ethylene episulfoxide from dimethyl sulfoxide by dehydrogenation is equal to that of ethylene sulfide from dimethyl sulfide.[26] The decomposition, $(CH_2)_2SO \rightarrow CH_2=CH_2+SO$, was found to be an exothermic reaction of about 39 ± 10 kcal/mol. (The uncertainty is mainly due to the assumption made above.)

The relative energies considered are shown schematically in Fig. 4. It is evident that the heat of decomposition is not enough to take the electronically-excited states of ethylene into the reaction path. The two possible reactions which yield both ethylene and sulfur monoxide in the ground states are as follows:

$$(CH_2)_2SO(^1A') + M \longrightarrow CH_2=CH_2(^1A_g) + SO(^3\Sigma^-) + M \qquad (2)$$

$$(CH_2)_2SO(^1A') \longrightarrow CH_2=CH_2(^1A_g) + SO(^1\Delta, {}^1\Sigma^+)$$

$$SO(^1\Delta, {}^1\Sigma^+) + X \longrightarrow SO(^3\Sigma^-) + X \qquad (3)$$

e) Assumed with inference for the oxygen molecule.[22-24]

The process (2) means the direct decomposition of ethylene episulfoxide into ethylene and sulfur monoxide by a collision with a third body, such as the hot surface of the reaction tube. Spin conservation[27] may be violated by such a collision. The reaction (3), however, is a reaction path which initially sets free the ethylene in the ground state and the sulfur monoxide in the excited singlet states. Then, the SO in the singlet states passes into the ground state under the influence of a third body.

According to Uehara,[28] no electron paramagnetic resonance lines of the SO in the $^1\Delta$ state[29] were detected in the pyrolysis of ethylene episulfoxide under conditions similar to those described above. The sensitivity of the spectrograph he used was about 1×10^{-11} spins/gauss. The lifetime of $^1\Delta$ SO should be rather long because the transition between the $^1\Delta$ and $^3\sum^-$ states is forbidden. Really, in the case of oxygen, the radiative lifetime of the O_2 in the $^1\Delta_g$ state is about 45 min.[25] Hence, the reaction (3) can not be the main process.

As a result, the main reaction of the thermal decomposition of ethylene episulfoxide must be (2): ethylene episulfoxide decomposes on the hot surface of the reaction tube to yield both the ethylene and SO molecules in the ground states.

In the above consideration, many unestablished assumptions have been used, such as those concerning the term energies of ethylene and SO, the heat of the decomposition of $(CH_2)_2SO$, and the sensitivity of the EPR spectrometer. The possibility of the reaction (3) should not, therefore, be excluded completely. To understand the mechanism further, it will be helpful to determine the heat of the decomposition of ethylene episulfoxide and to locate the $^1\Delta$ and $^1\sum^+$ states of SO.

The SO molecule thus generated is unstable. The decomposition of the SO molecule has been studied by many investigators. Schenk and Steudel have reviewed the research into this problem up to 1964.[30] The reaction of SO has not been specifically investigated in this study, but it is meaningful to refer to the decomposition of SO, especially since the present system of reaction is almost free from the oxygen atom and the oxygen molecule. As Table 1 shows, the rotational lines of SO_2 and S_2O were observed immediately after the pyrolysis. It was also noticed that solid sulfur adhered to the inner walls of the reaction tube and the trap. These facts can be explained by the following reactions, which have already been discussed[30,31]:

$$SO + SO \longrightarrow SO_2 + S$$
$$SO + S \longrightarrow S_2O$$

Schenk and Steudel[30] pointed out that the S_2O molecule was stable in the vapor phase, but that it polymerized in the cold trap and the polysulfur oxide decomposed into solid sulfur and SO_2 at room temperature. Thus, all of the oxygen atoms initially contained in the ethylene episulfoxide molecules passed into the SO_2 molecules. This mechanism explains why the ratio between ethylene and SO_2 in the final products of the pyrolysis was about two, by means of the following overall reaction:

$$6(CH_2)_2SO \longrightarrow 6CH_2{=}CH_2 + 3SO_2 + 3S$$

The author would like to thank Professor Yonezo Morino for his encouragement and valuable advice throughout this work. He also wishes to thank Dr. H. Uehara and Mr. Y. Nakano for their helpful discussions, and Dr. M. Fukuyama and Mr. K. Sato, who supplied the sample of ethylene episulfoxide.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 671—676 (1969)

The Charge-transfer Bands in the Crystal Spectra of Molecular Compounds of Tetramethylbenzidine and Those of Benzidine

Takako AMANO, Haruo KURODA and Hideo AKAMATU

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo

(Received August 7, 1968)

The polarized absorption spectra in the 280—1100 mμ region have been observed for the single crystals of eight molecular compounds which involve *N,N,N′,N′*-tetramethylbenzidine and benzidine as the electron donor and *p*-chloranil, TCNQ, 1,3,5-trinitrobenzene, and *p*-benzoquinone as the electron acceptor. The donor and acceptor molecules are not in the ionic states in the ground states of these molecular compounds, in spite of the low ionization potentials of tetramethylbenzidine and benzidine. The observed spectra are composed of absorption bands associated with intramolecular transitions in the constituent molecules and those associated with the charge transfer from the donor to the acceptor. It was found that the polarization of the second charge-transfer band is almost perpendicular to that of the first one in the case of chloranil and TCNQ compounds of benzidine and tetramethylbenzidine. In other cases, the first and second charge-transfer bands were confirmed to be polarized nearly parallel to each other as in a usual charge-transfer molecular compound.

Aromatic amines generally behave as a good π-electron donor. They form solid molecular compounds by the interaction with a variety of π-electron acceptors. These molecular compound crystals have been often found to be an organic semiconductor of relatively good electrical conductivity.[1,2] In a previous paper,[3] we have studied the electronic spectra of single crystals of molecular compounds which are formed by aromatic amines with chloranil. We have shown that a strong donor such as *N,N,N′,N′*-tetramethyl-*p*-phenylenediamine (TMPD) gives a salt-like, solid consisting of the positive ions of donor and the negative ions of acceptor, whereas a "charge transfer" molecular compound, where the constituent molecules are essentially in the non-ionic state, is formed by an aromatic amine of not very strong donor property. The molecular compound of *N,N,N′,N′*-tetramethylbenzidine with chloranil is anomalous in this respect. Although tetramethylbenzidine must be a strong donor with an ionization potential comparable to that of TMPD, this molecular compound has been reported to have a non-ionic structure.[1] Interestingly tetramethylbenzidine forms a non-ionic molecular compound even with a very strong π-electron acceptor such as 7,7,8,8-tetracyanoquinodimethane (TCNQ).[4]

In view of this unusual situation found for the molecular compounds of tetramethylbenzidine, we have attempted to obtain informations concerning the charge-transfer interaction in these molecular compounds by observing the electronic spectra of single crystals. In the present paper, we shall report the polarized absorption spectra in the visible and ultraviolet region observed for the molecular compound crystals which involve tetramethylbenzidine or benzidine as the donor and TCNQ, *p*-chloranil, 1,3,5-trinitrobenzene, and *p*-benzoquinone as the acceptor.

Experimental

Molecular compound crystals were obtained from benzene or carbon tetrachloride solutions containing appropriate amounts of donor and acceptor. The composition of each molecular compound was determined by the elementary analysis of the crystalline powder.

The infrared spectrum was examined on each molecular compound by use of the Nujol-mull method for the purpose to know if the component molecules are in the ionic state or not. The observed infrared spectra of molecular compounds were compared with those of the neutral molecules and ions of the components. We examined also the electron spin resonance absorption. All these results led us to conclude that none of the molecular compounds studied here is an ion-radical salt.

The polarized absorption spectra of single crystals, in the 280—1100 mμ region, were measured with a

microspectrophotometer, a modification of OLYMPUS MSP-A-IV. The details of the apparatus and experimental procedures have been already described elsewhere.[5] The measurement was carried out at the room temperature on the developed face of a crystal microscopic size, which have been carefully selected out from a freshly prepared crystalline powder. When we noticed the presence of several different crystal habits, the absorption spectra were observed on each type of crystal. The absorption spectra of the Nujol mulls of crystalline powders were also observed to obtain information concerning the low-energy absorption bands.

Results

The experimental results are shown in Figs. 1—9, where the polarized absorption spectra measured on one typical crystal only are shown for each molecular compound.

(a) Tetramethylbenzidine-Chloranil (1 : 1) Compound. The spectra shown in Fig. 1 indicate the presence of a strong band with an absorption maximum at a wave number below 9 kK. By examining the Nujol-mull spectrum of the crystalline powder, it was found that the maximum of this band is located at 8—9 kK and probably is the lowest-energy electronic band of this molecular compound crystal. This band is exclusively polarized in the direction parallel to one of the edges of a parallel piped crystal, which is denoted "X" in Fig. 1. The next band is found at 18.3 kK, which exhibits a polarization quite different from that of the first band, namely the absorption occurs strongly as the incident light is polarized in the Y-direction, *i. e.* a direction perpendicular to X. The polarization ratio, I_Y/I_X, was found to be about 4. These two bands can not be attributed to any intramolecular transition since the lowest transition is at 32.9 kK ($B_{1u}\leftarrow A_g$, π–π^*) in tetramethylbenzidine and at 27 kK (forbidden π–π^* transition) in chloranil. We shall tentatively assign them as the first and second charge-transfer bands. Seemingly the broad band in the 25—30 kK region is a local excitation band associated mainly with the 32.9 kK transition of tetramethylbenzidine.

(1) X-spectrum, (2) Y-spectrum

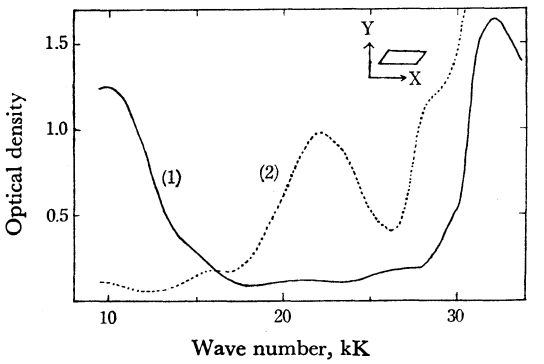

Fig. 2. Absorption spectra of benzidine-chloranil compound.
(1) X-spectrum, (2) Y-spectrum

(b) Benzidine-Chloranil (1 : 1) Compound. The spectra of this molecular compound are similar in many respects to those of the tetramethylbenzidine-chloranil compound. There are two bands in the region where we can expect no band due to intramolecular transition. We assign them as the first and second charge-transfer bands. The maxima of these bands are located respectively at 10 and 22.2 kK. These bands are polarized almost perpendicular to each other as in the tetramethylbenzidine-chloranil compound. A strong peak at 32 kK is probably due to the 35 kK π–π^* transition ($B_{1u}\leftarrow A_g$) of benzidine and/or the 35 kK π–π^* transition ($B_{1u}\leftarrow A_g$) of chloranil. Then we have to consider that these transitions have been shifted to lower energy by about 3 kK in the molecular compound crystal. Presumably a small shoulder at 28 kK is associated with the 27 kK transition (π–π^*, forbidden) of chloranil.

(c) Tetramethylbenzidine-TCNQ (1 : 1) Compound. As is well known, TCNQ is a very

strong acceptor, which forms ion-radical salts with a variety of electron donors. In effect, the TMPD-TCNQ compound is composed of $TMPD^+$ ion and $TCNQ^-$ ion, between which there exists a relatively strong charge-transfer interaction.[6] In the case of the tetramethylbenzidine-TCNQ compound, however, all experimental results suggest that the component molecules are essentially in the neutral states. We believe that this molecular compound can be regarded as a non-ionic molecular compound. The high-energy tail of an absorption band can be seen at the low wavenumber limit of the observed spectra shown in Fig. 3. The absorption maximum of this band was found to be located at 7.5 kK in the Nujol-mull spectrum of the powder. The second band is very broad and markedly asymmetric, the maximum of which is located at 16.5 kK. The polarization direction is nearly perpendicular to each other between these two bands. We assign them as the charge-transfer bands. The third band located at about 29 kK is likely to be a local-excitation band associated with the 32.9 kK transition of tetramethylbenzidine. An alternate assignment would be to attribute it to the lowest π–π^* transition of TCNQ (25.3 kK, $B_{1u} \leftarrow A_{1g}$). But the former assignment seems more plausible when we compare the spectrum in this region with that of the benzidine-TCNQ compound.

(d) Benzidine-TCNQ (1 : 1) Compound. Similar to the tetramethylbenzidine-TCNQ compound, we can assign the lowest-energy band at 8 kK and the next band at 18 kK as the first and second charge-transfer bands respectively. In the 25—35 kK region, there is a peak at 32 kK and a shoulder at about 26 kK. It should be noted that the benzidine-chloranil compound also exhibits a strong absorption band at 32 kK while the compound of tetramethylbenzidine with chloranil and that with TCNQ give a band at 29 kK. Therefore the 32 kK band in the benzidine compounds seems to be mainly associated with the intramolecular transition of benzidine, and not due to TCNQ. Presumably the 26 kK shoulder is associated with the 25.3 kK transition of TCNQ.

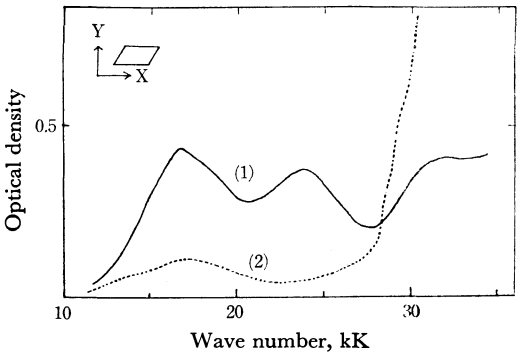

Fig. 5. Absorption spectra of tetramethylbenzidine-trinitrobenzene compound.
(1) X-spectrum, (2) Y-spectrum

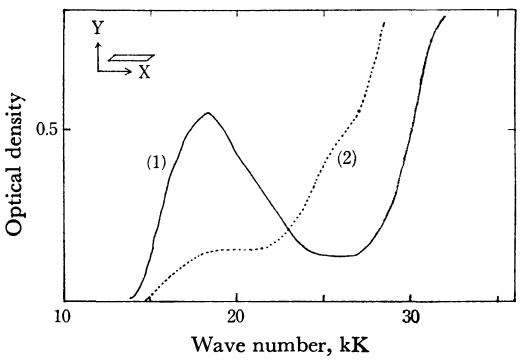

Fig. 6. Absorption spectra of benzidine-trinitrobenzene compound.
(1) X-spectrum, (2) Y-spectrum

(e) Tetramethylbenzidine-Trinitrobenzene (1 : 2) Compound. The two absorption bands, at 16.7 kK and 23.9 kK, can be assigned as the first and second charge-transfer bands. In this case, the polarization is not significantly different between these two charge-transfer bands. In this respect, this molecular compound is markedly different from the chloranil- and TCNQ-compounds mentioned above, but is similar to usual charge-transfer compounds. In order to obtain more precise information concerning the polarization direction, we observed the variation of optical density with the direction of polarization of incident light. The results obtained at the wavenumbers corresponding to the absorption maxima of the two charge-transfer bands are shown in Fig. 7, which indicates that the principal axis of absorption is slightly different between the two bands.

(f) Benzidine-Trinitrobenzene (1 : 1) Compound. The orientation of a trinitrobenzene molecule relative to a benzidine molecule in the

6) H. Kuroda, S. Hiroma and H. Akamatu, This Bulletin, **41**, 2855 (1968).

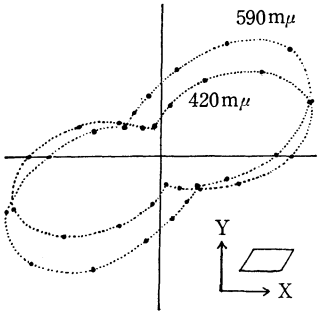

Fig. 7. Variation of optical density with the direction of polarization of incident light, measured for tetramethylbenzidine-trinitrobenzene compound.

crystal of this molecular compound has been reported to be as follows by Wallwork[7]: The benzidine and trinitrobenzene molecules are alternately stacked face-to-face on each other along a crystal axis, but the molecular center of trinitrobenzene is shifted sideway from the position where it would be directly over that of benzidine. In this sence, the arrangement of molecules in this molecular compound is analogous to those in a typical charge-transfer compound. This compound can be obtained in the form of a needle crystal, the elongated axis of which corresponds probably to the direction of the alternate stacking of donor and acceptor molecules. As shown in Fig. 6, we denoted this elongated direction as "X". The absorption band found at 18.3 kK is strongly polarized along the X-direction. This can be assigned as the first charge-transfer band. The second charge-transfer band is not clearly observed. In the Y-polarized spectrum, there is a weak shoulder around 26 kK, which might be due to the second charge-transfer band. If this is the case, we have to consider that there is a significant difference in the polarization direction between the first and second charge-transfer bands. But it is also possible that this 26 kK shoulder is

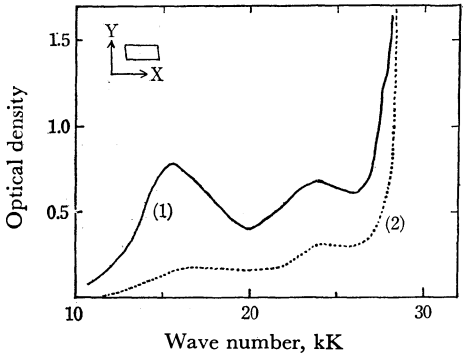

Fig. 8. Absorption spectra of tetramethylbenzidine-*p*-benzoquinone compound.
(1) X-spectrum, (2) Y-spectrum

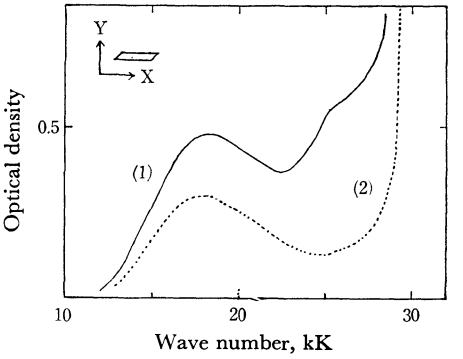

Fig. 9. Absorption spectra of benzidine-*p*-benzoquinone compound.
(1) X-spectrum, (2) Y-spectrum

associated with a local excitation, not with the charge transfer.

(g) Tetramethylbenzidine-*p*-Benzoquinone (1 : 2) Compound. The 15.6 kK and 23.8 kK bands in Fig. 8 can be assigned as the first and second charge-transfer bands respectively. The polarization direction is not appreciably different between these bands. The mole ratio of donor to acceptor is found to be 1 : 2. In these respects, the general situation seems to be similar to the tetramethylbenzidine-trinitrobenzene compound.

(h) Benzidine-*p*-Benzoquinone (2 : 1) Compound. Although the molecular size of benzidine is almost twice that of *p*-benzoquinone, the mole ratio was found to be 1 : 2. This fact seems to suggest that this molecular compound possesses some peculiar crystal structure. The 18kK band in Fig. 9 can be regarded as the first charge-transfer band. The polarization ratio I_X/I_Y is about 1.7 in this band. Presumably a weak shoulder at about 25 kK in the X-polarized spectrum corresponds to the second charge-transfer band.

Discussion

As we have shown above, most of the solid molecular compounds of tetramethylbenzidine and benzidine exhibit two absorption bands in the region where we can expect no local excitation band. We have tentatively assgin them as the first and second charge-transfer bands. The energies of these bands are plotted in Figs. 10 and 11 against the electron affinity of acceptor.*1 These plots clearly demonstrate that the excitation energies are, in fact, almost linearly dependent of the electron affinity of acceptor as expected for a band associated with the charge transfer from a donor molecule to an acceptor molecule.

In solution, tetramethylbenzidine and benzidine

○ solution, ● crystal

form molecular complexes with π-electron acceptor, in which the donor and acceptor molecules are in face-to-face contact with each other. The energies of the charge-transfer bands observed for these complexes are also plotted in Figs. 10 and 11. The first charge-transfer band of a molecular compound crystal is a little lower in energy compared with the corresponding band of the molecular complex formed in solution. The energy of the second charge-transfer band of a molecular compound crystal, however, nearly coincides with that of the corresponding band of the complex in solution.

* The following abbreviations are used; Q: *p*-benzoquinone, TNB: 1,3,5-trinitrobenzene, QCl_2: 2,5-dichloro-*p*-benzoquinone and QCl_4: chloranil.

As is well known, there is a simple relation between the ionization potential, I, of the donor and the energy of the charge-transfer band, $h\nu_{CT}$, of the 1 : 1 complex which is formed in solution between a donor molecule and an acceptor molecule. Briegleb and Czekalla have proposed the following empirical equation for a series of chloranil complexes.[9]

$$h\nu_{CT} = I - 5.7 + 0.44/(I-5.7) \quad [\text{eV}] \qquad (1)$$

We have reexamined the relation, and found that the energy of a charge-transfer band of a chloranil complex can be well expressed as follows.

$$h\nu_{CT} = 0.87I - 4.46 \quad [\text{eV}] \qquad (2)$$

We have calculated the self-consistent-field molecular orbitals (SCF-MO's) for the π-conjugated systems in benzidine and tetramethylbenzidine by the variable-β modification of Pariser-Parr-Pople method.*2 The energy and symmetry of the calculated SCF-MO are given in Table 1.

Table 1. Energies of SCF MO's of benzidine and tetramethylbenzidine

Level	Symmetry*	Orbital energy (eV)		
		Benzidine	Tetramethylbenzidine	
1	b_{3u}	−13.56	−13.46	occupied
2	b_{2g}	−13.29	−13.15	
3	b_{3u}	−12.14	−11.95	
4	b_{2g}	−10.97	−10.75	
5	a_u	− 9.90	− 9.85

7	b_{3u}	− 9.15	− 8.88	
8	b_{2g}	− 8.05	− 7.84	
9	b_{3u}	− 1.19	− 1.11	unoccupied
10	a_u	− 0.63	− 0.57	
11	b_{1g}	− 0.58	− 0.52	
12	b_{2g}	0.35	0.42	
13	b_{3u}	2.01	2.07	
14	b_{2g}	2.85	2.92	

* The long axis of benzidine molecule is taken as Z axis.

From these calculations, we can predict the ionization potential as 7.0 and 6.8 eV respectively in benzidine and tetramethylbenzidine.[10] Substituting these values in Eq. (1) as well as in Eq. (2), we estimated the energy of the first charge-transfer band for the chloranil complexes of these amines. The energy of the second charge-transfer

9) G. Briegleb and J. Czekalla, *Z. Elektrochem.*, **63**, 6 (1959).

*2 The procedures of SCF-MO calculation are described elsewhere.[10] The calculation was carried out by using HITAC 5020E at the computer center of The University of Tokyo.

band was estimated by assuming that its energy difference from the first band is equal to the separation between the highest occupied and second highest occupied orbitals of donor. The results are given in Table 2, which are in satisfactory agreement with the observations. Therefore we can conclude that, in the case of these complexes in solution, the first and second charge-transfer bands are associated respectively with the charge transfer from the highest occupied orbital of donor to the lowest vacant orbital of acceptor and that from the second highest occupied orbital of donor.

TABLE 2. CALCULATED AND OBSERVED FREQUENCIES OF THE FIRST AND SECOND CHARGE-TRANSFER BANDS OF BENZIDINE AND TETRAMETHYLBENZIDINE COMPLEXES WITH CHLORANIL IN SOLUTION (kK)

	Calcd		Obsd
	by Eq. (1)	by Eq. (2)

First CT band	13.2	13.2	14.2
Second CT band	22.1	22.0	22.0
Tetramethylbenzidine-Chloranil			
First CT band	12.1	11.8	11.7
Second CT band	20.4	20.2	19.7

In the molecular compound crystal, the electronic processes responsible for the charge-transfer bands could be different from those in the 1 : 1 complex in solution since a donor molecule is surrounded by several acceptor molecules in the crystal state. In this case, the charge transfer could take place from a donor molecule not only to the nearest acceptor molecule but also to the second nearest acceptor molecules or others. However, we can safely conclude that the first charge-transfer band of the crystal is associated with the charge transfer from the highest occupied orbital of donor molecule to the lowest vacant orbital of the nearest acceptor molecule since its excitation energy is a little lower than the first charge-transfer band of the corresponding complex formed in solution.

The situation is a little complicated in the second charge-transfer band. In the crystal of a typical charge-transfer compound, the donor and acceptor molecules are alternately stacked along one of the crystal axes. In such a case, an absorption band associated with the charge transfer from a donor molecule to the nearest acceptor molecule should be polarized parallel to this stacking axis unless it is markedly mixed with a local excitation. In effect the observed direction of polarization is in accord with this prediction for the first charge-transfer bands as well as for the second one in a variety of molecular compounds. However, in the molecular compounds of tetramethylbenzidine or benzidine with chloranil and in those with TCNQ, the second charge-transfer band in the crystal spectrum is polarized in the direction almost perpendicular to the polarization direction of the first charge-transfer band. This polarization of the second charge-transfer band could not be explained if we attribute the band to the charge transfer from a donor molecule to the neareast acceptor molecule as in the first charge-transfer band.*3

Presumably the second charge-transfer band is associated with the charge transfer from a donor molecule to the second-nearest acceptor molecule whereas the first one is associated with the charge transfer to the nearest acceptor molecule. If the distance of the second-nearest acceptor molecule from the donor is markedly larger than that of the nearest acceptor molecule, the band due to the charge transfer to the second-nearest acceptor molecule should be of extremely small intensity. This is not the case as can be seen in the spectra shown in Figs. 1—4. We have to consider therefore that the second-nearest acceptor molecule is also in a close contact with the donor molecule.

Then the large energy difference between the first and second charge-transfer bands could not be attributed to the difference in the Coulomb energy term only. A possible explanation would be as follows: the relative orientation of a donor molecule to the nearest acceptor molecule allows the charge transfer from the highest occupied orbital of donor to the lowest vacant orbital of acceptor, but not that from the next occupied orbital of donor, whereas the latter can effectively occur between a donor molecule and the second-nearest acceptor molecule. In other words, the second chrage-transfer band is mainly associated with the charge transfer from the second highest occupied orbital of a donor molecule to the lowest vacant orbital of the second nearest acceptor molecule. Thus the energy difference between the first and second charge-transfer band would be mainly determined by the energy difference between the highest two occupied orbitals of the donor. Anyway, the crystal structure analysis has to be carried out on one of these molecular compounds in order to clarify the validity of the above posturated explanation for the charge-transfer bands. It is now in progress in our laboratory on the tetramethylbenzidine-chloranil (1 : 1) compound.

The polarized crystal spectra of benzidine-TCNQ molecular compound shown in this paper was measured by Mr. S. Hiroma of our laboratory, to whom the authors' thanks are due.

*3 We can exclude the possibility that the first and second bands correspond to the factor group components of a single transition because they are separated from each other as large as 1 eV or more.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 677—681 (1969)

Solubility of Ag_2O in Na_2O-B_2O_3 Melts

Takashi MAEKAWA, Toshio YOKOKAWA and Kichizo NIWA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo

(Received August 8, 1968)

The solubility of silver oxide in Na_2O-B_2O_3 melts was determined as a function of the Na_2O contents, the temperature (825°C—935°C), and the oxygen partial pressures. The results show that the silver oxide dissolves in a borate as a network modifier, just like alkali metal oxides, which destroy the B–O–B bonds to produce four coordinated boron as well as three. In the Ag_2O-B_2O_3 binary system, the solubility of silver oxide increases with an increase in the oxygen partial pressures. In the Ag_2O-Na_2O-B_2O_3 ternary system, the solubility of Ag_2O decreases with an increase in the Na_2O contents. This shows that the silver oxide is a weaker base than sodium oxide. The activity of the oxygen ion, $a_{O^=}$, was determined from the iso-activity lines of silver oxide. In a constant basic oxide content, $a_{O^=}$ increases with an increase in the Na_2O content. By extrapolating the Ag_2O contents to zero, the oxygen-ion activity in the Na_2O-B_2O_3 melt was determined.

Molten oxides are quite interesting because of their special structures and have been studied from various aspects. The borates are especially distinguishable from such other mixed oxides as phosphates and silicates because of their structures. The boron atom can coordinate four oxygen atoms as well as three. Therefore, the borate melts show an exceptional behavior known as the boron anomaly.

Various attempts to explain the structure of molten oxides have been made. Lux and Flood[1,2] explained the thermodynamic properties in terms of acidity and basicity. Krogh-Moe[3,4] and Bray *et al.*[5], studied the structure of borate with techniques of X-ray, NMR, and phase diagrams and measured the ratio of four to three-coordinated boron atoms with various contents of alkali metal oxide. Shartsis *et al.*,[6,7] measured the density, viscosity, and electrical resistivity of molten alkali borates.

The present work was performed in order to clarify whether silver oxide dissolves in a boron oxide as a network modifier and in order to examine the behavior of silver oxide in the presence of sodium oxide. The solubility of silver oxide in B_2O_3 has already been measured by Willis and Hennessy.[8]

Another aim of this investigation was related to the basicity of oxide melts. The oxygen-ion activity in an oxide melt is an important factor, since the basicity of the melts, which varies with the melt composition and kind of basic oxide, is supposed to be determined by this quantity. Pearce[9] measured the solubility of carbon dioxide and obtained the oxygen-ion activity in soda-silica melts. In this work the oxygen-ion activity was determined from the solubility measurements of Ag_2O in the Na_2O-B_2O_3 system.

Experimental

(a) Material and Preparation. Samples were prepared from commercial chemicals of a guaranteed reagent grade. Their impurities were as follows; $SO_4<0.003\%$, heavy metals$<0.001\%$, and $Fe<0.002\%$ for B_2O_3; $SO_4<0.002\%$, $Cu<0.0005\%$, and $Fe<0.002\%$ for $AgNO_3$; $Cl<0.001\%$, $SO_4<0.002\%$, and $PO_4<0.002\%$ for borax.

To prepare the Na_2O-B_2O_3 mother melt, a suitable quantity of boric oxide and borax were melted in a platinum crucible.

(b) Chemical Analysis. For the determination of silver, a weighed sample of glass was dissolved in dilute HNO_3 and then the solution was titrated with standardized KSCN. The B_2O_3 was determined in the following way. The sample was dissolved in dilute nitric acid and the pH was adjusted with *p*-nitrophenol. Glycerol was then added, and the B_2O_3 was titrated with an NaOH standard solution.

(c) **Oxygen Pressure.** A gas mixture of oxygen and nitrogen, the oxygen partial pressure of which has previously been determined by being introducing it into the gas chromatograph at appropriate time intervals, was bubbled through the melt during each run.

(d) **Temperature.** The temperature was controlled with an Okura EC-51-type controller. During every run, the temperature was kept constant within ±1°C.

(e) **Procedure.** The method of Willis and Hennessy was employed. The sample melt was inserted in an Ag crucible and heated in an atmosphere containing oxygen of various partial pressures.

The solution reaction can be expressed by:

$$2Ag + \tfrac{1}{2}O_2 = Ag_2O \text{ (in borate)} \qquad (1)$$

The equilibrium constant, K, is defined by:

$$K = a_{Ag_2O}/\sqrt{P_{O_2}}\, a_{Ag}^2 \qquad (2)$$

at a given temperature.

Since a_{Ag} is set at unity under the present experimental condition, a_{Ag_2O} is directly proportional to the square root of the equilibrium oxygen partial pressure. Further, it is convenient to define the standard state of Ag_2O as the melt which is in equilibrium with 1 atm of oxygen. Therefore, the activity of Ag_2O is given simply by $\sqrt{P_{O_2}}$ when P_{O_2} is expressed in terms of atmosphere. The diameter of the silver crucible is 2 cm, and it is 4 cm deep. The sample in the crucible was maintained at the desired temperature in a tubular resistance furnace. An oxygen-nitrogen gas mixture was bubbled through the silver tube into this sample. The rate of the reaction (1) is very slow to the right direction, since the reaction proceeds one-dimensionally along the circle where the three phases are in contact. On the other hand, the backward reaction proceeds two-dimensionally on the surface of the melt, where the excess silver precipitates from the melt. The preliminary experiments showing this situation are represented in Fig. 1. The backward reaction required only about 20 hr, while it took more than 100 hr for the forward reaction to approach equilibrium. Therefore, the solubility of Ag_2O was measured mostly from the backward reaction.

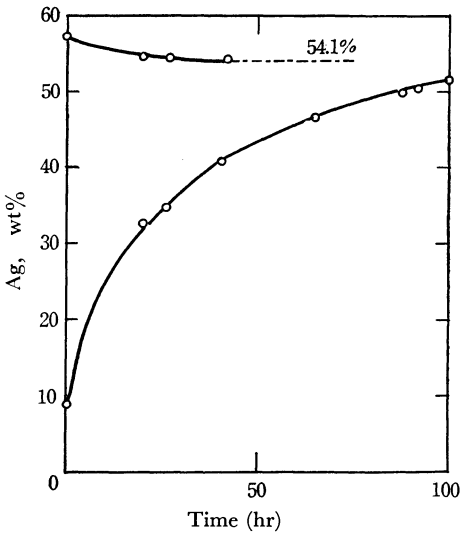

Fig. 1. Preliminary experiment of solution equilibrium of the reaction; $2Ag+\frac{1}{2}O_2=Ag_2O$ (in borate) at 900°C under 1 atm of oxygen. The equilibrium value is 54.1%.

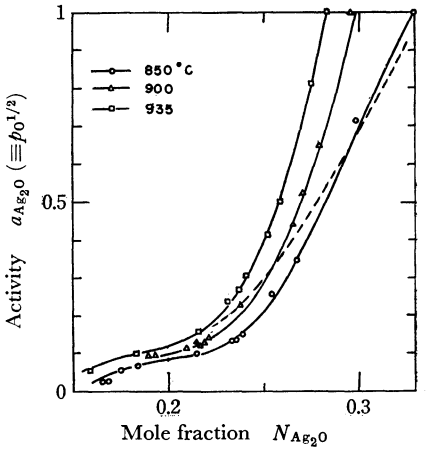

Fig. 2. The activity of Ag_2O, $a_{Ag_2O}(\equiv P_{O_2})$, at 850°C, 900°C, and 935°C. The dotted curve represents the Willis and Hennessy's data at 850°C. The standard state for Ag_2O is the melt in equilibrium with silver and oxygen at 1 atm.

Results and Discussion

(1) Ag_2O-B_2O_3 Binary System. Figure 2 shows the activity of Ag_2O as a function of the composition of Ag_2O at a constant temperature. The dotted curve represents the Willis and Hennessy data at 850°C. It should be noted first that the solubility of silver oxide increases with the oxygen pressure in accordance with Eq. (1). The curve of Willis and Hennessy agrees fairly well with that of the present binary system.

The partial-molar Gibbs free energy of the solution of Ag_2O is obtained from the relation:

$$\bar{G}_{Ag_2O} = RT \ln a_{Ag_2O} \qquad (3)$$

$\bar{G}_{Ag_2O}$ is plotted in Fig. 3 as a function of the Ag_2O concentration. Here one should note that the standard state is the solution in equilibrium with one atmosphere of oxygen.

From the temperature dependence of the partial-molar free energy of a solution, the partial-molar heat of the solution was derived; it is plotted as a function of the composition in Fig. 4. Because of the narrow temperature ranges, the values of the heat of solution are uncertain within the limits of error of ±1 kcal/mol.

The partial molar entropy is obtained from the equation;

$$\bar{S}_{Ag_2O} = (\bar{H}_{Ag_2O} - \bar{G}_{Ag_2O})/T \qquad (4)$$

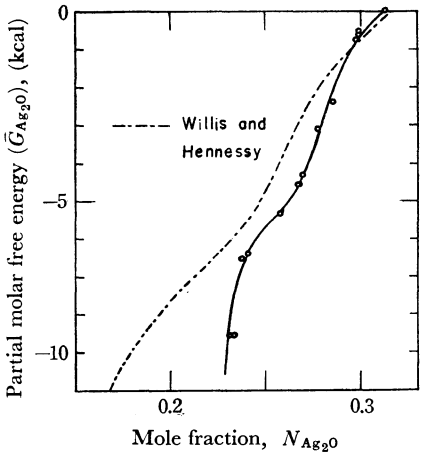

Fig. 3. Partial molar free energies of Ag_2O ($\bar{G}_{Ag_2O}$) in Ag_2O-B_2O_3 melts at 850°C.
The dotted curve represents the Willis and Hennessy's data. The standard state for Ag_2O; Silver and oxygen at 1 atm.

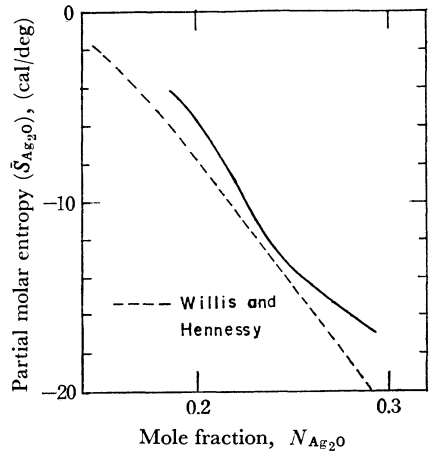

Fig. 5. Partial molar entropies of Ag_2O ($\bar{S}_{Ag_2O}$) in Ag_2O-B_2O_3 melts.
The dotted curve represents Willis and Hennessy's data. Standard state for Ag_2O: Silver and oxygen at 1 atm.

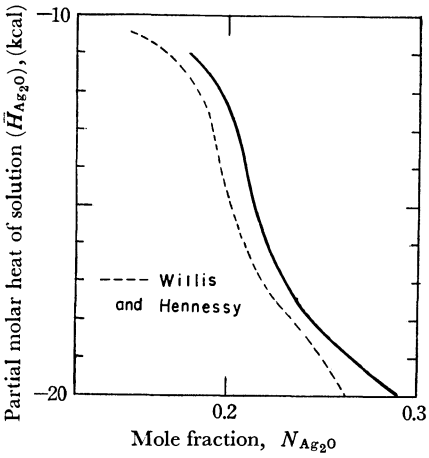

Fig. 4. Partial molar heat of solution of Ag_2O ($\bar{H}_{Ag_2O}$) in Ag_2O-B_2O_3 melts.
The dotted curve represents the Willis and Hennessy's data. Standard state for Ag_2O: silver and oxygen at 1 atm.

it is shown in Fig. 5.

In all cases there is an inflection at $N_{Ag_2O}=0.2$. These phenomena indicate that the structure of Ag-borate changes significantly around this composition. In the alkaline borate melts, the destruction of the network proceeds by means of the following reaction;

$$2\ \begin{matrix}O\\ O\end{matrix}\!\!>\!B\text{–}O\text{–} + O^{=} = 2\ \begin{matrix}O\\ O\end{matrix}\!\!>\!B\!<\!\begin{matrix}O^{-}\\ O\end{matrix} \quad \text{or} \quad 2\ \begin{matrix}O\\ O\end{matrix}\!\!>\!B\text{–}O^{-} \qquad (5)$$

The ratio of four- to three-coordinated boron atoms and the behavior of non-bridging oxygen ions, in the above reaction have been discussed by Beekenkamp[10] in the case of alkali borate glasses. He proposed the equation;

$$N_4 = X_4(X/1-X) \qquad (6)$$

where X_4 is defined by;

$$X_4 = [1+\exp(-\Delta G/KT)]^{-1} \qquad (7)$$

where ΔG is the thermodynamic potential difference between the BO_3-M unit and the BO_4-M unit, and where X is the mole fraction of alkali oxide. The same mechanism seems to be applicable in the present system. Thus, the inflection around $N_{Ag_2O}=0.2$ can be explained in terms of the equilibrium of the BO_3 unit and BO_4. If one follows the above line of approach, these experimental results seem to show that the formation of four-coordinated boron atoms is predominant to $N_{Ag_2O}=0.2$, while after this composition non-bridging oxygen ions gradually begin to be formed.

The infrared absorption spectra[11] and the electric conductivity[12] in the Ag_2O-B_2O_3 system, which have been determined in our laboratory, also support this view.

(2) Ag_2O-Na_2O-B_2O_3 Ternary System. Figure 6 shows the square root of the oxygen partial pressure, *i. e.*, a_{Ag_2O}, as a function of the composition, it also shows the Na_2O content at 850°C. The iso-activity lines in the Ag_2O-Na_2O-B_2O_3 ternary composition diagram are shown in Fig. 7. The solubility of silver oxide decreases with an

Curve 1, 2, 3, 4, 5, and 6 refer respectively to the ratio of $N_{Na_2O}/N_{B_2O_3}$ = 0, 1/18, 1/9.0, 1/5.0, 1/4.8, and 1/2.

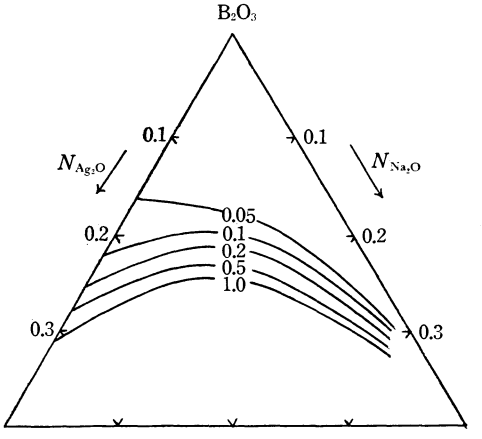

Fig. 7. The iso-activity lines of Ag_2O in Ag_2O-Na_2O-B_2O_3 ternary composition diagram at 850°C.
The standard state for Ag_2O is the melt in equilibrium with silver and oxygen at 1 atm.

increase in the Na_2O contents. This indicates that the silver oxide is a weaker base than sodium oxide. This is due to the fact that, while the silver ion and the sodium ion are both monovalent and are comparable in their ionic radii, the silver ion has a large polarizability and its bond to oxygen shows a somewhat covalent character. From Fig. 7 the following fact is shown: when the Ag_2O contents are small, the a_{Ag_2O} value increases with the increase in the Ag_2O contents at a constant composition of B_2O_3, but on the Ag_2O-rich side the inverse relation occurs. This might be explained by a possible strong negative interaction among silver ions when the Ag_2O contents increase. However, this idea is not acceptable in view of the fact that in the Ag_2O-B_2O_3 binary system Ag_2O behaves much like Na_2O. In molten oxide systems, it has been proposed that the strength of the base can be expressed in terms of the oxygen ion activity. This is an idea similar to that of the hydrogen ion concentration in aqueous solutions. An acid-base equilibrium was porposed by Lux and Flood to result from the following reaction;

$$\text{Base} = \text{Acid} + O^= \tag{8}$$

Therefore, the higher the oxygen ion activity in a melt, the stronger its basicity. The basicity of the melts will change with the relative contents of Ag_2O and Na_2O due to the difference in the oxygen-ion activity of the two components, even in the melts with an equal composition of total basic oxides. Thus Fig. 7 shows that the oxygen-ion activity of Ag-borate is smaller than that of Na-Borate. If Ag_2O and Na_2O dissociate perfectly in the melts, the following relations hold;

$$a_{Ag_2O} = a_{Ag^+}^2 \cdot a_{O^=} = N_{Ag^+}^2 \cdot \gamma_{Ag^+}^2 \cdot a_{O^=} = N_{Ag^+}^2 \cdot A \tag{9}$$

Here the A quantity is defined by;

$$A = a_{Ag_2O}/N_{Ag_2O} = \gamma_{Ag^+}^2 \, a_{O^=} \tag{10}$$

where;

$$N_{Ag^+} = N_{Ag_2O}/(N_{Ag_2O} + N_{Na_2O}) \tag{11}$$

Figure 8 shows the relation between A and N_{Ag} at a constant composition of basic oxides. From Fig. 8 it may be seen that, even at a constant basic oxide composition, A increases with the increase in the proportion of Na_2O to Ag_2O. If

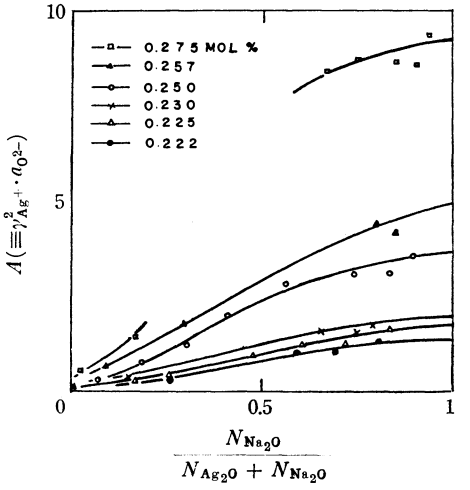

Fig. 8. The quantity $A(=\gamma_{Ag^+}^2 \cdot a_{O^{2-}})$ as a function of $N_{Na}(=N_{Na_2O}/(N_{Ag_2O}+N_{Na_2O})$ at constant basic oxide concentration at 850°C.

it is assumed that γ_{Ag^+} is independent of the composition. A becomes proportional to $a_{O^=}$. γ_{Ag^+} will be assumed to be constant at the lower limits

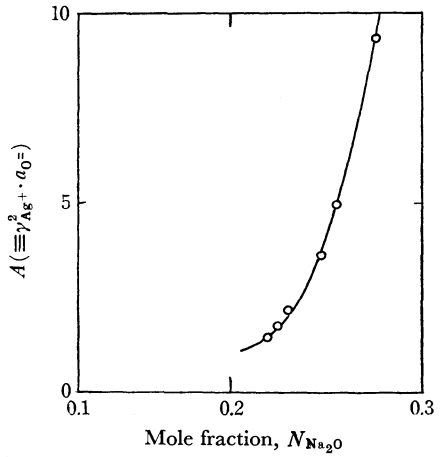

Fig. 9. The oxygen ion activity in arbitrary unit in Na_2O-B_2O_3 binary melt at 850°C.

of the Ag_2O concentration, even though this assumption is not acceptable over the complete range of the compositions. Therefore, the value of A extraporated to $N_{Ag_2O}=0$ indicates a quantity proportional to the activity of oxygen ions in the Na_2O-B_2O_3 binary system. This relation is plotted in Fig. 9. The oxygen-ion activity increases rapidly with an increese in the Na_2O contents.

(3) **Metallic Silver.** It has long been considered that the silver in a glass is in a metallic colloidal state, and that this causes the coloration. However, the fact that the definite solubility exists as a function of the temperature, the oxygen pressure, and the Na_2O content shows that the silver mostly dissolves in a glass as Ag_2O as far as a thermodynamic treatment is concerned. Another piece of evidence to support this view is the electric conductivity of this system, which will be reported on a separate paper. The electrical conductance of Ag-borate is similar to that of Na-borate in its absolute value as well as in its activation energy.

The color of this glass is yellow; it turns red with the increase in the Ag_2O content. This coloration is probably due to the covalent character of the Ag–O bond.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 681—685 (1969)

Electrical Conductance of Molten Salt Systems: Ag_2O-B_2O_3 and Ag_2O-Na_2O-B_2O_3

Hiroshi KODAMA, Yoshihiro KIMURA, Toshio YOKOKAWA and Kichizo NIWA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo

(Received August 8, 1968)

The electrical resistance of the Ag_2O-B_2O_3 and Ag_2O-Na_2O-B_2O_3 systems has been measured in the approximate temperature range from 750 to 1000°C. The equivalent conductance at 900°C and the activation energy of the conductance for the Ag_2O-B_2O_3 system were calculated. They were then compared with the corresponding values of alkali borate melts. The results led to the conclusion that the silver ion is not bound to the oxygen ion in the melt, but behaves like Li^+, Na^+, and K^+ which are known to be monovalent network modifiers and to be free to move in the melt.

Various physico-chemical properties of alkali borate melts have been reported by several groups of workers.[1] Electrical conductance, one of them, has been measured by a few investigators.[2,3] Silver oxide, as well as alkali metal oxide, dissolves into molten boron trioxide at high temperatures to form a silver borate melt.[4,5] Therefore, it seemed of interest to study the silver borate melt from the kinetic point of view. Thus, a comparison of the electrical conductance of the melts, of both Ag_2O-B_2O_3 and Ag_2O-Na_2O-B_2O_3, with that of alkali borate melt will provide important knowledge concerning the conduction mechanism in the silver-containing melt. Two possible, contradictory

results may be anticipated; One might expect to obtain data analogous to that on the conduction of the binary alkali borate melt, because the silver ion, which is considered to be the sole electric carrier, has the same charge as the sodium ion, and, moreover, their ionic radii are nearly the same. On the other hand, the silver ion might display, notwithstanding these similarities, quite a different behavior since the silver ion has a stronger covalency than the alkali metal ion.

This report will present data on the electrical conductance of the binary melt, Ag_2O-B_2O_3 as well as the ternary melt, Ag_2O-Na_2O-B_2O_3, in the approximate temperature range from 750 to 1000°C. Further, the equivalent conductance will be estimated for the binary melt with the aid of the density data.[6]

Experimental

Materials and Reagent. The silver borate melt was prepared in the following way. Anhydrous boron trioxide of a guaranteed reagent grade was put into a platinum crucible (34 mm in diameter and 38 mm high) and heated in an air atmosphere at about 1000°C for long enough for the water to be driven off from the oxide melt. Then, $AgNO_3$ of a guaranteed reagent grade was added in its melt. Silver nitrate decomposed with NO_2 fumes and reacted immediately with the molten boron trioxide to produce the silver borate. The melt of the required Ag_2O content was stirred sufficiently with a silver rod in order to achieve a uniform composition. The ternary melt, Ag_2O-Na_2O-B_2O_3, was made by adding $AgNO_3$ to the Na_2O-B_2O_3 binary melt which had been prepared by melting the required amounts of alkali carbonate and anhydrous boron trioxide in a platinum crucible. The samples were analyzed for B_2O_3 content by titration with a 0.1N NaOH aqueous solution and for Ag_2O content by titration with a KSCN solution.

Apparatus and Procedure. A diagramatic sketch of the apparatus for measuring electrical resistance is given in Fig. 1. A dipping electrode arrangement was used to measure the melt resistance. It consisted of a pair of parallel Pt wires. An alternating current signal was supplied to a Kohlrausch Bridge (Yokogawa Electric Works type K-1) by means of an Audio Frequency Oscillator (Trio Corporation Type AG-10). The output of the resistance bridge was fed into the vertical input of a cathoderay oscillograph (Daimatsu Electric Company Type LBO 3A). 20 mm of the electrodes were dipped into the melt in the cell, the immersion depth being fixed precisely by a device in the electrodes' connection with a cathetometer. Since the resistance was shown to be independent of the frequency between 1 and 10 kc, the measurements were made at 10 kc. The determination of the cell constant was made at 25°C by means of a 0.1N KCl solution.

$(1/T)$. These conductance-temperature relations are analogous to those of the sodium borate melt in magnitude as well as in the temperature coefficient, which had been measured by Shartsis.[3] Since an alkali borate melt is an ionic conductor, the present results suggest that the silver borate melt is also an ionic conductor.

It is clear in Fig. 2 that the graphs can be represented by curves rather than straight lines. A recent investigation[7] has established that the temperature dependence of the conductance at low temperatures can be described rather accurately by a modified form of the Arrhenius equation;

$$\Lambda = AT^{-1/2} \exp\left(\frac{-k}{T-T_0}\right)$$

where Λ is the equivalent conductance and where A, k, and T_0 are constants. This empirical equation has been supported by the theoretical treatment, too.[8,9] In the present investigation, $\log \Lambda + 1/2 \log T$ was tentatively plotted as a function of $\log (1/T - T_0)$ with various values of T_0. Although this procedure gave a better linear relation than the graphs in Fig. 2, a definite value of T_0 could not be evaluated from the data on the temperature range covered. Thus, the further consideration of T_0 was abandoned in the present study. The activation energy of the conductance was, therefore, estimated with an Arrhenius-type equation for the higher temperature range. The activation energy is shown in Fig. 3 as a function of the silver oxide concentration. In Fig. 3 the decrease in the activation energy with the increase in the amount of silver oxide is interpreted as the effect of the silver oxide's modification of the borate network structure as well as the effect of the change

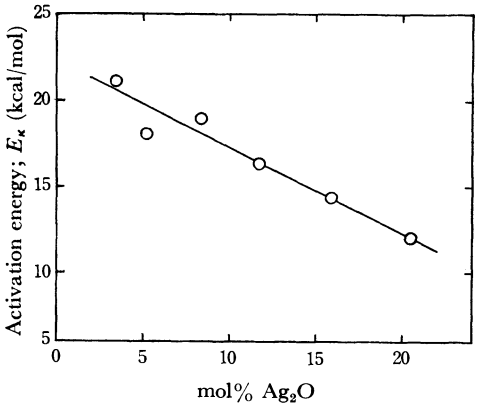

Fig. 3. Relation between activation energy and composition of silver borate melts at 900°C.

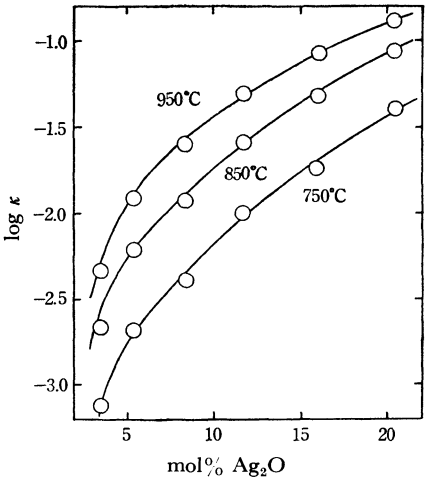

Fig. 4. Relation between specific conductance and composition of silver borate melts.

in thermal expansibility with the change in composition. The value of the activation energy for silver borate and the rate of its decrease are similar to those for alkali metal borates. In Fig. 4 $\log \kappa$ is plotted agnist the silver oxide contents. The conduction-composition isotherms show that the addition of silver oxide increases the conductance of the liquid. An increase similar to this has already been found in the case of alkali metal oxides (see also Fig. 9). For a discussion of the mehcanism of conductance, it is necessary to employ a equivalent conductance which is independent of the ionic concentration per unit of volume. For a system in which the conductance is due to a single ionic species, the equivalent conductance is given by:

$$\Lambda = \frac{100kM}{\rho nzx}$$

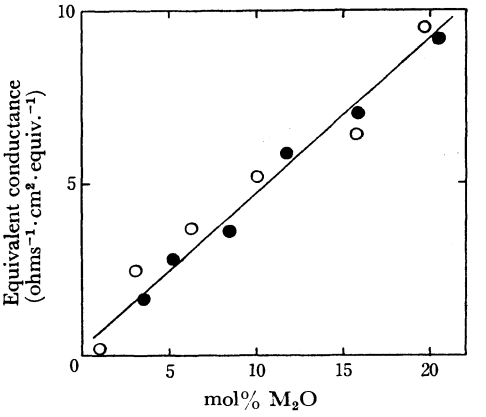

Fig. 5. Equivalent conductance isotherms for silver borate melt and sodium borate melt as functions of composition at 900°C.

where ρ is the density of the melt; n, the wt% of the melta oxide; M, the molecular weight of M_xO_y; z, the charge on M, and x, the number of M atoms per molecule of M_xO_y. In the present case, since only the silver ion contributes to the conductance, this equation is valid. Making use of the density data of Ono *et al.*,[6] the equivalent conductance was then calculated from the above equation.

Figure 5 shows the equivalent conductance isotherm for 900°C as a function of the concentration of silver oxide (with the concentrations ranging from zero to 20 mol%), as well as the corresponding value of sodium borate, determined by Shartsis *et al.* From this agreement of the concentration dependence of the two borates, it is evident that the gradual increase in the equivalent conductance with the increase in the silver oxide contents can be interpreted in terms of the "network-destruction effect."

Ternary Melts; Ag_2O-Na_2O-B_2O_3. As has been stated previously, silver oxide was added to

a Na_2O-B_2O_3 binary system, and the resistance was then measured for the region from 750 to 1000°C. This procedure was repeated several times. The starting compositions for binary systems were 3.97 (Series A), 7.91 (Series B), and 18.96 (Series C) at the molar ratio of Na_2O/B_2O_3. Plots of log κ against the functions of $1/T$ are shown in Figs. 6, 7, and 8. In Fig. 9 the log κ isotherms of both binary and ternary systems at 900°C are plotted as a function of the sum of the mole percents of Na_2O and Ag_2O. This figure shows that the data of Series A coincide with those of Na_2O-B_2O_3 or Ag_2O-B_2O_3, while Series B and C show some deviation. Considering the effect of the molar volume, this shows that the conductance is nearly additive with respect to silver and sodium ions. It may be concluded from the results of this conductance investigation that, when silver oxide dissolves in borate melt, silver oxide dissociated almost perfectly in silver- and oxygen-ions; that is, silver oxide acts as a network modifier of boric oxide and the silver ion shows a conductance behavior very similar to that of potassium, sodium, and lithium ions.

Zeeman Effect of Phosphorescence. II. Intensity Considerations on Pyrazine Phosphorescence

Tohru AZUMI, Mitsuo ITO and Saburo NAGAKURA

The Institute for Solid State Physics, The University of Tokyo, Roppongi, Minato-ku, Tokyo

(Received August 10, 1968)

The Zeeman splitting of pyrazine phosphorescence is observed. The amount of splitting is 1.4 cm^{-1} under the magnetic field of 15 kilogauss. This magnitude is just what one expects for the free spin, which means that the zero-field splitting parameters are small compared with the observed splitting. On the assumption of random orientations of the pyrazine molecules in the sample, the phosphorescence intensities from the three split subcomponents are expected to be in the ratio of $13g_1 : 16g_0 : 13g_{-1}$ where g's represent populations. This expectation is roughly manifested in the experimental observation. Finally, the theoretical calculation of the zero-field splitting parameters, D and E, is attempted, and the results are interpreted in terms of the experimental data.

Phosphorescence of organic molecules was interpreted by Terenin[1] and by Lewis and Kasha[2] to be the multiplicity forbidden emission; namely, for majority of organic molecules where the ground state is singlet, Jablonski's "phosphorescent state"[3] was identified as the triplet state. Since then, considerable efforts have been devoted to date to substantiate the mechanism suggested by these authors. It is at present the usual notion that the triplet nature of the phosphorescent state is fairly well established. However, it seems not unworthy to recall these efforts and to judge how much the usually accepted notion is founded.

Probably, the most direct works reported so far along this line are the measurements of paramagnetic susceptibility[4] in earlier days and the recent ESR measurements of the excited triplet state.[5] These works have revealed that the triplet state is produced by irradiation of solid solution of organic molecules by ultraviolet light and that it decays in a manner nearly identical to phosphorescence. The triplet state is considered simultaneously the phosphorescent state because of the *approximate* identity of the decay mode. Other evidence which shows the spin forbidden character of the phosphorescence comes from the heavy-atom effect, both intramolecular and intermolecular: McClure[6] found that the

introduction of heavy atoms such as halogen and sulfur to hydrocarbon molecules decreases the phosphorescence lifetime considerably, and that this lifetime decrease is quantitatively explained by the increase of spin-orbit coupling in the presence of heavy atom. The decrease of the phosphorescence lifetime in the heavy atom containing solvents is also interpreted by McGlynn[7] in a similar manner.

As is seen in the two examples cited above, the phosphorescence *lifetime* data have frequently been presented as evidence supporting the identity of the phosphorescent state to the triplet state. However, conclusions based on lifetime data are not unique, and can not be served as a conclusive evidence. For, it is not certain whether the phosphorescent state is simultaneously the triplet state itself or is a certain kinetically rate-limiting state or species produced *via* the triplet state. In view of the long lifetime of the triplet state and its potency to photochemical reactions this suspicion does not seem too unrealistic. A pertinent example is delayed thermal fluorescence,[8] or *alpha*-phosphorescence[9] in the widely used, but somewhat misleading, terminology.[10] This emission consists of thermal excitation to the singlet excited state followed by fluorescence emission. Even though its lifetime is identical to that of the phosphorescence, the emission starts out actually from the singlet state and not from the triplet state.

As described above many experiments carried out to date do not necessarily present conclusive evidence of the triplet nature of the phosphorescence. One might suppose that a Zeeman splitting of the phosphorescence would provide the most unambiguous verification of the triplet nature of the phosphorescent state. This experiment was already suggested by Weisman and Lipkin[16] in 1942; however, no attempts have been reported to date. The lack of such attempts is probably due to the difficulty in observing the phosphorescence spectrum sharp enough to resolve the Zeeman slpitting.

As reported in a previous paper[17] we have succeeded to observe the Zeeman splitting of the phosphorescence of pyrazine crystal. The pyrazine crystal was chosen because it emits fairly intense and quite sharp phosphorescence at 4.2°K. Moreover, for n,π^* triplet excited states of aza-aromatics ESR measurements have never been succeeded, and the phosphorescence measurements under magnetic field are likely to be the only means of identifying the three spin subcomponents. The present paper concerns the detailed analyses of this observation.

Experimental

Pyrazine was purified by repeated (seven times) sublimations in vacuum between room temperature and the dry ice temperature. After the final step of sublimation, the sample was transferred to a quartz cell and the cell was sealed off. All procedures were carried out in vacuum and a contact with air was rigorously avoided.

The emission was taken at 4.2°K in a polycrystalline form. A liquid helium cryostat was placed between the poles of a JEOL JM210 magnet. The magnetic field applied was 15400 gauss. Excitation was effected to the region of $^1B_{2u}(\pi,\pi^*)$ excited state with light from a 500 W high pressure mercury lamp passed through a following filter combination: (1) Toshiba's glass filter UV-D2, (2) 1 cm path of 10^{-3}M K_2CrO_4 aqueous solution, and (3) 1 cm path of $NiSO_4$ and $CoSO_4$ mixed aqueous solution (0.55M and 0.15M, respectively). Because of the geometrical limitations a phosphoroscope was not used. The emission spectrum thus obtained was identical to that obtained with a Becquerel type phosphoroscope and without any filters. The emission was photo graphed on a Kodak 103a-F plate in the second order of a 1200 grooves/mmg rating (blaze at 5000 Å) mounted on a Spex Spectrometer Model 1700-II.

Results

The detailed analyses of the phosphorescence spectrum as well as of the singlet to triplet absorption spectrum will be published elsewhere. Our

interest is now focussed on the four emission lines near the onset of the spectrum which are quite sharp and intense, and are consequently suited to Zeeman effect experiments. The group of these four lines are repeatedly found in progressions of 606, 759, 953, and 1254 cm^{-1}. In view of the agreement of these progressions with the Raman frequencies,[18] the above mentioned four lines are interpreted to be due to pyrazine.[19] The effect of magnetic field on these lines is shown in Fig. 1.

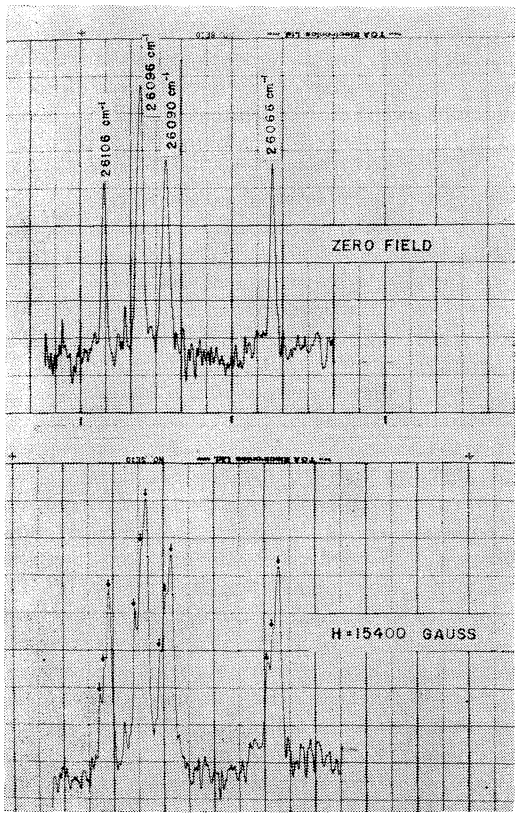

Fig. 1. Zeeman effect of the phosphorescence of pyrazine crystals.

It is immediately clear that magnetic field splitts the emission lines into the three subcomponents, as are indicated by arrows. For all the four lines, separation between two nearest subcomponents is approximately 1.4 cm^{-1}. Also, Fig. 1 clearly indicates that the lower energy subcomponent emitts more intensely than the higher one. This marked difference in intensity might at first seem quite natural in view of the population differences. However, noting that the phosphorescence intensities are determined not only by population but also, more importantly, by the matrix elements connecting the upper and the lower levels, one needs to consider further. The following discussion concerns this point.

Discussion

In analyzing the above results we have, in principle, to consider the effect of magnetic field on the triplet excitons. However, the nature of the triplet excitons is not sufficiently enough understood for pyrazine crystal to warrant detailed analysis. Further, it is believed that the intermolecular interaction is not very significant as compared with the effect of magnetic field. Hence, as a preliminary approach, in the following, we neglect any intermolecular interaction.

Let the lowest triplet state be produced by an excitation of an electron from a molecular orbital ϕ_a to a molecular orbital ϕ_b.[20] We choose the following zeroth order triplet eigenfunctions:

$$\begin{aligned} |T_x\rangle &= 2^{-1/2}(|\bar{\phi}_a\bar{\phi}_b| - |\phi_a\phi_b|) \\ |T_y\rangle &= 2^{-1/2}(|\bar{\phi}_a\bar{\phi}_b| + |\phi_a\phi_b|) \\ |T_z\rangle &= 2^{-1/2}(|\phi_a\bar{\phi}_b| + |\bar{\phi}_a\phi_b|) \end{aligned} \quad (1)$$

The Hamiltonian for Zeeman effect is represented by

$$\mathcal{H} = g\beta\mathrm{H}(lS_x+mS_y+nS_z) + DS_z^2 + E(S_x^2-S_y^2) \quad (2)$$

where l, m, and n are direction cosines of molecular axes, x, y, and z, respectively, with the field direction, and D and E are the zero-field splitting parameters. The displacement of the triplet levels due to (2) should be asymmetric because of the terms involving D and E. However, as pointed out above, within the accuracy of our experiments both the higher and the lower energy subcomponents are displaced from the middle component by 1.4 cm^{-1}. Furthermore, the amount of 1.4 cm^{-1} is just one expects from the term $g\beta$H under the magnetic field of 15400 gauss. It is consequently assumed that the terms involving D and E may be neglected. The eigenvectors $|T_1\rangle$, $|T_0\rangle$, and $|T_{-1}\rangle$ are then easily obtained as

$$\begin{pmatrix} |T_1\rangle \\ |T_0\rangle \\ |T_{-1}\rangle \end{pmatrix} = \begin{pmatrix} \sqrt{\frac{1-l^2}{2}} & \frac{n+ilm}{\sqrt{2(1-l^2)}} & \frac{-(nl+im)}{\sqrt{2(1-l^2)}} \\ l & im & n \\ \sqrt{\frac{1-l^2}{2}} & \frac{n-ilm}{\sqrt{2(1-l^2)}} & \frac{-(nl-im)}{\sqrt{2(1-l^2)}} \end{pmatrix} \begin{pmatrix} |T_x\rangle \\ |T_y\rangle \\ |T_z\rangle \end{pmatrix} \quad (3)$$

For the spin-forbidden phosphorescence to be observed, there must be a singlet state, or states, which may mix with the lowest triplet state by

19) These lines, however, do not coincide with the onset of the singlet to triplet absorption. Detailed examinations have revealed that these are due to the pyrazine molecule at some crystalline defects. T. Auzmi, Y. Nakano and M. Ito, to be published.

20) Here, configuration interactions with other singly excited or with doubly excited configurations are not considered. However, the inclusion or them does not alter the conclusions.

spin-orbit interaction, and further may have a dipole allowed transition to the ground state. Alternatively, one may consider a mechanism in which the singlet ground state mixes with a triplet state by the spin-orbit interaction. However, as far as group theoretical considerations are concerned, these two mechanisms result in identical conclusions; hence, in the following treatment, only the perturbation to the lowest triplet state is considered. Spin-orbit interaction is, in general, expressed as the sum of one-electron and two-electron operators;[21] however, only the former is considered here. Specifically,

$$\mathcal{H}_{so} = \sum_i \xi_i l_i s_i \tag{4}$$

Restricting the spin-orbit interaction to one-electron operator, the singlet state which may mix with the triplet state is only of the type

$$|S\rangle = 2^{-1/2}(|\phi_a\bar{\phi}_c| + |\phi_c\bar{\phi}_a|) \tag{5}$$

here the molecular orbital ϕ_c is chosen so that the transition between $|S\rangle$ and the ground state is dipole-allowed. The matrix elements for the spin-orbit interaction are now readily obtained as follows:

$$\begin{aligned} \langle S|\mathcal{H}_{so}|T_x\rangle &= -(h/4\pi)\xi\langle\phi_c|l_x|\phi_b\rangle \\ \langle S|\mathcal{H}_{so}|T_y\rangle &= i(h/4\pi)\xi\langle\phi_c|l_y|\phi_b\rangle \\ \langle S|\mathcal{H}_{so}|T_z\rangle &= -(h/4\pi)\xi\langle\phi_c|l_z|\phi_b\rangle \end{aligned} \tag{6}$$

In the expansion of the integrals over *molecular orbitals* in (6) in terms of integrals over *atomic orbitals*, we choose to neglect all multi-center integrals other than the one-center terms. With this approximation, and further if the molecular axes are chosen[22] as shown in Fig. 2, it is immediately

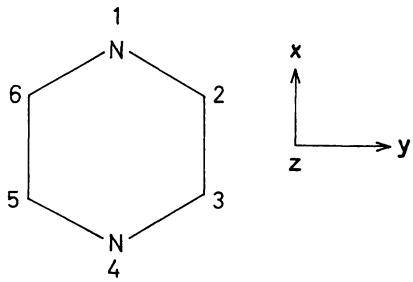

Fig. 2. Molecular axes and the numbering of atoms in pyrazine molecule.

clear that the first and the third integrals in (6) necessarily vanish since the operator l transform like rotation. It is, therefore, concluded that only the $|T_y\rangle$ component is emissive.

Let the phosphorescence intensities from the three subcomponents, $|T_1\rangle$, $|T_0\rangle$, and $|T_{-1}\rangle$ be denoted by I_1, I_0, and I_{-1}. Then from (3)

$$I_1 : I_0 : I_{-1} = [(1-m^2)/2]g_1 : m^2 g_0 : [(1-m^2)/2]g_{-1} \tag{7}$$

where g_1, g_0, and g_{-1} denote the population of the three subcomponents.

The relationship expressed by (7) may be verified using an oriented sample; this is the subject we are presently attempting to work. In the present case, however, the sample is polycrystalline and the above relationship can not be used as it is. In what follows intensity relationship is derived on the assumption that our polycrystalline sample is randomly oriented. The discussion closely follows that of photoselection by Albrecht.[24] Two sets of coordinates are defined, the laboratory-fixed set (a, b, c) and the molecule-fixed set (x, y, z). Assigning these a common origin we then specify the orientation of a molecule in using Eulerian angles θ, ϕ, and ψ. The cosines of the angles between the axes of the two sets of coordinates are denoted by t_{ax}, *etc.*

Let unpolarized exciting light be incident along b axis onto the ac face, and the phosphoresecnce is viewed also along b axis. In our experimental setup the magnetic field is applied along c axis, and therefore $m^2 = t_{cy}^2$. The exciting light is absorbed mainly to $^1B_{2u}(\pi,\pi^*)$ state (y axis). As determined by Krishna and Goodman,[25] phosphorescence is polarized along x axis. In the case of $^1B_{2u}(\pi,\pi^*)$ excitation, the probability that a single molecule at θ, ϕ, and ψ is photoselected is $(t_{ay}^2+t_{cy}^2)/2$, while the probability of viewing the phosphorescence with unpolarized light is $(t_{ax}^2+t_{cx}^2)/2$. Then, the phosphorescence intensities from the three subcomponents are expressed as:

$$\begin{aligned} I_1 : I_0 : I_{-1} = {} & g_1(t_{ay}^2+t_{cy}^2)(t_{ax}^2+t_{cx}^2)(1-\tfrac{1}{2}t_{cy}^2) : \\ & g_0(t_{ay}^2+t_{cy}^2)(t_{ax}^2+t_{cx}^2)t_{cy}^2 : \\ & g_{-1}(t_{ay}^2+t_{cy}^2)(t_{ax}^2+t_{cx}^2)(1-\tfrac{1}{2}t_{cy}^2) \end{aligned} \tag{8}$$

This expression should be integrated over the Eulerian angles

$$\int_0^{\pi}\sin\theta\,d\theta\int_0^{2\pi}d\phi\int_0^{2\pi}d\psi$$

The final results for $^1B_{2u}(\pi,\pi^*)$ excitation is

$$I_1 : I_0 : I_{-1} = 13g_1 : 16g_0 : 13g_{-1} \tag{9}$$

Similarly for $^1B_{1u}(n,\pi^*)$ excitation,

$$I_1 : I_0 : I_{-1} = 8g_1 : 5g_0 : 8g_{-1} \tag{10}$$

If these ratios are calculated with the Boltzmann distribution at 4.2°K for three substates that are 1.4 cm^{-1} apart successively,

21) H. A. Kramers, "Quantum Mechanics," North-Holland Publishing Co., Amsterdam (1957).

22) This choice of axes, which is different from that of Mulliken's recommendation,[23] is convenient since the familiar form of Eq. (2) is consistent with the condition, $D>3E>0$.

24) A. C. Albrecht, *J. Mol. Spectry.*, **6**, 84 (1961).

25) V. G. Krishna and L. Goodman, *J. Chem. Phys.*, **36**, 2217 (1961).

$$I_1 : I_0 : I_{-1} = 1.0 : 0.76 : 0.38 \quad \text{for } {}^1B_{2u}(\pi,\pi^*) \text{ excitation} \tag{11}$$

and

$$I_1 : I_0 : I_{-1} = 1.0 : 0.39 : 0.38 \quad \text{for } {}^1B_{1u}(n,\pi^*) \text{ excitation} \tag{12}$$

It is, at this stage, impossible to obtain the accurate intensity ratio from Fig. 1, for there is, to a certain extent, a band overlap, and also the ordinate in the microphotometer tracing is not calibrated to intensity scale. Moreover, our polycrystalline sample can not be expected to be perfectly random. Yet, it is evident from Fig. 1 that the intensity relationship is more in conformity with the ${}^1B_{2u}$-(π,π^*) excitation, which is just we expect from our experimental condition. (*vide supra*).

Conclusions and Remarks

The Zeeman splitting of the phosphorescence was observed for pyrazine and thereby the triplet nature of the phosphorescence is definitely substantiated. The observed intensities of the three phosphorescence subcomponents are roughly in agreement with theoretical predictions. It may also be concluded that the population of the three triplet subcomponents is governed by the Boltzmann distribution at 4.2°K.

In the above discussions we have adopted a number of approximations. In the first place our discussion is confined to the case of the pyrazine solution in which solutes are oriented randomly. Although this treatment is in principle unjustified for polycrystalline sample, it may be justified in rough estimates. More detailed analysis on triplet excitons are the subject of future investigations. We have further neglected the zero-field splitting parameters, D and E. This approximation was based on our experimental data on energy splitting. However, it is not immediately certain if this assumption is also valid when intensities are evaluated in a manner discussed above. Unfortunately, there have not been any ESR observations for pyrazine triplet state, and no data are available, at present, for the zero-field splitting parameters. In view of the lack of data, theoretical evaluations of these values are of interest and are attempted in Appendix.

We wish to express our appreciation to Professor Shigeo Shionoya and his associates for their kindness in letting us use the magnet and the cryostat. We are also grateful to Mr. Yasuo Udagawa for experimental assistance and for stimulating discussions.

Appendix

Calculations of the Zero-Field Splitting Parameters. The purpose of this calculation is to obtain an order of magnitude of D and E values, and hence, semi-empirical approach is adopted.

The molecular orbitals are obtained by the usual Pariser-Parr-Pople method. The coordinates of atoms in pyrazine molecule are taken from the results of an X-ray analysis by Wheatley.[26] Ionization potentials and electron affinities are taken from the table of Pilcher and Skinner.[27] Zero-differential overlap is assumed throughout and penetration integrals are neglected. Two-center repulsion integrals are calculated by uniformly charged sphere model formula given by Pariser and Parr.[28] Core resonance integrals between adjacent atoms are chosen to proportional to overlap integrals, and

$$\beta_{CC} = -2.526\,\text{eV}, \quad \beta_{CN} = -2.162\,\text{eV} \tag{A1}$$

The lowest vacant SCF molecular orbital, π_4^*, thus obtained[29] is

$$\pi_4^* = -0.5349(\chi_1+\chi_4) + 0.3270(\chi_2+\chi_3+\chi_5+\chi_6) \tag{A2}$$

where χ_r is $2p\pi$ atomic orbital on rth atom and where numbering of atoms is shown in Fig. 2.

The lowest triplet state may be successfully expressed by a single configuration of the type (n_-,π_4^*), where n_- represents the minus combination of the two nitrogen nonbonding orbitals. Only configuration which has the same symmetry species with this is of the type (n_+, π_6^*), but because it locates at higher energy, the mixing may well be neglected.

The one-center integrals are computed exactly from the SCF atomic orbitals expanded in Slater orbitals by Clementi and Roothaan[30] by means of analytical formulas given by Higuchi.[31] The final results are[32]

$$D = 0.31\,\text{cm}^{-1} \text{ and } E = 0.01\,\text{cm}^{-1}.$$

The value of D thus obtained is a little larger than the D values for π,π^* triplet states of aromatic hydrocarbons, and is roughly in the same order of magnitude as those of n,π^* ground state obtained experimentally[33,34] and theoretically.[31] It is consequently believed that the calculated values are not much off.[35] If this asertion is correct, the zero-field splitting is not very significantly small compared with the Zeeman splitting, and might be observed in a high resolution work.

A Spectrophotometric Study of the Uranyl Chelate of 2-(1,8-Dihydroxy-3,6-disulfo-2-naphthylazo)-phenoxyacetic Acid

Yasuaki SHIMOISHI*1

Department of Chemistry, Faculty of Science, Okayama University, Tsushima, Okayama-shi

(Received June 8, 1968)

2-(1,8-Dihydroxy-3,6-disulfo-2-naphthylazo)-phenoxyacetic acid reacts with the uranyl ion in an acidic medium to form a violet chelate. The composition of the chelate is 1:1 in the molar ratio. The apparent stability constants over the pH range from 3.4 to 5.2 and the formation constant of the chelate, are estimated spectrophotometrically at 25°C and an ionic strength of 0.1 by the use of KNO_3. The value of the formation constant was calculated as 1.25×10^{10} from the apparent stability constants.

A new chelating agent, 2-(1,8-dihydroxy-3,6-disulfo-2-naphthylazo)-phenoxyacetic acid [PAC],[1] one that was first introduced by our laboratory, reacts with several metal ions to give its colored chelates. The apparent stability constants of a stable 1 : 1 chelate with the thorium ion, and the use of the chelate in the determination of micro amounts of the fluoride ion, have been reported in previous papers.[2,3]

This paper will describe the properties of the reagent and the reaction between the reagent and the uranyl ion. The acid form of the reagent has three molecules of the water of crystallization; it loses two of them at 135°C, and one at 175°C. Moreover, the anhydride gradually decomposes above 190°C. The reagent forms a 1 : 1 violet chelate with the uranyl ion between the pH values of 3.4 and 5.2; the apparent stability constants, log K', of the chelate over that pH range are measured spectrophotometrically.

In the pH range measured, the reagent exists predominantly as the diprotonated form, considering the value of its acid dissociation constants. From the relation between log K' and pH, however, it was found that the uranyl ion displaces one proton from the reagent in that pH range to form a chelate. This fact shows that the other proton existing between two oxygen atoms of chromotropic acid does not take part in the formation of the chelate.

The formation constant of the chelate is calculated from the values of the apparent stability constants to be 1.25×10^{10} at 25°C and at an ionic strength of 0.1 (KNO_3).

Experimental

Reagent. A pure reagent, 2-(1,8-dihydroxy-3,6-disulfo-2-naphthylazo)-phenoxyacetic acid·$3H_2O$, was obtained in the form of black violet needles after purification from a concentrated hydrochloric acid. The purity was checked by flame analysis and elementary analysis.

Found: C, 39.13; H, 3.65; N, 5.07%. Calcd for $C_{18}H_{20}O_{14}N_2S_2$: C, 39.13; H, 3.73; N, 5.15%.

Uranyl Nitrate Solution. A standard stock solution of uranyl was prepared by dissolving the uranyl nitrate (E. Merck's guaranteed-grade reagent) in deionized distilled water. The standardization of the uranyl solution consisted of the precipitation of the hydrous oxide, followed by ignition to oxide.[4]

Apparatus. *Spectral and pH Measurements.* A Hitachi Model EPS-2 automatic recording spectrophotometer was used for the measurement of the absorption spectra. For quantitative measurements a Hitachi Model 139 spectrophotometer with 1-cm glass cells was used. The pH was measured by using a Towa-Denpa Model HM-8 glass electrode pH meter.

Thermal Analysis. The thermal analysis was carried out using a thermal balance and a differential thermal analyzer, both made by Rigaku Denki.

Procedure. The uranyl chelate solution at various pH values was prepared as follows. Five mililiters of a 2.7×10^{-4}M uranyl nitrate solution and the same volume of a 2.7×10^{-4}M reagent solution were placed in a 50-m*l* volumetric flask; then a 1M potassium nitrate solution was added to maintain the ionic strength at 0.1. The pH of the solution was then adjusted from 3.4 to 5.2 by the addition of nitric acid or of a sodium hydroxide solution. The solution was finally diluted to 50 m*l* with deionized distilled water. After the solutions had been allowed to stand for one hour at

25°C, their absorbances for water and the pH of the solutions were measured.

Results and Discussion

The Water of Crystallization of the Reagent. In order to confirm the water of crystallization of the reagent, a thermal analysis was employed. As is shown in Fig. 1, the curve from a thermal

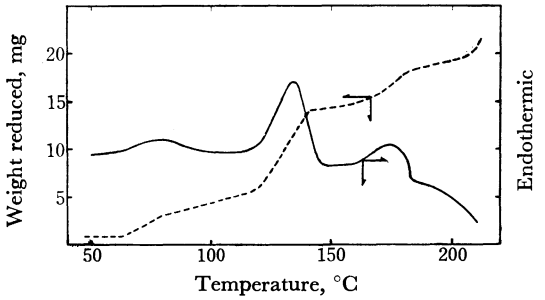

Fig. 1. Thermal analysis of the reagent.
--- Thermal balance curve
—— Differential thermal curve

balance had inflection points in changes in the sample weight over the temperature range between 50 and 210°C. The thermal differential curves showed four changes, at 80, 135, and 175°C corresponding to an endothermic change, and above 190°C, corresponding to a exothermic change. The first endothermic change, at 80°C, corresponds to the elimination of the hydrated water of the reagent, while the second and the third changes denote the elimination of the water of crystallization. However, the reagent after the treatment at 60°C in a vacuum has no inflection points in changes in weight below 180°C. From these results, it was found that the reduced weight of the sample at 135°C and 175°C includes the weight of three moles of water of crystallization. Above 190°C, the reagent gradually decomposes.

The Acid Dissociation Constants. The reagent dissociates in water as follows:

$$H_3R^{2-} \rightleftharpoons H_2R^{3-} + H^+$$
$$H_2R^{3-} \rightleftharpoons HR^{4-} + H^+$$

and

K_{a1} and K_{a2} represent, respectively, the dissociation of the carboxyl group and that of one of the naphtholic hydroxyl groups in the reagent. The values of pK_{a1} and pK_{a2} were found to be 2.99 and 9.76[2] respectively at 25°C and μ= 0.1.

Absorption Spectra. The absorption spectra of the solutions containing uranyl and the reagent in a molar ratio of 1 : 1 are shown in Fig. 2 over the pH range from 3.4 to 5.2. The curves show that the absorbance at 600 mμ becomes higher with an increase in the pH value.

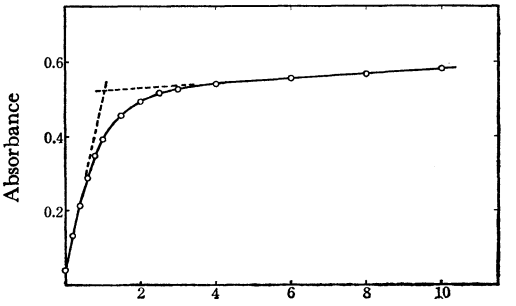

Fig. 4. Mole-ratio method.
at 605 mμ, pH 5.2.
The reagent concn. = 2.7×10^{-5} mol/l
Uranyl concn. varied

The Stability of the Color. The color of the complex reached its maximum within a few minutes after mixing; the absorbance then remained almost constant for at least two hours.

The Composition of the Chelate. Figure 3 shows the results obtained by the continuous variation method, the maximum absorbance of the chelate being obtained at a molar ratio of 1 : 1. The molar-ratio method in Fig. 4 was also employed at pH 5.1 for various uranyl concentrations. The results again clearly indicated the formation of a 1 : 1 chelate.

The Apparent Stability Constants. The apparent stability constant, K', and the acid dissociation constants, K_{a1} and K_{a2}, are expressed as follows:

$$K' = [MHR]/[M][H_3R + H_2R + HR] \quad (1)$$
$$K_{a1} = [H][H_2R]/[H_3R] \quad (2)$$
$$K_{a2} = [H]/[HR]/[H_2R] \quad (3)$$

where the ionic charge was neglected for the sake of convenience. The total concentrations of the reagent and uranyl are given as:

$$C_R = [H_3R] + [H_2R] + [HR] + [MHR] \quad (4)$$
$$C_M = [M] + [MHR] \quad (5)$$

where [M] represents the uranyl ion concentration. Under the experimental conditions studied, at pH values below 6 [HR] can be disregarded, judging from the pK_{a2} value (9.76[1]).

On the other hand, the absorbance of the chelate solution, E, is given by Eq. (6). The uranyl ion gives no absorption at around 605 mμ and $\varepsilon_M[M]$ can be neglected.

$$E = \varepsilon_{H_3R}[H_3R] + \varepsilon_{H_2R}[H_2R] + \varepsilon_{MHR}[MHR] \quad (6)$$

where ε_{H_3R}, ε_{H_2R}, and ε_{MHR} are the molar absorption coefficients of the reagent and the uranyl chelate respectively. The value of ε_{MHR} was calculated from the absorbance of a solution in which an excess amount of uranyl was added to the reagent; the complete formation of the chelate from the reagent could be assumed.

The apparent stability constant was estimated from the following equation by substituting Eqs. (2)—(6) into Eq. (1):

$$K' = [C_R - A]/[C_M - (C_R - A)]A \quad (7)$$

where:

$$A = (1 + K_{a_1}/[H])(E - \varepsilon_{MHR} C_R)/[\varepsilon_{H_3R} + \varepsilon_{H_2R}(K_{a_1}/[H]) - \varepsilon_{MHR}(1 + K_{a_1}/[H])]$$

The constants, log K', estimated from Eq. (7) are listed in Table 1.

The Relation between the Apparent Stability and the Acid Dissociation Constants. Owing to the existence of a strong hydrogen bridge between two oxygen atoms of the chromotropic acid of the reagent, the remaining naphtholic hydroxyl group, corresponding to K_{a3}, does not dissociate under ordinary experimental conditions. Therefore, the reagent may be considered to be a tetrabasic acid; the reaction steps and the probable structure of chelate are:

$$UO_2^{2+} + H_2R^{3-} \rightleftarrows UO_2HR^{2-} + H^+,$$

TABLE 1. APPARENT STABILITY CONSTANT AND STABILITY CONSTANT OF THE URANYL CHELATE (25°C, μ=0.1)

$C_R = C_{UO_2} = 2.70 \times 10^{-5}$ M

5.03	0.380	5.16	10.09
5.19	0.394	5.23	10.11

under the present experimental conditions (in the pH range between pK_{a1} and pK_{a2}).

In these experimental conditions (pH values from 3.4 to 5.2), the reagent exists predominantly in the diprotonated form and uranyl ion may displace one proton to form a 1 : 1 chelate.

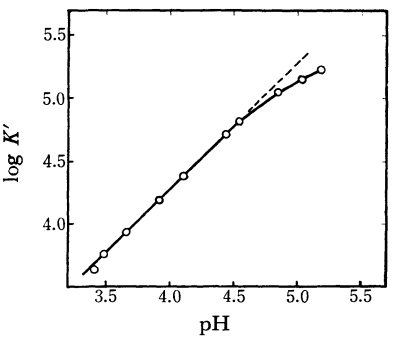

Fig. 5. Relationship between pH and log K. at 25°C, μ = 0.1.

In Fig. 5, the value of log K' is plotted against the pH value. The experimental data obtained are in good agreement with the curve whose slope was 1. This supports the assumption of the above equation, that only a UO_2HR^{2-} chelate is formed. Above pH 4.8, uranyl hydroxide begins to precipitate, so the value of log K' gradually becomes smaller.

The Formation Constant. The formation constant of the uranyl chelate, K, was represented as follows:

$$K = [MHR]/[M][HR] \quad (8)$$
$$K = K'\alpha_M\alpha_H \quad (9)$$

where:

$$\alpha_M = 1 + [OH][M]K^{OH}_{M_2(OH)} + [OH]^2[M]K^{2OH}_{M_2(OH)_2} \quad (10)$$

$$\alpha_H = 1 + K_{a_2}/[H] + K_{a_1}K_{a_2}/[H]^2 \quad (11)$$

As to α_M, the second and third terms of Eq. (10) can be neglected when the pH value is lower than 4.5 ($\alpha_M = 1$), but they cannot be neglected above pH 4.5, as the hydroxo uranyl complexes $M_2(OH)$ and $M_2(OH)_2$ are formed. Therefore, the values of α_M above pH 4.5 were calculated from Eq. (10) using the values of $K^{OH}_{M_2(OH)} = 1.2 \times 10^{10}$ and $K^{2OH}_{M_2(OH)_2} \times 1.0 \times 10^{22}$.[5]

α_H was calculated from Eq. (11), using the values of $K_{a1} = 1.002 \times 10^{-3}$ and $K_{a2} = 1.738 \times 10^{-10}$.[2]

Thus, the values of the formation constant were calculated from Eq. (9). They are also listed in Table 1. The average value of the constant is found to be 1.25×10^{10}.

The author is indebted to Dr. Kyoji Tôei for his guidance, to Dr. Tadashi Hayami for his encouragement, and to Mr. Tatsuo Higashimaya for the measurement of the thermal balance.

Emission Spectrographic Analysis of Metal Solid Samples with Plasma Jet Flame. I. Application of Nitrogen Plasma Flame*1

Kichinosuke HIROKAWA and Hidehiro GOTÔ

The Research Institute for Iron, Steel and Other Metals, Tohoku University, Sendai

(Received June 20, 1968)

A small plasma jet burner for direct excitation of metal solid samples was developed. The optimum operating conditions are as follows; d.c. arc current about 15 A, flow rate of nitrogen tangentially introduced gas about 1.5—2 *l*/min, and that of atomizer gas about 3.5—4 *l*/min. The limit of detection of some elements were determined with solution samples. Satisfactory calibration curves were also obtained for analyses of alloying elements in some solid form alloys.

For the plasma jet flame of emission spectroscopic source,[1] argon or helium gas are used as plasma gas, and a high current of approximately one to a few hundred amperes are employed to excite solution samples. They can be also excited by wall stabilized d. c. arc plasma. Further in usual solution methods, the preparation of standard samples is not necessary. For the solution method, however, the effects of water (solvent), acid, alkali and impurities in the solution on the property of plasma flame must be considered. Therefore, sometimes, the direct excitation of solid sample is desired, and a plasma burner for solid samples was assembled. The small burner developed in our laboratory works with the usual power supply for spectrographic d. c. arc. Nitrogen was employed as tangentially introduced gas and as atomizer gas, so that temperature of plasma flame becomes considerable low, and spectra of low back ground and sharp atom lines are obtained. After the limit of detection for some elements had been studied with solution samples, application of this plasma flame to the analyses of solid metal samples was tried.

Experimental and Results

Instruments. The spectrograph was Shimadzu's Fastie-Ebert type spectrograph GE-340 with a grating of 3000 Å blased. The excitation source was the d. c. arc power supply of Shimadzu High

Precision Source Unit. The cross sectional drawing of the burner is given in Fig. 1 and photographs of its before and after assembling are shown in Fig. 2.

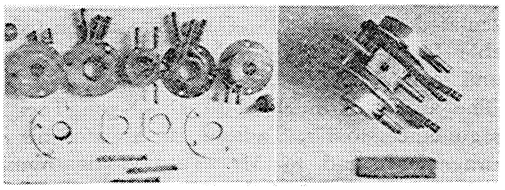

Fig. 2. Plasma burner before and after assembling.

Characteristics of the Plasma Burner and Tests with Solution Sample. The optimum operating conditions of the nitrogen plasma burner must be strictly controlled. An example of good condition is shown in Table 1. With tangentially introduced gas flow rate of about 2 *l*/min, condenser voltage of about 230 V and arc current of 15 A, a stable flame as Fig. 3 was obtained. With a flow rate of below about 1 *l*/min, however, a small flame as Fig. 4 and with a flow rate of over 2.5 *l*/min, a turbulent flame as Fig. 5 was obtained. Then the properties of plasma flame obtained with

TABLE 2. DETECTION LIMIT OF SOME ELEMENTS IN μg/ml

Center part of burner used	A	B	C
Mode of sample charging	Vertically to the axis of plasma flame	Into center part of plasma core	Into the same direction of tangentially introduced gas
Flow rate of tangentially introduced gas (*l*/min)	1.9	1.5	1.5
Flow rate of atomizer gas (*l*/min)	2.0	4.0	4.0
Al I 3961.5 Å	18	1.4	1.1
Mn I 4031 Å	4.5	1.3	1.2
Fe I 3581 Å	6.7	1.0	1.4
Fe I 3720 Å	2.7	0.95	1.1
Co I 3453.5 Å	4.4	0.92	1.1
Ni I 3414.8 Å	4.5	1.3	1.5
Pb I 4057 Å	11.0	—	1.2

three modes of sample charging (*cf.* Fig. 6 and Table 2) were tested. One tenth normal nitric acid solution of each element in Table 2 was introduced into the plasma flame with an ultrasonic nebulizer, and limits of detection[2] of the elements were studied under optimum conditions as shown in Table 2 in each case. The measurements were carried out by photographic method with slit width of 50 μ and exposure time of 90 sec. Fuji spectrographic photoplates were developed with F.D. 131 at 20°C for 4 min. The discharge conditions were as follows; primary excitation voltage 200 V, condenser voltage 230—240 V, arc current 13—14 A. The coefficient of variation for iron of 0.8 mg/m*l* with Fe I 3720 Å was about 5 per cent. When the solution was introduced into the flame, the flame temperature, measured with the two line method, was around 5500°K.

Application to Metal Solid Samples. In the present experiment, pin-form metal samples were employed as anodes (*cf.* Fig. 1). The operating conditions were the same as the case of c in Table 2, but the flow rate of atomizer gas was 3.5 *l*/min. The time-intensity curve for chromium in chromium steel was obtained as given in Fig. 7-a, and those for chromium, niobium and molybdenum in S-816 alloy (Mn: 1.5, Cr: 20.0, Ni: 20,0, Co: 43.0, Mo: 4.0, W: 4.0, Nb: 4.0, Fe: 3%) were as in Fig. 7-b. After 30 sec pre-discharge,

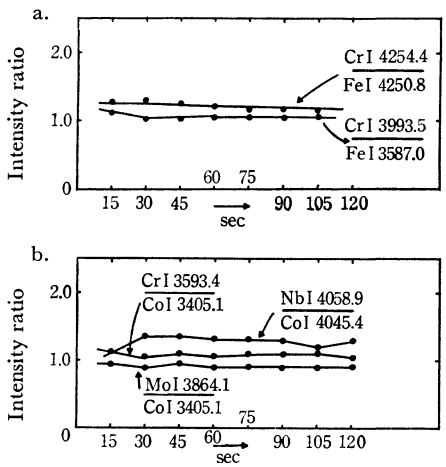

Fig. 7. Time-intensity curve for Cr in Cr-steel (a) and of some elements in S-816 alloy (b).

a nearly constant spectral line intensity ratio was obtained in each case. The calibration curve for chromium in chromium steel was prepared under the following conditions: sample 15 mm in length, 5 mm in diameter, polarity anode, excitation 230 V and 15 A, tangentially introduced gas flow rate 1.5 *l*/min, atomizer gas flow rate 3.5 *l*/min, slit width of the spectrograph 30 μ, pre-discharge time 30 sec and exposure time 10 sec. A calibration curve with good linearity was obtained in a wide concentration range of chromium in steel (Fig. 8).

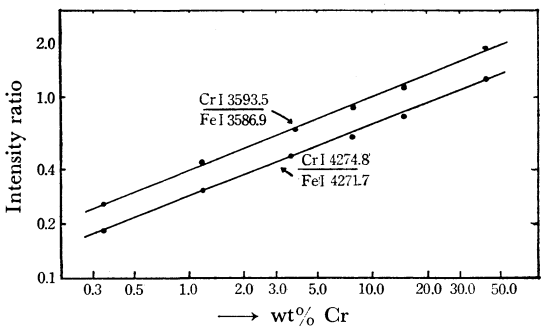

Fig. 8. Calibration curve for Cr in Cr-steel.

In this case the plasma temperature was about 6100°K. For the small amounts of elements in aluminum alloys, time-intensity curves were given as shown in Fig. 9 and the calibration curve for iron in aluminum alloy was given as in Fig. 10.

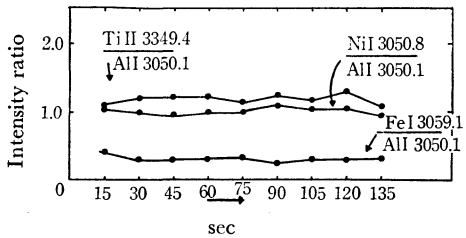

Fig. 9. Time-intensity curve for Ti, Ni and Fe in Al.

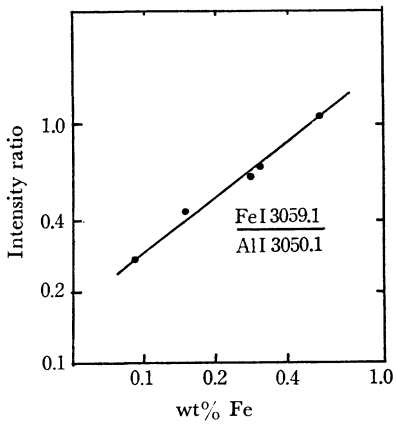

Fig. 10. Calibration curve for Fe in Al.

In this case, however, the operating conditions were the same except the exposure time of 15 sec. In the analyses of aluminum alloys with this nitrogen plasma flame, aluminum reacts with nitrogen and sputters as aluminum nitride, so that the precision for the determination of alloying elements in aluminum alloys is not satisfactory.

Chemical Effects Associated with β-Decay Process. IV. Kinetic Studies of the Chemical Behavior of ^{144}Pr Decayed from the ^{144}Ce(III)-Diethylenetriaminepentaacetate Complex

Takanobu SHIOKAWA and Takashi OMORI

Department of Chemistry, Faculty of Science, Tohoku University, Katahira-cho, Sendai

(Received June 22, 1968)

The chemical behavior of ^{144}Pr as a result of the β^--decay of the ^{144}Ce(III)-diethylenetriaminepentaacetate (^{144}Ce(III)-DTPA) complex was investigated in detail on the basis of the substitution reaction mechanism. The experimental results, represented in terms of the yield of the ^{144}Pr(III)-DTPA complex, were explained quantitatively by the application of Bateman's equation. An increase in the nuclear charge in the β^--decay of the ^{144}Ce(III)-DTPA complex may result in the formation of ^{144}Pr(IV)-DTPA, which would then be reduced to an intermediate complex of ^{144}Pr(III) by an intramolecular electron-transfer. The mechanisms and the rate constants are established for the decomposition of the intermediate leading to the formation of the uncomplexed ion. It was also suggested that the uncomplexed ^{144}Pr(III) ion is produced directly by an exhaustive bond-rupture of the daughter complex ion, without any formation of the intermediate. The ratio of bond-rupture was determined to be 0.25; this value is in accordance with the theoretical value for the formation of the multiply-charged ^{144}Pr ion due to electron shake-off and the internal conversion of γ-rays, followed by the Auger process.

In a previous paper,[1] the chemical behavior of ^{144}Pr produced by the β^--decay of the ^{144}Ce(III)-EDTA complex was investigated on the basis of kinetic considerations. The kinetic treatment indicated that the decomposition rate of an intermediate complex produced as a result of an increase in the nuclear charge in the β^--decay of the ^{144}Ce(III)-EDTA complex, is very important in determining the yield of the ^{144}Pr(III)-EDTA complex.

Recently, Glentworth and Wiseall[2] extensively investigated the chemical behavior of ^{144}Pr in various aminopolycarboxylate complex systems, but the model they proposed does not necessarily account for all of their results.

It appeared necessary to investigate further the stabilization process of ^{144}Pr decayed from the ^{144}Ce(III)-aminopolycarboxylate complexes. As the chelating agent, diethylenetriaminepentaacetic acid (DTPA) was chosen, for with it the lanthanide ions form more stable complexes than with EDTA.[3] In the present paper, the chemical behavior of ^{144}Pr will be discussed in terms of the yield of the ^{144}Pr(III)-DTPA complex, and on the basis of the exchange reaction mechanisms of both $^{144}Ce^{3+}$ and $^{144}Pr^{3+}$ with the cerium(III)-DTPA complex in aqueous solutions.

Experimental

G. R.-grade DTPA was used without further purification. An approximately 10^{-2}M stock solution of Na_3H_2DTPA was prepared by the partial neutralization of the directly-weighed acid with carbonate-free sodium hydroxide. The chelating agent solution was standardized against a standard zinc (II) solution by volumetric titration, using Eriochrome Black T as an indicator.

All the other chemicals and the experimental procedures employed here were substantially the same as those described previously.[1]

Results

Isotopic Exchange Reaction. The exchange rates and mechanisms for the following systems were established:

$$^{144}Ce^{3+} + CeY^{2-} \rightleftharpoons {}^{144}CeY^{2-} + Ce^{3+} \quad (1)$$

$$^{144}Ce^{3+} + PrY^{2-} \rightleftharpoons {}^{144}CeY^{2-} + Pr^{3+} \quad (2)$$

where Y^{5-} indicates the pentavalent DTPA anion. The isotopic exchange rate, R, between the uncomplexed ^{144}Ce(III) ion and the cerium(III)-DTPA complex ion in the pH range of 4.8—5.8 can be expressed as:

$$R = k_{Ce}[H^+]^2[CeY^{2-}] \quad (3)$$

1) T. Shiokawa and T. Omori, This Bulletin, **38**, 1892 (1965).

2) P. Glentworth and B. Wiseall, "Chemical Effects of Nuclear Transformations," Vol. II, IAEA, Vienna (1965), p. 483.

3) L. G. Sillén and A. E. Martell, "Stability Constants of Metal-Ion Complexes," The Chemical Society, London (1964).

Glentworth *et al.*[2] have found that, in the DTPA complex system, the exchange rate is expressed as follows:

$$R = k_{Ce}[H^+]^2[CeY^{2-}] + k'_{Ce}[Ce^{3+}][CeY^{2-}] \quad (3')$$

However, the contribution to the exchange rate of the second term on the right hand of Eq. (3') is fairly small and seems to have little importance in a discussion of the reaction mechanism. Therefore, further study was not made of this effect.

When the equilibrium constant, K, for the reaction expressed by Eq. (2) and k_{Ce} for Eq. (3) are known, the rate constant, k_{Pr}, can be calculated by using the following relation[1]:

$$K = \frac{[Pr^{3+}]_e[^{144}CeY^{2-}]_e}{[PrY^{2-}]_e[^{144}Ce^{3+}]_e} = \frac{k_{Pr}}{k_{Ce}} \quad (4)$$

where the subscript e indicates the chemical equilibrium. The equilibrium constant, K, was determined to be 0.28_7 in the presence of an 0.04M acetate buffer and 0.3M sodium chloride at 25°C. Also, the isotopic exchange rate constants were found to be:

$$k_{Ce} = 7.7_5 \times 10^8\ l^2mol^{-2}min^{-1}$$
$$k_{Pr} = 2.2_3 \times 10^8\ l^2mol^{-2}min^{-1}$$

Substitution Reaction of $^{144}Pr^{3+}$ with the Ce(III)-DTPA Complex Ion. According to the results obtained in the preceding section, the rate of the substitution reaction of $^{144}Pr^{3+}$ and the cerium(III)-DTPA complex may be expressed as:

$$\ln(1-F) = \ln\left\{\frac{[^{144}PrY^{2-}]_e - [^{144}PrY^{2-}]}{[^{144}PrY^{2-}]_e}\right\} = -\left\{k_{Ce}\frac{[CeY^{2-}]}{[Ce^{3+}]} + k_{Pr}\right\}[H^+]^2t \quad (5)$$

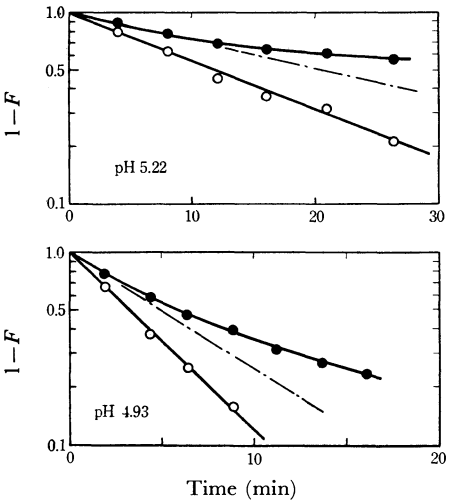

Fig. 1. Relation between $(1-F)$ values and time in the substitution reaction of $^{144}Pr^{3+}$ with cerium-(III)-DTPA complex(I).
25°C; $[Ce^{3+}] = [CeY^{2-}] = 1.00 \times 10^{-4}$ M

where F indicates the fraction of the reaction.

Figures 1 and 2 show plots of the $(1-F)$ values against the reaction time, t. In all cases the discrepancy of $(1-F)$ values from those calculated by Eq. (5) increases with the lapse of time. This is partly to be ascribed to the accumulation of the ^{144}Ce(III)-DTPA complex with the reaction time.

In a previous paper,[1] the chemical behavior of ^{144}Pr was analyzed satisfactorily by using the average life of ^{144}Pr as the reaction time; however, the results obtained at pH 4.8 cannot be rigorously explained by using the average life of ^{144}Pr. It is clearly desirable to introduce a more complete treatment for the stabilization mechanism of ^{144}Pr.

The Chemical Behavior of ^{144}Pr. After a complete equilibration with respect to ^{144}Ce had been attained chemically, the $^{144}PrY^{2-}$-yield, which is defined as the ratio of the γ-activity of the eluate to the total activity, was obtained at 25 and 5°C. As is shown in Figs. 3 and 4, the $^{144}PrY^{2-}$-yield curves have characteristic shapes in comparison with those obtained in the EDTA complex system.[1] The $^{144}PrY^{2-}$-yield at 25°C decreases abruptly up to pH 5.6, while above this point it increases gradually with the pH. At 5°C the minimum point in the $^{144}PrY^{2-}$-yield curve would shift to the lower pH region, and above pH 5.6 the $^{144}PrY^{2-}$-yields are higher than those at 25°C.

It should be noted that, throughout the investigated pH range, the $^{144}PrY^{2-}$-yields obtained

are less than the equilibrium values to be expected from the relation expressed by Eq. (4).

Chemical Properties of Ce(IV)-DTPA and Its Reduced Complexes. Although a knowledge of the chemical properties of the ^{144}Pr(IV)-DTPA complex is necessary, the higher oxidation potential Pr^{3+} to Pr^{4+}, reported to be −2.86 V,[4] makes this subject difficult to investigate. Thus, some experiments have been carried out on the cerium(IV)-DTPA complex system, on the supposition that the results obtained may be applicable to the ^{144}Pr(IV)-DTPA complex system.

The absorption spectra of the cerium(IV)-DTPA complex and its reduced complex are shown in Fig. 5, together with that of the cerium(III)-DTPA

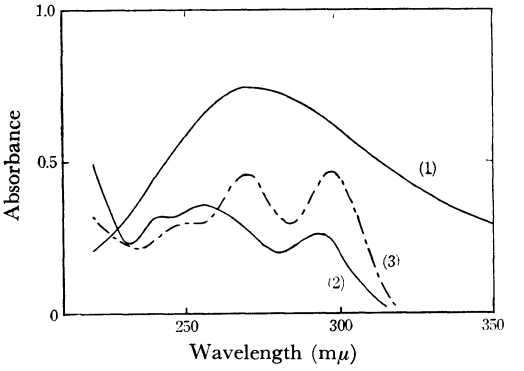

Fig. 5. Absorption spectra of cerium complexes.

(3) Ce(III)-DTPA (8.00×10^{-4} M)

complex. Spectrophotometric investigation showed that the cerium(IV)-DTPA complex is relatively stable in the dark. The decomposition rate is first order with respect to the concentration of the cerium(IV)-DTPA complex. A slight dependence of the rate on the concentration of the hydrogen ion was observed above pH 4.5. The apparent rate constant was obtained as $10^{-2.6}$ min^{-1} at 25°C in the dark.

The cerium(III) complex with an oxidation product of DTPA, Ce(III)Z, is stable in an aqueous solution, but it is converted into the DTPA complex in the presence of excess DTPA. The cerium(III) complex produced by the reduction of the ^{144}Ce-(IV)-DTPA complex is not adsorbed on the cation exchange resin above pH 6, though an abrupt increase in the adsorption coefficient is observed below pH 6, indicating that the formation constant of Ce(III)Z is not very large.

Discussion

Unusual chemical behavior of ^{144}Pr decayed from ^{144}Ce was observed more remarkably in the DTPA complex system than in the EDTA complex system. These results indicate that the chemical behavior of ^{144}Pr in the DTPA complex system cannot be explained sufficiently by the deactivation process proposed in the EDTA complex system.[1]

In order to treat the chemical behavior of ^{144}Pr more strictly, let us re-examine the assumption proposed in the EDTA complex system.

a) Life Time of the ^{144}Pr(IV)-DTPA Complex. The cerium(IV)-DTPA complex is fairly stable compared to the cerium (IV)-EDTA com-

4) L. Eyring, H. Lohr and B. B. Cunningham, *J. Am. Chem. Soc.*, **74**, 1186 (1952).

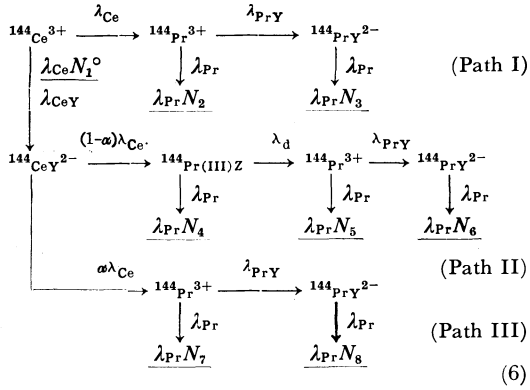
plex.[5] Although the praseodymium(IV)-DTPA complex must be reduced to a tripositive state because of its thermodynamical instability, it may have a finite life time, with several possibilities.

b) Decomposition Processes of ^{144}Pr(III)Z. Cerium(III)Z is stable in the aqueous solution, but its stability constant may be fairly small compared to the corresponding DTPA complex. The trace amount of ^{144}Pr(III)Z, therefore, apparently decompose when a large excess of the DTPA complex is present.

c) Adsorbability of ^{144}Pr(III)Z on the Cation Exchange Resin. The ^{144}Pr(III)Z which may be produced by an intramolecular electron-transfer of the ^{144}Pr(IV)-DTPA complex still has a negative charge. Consequently, it will not be adsorbed on the resin.

d) Chemical Behavior of ^{144}Pr Decayed from $^{144}Ce^{3+}$. ^{144}Pr will be reduced instantaneously to a tripositive state and exhibits the normal substitution reaction described above.

In view of these considerations, the introduction of Bateman's equation[6] has been undertaken in order to establish rigidly the stabilization process for the ^{144}Pr decayed from ^{144}Ce. The chain mechanism for the stabilization of ^{144}Pr can be expressed as follows:



(6)

where λ_{Ce} and λ_{Pr} are the decay constants of ^{144}Ce and ^{144}Pr respectively; λ_{CeY} and λ_{PrY} denote the respective exchange rate constants of $^{144}Ce^{3+}$ and $^{144}Pr^{3+}$ with the cerium(III)-DTPA complex; λ_d, is the decomposition rate constant of an intermediate complex, and α is the ratio of bond-rupture, which is defined as the ratio of the $^{144}Pr^{3+}$ produced directly from the ^{144}Ce(III)-DTPA complex without any formation of the intermediate.

Since the system considered here possesses a radiochemical equilibrium on the whole, the disintegration rate of ^{144}Ce, $\lambda_{Ce}N_-$, is equal to the sum of the disintegration rates of the respective fractions of ^{144}Pr, *i.e.*, to $\sum_{n=2}^{8}\lambda_{Pr}N_n$. For the sake of simplicity, it is assumed that in the introduction of the chain mechanism, the tetrapositive praseodymium produced by the β^--decay is promptly reduced to a tripositive state, and that the intermediate is not transferred to the cationic fraction upon separation. In Eq. (6), therefore, only the $\lambda_{Pr}N_3$, $\lambda_{Pr}N_4$, $\lambda_{Pr}N_6$, and $\lambda_{Pr}N_8$ fractions give any yield of $^{144}PrY^{2-}$. Thus, the solutions of Bateman's equation can be obtained for each fraction as follows:

i) The substitution reaction of the $^{144}Pr^{3+}$ initially present with the cerium(III)-DTPA complex gives the $^{144}PrY^{2-}$. After a lapse of time, t, the fraction of $^{144}PrY^{2-}$ is given by the following equation:

$$(\lambda_{Pr}N_3)_I = \lambda_{Ce}N_1^\circ(e^{-\lambda_{Pr}t} - e^{-(\lambda_{Pr}+\lambda_{PrY})t})\frac{[^{144}PrY^{2-}]_e}{[^{144}Pr^{3+}]_e + [^{144}PrY^{2-}]_e} \tag{7}$$

ii) Fraction of the formation of $^{144}PrY^{2-}$ by path I:

$$(\lambda_{Pr}N_3)_{II} = \lambda_{Ce}N_1^\circ\left(\frac{\lambda_{Pr}}{\lambda_{Pr}+\lambda_{PrY}-\lambda_{CeY}}\right)\left\{e^{-(\lambda_{Pr}+\lambda_{PrY})t} + \frac{\lambda_{PrY}e^{-\lambda_{CeY}t}}{\lambda_{Pr}-\lambda_{CeY}} - \left(\frac{\lambda_{Pr}+\lambda_{PrY}-\lambda_{CeY}}{\lambda_{Pr}-\lambda_{CeY}}\right)e^{-\lambda_{Pr}t}\right\}\frac{[CeY^{2-}]}{[Ce^{3+}]+[CeY^{2-}]}\cdot\frac{[^{144}PrY^{2-}]_e}{[^{144}Pr^{3+}]_e + [^{144}PrY^{2-}]_e} \tag{8}$$

iii) When ^{144}Ce has reached the chemical equilibrium, it exists in the uncomplexed-ion form in the ratio of $[Ce^{3+}]/\{[Ce^{3+}]+[CeY^{2-}]\}$. Consequently, it is necessary to obtain the fraction of the formation of $^{144}PrY^{2-}$ from $^{144}Ce^{3+}$ in path I without regard to the branches to path II and path III.

$$(\lambda_{PI}N_3)_{III} = \lambda_{Ce}N_1^\circ\left(\frac{\lambda_{PrY}}{\lambda_{Pr}+\lambda_{PrY}}\right)\left\{1+\frac{\lambda_{Pr}}{\lambda_{PrY}}e^{-(\lambda_{Pr}+\lambda_{PrY})t} - \left(\frac{\lambda_{Pr}+\lambda_{PrY}}{\lambda_{PrY}}\right)e^{-\lambda_{Pr}t}\right\}\frac{[Ce^{3+}]}{[Ce^{3+}]+[CeY^{2-}]}\cdot\frac{[^{144}PrY^{2-}]_e}{[^{144}Pr^{3+}]_e + [^{144}PrY^{2-}]_e} \tag{9}$$

iv) Contribution of the intermediate complex:

$$\lambda_{Pr}N_4 = (1-\alpha)\lambda_{Ce}N_1^\circ\left\{\frac{\lambda_{Pr}}{\lambda_{Pr}+\lambda_d} - \frac{\lambda_{Pr}e^{-\lambda_{CeY}t}}{\lambda_{Pr}+\lambda_d-\lambda_{CeY}} - \frac{\lambda_{Pr}\lambda_{CeY}e^{-(\lambda_{Pr}+\lambda_d)t}}{(\lambda_{Pr}+\lambda_d)(\lambda_{CeY}-\lambda_{Pr}-\lambda_d)}\right\}\frac{[CeY^{2-}]}{[Ce^{3+}]+[CeY^{2-}]} \tag{10}$$

5) T. R. Bhat and D. Radhamma, *Indian J. Chem.*, **3**, 151 (1965).

6) H. Bateman, *Proc. Cambridge Phil. Soc.*, **15**, 423 (1910).

v) The degree of formation of $^{144}PrY^{2-}$ by path II:

$$\lambda_{Pr}N_6 = (1-a)\lambda_{Ce}N_1^{\circ}\left\{\frac{\lambda_{PrY}\lambda_d}{(\lambda_{Pr}+\lambda_{PrY})(\lambda_{Pr}+\lambda_d)} - \frac{\lambda_{Pr}\lambda_{PrY}\lambda_d e^{-\lambda_{CeY}t}}{(\lambda_{Pr}-\lambda_{CeY})(\lambda_{Pr}+\lambda_d-\lambda_{CeY})(\lambda_{Pr}+\lambda_{PrY}-\lambda_{CeY})}\right.$$
$$+\frac{\lambda_{Pr}\lambda_{PrY}\lambda_{CeY}e^{-(\lambda_{Pr}+\lambda_d)t}}{(\lambda_{Pr}+\lambda_d)(\lambda_{PrY}-\lambda_d)(\lambda_{CeY}-\lambda_{Pr}-\lambda_d)} - \frac{\lambda_{CeY}e^{-\lambda_{Pr}t}}{\lambda_{CeY}-\lambda_{Pr}} + \left.\frac{\lambda_{Pr}\lambda_{CeY}\lambda_d e^{-(\lambda_{Pr}+\lambda_{PrY})t}}{(\lambda_{Pr}+\lambda_{PrY})(\lambda_d-\lambda_{PrY})(\lambda_{CeY}-\lambda_{Pr}-\lambda_{PrY})}\right\}$$
$$\times\frac{[CeY^{2-}]}{[Ce^{3+}]+[CeY^{2-}]}\cdot\frac{[^{144}PrY^{2-}]_e}{[^{144}Pr^{3+}]_e+[^{144}PrY^{2-}]_e} \tag{11}$$

vi) The degree of formation of $^{144}PrY^{2-}$ by path III:

$$\lambda_{Pr}N_8 = a\lambda_{Ce}N_1^{\circ}\left\{\frac{\lambda_{PrY}}{\lambda_{Pr}+\lambda_{PrY}} - \frac{\lambda_{Pr}\lambda_{PrY}e^{-\lambda_{CeY}t}}{(\lambda_{Pr}+\lambda_{PrY}-\lambda_{CeY})(\lambda_{Pr}-\lambda_{CeY})}\right.$$
$$\left.+\frac{\lambda_{Pr}\lambda_{CeY}e^{-(\lambda_{Pr}+\lambda_{PrY})t}}{(\lambda_{CeY}-\lambda_{Pr}-\lambda_{PrY})(\lambda_{Pr}+\lambda_{PrY})} - \frac{\lambda_{CeY}e^{-\lambda_{Pr}t}}{\lambda_{CeY}-\lambda_{Pr}}\right\}\frac{[CeY^{2-}]}{[Ce^{3+}]+[CeY^{2-}]}\cdot\frac{^{144}PrY^{2-}]_e}{[^{144}Pr^{3+}]_e+[^{144}PrY^{2-}]_e} \tag{12}$$

In deriving these equations, λ_{Ce} is very small compared to λ_{Pr}, λ_{CeY}, λ_{PrY}, and λ_d, and could be considered to be effectively zero. After a sufficient lapse of time, when a chemical equlibrium with respect to ^{144}Ce has been attained and when the $^{144}Pr^{3+}$ initially present has decayed out, only the iii, iv, v, and vi fractions contribute to the $^{144}PrY^{2-}$- yield. In addition, the exponential terms in all the equations become, in effective, zero; hence, the $^{144}PrY^{2-}$-yield is given by the following equation:

$$^{144}PrY^{2-}\text{-yield}(\%) = \left\{\frac{\lambda_{PrY}}{\lambda_{Pr}+\lambda_{PrY}}\cdot\frac{[Ce^{3+}]+a[CeY^{2-}]}{[Ce^{3+}]+[CeY^{2-}]}\cdot\frac{[^{144}PrY^{2-}]_e}{[^{144}Pr^{3+}]_e+[^{144}PrY^{2-}]_e}\right.$$
$$+\frac{(1-a)\lambda_{Pr}}{\lambda_{Pr}+\lambda_d}\cdot\frac{[CeY^{2-}]}{[Ce^{3+}]+[CeY^{2-}]}+\frac{(1-a)\lambda_{PrY}\lambda_d}{(\lambda_{Pr}+\lambda_{PrY})(\lambda_{Pr}+\lambda_d)}$$
$$\left.\times\frac{[CeY^{2-}]}{[Ce^{3+}]+[CeY^{2-}]}\cdot\frac{[^{144}PrY^{2-}]_e}{[^{144}Pr^{3+}]_e+[^{144}PrY^{2-}]_e}\right\}\times 100 \tag{13}$$

where the effect of the disintegration of ^{144}Ce can be ignored; by convention, the value for $\lambda_{Ce}N_1^{\circ}$ is taken as unity. Thus, the $^{144}PrY^{2-}$-yield becomes a constant, independent of the reaction time.

In Eq. (13), since the values for λ_{Pr} and λ_{PrY} have already been established, λ_d and α can be obtained by insertion of the experimental values for the $^{144}PrY^{2-}$-yields. It was found that α is a constant independent of the temperature, while λ_d is a function of the concentration of hydrogen ion; that is,

$$\lambda_d = k_d[H^+] \tag{14}$$

The values for the decomposition rate constants of the intermediate, k_d, and for α obtained which best fit the experimental results are given below:

(25°C) $k_d = (5\pm1)\times10^4\ l\,mol^{-1}min^{-1}$
(5°C) $k_d = (2\pm1)\times10^4\ l\,mol^{-1}min^{-1}$
$\alpha = 0.25$

The experimental and calculated values for the $^{144}PrY^{2-}$-yields are compared in Fig. 3, using the following numerical values:

$\lambda_{Pr} = 0.0396$, $\lambda_d = 10^{4.7}[H^+]$, $\alpha = 0.25$ and
$\lambda_{PrY} = \{10^{8.90}[CeY^{2-}]/[Ce^{3+}]+10^{8.36}\}[H^+]^2$

The values for $(1-F)$ in Eq. (5) were also calculated with Eqs. (7)—(12), as shown in Fig. 6. The good agreement between the experimental and calculated values for the $^{144}PrY^{2-}$-yields supports the proposed decomposition process of the intermediate complex, which is substantially analogous to that proposed in the EDTA complex system.[1]

The theoretical considerations of the β^--decay, in addition to the results of the charge spectrometric studies, would predict that a large fraction of the transformation of a β-active atom in a molecule would leave the daughter molecular ion in a little-excited or not in an excited state at all. Furthermore, in the β^--decay of ^{144}Ce, multiple charging resulting from electron shake-off and the internal conversion of γ-rays is of minor importance, and the maximum amount of internal energy

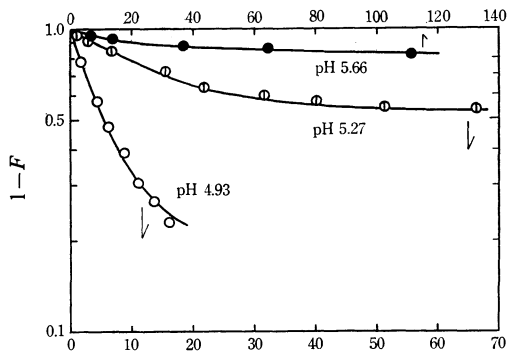


Fig. 6. The $(1-F)$ values calculated by Eqs. (7)—(12).
The circles indicate the experimental values.
The solid curves were calculated by Eqs. (7)—(12).

available from the recoil is less than the bond energies. Thus, the chemical properties of the daughter molecular ion (^{144}Pr(IV)-DTPA complex) play the most important role in determining the fate of the ^{144}Pr decayed from the β^--decay of ^{144}Ce.

Glentworth *et al.*[2] have reported that an attack of the hydrogen ion on the charged excited intermediate molecules ($[^{144}Pr^{IV}Y]^*$) produced by β^--decay results in an enhanced break-up of the daughter complex ion. However, by taking into consideration the facts that the praseodymium(IV) ion is a very powerful oxidizing agent and that inversely, aminopolycarboxylic acids are reducing agents, it is more likely that, before the attack of the hydrogen ion on the ^{144}Pr(IV)-DTPA complex, a unimolecular decomposition resulting from an intramolecular electron-transfer takes place predominantly. Evidence for the reduction by the intramolecular electron-transfer has been found in the cerium(IV)-DTPA complex.

In view of the decomposition mechanism and rate canstants, there is no doubt that the intermediate complex is present. The intramolecular electron-transfer would cause the decarboxylation of a coordinated carboxylate group, and the resultant intermediate complex is possibly less stable than the corresponding parent complex. The value for the rate constant, k_d, is consistent with these considerations.

The multiple charging of the daughter ion resulting from electron shake-off and the internal conversion of γ-rays is of minor importance in the β^--decay of ^{144}Ce, but it cannot be ignored completely.[7] About 18 per cent of ^{144}Pr possesses a charge higher than +5 resulting from the electron shake-off, judging from the results in the β^--decay of ^{133}Xe.[8] Furthermore, the yield of 13 per cent for the multiply-charged species is estimated from the internal conversion coefficient.[9] Consequently, a considerable part of ^{144}Pr might be found in the multiply-charged state, while in about 70 per cent of the events the daughter would be formed in an oxidation state one higher than its parent in the β^--decay of ^{144}Ce. Multiple charging may cause an exhaustive decomposition of the daughter complex, resulting in the liberation of ^{144}Pr in the free-ion form. Indeed, the ratio of the bond rupture of 0.25 corresponds to the extent of the formation of the multiply-charged ^{144}Pr ion.

In addition, in higher pH regions the degree of bond-rupture should give plateau values for the $^{144}PrY^{2-}$-yield curves indepedent of the temperature. As is shown in Fig. 4, both the $^{144}PrY^{2-}$-yields at 25 and 5°C seem to reach the plateau value of 37.5 per cent with an increase in the pH; however, as a result of the hydrolysis of the uncomplexed cerium(III) ion, further investigation could not be carried out.

In conclusion, these considerations lead to a possible stabilization process for the ^{144}Pr decayed from ^{144}Ce, as is illustrated schematically in Fig. 7.

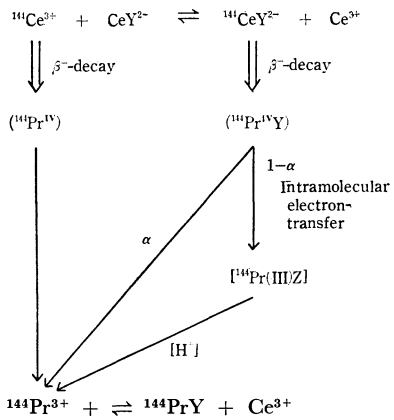

Fig. 7. Stabilization processes of ^{144}Pr produced by β^--decay of ^{144}Ce in the DTPA complex system.

(Received July 13, 1968)

The SCF MO's for the π-electron system of 1,10-phenanthroline have been determined by following the Pariser-Parr-Pople's treatment. For the description of the lower excited states, the configuration interaction among nineteen singly-excited configurations with lower energy has been taken into account. The electronic spectrum of 1,10-phenanthroline has been interpreted on the basis of the results of the theoretical calculation. The SCF MO's for the π-electron system of a coordinated 1,10-phenanthroline in the tris-iron(II) complex have been determined to be self-consistent under the electrostatic potential field of the central metal ion and the other ligand molecules. On the basis of the results for coordinated ligand, the π-electronic structure of tris-(1,10-phenanthroline)iron(II) ion has been investigated from the theoretical point of view. It has been shown that two kinds of the charge-transfer transitions are responsible for an intense absorption band in the visible region, namely electron transfers from the $3d\pi$ orbital of iron to the lowest and the second lowest vacant π MO's of the ligand 1,10-phenanthroline. The discussions have been given on the change of the π–π^* states of 1,10-phenanthroline by the coordination.

The nature of the intensely colored complexes which iron(II) ions form with heterocyclic diamines, such as 2,2′-bipyridine (bipy) and 1,10-phenanthroline (phen), has received much attention and has been extensively studied. The π-bond formation between the central metal atom and the ligand molecules seems to play an important role on the nature of these complexes.[1)]

The π electronic structures of such a type of metal complexes were theoretically treated with success at first on acetylacetonato complexes of metal ions of the first transition series[2)] and then on tris-(2,2′-bipyridine)-[3)] and tris(α-diimine)iron(II)[4)] complexes.

The purpose of the present work is to extend this theoretical treatment to tris(1,10-phenanthroline)-iron(II) ion, $[Fe(phen)_3]^{2+}$. The outline of the calculation will be given, because the method of theoretical treatment was previously described.[2,4)] The integral values characteristic for the present system, however, will be discussed in detail.

Experimental

Materials. Commercial 1,10-phenanthroline monohydrate (Yoneyama Chemical Industries Co., Ltd). was used without further purification. $[Fe(phen)_3]Cl_2 \cdot 7H_2O$[5)] and tris(2,2′-bipyridine)iron(II) perchlorate, $[Fe(bipy)_3](ClO_4)_2$,[6)] were prepared by the standard methods and identified by the chemical analysis.

Measurements. Electronic absorption spectra were measured by a Hitachi recording spectrophotometer Model EPS-3.

SCF MO and Lower Excited States of 1,10-Phenanthroline

The structures of 1,10-phenanthroline and $[Fe(phen)_3]^{2+}$ are shown in Fig. 1 together with the coordinate system used. Also shown are the numbering of the atom and the name of the ligand.

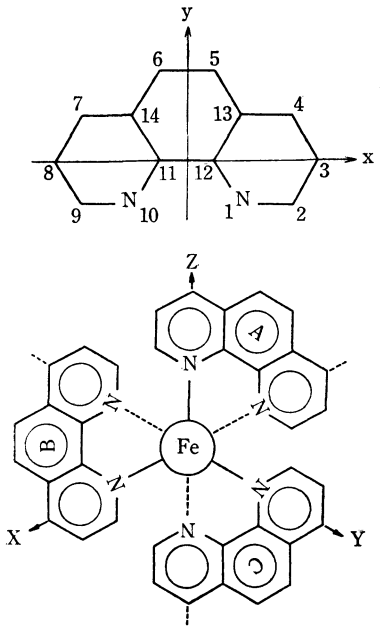

Fig. 1. The geometrical structures of 1,10-phenanthroline and $[Fe(phen)_3]^{2+}$ ion.

Since no experimental work on their geometrical structures has been reported, the bond lengths of all C–C and C–N bonds in the ring were assumed to be 1.39 Å and that of the Fe–N bond was assumed to be 1.97 Å.*3

Free Molecule. The π-electron system of 1,10-phenanthroline, containing 14 π-electrons, was studied by following the Pariser-Parr-Pople's treatment.[8,9]

The valence state ionization potential (I) and the electron affinity (A) were obtained from the table given by Pilcher and Skinner[10] as follows:

$I = 11.22$ eV and $A = 0.62$ eV for carbon
$I = 14.51$ eV and $A = 1.20$ eV for nitrogen

The core resonance integrals between the nearest neighbor AO's (atomic orbitals), β_{ij}, were calculated by the equation,

$$\beta_{ij} = \frac{S_{ij}}{S_0}\beta_0$$

where S_0 (0.248) and β_0 (−2.39 eV) are the overlap integral and the core resonance integral for benzene molecule, respectively. Evaluating the overlap integral, S_{ij}, from the table of Mulliken *et al.*,[11] the core resonance integrals were determined to be

$$\beta_{CN} = -1.879 \text{ eV} \quad \text{and} \quad \beta_{CC} = -2.39 \text{ eV}$$

Table 1 gives the SCF MO's (self-consistent field molecular orbitals) and their orbital energies for 1,10-phenanthroline. The electron densities are given in Table 2. The energies and the wave functions of the lower excited states of 1,10-phenanthroline were obtained by the configuration interaction calculation taking into account nineteen singly-excited configurations with lower energy.

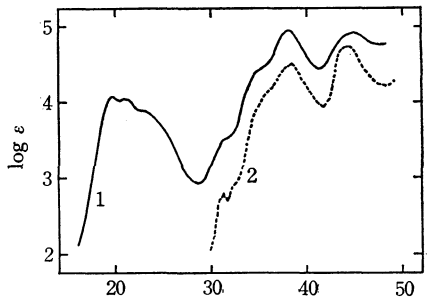

Fig. 2. The absorption spectra of (1) $[Fe(phen)_3]Cl_2 \cdot 7H_2O$ in aqueous solution and (2) 1,10-phenanthroline in ethanol solution.

In Table 3, the predicted π–π^* transition energies and oscillator strengths are presented in comparison with the experimental results. The electronic absorptin spectra of 1,10-phenanthroline and $[Fe(phen)_3]^{2+}$ are shown in Fig. 2. As is seen in Table 3, an agreement between the calculated and the observed results looks satisfactory.

12) G. Favini and E. Paglia, *J. Inorg. Nucl. Chem.*, **8**, 158 (1958).

Badger and Walker[13] found no evidence for n–π^* transition in the absorption spectrum of 1,10-phenanthroline. Their conclusion was based on the absence of solvent effect with variation of solvent polarity. Perkampus and Köhler[14] studied the absorption spectra in methanol and acid methanol solution in detail. They reported that the general structure of the absorption spectrum of phenanthrene was maintained even in 1,10-phenanthroline. Noticeable difference is only the loss of the vibrational structure in the 1,10-phenanthroline spectrum. Consequently, the π–π^* excited states are considered to be similar to these two molecules. Nishimoto and Forster[15] and Skancke[16] gave the assignments for phenanthrene molecule on the basis of the theoretical calculation. Their assignments are similar to the present one for 1,10-phenanthroline. These seem to provide a further support for the present theoretical result.

Coordinated Ligand. The SCF MO's of chelated 1,10-phenanthroline in $[Fe(phen)_3]^{2+}$ were determined, considering not only the field of the 1,10-phenanthroline itself but also the electrostatic potential field due to the central metal atom and the distribution of the π-electrons in the other ligands.*4 Such calculations were carried out for three cases in which the number of the formal charge of iron was assumed to be 0, +1 and +2, since the degree of σ-donation caused by the coordination was not certain. Table 4 shows the result for the case when the formal charge of iron is zero. This was used in the calculation given in this paper. The reason for this is as follows:

Table 4. Calculated transition energy (E) and oscillator strength (f) for coordinated 1,10-phenanthroline in iron complex*

*4 The details of the SCF procedure are referred to Ref. 2.

The energy of an electron transfer from the 3*d* AO of iron to the vacant ligand π-MO depends strongly on the formal charge of iron, in other word, the σ-electron distribution in the metal complex.[17] The parametrization of this energy to the observed value suggested that the formal charge of iron was close to zero.[17] As is seen in Table 4, the spectral feature of a coordinated ligand is not greatly different from that of the free ligand molecule, although the π-electrons of the ligand in the metal complex are conceivably subjected to the strong electrostatic potential field by the central metal atom and the other ligand molecules.

Electronic Structure of Tris(1,10-phenanthroline)iron(II) Complex

The so-called π-electron approximation was adopted in the present study.*5 As component orbitals, π-type 3*d* AO of iron and π-MO's of ligands were taken into account. By placing π-electrons in the appropriate orbitals, the following three types of electronic configurations are obtained: (1) the ground configuration (G), (2) the locally excited configuration (LE) and (3) charge transfer configuration (CT). The π-electronic structure of $[Fe(phen)_3]^{2+}$ was studied by the configuration interaction calculation among these configurations.

Symmetries of Electronic Configurations. The electronic spin of $[Fe(phen)_3]^{2+}$ is singlet in the ground state.[18] Therefore, six *d*-electrons of iron(II) may be in the π-type 3*d* AO, d_{xy}, d_{yz} and d_{zx} with antiparallel spins. The π-electron system of this complex can be divided into four components, namely a π-electron system of iron AO and those of three ligands. The wave function for the ground configuration (G) can be represented as follows:

$$G = |(1\bar{1}2\bar{2}3\bar{3}4\bar{4}5\bar{5}6\bar{6}7\bar{7})^{A}(\ )^{B}(\ )^{C} d_{xy}\bar{d}_{xy}d_{yz}\bar{d}_{yz}d_{zx}\bar{d}_{zx}|$$ *6

where the superscripts A, B and C denote the three coordinated 1,10-phenanthroline molecules shown in Fig. 1. In addition to the ground configuration, thirty six charge transfer (CT) configurations and thirty locally excited (LE) configurations were taken into account, which are given in Table 5. In a way similar to the ground configuration, the wave function for the CT configuration in which an electron is transferred from d_{xy} to φ_8^A is expressed as,

$$CT(d_{xy}\rightarrow\varphi_8^A) = \frac{1}{\sqrt{2}}\left\{\begin{array}{l}|(\ )^{A}(\ )^{B}(\ )^{C}\,8^{A}\bar{d}_{xy}d_{yz}\bar{d}_{yz}d_{zx}\bar{d}_{zx}| \\ +|(\ )^{A}(\ )^{B}(\ )^{C}d_{xy}\bar{8}^{A}d_{yz}\bar{d}_{yz}d_{zx}\bar{d}_{zx}|\end{array}\right\}$$

Table 5. Singly-excited configurations taken into account for the configuration interaction calculation

Configuration	Character	Total number
CT	from $\left\{\begin{array}{l}d_{xy}\\d_{yz}\\d_{zx}\end{array}\right\}$ to $\{\varphi_8, \varphi_9, \varphi_{10}, \varphi_{11}\}$ in each ligand A, B, C	36
LE	lower ten excited states in each ligand A, B, C	30

The wave function for the LE configuration in which only the ligand A is in the μth excited state is expressed as,

$$LE(\Phi_\mu^A) = \sum a_{ij}\frac{1}{\sqrt{2}}\left\{\begin{array}{l}|(\ldots i\bar{j}\ldots)^{A}(\ )^{B}(\ )^{C}d_{xy}\bar{d}_{xy}d_{yz}\bar{d}_{yz}d_{zx}\bar{d}_{zx}| \\ +|(\ldots j\bar{i}\ldots)^{A}(\ )^{B}(\ )^{C}d_{xy}\bar{d}_{xy}d_{yz}\bar{d}_{yz}d_{zx}\bar{d}_{zx})\end{array}\right\}$$

where i and j mean the number of the occupied and the vacant MO of the ground configuration, respectively and a_{ij} means the coefficient of the $(\varphi_i-\varphi_j)$ excited configuration for the μth excited state. The value of a_{ij} was determined in the configuration interaction calculation for coordinated 1,10-phenanthroline. Other CT and LE configurations are expressed in a similar way. The ground, the CT and the LE configurations are classified into the irreducible representations of D_3 symmetry by taking the linear combination, which are given in Table 6.

Configuration Interaction. The matrix elements of the total electronic Hamiltonian between the configurations were calculated in a way similar to the case previously reported.[2,4] The accurate evaluation of the diagonal element of the CT configuration, E_{CT}, is extremely difficult. The difficulty mainly comes from the fact that the value of E_{CT} is very sensitive to the σ-electron distribution, which is uncertain.[2,4] It is also difficult to obtain any reliable value of the π-electron affinity of the coordinated ligand. Therefore, in the present calculation, the diagonal element of the CT configuration with the lowest energy was treated as a parameter. The values of the other CT diagonal elements were determined, considering the difference of the MO's to which an electron is transferred. The diagonal elements of LE configurations are expressed as the sum of the excitation energy in the coordinated 1,10-phenanthroline and the additional term, the latter of which originates from the inter-ligand interaction of the transition dipoles. The interaction energies of the transition dipoles on different ligands, $K'_{\mu\nu}$, were calculated in the same way as previously used.[3] ($K'_{\mu\nu}$ is the interaction energy of the transition dipoles accompanied by the μth transition in ligand A and the νth transition in ligand B). The off-diagonal

17) See Ref. 4.

*5 The applicability of this approximation was already discussed in Ref. 2.

18) F. H. Burstall and R. S. Nyholm, *J. Chem. Soc.*, **1952**, 3570.

*6 The abbreviated notation $(\ )^{\mu}$ means $(1\bar{1}2\bar{2}3\bar{3}4\bar{4}5\bar{5}6\bar{6}7\bar{7})^{\mu}$.

* The subscript(μ) of LE_μ^s means that LE_μ^s corresponds to the μth excited state of the ligand 1,10-phenanthroline.

matrix elements between G and CT and between CT and LE were accounted for by β, the core resonance integral between the appropriate $3d\pi$ AO of iron and $2p\pi$ AO of nitrogen. It was evaluated with the usual relation,

$$\beta = -S\frac{I_{Fe} + I_N}{2}$$

where S is the overlap integral, and I_{Fe} and I_N are the valence state ionization potentials of iron and nitrogen, respectively. The overlap integral was estimated with the aid of the Slater AO of nitrogen and the double zeta expanded $3d$ AO of iron determined by Richardson *et al.*[19] It was calculated to be 0.090, using the table given by Jaffé.[20] I_{Fe} and I_N are 5.08 eV and 18.68 eV respectively and β amounts to -1.07 eV. In the off-diagonal elements between the CT configurations, only the two-center repulsion integrals of the type $(d_i d_i | \varphi_k^\mu \varphi_l^\mu)$ are taken into account with the point charge approximation. The off-diagonal matrix elements between the LE configurations are expressed in terms of $K'_{\mu\nu}$.

The results obtained by the configuration interaction are shown in Table 7 and the calculated transition energies and the oscillator strengths are given in Table 8 together with the observed ones.

Interpretation of the Electronic Spectrum. From the results given in Tables 7 and 8 it can be concluded that the intense band at the visible region is reasonably assigned to the almost pure CT absorption due to the π-electron migration from the $3d\pi$ AO of iron to the lowest vacant MO, φ_8, of the ligand. The observed absorption bands are too broad and poorly resolved to indicate the components. However, the broad tail appearing

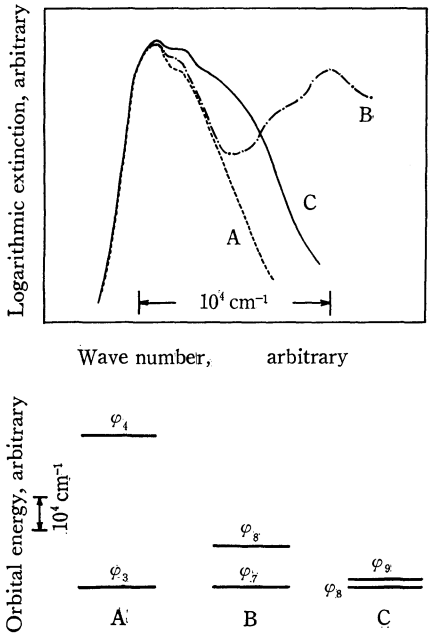

Fig. 3. The CT band shapes and the energies of the two lowest vacant ligand MO's for (A) tris(biacetyl-bis-*N*-methylimine), (B) tris(bipyridine) and (C) tris(phenanthroline) complexes of iron(II).
The spectra are drawn at the appropriate position and on the appropriate intensity scale as the longer wavelength part of the spectrum overlap each other. In the energy level diagram the energy of the lowest vacant orbital is taken equal in order to make easier the comparison of the energy separations between the lowest and the nesxt lowest vacant orbital.

at the shorter wavelength side of this band may be assigned to the overlapping of the second CT band ($3d\pi \rightarrow \varphi_9$). Figure 3 shows the CT band shapes of tris(biacetyl-bis-*N*-methylimine) iron (II), $[Fe(bipy)_3]^{2+}$ and $[Fe(phen)_3]^{2+}$ ions. Also shown are the lowest two vacant MO's for these ligand molecules, to which an electron is transferred. These complexes are considered to have similar electronic structures. As is shown in the previous paper,[4] the CT band of tris(biacetyl-bis-*N*-methylimine)-iron(II) is composed of one kind of CT, namely $3d\pi \rightarrow \varphi_3$. The orbital energy level of the next lowest vacant MO, φ_4, is far from that of φ_3. On the other hand, the lowest two levels are very close to each other for 1,10-phenanthroline and moderately separated for 2,2′-bipyridine. It can be seen in Fig. 3 that the CT band in the visible region is composed of one kind of CT transition for the biacetyl-bis-*N*-methylimine complex, whereas it is composed of two kinds of very closely located CT transitions for the 1,10-phenanthroline complex. It is also clear that such CT bands for the 2,2′-bipyridine complex are resolved into two components.

From great similarities between the absorption curve of 1,10-phenanthroline and $[Fe(phen)_3]^{2+}$, the bands of the complex above 30000 cm^{-1} have been ascribed to the ligand transition beyond reasonable doubt. (See Fig. 2). This was confirmed by the present study. However, it was also shown that the π–π^* transition in the ligand becomes complicated when the ligand is coordinated to form the tris-complex.

One reason for the complication of the absorption bands is that the higher CT bands ($3d\pi \rightarrow \varphi_{10}$ and φ_{11}) appear in the ultraviolet region. They appear in overlap with the LE bands. This situation may be seen clearly in the circular dichroism (CD) spectrum.*7

Since 1,10-phenanthroline has C_{2v} symmetry, the π–π^* transitions should be either y-polarized along the two-fold axis, or x-polarized along the long axis of the ligand molecule (Fig. 1). As has been discussed,[4,21] the x-polarized transition of three ligands in metal complex with D_3 symmetry gives rise to the $A_1 \rightarrow A_2$ and the $A_1 \rightarrow E$ transition while the y-polarized transition gives rise to the $A_1 \rightarrow A_1$ and the $A_1 \rightarrow E$ one, the $A_1 \rightarrow A_1$ transition being symmetrically forbidden. Consequently, if the transition is y-polarized, the resultant electronic absorption spectrum of metal complex consists of single band, which is three times as intense as that of a free 1,10-phenanthroline. On the other hand, if the μth transition is x-polarized, the intensity ratio of the $A_1 \rightarrow E$ to the $A_1 \rightarrow A_2$ transition must be 1 : 2. The transition energy for the $A_1 \rightarrow E$ is smaller by $3K'_{\mu\mu}$ than that for the $A_1 \rightarrow A_2$.*8 Such changes by the coordination take place on each π–π^* level of 1,10-phenanthroline, although the situation becomes more complicated because of the mixing of several LE configurations through the configuration interaction.

The correspondence of the third LE transition theoretically predicted to the observed peak at 37600 cm^{-1} is obvious. The theoretical result shows that this band is intense and x-polarized, which splits into two components in the tris-complex. This splitting is undoubtedly responsible for the observation that an optically active $[Fe(phen)_3]^{2+}$ shows two intense CD peaks with the opposed sign in regard to this absorption band.[22–24]

*7 Two of the present authors (I. H. and S. N.) studied theoretically the CD spectrum of $[Fe(phen)_3]^{2+}$, on the basis of the present results. The details will be reported elsewhere.

The overall agreement of the theoretical transition energy with the observed one is rather poor compared with the case studied previously.[2-4] The calculated transition energies are somewhat high. This discrepancy may probably be attributed to the neglect of the doubly excited LE configurations. In fact, some doubly excited configurations usually appear in a considerably lower energy region, which will possibly bring about a strong effect on the lower singly-excited LE transitions.

The energies of some of the LE transitions are very close to each other in molecules which have the extensive π-electron system such as 1,10-phenanthroline. The transition dipole interaction between the different excited configurations in such a case has an important influence on the electronic states of metal complex through the configuration interaction. The calculated third π-π^* level is close to the fourth one. In metal complex, therefore, the E component of the third level mixes strongly with the fourth one to acquire a larger intensity than what is expected when the configuration interaction is neglected. This fact may partly account for the observation that the lower energy component of the corresponding CD peaks is usually more intense than the higher energy one.*9

Stabilization by the Charge-Delocalization. According to the present theoretical study, $[Fe(phen)_3]^{2+}$ is stabilized by 1.14 eV (26.3 kcal/mol). This stabilization is caused by the mixing of CT configurations into the ground state. In other words, the π-bonding is formed between the iron atom and the ligand molecules. This large stabilization is undoubtedly responsible for the high stability of this complex.

The authors wish to express their thanks to Drs. A. Ishitani and S. Iwata for their kind help in the use of the computer. They also thank the Ministry of Education for the financial support granted for this research.

The numerical calculation was carried out by means of an OKITAC 5090H electronic computer at the Institute of Physical and Chemical Research, a NEAC 2230 at Tohoku University and a HITAC 5020 at the University of Tokyo.

*9 The zero-order rotational strength (R) of these two states is related by the equation, $R(A_2) = -R(E)$.

(Received July 23, 1968)

Nitrosylpentaamminechromium chloride (brown), perchlorate (green) and other salts of different colors were studied by visible, IR and ESR spectroscopy and by magnetic susceptibility measurements. The easy shift of visible absorption bands caused by the replacement of outer anions which are responsible for the color difference, ripples observed in one of the absorption bands, *g*-values from ESR and a spin state 1/2 suggested by the susceptibility measurements are interpreted on the basis of a qualitative MO theory for metal nitrosyl complexes.

A series of transition metal nitrosyl compounds $[MNOL_5]X_n$[1] are known, where M is Fe, Mn, Co, Cr or Pt, L is CN, NH_3 or H_2O and X is Cl, Br, NO_3 or ClO_4, *etc.* These compounds are known to be quite peculiar, both from phenomenological and theoretical view points. Most of these compounds have very short M–N distances, for example, 1.63 Å in $[Fe(CN)_5NO]^{2-}$,[2] which

shows the existence of π-bonding between M and NO resulting in a strong ligand field around the metal ion. This is confirmed by magnetic measurements, which indicate low spin.

Gray and Ballhausen[3] considered that such a short distance should result in a strong axial destabilization of d orbitals, and gave an orbital energy level scheme for $M(CN)_5NO$ ion based on crystalline field theory. Gray and Bernal[4] treated the same problem by molecular orbital theory, where they considered the formation of strong π-bonds involving the metal nd_{xz} and nd_{yz} orbitals and the nitrosyl $\pi^*(2p_x, 2p_y)$ antibonding orbitals. Recently, a more detailed molecular orbital calculation has been made by Gray, Manoharan, Pearlman and Riley[5] and Manoharan and Gray.[6] Their results suggest that the energy level derived mainly from the nitrosyl antibonding orbital π^* NO (which corresponds to the 4e level of Fig. 4), lies much lower than previously suspected.

Extensive optical spectroscopy[3,6,7] and ESR experiments[8] were carried out on transition metal nitrosyl complexes, especially on $[Fe(CN)_5NO]^{3-}$, $[Cr(CN)_5NO]^{3-}$, $[CrNO(NH_3)_5]^{2+}$ and $[CrNO(H_2O)_5]^{2+}$ ions. Infrared absorptions[9,10] of nitrosyl ligands in these compounds were also well investigated.

It is known that $[CoNO(NH_3)_5]^{2+}$ salts have two isomeric forms, one being the red series and the other the black series. From the rocking frequencies[11] of ammonia ligands in these compounds, it was inferred that the oxidation state of Co ion is three in both the red and black series. The electric conductivity[12] of solutions of these complexes showed that the red series of $CoNO(NH_3)_5$ salts are dimers and the black ones monomers, the latter result being consistent with X-ray data.[13]

Nitrosylpentaamminechromium salts,[14] which are subjects of the present study, also have several characteristic properties. Their color is a function of the outer anions present in the solid state. This suggests considerable effects of outer anions on the ligand field at the metal ion (*cf.* Fig. 1). Thus, solid nitrosylpentaamminechromium chloride, bromide and nitrate are brown, while perchlorate,

with studies of visible reflection, visible absorption, infrared and ESR spectra and of the magnetic susceptibilities of nitrosylpentaamminechromium salts.

Experimental

The nitrosylpentaamminechromium salts were prepared by the method reported by Mori, Ueshiba and Kawaguchi.[14] In this paper, previously unreported tetraphenylborate and the picrate of this complex were prepared by adding the corresponding sodium salt or free acid to aqueous solutions of the chloride.

Found in nitrosylpentaamminechromium picrate: Cr, 8.16; NH_3, 12.80%. Calcd for $[CrNO(NH_3)_5](C_6H_2N_3O_7)_2$: Cr, 8.32; NH_3, 13.58%. Found in nitrosylpentaamminechromium tetraphenylborate: C, 71.69; H, 6.76; N, 9.58%. Calcd for $[CrNO(NH_3)_5][B(C_6H_5)_4]_2$: C, 71.7; H, 6.88; N, 10.44%.

Hexaamminechromium(II) perchlorate was prepared by mixing chromium(II) acetate (prepared from 5 g of potassium dichromate[16]) with 15 g of ammonium perchlorate and 75 m*l*, of 15 M aqueous ammonia in the absence of atmospheric oxygen. The blue precipitate formed was centrifuged or filtered and washed, first with an ammonical aqueous solution of ammonium perchlorate, then with ethanol and finally with petroleum ether. The compound readily oxidizes in air, so that weighing the sample is difficult. However, the atomic ratio was determined to be Cr : NH_3 : ClO_4=1 : 6.10 : 1.97 in a mixed solution prepared by adding the sample wet with petroleum ether to dilute hydrochloric acid. At the same time, the precipitate was shown to be isomorphous with $[M(NH_3)_6](ClO_4)_2$ (M=Mn, Fe, Co, Ni) by an X-ray powder technique. It is thus clear that the blue compound was $[Cr(NH_3)_6](ClO_4)_2$. For the IR study, the mother liquor was further replaced with liquid paraffine. In this liquid, the compound was comparatively stable even between the two plates of sodium chloride used for IR spectroscopy.

The reflection spectra of these complex compounds in powder were obtained using a Hitachi Perkin-Elmer 139 UV-VIS Spectrophotometer. In Fig. 1, such spectra are expressed in terms of $\log[(1-R_d)^2/2R_d]$, where R_d is the diffuse reflectance. This type of curve more clearly shows the relation to absorption spectra. The positions of main maxima in such curves for various

compounds are given in Table 1. The absorption spectra in the visible region of these complex compounds in aqueous solutions were obtained using a Hitachi EPS-2 Recording Spectrometer. In aqueous solutions all compounds showed spectra indistinguishable from each other, irrespective of outer anions.

Infrared absorptions of nitrosylpentaamminechromium salts were observed using a Hitachi EPI infrared Spectrometer. The numerical results are listed in Table 2.

Electron spin resonance spectra were obtained on a Tokyo Denki Seiki T-1000 AX ESR Spectrometer. The results are given in Table 3 and shown in Fig. 2.

The magnetic susceptibilities in the temperature region 1.2°K to 20°K were observed by an alternating current method using a Hartshorn Bridge. The accuracy was ±0.1%. The susceptibilities obeyed the Curie-Weiss law (Fig. 3) and the effective magnetic moments and Curie-Weiss constants were obtained as given in Table 4.

Discussion

The magnetic moments obtained at low temperatures (Table 4) indicate that both brown and green salts are in the same spin state of 1/2, and are in agreement with the room temperature data (2.3 Bohr magnetons) reported for the chloride by Griffith.[1] The fact that the susceptibilities obey the Curie-Weiss law down to 1.2°K proves that no dimerization occurs, and in this sense both brown and green salts correspond to the black series of nitrosylpentaamminecobalt salts. However, the Curie-Weiss constants of the brown halides are greater than those of the green salts, suggesting a greater interaction of spins in the former, presumably through anions. As seen from numerical data in Tables 1—4, the various properties, as well as the colors of these chromium complexes, change continuously rather than abruptly from complex to complex. Consequently, such differences in properties, although considerable in some cases, are thought to be due only to a change in the degree of an interaction between the complex cation and the outer anion.

The rocking frequency of ligand ammonia is known to be sensitive to the oxidation state of the central metal ion. The rocking frequency of ammonia ligands in hexaamminechromium(III) perchlorate is 718 cm^{-1}, and that in hexaamminechromium(II) perchlorate, which we newly prepared, was found at 660 cm^{-1}. The rocking frequencies in the nitrosylpentaamminechromium salts (730—770 cm^{-1}, Table 2) fall within the range for Cr(III) complexes, and are considerably higher than that of the Cr(II) complex. Further-

more, the stability in water of our nitrosylpentaamminechromium complexes is comparable to that of Cr(III) ammine complexes. These results may appear to contradict the magnetic data, because the spin state of 1/2 suggests monovalent Cr. However, we note that the same spin state of 1/2 is reached either when we start with monovalent $Cr(3d^5)$ and a NO^+ ligand by considering extensive back donation, or when we start with trivalent $Cr(3d^3)$ and NO^- ligand and consider electron pairing. In any interpretation, the result is the formation of a strong π-bond between Cr and NO as proposed by many investigators, and the concept of oxidation state seems to lose its strict meaning in harmony with Orgel's view.[17] The anomalous bond strength between chromium and nitrosyl is also supported by the fact that the nitrosylpentaamminechromium salts are changed into pentacyanonitrosylchromium salts in KCN solutions without inducing cleavage of the chromium-nitrosyl bond. In this respect, molecular orbital treatment seems to be suitable for a theoretical consideration of the orbital energy levels of these complexes. Manoharan and Gray[6] made a molecular orbital calculation using $[Fe(CN)_5NO]^{2-}$ as the model ion, and the essential features should remain unchanged for $[CrNO(NH_3)_5]^{2+}$ ion. Thus, the general idea of the energy level scheme of the latter ion could be illustrated as in Fig. 4. Here we assume linearity and the arrangement order Cr–N–O, which seem probable from the recent IR study by Miki *et al.*[18]

Clear-cut assignments of the observed absorption spectra seem difficult, but some characteristics of the absorption bands can be treated as follows:

Reflection spectra in powders indicate that the color changes of the above solid complexes are due to a shift of the visible absorption band in the range 16000—17000 cm^{-1} ($\varepsilon=18.2$ in aqueous spectrum). The easy shift of this band can be interpreted by assigning it to a one-electron transition $1b_2(3d_{xy})\rightarrow 4e(\pi^*NO,3d_{xz},3d_{yz})$ (*i. e.*, $B\rightarrow {}^2E$). The excited orbital 4e is a π-type antibonding molecular orbital located mainly on the nitrosyl, and should be easily influenced by an anion. The direction of shift of the absorption band agrees with this assumption, because the chloride ion which is thought to behave as an electron donor and thus raises the π^*NO level by interaction, actually causes the band to shift toward shorter wavelengths.

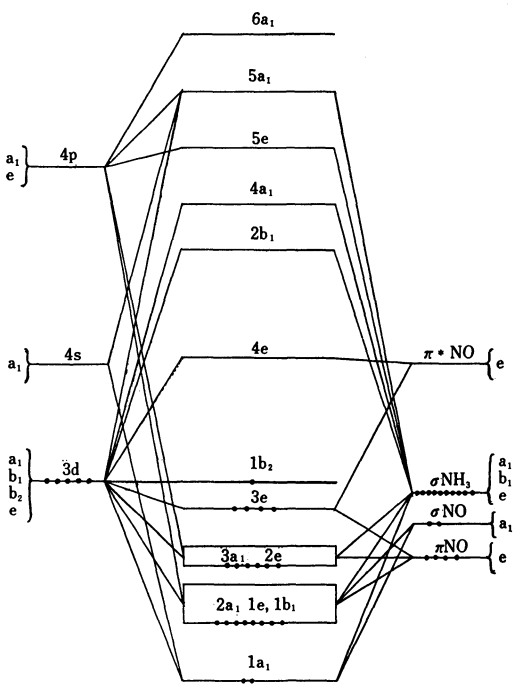

Fig. 4. Molecular orbital energy level for $[CrNO(NH_3)_5]^{2+}$.

The powder spectra also show that the above band is composed of two closely spaced peaks, one of which appears as a shoulder (Fig. 1 and Table 1). This may either be due to a splitting of the 4e level by crystal anisotropy or to the superposition of another band, $3e(3d_{xz},3d_{yz})\rightarrow 4e(\pi^*NO, 3d_{xz},3d_{yz})$ (*i. e.*, $B_2\rightarrow B_2+B_1+A_2+A_1$).

The absorption band near 22000 cm^{-1} ($\varepsilon=101$ in aqueous spectra) is accompanied by ripples spaced at about 480—490 cm^{-1} intervals in aqueous as well as in powder reflection spectra, as shown in Fig. 1, a—f. The wave numbers of small peaks or shoulders in such ripple structures and their spacings are given in Table 5. It seems most probable that the ripple is caused by the coupling of vibrations with the electric dipole transition. We note that vibrational structures on absorption bands have never been reported in other ammine complexes, even when such bands are thought to be allowed only through coupling with vibrational modes. We are thus inclined to think that in this nitrosyl ammine complex there is a special situation in addition to such coupling which made the vibrational structure perceptible in actual spectra. We attribute this to the vibrational stability in the excited state brought about by metal-nitrosyl double bonding, in the sense that there is a well-defined potential minimum even in the excited electronic state. We shall now give some interpretation of a more detailed nature on the problem on these lines.

The band with ripples under discussion (22000 cm^{-1}) is one which undergoes the least change in wave numbers with the substitution of outer anions. This fact, as well as the energy value, suggests the assignment $1b_2(3d_{xy}) \rightarrow 2b_1(3d_{x^2-y^2})$, $(B_2 \rightarrow B_1)$ for this band. This transition must couple with a vibration of E symmetry in order to be allowed. Vibrations of E symmetry observed in IR spectra in the neighborhood of 500 cm^{-1} are a bending vibration of the CrNO skeleton as observed by Miki *et al.*[18] at 531—535 cm^{-1}, and a Cr–NH_3 stretching vibration as observed at 420—440 cm^{-1} by the present authors (Table 2). Although Bernal cited the possibility that the ripple structure on the 22000 cm^{-1} absorption band is due to coupling of the latter vibration, it is felt even more probable to the present authors that it should be due to coupling with the Cr–N–O bending vibration, since the vibrational frequencies are expected to decrease in the excited level. Furthermore, if it were attributable to the Cr–NH_3 E stretching mode as in Bernal's assumption, the ripple structure should appear in other ammine complexes as well, which is not the case. Furthermore, our assumption does not contradict the fact that the excitation $B_2 \rightarrow B_1$ does not break the Cr–N–O linkage.

Other absorption bands, *i. e.*, at 28000 cm^{-1} and 33000 cm^{-1} observed for the perchlorate, also shift toward the violet region by about 1000 cm^{-1} upon substituting the outer anions with halide ions. They probably include transitions $3e(3d_{xz},3d_{zy}) \rightarrow 4a_1(3d_{z^2})(B_2 \rightarrow E)$, $1b_2(3d_{xy}) \rightarrow 4a_1(3d_{z^2})(B_2 \rightarrow A_1)$, *etc.*

The ESR results on nitrosylpentaamminechromium complexes in solution agrees with the results of Bernal and Harrison[8] and Danon, Panepucci and Misetich.[8] Though the nitrosylpentaamminechromium salts could not be obtained as single crystals, powder spectra of tetraphenylborate and of picrate at liquid N_2 temperature gave structures typical of an anisotropic *g*-tensor, and $g_\perp$ and $g_{//}$ were estimated using Kneubühl's method.[19] The situation seems analogous to the case of dimelammonium hexachlorocuprate,[20] which also has a large organic ion exhibiting a dilution effect, enabling one to observe an anisotropic fine structure. The spin-orbit interaction constant calculated from the $g_{//}$ obtained using the energy gap $E(B_{1g} - B_{2g}) = 22000$ cm^{-1} is $\zeta = 158$ cm^{-1}.

Conclusion

Nitrosylpentaamminechromium salts, both the brown and green series, are in low spin states (1/2) and are thus thought to be monomers. The easy shift of the absorption band in the range 16000—17000 cm^{-1}, observed as color differences in powders, is attributable to a rise in energy of the excited level π^*NO cused by a donor-acceptor interaction with anion acting as a donor. Ripples having intervals of about 500 cm^{-1}, observed on the absorption bands near 22000 cm^{-1}, are presumably the result of coupling of vibrational frequencies of the Cr–N–O bending mode (E) with the electric dipole transition $B_1 \rightarrow B_2$.

The authors express their sincere thanks to Professor Ichiro Nakagawa of the University of Tokyo and Professor Hiroshi Tsubomura of Osaka University for their valuable discussions.

Geochemical Fractionation of Induced Radionuclides in Fresh Nuclear Debris through the Atmosphere—Np-239 and Co-60

Takeshi SOTOBAYASHI, Toshio SUZUKI and Seitaro KOYAMA

Department of Chemistry, Faculty of Science, University of Niigata, Niigata

(Received July 23, 1968)

The atmospheric fractionation of induced radionuclides is discussed in some detail on the basis of results obtained by making a radiochemical analysis of fresh nuclear debris originating from recent Chinese nuclear test explosions. Among fresh nuclear debris particles collected at Niigata about 4000 km downwind from the Chinese test site, the trend for the enrichment of ^{239}Np was somewhat modified as compared with that derived from an averaged sample collected by a large-scale and high-altitude sampling procedure; more ^{239}Np was present in smaller-size fallout particles. Furthermore, it was found, in rain-water samples collected after the third Chinese nuclear explosion, that the atomic ratio at time-zero of ^{60}Co/^{95}Zr increased with a decrease in the ^{95}Zr-concentration in rain and *vice versa*. This suggests that the atmospheric fractionation of ^{60}Co-rich particles from ^{95}Zr-rich ones takes place during the travel of atomic clouds around the world.

Several papers[1–3] have been published on the atmospheric fractionation of nuclear debris of known origin. We have made a preliminary discussion of the unique fractionation behavior of ^{239}Np in fresh nuclear debris particles of a larger size which originated from the May 9, 1966, Chinese nuclear test explosion.[4] In this paper we will discuss in more detail the geochemical fractionation behavior of ^{239}Np. Furthermore, by comparing the fallout pattern of an induced nuclide ^{60}Co with that of a refractory fission product ^{95}Zr, we have established the geochemical fractionation of another induced nuclide, ^{60}Co; measurements of the variation in the ^{60}Co/^{95}Zr ratio, in fact, yielded experimental evidence for the geochemical fractionation of nuclear debris during the global circulation of the atomic clouds.

Experimental

Particle samples were collected on the roof of the 8-story Niigata City Hall; the roof surface was carefully surveyed by a G-M counter, and radioactive particles were picked off the roof, possibly along with a small amount of inactive dust material, and isolated under a microscope. Rain samples were collected by a stainless-steel funnel (1 m^2 in area) installed on the campus of the Niigata University. The radiochemical separation of each radionuclide was carried out by a combination of conventional precipitation, ion-exchange, and liquid-liquid extraction methods. The measurements of the radioactivity were made using a gas-flow counter or a NaI(Tl) scintillation detector (1¾ in × 1 in or 3 in × 3 in) with a 200-channel pulse-height analyzer.

Results and Discussion

Physical Properties of Hot Particles from the May 9, 1966 Explosion. A large number of highly-radioactive nuclear debris particles were detected within 36 hr of the third Chinese nuclear test on May 9, 1966. The individual particles, collected on May 11, ranged in total β-activity over a factor of 100, while the particles ranged in size from 5 to 24 μ in diameter. Particularly, sixteen single particles were carefully examined under a microscope; they were reddish-brown, and the particle ranged in size from 8 to 24 μ in diameter. The ^{95}Zr-content varied from 10^7 to 10^9 atoms/particle (Fig. 1), and the specific activity, from 2.3 to 7.3×10^{17} ^{95}Zr-equivalent fissions per gram. The average specific activities of surface-burst debris has been reported to be of the order of 10^{14} ^{95}Zr-equivalent fissions per gram, and air-burst debris particles are believed to have specific activities from 10^4 to 10^7 times higher.[5] Thus, the specific activity of the 16 single particles was

confined within a narrow range, the highest one among the reported specific activities observed in the case of a land-surface burst.

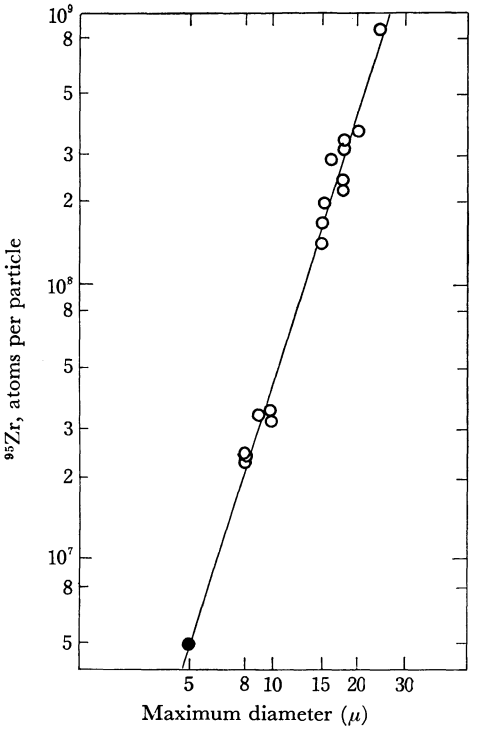

Fig. 1. Correlation between the number of ^{95}Zr atoms and the maximum diameter for 16 single particles collected on May 11, 1966.
●, the average number of atoms/particle for a combined sample of 9 particles.

Figure 1 shows the correlation between the particle size and the number of ^{95}Zr atoms for the 16 single particles. The number of ^{95}Zr atoms is plotted on a logarithmic scale as a function of the logarithm of the maximum diameter of an individual particle. In this graph the data points seem to lie near a solid line with a slope of 3.2. This finding implies that the atoms of ^{95}Zr are incorporated into a single particle with a uniform density. Moreover, the number of ^{95}Zr atoms could, in this case, be used for making a rough estimate of the particle size of nuclear debris.

Unique Fractionation Behavior of ^{239}Np. The debris particles of a larger size were strongly fractionated; concerning short-lived fission products (half-life, 1—3 days), the collected particles, about 250 particles, were all rich in refractory fission products, ^{97}Zr, ^{99}Mo and ^{143}Ce, and poor in ^{132}Te-^{132}I and ^{133}I, as would be expected from their chemical and nuclear properties in such larger particles. Most of the particles were poor in ^{239}Np, but some of them (less than 10 percent) were markedly rich in ^{239}Np, with no detectable amount of the ^{132}Te-^{132}I and ^{133}I in them, while a rain sample collected on May 10—11 was rich in volatile fission products, as is shown in Fig. 4. Figure 2 shows two γ-ray spectra of such two extreme-type particles, A and B; the total β-activity of the A particle was 1.1×10^5 pCi, and that of the B particle, 3.6×10^5 pCi, on May 11. Here the two spectra are normalized to equal the activity level of radiozirconium. The γ-ray spectrum obtained by plotting the difference in counts per channel between the two spectra had a shape similar to the γ-ray spectrum of ^{239}Np, as is shown in the inset. Figure 2 seems to suggest quite similar fractionation behavior in ^{97}Zr, ^{99}Mo, and ^{143}Ce in spite of the difference in ^{239}Np content.

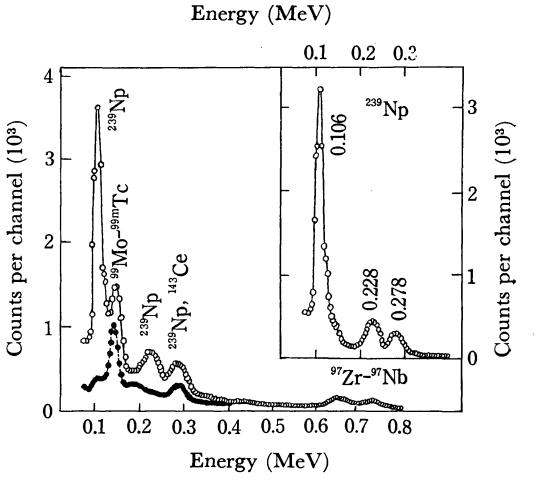

Fig. 2. Gamma-ray spectra of two extremely fractionated hot particles collected on May 11, 1966.
—○—, Particle A; —●—, Particle B

First, this result may be explained by the tentative assumption that the ^{239}Np found in A-type particles is not incorporated into debris particles simultaneously with such refractory fission products as ^{97}Zr at the earlier stages of the debris formation processes, but precipitates a little later on the surface of particles which had condensed at the earlier stages.[6] Further, according to the extensive studies by Freiling[5] and Crocker[7] on the radionuclide fractionation in nuclear debris particles, ^{239}Np originating from a land-surface shot seems to behave like a refractory group. The May 9, 1966, Chinese nuclear explosion was believed to have been blasted near the land surface; this belief is based on the fractionation data for the fallout particles collected in the lower stratosphere.[8] On the other hand, in the present observations, ^{239}Np

seemed to be present along with refractory fission products in less than 10 percent of the total particles collected. Here it should be mentioned that the particle samples studied in the present work were collected at ground level, at a particular location far away from the place of their formation and shortly after the explosion. Taking these points into consideration, such a unique distribution pattern of ^{239}Np and the observed narrow range of specific activity in the present samples may result mainly from the particular sampling conditions. From an alternative point of view, the present data may suggest the gravitational and meteorological forces and the differences in size and density among the debris particles combine to cause particle separation during the travel of the atomic cloud through the atmosphere. The fractionation behavior of ^{239}Np in this case seemed to be somewhat modified as compared with that seen in an averaged sample collected by a large-scale and high-altitude sampling procedure using air craft.

Variation in the ^{239}Np Content with Particle Size. We have presented the γ-ray spectra of two composite samples in order to examine the change in the enrichment of ^{239}Np with the particle size; the particles were grouped in terms of their total β-activity. A combined sample (I) of 9 particles ranged in total β-activity from 10^3 to 10^4 pCi/particle 2 days after the explosion. Their average size was estimated to be 5μ in diameter by comparing their average atom number of ^{95}Zr per particle with a point on the experimental line (the solid circle in Fig. 1, 4.6×10^6 atoms/particle). The single particles of another composite sample (II) of 8 particles all had more than 10^5 pCi/particle when two days old; their average number of ^{95}Zr-atoms/particle was 2.1×10^8 atoms/particle, and their average diameter was estimated to be 16μ. Figure 3 shows the γ-ray spectra of the two combined samples measured 7 days after the explosion; these spectra are also normalized so as to be equal to the activity level of ^{95}Zr-^{95}Nb. These two composite samples were also poor in volatile fission products. The γ-ray spectrum shown in the inset of Fig. 3 was, as in Fig. 2, plotted by subtracting the γ-ray spectrum of the 9-particle sample from that of the 8-particle one. The spectrum in this inset indicates that the smaller-size particles were, on the average, richer in ^{239}Np than the larger ones. The 9-particle sample (I) belonged to the smallest-size range (5μ) among all the particles collected. Thus, the trend toward the enrichment of ^{239}Np may be believed to depend greatly upon the size of the debris particles.

It should be noted in Fig. 3 that smaller particles were also richer in nuclides with the photopeak at 0.14 MeV, mainly ^{99}Mo-^{99m}Tc, relative to ^{95}Zr-^{95}Nb. This, for reasons to be given below, may present a unique fractionation picture—that one

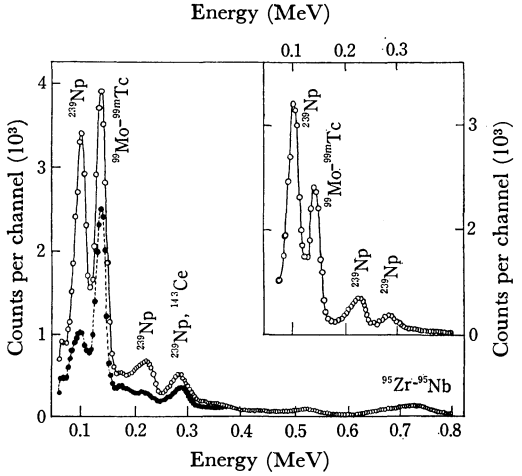

Fig. 3. Gamma-ray spectra of two composite particle samples, I and II.
—○—, Sample (I) of 9 paritcles;
—●—, Sample (II) of 8 particles.

of the most refractory nuclides, ^{99}Mo, shows the same enrichment trend as an induced nuclide, ^{239}Np; (1) the first member of the 99, mass chain, is the completely refractory 35.5-s ^{99}Zr (bp, 4750°C) and an earlier member of mass chain 95, with a significant half-life value, is a less refractory nuclide, 0.7-m ^{95}Sr (bp, 1366°C); (2) the time required for fission products to condense and to form a hot particle at earlier stages of particle formation processes is, on the average, 40 sec or less;[9] (3) larger particles are richer in more refractory fission products.[10] Taking these points into consideration, it may be expected that larger particles will be richer in ^{99}Mo than in ^{95}Zr. The present observations, however, exhibited quite the reverse tendency (Fig. 3).

It is tempting to make a somewhat speculative assumption on the origin of ^{99}Mo in order to explain this finding. Molybdenum metal is present as a minor constituent in the structural material of a nuclear-weapons device, and the isotopic abundance of ^{98}Mo for the element is 23.4%. Some fraction of the total ^{99}Mo observed might be produced by a ^{98}Mo(n,γ)^{99}Mo reaction which takes place during the nuclear fission. The ^{99}Mo fraction may then additionally precipitate on smaller-size particles in a way similar to that in which an induced nuclide, ^{239}Np, is deposited on smaller ones, as has been described above. This assumption is considered to be compatible with the fact that the fractionation correlation parameter of ^{99}Mo is dependent upon the total yield of a nuclear-weapons device.[5]

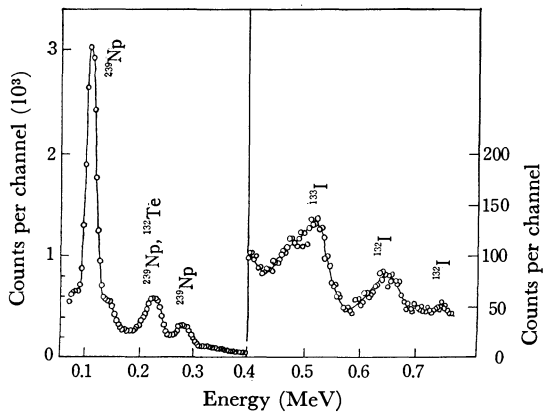

Fig. 4. The γ-ray spectrum of a rain sample (20 l) collected on May 10—11, 1966.

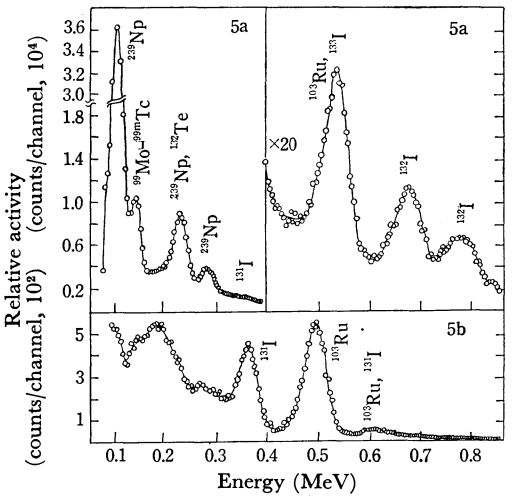
Np-239 in a Rain Sample. It is of interest to note that a rain sample (20 l) collected between 21 : 00 hr on the 10th and 5 : 00 hr on the 11th of May, 1966, before highly-radioactive particles were found in surface air at Niigata, had a unique radiochemical composition, consisting mainly of ^{239}Np, ^{132}Te-^{132}I and ^{133}I, with no detectable amount of refractory fission products, as is shown in Fig. 4. First, it is obvious in this figure that the ^{239}Np in the rain sample behaved nearly volatilely, while in the rain sample of May 15—16 the enrichment behavior of ^{239}Np was similar to that seen in the above-mentioned sample of 9 smaller-size particles. Secondly, this finding suggests that upper-air-borne particles rich in ^{239}Np, perhaps fine in size, first appeared in the atmosphere over Japan and that a part of them fell to the ground by means of wash-out in rain. Therefore, the observation of such rainwater activities also indicates that particle separation may have taken place to a considerable extent in the course of the 1.5-day travel of the atomic cloud from the Chinese test site to Japan.



Figs. 5a and 5b. Gamma-ray spectra of a hot particle collected on Dec. 28, 1966.
5a: A γ-ray spectrum measured 2 days after the explosion.
5b: A γ-ray spectrum measured 28 days after the explosion.

Np-239 in Hot Particles from the December 28, 1966, Explosion. More recently we have measured on December 30 the radioactivities of fresh nuclear debris; this debris evidently resulted from the fifth Chinese nuclear test explosion, on December 28, 1966. The highest total β-activity among all the single fallout particles collected was 4.9×10^4 pCi/particle 2 days after the explosion; most of the collected particles had a total β-activity of the order of $\sim 10^3$ pCi/particle an age of 2 days. Figures 5a and 5b show two γ-ray spectra for one such particle, measured 2 and 28 days after the explosion respectively. In Fig. 5a the two photopeaks at 0.67 and 0.78 MeV should be ascribed to ^{132}I, the daughter of ^{132}Te, and the contribution from ^{97}Zr-^{97}Nb radiations to the photopeaks is negligibly small. For this reason, the spectrum in Fig. 5b shows no discernible photopeaks arising from ^{95}Zr-^{95}Nb radiations with a half-life of 65 d in the 0.66—0.80 MeV range and only the well-defined photopeaks resulting from ^{103}Ru are recorded at 0.50 and 0.62 MeV. As a result, the measured particle consisted mainly of ^{239}Np and some volatile fission products, such as ^{131}I, ^{132}Te-^{132}I, ^{133}I, and ^{103}Ru. Thus, in this case, ^{239}Np behaved completely like the volatilely-behaving fission products observed in the rain sample collected on May 11, 1966 (Fig. 4).

Time Variation of the ^{60}Co/^{95}Zr Ratio in Rain Samples. Table 1 shows the experimental

—○—, ^{95}Zr concentration; ---●---, ^{60}Co/^{95}Zr

data on ^{60}Co and ^{95}Zr in rain samples collected between May 11 and August 15, 1966. Since no discernible photopeaks for these nuclides were found in the γ-ray spectra of rain samples collected before May 9, it was believed that the two nuclides originated only from the May 9, 1966, Chinese nuclear explosion. Figure 6 shows the ^{60}Co/^{95}Zr ratio at time-zero and the number of ^{95}Zr atoms/liter as a function of the time. First, it should be noted that no measurable amounts of ^{60}Co could be found in any particle or rain sample collected between May 11 and 24, shortly after the explosion. This still remains a puzzling question. It may, however, be seen from Fig. 6. that the ^{60}Co/^{95}Zr atomic ratio in rain increased with a decrease in the ^{95}Zr concentration, and *vice versa*. On the other hand, the first arrival at Niigata of the atomic clouds from the May 9, 1966, event brought about rainfalls with a very low concentration of ^{95}Zr (less than 10^6 atoms/l) on May 10—11, 16, and 24, but the two peak values of the ^{95}Zr concentration in the rain were found 19 and 40 days after the first arrival, as is shown in Fig. 6. The time taken for the atomic cluouds to circulate around the world has been estimated to be 3—4 weeks in spring and summer by measuring the time variation of some fission product ratios.[2] As a result, these two peaks (Fig. 6) can possibly be ascribed to the second and perhaps even the third arrivals of the atomic clouds of the Chinese nuclear explosion, although the second peaks, around June 24, was not well defined. From these findings it is expected that the different distribution patterns between ^{95}Zr-rich and ^{60}Co-rich particles would be established in the rain-producing layers of the atmosphere during their fairly long travel of more than 20 days through the atmosphere. This suggests that the separation of ^{60}Co-rich particles from ^{95}Zr-rich particles would take place during their travel, and that the ^{60}Co-rich particles would remain a longer time than the particles rich in ^{95}Zr. This, therefore, provides evidence that ^{60}Co would be richer in smaller-size particles in the same way that ^{239}Np is.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 721—724 (1969)

Polarographic Study of Thallium(I) Chelates of 2,2′-Ethylenedioxybis[ethyliminodi(acetic acid)] and Cyclohexane-1,2-diamine-*N*,*N*,*N*′,*N*′-tetraacetic Acid

Mutsuo KODAMA and Yayoe TOMINAGA

Department of Chemistry, Ibaraki University, Mito, Ibaraki

(Received July 24, 1968)

D.c. polarographic behavior of thallium(I) ion in 2,2′-ethylenedioxybis[ethyliminodi(acetate)] (GEDTA) and cyclohexane-1,2-diamine-*N*,*N*,*N*′,*N*′-tetraacetate (CyDTA) solutions was studied systematically. Compositions and stability constants of thallium(I)-GEDTA and CyDTA chelates were determined from the shift of the half-wave potential. In both GEDTA and CyDTA systems, thallium(I) ion gave a single well-defined wave corresponding to the following reversible one-electron reduction.

$$\begin{array}{ccc} TlZ^{3-} + Hg + e^- = Tl(Hg) + Z^{4-} \\ \uparrow\downarrow H^+ \qquad\qquad \uparrow\downarrow nH^+ \\ TlHZ^{2-} \qquad\qquad H_nZ^{n-4} \end{array}$$

In contrast to the finding of Anderegg and Bottari, thallium(I) ion was found to form not only a normal chelate but also a protonated chelate with CyDTA.

In a previous paper,[1] both the d.c. and a.c. polarographic behaviors of thallium(I) ion in diethylenetriaminepentaacetate (DTPA) solution were studied systematically, and the electrode reaction mechanism determined. From the shift of the half-wave potential or the a.c. peak potential due to complex formation, the composition and stability constant of thallium(I)-DTPA chelate were also estimated.

In this paper, the d.c. polarographic behavior of thallium(I) chelates of 2,2′-ethylenedioxybis-[ethyliminodi(acetic acid)] (GEDTA) and cyclohexane-1,2-diamine-*N*,*N*,*N*′,*N*′-tetraacetic acid (CyDTA) are dealt with, and their compositions and stability constants determined. Thallium(I) ion was found to form not only a normal chelate but also a protonated chelate with these chelating reagents.

Experimental

Reagents. The preparation and standardization of GEDTA and CyDTA solutions were described previously.[2,3] The preparation of thallium(I) perchlorate solution was also described in a previous paper.[1] All other chemicals were of analytical reagent grade and used without further purification. The ionic strength of the sample solution was adjusted to 0.30 by adding an appropriate amount of $NaClO_4$.

Apparatus and Experimental Procedures. All apparatus and experimental procedures were as employed previously.[1,4]

Results and Discussion

D. c. polarographic behavior of thallium(I)-GEDTA chelate was studied with a solution containing an excess of un-complexed GEDTA in the pH range 8.00 to 10.00. Since, in this pH range, a solution containing an excess of un-complexed GEDTA has enough buffer capacity to keep the pH value of the solution constant, no buffer reagent was used. In the CyDTA system, to avoid equilibrium complexity due to the presence of other complex-forming substances, all experiments were conducted with solutions containing an excess of CyDTA in the pH range 10.0 to 11.70.

As shown in Figs. 1 and 2, both thallium(I)-GEDTA and -CyDTA chelates invariably gave single well-defined waves. In both cases, a log-plot gave a linear relation with a slope of −60 mV corresponding to a one-electron reversible reduction. Furthermore, the wave height was exactly proportional to the square-root of the effective pressure on the dropping mercury electorde (DME) and the bulk concentration of thallium(I) ion in both cases. Results are not shown here.

As illustrated by data in Table 1, the half-wave potential, $(E_{1/2})_{TlZ}$, was shifted to more negative potentials with increase in the bulk concentration of un-complexed chelating reagent (GEDTA or CyDTA) according to relation (1), but was independent of thallium(I) concentration.

$$(E_{1/2})_{TlZ} = \text{constant} - 0.0591 \log [Z]_f \qquad (1)$$

where $[Z]_f$ is the concentration of the un-complexed chelating reagent.

In GEDTA solution, $(E_{1/2})_{TlZ}$ was also shifted

15.0	−0.550	0	0
27.2	−0.567	−16	−17
47.2	−0.581	−29	−31

to more negative potentials with increasing pH of the solution, but no linear relation could be found between $(E_{1/2})_{TlZ}$ and $\log(\alpha_H)_Z$ (Fig. 3). Here, $(\alpha_H)_Z$ is expressed as:

$$(\alpha_H)_Z = 1 + \frac{[H^+]}{k_4} + \frac{[H^+]^2}{k_4 \cdot k_3} + \frac{[H^+]^3}{k_4 \cdot k_3 \cdot k_2} + \frac{[H^+]^4}{k_4 \cdot k_3 \cdot k_2 \cdot k_1} \qquad (2)$$

where k's are the dissociation constants of GEDTA.

The magnitude of deviation from the linear relation of +60 mV slope expected theoretically for the reversible one-electron reduction of a normal chelate increases with decreasing pH (increasing $(\alpha_H)_Z$ value). In the case of the CyDTA system, $(E_{1/2})_{TlZ}$ was almost independent of the pH value under present experimental conditions (10.00 <pH<11.70) (Fig. 3). Since CyDTA has the

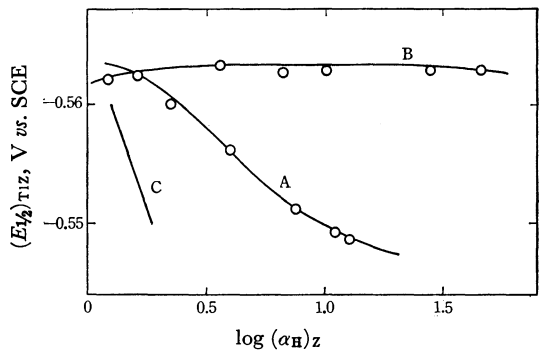

Fig. 3. The relation between $(E_{1/2})_{TlZ}$ and $\log (\alpha_H)_Z$.

C: The line theoretically predicted

pK_4 value of 11.43 (μ=0.30), if only a normal chelate is formed between thallium(I) and CyDTA, the half-wave potential should shift simply to more negative potentials with decreasing pH according to the following relation.

$$(E_{1/2})_{TlZ} = \text{constant} + 0.0591 \log (\alpha_H)_Z \quad (3)$$

where $(\alpha_H)_Z$ is the (α_H) value of CyDTA.

Thermodynamically, the formation of a protonated chelate always means an increase in the conditional formation constant, and hence, a negative shift of the half-wave potential. Therefore, the above facts clearly indicate that thallium(I) ion forms not only a normal chelate, TlZ^{3-}, but also a protonated chelate, TlH_nZ^{n-3}, with both GEDTA and CyDTA. Thus, from the above experimental results and discussion, the following electrode reaction can be assumed,

$$\begin{array}{ccc} TlZ^{3-} + Hg + e^- = Tl(Hg) + Z^{4-} & & \\ \updownarrow nH^+ & & \updownarrow nH^+ \\ TlH_nZ^{n-3} & & H_nZ^{n-4} \end{array} \quad (4)$$

with the half-wave potential expressed as:

$$(E_{1/2})_{TlZ} = E^0_{Tl} - 0.0591\left[\log K_{TlZ}(1 + K^H[H^+] + \cdots + K^{nH}[H^+]^n) - \log (\alpha_H)_Z - \log f_{Tl^+} + \log [Z]_f + \log \frac{k_{Tl(Hg)}}{k_{TlZ}}\right] \quad (5)$$

where K_{TlZ} is the formation constant of a normal thallium(I) chelate, $K^{nH}=[TlH_nZ^{n-3}]/[TlZ^{3-}]\cdot[H^+]_n$, n, 1,2,3,$\cdots$, and other symbols have their usual meanings.[1,4]

As discussed previously on the polarography of thallium(I)-DTPA chelate,[1] when normal and protonated chelates are formed and the electrode reaction is reversible, the following relation can be expected.

$$K_{TlZ}(1+K^H[H^+]+\cdots+K^{nH}[H^+]^n) = \text{antilog}\left[\frac{\Delta E_{1/2}}{0.0591} - \log [Z]_f + \log \frac{k_{Tl^+}}{k_{TlZ}} + \log (\alpha_H)_Z\right] \quad (6)$$

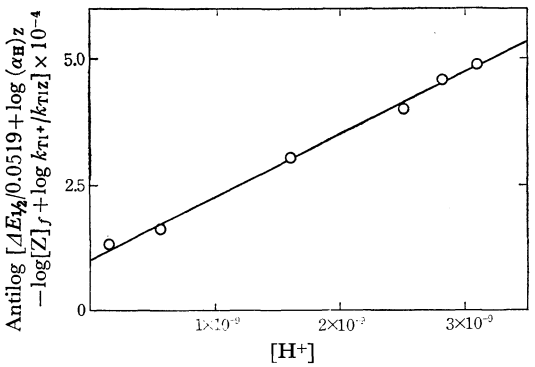

Fig. 4. The relation between antilog [$\Delta E_{1/2}$/0.0591 + log $(\alpha_H)_Z$ − log $[Z]_f$ + log (k_{Tl^+}/k_{TlZ})] and the hydrogen ion concentration.
GEDTA system: μ=0.30,

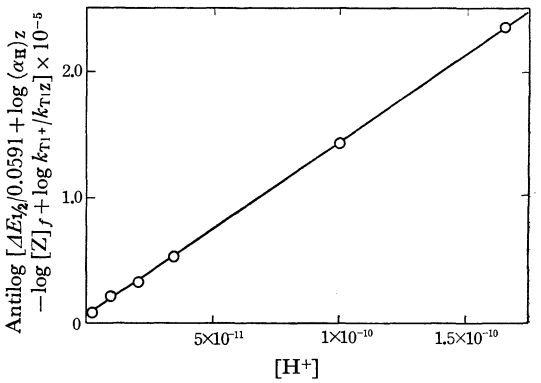

Fig. 5. The relation between antilog [$\Delta E_{1/2}$/0.0591 + log $(\alpha_H)_Z$ − log $[Z]_f$ + log (k_{Tl^+}/k_{TlZ})] and the hydrogen ion concentration.
CyDTA system: μ=0.30,
Concentration of thallium(I) = 1.09 mM

where $\Delta E_{1/2}$ denotes the shift of the half-wave potential due to complex formation.

With the aid of Eq. (6), the composition and stability constants of thallium(I)-GEDTA and -CyDTA chelates were determined using some typical $\Delta E_{1/2}$ values. Results are shown in Figs. 4 and 5. These results clearly show that, in both

GEDTA and CyDTA systems, thallium(I) ion forms chelates with the compositions TlZ^{3-} and $TlHZ^{2-}$. From the intercepts and slopes of the linear relation between the right hand side of Eq. (6) and the hydrogen ion concentration, K_{TlZ} and K^{H} values were determined and given in Table 2 together with k values used in the calculation of $(\alpha_H)_Z$.

The finding that thallium(I) ion forms normal and protonated chelates with CyDTA is in contrast to the results of Anderegg and Bottari.[5] They have studied the complexation reaction of thallium(I) with CyDTA employing a pH titration method and concluded that thallium(I) ion forms only a normal chelate with a 1-to-1 composition (log $K_{TlZ}=6.7$, $\mu=0.10$); no detailed experimental results were given, and thus, no satisfactory explanation for this discrepancy can be given.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 724—727 (1969)

Polarographic Studies of Copper(II) Chelates of Ethylenediamine-*N*,*N*,*N*′,*N*′-tetrapropionic Acid and Diethylenetriamine-pentaacetic Acid

Mutsuo KODAMA and Yayoe TOMINAGA

Department of Chemistry, Ibaraki University, Mito, Ibaraki

(Received July 24, 1968)

D. c. polarographic behavior of copper(II) in ethylenediamine-*N*,*N*,*N*′,*N*′-tetrapropionate (EDTP) and diethylenetriaminepentaacetate (DTPA) solutions was studied systematically. In EDTP solution, copper(II) ion invariably gave a single well-defined wave corresponding to the following reduction.

$$CuX^{2-} + nH^+ + Hg + 2e^- = Cu(Hg) + H_nX^{n-4}$$

In the DTPA solution, copper(II) ion gave a single wave reversible in nature at pH below 5.0, corresponding to the following electrode reaction.

$$\begin{array}{l} CuZ^{3-} + nH^+ + Hg + 2e^- = Cu(Hg) + H_nZ^{n-5} \\ \quad\quad\quad\quad \uparrow\downarrow H^+ \\ \quad\quad\quad\quad CuHZ^{2-} \end{array}$$

At higher pH, however, two waves could be observed. The second step was irreversible and its wave-height increased with increasing pH at the expense of the height of the first step.

In a previous paper,[1] d.c. polarographic behavior of copper(II)-*N*-(2-hydroxyethyl)-ethylenediamine *N*,*N*′,*N*′-triacetate and -2,2′-ethyldioxybis[ethyliminodi(acetato)] chelates was studied systematically. In *N*-(2-hydroxyethyl)-ethylenediamine *N*,*N*′,*N*′-triacetate (EDTA-OH) solution, copper(II) ion was found to form only a normal chelate with a 1-to-1 composition with EDTA-OH, and to give invariably a single well-defined wave over the entire pH range covered. In 2,2′-ethylenedioxybis[ethyliminodi(acetate)] (GEDTA) solution, however, copper(II) ion gave two waves. The first wave was reversible in nature, but the second irreversible. The precise nature of the first step could be satisfactorily described by assuming that a normal copper(II)-GEDTA chelate of a 1-to-1 composition, which is in equilibrium with a normal chelate of a 1-to-2 composition, a protonated chelate and a mixed ligand chelate involving an acetate ion in solution, undergoes a reversible two-electron reduction at the mercury electrode.

In the present paper, results of a d.c. polarographic study on copper(II) chelates of ethylenediamine-*N*,*N*,*N*′,*N*′-tetrapropionic acid (EDTP) and diethylenetriaminepentaacetic acid (DTPA) are presented.

Experimental

Reagents. The preparation and standardization of copper(II) perchlorate solutions were described previously.[2] The purification of EDTP and DTPA and the preparation of their solutions were also described previously.[3] All other chemicals were of analytical reagent grade and used without further purification. The ionic strength of the sample solution was adjusted to 0.30 by adding an appropriate volume of 1.0 M $NaClO_4$ solution.

Apparatus and Experimental Procedures. All apparatus and experimental procedures were as employed

1) M. Kodama and Y. Tominaga, This Bulletin, **42**, 721 (1969).

2) M. Kodama and H. Ebine, This Bulletin, **40**, 1857 (1967).

previously.[3,4]

Results and Discussion

D.C. Polarographic Behavior of Copper(II) Ion in EDTP Solution. D. c. polarographic behavior of copper(II)-EDTP chelate in solutions containing an excess of un-complexed EDTP was studied systematically in the pH range 3.46 to 7.80. In the pH range from 3.46 to 5.80, an acetate buffer (total concentration of acetate, 0.10 M) was used in order to maintain the pH of the solution at a constant value. At pH above 5.80, no buffer reagent was used because in this pH region, the present system containing un-complexed EDTP is considered to have enough buffer capacity to keep the pH constant.

As in the EDTA-OH system,[1] copper(II) ion in EDTP solution gave a single well-defined wave, the height of which was exactly proportional to the bulk concentration of copper(II) ion and the square-root of the effective pressure on the dropping mercury electrode (DME). The result is not shown here. A typical polarogram and the result of a log-plot are shown in Figs. 1 and 2. These results clearly indicate that the copper(II) ion in the EDTP solution undergoes a reversible, two-electron reduction at the mercury electrode. As shown in Fig. 3, the half-wave potential, $(E_{1/2})_X$, was found to shift to more negative potentials with increasing pH of the solution according to the

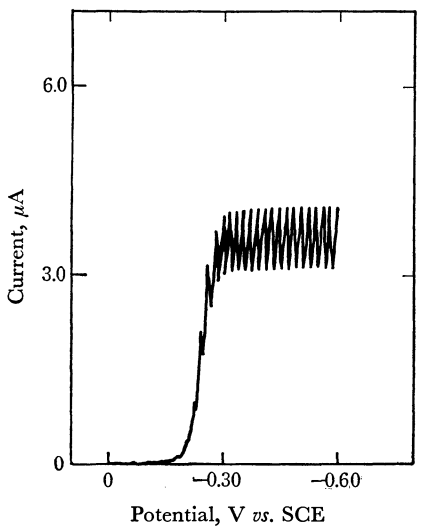

Fig. 1. D.c. polarogram of copper(II)-EDTP chelate.

following relation.

$$(E_{1/2})_X = \text{constant}_1 + 0.0296 \log (\alpha_H)_X \quad (1)$$

where $(\alpha_H)_X = 1+[H^+]/k_4+[H^+]^2/k_4 \cdot k_3+[H^+]^3/k_4 \cdot k_3 \cdot k_2+[H^+]^4/k_4 \cdot k_3 \cdot k_2 \cdot k_1$, and k's are the dissociation constants of EDTP.

The half-wave potential also shifted to more negative potentials with increasing concentration of un-complexed EDTP, $[X]_f$, according to the following relation,

$$(E_{1/2})_X = \text{constant}_2 - 0.0296 \log [X]_f \quad (2)$$

but it is independent of the concentration of acetate and copper(II) ions. Results are given in Table 1.

TABLE 1. DEPENDENCE OF $(E_{1/2})_X$ ON THE CONCENTRATION OF EDTP OR ACETATE ION
pH=5.33, μ=0.30
Concentration of copper(II)=0.682 mM

A) Dependence of $(E_{1/2})_X$ on the concentration of EDTP.
Total concentration of acetate=0.10 M

Concentration of EDTP mM	$(E_{1/2})_X$ V *vs.* SCE	$\Delta(E_{1/2})_X$, mV Calcd	Obsd
15.0	−0.229	3.6	4.0
20.0	−0.233	0	0
40.0	−0.241	−9.0	−8.0
40.0*1	−0.242	−9.0	−9.0

*1 Concentration of copper(II)=1.364 mM

B) Dependence of $(E_{1/2})_X$ on the concentration of acetate.
Concentration of EDTP=20.0 mM

Concentration of acetate, M	$(E_{1/2})_X$ V *vs.* SCE
0.05	−0.233
0.10	−0.233
0.30	−0.231

From the above experimental results, it can be safely concluded that copper(II) ion forms only a normal 1-to-1 chelate with EDTP under the present experimental conditions and the electrode reaction can be expressed as,

$$CuX^{2-} + nH^+ + Hg + 2e^- = Cu(Hg) + H_nX^{n-4} \quad (3)$$

with the half-wave potential corresponding to:

$$(E_{1/2})_X = E^0_{Cu} + 0.0296[\log f_{Cu^{2+}} + \log\frac{k_{Cu(Hg)}}{k_{CuX}} + \log(\alpha_H)_X - \log K_{CuX} - \log[X]_f] \quad (4)$$

where CuX^{2-} and H_nX^{n-4} refer to copper(II)-EDTP chelate and incompletely dissociated EDTP anion, respectively, and $f_{Cu^{2+}}$, $k_{Cu(Hg)}$, k_{CuX}, K_{CuX} and E^0_{Cu} have their usual meanings. Therefore, as discussed previously,[1] the shift of the half-wave potential of copper(II), $\Delta E_{1/2}$, by complex formation with EDTP, can be given by:

$$\Delta E_{1/2} = 0.0296[\log K_{CuX} + \log\frac{k_{CuX}}{k_{Cu^{2+}}} + \log[X]_f - \log(\alpha_H)_X] \quad (5)$$

where $k_{Cu^{2+}}$ has the same meaning as in a previous paper.[1]

With the aid of Eq. (5), log K_{CuX} value was calculated to be 15.1 from the $\Delta E_{1/2}$ value at $(\alpha_H)_X=1$. In the calculation, $k_{CuX}/k_{Cu^{2+}}$ determined experimentally as 1/1.20 was used. The logK_{CuX} value thus obtained agreed well with the reported one (14.80 at μ=0.30).[5] This agreement lends strong support to the above explanation.

D. C. Polargraphic Behavior of Copper(II) Ion in Diethylenetriaminepentaacetate Solution. Polarographic behavior of copper(II)-DTPA chelates was also studied under experimental conditions similar to those in the EDTP system. At pH below 5.0, copper(II) ion in DTPA solutions invariably gave a single well-defined wave, the height of which was exactly proportional to the concentration of copper(II) ion and the square-root of the effective mercury pressure on the DME. The plot of $\log(i/(i_d-i))$ against applied d. c. potential, E, gave a linear relation with a slope of −31 mV, suggesting a reversible two-electron reduction. The results are not shown here. As shown by the curve in Fig. 4, at pH above 5.0,

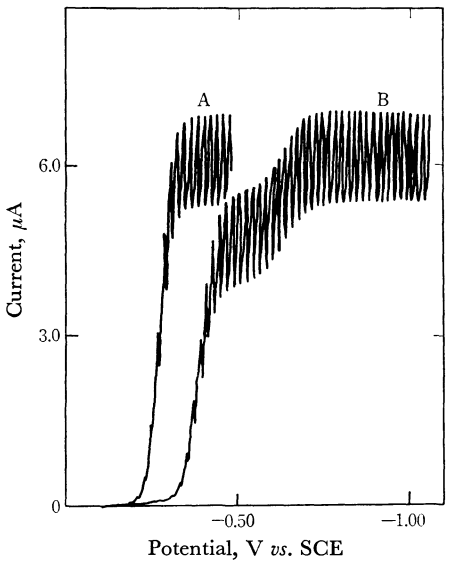

Fig. 4. D.c. polarogram of copper(II)-DTPA chelate.
μ=0.30
Concentration of DTPA=20.0 mM
Concentration of copper(II)=1.364 mM
A: pH=4.15 B: pH=6.01

however, copper(II) ion gave two waves. The first wave is reversible to such an extent that a log-plot gave a linear relation with a slope of −45 mV, and the wave-height increases with increase in hydrogen ion concentration at the expense of the second wave height. The second wave was irreversible in nature. Therefore, in the present study, results obtained mainly at pH below 5.0 will be given. At pH below 3.50, no buffer reagent was used because a system containing a large excess of un-complexed DTPA has enough buffer capacity to maintain the pH value of the solution constant.

As in the EDTP system, at a given pH, the half-wave potential of copper(II)-DTPA chelate, $(E_{1/2})_Z$, shifted to more negative potentials with increase in the bulk concentration of DTPA, $[Z]_f$ according to the following relation:

$$(E_{1/2})_Z = \text{constant}_3 - 0.0296\log[Z]_f \quad (6)$$

but, it is independent of the concentrations of acetate and copper(II) ions. The results are shown in Table 2. These facts clearly indicate that copper(II) ion forms only a normal chelate of a 1-to-1 composition with DTPA under the present experimental conditions. The half-wave potential also shifted to more negative potentials with increasing pH of the solution. But, in contrast with findings in the EDPT system, the plot of $(E_{1/2})_Z$ *vs.* $\log(\alpha_H)_Z$ did not give a linear relation with a slope of +30 mV. Here, $(\alpha_H)_Z$ is the (α_H) value of DTPA.

As discussed previously on the polarography of thallium(I)-DTPA chelate,[4] when copper(II) ion forms both normal and mono-protonated chelates with DTPA, and when the electrode reaction can be expressed as,

$$\begin{array}{l} CuZ^{3-} + nH^+ + Hg + 2e^- = Cu(Hg) + H_nZ^{n-5} \\ \quad\uparrow\downarrow H^+ \\ CuHZ^{2-} \end{array} \qquad (7)$$

the following relation can be expected thermodynamically.

$$K_{CuZ}(1+K^H_{CuZ}\cdot[H^+]) = \text{antilog}\left[\frac{\Delta(E_{1/2})_Z}{0.0296} + \log(\alpha_H)_Z - \log[Z]_f + \log\frac{k_{Cu^{+2}}}{k_{CuZ}}\right] \qquad (8)$$

where $\Delta(E_{1/2})_Z$ is the shift of the half-wave potential due to chelate formation with DTPA, K_{CuZ} the formation constant of copper(II)-DTPA chelate and $K^H_{CuZ}=[CuHZ^{2-}]/[CuZ^{3-}]\cdot[H^+]$. This relation was examined using some experimental data. The result shown in Fig. 5 clearly confirms the above explanation given by the present authors. From

Asymmetric Reactions. II. Anomalous Stereoselectivity of the Grignard Reaction with *N*-Benzyl-2,3-*O*-isopropylidene-D-glyceraldimine

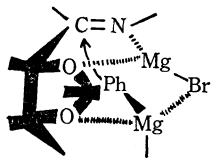
Yoshiaki OHGO, Juji YOSHIMURA and Tetsuo SATO

Laboratory of Organic Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

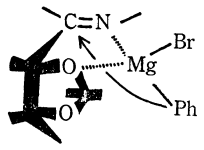
(Received March 23, 1968)

Stereoselectivity of the organomagnesium reaction with *N*-benzyl-2,3-*O*-isopropylidene-D-glyceraldimine was examined under various conditions (change of molarity, solvent, and composition ratio of reagents). The selectivity was not effected by the molarity of the reagents but by the solvent. When the substrate was treated with a mixture of various ratio of magnesium bromide and diphenylmagnesium, a remarkable effect of the ratio on the stereoselectivity was observed. Maximum ratio of *erythro*/*threo* was obtained at the point of equimolar mixture of magnesium bromide and diphenylmagnesium in ether. The structure of the transition intermediate was discussed.

The authors have reported the difference in stereoselectivity between the Grignard and alkyllithium reactions of *N*-phenyl-3,4;5,6-di-*O*-isopropylidene D-glucosaminonitrile,[1] *N*-substituted 3,4-*O*-isopropylidene-D-tetrosaminonitriles, 2,3-*O*-isopropylidene-D-glyceraldimines,[2] and 2,3-*O*-isopropylidene-D-glyceraldehyde,[3] in which the configuration of the major product in the Grignard reactions was inconsistent with that deduced from Cram's rigid model.[4] This stereoselectivity of the Grignard reaction was explained by two possible models A and B.



A



B

A similar steric difference was observed by Stocker *et al.* between phenyllithium and phenylmagnesium halide reactions with α-hydroxyketones or α,β-diketones.[5-7]

The composition of the Grignard reagents under the reaction condition seems to play an important role on such an anomaly. Although the structure of the crystalline Grignard reagent prepared from magnesium and bromobenzene or ethyl bromide in ether was formulated by X-ray diffraction method as $RMgBr \cdot 2Et_2O$ (R=phenyl or ethyl),[8,9] the reagent in the solution exists as an equilibrium mixture of several species as follows. Molecular weight determination by ebullioscopic method showed that the Grignard reagents exist as monomeric species in low molarity in ether solution (10^{-2} M concentration) and are apt to associate in higher molarity,[10,11] while in tetrahydrofuran they exist as monomers even in a higher molarity.[12] IR spectroscopic data suggested that species of the Grignard reagent changes considerably with varying solvent, the nature of the organic part and halogen atom.[13]

The authors examined the effect of the reaction conditions (*i. e.*, change of molarity, solvent and composition ratio of reagents) on the above mentioned stereoselectivity in the reaction of the Grignard reagent with *N*-benzyl-2,3-*O*-isopropylidene-D-glyceraldimine (I), in order to obtain information on the structure of the transition state. Model (A) was found to be more probable.

Results

Effects of Concentration and Solvent. I was treated with 3 molar equivalent of organomagnesium compounds under various conditions followed by hydrolysis to give a diastereoisomeric mixture of 1-benzylamino-1-deoxy-1-*C*-phenyl-*threo*- and -*erythro*-D-glyceritols. Diastereoisomeric ratios (*erythro*/*threo*) were calculated from the optical rotations as previously reported.[2)]

The results obtained by changing solvent and molarity are shown in Table 1.

Table 1. Effect of solvent and molarity on the stereoselectivity

Run	Solvent	Molarity	E/T
1	Ether	1.5 M	3.5[2)]
2	Ether	0.081 M	3.4
3	THF	1 M	1.6
4	Benzene	1 M	4.26
5	Ether+TEA[a)]	1.7 M	3.0
6	Ether+TEA[b)]	1.6 M	2.9
7	Ether+TEA[c)]	1.1 M	2.9

a) A mixture of ether (40 m*l*) and triethylamine (3.2 m*l*).
b) A mixture of ether (40 m*l*) and triethylamine (6.4 m*l*).
c) A mixture of ether (40 m*l*) and triethylamine (26 m*l*).

Table 2. Effect of the molar ratio ($MgBr_2/Ph_2Mg$) on the stereoselectivity

Run	Reagent (moles/mole substrate) Ph_2Mg	Reagent (moles/mole substrate) $MgBr_2$	E/T
8	2.15	0	1.56
9	1.29	0.5	3.0
10	1.29	1	4.4
11	1.29	2	5.45
12	1.29	3	4.87
13	1.29	5	3.76
14	1.29	10	2.9

As was shown in runs 1, 2, 5, 6 and 7, the stereoselectivity was not effected by the molarity of the reagents. However, it is worth mentioning that a remarkable difference was found between stereoselectivity in THF solution and in ether solution of lower molarity. No remarkable effect was observed by addition of triethylamine.

Effect of Composition of the Grignard Reagent. I was treated with a mixture of various ratio of magnesium bromide to diphenylmagnesium in ether.

The results are shown in Table 2 and Fig. 1. Figure 1 was obtained by plotting E/T against the molar ratio of magnesium bromide to diphenylmagnesium. It shows that E/T increases steeply with the increase of the ratio of $MgBr_2/Ph_2Mg$ until the ratio reaches about 1, and then begins to decrease gradually with a further increase of the ratio of $MgBr_2/Ph_2Mg$ (>1). Maximum E/T (>5.45) was much greater than that previously obtained by conventional Grignard reagent ($E/T=3.5$).[2)]

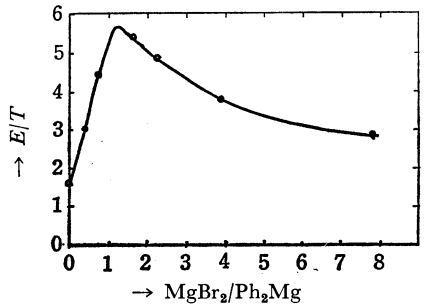

Fig. 1. The effect of the ratio of $MgBr_2/Ph_2Mg$ on the stereoselectivity.

Composition of the Complex formed in the Reaction and the Stereoselectivity by Reverse Addition Mode. In the ordinary Grignard reactions in which the solution of the substrate is added into the Grignard solution, it is observed that a white precipitate appears instantly and then disappears probably on account of being dissolved by excess Grignard solution. If so, a reverse mode of addition in which the reagent is added into the substrate solution should cause precipitation. As expected, the precipitate appeared and increased with the amount of the reagent added till about 1—1.5 equivalent to the substrate, and then began to dissolve with further addition. At the point of the equivalent molar ratio, the precipitate was separated from the solution. The molar ratio of phenylmagnesium bromide to the substrate in precipitate and that in the solution were determined from the content of magnesium and bromide to be 1.5 and 0.16 respectively. This shows that the reagent is considerably concentrated in the precipitate.

Table 3. The stereoselectivities obtained by the reverse addition mode

Run	PhMgBr (moles/mole substrate)	Product E/T
15	1	2.7
16	2	3.16

Two examples of E/T in the reverse addition mode are shown in Table 3. The results show that the stereoselectivity decreased as a whole to some extent, and is apt to increase with an increased amount of the reagent (compare runs 15, 16 and 1).

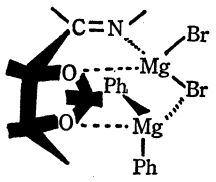
Discussion

The monomeric Grignard reagent in ether solution [run 2, $E/T=3.4$] gives the same results as the dimeric Grignard ethereal solution [run 1, $E/T=3.5$]. But the result is quite different in THF solution [run 3, $E/T=1.6$] in which the Grignard reagent exists also in monomeric form. This marked difference suggests that species in THF solution differ from those in ether solution, or stronger coordination ability of THF prevents magnesium from bridging between N and C_2-O. The former agrees with the infrared spectroscopic data presented by Salinger and Mosher.[13]

Monomeric species in the Grignard reagent should be diphenylmagnesium, magnesium bromide and phenylmagnesium bromide. In the devised Grignard reaction in which the two monomeric species (magnesium bromide and diphenylmagnesium) are freshly mixed, E/T value increased sharply and linearly with increasing amount of magnesium bromide in the ratio of $MgBr_2/Ph_2Mg<1$ and decreased gradually with increasing amount of magnesium bromide in the region of the ratio >1. The maximum E/T value at $MgBr_2/Ph_2Mg\simeq 1$ was considerably greater than that in the conventional Grignard solution. This result implies that the equimolar mixture of diphenylmagnesium and magnesium bromide is of greater importance than phenylmagnesium bromide to give *erythro* product, and also that alkyl-bromine exchange is not so rapid under the reaction conditions because results with a mixture of magnesium bromide and diphenylmagnesium should be identical with that of conventional Grignard reagent if the exchange is rapid.

From these facts, it may be inferred that the transition state based upon the coordinative interaction (A) plays a greater role for governing the steric direction of the Grignard reaction than that based upon the electrostatic repuslion (B). Here, we must infer a more detailed structure of the possible transition state; which component forms a bridge between C_2-O and nitrogen, and which component coordinates to C_3-O (magnesium bromide or diphenylmagnesium).

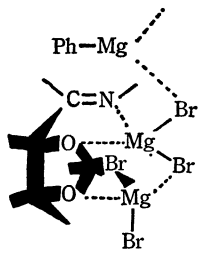
Magnesium bromide is more acidic than diphenylmagnesium. Therefore it can be assumed that at first magnesium bromide preferentially makes a bridge between nitrogen and C_2-O by coordination and then diphenylmagnesium coordinates with C_3-O and bromine of the magnesium bromide as shown by C.



C

Model C explains that an equimolar mixture of magnesium bromide and diphenylmagnesium gives the highest yield of *erythro* derivative, because there is no phenyl group above the five membered ring made by N, C_1, C_2, O and Mg, but under the ring. This model is also in agreement with the results obtained by the reverse addition made. The ratio (reagent/substrate)$=1.5$ in the precipitate implies that half of the substrate is coordinated with dimeric species or two magnesium. It may be considered that the ratio of the substrate coordinated with the dimeric Grignard species increases further on increasing the amount of reagent. Therefore, the stereoselectivity is apt to increase with an increased amount of the reagent (run 15, 16 and 1).

The effect of excess magnesium bromide to lower the E/T can also be explained as follows. When the ratio of magnesium bromide to diphenylmagnesium becomes larger, magnesium bromide will coordinate with C_3-O competitively, and then, Ph-Mg species must approach from above the ring as is shown in diagram D. Consequently, excess magnesium bromide acts to lower the E/T value (run 12, 13, 14 and Fig. 1).



D

Cram *et al.* have explained reversal of the stereoselectivity of phenylmagnesium bromide reaction *vs.* phenyllithium reaction with α,β-diketones or hydroxyketones (Stocker's observation) by dipolar model.[14] However, it cannot be explained by the dipolar model that the reaction with low molar concentration of the Grignard reagent in ether (monomeric reagent) gave almost the same value as that with high molar concentration of the ethereal Grignard reagent (run 1 and 2), and

Each specific rotation was measured in ethanol ($c=1.0$, $l=1$).

also that excess of magnesium bromide disturbs formation of *erythro* derivative (Table 2 and Fig. 1).

Experimental

Preparation of the Grignard Reagent in Various Solvent. The Grignard reagent in ether or tetrahydrofuran was prepared as follows.

To a suspension of 1.7 g (0.07 g atom) of magnesium in 100 m*l* of ether or 70 m*l* of tetrahydrofuran was added dropwise a solution of 7.2 m*l* (0.069 mol) of bromobenzene in ether on heating.

The ethereal Grignard solution in low molarity (0.083 M concentration) was prepared by dilution of the above solution with ether (about 700 m*l*; to the final volume of 850 m*l*).

The Grignard benzene solution was prepared by addition of benzene (70 m*l*) to the syrup obtained by removal of ether from ethereal reagent described above.

The Grignard solution with a mixed solvent of ether and triethylamine was prepared by addition of 3.2 m*l*, 6.4 m*l* or 26 m*l* of triethylamine into the ethereal solution described above.

0.25 M Diphenylmagnesium Solution. Diphenylmagnesium was prepared according to the Schlenk method,[15] by shaking 148 g of diphenylmercury and 110 g of magnesium in 1700 m*l* of ether under nitrogen atmosphere for 30 days. Molarity was determined by residual titration with alkali.

2.5 M Magnesium Bromide Solution. An ether solution of magnesium bromide was prepared by the reaction of magnesium with ethylene bromide in ether.[16] The reaction mixture was filtered through glass filter under dried nitrogen atmosphere. The reagent was analyzed by titrating bromine with 0.5 N $AgNO_3$ solution using K_2CrO_3 as an indicator.

A Mixture of Diphenylmagnesium and Magnesium Bromide. In runs 8—14, 120 m*l* of 0.25 M diphenylmagnesium solution was mixed with 4.5 m*l*, 9 m*l*, 18 m*l*, 27 m*l*, 45 m*l* or 90 m*l* of 2.5 M $MgBr_2$ solution respectively, just before the reaction.

General Procedure for the Reaction of *N*-Benzyl-2,3-*O*-isopropylidene-D-glyceraldimine with Various Grignard Reagents. An ether solution of 5 g (0.0228 mol) of *N*-benzyl-2,3-*O*-isopropylidene-D-glyceraldimine was added at 0—5°C under nitrogen atmosphere to the Grignard solution described above. The reaction mixture was stirred at 0—5°C for 1 hr, and then refluxed with stirring for 6—10 hr. It was poured into ice-water containing ammonium chloride covered with 100 m*l* of ether. Ether layer was separated, washed with water, dried, and concentrated *in vacuo* to a syrup. The syrup was treated with 6 N hydrochloric acid (20 m*l*) at 100°C for 3 hr. An insoluble residue was removed by filtration through activated carbon. The filtrate was decolorized with activated carbon, and then extracted four times with 50 m*l* portions of ethyl acetate, after adjustment of the pH to about 10 with sodium hydroxide solution. The combined ethyl acetate solution was washed with water and dried over anhydrous sodium sulfate. The solution was concentrated under reduced pressure to give a diastereoisomeric mixture of the crude 1-benzylamino-1-deoxy-1-*C*-phenyl-D-glyceritol. Thin layer chromatography of each raw product gave a single spot (R_f: 0.63±0.01; solvent=ethanol - benzene mixture (7 : 3)) identical with authentic sample. Analytical values in every case were in agreement with that calculated for $C_{16}H_{19}O_2N$. The specific rotations of the crude products were measured and the results were summarized in Table 4. The mixture was fractionally crystallized from ethanol - acetone to isolate the two pure diastereoisomers. 1-Benzylamino-1-deoxy-1-*C*-phenyl-*threo*-D-glyceritol [mp 101—102°C, $[\alpha]_D$ −81 (*c* 1, ethanol)] and 1-benzylamino-1-deoxy-1-*C*-phenyl-*erythro*-D-glyceritol [mp 89—90°C, $[\alpha]_D$ +68 (*c* 1, ethanol).[2]

Reaction by Reverse Addition Mode. To an ethereal solution of 5 g (0.0228 mol) of I was added an equimolar or two molar equivalent Grignard solution in ether. The reaction mixture was treated by the same procedure as above.

The precipitate appeared on addition of equimolar amount of the reagent (0.00137 mol) into an ethereal solution of I (0.00137 mol) was separated from the solution and washed with ether. The precipitate was dried which weighed 3.15 g. The ether solution was concentrated *in vacuo* to give 1.25 g of a syrup. Combustion of 0.2090 g of the precipitate gave 0.0255 g of magnesium oxide. The ratio of the reagent to the substrate was calculated from this value. The calculated ratio (magnesium/substrate) was 1.5. Similar results were obtained by determination of bromine (using 0.5 N $AgNO_3$ solution). The molar ratio (bromine/substrate) was 1.47.

On the other hand, the ratio (reagent/substrate) in the syrup obtained from the solution was 0.16 by combustion analysis, and 0.35 by bromine determination

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 732—737 (1969)

Reaction of Methylsulfinyl Carbanion with Substituted Phthalic Esters

Yoshio Otsuji, Hideo Yabune and Eiji Imoto

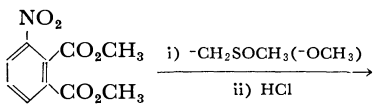
Department of Applied Chemistry, Faculty of Engineering, University of Osaka Prefecture, Sakai-shi, Osaka

(Received April 19, 1968)

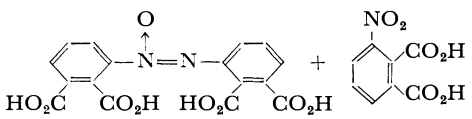
The treatment of dimethyl 3-nitrophthalate (I) with a mixture of dimethyl sulfoxide and sodium methoxide, followed by the acidification of the resulting mixture with hydrochloric acid, gave azoxybenzene-2,2',3,3'-tetracarboxylic acid (II) and 3-nitrophthalic acid (III). The similar treatment of dimethyl 4-nitrophthalate (IV) afforded 5-methoxy-2-nitroso-1,3-indanedione (V) and 4-methoxyphthalic acid (VI). The similar treatment of dimethyl 4-methoxyphthalate (XV) and dimethyl phthalate gave 2-chloro-2-methylthio-5-methoxy-1,3-indanedione (XVII) and 2-chloro-2-methylthio-1,3-indanedione (XIX) respectively. The general features of these reactions are described.

Becker and Russell[1,2] have recently found that the treatment of diethyl phthalate with methylsulfinyl carbanion and the acidification of the resulting mixture with hydrochloric acid give 2-chloro-2-methylthio-1,3-indanedione, which can then readily be converted to ninhydrin. We have extended this reaction to substituted phthalic esters in the hope of obtaining substituted ninhydrins. During the course of this investigation we have established several new features of this reaction, features which will be reported in this paper.

When dimethyl 3-nitrophthalate (I) was treated in a stream of nitrogen in dimethyl sulfoxide (DMSO) with methylsulfinyl carbanion prepared from DMSO and sodium methoxide, and when the resultant reaction mixture was acidified with hydrochloric acid, azoxybenzene-2,2',3,3'-tetracarboxylic acid (II) and the hydrolysis product, 3-nitrophthalic acid (III), were obtained in 50 and 43% yields respectively.

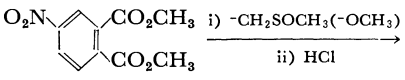


(I)

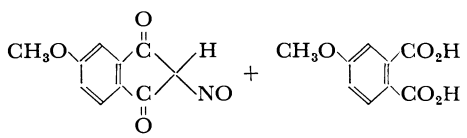


(II) (III)

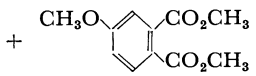
The similar treatment of dimethyl 4-nitrophthalate (IV) gave 5-methoxy-2-nitroso-1,3-indanedione (V) and 4-methoxyphthalic acid (VI). The yields of V (48—14%) and VI (49—73%) varied to some extent from run to run. In some runs dimethyl 4-methoxyphthalate (VII) was also obtained.



(IV)

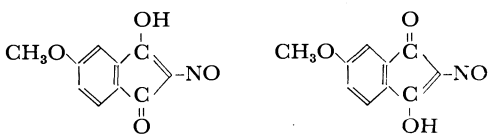


(V) (VI)

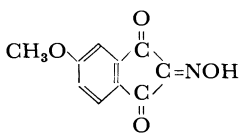


(VII)

The structure of V was established on the basis of its elemental analysis and by a study of its infrared and NMR spectra. The NMR spectrum of V in DMSO-d_6 showed the presence of an acidic proton at $-4.25\ \tau$, suggesting that V exists in the forms of Va, Vb, and Vc in polar solvents.



(Va) (Vb)



(Vc)

In accordance with this observation, the acetylation of V with acetic anhydride in pyridine gave a mono-acetylated product. The compound V

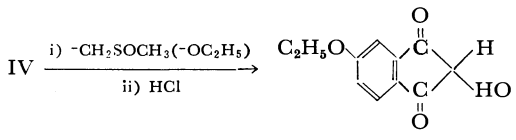
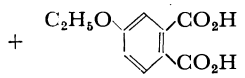
2) H-D. Becker, *ibid.*, **29**, 1358 (1964).

also underwent alkaline hydrolysis to give VI. All the properties of the acid VI were identical with those of the acid obtained by the alkaline hydrolysis of the ester VII.



(VIII)

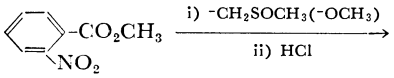


(IX)

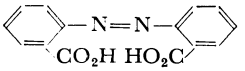
The above unexpected behavior of IV was observed even when the anion species was changed from methoxide to ethoxide. Thus, the treatment of IV with methylsulfinyl carbanion prepared from DMSO and sodium ethoxide and a similar work-up of the resultant mixture gave 5-ethoxy-2-nitroso-1,3-indanedione (VIII) and 4-ethoxyphthalic acid (IX) in 51 and 32% yields respectively.

The above reactions of IV have two noticeable features: (1) the replacement of the nitro group by the alkoxyl group, and (2) the formation of nitroso compounds.

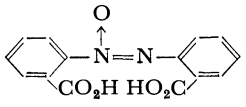
The nucleophilic replacement of a nitro group attached to an aromatic ring by an alkoxide ion has been found to occur in the aromatic nitro compounds which are activated by an electron-withdrawing group such as nitro,[3] cyano[4] or carbonyl[5]. In the compound IV two methoxycarbonyl groups act as the activating groups. The failure of the replacement of the nitro group in I may be supposed to be due to a steric hindrance caused by the neighboring methoxycarbonyl group. The following observations are of interest in this connection. When methyl *o*-nitrobenzoate (X) was subjected to the above reaction under similar conditions, azobenzene-2,2'-dicarboxylic acid (XI) and azoxybenzene-2,2'-dicarboxylic acid (XII) were obtained in 44 and 33% yields respectively. On the other hand, methyl *p*-nitrobenzoate (XIII) afforded only the hydrolysis product, *p*-nitrobenzoic acid (XIV).



(X)



(XII)



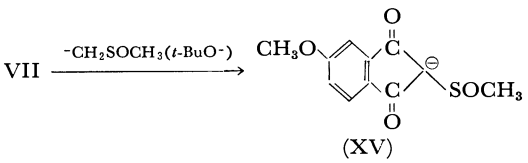
(XII)

(XIII) (XIV)

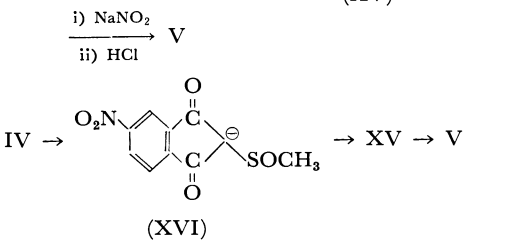
These results seem to indicate that at least two methoxycarbonyl groups are needed for the nucleophilic replacement of the nitro group by the alkoxyl group.

The nitroso compounds, V and VIII, were supposed to be formed from dimethyl 4-alkoxyphthalate, which is produced by the replacement of the nitro group in IV by the methoxyl or the ethoxyl group if the nitrite ion is present in the reaction system (the nitrite ion was, in fact, found to be liberated during the course of the reaction leading from IV to V or VIII).

This theory was partly verified by the fact that the treatment of dimethyl 4-methoxyphthalate with methylsulfinyl carbanion prepared from DMSO and potassium *t*-butoxide, the addition of sodium nitrite, and then the acidification of the resultant mixture with hydrochloric acid gave V in a 66% yield. This reaction probably proceeds through an anion of the *β*-keto sulfoxide (XV).



(XV)



(XVI)

However, another possibility regarding the pathway of the reaction must also be considered. As will be mentioned later, VII did not undergo any condensation reaction leading to XV or its derivatives, but underwent hydrolysis to give the diacid VI when methylsulfinyl carbanion prepared from DMSO and sodium methoxide was used. On the other hand, the nitroso compound was produced from IV even when methylsulfinyl carbanion prepared from DMSO and sodium methoxide was used. Obviously, in the process of the formation of V from IV the condensation of the ester with methylsulfinyl carbanion, which gives an intermediate such as *β*-keto sulfoxide XVI, must be involved. These arguments, therefore, lead to a pathway in which the condensation of IV

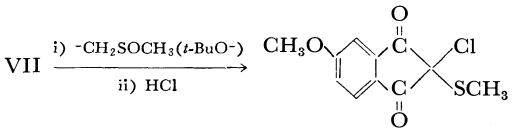
3) F. Reverdin, "Organic Syntheses," Coll. Vol. 1, p. 219 (1956).

4) V. V. Richter, *Ber.*, **4**, 21, 459, 553 (1871); **8**, 1418 (1875).

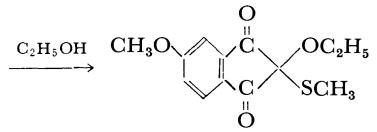
5) J. H. Gorvin, *Chem. and Ind.*, **1967**, 1525.

with methylsulfinyl carbanion may occur prior to the replacement of the nitro group by the alkoxyl group: that is, V, might be formed through 2-methylsulfinyl-5-nitro-1,3-indanedione or its anion (XVI). A detailed examination of the mechanism and a synthetic application of these reactions to afford nitroso compounds are now under way in our laboratory; our results will be published in a separate paper.

The reaction of VII with methylsulfinyl carbanion was then studied in some detail. The treatment of VII with methylsulfinyl carbanion prepared from DMSO and sodium methoxide, and the acidification of the resultant mixture with hydrochloric acid, led to the hydrolysis product, VI. However, when methylsulfinyl carbanion prepared from DMSO and potassium *t*-butoxide was used, 2-chloro-2-methylthio-5-methoxy-1,3-indanedione (XVII) was obtained; upon being refluxed in ethanol, this compound yielded 2-ethoxy-2-methylthio-5-methoxy-1,3-indanedione (XVIII).



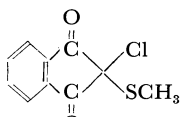
(XVII)



(XVIII)

The structure of XVIII was established on the basis of its elemental analysis, and on a study of its infrared and NMR spectra.

Since, in the above reactions, methylsulfinyl carbanion is formed in the pre-equilibrium stage, the use of a much stronger base would produce a higher concentration of the carbanion. The above results suggest, therefore, that the higher concentration of methylsulfinyl carbanion makes it possible to accomplish the condensation reaction of the carbanion with such compounds as VII, in which the reactivity of the carbonyl group toward nucleophiles is somewhat lowered by the presence of an electron-releasing group.



(XIX)

Finally, we repeated the Becker and Russell reaction on dimethyl phthalate using methylsulfinyl carbanions prepared from DMSO and sodium methoxide, and DMSO and potassium *t*-butoxide. In these cases 2-chloro-2-methylthio-1,3-indanedione (XIX) was obtained in yields of 44 and 57% respectively.

Thus, the following conclusions can be drawn from these studies: 1) for the phthalic esters having the nitro group as a substituent, the reaction leads to the reduction of the substituent or the replacement of the substituent by the nucleophiles which are present in the reaction system; 2) for the unsubstituted phthalic esters and phthalic esters with an electron-releasing substituent such as the methoxyl group, a substitution reaction with methylsulfinyl carbanion on the ester carbonyl group takes place.

Experimental

All the melting points are uncorrected. The infrared spectra were obtained with a Hitachi EPI-S_2 infrared spectrophotometer. The NMR spectra were recorded on a Hitachi H-60 high-resolution NMR spectrometer, using tetramethylsilane as the internal standard. Elemental analyses were performed with a Yanagimoto MT-1 CHN Corder.

Reagents. The dimethyl sulfoxide (DMSO) was purified by two distillations over calcium hydride at about 1 mmHg. The sodium methoxide was prepared from sodium and methanol and dried by heating at 100°C under reduced pressure. The sodium ethoxide was prepared from sodium and ethanol and dried similarly. Unless otherwise indicated, the other reagents were of commercial origin or were synthesized by known methods and purified by recrystallization or distillation.

Reaction of Dimethyl 3-Nitrophthalate (I). With DMSO-Sodium Methoxide. A suspension of 5.4 g (0.1 mol) of sodium methoxide in 45 m*l* of DMSO was stirred by introducing a stream of nitrogen into the suspension. A solution of 6.0 g (0.025 mol) of I in 30 m*l* of DMSO was added, drop by drop, to the suspension. The reaction mixture, which soon turned red-brown, was kept under nitrogen at room temperature for 4 hr, and then most of the solvent was evaporated at 1 mmHg. To the residue were added 50 m*l* of ether and 50 m*l* of ice water. The aqueous layer was added, drop by drop, to an ice-cold 100 m*l* of 4 N hydrochloric acid to obtain a precipitate. This precipitate was separated from the aqueous solution (A) by filtration to give 2.4 g (50%) of azoxybenzene-2,2',3,3'-tetracarboxylic acid (II). The analytical sample was obtained by recrystallization from water: mp 236—238°C (decomp); N. E. 93 (calcd 94). The infrared spectrum (in KBr disk) showed hydrogen-bonded multiplet hydroxyl absorptions at 3000—2500 cm^{-1}, and carbonyl absorptions at 1730 and 1680 cm^{-1}.

Found: C, 51.26; H, 2.60; N, 7.32%. Calcd for $C_{16}H_{10}O_9N_2$: C, 51.34; H, 2.69; N, 7.49%.

The acidified aqueous solution, A, was extracted with ether. The ether was evaporated to dryness to give 1.5 g (43%) of 3-nitrophthalic acid (III), which showed a mp of 214—217°C after recrystallization from water. The mixed melting point with an authentic sample prepared by the alkaline hydrolysis of the starting material showed no depression.

Reaction of Dimethyl 4-Nitrophthalate (IV) With DMSO-Sodium Methoxide. An experimental run in which dimethyl 4-methoxyphthalate was obtained will be described as a typical example. A solution of 6.0 g (0.0025 mol) of I in 30 m*l* of DMSO was added to a suspension of 5.4 g (0.1 mol) of sodium methoxide in 45 m*l* of DMSO in a stream of nitrogen. The mixture was kept at room temperature under nitrogen for 4 hr. Most of the solvent was then removed by distillation under reduced pressure. To the residue there were added 50 m*l* of ether and 50 m*l* of water, and the mixture was separated into the aqueous (A) and ether (B) layers. The ether layer, B, was dried over anhydrous sodium sulfate. The ether was removed and the residue was distilled under reduced pressure to give 1.2 g (22%) of dimethyl 4-methoxyphthalate (VII), bp 136—137°C/3 mmHg. The infrared spectrum showed carbonyl absorption at 1725 cm^{-1}. The NMR spectrum (in CCl_4) showed one aromatic proton at 2.28—2.43 τ (1H, broad doublet), two aromatic protons at 3.07—3.20 τ (2H, broad doublet), and two methoxyl singlets at 6.20 and 6.23 τ (the total of the protons due to these two singlets was 9H).

Found: C, 59.04; H, 5.35%. Calcd for $C_{11}H_{12}O_5$: C, 58.92; H, 5.45%.

The aqueous layer A was added to 100 m*l* of cold 4 N hydrochloric acid. The precipitate thus obtained was then separated from the aqueous acid solution (C) by filtration. The precipitate consisted of 0.7 g (13%) of 5-methoxy-2-nitroso-1,3-indanedione (V). The analytical sample of V was obtained by recrystallization from isopropyl alcohol, mp 204—206°C (decomp). The infrared spectrum showed a hydroxyl absorption at 3500 cm^{-1} and carbonyl absorptions at 1730 and 1690 cm^{-1}. The hydroxyl absorption at 3500 cm^{-1} was sometimes missing, and instead a broad absorption appeared at 3150 cm^{-1}. The NMR spectrum (in DMSO-d_6) showed an acidic proton at -4.25 τ (1H, broad singlet), one aromatic proton at 2.02—2.15 τ (1H, broad doublet), two aromatic protons at 2.50—2.65 τ (2H, broad doublet), and a methoxyl singlet at 6.00 τ (3H). The molecular weight, as measured by the Rast method, was 225 (calcd 205).

Found: C, 58.72; H, 3.38; N, 6.65%. Calcd for $C_{10}H_7O_4N$: C, 58.54; H, 3.44; N, 6.83%.

The aqueous acid solution C was extracted with ether. The ether was then evaporated, and the residue was washed with benzene to give 2.8 g (51%) of 4-methoxyphthalic acid (VI). The analytical sample was obtained by recrystallization from water: mp 157—160°C, (lit.[6] mp 168—170°C); N. E. 97 (calcd 98). The acid VI was identical in every respect with the acid obtained by an alkaline hydrolysis of the ester VII.

Found: C, 54.92; H, 4.20%. Calcd for $C_9H_8O_5$: C, 55.10; H, 4.11%.

In a separate experiment, the compounds V and VI were obtained respectively, in 49 and 48% yields while none of the ester VII was isolated.

Acetylation of 5-Methoxy-2-nitroso-1,3-indanedione V. A mixture of 500 mg (0.0024 mol) of V, 5 m*l* of acetic anhydride, and 5 m*l* of pyridine was heated at reflux for 10 min. After cooling, the reaction mixture was subjected to distillation under reduced pressure to remove the unreacted reagents at room temperature. The residue was then washed with cold methanol and recrystallized from benzene to give 280 mg (47%) of a yellow monoacetylated product, mp 185—189°C (decomp). The infrared spectrum showed carbonyl absorptions at 1802, 1747, and 1708 cm^{-1} and absorptions at 1626 (w), 1590 (s), 1492 (s), 1470 (w), and 1436 (w) cm^{-1}. The NMR spectrum showed an aromatic proton at 1.97—2.13τ (1H, broad doublet), two aromatic protons at 2.41—2.57 τ (2H, broad doublet), a signal due to methoxyl at 6.03 τ (3H, singlet), and a signal due to acetyl at 7.72 τ (3H, singlet). The molecular weight, as measured with a Hitachi-Perkin Elmer 115 molecular-weight apparatus, using benzene as the solvent, was 254 (calcd 248).

Found: C, 58.33; H, 3.84; N, 5.68%. Calcd for $C_{12}H_9O_5N$: C, 58.30; H, 3.67; N, 5.67%.

Alkaline Hydrolysis of V. A mixture of 500 mg (2.4 mmol) of V and 4 g of potassium hydroxide in 13 m*l* of methanol and 8 m*l* of water was refluxed for 48 hr, and then most of the solvent was removed by distillation under reduced pressure. The residue was neutralized with hydrochloric acid, extracted with ether, and dried over anhydrous sodium sulfate. The ether was evaporated to give a precipitate. The recrystallization of the precipitate from water gave 400 mg (83%) of 4-methoxyphthalic acid VI, mp 158—160°C, which was identical in every respect with the acid VI obtained above.

Detection of Nitrite Ion Liberated During the Course of the Reaction of IV with DMSO-Sodium Methoxide. The reaction of IV with DMSO-sodium methoxide was carried out in a nitrogen stream as above. The Griess-Romijn reagent[7] was then added to a small portion of the aqueous acid solution C (see above) obtained in this experiment. The ultraviolet spectrum of the resultant solution showed an absorption maximum at 514 mμ, indicating the presence of the nitrite ion.

Reaction of IV with DMSO-Sodium Ethoxide. This experiment was carried out by a method similar to that employed for the reaction of IV with DMSO-sodium methoxide. However, in this case the DMSO-sodium ethoxide system was used for the preparation of methylsulfinyl carbanion. This experiment gave 5-ethoxy-2-nitroso-1,3-indanedione (VIII), mp 174—181°C, and 4-ethoxyphthalic acid (IX), mp 151—154°C, in yields of 51 and 32% respectively. The infrared spectrum of VIII showed a hydroxyl band at 3510 cm^{-1} and carbonyl bands at 1742 and 1694 cm^{-1}. The NMR spectrum (in DMSO) showed an acidic proton at -4.10τ (1H, broad singlet), one aromatic proton at 2.16—2.27 τ (1H, broad doublet), two aromatic protons at 2.59—2.75 τ (2H, broad doublet), two methylene protons in the ethoxyl group at 5.66—6.01 τ (2H, quartet), and three methyl protons in the ethoxyl group at 8.56—8.84 τ (3H, triplet). However, since the analytical data showed that the VIII obtained here was slightly contaminated even after repeated recrystallizations from ethanol - water, the VIII was converted to the *O*-acetyl derivative and the structure was confirmed (see below).

7) F. H. Welcher, "Organic Analytical Reagents," Vol. 11, D. van Nostrand, New York, N. Y. (1948), p. 406.

The structure of IX was established on the basis of the following data. The neutralization equivalent was 101 (calcd 105). The infrared spectrum was consistent with the structure of IX in every respect.

Found: C, 56.92; H, 4.85%. Calcd for $C_{10}H_{10}O_5$: C, 57.14; H, 4.80%.

Acetylation of 5-Ethoxy-2-nitroso-1,3-indanedione (VIII). A mixture of 300 mg of the crude VIII, 3 m*l* of acetic anhydride, and 3 m*l* of dry pyridine was refluxed for 10 min. The unreacted reagents were evaporated at room temperature under reduced pressure. The residue was washed to give 290 mg (96%) of the acetylated product. The analytical sample was obtained by recrystallization from ligroin, mp 137—141°C (decomp). The infrared spectrum showed carbonyl absorptions at 1798, 1748 (w), and 1713 cm^{-1}.

Found: C, 60.00; H, 4.80; N, 5.44%. Calcd for $C_{13}H_{11}O_5N$: C, 59.77; H, 4.24; N, 5.36%.

Reaction of Methyl *o*-Nitrobenzoate (X) with DMSO - Sodium Methoxide. To a suspension of 5.4 g (0.1 mol) of sodium methoxide in 75 m*l* of DMSO, there was added, drop by drop, 4.5 g (0.25 mol) of X in a stream of nitrogen at room temperature. The reaction mixture was kept under the same conditions for 4 hr, and then most of the solvent was evaporated under reduced pressure. The addition of 50 m*l* of ether and 50 m*l* of ice water to the residue, and the subsequent acidification of the aqueous layer with 100 m*l* of 4 N hydrochloric acid, gave a red precipitate. This precipitate was separated from the aqueous acid solution (A) to afford 1.5 g (44%) of azobenzene-2,2'-dicarboxylic acid (XI). The analytical sample of XI was obtained by recrystallization from acetic acid, mp 230—232°C (decomp) (lit.[8] mp 238—239°C (decomp)).

The neutralization equivalent was 135 (calcd 135).

Found: C, 62.60; H, 3.81; N, 10.10%. Calcd for $C_{14}H_{10}O_4N_2$: C, 62.22; H, 3.73; N, 10.37%.

The extraction of the aqueous acid solution A with ether and the evaporation of the ether gave 1.2 g (33%) of azoxybenzene-2,2'-dicarboxylic acid (XII), which, after recrystallization from acetic acid, showed a mp 230°C (decomp) (lit.[9] 253—255°C (decomp)). The neutralization equivalent was 147 (calcd 143).

Found: C, 59.04; H, 3.46; N, 9.32%. Calcd for $C_{14}H_{10}O_5N_2$: C, 58.74; H, 3.52; N, 9.79%.

Reaction of Methyl *p*-Nitrobenzoate (XIII) with DMSO - Sodium Methoxide. The compound XIII was allowed to react with DMSO-sodium methoxide in a manner similar to that described above. By this reaction *p*-nitrobenzoic acid, mp 238—240°C, was obtained in an almost quantitative yield.

Formation of 5-Methoxy-2-nitroso-1,3-indanedione (V) from Dimethyl 4-Methoxyphthalate (VII). Potassium (0.8 g, 0.02 g-atom) was dissolved in 20 m*l* of refluxing *t*-butyl alcohol. After cooling to room temperature, 15 m*l* of DMSO was added and the solution was distilled under a reduced pressure of about 2 mmHg, using a Vigreux column, until the DMSO started to distill out (bp 45°C), and then the solution was cooled. To the partially-solidified residue there was added, drop by drop, 1.0 g (4.5 mmol) of VII in 5 m*l* of DMSO in a stream of nitrogen at room temperature. The reaction mixture was kept for 2.5 hr under nitrogen, and then most of the solvent was evaporated under reduced pressure. Ether (10 m*l*) and ice water (10 m*l*) were added to the residue, and the aqueous layer was separated. To this aqueous solution there was added, drop by drop, a solution of 800 mg of 97% sodium nitrite in 40 m*l* of 4 N-hydrochloric acid under ice-cooling. A yellow precipitate soon appeared; it was separated by filtration to give 630 mg (66%) of V. Recrystallization from isopropyl alcohol showed a mp of 203—206°C (decomp). This material was identical in every respect with that obtained in the reaction of IV with DMSO - sodium methoxide.

Reaction of Dimethyl 4-Methoxyphthalate (VII) with DMSO - Potassium *t*-Butoxide. A mixture of potassium *t*-butoxide in DMSO was prepared from 2.8 g (0.072 g-atom) of potassium, 70 m*l* of *t*-butyl alcohol and 70 m*l* of DMSO as has been described above. To this mixture there was added, drop by drop, 3.5 g (0.016 mol) of VII in 10 m*l* of DMSO in a stream of nitrogen at room temperature. The reaction mixture, which first turned green and then brown, was kept for 3 hr under nitrogen. Most of the solvent was evaporated under reduced pressure, and 36 m*l* of ether and 36 m*l* of ice water were added to the residue. The aqueous layer was separated and acidified with 75 m*l* of 4N-hydrochloric acid. The precipitate thus obtained was separated by filtration to give 3.7 g (92%) of a material which contained sulfur and chlorine atoms. This material, mp 110—115°C, showed absorption bands at 1752, 1713, 1600, 1493 cm^{-1} in its infrared spectrum and the positive Beilstein test. Therefore, the compound was presumed to be 5-methoxy-2-chloro-2-methylthio-1,3-indanedione (XVII). However, no pure sample of this material was obtained because of the difficulty of purification.

Therefore, XVII was converted to 2-ethoxy-5-methoxy-2-methylthio-1,3-indanedione (XVIII). A mixture of 500 mg (2 mmol) of the crude XVII in 5 m*l* of ethanol was refluxed for 3 hr. The solvent was then evaporated under reduced pressure to give an oil which solidified upon standing for 2 days. The recrystallization of the solid from petroleum ether gave 400 mg (80%) of XVIII, mp 73—74.5°C. This compound contained sulfur atoms. The infrared spectrum showed carbonyl absorptions at 1742 and 1707 cm^{-1}. The NMR spectrum (in CCl_4) showed an aromatic proton at 2.10—2.26 τ (1H, broad doublet), two aromatic protons at 2.61—2.76τ (2H, broad doublet), two methylene protons of the ethoxyl group at 5.81—6.16τ (2H, quartet), three methyl protons of the methoxyl group at 6.05τ (3H, singlet), three methyl protons of the methylthio group at 7.84 τ (3H, singlet), and three methyl protons of the ethoxyl group at 8.67—8.91 τ (3H, triplet).

Found: C, 58.90; H, 5.39%. Calcd for $C_{13}H_{14}O_4S$: C, 58.64; H, 5.30%.

Reaction of Dimethyl 4-Methoxyphthalate (VII) with DMSO-Sodium Methoxide. This reaction was carried out in a manner similar to that employed for the reaction of I with DMSO - sodium methoxide, using VII as a substrate. By this reaction 4-methoxyphthalic acid was obtained in an almost quantitative yield.

Reaction of Dimethyl Phthalate with DMSO-Sodium Methoxide and DMSO - Potassium *t*-Butoxide. The reaction of dimethyl phthalate with

9) J. S. Morley, *ibid.*, **1959**, 2280.

DMSO-sodium methoxide was carried out in a manner similar to that described for the reaction of I with DMSO-sodium methoxide to give 2-chloro-2-methylthio-1,3-indanedione (XIX) in a 44% yield, mp 63—64°C (lit.[1] 63—64°C).

The reaction of dimethyl phthalate with DMSO-potassium *t*-butoxide was carried out in a manner similar to that described for the reaction of VII with DMSO-*t*-butoxide to give XIX in a 62% yield.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 737—740 (1969)

Eine Dienon-Phenol-Umlagerung von 5-Oxo-2-methyl-4,4-dibenzyl-3-äthoxycarbonyl-4,5-dihydro-indol

Tadashi SUEHIRO und Koji EIMURA

Chemisches Institut, Gakushuin Universität, Mejiro, Toshima-ku, Tokio

(Eingegangen am 18. Mai, 1968)

Bei der Einwirkung von Acetanhydrid-Schwefelsäure auf 5-Oxo-2-methyl-4,4-dibenzyl-3-äthoxycarbonyl-4,5-dihydro-indol (I) bei 0°C, findet eine Dienon-Phenol-Umlagerung von I zu 4-Acetoxy-2-methyl-5,6-dibenzyl-3-äthoxycarbonyl-indol (III) statt, dessen Struktur aus der leichten Verseifbarkeit der 3-Äthoxycarbonyl-Gruppe von III und aus den spektroskopischen Befunden der von III abgeleiteten Verbindungen folgte.

5-Oxo-2-methyl-4,4-dibenzyl-3-äthoxycarbonyl-4,5-dihydro-indol (I) lagert sich beim Kochen mit Eisessig-Schwefelsäure unter Abspaltung des Äthoxycarbonyl-Restes zu 5-Hydroxy-2-methyl-4,6-dibenzyl-indol (II) um.[1] In der Kälte findet eine andere Dienon-Phenol-Umlagerung von I statt, und zwar beim Stehen von I in einer Acetanhydrid-Lösung mit etwas Schwefelsäure unter Eis-Kühlung fallen allmählich Kristalle vom Schmp. 224—226°C, zers. (II) in 36% Ausbeute aus. III lässt sich sehr leicht durch 2 stdg. Kochen mit Äthanol-2N Natronlauge in 4-Hydroxy-2-methyl-5,6-dibenzyl-indol-3-carbonsäure vom Schmp. 211—213°C, zers. (IV) verseifen. Die leichte Verseifung des Äthoxycarbonyl-Restes von III weist, wie es nachher erwähnt wird, auf die 4-Acetoxy-Struktur von III hin. IV verliert Carboxyl-Gruppe beim Erhitzen mit Essigsäure und liefert 4-Hydroxy-2-methyl-5,6-dibenzyl-indol vom Schmp. 149—150°C (V). Dieser Schmelzpunkt ist anders als der von II, 111—113°C.[1] Durch Einengen der Mutterlauge von III erhält man in 3% Ausbeute 4-Hydroxy-2-methyl-5,6-dibenzyl-indol-3-carbonsäureäthylester vom Schmp. 232—233°C (VI), dessen Struktur durch Überführung zu IV festgestellt wurde. Aus der Mutterlauge von VI kam bei der Vakuum-Destillation ein dickes Öl vom $Sdp_{0.002}$ 245—260°C (Badtemperature) (VII) über. VII zeigt IR-Bande bei 1755,*1 1735 und 1700/cm im Gegensatz zu III mit 1725 und 1705/cm. VII kann vielleicht ein Zwischenprodukt der Umlagerung sein, dafür konnten wir leider keinen Beweis beibringen und wir haben die Aufarbeitung damit aufgegeben. (Schema 1)

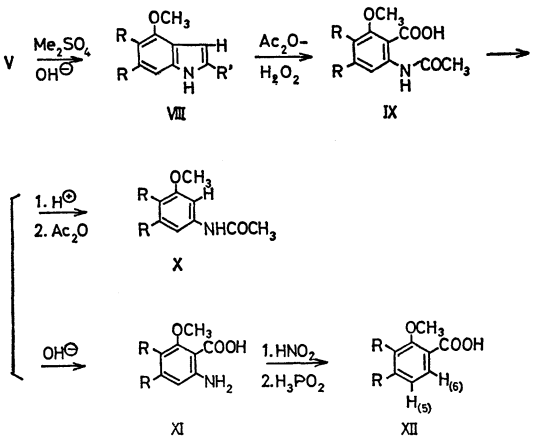
Abbild 1. NMR-Spektrum von XII

Um die Struktur V klar zu machen, haben wir die Abbau-Reaktion von V wie bei dem früheren Fall[1] versucht. V lässt sich zuerst mit Dimethylsulfat und Alkali in den Methyläther vom Schmp. 108—109.5°C (VIII) methylieren. VIII gibt bei der Oxydation mit Acetanhydrid-Wasserstoffsuperoxyd in Gegenwart von Molybdat in 50% Ausbeute 6-Acetamino-2-methoxy-3,4-dibenzyl-benzoesäure vom Schmp. 190—191°C, zers. (IX). IX liefert beim Kochen mit 3 N alkoholischer Salzsäure und anschliessenden Acetylieren 5-Acetamino-2,3-dibenzyl-anisol vom Schmp. 120.5—121.5°C (X). Wenn man IX alkalisch verseift, erhält man 6-Amino-2-methoxy-3,4-dibenzyl-benzoesäure vom Schmp. 124—125°C, zers. (XI), die bei der Deaminierung durch Diazo-Reaktion 2-Methoxy-3,4-dibenzyl-benzoesäure vom Schmp. 119—119.5°C, zers. (XII) gibt. (Schema 2)



R : $-CH_2C_6H_5$
R' : $-CH_3$

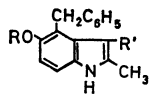
Schema 2

Das UV-Spektrum von X ähnelt denen von 2- und 3-Acetaminoanisole. Man kann daraus aber X nicht eindeutig die Struktur von 2- oder 3-Acetamino-Verbindung zuschreiben. Das NMR-Spektrum von XII (Abbild. 1) zeigt ein Singulett (1H) bei δ 12.5, ein Dublett (1H) bei δ 7.86 (J= 8.4 Hz), ein Multiplett (11H) bei δ 7.10, zwei Singuletts bei δ 4.08 und 3.87 (jede 2H) und ein Singulett (3H) bei δ 3.73. Dem Dublett bei δ 7.86 weisen wir C(6)-H von XII zu, das führt zu dem Schluss, dass XII an C(5) noch ein Wasserstoff-Atom trägt, d. h. V ist an der 7-Stellung frei von dem Substituenten. Zu demselben Schluss kommt man aus den Signalen der aromatischen Protonen von X wieder. Es bleibt noch die Frage, ob die Hydroxyl-Gruppe von V an der 4-oder 6-Stellung steht.

Die 4-Stellung ziehen wir vor für die Hydroxyl-Gruppe nach dem Befunde, dass die 3-Äthoxycarbonyl-Gruppe von III viel leichter als die von 5-Methoxy-2-methyl-4-benzyl-3-äthoxycarbonyl-indol (XIII) verseift wird.[2] Um XIII zu verseifen mussten wir ihn 70 Stdn. bei höheren Temperaturen mit Alkali erhitzen. Unter den Bedingungen, wo III in 63% Ausbeute (Rohprodukt in fast quantitativer Ausbeute) zu IV verseift wird, lässt sich 5-Hydroxy-2-methyl-4-benzyl-3-äthoxycarbonyl-indol (XIV) auch nicht verseifen und in 77% Ausbeute wird die reine Ausgangssubstanz zurückerhalten. Die Schwierigkeit in der Verseifung von XIII und XIV führt zu der Annähme, dass 6-Hydroxy-2-methyl-4,5-dibenzyl-3-äthoxycarbonyl-indol wieder reaktionsträge in der Verseifung ist, weil 5-Hydroxy-indol-3-carbonsäure eine stärkere Carbonsäure als 6-Hydroxy-carbonsäure sein soll,[3] und weil die Estern der stärkeren

2) T. Suehiro, *Chem. Ber.*, **100**, 910 (1967).
3) M. S. Melzer, *J. Org. Chem.*, **27**, 496 (1962).

Carbonsäuren schneller als die der schwächeren Carbonsäuren verseift werden.[4] Auf diesen Betrachtungen soll 6-Hydroxy-2-methyl-4,5-dibenzyl-3-äthoxycarbonyl-indol langsamer als 5-Hydroxyindol - Derivate verseift werden. Die leichte Verseifung von III zu IV ist gut zu verstehen, wenn einmal die Acetoxyl-Gruppe hydrolysiert wird, wie bei den Salicylsäureestern,[5] weil die 4-Hydroxyl- und 3-Äthoxycarbonyl-Gruppen von VI, wie die 1,3-diaxialen Substituenten der Cyclohexan-Reihe, miteinander in Berührung kommen. Für diese sterische Lage sprechen die IR-Banden von VI, ν_{OH} 3160/cm und $\nu_{C=O}$ 1600/cm im Gegensatz zu der monomeren ν_{OH}3630/cm bei V.



XIII: R=-CH_3, R'=-$COOC_2H_5$
XIV: R=-H, R'=-$COOC_2H_5$

Abbild 2.

Die Bildung von III aus I lässt sich wohl nach dem Schema 3 verstehen, in dessen 3. Stufe die Acetoxyl-Gruppe vorwiegend von der 5- zur 4-Stellung wandert. Die bevorzugte Wandrung vom Acetoxyl Rest findet man in mehreren Beispielen,[6] aber dieses Schema ist nicht ähnlich dem von Marvell und anderen,[6a] nach dem letzternen I 7-Acetoxy-4,5-dibenzyl-indol-Derivat liefern sollte.

Frl. H. Watanabe danken wir für die Mikroanalyse.

Beschreibung der Versuche[*2]

Umsetzung von 5-Oxo-2-methyl-4,4-dibenzyl-3-äthoxycarbonyl-4,5-dihydro-indol (I) mit Acetanhydrid - Schwefelsäure zu 4-Acetoxy-2-methyl-5,6-dibenzyl-3-äthoxycarbonyl-indol (III). Zu einer 2.18 *l* Acetanhydrid Lösung von 106 g (0.27 Mol) I tropft man unter Eis-Kühlung und Umrühren 6.8 ccm konz. Schwefelsäure. Die Farbe der Lösung ändert sich von grün-gelb über orange-rot zu hell braun und in einigen Minuten kommen Kristalle aus. Nach dem Stehenlassen im Kühlschrank über Nächte saugt man die Kristalle ab, wäscht sie mit Wasser und trocknet im Exsiccator. Das Rohprodukt (49.5 g, Schmp. 200—205°C) zeigt nach dem Umkristallisieren aus Essigester den Schmp. 224—226°C. Ausbeute 42.2 g (36%) in farblosen Nadeln. IR-Bande(KBr) bei 3380, 1725, 1705/cm.

Gef.: C, 76.26; H, 6.30; N, 3.17%. Ber. für $C_{28}H_{27}NO_4$: C, 76.17; H, 6.16; N, 3.17%.

4-Hydroxy-2-methyl-5,6-dibenzyl-indol-3-carbonsäure (IV). Man Kocht 8.72 g (0.0198 Mol) III 2 Stdn. unter Rückfluss mit 0.12 *l* 2 N Natronlauge und 0.96 *l* Äthanol. Äthanol destilliert man unter vermindertem Druck ab, verdünnt den Rückstand mit Wasser und säuert mit Essigsäure an, wobei 7.19 g Rohprodukt auskam. Man kristallisiert das Produkt aus Essigester-Äthanol (5 : 1) um und erhält 46 g (63%) farblose Nadeln vom Schmp. 211—213°C, zers. IR-Bande (KBr) bei 3450, 2700—3000, 2630, 2550, 1600/cm.

Gef.: C, 77.65; H, 5.53; N, 3.56%. Ber. für $C_{24}H_{21}NO_3$: C, 77.60; H, 5.70; N, 3.77%.

4-Hydroxy-2-methyl-5,6-dibenzyl-indol (V). Man erhitzt 20 g (53.9 mMol) IV mit 400 ccm Eisessig und 20 ccm Wasser 2 Stdn. auf dem Wasserbad. Die Lösung wird violett. Man engt die Lösung unter vermindertem Druck ein und verdünnt den Rückstand mit Wasser, dabei kamen Kristalle aus. Man reinigt das Rohprodukt durch Florisil-Säule-Benzol und kristallisiert aus Benzol - *n*-Hexan (4 : 1) um. Ausbeute 16.4 g (93%) im farblosen Pulver vom Schmp. 149—151°C. IR-Bande (KBr) bei 3630, 3500/cm.

Gef.: C, 84.45; H, 6.47; N, 4.36%. Ber. für $C_{23}H_{21}NO$: C, 84.37; H, 6.47; N, 4.28%.

4-Hydroxy-2-methyl-5,6-dibenzyl-3-äthoxycarbonyl-indol (VI). Nach dem Entfernen von III aus dem Reaktionsgemisch von 7.5 g I mit Acetanhydrid-Schwefelsäure, zersetzt man die Mutterlauge mit Wasser, engt unter vermindertem Druck ein und verdünnt mit Wasser, wobei ein Öl mit 0.54 g Kristalle

*2 Die IR-Spektren wurden mit einem Gerät von Hitachi EPI-S aufgenommen. Die Aufnahme von NMR-Spektrum erfolgte mit dem Gerät A60 der Firma Varian Ass. bei 60 MHz. Die Schemlzpunkte sind nicht korrigiert.

auskam. Umkristallisieren des Produktes aus Essigester gibt 0.21 g farblose Nadeln vom Schmp. 232—233°C. Ausbeute 3%. IR-Bande (Nujol) bei 3400, 3160, 1600/cm, ν_{CH} (3.5×10^{-3} M in CS_2) 3150/cm.

Gef.: C, 77.76; H, 6.74; N, 3.22%. Ber. für $C_{26}H_{25}NO_3$: C, 78.17; H, 6.31; N, 3.51%.

Das Öl, befreit von VI, nimmt man in Benzol auf und wäscht mit Soda-Lösung. Beim Vakuum-Destillation unter 0.002 mmHg kommt bei 245—260°C (Badtemperature) 2.5 g dickes Öl (VII) über. IR-Bande bei 3370, 1750, 1740, 1690/cm. Es wurde weiter nicht erforscht.

Uberführung von VI zu IV. Man kocht 0.11 g VI 4 Stdn. mit 2 ccm Äthanol und 1 ccm 2 N Natronlauge unter Rückfluss. Beim Ansäuern der alkalischen Lösung erhält man 69 mg Kristalle vom Schmp. 212°C, zers., deren IR-Spektrum mit dem von IV übereinstimmt und die Mischprobe zeigte keine Depression.

Versuche der Verseifung von 5-Hydroxy-2-methyl-4-benzyl-3-äthoxycarbonyl-indol[1]. Man kocht 1.0 g (3.24 mMol) von dem Indol (Schmp. 159—160°C) 2 Stdn. unter Rückfluss mit 14.8 ccm 2 N Natronlauge und 110 ccm Äthanol. Nach dem Einengen verdünnt man den Rückstand mit Wasser und säuert mit Essigsäure an, wobei 0.77 g Ausgangssubstanz vom Schmp. 158—160°C auskam.

4-Methoxy-2-methyl-5,6-dibenzyl-indol (VIII). Man methyliert 15 g (46 mMol) V bei Raumtemperatur in einer Mischung von 80 ccm 2 N Natronlauge und 120 ccm Äthanol mit 10 ccm (106 mMol) Dimethylsulfat. Aus dem dunkelvioletten Reaktionsgemisch kommt Rohprodukt (15 g) vom Schmp. 105—108°C aus. Man reinigt es durch eine Kolonne von Florisil-Benzol und kristallisiert aus Benzol - *n*-Hexan (10 : 1) um. Ausbeute 13.5 g in farblosen Blättchen vom Schmp. 108—109.5°C.

Gef.: C, 84.70; H, 6.48; N, 4.15%. Ber. für $C_{24}H_{23}NO_4$: C, 84.42; H, 6.79; N, 4.10%.

6-Acetamino-2-methoxy-3,4-dibenzyl-benzoesäure (IX): Man löst 10 g (29.3 mMol) VIII in 400 ccm Acetanhydrid und tropft dazu unter Eis-Kühlung 1 ccm 1% Molybdat Lösung und dann 90 ccm 30% Wasserstoffsuperoxyd. Man lässt die Mischung 2 Tage im Kühlschrank stehen. Man zersetzt Peroxyd mit wässr. Natriumhydrogensulfid und dampft die Reaktionsmischung ein. Der Rückstand wird beim Stehen fest. Man löst ihn in Sodalösung auf und fällt daraus 6.8 g Rohprodukt vom Schmp. 185—187°C, zers,. durch Ansäuern aus. Umkristallisieren aus 70% Essigsäure gibt 5.6 g (50%) farblose Nadeln vom Schmp. 190—191°C, zers. IR-Bande (KBr) bei 3300, 2700, 1695, 1630, 1600/cm.

Gef.: C, 73.93; H, 5.74; N, 3.49%. Ber. für $C_{24}H_{23}NO_4$: C, 74.02; H, 5.95; N, 3.60%.

5-Acetamino-2,3-dibenzyl-anisol (X). 114 mg (0.293 mMol) IX kocht man mit 5 ccm 6 N Salzsäure und 5 ccm Äthanol 6.5 Stdn. unter Rückfluss. Nach dem Verdünnen mit Wasser und Alkalisch-Machen schüttelt man das Reaktionsgemisch mit Benzol aus. Den Rückstand aus der Benzol-Lösung lässt man über Nacht mit 1 ccm Methanol und 1 ccm Acetanhydrid stehen. Rohprodukt kristallisiert man aus 70% Methanol um und erhält 37 mg (38%) farblose Nadeln vom Schmp. 119.5—120.5°C IR-Bande (KBr) bei 3350, 1655, 1600, 1550, 850/cm. UV-Spektrum (Äthanol) λ_{max} ($\log\varepsilon$): 254 mμ (4.18), 282 (3.66), 286 (3.66), 292 (3.67). Reactive Fiber. VII. Preparation and Polymerization of Vinyl Sulfonyl (β-Chloroethyl)amide

Yoshio IWAKURA, Keikichi UNO, Nobuo NAKABAYASHI*1 and Wen-Yen CHIANG

Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Tokyo

(Received June 6, 1968)

Vinyl sulfonyl (β-chloroethyl)amide (III) was prepared from vinyl sulfonyl chloride and aziridine. The monomer reactivity ratios of III (M_2) ($r_1=3.0$, $r_2=0.075$) were determined from the result of copolymerization with styrene (M_1), and Q_2 and e_2 values calculated were 0.13 and 0.42 respectively. Radical polymerization of III gave a polymer with low viscosity and the polymer had good reactivity with nucleophilic reagents. To compare the functional group in polymer chain with that of monomeric compound, methane sulfonyl (β-chloroethyl)amide (IV) was prepared and the reaction between the function and several nucleophiles was studied. Reactive fibers were obtained from copolymers of acrylonitrile and III. Reaction of the fibers with Congo Red was carried out in the presence of pyridine.

The idea of addition reaction was introduced as a reaction species of a reactive polymer which has groups highly reactive to a polymer chain. We reported already several kinds of useful groups to prepare reactive polymers. They are isocyanate,[1] aziridine,[2] epoxide,[3] azlactone,[4] and sulfonyl (β-chloroethyl)amide,[5] *etc.*

In the present paper, the preparation and polymerization of vinyl sulfonyl (β-chloroethyl)amide (III) and the reaction of the resulting reactive polymers are described. Preparation and polymerization of *p*-styrene sulfonyl (β-chloroethyl)-amide have already been published.[6] In order to compare reactive polymer and fiber derived from the styrene derivative with vinyl derivative, we prepared III. The preparation of vinyl sulfonyl aziridine (III') was unsuccessful because of its unstability. Addition of hydrochloric acid to the crude III' gave stable III. The reactivity of sulfonyl (β-chloroethyl)amide with several nucleophilic reagents seemed to be similar to that of sulfonyl aziridine with nucleophiles in the presence of bases.

Experimental

Preparation of Vinyl Sulfonyl (β-Chloroethyl)-amide (III). Into a solution of 44.8 g (0.354 mol) of vinyl sulfonyl chloride in 450 m*l* of methylene chloride was added a mixture of 15.3 g (0.354 mol) of aziridine and 35.8 g (0.354 mol) of triethylamine dropwise with stirring at a temperature of −4°C to 0°C during an hour. The reaction was continued at room temperature for another 30 min. Precipitated triethylammonium chloride was filtrated off and 25 m*l* of concentrated hydrochloric acid was added dropwise into the filtrate with stirring at an ice cooling temperature. Fifteen minutes later the organic layer was taken out and was washed by water several times and dried over calcium chloride. After the evaporation of the solvent *in vacuo* the fraction boiling at 139.5—140.5°C/2 mmHg was obtained. The yield was 20.9 g (34.8%).

Found: C, 28.18; H, 4.50; N, 8.40%. Calcd for $C_4H_8SO_2NCl$: C, 28.32; H, 4.75; N, 8.26%.

Preparation of Methane Sulfonyl (β-Chloroethyl)amide (IV). The compound was prepared by the method of Bestian.[7]

Polymerization of III. III and an initiator, AIBN, were sealed in an ampoule under an atmosphere of nitrogen and the polymerization was carried out at 65—70°C for 20—70 hr. The viscous oily polymer was poured into ether to separate poly-III. The purification of the polymer was performed by reprecipitation technique (THF-ether system). The results are listed in Table 1.

Found: N, 8.16%. Calcd for $(C_4H_8SO_2NCl)_n$: N, 8.26%.

Determination of Monomer Reactivity Ratios. About 2.5—3.5 g of a pair of accurately weighed

monomers, styrene (M_1) and III (M_2), were mixed with 5 mg of AIBN in an ampoule cooled with Dry-Ice under an atmosphere of nitrogen and the ampoule was sealed. The copolymerization was carried out at 62°C up to a conversion of 10%. After the copolymerization, the viscous mixture was poured into methanol and white flakes were collected. The reprecipitation was repeated three times. The copolymer was dried *in vacuo*. The composition was determined by elementary analyses.

Styrene - III Copolymer. A mixture of 2.07 g of styrene, 1.37 g of III and 0.01 g of AIBN in an ampoule under an atmosphere of nitrogen was heated at 70°C for 25 hr. The copolymer was dissolved in THF and precipitated in methanol. The purification was repeated three times from THF and methanol system. The yield was 2.1 g (60%). $[\eta]=0.54$ (100 m*l* DMF/g at 30°C).

Acrylonitrile - III Copolymer. *(A) Polymerization in THF.* A solution of 53.0 g (1.00 mol) of acrylonitrile, 2.06 g (0.012 mol) of III and 0.015 g of AIBN in 3.5 m*l* of THF was stirred at 65°C for 90 min under an atmosphere of nitrogen. The reaction mass was put into methanol and the resulting white powder was filtered and washed several times by methanol. The yield was 11.0 g (20.0%). $[\eta]=2.7$ (100 m*l* DMF/g at 30°C). The copolymer contained 0.22% (molar) of III unit based on chlorine analysis, 0.15%.

(B) Slurry Polymerization. A suspension of 53.0 g (1.00 mol) of acrylonitrile and 1.7 g (0.01 mol) of III in 1.0 *l* of distilled water and 7.0 m*l* of 0.1 N of sulfuric acid was stirred at 55°C for 10 min with bubbling nitrogen. A pair of initiators, 1.6 g of ammonium persulfate and 0.80 g of sodium metabisulfite, were separately added into the suspension. The copolymerization was carried out for 2.5 hr at the same temperature. The milky mixture obtained was filtered. The collected white powder was suspended into methanol and separated by filtration and washed with methanol several times. The yield was 51.0 g (92.7%). $[\eta]=1.7$ (100 m*l* DMF/g at 30°C).

Wet Spinning of Acrylonitrile - III Copolymer. Copolymer was dissolved in hot DMF and the solution was allowed to stand overnight at room temperature. The dope was extruded into an ethylene glycol coagulation bath at room temperature by a pressure of 1 atm of nitrogen through a spinneret of six holes (0.12 mm diameter). The extruded fiber was drawn three times in a hot water bath kept at 95—98°C.

Polymer Reaction. *Reaction of Poly-III with Thiophenol.* A solution of 0.08 g of poly-III ,0.15 g of triethylamine and 0.15 g of thiophenol in 1 m*l* of THF was sealed into an ampoule. The reaction was carried out at room temperature for a day and at 100°C for another 4 hr. The polymer solution was concentrated by evaporation of THF *in vacuo* and the residue was poured into distilled water to precipitate the polymer. The obtained polymer was dissolved in THF and the solution was poured into water. The collected one was dried *in vacuo*.

Found: N, 5.72%. Calcd for $(C_{10}H_{13}S_2O_2N)_n$: N, 5.76%.

Reaction of Styrene-III Copolymer with p-Toluidine. A solution of the copolymer, *p*-toluidine and pyridine was refluxed for listed interval in Table 7. Methanol was added into the residue to precipitate the polymer after removal of the solvent from the reaction mixture. The reprecipitation (THF-methanol) was carried out three times. The conversion was calculated from chlorine analyses.

Reaction of Methane Sulfonyl (β-Chloroethyl)-amide with Various Nucleophiles. Typical example: A solution of 1.58 g (0.01 mol) of IV, 1.07 (0.01 mol) of *p*-toluidine, 1.01 g (0.01 mol) of triethylamine in 10 m*l* toluene was refluxed for 10 hr under an atmosphere of nitrogen. After separation of precipitated triethylammonium chloride, oily product was obtained by evaporating the solvent from the filtrate. The etheral solution of the oil gave crystals. The melting point was 68.5—70°C. Analytical data are summarized in Table 4.

Reaction of Fiber (Copolymer of III - AN) and Congo Red. The reaction of fiber and Congo Red are carried out at a ratio of 1 : 125 (0.04 g of fiber in 5 m*l* of dye solution) at a temperature of 95°C for 1 hr. The amount of dye combined chemically with the fiber was determined by measuring the unreacted dye in the solution colorimetrically using a Hitachi Photoelectric Photometer, Type EPO-B.

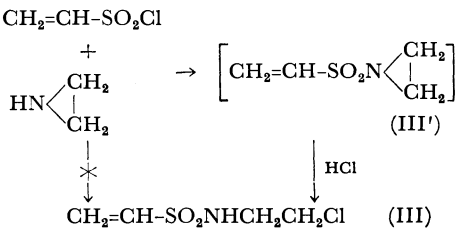
Results and Discussion

Preparation of Vinyl Sulfonyl (β-Chloroethyl)amide. Vinyl sulfonyl (β-chloroethyl)amide was prepared from ethylene bromide according to the following equations[8-10]:

$$BrCH_2CH_2Br + Na_2SO_3 \rightarrow BrCH_2CH_2SO_3Na$$

$$BrCH_2CH_2SO_3Na + NaOH \rightarrow CH_2{=}CH{-}SO_3Na \quad (I)$$

$$CH_2{=}CH{-}SO_3Na + PCl_5 \rightarrow CH_2{=}CH{-}SO_2Cl + CH_2ClCH_2SO_2Cl \quad (II)$$



The reaction between sodium vinyl sulfonate and phosphorus pentachloride gave vinyl sulfonyl chloride and 2-chloroethane sulfonyl chloride. Isolation of vinyl sulfonyl aziridine (III'), which is a desirable compound for a reactive monomer, was unsuccessful because of lack of stability. To stabilize the unstable sulfonyl aziridine it was converted to sulfonyl (β-chloroethyl)amide by addition of concentrated hydrochloric acid. The direct preparation of III from II and aziridine was tried, and II was recovered. The infrared absorption spectrum of III showed absorptions of NH at 3280 cm^{-1}, SO_2 at 1333 cm^{-1} and 1150 cm^{-1},

and CH_2=CH at 3080 cm^{-1}, 3050 cm^{-1}, 1610 cm^{-1}, 970 cm^{-1} and 915 cm^{-1}, respectively.

Polymerization and Copolymerization of III. Poly-III was not obtained by UV irradiation. But using a radical initiator gave only low viscosity polymer even after a prolonged polymerization time. The polymer obtained was soluble in tetrahydrofuran (THF), dimethylformamide (DMF), methanol, benzene and acetone but insoluble in ether, water, and chloroform. The polymer of III decomposed at 95—105°C. The infrared absorption spectrum of poly-III showed no absorptions due to C=C double bond bands. The results of the polymerization are shown in Table 1.

a) Triethylamine.
b) Data was calculated from chlorine analysis.

of the reaction. Table 4 shows the elementary analyses of model compounds. From these results, main reaction of IV with nucleophiles may be concluded as a substitution reaction at β-carbon of β-chloroethyl amido group. The reaction is shown as Eq. (1).

$$CH_3SO_2NHCH_2CH_2Cl + RH \rightarrow CH_3SO_2NHCH_2CH_2R + HCl \quad (1)$$

As shown in Table 5, the reaction of IV with aniline proceeded without triethylamine as an acid acceptor and the fact suggests that aniline itself acts as an acid acceptor. When triethylamine was used, the reaction proceeded more smoothly and a high yield of the product was obtained in a short time.

Reaction of Poly-III and Nucleophiles. Poly-III was found to be reactive with nucleophiles such as phenol, aniline and *p*-toluidine like methane sulfonyl (β-chloroethyl)amide. The results are summarized in Table 6.

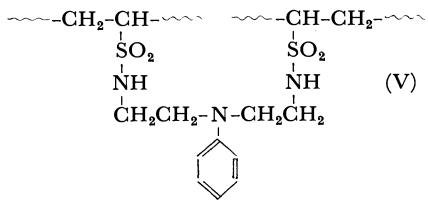
Table 7. Reaction of copolymer of styrene-III with *p*-toluidine in the presence of pyridine

Exp. No.	Reaction time (min)	Recovered yield (%)	Cl % of reacted polm.	Conversion (%)
1	Original	—	5.42	—
2	5	90	5.28	2.3
3	15	94	5.26	2.7
4	60	75	5.21	3.5
5	120	73	—	6.3[a]
6	240	73	5.08	5.7
7	1800	64	1.05	79.0

a) Conversion was calculated from nitrogen analysis.

Reaction of Copolymer with Nucleophiles. The reaction of styrene-III copolymer with *p*-toluidine was carried out and the results are listed in Table 7. The degree of reaction was calculated by chlorine analysis of the resulting copolymer. The reaction seemed to proceed very slowly. From the values of monomer reactivity ratios of III with styrene, III unit should be placed separately on a copolymer chain. This is very different from homopolymer. The low degree of reaction of the copolymer might reflect the difference of polymer structure.

Polymer of III reacted with thiophenol was soluble in THF, but reaction of polymer III with aniline or *p*-toluidine gave cross-linked polymer. Aniline and *p*-toluidine appeared to act as a bifunctional reagent to make crosslinking as shown in V. The crosslinking presumably disturbs the amine to approach reacting sites and conversion of the reaction becomes low.



The fiber spun from copolymer of III with acrylonitrile was treated with Congo Red, a kind of amine, in aqueous solution at 95°C for an hour in the presence of pyridine. The amount of dye taken up by the fiber was determined by the colorimetric method. Usual acrylic fibers could not be dyed by Congo Red, a direct dye. The extraction of colored fiber with hot water gave no decoloration. We could conclude that the dye taken up was combined

chemically with the fiber. Effect of pyridine concentration in the dye solution on the reaction is shown in Table 9 and Fig. 2. The concentration of pyridine seemed to affect partition coefficient of the dye in the solution and the fiber, which played an important role in the reaction. Finally, we concluded that the reactivity of the sulfonyl (β-chloroethyl)amide groups derivatives of *p*-styrene and vinyl are the same, but the polymerizability and copolymerizability of styrene derivative are better than those of vinyl derivative.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 746—749 (1969)

Deoxygenation of Styrene Oxide by Zinc Metal and Lewis Acid

Sotaro MIYANO, Mitsuhiko HIDA and Harukichi HASHIMOTO

Department of Synthetic Chemistry, The University of Tokyo, Hongo, Tokyo

(Received June 13, 1968)

Styrene oxide was deoxygenated to styrene in 83% yield by zinc metal and zinc chloride in aqueous ether. Under the same reaction conditions phenyl glycidyl ether gave only 2.8% of phenyl allyl ether, and propylene oxide did not give propylene. Effects of the reaction variables on the deoxygenation of styrene oxide were investigated. The yield of styrene was varied with metal halide in anhydrous THF in the following order; $ZnI_2 > ZnCl_2 \sim ZnBr_2 > AlCl_3 > SnCl_4 > FeCl_3 > NaI \gg MgBr_2$. Styrene was formed from styrene oxide by zinc metal and zinc chloride in *ca.* 50% yield in THF, acetone, acetic acid, and aqueous ethanol, but not in anhydrous benzene. The yield of styrene increased almost proportionally with the increase of the molar ratio of zinc chloride to styrene oxide up to 1 : 1. 2-Phenyl-2-chloroethanol gave styrene when treated with zinc metal in the presence or absence of zinc chloride, but 1-phenyl-2-chloroethanol did not. Possible reaction paths of the deoxygenation of styrene oxide by zinc metal and metal halide were discussed.

It is well known that 1,2-epoxides give halohydrins, rearrange to carbonyl compounds, or polymerize to polyethers when treated with Lewis acids.[1] On the other hand, in the course of the investigation of the reaction of zinc-methylene complex with epoxides,[2] we found that styrene oxide is deoxygenated to styrene by zinc metal and Lewis acid. In this paper, we report further investigation of the reaction.

Experimental

Materials. *Epoxides.* Commercial styrene oxide (bp 80°C/16 mmHg). Propylene oxide (Mitsui Chem. Co.) was refluxed and distilled over KOH (bp 34°C). Phenyl glycidyl ether was obtained by conventional method[4] (bp 118—118.3°C/11 mmHg; lit. bp 114—118°C/12 mmHg).

Metal Halides. Anhydrous magnesium bromide was prepared from magnesium turnings and bromine in THF or ether.[5] Anhydrous stannous chloride was prepared by dehydration of $SnCl_2 \cdot 2H_2O$ with acetic anhydride.[6] Zinc halides were either prepared from zinc dust and hydrogen halides, or were of commercial reagent grade.

Styrene Chlorohydrins. 2-Phenyl-2-chloroethanol was obtained by adding HCl gas to styrene oxide in chloroform[7] (bp 97—98.5°C/2.5 mmHg; lit. bp 97—99°C/1.2 mmHg). 1-Phenyl-2-chloroethanol was obtained by the addition of hypochlorite to styrene[8] (bp 106—109°C/7.5 mmHg; lit. bp 110—111°C/6 mmHg).

All solvents were purified as usual before use. Zinc-copper couple was prepared by LeGoff's method[9] and washed several times with the solvent used in the reaction.

Reaction of Styrene Oxide with Zinc Chloride and Zinc-Copper Couple. The reaction was carried out in a 100 m*l*, three necked reaction flask equipped with a dropping funnel, thermometer and reflux condenser topped with calcium chloride drying tube.

Freshly prepared zinc-copper couple obtained from 0.12 g-atom of zinc and 0.5 g of $Cu(OAc)_2 \cdot H_2O$ were mixed with 0.051 mol of zinc chloride and 30 m*l* of THF in a reaction flask. Into the mixture, styrene oxide (0.050 mol) dissolved in 20 m*l* of THF was added for 1 hr at 34—35°C with stirring. After the addition had been completed, reaction was continued for another 5 hr at 35°C with stirring. Then the flask was chilled in ice-water, and the amount of styrene was determined by g.l.c. with *t*-butylbenzene as an internal standard. The reaction mixture was treated as reported previously.[3] Styrene was isolated by distillation and identified by elemental analysis and IR spectrum; bp 58°C/39 mmHg (Found: C, 91.21; H, 7.85%). From the result of g.l.c. analysis the minimum amount of the reacted styrene oxide seemed to be determined, because

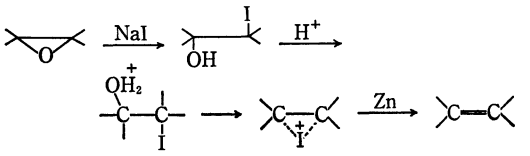
styrene oxide showed all the same retention time on g.l.c. (DOP diasolid column) as phenylacetaldehyde, which may be present in the reaction mixture as the result of rearrangement of styrene oxide.

Reaction of Propylene Oxide with Zinc Metal and Zinc Iodide in Aqueous Ether. Aqueous solution of 57% HI (HI; 0.20 mol, H_2O; 1.09 mol) was added to the zinc dust (0.588 mol) covered with 100 ml of ether with stirring. After the evolution of gas subsided, propylene oxide (0.20 mol) dissolved in 50 ml of ether was dropped to the stirred suspension for 1 hr under gentle reflux (34—35°C). The reaction was continued for another 5 hr at 35°C. Gas evolved during the reaction was introduced with nitrogen into an another flask containing bromine - CCl_4 solution, in which propylene was converted into 1,2-dibromopropane. The dibromide was isolated by distillation, and confirmed by NMR and IR spectra. The yield was determined by g.l.c.

Results and Discussion

Reaction of Epoxides with Zinc Metal and Zinc Halides. Table 1 shows the results of the reaction of styrene oxide, propylene oxide and phenyl glycidyl ether with zinc metal and zinc halide in THF or aqueous ether. Styrene oxide was deoxygenated to styrene in high yields. Propylene oxide gave no propylene, but afforded a 4 : 1 mixture of 1-chloro-2-propanol and 2-chloro-1-propanol (bp 80.5—80.6°C/164 mmHg, 56% based on propylene oxide) (No. 5). When propylene oxide was treated with zinc iodide and zinc, propylene was obtained only in the low yield, but 1-iodo-2-propanol was also isolated in 48% yield based on propylene oxide; bp 76°C/22 mHg (No. 7). On the other hand, propylene was obtained in good yield in the presence of sodium iodide, zinc dust and sodium acetate in aqueous acetic acid, as described by Cornforth *et al.*[10] (No. 9). They reported the deoxygenation of alkylene oxides to alkenes by zinc metal and sodium iodide in acetic acid, and suggested the following reaction mechanism:



However, in our case, at least in anhydrous THF, the above protonation and dehydration mechanism may not be responsible for the styrene formation from styrene oxide with zinc metal and zinc halides (*vide infra*).

Deoxygenation of Styrene Oxide. *Effect of Metal Halides.* All metal halides except anhydrous magnesium bromide in combination with zinc-copper couple gave fairly good yield of styrene from styrene oxide (Table 2). The inactivity of anhydrous magnesium bromide for styrene formation has not yet been understood clearly. Even sodium iodide gave styrene in a lower yield, but the addition of zinc acetate improved the yield of styrene. In the latter case, it seems that the resultant zinc iodide was an active catalyst. Lower yield of styrene in anhydrous THF compared with that in

aqueous ether may be due to side reactions such as rearrangement to phenylacetaldehyde.[1)]

Effect of Reagent Molar Ratio. The effect of the amount of zinc chloride on the styrene yield was shown in Fig. 1. No styrene was obtained when styrene oxide was treated only with zinc chloride, or only with zinc metal. The presence of both zinc metal and metal halides is necessary for styrene formation.

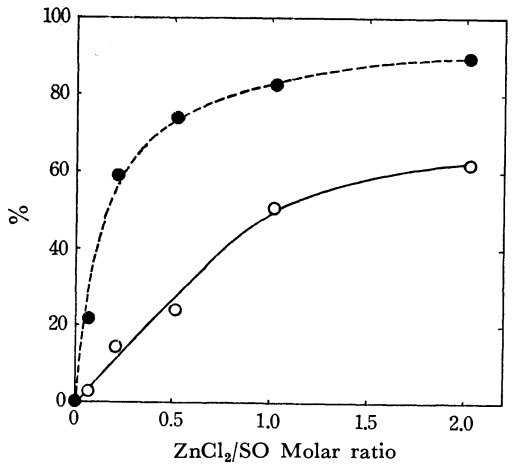

Fig. 1. Effect of the molar ratio of zinc chloride to styrene oxide.

Reducing Reagents Other than Zinc Metal. Zinc metal can be replaced by triphenylphosphine[11)] or magnesium metal, though the yield of styrene was reduced. However, stannous chloride was not effective (Table 4). Magnesium metal was used in the form of turnings, and triphenylphosphine may form acid-base complex with zinc chloride as suggested by Wittig and Haag.[11)] These factors may partly be responsible for the lower yield of styrene.

Reaction of Styrene Chlorohydrins and Mechanistic Consideration of Deoxygenation of Styrene Oxide. Reactions of 1-phenyl-2-chloroethanol and 2-phenyl-2-chloroethanol with zinc metal in the presence or absence of zinc chloride were compared with those of styrene oxide (Table 5). Though zinc can not eliminate hypochlorite from alkyl chlorohydrins[10,12)] except from those of

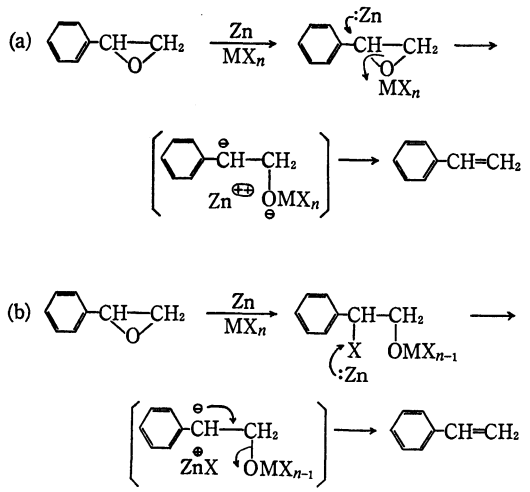
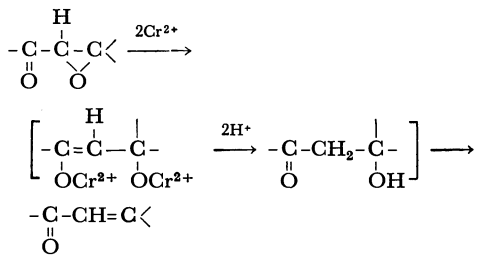
special steroidal series,[13] benzylic chloride in 2-phenyl-2-chloroethanol was active enough to give styrene. It may be noticeable that the dechlorohydrination of *erythro*-1,2-diphenyl-2-chloroethanol by zinc dust in acetic acid is well known as the synthetic method of *trans*-stilbene.[14] From these facts the following two reaction paths seem to be probable for the formation of styrene from styrene oxide by zinc metal and metal halides.



Path (a) shows a concerted electron transfer from zinc to benzylic carbon, followed by an elimination of $OMXn^{-2}$. Path (b) shows the formation of metal salt of 2-phenyl-2-haloethanol as an intermediate. The formation of organozinc intermediate is excluded since no phenethyl alcohol was formed even in acetic acid. Several authors suggested the formation of transient carbanion in the elimination of hypobromite from boromohydrins by zinc metal.[15] Cole and Julian showed that α,β-epoxy ketones and styrene oxide are deoxygenated to olefins by chromous chloride in acetic acid.[16] They suggested the direct attack of chromous ion to α,β-epoxy ketones as follows:



Though they did not mention the mechanism of styrene formation from styrene oxide by chromous chloride, the above two reaction paths (a and b) may be plausible also.[17] Kharasch *et al.* suggested radical chain mechanism for the propylene formation from propylene oxide or two isomers of propylene chlorohydrins by Grignard reagent in the presence of transition metal halide.[18] But styrene was not formed from 2-phenyl-2-chloroethanol by phenylmagnesium bromide in the presence of zinc chloride in THF (Table 5). Further investigation seems to be necessary for the detailed discussion of the reaction of epoxides with zinc metal and metal halide.

Studies of Purine *N*-Oxides. III. The Synthesis of Purine 3-*N*-Oxides[1]

Hideaki KAWASHIMA and Izumi KUMASHIRO

Central Research Laboratories, Ajinomoto Co., Inc., Suzuki-cho, Kawasaki

(Received June 15, 1968)

6-Methoxy- and 6-ethoxypurine 3-*N*-oxides were obtained by the direct oxidation of the corresponding 6-alkoxypurines with hydrogen peroxide in aqueous acetic acid. 6-Chloropurine was oxidized with monoperphthalic acid in ether to give 6-chloropurine 3-*N*-oxide. These purine 3-*N*-oxides were then converted to hypoxanthine 3-*N*-oxide by hydrolysis with a sodium hydroxide solution. 6-Methoxypurine 3-*N*-oxide and hypoxanthine 3-*N*-oxide were identified with authentic samples unambiguously synthesized from 6-methylsulfonylpurine 3-*N*-oxide, which had itself been obtained by the oxidation of 6-methylthiopurine 3-*N*-oxide. The treatment of hypoxanthine 3-*N*-oxide with hydrochloric acid gave 6,8-dihydroxypurine, 8-chlorohypoxanthine, hypoxanthine, and 2-chloro-4-amino-5-imidazolecarboxamide.

The synthesis of 3-*N*-oxides of purine derivatives by direct oxidation has never been described. Adenine,[2,3] 2,6-diaminopurine,[2] 6-methylpurine,[4] and 6-methyl-8-hydroxypurine[4] are, however, known to be converted to the corresponding 1-*N*-oxides by direct oxidation. Purine[4] and 8-hydroxypurine[4] have been oxidized to mono-*N*-oxides, in which the positions of the *N*-oxide groups are still unknown. Guanine[5,6] was oxidized to guanine 7-*N*-oxide with trifluoroperacetic acid.

Generally, purine 3-*N*-oxides have been synthesized by a cyclization process (*e.g.*, 7-methyladenine 3-*N*-oxide[7] and xanthine 3-*N*-oxide[8]). 6-Mercaptopurine 3-*N*-oxide was obtained from 7-aminothiazolo[5,4-d]pyrimidine 6-*N*-oxide by treating it with a sodium hydroxide solution.[9,10]

In the present paper the synthesis of purine 3-*N*-oxides by direct oxidation will be described. 6-Methoxy purine (Ia) was treated with a mixture of a 30% hydrogen peroxide solution and acetic acid at room temperature. After fifteen days the reaction mixture was evaporated to dryness, and the resulting residue was washed with ethanol and crystallized from water to give fine, colorless crystals. Elementary analysis revealed the composition of the oxidation product (IIa) to be $C_6H_6N_4O_2$, corresponding to that of the expected 6-methoxypurine *N*-oxide. The reduction of this oxidation product (IIa) with hydrogen in the presence of Raney nickel gave 6-methoxypurine (Ia). In addition, IIa possesses a strong absorption maximum in neutral and alkaline solutions near 230 mμ; this is characteristic of purine *N*-oxides in general.[2,11] These properties of this product (IIa) suggest its mono-*N*-oxide structure. 6-Ethoxypurine (Ib) was then similarly oxidized to give a mono-oxidized product (IIb); it had the composition of $C_7H_8N_4O_2$, and showed the properties of purine *N*-oxides.

The direct oxidation of 6-chloropurine has been reported to yield the nonoxidizable hypoxanthine.[9] Since this failure was considered to be due to the presence of water, the oxidation of 6-chloropurine was attempted under an anhydrous condition. 6-Chloropurine (III) partially suspended in an ether solution of monoperphthalic acid was stirred at room temperature for a few days. The resulting precipitation was washed with ether to remove the unchanged 6-chloropurine and the phthalic acid. The ether-insoluble residue showed a new single spot on a paper chromatogram. Since this product was decomposed upon heating in water or some organic solvents, it was reprecipitated from an ammonia-methanol solution by the addition of ether to give pure crystals. The crystals had the

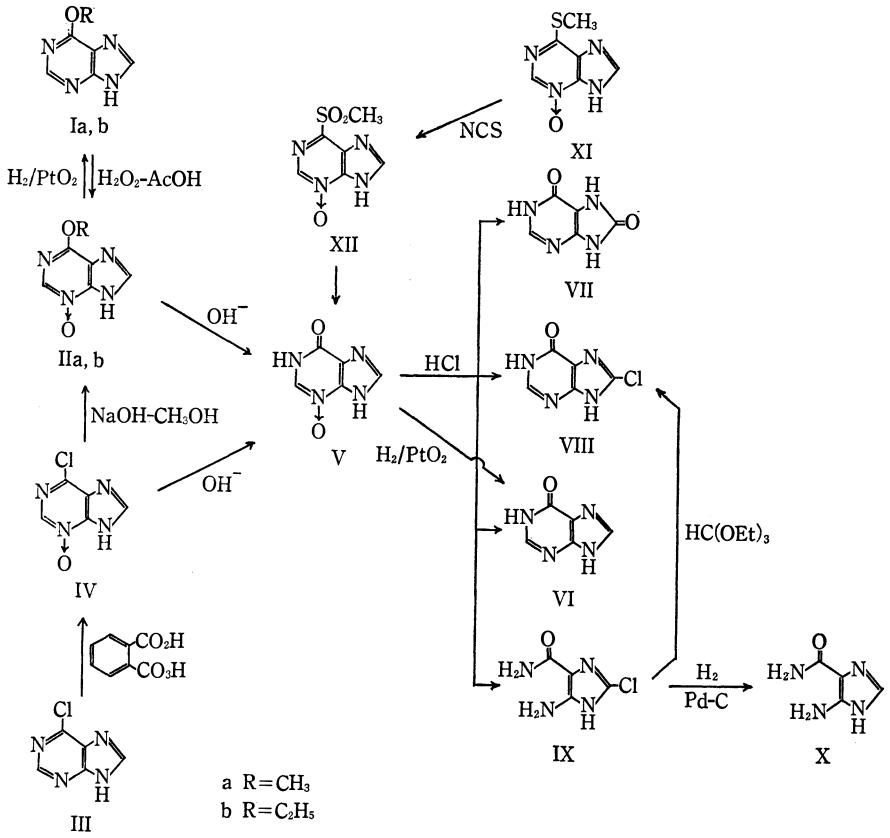

Fig. 1

composition of $C_5H_5N_4OCl \cdot NH_3$ and were convertible to 6-methoxypurine *N*-oxide (IIa) when treated with sodium methoxide. From these properties, the structure of this product was considered to be 6-chloropurine mono-*N*-oxide (IV).

Upon being heated in a 1 N sodium hydroxide solution under refluxing, these 6-alkoxypurine *N*-oxides (IIa, b) and 6-chloropurine *N*-oxide (IV) were both converted to the same new product (V). This new product (V) possessed the composition of $C_5H_4N_4O_2$ and a strong absorption maximum in an alkaline solution at about 230 mμ. Though V was reduced with hydrogen in the presence of Raney nickel to yield hypoxanthine (VI), it was not identified with hypoxanthine 1-*N*-oxide.[11-13] Consequently, V is likely to be hypoxanthine 3-, 7-, or 9-*N*-oxide.

In order to elucidate the structure of V, we attempted the hydrolysis of V with 3 N hydrochloric acid. The hydrolysis products were separated through a Dowex 50 (H^+ type) column to give 6,8-dihydroxypurine (VII), 8-chlorohypoxanthine (VIII), hypoxanthine (VI) and 2-chloro-4-amino-5-imidazolecarboxamide (IX). Compounds VII and VIII were identified with the respective authentic samples.[14]

The structure of IX was determined from the following reactions of IX. The catalytic reduction of IX with hydrogen in the presence of 10% palladium-on-charcoal gave 4-amino-5-imidazolecarboxamide. A cyclization of IX with ethyl orthoformate resulted in the formation of 8-chlorohypoxanthine (VIII).[14]

Purine *N*-oxides have been known, upon hydrolyis in an acid, to give hydroxylaminopyrimidine or -imidazole derivatives by the loss of the carbons adjacent to the *N*-oxide groups. For instance, 2,6-diamino-8-phenylpurine 7-*N*-oxide has been hydrolyzed to give 2,4,6-triamino-5-hydroxylaminopyrimidine,[15] and adenine 1-*N*-oxide has similarly been converted to 4-amino-5-imidazolecarboxamidoxime.[3]

Contrary to expectations, however, the hydrolysis

Fig. 3

of hypoxanthine 3-*N*-oxide (V) produced 2-chloro-4-amino-5-imidazolecarboxamide (IX), but not 4-hydroxylamino-5-imidazolecarboxamide (XIII). The opening of the pyrimidine ring of V, with an accompanying loss of 2-carbon, suggests the 3-*N*-oxide structure of V. However, more evidence is desirable.

The identification of V with an authentic hypoxanthine 3-*N*-oxide unambiguously synthesized from 6-mercaptopurine 3-*N*-oxide[9,10] was attempted.

6-Methylthiopurine is known to be oxidized with *N*-chlorosuccinimide to yield 6-methylsulfonylpurine.[16] This method was applied to the synthesis of 6-methylsulfonylpurine 3-*N*-oxide (XII) from 6-methylthiopurine 3-*N*-oxide (XI). XII was treated with a 1 N sodium hydroxide solution to give hypoxanthine 3-*N*-oxide, which was identified with V. Consequently, the 3-*N*-oxide structures of IIa, IIb, IV, and V were confirmed. XII was converted to 6-methoxypurine 3-*N*-oxide (IIa) upon being treated with a solution of sodium hydroxide in methanol.

The route to 2-chloro-4-amino-5-imidazolecarboxamide (IX) from hypoxanthine 3-*N*-oxide (V) upon hydrolysis was estimated to be as follows.

8-Chlorohypoxanthine (VIII), one of the hydrolysis products of hypoxanthine 3-*N*-oxide (V), is not certainly a direct precursor of IX, since VIII is converted to 6,8-dihydroxypurine (VII) upon being refluxed in 3 N hydrochloric acid. At first, prior to the halogenation, V may be hydrolyzed to the presumed ring-opening intermediate (XIII). Then the latter may be attacked by the chloride anion at 2-position to give IX, accompanied by N-O bond breaking (Fig. 2).

Further, the mechanism of the formation of 6,8-dihydroxypurine (VII) and 8-chlorohypoxanthine (VIII) from V upon hydrochloric acid treatment was suggested to be as follows (Fig. 3).

Experimental

6-Methoxypurine 3-*N*-Oxide (IIa). A 30% aqueous hydrogen peroxide solution (150 m*l*) was added to a solution of 6-methoxypurine hemihydrate (15 g) in glacial acetic acid (375 m*l*), and then left to stand at room temperature for 17 days. The volatile materials were removed from the reaction mixture at 40°C under reduced pressure. The yellow residue was washed with ethanol and then twice with hot ethanol to give a white powder of IIa (11.2 g, 72%). The paper chromatogram (solvents A and B) of the

resultant white powder showed a single spot. A portion of this product was crystallized from water to give colorless crystals, mp 215°C (d).

Found: C, 43.30; H, 3.49; N, 33.57%. Calcd for $C_6H_6N_4O_2$: C, 43.37; H, 3.63; N, 33.73%.

Hydrogenation of 6-Methoxypurine 3-*N*-Oxide (IIa). IIa (1 g) was dissolved in a 2 N ammonium hydroxide solution (100 m*l*), and Raney nickel (2 m*l*) was added. The mixture was shaken at room temperature for 35 hr until 145 m*l* of hydrogen had been absorbed. The catalyst was then removed and the filtrate was evaporated to dryness. The residue (600 mg) was crystallized from water; and it was identified with authentic 6-methoxypurine by R_f in solvents A and B, and by a study of the ultraviolet and infrared spectra.

6-Ethoxypurine 3-*N*-Oxide (IIb). A 30% aqueous hydrogen peroxide solution (40 m*l*) was added to a solution of 6-ethoxypurine hemihydrate (4 g) in glacial acetic acid (100 m*l*), and then left to stand at room temperature for 11 days. The reaction mixture was treated in the same manner as the case of 6-methoxypurine 3-*N*-oxide (IIa) to yield IIb (1.5 g, 36%). The resulting powder was crystallized from water to give light-yellow crystals, mp 213°C (d).

Found: C, 46.74; H, 4.80; N, 31.19%. Calcd for $C_7H_8N_4O_2$: C, 46.66; H, 4.48; N, 31.10%.

6-Chloropurine 3-*N*-Oxide (IV). 6-Chloropurine (5 g) was suspended in 1500 m*l* of an ether solution containing 105 g of monoperphthalic acid, and then stirred at room temperature for 12 days. After the reaction, a solid material was collected. From this soild 6-chloropurine and phthalic acid were continuously extracted with ether for 50 hr. The resulting residual light-yellow powder (2.5 g, 45%) showed a single spot on a paper chromatogram (solvents A and B). Methanolic ammonia was then added to the powder, and an insoluble solid was removed by filtration. To the filtrate ether was added to precipitate ammonium salt of 6-chloropurine 3-*N*-oxide (IV). There precipitation

a) The effluent was evaporated to dryness. The residue was recrystallized from water, and identified with the authentic sample by R_f (solvents A and B) and ultraviolet and infrared spectra.

b) The effluent was evaporated under reduced pressure at 40°C to dryness. The residue was precipitated from methanol by addition of ether.

was performed once more to yield a colorless powder, mp 165°C (d).

Found: C, 31.87; H, 3.58; N, 36.94; Cl, 18.50%. Calcd for $C_5H_3N_4OCl \cdot NH_3$: C, 32.01; H, 3.22; N, 37.33; Cl, 18.90%.

The Reaction of 6-Chloropurine 3-*N*-Oxide (IV) with Sodium Methoxide. 6-Chloropurine 3-*N*-oxide (1 g) was dissolved in a sodium methoxide solution prepared from 300 mg of sodium and 30 ml of methanol, and then heated to 100°C for 4 hr in a sealed tube. The reaction mixture was evaporated to dryness, and water (20 ml) was added to the residue. The solution was filtered and acidified to pH 4 to precipitate light-yellow crystals. These crystals showed a single spot on a paper chromatogram (solvent A), and the R_f, ultraviolet, and infrared spectra agreed with those of 6-methoxypurine 3-*N*-oxide (IIa).

Hypoxanthine 3-*N*-Oxide (V) from 6-Methoxypurine 3-*N*-Oxide (IIa). 6-Methoxypurine 3-*N*-oxide (8 g) was dissolved in a 1 N sodium hydroxide solution (400 ml), and the mixture was refluxed for 1.5 hr. After the reaction mixture had cooled, concentrated hydrochloric acid was added to adjust the pH to 9, and the mixture was decolorized with charcoal. The solution was acidified to pH 1 to precipitate a light yellow powder of V (6.1 g, 83%). This product was reprecipitated twice with a sodium hydroxide solution-hydrochloric acid, and washed well with water, to yield a fine, colorless powder. The product darkened slowly from 210°C to 300°C.

Found: C, 39.71; H, 2.75; N, 36.68%. Calcd for $C_5H_4N_4O_2$: C, 39.48; H, 2.65; N, 36.84%.

Hypoxanthine 3-*N*-Oxide (V) from 6-Chloropurine 3-*N*-Oxide (IV). 6-Chloropurine 3-*N*-oxide (0.1 g) was dissolved in a 1 N sodium hydroxide solution (5 ml), and the mixture heated under refluxing for 1 hr. The reaction mixture showed a single spot on a paper chromatogram (solvents A and B), and its R_f and ultraviolet spectra agreed with those of hypoxanthine 3-*N*-oxide (V).

Hydrogenation of Hypoxanthine 3-*N*-Oxide (V). Hypoxanthine 3-*N*-oxide (1 g) was dissolved in a 2 N ammonium hydroxide solution (100 ml). Raney nickel (5 ml) was then added, and the mixture was shaken at room temperature with hydrogen at an atmospheric pressure for 22 hr, by which time 160 ml of hydrogen had been absorbed. The catalyst was then removed, and the filtrate was evaporated to dryness. The residue (500 mg) was crystallized from water and identified with hypoxanthine by R_f (solvents A and B), and by a study of the ultraviolet and infrared spectra.

Hydrolysis of Hypoxanthine 3-*N*-Oxide (V) with Hydrochloric Acid. Hypoxanthine 3-*N*-oxide (10 g) was divided into five aliquots. Each of them was dissolved in 3 N hydrochloric acid (100 ml), refluxed for five minutes, and cooled immediately. After being cooled, the five reaction mixtures were combined and passed through a column packed with 1200 ml of Dowex 50WX4 (H^+ type), and then eluted with water and 1.2 N hydrochloric acid. The eluting procedure and the results are presented on Table 2.

Reduction of 2-Chloro-4-amino-5-imidazolecarboxamide (IX). 2-Chloro-4-amino-5-imidazolecarboxamide hydrochloride (50 mg) was dissolved in water (20 ml). To this solution 10% palladium on charcoal (100 mg) was added, and the mixture was shaken for 3 hr at room temperature with hydrogen at atmospheric pressure. The catalyst was then removed by filtration. The filtrate showed a single spot on a paper chromatogram, and its R_f (solvents A and B) and ultraviolet spectrum were identical with those of 4-amino-5-imidazolecarboxamide (X).

Cyclization of 2-Chloro-4-amino-5-imidazolecarboxamide (IX). 2-Chloro-4-amino-5-imidazolecarboxamide hydrochloride (350 mg) was dissolved in a mixture of ethyl orthoformate (10 ml) and acetic anhydride (1 ml), and the resultant mixture was refluxed for 30 min. After being cooled, the reaction mixture

was evaporated to dryness under reduced pressure. The residue was dissolved in water (50 m*l*) passed, through a column packed with 100 m*l* of Dowex 50W X4 (H^+ type), and eluted with water. The first 600-m*l* portion of the effluent was discarded; the next 350-m*l* portion of the effluent was evaporated to dryness under reduced pressure to give 8-chlorohypoxanthine (0.1 g). Its R_f (solvents A and B) and ultraviolet and infrared spectra agreed with those of the authentic sample.

6-Methylsulfonylpurine 3-*N*-Oxide (XII). 6-Methylmercaptopurine 3-*N*-oxide (300 mg) was suspended in 50% methanol (30 m*l*). *N*-Chlorosuccinimide (870 mg) was then added, and the mixture was stirred for 6 hr at room temperature. After the reaction mixture had been left to stand overnight, the precipitated product was filtered and washed with methanol. The crystals obtained (0.2 g, 57%) were recrystallized from water. Mp 197—198°C (d).

Found: C, 33.55; H, 2.76; N, 26.25%. Calcd for $C_6H_6N_4O_3S$: C, 33.64; H, 2.82; N, 26.16%.

Hypoxanthine 3-*N*-Oxide from Methylsulfonylpurine 3-*N*-Oxide (XII). 6-Methylsulfonylpurine 3-*N*-oxide (500 mg) was dissolved in a 1 N sodium hydroxide solution (25 m*l*), and the mixture was refluxed for 2 hr. After being cooled, the reaction mixture was decolorized by adding charcoal and acidified to pH 3 with concentrated hydrochloric acid; this precipitated a light-yellow powder of hypoxanthine 3-*N*-oxide (230 mg, 65%). This product was reprecipitated with a sodium hydroxide solution - hydrochloric acid, and washed well with water, to yield a fine colorless powder. The product darkened slowly above 230°C.

Found: C, 39.62; H, 2.81; N, 36.77%. Calcd for $C_5H_4N_4O_2$: C, 39.48; H, 2.65; N, 36.84%.

6-Methoxypurine 3-*N*-Oxide from 6-Methylsulfonylpurine 3-*N*-Oxide. 6-Methylsulfonylpurine 3-*N*-oxide (0.5 g) was dissolved in a methanol solution (20 m*l*) which contained sodium hydroxide (0.8 g), and the mixture was refluxed for 1 hr. After being cooled, the reaction mixture was neutralized by adding glacial acetic acid and evaporated to dryness. The residue was dissolved in water adsorbed on a column packed with 100 m*l* of Amberlite IR-120 (H^+ type), washed well with water, and eluted with a 1 N ammonium hydroxide solution. The effluent was evaporated to dryness to give 6-methoxypurine 3-*N*-oxide (IIa, 250 mg, 64%), which was then recrystallized from water. This product darkened from 200 to 215°C.

Found: C, 41.93; H, 4.06; N, 33.06%. Calcd for $C_6H_6N_4O_2 \cdot \frac{1}{4}H_2O$: C, 42.23; H, 3.84; N, 32.83%.

The authors wish to thank Mr. Shinichi Motozaki, director of this laboratory for his interest and encouragement. The assistance of Mr. Akio Kakuta throughout this work is also grateful acknowledged.

Amination of Benzoic Acid in the γ-Radiolysis of Liquid Ammonia

Akihisa SAKUMOTO

Japan Atomic Energy Research Institute, Tokai-mura, Ibaraki

(Received June 25, 1968)

Ammonia and aqueous ammonia solutions of benzoic acid, ^{14}C-carboxyl labeled, were irradiated with ^{60}Co γ-rays at absorbed doses of 1.9×10^{20} and 4.4×10^{20} eV/g respectively. The irradiation temperature was 0°C in both cases. An isotope dilution method was applied to measure the products in irradiated solutions. The *G* values of *o*-, *m*-, and *p*-aminobenzoic acids were 0.016, 0.022, and 0.027 respectively in an ammonia solution. On the other hand, the *G* values of products in an aqueous ammonia solution were 0.011, 0.013, and 0.017 for *o*-, *m*-, and *p*-aminobenzoic acids and 0.029, 0.033, and 0.040 for *o*-, *m*-, and *p*-hydroxybenzoic acids. The disappearance of benzoic acid in an ammonia solution corresponded to a *G* value of about 1.46. From the ratio of the relative partial rate factors, it was deduced that the aminating agent was the amino radical in both cases.

The amination of aromatic compounds has been fairly extensively investigated by using hydroxylammonium chloride in the presence of Friedel-Crafts catalysts,[1] hydroxylamine-*O*-sulfonic acid and some of its derivatives,[2,3] and hydroxylamine-titanous ion in an acid solution.[4] On the other hand, aromatic amination induced by ionizing radiation has received relatively little attention.

The products from radiolysis of liquid ammonia are similar to those from liquid water.[5] The

amination in the nucleus of aromatic compounds, therefore, may be expected to occur during the irradiation of its ammonia solution with ionizing radiation. Puig and Schwarz[6] studied the radiolysis of an ammonia solution of benzene with ^{60}Co γ-rays and found aniline to be formed, corresponding to phenol in an aqueous solution, with a G value of 0.55.

In the mono-substitution of mono-substituted benzene derivatives, the ratio of the products depends upon the degree to which the substituent displays electron-withdrawing or electron-donating properties. The carboxyl group of benzoic acid is particularly interesting as an aromatic substituent because of its *meta*-directional effect on an attacking reagent for the aromatic nucleus. Consequently, some information about an attacking species may be obtained by investigating the ratio of the isomers of substituted benzoic acid.

The aim of this work has been to elucidate the attacking species concerned in the amination reaction in the γ-radiolysis of ammonia solutions. Some results obtained by irradiating ammonia and aqueous ammonia solutions of ^{14}C-carboxyl labeled benzoic acid at a relatively high dose will be described. The reaction products were determined by means of an isotope dilution method. On the basis of the isomeric distribution of the aminobenzoic acids thus obtained, the attacking species participating in the amination reaction in the aromatic nucleus of benzoic acid will be deduced.

Experimental

Materials. The liquid ammonia used was purified in the following manner. An aqueous ammonia solution was placed in a 1 *l* round-bottomed flask fitted with a reflux condenser. The flask was then heated slowly in a water bath. The ammonia gas evolved, after passing through the condenser, was introduced into columns packed with soda-lime and sodium hydroxide; then it was collected into a storage vessel cooled by dry ice-acetone and stored at least for 15 hr as a liquid over metallic sodium. Just before use as a solvent, the ammonia in the storage vessel was distilled under diminished pressure into another vessel immersed in dry ice-acetone in order to eliminate any residual metallic sodium and any other solid impurities; it was then distilled three more times in order to remove any hydrogen formed during purification by metallic sodium.

The water used had been triply distilled, the final distillation being from alkaline potassium permanganate.

The non-radioactive acids used as the carriers of the isotope dilution method were obtained from commercial sources. All of these acids were GR grade and had then been purified further by recrystallization.

Benzoic acid, ^{14}C-carboxyl labeled, was purified by recrystallization from ethyl alcohol - water and then diluted to the specific activities of 1.41×10^{10} dpm/mol and 3.40×10^{10} dpm/mol respectively.

6) J. R. Puig and E. Schwarz, *Industrial Uses of Large Radiation Source*, **1**, 57 (1963).

Preparation of Solutions. In an irradiation vessel there was placed 150 mg of ^{14}C-labeled benzoic acid, with a specific activity of 1.41×10^{10} dpm/mol. Then the vessel was connected to a vacuum line and carefully degassed. After the degasification, 1.52 mol of liquid ammonia, purified by the method described above, was distilled under diminished pressure into a vessel cooled by dry ice-acetone. Then the irradiation vessel with an ammonia solution, cooled by liquid nitrogen, was sealed off.

An aqueous ammonia solution of benzoic acid was prepared by distillating 0.88 mol of liquid ammonia into an irradiation vessel already containing an aqueous benzoic acid solution which had been prepared by adding 150 mg of ^{14}C-labeled benzoic acid (with a specific activity of 3.40×10^{10} dpm/mol) to 0.83 mol of triply-distilled water which has been degassed by repetitions of the freezing-pumping process.

Irradiation. A ^{60}Co γ-rays source of about 16 kCi was used. The ammonia solution was irradiated at the absorbed dose of 1.9×10^{20} eV/g and at the dose rate of 3.5×10^{17} eV/g/min. The total dose given to an aqueous ammonia solution was 4.4×10^{20} eV/g at the dose rate of 6.7×10^{17} eV/g/min. The irradiation temperature of both samples was 0°C, which was controlled with ice-water. The dose rate was measured by Fricke dosimetry, taking $G(Fe^{3+})$ to be 15.5. Appropriate corrections were made for the difference in the electron densities of liquid ammonia and water.

Radioactive Assay. After irradiation, the break-seal of the irradiation vessel was broken. The contents were transferred to a beaker immersed in liquid nitrogen. The irradiation vessel was washed with about 10 cc of demineralized water. After it had stood overnight in order to evaporate any excess ammonia, the combined aqueous solution was diluted to a total volume of 25 cc with demineralized water. An aliquot of the diluted solution was then thoroughly mixed with an accurately-weighed quantity of the carrier acid in ethyl alcohol. The solution was evaporated to dryness, and the precipitate was purified by recrystallization from a suitable solvent until a constant counting rate was obtained. The aminobenzoic acids in products were derived to acetoamidobenzoic acids and purified.

An aliquot of a purified sample was dissolved in the solution of 10 cc of liquid scintillant (4 g of PPO (2,5-diphenyloxazole), 100 mg of POPOP (1,4-bis-2-(5-phenyloxazole)benzene)/*l* of toluene) and 5 cc of methyl alcohol and then counted in a Packard 314 EX-type liquid scintillation spectrometer assembly. A liquid scintillant solution of ^{14}C-labeled benzoic acid (with a specific activity of 3200 dpm/mg) was used as the internal standard for the determination of the counting efficiency.

Results

An ammonia solution of ^{14}C-labeled benzoic acid was irradiated with ^{60}Co γ-rays, and the amount of remaining benzoic acid and the presence of the three mono-aminobenzoic acids and 2,2'-biphenyldicarboxylic acid in the irradiated solution were confirmed by a radioactive-tracer technique. The yield and the G value of each reaction product obtained are summarized in Table 1.

Table 1. Products in γ-radiolysis of ammonia solution of benzoic acid

o-Hydroxybenzoic acid	$(3.22\pm0.08)\times10^{-6}$	0.26	0.029
m-Hydroxybenzoic acid	$(3.67\pm0.03)\times10^{-6}$	0.30	0.033
p-Hydroxybenzoic acid	$(4.42\pm0.14)\times10^{-6}$	0.36	0.040

Dose, 4.4×10^{20} eV/g, dose rate, 6.7×10^{17} eV/g/min.
Irradiation temperature, 0°C.

The remaining benzoic acid in the irradiated solution, 1.11×10^{-3} mol was recovered. This corresponds to 90.4 per cent of the initial amounts of the acid. Consequently, the amount of the total reaction of benzoic acid is 1.18×10^{-4} mol and the G value of the disappearance of the acid, shown as −benzoic acid in Table 1, is calculated to be 1.46. The G value of 1.46 is smaller than that obtained in the case of an aqueous solution of benzoic acid.[7] The G value for mono-aminobenzoic acids were: *ortho*, 0.016; *meta*, 0.022; and *para*, 0.027. The total G value is 0.065, only about a quarter of that of the mono-hydroxybenzoic acids obtained in an aqueous solution.

When the irradiation of an aqueous ammonia solution of benzoic acid was carried out at an absorbed dose of 4.4×10^{20} eV/g, isomers of mono-aminobenzoic acids and of mono-hydroxybenzoic acids were observed as products. The yields are given in Table 2. The total yield of mono-aminobenzoic acids was about 4.5×10^{-6} mol, while that of mono-hydroxybenzoic acids was about 1.1×10^{-5} mol. Therefore, the ratio of mono-aminobenzoic acid to mono-hydroxybenzoic acids is about 1 : 2.4.

From Table 2, the G value of mono-aminobenzoic acids in an aqueous ammonia solution can be seen to be 0.041. In spite of the low G value of mono-aminobenzoic acids in an aqueous ammonia solution, the G value ratio, calculated to be 0.65 : 0.76 : 1 for *o*- : *m*- : *p*-isomers, agrees fairly well with that of 0.59 : 0.81 : 1 in an ammonia solution. The total G value of the mono-hydroxybenzoic acids was 0.10. Although this value is less than a half of that obtained in an aqueous solution, the *o*- : *m*- : *p*-isomer ratio, 0.73 : 0.83 : 1, was similar to that, 0.72 : 0.84 : 1, obtained in an aqueous solution.[7]

Discussion

When an ammonia or aqueous ammonia solution of benzoic acid is subjected to irradiation with ionizing radiation, there is the possibility of some reactions in addition to the amination of the acid. The decarboxylation of ^{14}C-labeled benzoate occurred during the irradiation of a dilute, aerated aqueous solution by ^{60}Co γ-rays.[8,9] Therefore, it may be assumed that a similar decarboxylation occurs in the irradiation of an ammonia solution of benzoic acid. However, no carbon dioxide was measured in this work.

In the γ-radiolysis of an aqueous benzoic acid solution, the ratio of the mono-hydroxybenzoic

acids to biphenyldicarboxylic acids produced was about 1 : 3.[7] However, in the γ-radiolysis of an ammonia solution of benzoic acid, the G value of 2,2'-biphenyldicarboxylic acid, the most abundant isomer in an aqueous solution, was smaller than that of any isomer of mono-aminobenzoic acids shown in Table 1. The reason for this is not obvious. When an aqueous solution of *p*-aminobenzoic acid was irradiated with X-rays, 3-hydroxy-4-aminobenzoic acid was observed as the main product, while *p*-hydroxybenzoic acid and aniline were also produced in trace amounts.[10] Therefore, as the production of mono-aminobenzoic acids increases, the similar reaction of the acids will gradually increase in ammonia and aqueous ammonia solutions.

In order to understand the amination reaction of the aromatic nucleus of benzoic acid in the γ-radiolysis of ammonia solutions, consideration must be given to the possibility that the reaction products of the acid with reactive species produced in the γ-radiolysis of ammonia might give aminobenzoic acids. When the pulse radiolysis of an alkaline solution of benzoic acid was carried out using a 15 MeV electron pulse, the acid readily reacted with the hydrated electron produced by the irradiation.[11,12] Nitrobenzene, in which the nitro group has the *meta*-directional effect, also reacted readily with the hydrated electron.[13,14] The hydrated electron scavengers have little or no effect on the yield of *o*-nitrophenol produced in the γ-radiolysis of an aqueous nitrobenzene solution.[15] This means that the product of the electron-nitrobenzene reaction is not a precursor of nitrophenols. Therefore, it may be assumed that there is little possibility of the reaction product of benzoic acid with the solvated electron giving aminobenzoic acids when an ammonia solution is irradiated with ^{60}Co γ-rays.

One of several methods for obtaining information on the attacking reagent involved in a radiation-induced amination reaction is to study the partial rate factors for amination in the nucleus of benzoic acid. It has been evident[16] that, in the further substitution reaction of the mono-substituted benzene derivatives, C_6H_5X, in which the substitutent X is assigned to a $-E$ effect such as that of the carboxyl group, if the entering substituent is an electrophilic heterolytic reagent (*e.g.*, NO_2^+) the partial rate factor at the *meta*-positions with respect to the substituent already present is larger than that at the *ortho*- and *para*-positions. On the other hand, if the mono-substituted benzenes are attacked by a homolytic reagent such as the phenyl radical, a large partial rate factor is obtained at the *ortho*- and *para*-positions rather than at the *meta*-positions. Therefore, a comparison of the partial rate factors will offer information about the attacking reagent participating in the substitution reaction.

When an ammonia solution of benzoic acid was irradiated at the absorbed dose of 1.9×10^{20} eV/g, the amounts of mono-aminobenzoic acids were: *ortho*, 1.31×10^{-6} mol (0.11 per cent of the theoretical amount); *meta*, 1.74×10^{-6} mol (0.14 per cent); *para*, 2.18×10^{-6} mol (0.18 per cent). Unfortunately, the partial rate factor itself for the amination reaction at each nuclear position of benzoic acid can not be obtained from these values. However, in the mono-substituted benzene, C_6H_5X, the partial rate factors at *o*-, *m*-, and *p*-positions with regard to the substituent X are given by the three following expressions respectively:

$$ {}^{X}_{H}k_o = 6\cdot{}^{X}_{H}K\cdot(o)/2 $$
$$ {}^{X}_{H}k_m = 6\cdot{}^{X}_{H}K\cdot(m)/2 $$
$$ {}^{X}_{H}k_p = 6\cdot{}^{X}_{H}K\cdot(p) $$

where (o), (m), and (p) represent the yield of the respective isomers of the reaction products. Therefore, it is possible to use the yield of mono-aminobenzoic acids as a measure of the partial rate factor of the amination reaction at any position in the aromatic nucleus of benzoic acid, if the isomeric distribution accurately reflects the extent of attack by the reagent on the three different positions of benzoic acid. In the case of a radiation-induced reaction, it is preferable to use the G value, used as a measure of the radiation-chemical yields, rather than chemical yields of products. Then, using the G value thus obtained, the relative partial rate factors were calculated to be 0.008, 0.011, and 0.027 for $(o)/2$, $(m)/2$, and (p) in an ammonia solution, as is shown in Table 3. The relative partial rate factor at the *para*-position was larger than that at the *meta*-position. This result demonstrates that the attacking species in amination is uncharged.

Yoshida, Matsumoto, and Oda[17] have reported on the amination of benzoic acid using the hydroxylamine-ferrous ion, which is well known as an aminating reagent with the amino radical. The values they obtained are also presented in Table 3 for the sake of comparison. In this amination, if an aqueous solution of hydroxylamine-ferrous

*2 See Ref. 17.

ion was used, 52 per cent of the aminobenzoic acids produced were poly-aminobenzoic acids. On the other hand, if the solvent was 96 per cent sulfuric acid, the poly-aminobenzoic acids composed only 0.9 per cent of the aminobenzoic acids. In spite of this difference in the ratio of poly-aminobenzoic acids to aminobenzoic acids, the large relative partial rate factor was obtained at the *para*-position rather than at the *meta*-position in both cases. It is also clear from Table 3 that the ratio of the relative partial rate factor obtained in the γ-radiolysis of an ammonia solution agrees fairly well with that obtained in amination using the hydroxylamine-ferrous ion.

The reaction rate constants of the hydroxyl radical with the substituted benzenes, C_6H_5Y, are larger than those of the hydroxyl radical with benzene, regardless of Y substituent, if the Y substituent is an electron-donating group.[18] Therefore, it may be assumed that the amination of mono-aminobenzoic acids is easier than that of benzoic acid in the γ-radiolysis of an ammonia solution. When the irradiation of an aqueous benzoic acid solution was carried out, di-hydroxybenzoic acids composed about 15 per cent of the mono-hydroxybenzoic acids, even under conditions favorable for hydroxylation.[7] Accordingly, it is reasonable to presume that there is little formation of poly-aminobenzoic acids in the range of the irradiation. No poly-aminobenzoic acids were measured, so the results obtained cannot be used as an accurate measure of the partial rate factors in the amination reaction. However, it can be deduced from the ratios of the relative partial rate factors summarized in Table 3 that the attacking reagent concerned in the amination reaction during the irradiation of an ammonia solution of benzoic acid is the amino radical.

Returning now to the irradiation of an aqueous ammonia solution of benzoic acid, a lower *G* value of aminobenzoic acids was obtained than that in an ammonia solution. In an aqueous solution of ammonia, the ammonia molecule and the water molecule are attracted to each other by the hydrogen bond, which is roughly 5 per cent of the energy of a covalent bond.[19] Since the energy of activation of such a bond is small, the bond forms and breaks with ease at ordinary temperatures. In a 0.1 molar solution of ammonia, only about a half of the ammonia molecules are hydrated, and although it is possible to isolate two stable crystalline hydrates, $NH_3 \cdot H_2O$ and $(NH_3)_2 \cdot H_2O$, at low temperatures, there is no evidence that undissociated NH_4OH is present.[20] Therefore, it may be assumed that the amount of energy absorbed in each component in an aqueous solution of ammonia is proportional to the total number of electrons in each component when such a solution is irradiated with ^{60}Co γ-rays. Now, by assuming that only ammonia is involved in the formation of aminobenzoic acids in such a solution, the amount of the acids should be related to the amount of energy absorbed in ammonia in the mixture. The determination of the *G* values of hydroxybenzoic acids was also performed in the same manner by assuming that only water is involved in the formation of the acids. The *G* values calculated were 0.021, 0.026, and 0.033 for *o*-, *m*-, and *p*-aminobenzoic acids and 0.060, 0.069, and 0.083 for *o*-, *m*-, and *p*-hydroxybenzoic acids, respectively.

The total *G* value of the aminobenzoic acids was calculated to be 0.080. This value is about 23 per cent larger than that obtained in an ammonia solution. These two *G* values should be in accord with each other provided there is no interaction between the ammonia and water involved in the reaction. The above difference in *G* value, therefore, suggests that there is some interaction between ammonia and water in such a mixture. This suggestion is supported by the enhancement of hydrazine in the γ-radiolysis of an aqueous solution of ammonia.[21] From the proton affinity[22] for ammonia, the proton transfer to ammonia may be expected to occur. If the neutralization of the produced NH_4^+ by solvated electrons were to

produce amino radicals,[23] some increase in the yields of aminobenzoic acids can be explained. On the other hand, the G value of hydroxybenzoic acids was calculated to be 0.212, slightly less than that obtained in an aqueous solution. Consequently, there might be the possibility of the following interaction:[24]

$$NH_3 + \cdot OH \rightarrow \cdot NH_2 + H_2O$$

If the amino radical is the attacking reagent participating in the amination reaction in an aqueous ammonia solution, the ratio of the relative partial rate factors may be in accord with that obtained in an ammonia solution. On the basis of the assumption that the amount of aminobenzoic acid is proportional to the amount of energy absorbed in ammonia in an aqueous ammonia solution, the relative partial rate factors, $(o)/2$, $(m)/2$ and (p), in such a solution were calculated to be 0.011, 0.013 and 0.033 respectively, as is shown in Table 3. The $(o)/2 : (m)/2 : /(p)$ ratio, 0.32 : 0.38 : 1, is in striking agreement with the ratio, 0.30 : 0.41 : 1, obtained in an ammonia solution. Therefore, it is possible to deduce that the attacking species involved in the amination reaction in an aqueous ammonia solution is also the amino radical.

The ratio of the G value of m-aminobenzoic acid to that of p-aminobenzoic acid was less than 2. This is attributable to some degree of electrophilic character of the amino radical.

The author wishes to thank Dr. G. Tsuchihashi, Sagami Chemical Research Center, for his valuable discussions, and Drs. A. Danno and K. Motojima for their encouragement throughout this work.

Reaction of *trans*-Stilbene with *n*-Butyllithium in Tetrahydrofuran

Yoshio OKAMOTO, Masahiko KATO and Heimei YUKI

Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka

(Received July 1, 1968)

The reaction of *trans*-stilbene with *n*-butyllithium was investigated in tetrahydrofuran at 0°C. The structures of the products fractionated by column chromatography were determined by elementary analysis, a molecular-weight determination, and a study of the IR, UV, and NMR spectra. The main products were 1,2-diphenylhexane, 1,2-diphenylethane, and 1,2,3-triphenylpropene which was formed by the cleavage of a C-C bond of a product. The reaction mixture showed an ESR signal. The observed results are explained in terms of the anionic copolymerization of *trans*-stilbene and styrene reported previously.

In a previous paper,[1] a study of the anionic copolymerization of styrene and *trans*-stilbene by *n*-butyllithium (*n*-BuLi) has been reported. The results have shown that in tetrahydrofuran (THF) a chain-transfer reaction to the *trans*-stilbene occurs, while in benzene the copolymerization proceeds without any chain-transfer. In the copolymerization, the color of the reaction mixture changes in time; it was followed spectrophotometrically.

The work reported here was carried out in order to clarify two points: the reaction mechanism of the chain-transfer and the change in the color in the copolymerization. Wyman and Altares[2] carried out the same reaction in benzene, but their results differ greatly from ours.

Experimental

Reagent. The preparations and purifications of *trans*-stilbene, *n*-BuLi, and THF were previously described.[1]

Reaction. The reaction was carried out under dry nitrogen in a glass ampoule equipped with a three-way stopcock. To a solution of *trans*-stilbene (10.0 g, 5.56×10^{-2} mol) in THF (250 m*l*), *n*-BuLi (2.83×10^{-2} mol) was added with a syringe over a three-minute period at 0°C. The color of the reaction mixture changed from red to purple in time. After 48 hr, the reaction was terminated by adding methanol (1.1 m*l*, 2.6×10^{-2} mol) until the color of the solution disappeared. The solvent was evaporated *in vacuo*, and then the residue was dissolved in diethyl ether. The ether solution was

2) D. P. Wyman and T. Altares, Jr., *Makromol. Chem.*, **72**, 68 (1964).

washed with water and dried over magnesium sulfate; then the ether was removed to give 11.6 g of an oily product.

Fractionation of Product. The fractionation of the above product was carried out by column chromatography with activated alumina, using *n*-hexane, benzene, and methanol as solvents.

Measurements. The measurements of the molecular weight, the elementary analysis, and the IR, UV, and NMR spectra were made according to methods reported previously.[1] The ESR spectrum was measured with a JES-3BX Spectrometer.

Results

Fractionation of Product. Before the fractionation of the reaction product by column chromatography, the product was submitted to sublimation in order to exclude any unchanged *trans*-stilbene. However, no *trans*-stilbene was recovered. The addition of *n*-hexane to the product gave no precipitate of *trans*-stilbene, which is almost insoluble in this solvent at 0°C. The results of the fractionation by column chromatography are shown in Table 1. Fraction 1, which is not shown in the table, was fractionated by subsequent chromatography, using *n*-hexane as a solvent, to give two fractions, 1A and 1B.

Characterization of Each Fraction. The results of the elementary analysis, the molecular weight, and the molecular formula of each fraction are listed in Table 1. The characteristics of the IR and UV spectra, and the ratio of the number of aromatic to that of aliphatic protons (H_{ar}/H_{al}) of the fraction are summarized in Table 2.

Compounds Formed in the Reaction Mixture. Table 3 shows the molecular formulae, the structural formulae, the results of the elementary analyses, the molecular weights, and the ratios of the number of aromatic to that of aliphatic protons (H_{ar}/H_{al}) of the compounds which may be supposed to be the reaction products on the basis of the results.

Structure of Each Fraction. *Fraction 1A.* This fraction was liquid; the results of its elementary analysis and its molecular weight and the molecular formula derived from them were most consistent with those of 1,2-diphenylhexane, Ia, in Table 3. In the NMR spectrum of the fraction 1A (Fig. 1), the chemical shifts of the Ph, $-CH(Ph)-CH_2Ph$, $-CH_2-$, and CH_3-protons, and the relative areas of the peaks, 10.0 : 2.9 : 6.1 : 3.0, also support the above structure. The IR spectrum showed the absence of a C=C double bond, as was also speculated on the basis of the UV spectrum.

Fraction 1B. The melting point of the fraction 1B was 50—52°C. Its molecular formula was similar to that of 1,2-diphenylethane, Ib, in Table 3, the melting point of which is 53°C.[3] The NMR spectrum of this fraction also completely agreed with that of the authentic sample. The NMR spectrum of the fraction 1 indicated that this fraction contained only Ia and Ib in a molar ratio of 3.3.

a) The ratio of the numbers of aromatic to aliphatic protons.

Fraction 2. The molecular formula of the fraction 2 was in best accord with 1,2,3-triphenylpropene, II, in Table 3. In the NMR spectra (Fig. 2), the peaks at 3.65 and 6.29 τ were assigned to the methine and methylene protons, respectively, of the *cis*-isomer, judging from the NMR spectra of *cis*- and *trans*-stilbene. The peak at 5.96 τ was assigned to the methylene protons of the *trans*-isomer, while the absorption of its methine proton might overlap with those of aromatic protons near 3 τ. The IR spectrum of the fraction 2 showed an absorption due to a three-substituted olefin at 870 cm^{-1}. A further separation of this fraction by column chromatography gave the *cis*-isomer as the initial fraction; its melting point was 61—62°C (lit.,[4] 62—63°C). The fraction eluted at the later stage of the chromatography was largely composed of the *trans*-isomer, but it always contained a small portion of the *cis*-isomer. In the UV spectra, the absorption maxima of *cis*- and *trans*-1,2,3-triphenylpropene appeared at 260 mμ (ε_{max} 14200) and 273 mμ (ε_{max} 16100) respectively. The molar ratio of the *trans*- to the *cis*-isomer was 1.9; this ratio was calculated from the relative strength of the corresponding absorptions in the NMR spectrum of the fraction 2.

Fraction 3. The molecular weight of the fraction 3 was 345. This rather large value indicates that a compound composed of at least two molecules of *trans*-stilbene must have been a component of this fraction. The sharp peak at 5.96 τ in the NMR spectrum (Fig. 3) suggests that the tailing of *trans*-1,2,3-triphenylpropene, which was present in the fraction 2, is incorporated into this fraction.

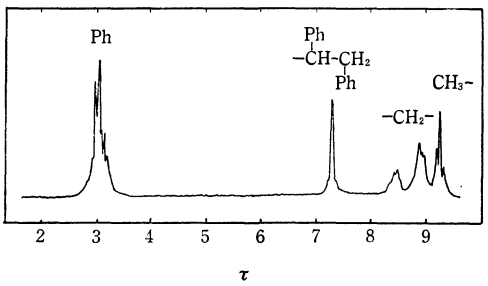

Fig. 1. NMR spectrum of fraction 1A.

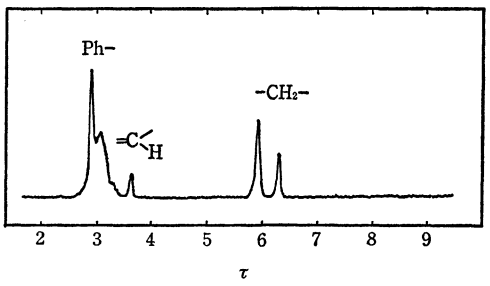

Fig. 2. NMR spectrum of fraction 2.

4) A. Orechoff, *Ber.*, **47**, 89 (1914).

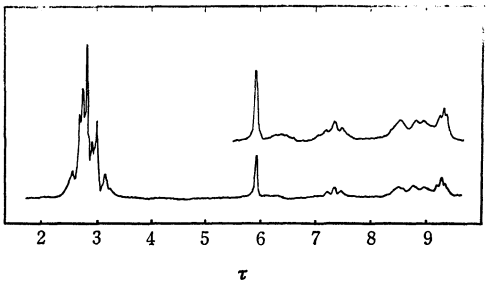

Fig. 3. NMR spectrum of fraction 3.

However, 1,2,3,4-tetraphenyloctane, III in Table 3, must be the main component of this fraction, judging from the absorption at 9.1 τ due to the methyl group and absorptions at 7.5—8.9 τ due to methylene and methine groups in the NMR spectrum, and judging from the molecular weight of this fraction.

This fraction also contained a small amount (about 100 mg) of a compound insoluble in petroleum ether at 0°C; this compound was identified as 1,2,3,4-tetraphenylbutane, V in Table 3. Its melting point was 181—183°C (lit.,[5] 182°C), and the observed H_{ar}/H_{al} ratio in the NMR spectrum was 3.5. Found: C, 92.76; H, 7.24%.

Fraction 4. Judging from the elementary analysis, this fraction consisted of a compound containing oxygen. The IR spectrum suggested the presence of an OH group by means of the strong absorption at 3300 cm^{-1}. Although the NMR spectrum was complicated, the H_{ar}/H_{al} ratio was 0.66. This small value means that there were more aliphatic protons than aromatic ones. The reaction of a carbanion with THF must have formed an alcohol containing the greater portion of the aliphatic protons. A compound such as IV in Table 3 may be proposed as one of the alcohols.

Yields of Product Compounds. The yields of the product compounds identified were calculated from the NMR spectrum of the unfractionated mixture and from the weights of the compounds fractionated by column chromatography. The results are shown in Table 4. The yields of 1,2,3-triphenylpropene (II) and 1,2-diphenylethane (Ib), after reactions of 25 and 180 min carried out under the same conditions as those shown in the Experimental section, were obtained by means of the NMR spectra of the respective reaction mixtures, as are shown in Table 4. The ratios of 1,2,3-triphenylpropene to 1,2-diphenylethane were about 2, regardless of the reaction time.

Table 4. Yields of product compounds[a]
Reaction condition: [Stilbene]/[*n*-BuLi]=2.0, in THF, at 0°C

5) D. P. Wyman, *J. Org. Chem.*, **27**, 3712 (1962).

Electronic Spectrum of Reaction Mixture. The electronic spectra of the reaction mixtures of *trans*-stilbene and *n*-BuLi in THF at room temperature are shown in Fig. 4. In the reaction of *trans*-stilbene with an excess of *n*-BuLi, the spectrum showed a peak at 332 mμ which was stable for a prolonged time and might be based on a benzyl-type anion, $C_4H_9CH(Ph)-CH(Ph)^-Li^+$. On the other hand, when the molar ratio of *trans*-stilbene to *n*-BuLi was 6.2, new peaks appeared at 555 and 420 mμ in time. When *n*-BuLi was added to the solution of 1,2,3-triphenylpropene in THF, the

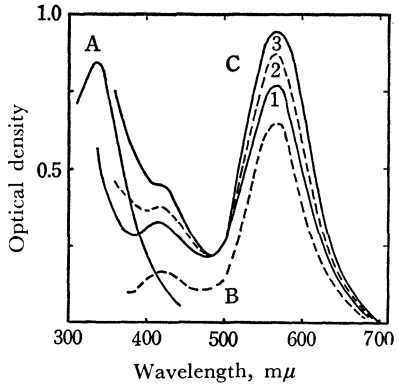

Fig. 4. Electronic spectrum of reaction mixture.
A: [Stilbene]/[*n*-BuLi]=0.25
B: 1,2,3-Triphenylpropene+*n*-BuLi (1 : 1)
C: [Stilbene]/[*n*-BuLi]=6.2
Time: (1) 46 min, (2) 1.4 hr, (3) 2.4 hr

peaks at 555 and 420 mμ appeared instantaneously in the UV spectrum of the solution. Then, 1,2,3-triphenylpropene-3-d_1, was recovered by terminating the reaction with deuterium oxide. This was confirmed by a study of the NMR spectrum.

ESR Spectrum of Reaction Mixture. The ESR spectrum of the reaction mixture in THF was

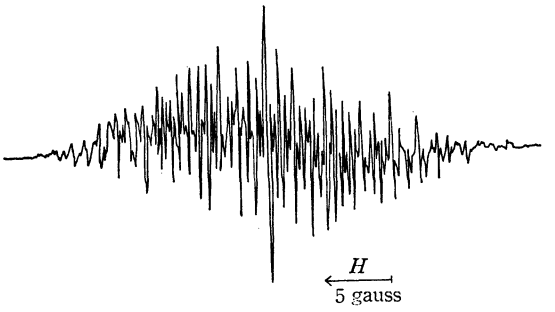

Fig. 5. ESR spectrum of reaction mixture.
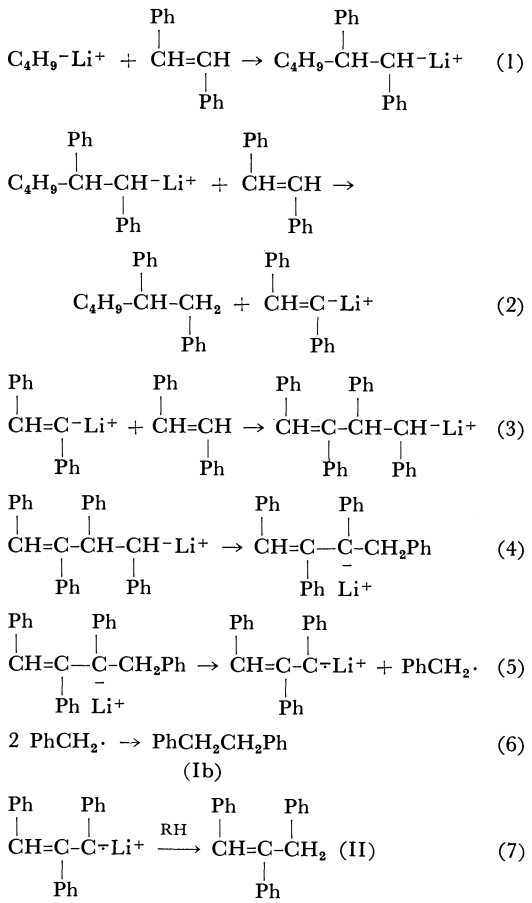
[Stilbene]/[*n*-BuLi]=2.0, temp.: room temp.

measured at room temperature, the molar ratio of *trans*-stilbene to *n*-BuLi being 2.0. The spectrum is shown in Fig. 5. In the reaction of 1,2,3-triphenylpropene with *n*-BuLi in THF, however, no ESR signal was observed.

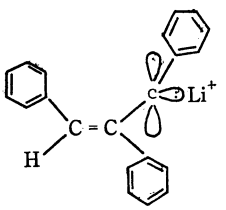
Discussion

The compounds identified as the main products were 1,2-diphenylhexane (Ia), 1,2-diphenylethane (Ib), and 1,2,3-triphenylpropene (II). It is noteworthy that no *trans*-stilbene was recovered and that 1,2-diphenylethane and 1,2,3-triphenylpropene were obtained instead. The mechanisms of the formations of these two compounds cannot be explained by simple addition or abstraction reactions of carbanions. The 1,2,3-triphenylpropene can be produced only by the cleavage of a C–C bond because there is no compound with odd carbons in the starting materials. The molar ratio of the yield of 1,2,3-triphenylpropene to 1,2-diphenylethane was two, regardless of the reaction time; this suggests that the formations of these compounds are interrelated. The following processes (1)—(7) constitute our proposed mechanisms for the production of the above compounds.

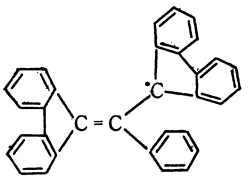


The total product yield indicates that the process (1), which is an addition reaction of *n*-BuLi to *trans*-stilbene, takes place easily. As may be seen from the electronic spectrum of the reaction mixture, the benzyl-type anion formed in the process (1) is stable, if no excess *trans*-stilbene is present. However, the acidity of the methine protons of *trans*-stilbene is rather strong, as is shown by the isomerization of *cis*-stilbene to the *trans*-isomer by a base such as potassium *t*-butoxide.[6] Therefore, if excess *trans*-stilbene is present, the process (2) will occur. This process must be a chain-transfer reaction in the copolymerization of *trans*-stilbene and styrene.[1]

The new anion produced in the process (2) reacts with *trans*-stilbene to give a dimer anion, which may accompany the cleavage of a C–C bond with the production of the benzyl radical and the 1,2,3-triphenylpropenyl radical anion (the process (5)), *via* a proton shift reaction in the process (4). This radical anion may be of new type. The structure of the 1,2,3-triphenylpropenyl radical anion may be represented as shown by RA-II. This radical anion, if present, can be greatly stabilized by the delocalization of an electron on the benzene rings. It has been established that the 1,3-bis(diphenyl)-2-phenylallyl radical, with a similar structure to that of RA-II, is very stable even in air.[7]



(RA-II)



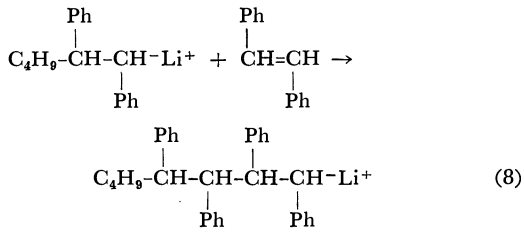
(1,3-Bis(diphenylene)-2-phenylallyl radical)

The reaction mixture of *trans*-stilbene and *n*-BuLi showed an ESR signal (Fig. 5). This might be because of the mono lithium-adduct of *trans*-stilbene. However, no absorption maximum at 480 mμ (ε_{max} 62000)[8] due to the adduct in THF could be observed in the electronic spectrum of the reaction mixture (Fig. 4). The hyperfine structure of the ESR spectrum observed herein suggests the presence of a radical with a rather complicated structure, although it is not certain at present whether or not the ESR signal is due to the radical anion, RA-II. The coupling of benzyl radicals gives 1,2-diphenylethane, as is shown in the process (6).

Although the yield was rather low, 1,2,3,4-tetraphenyloctane was also obtained. This means

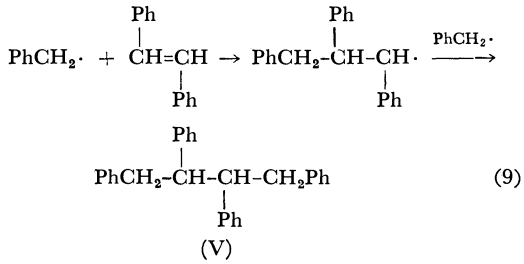
6) D. H. Hunter and D. J. Cram, *J. Am. Chem. Soc.*, **88**, 5765 (1966).
7) W. O. Hamilton and G. E. Pake, *J. Chem. Phys.*, **39**, 2694 (1963).
8) E. R. Zabolotny and J. F. Garst, *J. Am. Chem. Soc.*, **86**, 1645 (1964).

that a stilbene anion can add to *trans*-stilbene to give a dimer, even if the reaction is very slow (the process (8)).



(8)

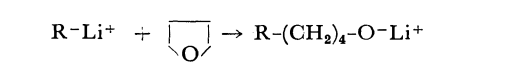
The formation of a small amount of 1,2,3,4-tetraphenylbutane can be explained by the following process:



(9)

(V)

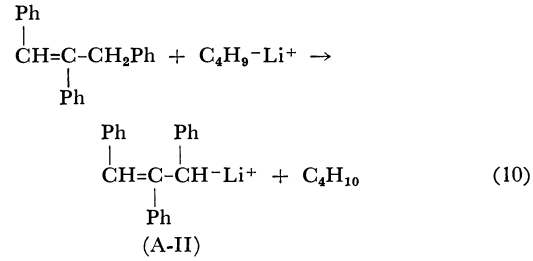
The carbinol in the fraction 4 may be produced through the following process:[9,10]



Judging from the yield of each compound obtained in this experiment, *n*-BuLi is considered to be consumed almost quantitatively in the process (1); about 49% of the 1,2-diphenylhexyl anions produced in the process reacted with *trans*-stilbene to give 1,2-diphenylhexane, 1,2,3-triphenylpropene, and 1,2-diphenylethane. About 10% of the 1,2-diphenylhexyl anions were apparently consumed in the formation of 1,2,3,4-tetraphenyloctane, while about 20% of the anions remained free from the subsequent reactions. The residual 1,2-diphenylhexyl anions and also probably a part of the 1,2,3,4-tetraphenyloctyl anions reacted with THF to yield alcohols. The absence of 1,2,3,4-tetraphenylbutene indicates that the anions produced in the processes (3) and (4) are rather unstable.

The reaction mixtures both of *trans*-stilbene with *n*-BuLi and of 1,2,3-triphenylpropene with *n*-BuLi showed the same absorption maxima, at 555 and 420 mμ. It is likely that the A-II anion, which may be produced from RA-II by the abstraction of a hydrogen from any material in the system, will be present in the reaction mixture of *trans*-stilbene and *n*-BuLi. It may be supposed that the radical anion, RA-II, shows the same absorption maxima, at 555 and 420 mμ.

The reaction of 1,2,3-triphenylpropene with *n*-BuLi proceeds as follows:

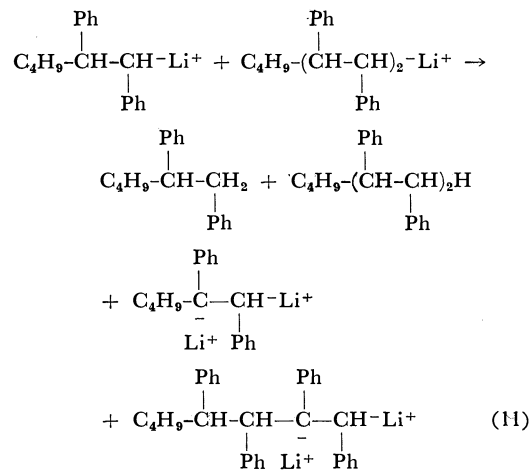


(10)

(A-II)

since the 1,2,3-triphenylpropene with a deuterium at the methylene position is recovered when the reaction is terminated by deuterium oxide.

A distinct solvent effect exists in the reaction of *trans*-stilbene and *n*-BuLi. Wyman and Altares[2] have studied the reaction of *trans*-stilbene and *n*-BuLi in benzene at 60°C. Contrary to the reaction in THF, the main process (11) was found to follow the processes (1) and (8), thus giving the dianions shown below.



(11)

The results obtained in the present study establish that the chain-transfer in the copolymerization of *trans*-stilbene and styrene occurs by means of the abstraction of a proton from the *trans*-stilbene, as is shown by the process (2), and that the change in the color observed in the copolymerization is associated with the 1,2,3-triphenylpropenyl anion or the radical anion.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 766—772 (1969)

Photo-Aryl Coupling and Related Reactions. II. The Formation of Triphenylenes from Halogeno-*o*-terphenyls[1]

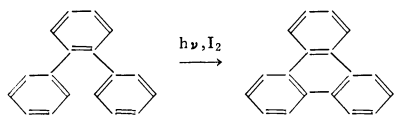
Takeo SATO, Shigeru SHIMADA and Kazuo HATA

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya, Tokyo

(Received July 9, 1968)

Electronic effects on the photochemical conversion of *o*-terphenyl to triphenylene were examined by comparing the ultraviolet irraiation reaction, carried out in a benzene solution using iodine as an oxidant, of three classes of *o*-terphenyl derivatives, 4- (**3**) and 4'-substituted (**4**) and 4,4''-disubstituted derivatives (**5**). While a strong electron-withdrawing group such as nitro group, hindered the cyclization reaction to occur, methoxy, fluoro, chloro and bromo compounds afforded the corresponding triphenylene derivatives. With bromo and iodo compounds, however, a complex mixture of the products resulted due to photochemical cleavage of a carbon-halogen bonding, which led to the formation of phenylation products and hence phenyltriphenylenes together with reduction products. Further, with iodo compounds, it was found that no oxidant was necessary to effect the cyclodehydrogenation reaction since iodine was liberated during the photolysis. Possible pathways for the formation of the photolysis products from bromo and iodo compounds were discussed in relation to the relative rates of carbon-halogen cleavage and cyclization reactions. Comparison among three classes of halogeno compounds indicated that, with the exception of iodides, the cyclization reaction occurred more readily with type **4** compound than type **3** compounds, while type **5** compounds reacted only with difficulty.

Recently, we have developed[2] an efficient, quite simple method for the preparation of triphenylene (**2**) employing a photo-aryl coupling reaction of *o*-terphenyl (**1**). By this procedure **2** was obtainable in an optimum yield of 88%. A similar observation has also been announced, in the form of a preliminary account, by Kharasch and co-workers.[3]



1 **2**

This cyclodehydrogenation reaction, induced by iodine, is regarded as an extention of thoroughly studied *cis*-stilbene - phenanthrene reactions,[4] representing a special case where the central unsaturated linkage of *cis*-stilbene is incorporated into an aromatic system. Mallory and co-workers,[5] during their extensive studies on the photochemistry of stilbenes, have been the first to irradiate **1** but to obtain negative results. Failure could be ascribed, in addition to the problem of a light source, to the choice of cyclohexane as a solvent, since the reaction had been shown to be much slower in this solvent[2] than in benzene in contrast to the *cis*-stilbene case where both solvents are equally suited.

Besides this solvent effect, it has been found[2] that oxygen is ineffective to bring about the cyclization reaction of **1**, thus showing a marked contrast again with the *cis*-stilbene case where iodine, oxygen or preferably a combination of these are employed as the oxidant.

In this paper, electronic effects on the photo-aryl coupling reaction were examined by choosing three representative classes of compounds **3**—**5**. Types **3** and **4** compounds are assumed to give the same product, 2-substituted triphenylene (**6**), whereas

a) Lit. 105—106°C,[6] 115.5—116.5°C.[7]
b) Lit. (D. H. Hey, M. J. Perkins and G. H. Williams, *J. Chem. Soc.*, **1961**, 749) 159.5—160.5°C.
c) Prepared by the direct bromination of *o*-terphenyl. Formerly, Woods and Scotti[25] prepared the compound from 2-phenyl-2-cyclohexane by the Grignard reaction (reported mp 89—90.5°C).
d) Lit. 118—119°C.[8] Allen and Burness[7] obtained the compound as a by-product on nitration of *o*-terphenyl, but did not determine the position of the nitro group (reported mp 119.5°C).
e) Lit. 218°C.[6]
f) Lit. 170°C.[6] Since 4,4',4''-tribromo derivative[6] also had a similar mp (170°C), the structure was confirmed by elemental analysis.
g) Lit. 182—184°C.[25]
h) Values for nitrogen.

3,6-disubstituted triphenylene (**8**) may be obtained from **5**. In view of difficulties in preparing triphenylene derivatives possessing a definite structure either by ring construction or by substitution method, the present attempt was designed to provide useful synthetic means for them.

o-Terphenyl derivatives used for the photochemical studies are listed in Table 1. Except for bromides (**3**, **5**/Br),*1 which were obtained by the vapor phase bromination[6] of **1**, other types **3** and **5** compounds were prepared by the diazo reaction of amines (**3**,**5**/NH_2).[6,7] 4'-Nitro-[8] and 4'-bromo-*o*-terphenyls (**4**/NO_2, Br) were prepared by the decomposition of 5-substituted 2-(*N*-nitrosoacetamido)biphenyls in benzene solutions.

The ultraviolet irradiation reactions were performed with a 1-kW high-pressure mercury arc lamp housed in a water bucket, into which a sample solution in a quartz tube was immersed. A typical example is illustrated by the case of fluoride (**3**/F): A dilute benzene solution, 1.67×10^{-2} M, containing an equimolar quantity of iodine was irradiated for 96 hr under nitrogen atmosphere. By column chromatography on alumina, there was obtained a 77% yield of 2-fluorotriphenylene (**6**/F).[9] Structural proof was achieved by UV, IR and analytical data. The results of the photochemical reactions are summarized in Table 2. Physical properties and UV data of the triphenylene derivatives are compiled in Table 3.

Whereas chloride (**3**/Cl) reacted similarly to the fluoride to give a 45% yield of 2-chlorotriphenylene (**6**/Cl), bromide (**3**/Br) was found to afford a complex mixture of the products, consisting of starting material (18%), triphenylene (**2**, 6%), 2-bromotriphenylene (**6**/Br, 26%)[10] and 2-phenyltriphenylene (**7**, 28%)[11] listed in the order of elution from alumina column (Exp. 4).

The photolytic cleavage of a carbon-halogen bond is also responsible for the formation of **2** and **7** from iodide (**3**/I). Total triphenylene fraction

a) Unless otherwise stated, the photochemical reactions in a benzene solution (60 ml) were carried out in a quartz cell using a 1-kW high-pressure mercury lamp under a nitrogen atmosphere.
b) The reaction was carried out under oxygen.
c) Carried out in cyclohexane.
d) Carried out in toluene.
e) Other products are shown in the schemes in the text.
f) Less amount of benzene was used to adjust the concentration to 1.67×10^{-2} M.
g) Infrared spectrum of the product was completely superimposable with that of the starting material.

(**2** plus **7**) amounted to 81% even with shorter irradiation period compared with other halides (Exp. 6). The cleavage of the carbon-iodine bond was so extensive that only isolable iodo compound was a small amount of starting material and no 2-iodotriphenylene (**6**/I) was detected.

The extensive cleavage of the carbon-iodine bond suggested that the liberated iodine might serve as an oxidant to induce the oxidative aryl coupling reaction. That this was indeed the case was confirmed by the experiments carried out in the absence of iodine (Exp. 7—10). The reaction proceeded similarly with irradiation under oxygen (Exp. 7), which itself was ineffective as an oxidant to bring about the cyclization.[2] In contrast, no cyclization occurred when bromides (**3**, **4**/Br) were irradiated in the absence of iodine (Exp. 5, 15).

Although the studies on the photolysis of iodoaromatic compounds date back to 1924 when Job and Emschwiller[12] investigated bond strength of a carbon-iodine bonding, the mechanistic aspects and synthetic applicability have been explored only quite recently.[13] Lately, intermolecular as well as intramolecular aryl coupling reactions induced by the photolysis of iodoaromatics have found wide application not only for the formation of polyphenyls and phenanthrenes but also for the complex natural product[14] and heterocyclic compounds.[15-17]

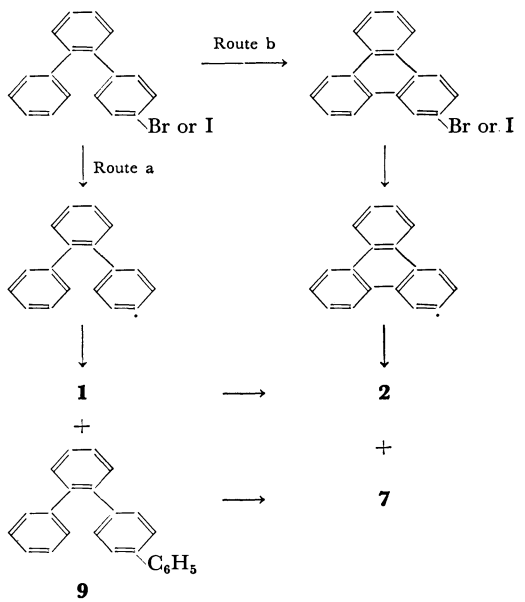
These arylation reactions are assumed[13] to be initiated by the formation of an aryl radical which attacks a benzene nucleus to give an arylcyclohexadienyl radical, dehydrogenation of which with iodine then terminates the reaction. The formation of phenylation products from halogeno-*o*-terphenyls may follow similar steps.

As more closely related studies, Kampmeier and Hoffmeister[18] have shown that the photolysis of 1,2-diiodobenzene in a benzene solution leads to the formation of a small amount of **2** (4% after 175 hr). Similarly irradiation of 2-iodobiphenyl for 60 hr also led to **2** in a small yield.[13,18] The cyclization step leading to **2** and **7** in the present cases would be similar with these.

There are two routes which may account for the formation of **2** and **7**, namely routes a and b:

Route a is initiated by the homolysis of a carbon-halogen bond to give *o*-terphenyl radical, which, *via* *o*-terphenyl (**1**) and 1,1′ : 2′,1″ : 4″,1‴-quaterphenyl (**9**),[3] cyclizes to **2** and **7**. In the alternative route b, cyclization reaction occurs first to afford 2-halogenotriphenylenes (**6**), which then loses a halogen atom by the homolytic cleavage.



18) J. A. Kampmeier and E. Hoffmeister, *J. Am. Chem. Soc.*, **84**, 3788 (1962).

Hydrogen abstraction and phenylation of triphenylene radical thus formed yield **2** and **7**. Whether a given halogeno-*o*-terphenyl decays after either the two competitive routes a or b is determined by the bond energies of the carbon-halogen linkage and the rate of aryl coupling reaction.

The fact that the ease with which the cyclization occurs is related to the electron density on the terminal benzene rings is illustrated by the extreme cases of three nitro derivatives (**3**—**5**/NO_2), which have been recovered unchanged even after 77—96 hr irradiation (Exp. 1, 13, 17). The results could be compared with a facile reaction of methoxy derivative (**3**/OCH_3), which afforded the expected 2-methoxytriphenylene (**6**/OCH_3) in a 65% yield together with a small amount of triphenylene[19] (Exp. 12). This electronic effect is assumed to be operated among halides **3**, although in a less degree. Another factor, carbon-halogen bond cleavage, however, becomes important only with bromides[23,24] and especially with iodides.[13]

Bond energy considerations favor route a over route b, since a halogen atom is more firmly attached to the resonance-stabilized triphenylene ring than to *o*-terphenyl moiety. Evidence indicated that **2** and **7** arose *via* route a were obtained in the following manner: i) 2-Bromotriphenylene (**6**/Br), the intermediate for route b, was shown to be quite stable (Exp. 23, 24). ii) Obviously, the cyclization of iodide (**3**/I) in the absence of iodine requires the carbon-iodine cleavage as the initial reaction. Further, the fact that the efficiency of the cyclization of the iodide was comparable to **1** itself and was much more rapid than other halides, suggested the loss of iodine in an earlier stage of the reaction.

These results showed that, whereas bromide (**3**/Br) decayed in both ways, the ratio of route a and route b in 3 : 4, iodide (**3**/I) followed most probably after route a and that the cleavage of the carbon-iodine bond ocurred much more rapidly than the cyclization reaction. Comparing between isomeric bromides (**3**, **4**/Br), 4-isomer afforded **6**/Br in a higher yield (66% compared with 26%) even with shorter reaction time (Exp. 4 *vs.* 14).

The reactions in cyclohexane or toluene afforded a reduction product. Thus *o*-terphenyl was isolated in a 36—37% yield by the irradiation of iodide (**3**/I) in a cyclohexane solution (Exp. 8, 9), in which the photo-aryl coupling reaction proceeds more slowly than in benzene (Exp. 10). The photolysis in toluene also afforded a 37% yield of **1** (Exp. 11). Similarly **1** was obtainable in a 20% yield by the irradiation of bromide (**4**/Br) in cyclohexane (Exp. 16).

Ultraviolet irradiation of dihalides (**5**/Cl, Br) revealed that the reactions were even difficult compared with monohalides as evidenced by the higher rates in the starting material recovery (Exp. 18, 19, 20, 21). Dichloride (**5**/Cl) afforded only a trace amount of **8**/Cl, which was characterized by the mass spectrum (parent peak had *m/e* 296).

If the cleavage of a carbon-halogen bond is to occur as above, then, a complex mixture of the products would be expected from the dihalides **5**. The replacement of the halogen atom by a hydrogen or phenyl group would give rise to five *o*-terphenyl structures. They include those *o*-terphenyls **1**, **3**, and **9** of which cyclization and transformation products would be similar to those of the monohalides. New types of *o*-terphenyl derivatives are 4-halogeno-4''-phenyl-*o*-terphenyl (such as **10** and **12**) and 1,1' : 4',1'' : 2'',1''' : 4''',1''''-quinquephenyl (**13**).[25]

Chromatography on alumina of the reaction mixture obtained from dibromide (**5**/Br) afforded four compounds (Exp. 21), among which the starting material was shown to be present in the largest amount (35%). Other compounds, identified by IR, UV and analytical data, were shown in the accompanying scheme (in the order of elution from the column). Diiodide (**5**/I) afforded five compounds which were separated by column chromatography on alumina (Exp. 22). Small amounts of the starting material (1%) and monoiodide (**3**/I, 1%) were eluted first, followed by three compounds as were shown in the scheme. When the reaction was further continued for 7 days, iodo compounds were found to be completely transformed into phenylation and reduction products. Thus only three hydrocarbons were isolated; they were 32% of the quinquephenyl (**13**), 5% of 2-phenyltriphenylene (**7**) and 37% of 3,6-diphenyltriphenylene (**14**). By an independent experiment, the irradiation of **13**, in the presence of iodine, was shown to yield **14** (9% after 92 hr). All the compounds had IR and UV spectra consistent with the assigned structures. Spectral

19) The formation of triphenylene was clearly demonstrated by gas chromatography. It could possibly be formed by carbon-oxygen cleavage of either **3**/OCH_3 or **6**/OCH_3. A small amount of phenolic material was also detected. Photolytic cleavage of ether linkage was noticed by several authors.[20-22] As another model compound having electron-releasing group 4-acetamido-*o*-terphenyl (**3**/$NHCOCH_3$) was irradiated, but soon after the start of the reaction, the compound began to separate out on the wall of the vessel and the reaction had to be discontinued.

data and analytical figures are compiled in Tables 1 and 3. The formation of **13** and **14** suggested the potential utility of the present method for the synthesis of polyphenyls and their condensation products, such as phenyltriphenylenes.[26]

Of the triphenylene derivatives here obtained, the UV spectra of 2-fluoro- (**6**/F)[8] and 2-phenyltriphenylenes (**7**)[11] were recorded previously. Triphenylene and its derivatives usually display up to ten absorption bands (or shoulders) in the UV region. Slight bathochromic shifts, amounting 2—3 mμ, of each bands occurred with chloride (**6**/Cl) and bromide (**6**/Br) compared with the fluoride. 3,6-Dibromotriphenylene (**8**) showed a quite similar spectrum with the monohalides with slightly more bathochromic shifts (3—6 mμ from **6**/F). Attachment of a phenyl group simplified the spectrum enormously; thus only one peak at 268 mμ, together with three shoulders, were observed for **7**. Similarly, the absorption curves for 3-bromo-6-phenyl- (**11**) and 3,6-diphenyltriphenylenes (**14**) were similar to that of **7**, except that the absorption maximum was shifted to a long wavelength by 3 and 8.5 mμ respectively.

In conclusion, it was found that, with the exception of the iodides, introduction of two halogen substituents at the terminal benzene rings of *o*-terphenyl moiety retards the cyclization reaction significantly, whereas, introduction of one halogen substituent does it only moderately. On the other hand, the presence of a bromine substituent on the central benzene ring does not affect the reaction rate. The fact that benzene is superior over cyclohexane as the solvent for the photo-aryl coupling reaction strongly suggested the importance of the aromatic solvent as a good sensitizer.[13,27,28]

Experimental[29]

Materials. *o*-Terphenyl derivatives subjected to photochemical studies are tabulated in Table 1. Of these, six are known compounds. New syntheses and modifications of known methods will be briefly described.

4-Fluoro-*o*-terphenyl (3/F). To a diazonium chloride solution prepared from 4-amino-*o*-terphenyl (**3**/NH_2),[6] a 42% solution of fluoroboric acid was added. The resulting diazonium fluoroborate was decomposed thermally[30] and the reaction mixture was extracted with benzene. The fluoride (**3**/F) was obtained as colorless prisms, mp 77.5—79°C (recrystallized from *n*-hexane).

4-Chloro- and 4,4''-Dichloro-*o*-terphenyls (3, 5/Cl). They were prepared by the Sandmeyer reaction[31] of amines (**3,5**/NH_2).[6,7] The mono- and dichloride were obtained respectively as colorless plates, mp 82.5—83°C and 136—136.5°C (each recrystallized from *n*-hexane).

4-Bromo- and 4,4''-Dibromo-*o*-terphenyl (3, 5/Br). *o*-Terphenyl was brominated with bromine vapor after the method of Allen and Pingert.[6]

The dibromide was obtained as colorless plates, mp 168—170°C (recrystallized from *n*-hexane). Since 4,4',4''-tribromo-*o*-terphenyl was reported to have a similar mp (170°C), the structure was confirmed by elemental analysis.

The above bromination reaction was stopped when the reaction mixture started to solidify after remaining a viscous liquid. The reaction product in that case was found to be mainly the monobromide, colorless plates, mp 93—94°C (recrystallized from *n*-hexane). The monobromide was formely prepared[25] from 2-phenyl-2-cyclohexanone by the Grignard reaction.

4-Iodo- and 4,4''-Diiodo-*o*-terphenyl (3, 5/I). They were prepared in the usual way by the decomposition of diazonium or bis(diazonium) chloride with potassium iodide.

The monoiodide was obtained as colorless plates, mp 116—116.5°C (recrystallized from *n*-hexane).

The diiodide was obtained as nearly colorless plates, which discolored on standing, mp 224—226°C (recrystallized from benzene).

4-Methoxy-*o*-terphenyl (3/OCH_3). 4-Hydroxy-*o*-terphenyl was prepared by the decomposition of the diazonium sulfate made from **3**/NH_2. Without further

26) The photolytic bisphenylation of diiodopolyphenyls would become a general synthetic method of polyphenyls having two more benzene rings. Studies on this matter will be reported elsewhere.

27) H. Morrison, *J. Am. Chem. Soc.*, **87**, 932 (1965).

28) F. Wilkinson, *J. Phys. Chem.*, **66**, 2569 (1962).

29) All melting points are uncorrected. UV spectra were recorded on a Cary 15 spectrophotometer. The authors are grateful to Mr. H. Kohashi of Osaka University for providing us with the data. Gas chromatography was performed with Hitachi K 53 chromatograph using 5% silicone gum XE-60 on Chromosorb W. column.

30) A. Roe, *Organic Reactions*, **5**, 193 (1957).

purification, it was methylated with dimethyl sulfate, colorless plates, mp 61.5—62.5°C (recrystallized from *n*-hexane).

4'-Bromo-*o*-terphenyl (4/Br). 2-Acetamido-5-bromobiphenyl,[32] mp 130°C, was nitrosated with nitrosyl chloride and was decomposed in a benzene solution in the usual manner.[33] The bromide was purified by passing through alumina column as a benzene solution, and was obtained as colorless plates, mp 103.5—104.5°C (recrystallized from *n*-hexane).

4'-Nitro-*o*-terphenyl (4/NO_2). It was prepared by the decomposition of 5-nitro-2-(*N*-nitrosoacetamido)-biphenyl,[8,34] mp 133°C, in a benzene solution following the method of Case,[8] colorless plates, mp 118.3—118.5°C (recrystallized from *n*-hexane). The compound was reported to be obtainable as a minor product by the direct nitration of *o*-terphenyl and once was referred to as *x*-nitro-*o*-terphenyl, mp 119.5°C.[7]

Photochemical Reactions. *General Procedure.* A sample solution (1.67×10^{-2} M) in a quartz vessel equipped with gas inlet and outlet tubes, was irradiated externally with a 1-kW high-pressure mercury arc lamp (Wako HBC-1000) immersed in a bucket. Cooling was given by running water. During the irradiation a stream of nitrogen (or air) was bubbled through the solution.

The results of photolysis studies are summarized in Table 2. Analysis of the reaction products were performed by column chromatography on alumina, which was eluted with a mixture of *n*-hexane and benzene of varying ratio. A fraction of approximately 100 m*l* was collected. Identification of *o*-terphenyl and triphenylene were also achieved by gas chromatography, though the use of which was limited to a few cases.

The physical properties and UV data of triphenylene derivatives prepared in this study are summarized in Table 3. Since the reaction conditions are given in Table 2, and the work-up procedure of the reaction mixtures from nitro-, fluoro-, chloro-, and methoxy-*o*-terphenyls are straight-forward, only representative experiments on bromides and iodides are briefly mentioned.

4-Bromo-*o*-terphenyl (3/Br). *Exp. 4.* A solution of 319 mg (1.03 mmol) of **3**/Br, 260 mg (1.02 mmol) of iodine in 60 m*l* of benzene was irradiated under nitrogen for 96 hr. After the irradiation reaction was over, the solution was successively washed with sodium thiosulfate solution and water, and was dried over magnesium sulfate. The product was then subjected to column chromatography on alumina using a 10 : 1 mixture of *n*-hexane - benzene as an eluent. By checking the elutes with IR spectra, the products were separated into the following four fractions; 56.5 mg (18%) of **3**/Br, mp 93—94°C (colorless plates from *n*-hexane), 14.2 mg (6%) of **2**, mp 193—194°C (colorless needles from ethanol), 81.3 mg (26%) of **6**/Br,[10] mp 129—131°C (colorless needles from acetone) and 88.2 mg (28%) of **7**,[11] mp 180.5—181°C (colorless needles from ethanol).

Exp. 5. When irradiated in the absence of iodine, the starting material was completely recovered.

4-Iodo-*o*-terphenyl (3/I). *Exp. 10.* A benzene solution of 356 mg (1.00 mmol) of **3**/I was irradiated for 48 hr. By chromatography on alumina, eluted with a 4 : 1 *n*-hexane - benzene mixture, there were obtained 37.1 mg (18%) of **2** (fractions 14—20) and 113 mg (41%) of **7** (fraction 30~).

Exp. 8, 9 and 11. The photolysis in cyclohexane or toluene yielded *o*-terphenyl, which was eluted first from alumina column.

4'-Bromo-*o*-terphenyl (4/Br). *Exp. 14.* A solution of 311 mg (1.01 mmol) of **4**/Br, 250 mg (0.99 mmol) of iodine in 60 m*l* of benzene was irradiated under nitrogen for 24 hr. By chromatography on alumina, eluted with a 9 : 1 *n*-hexane - benzene mixture, there were obtained 31.3 mg (14%) of **2** (fractions 70—76), 204.5 mg (66%) of **6**/Br (fractions 77—120) and 34.2 mg (11%) of **7** (fractions 126—132).

Exp. 16. The irradiation reaction products were first eluted with *n*-hexane, which afforded 44.9 mg (20%) of **1** (fractions 20—30) and 34.9 mg (11%) of **4**/Br (fractions 32—42). The solvent was switched to a 9 : 1 *n*-hexane - benzene mixture to obtain 61.5 mg (27%) of **2** (fractions 61—80) and 83.0 mg (27%) of **6**/Br (fractions 82~).

4,4''-Dibromo-*o*-terphenyl (5/Br). *Exp. 21.* A solution of 388 mg (1.00 mmol) of **5**/Br, 259 mg (1.02 mmol) of iodine in 60 m*l* of benzene was irradiated under nitrogen for 96 hr. The reaction product was analyzed by column chromatography on alumina. After elution with *ca.* 1400 m*l* *n*-hexane, the eluent was changed to a 9 : 1 *n*-hexane - benzene mixture. Starting material (135.2 mg, 35%) came out first (fractions 20—25) which was followed by 39.6 mg (10%) of **10**, mp 151—151.5°C as colorless plates from *n*-hexane (fractions 43—44), 21.8 mg (6%) of **8**/Br, mp 232—234°C as colorless needles from *n*-hexane (fractions 46—48) and 63.0 mg (16%) of **11**, mp 153—155°C, as colorless amorphous material from ethanol (fractions 64—75).

4,4''-Diiodo-*o*-terphenyl (5/I). *Exp. 22.* A solution of 484 mg (1.01 mmol) of **5**/I in 60 m*l* of benzene was irradiated under nitrogen for 48 hr. Since the reaction mixture discolored considerably due to liberated iodine after about 26 hr, it was necessary to remove it by washing the reaction mixture with sodium thiosulfate solution. By column chromatography on alumina, there were obtained five fractions by elution with a 9 : 1 *n*-hexane - benzene mixture; 5.5 mg (2%) of **3**/I (fractions 8—10), 7.2 mg (1%) of **5**/I (fractions 15—19), 42.1 mg (10%) of **12**, mp 144—146°C as colorless plates from *n*-hexane (fractions 39—55), 88.9 mg (23%) of **13**, mp 181—182°C as colorless plates from *n*-hexane (fractions 65—115) and 5.5 mg (1%) of **14** as colorless needles (fractions 116~).

Photochemical conversion of **13** to **14** was confirmed by an independent experiment, in which 50 mg of **13** and 35 mg of iodine in a benzene solution (15 m*l*) was irradiated for 92 hr. By chromatography on alumina, **14**, mp 262—263°C, was isolated in a 9% yield. Quinquephenyl **13** was recovered in 71% yield.

The authors are indebted to the members of the analytical section of the Institute of Physical and Chemical Research for carrying out microanalyses.

Photo-Aryl Coupling and Related Reactions. III. The Transannular Dehydrogenation of [2.2]Metacyclophane Induced by Iodine[1]

Takeo SATO,* Meiko WAKABAYASHI,* Shigenari HAYASHI** and Kazuo HATA*

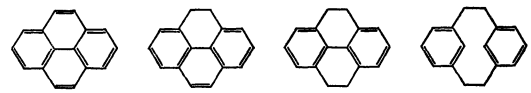
* *Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya, Tokyo*
** *Department of Chemistry, Nihon University, Setagaya, Tokyo*

(Received July 9, 1968)

The ultraviolet irradiation of [2.2]metacyclophane (I) with iodine in a cyclohexane solution was shown to afford 4,5,9,10-tetrahydropyrene (II), which, on further dehydrogenation, was led to 4,5-dihydropyrene and pyrene. The transannular reaction leading to II occurred much more rapidly than the subsequent dehydrogenation reactions. Thus II was obtainable in an optimum yield of 62% by the irradiation of I in the presence of an equimolar amount of iodine and an excess of sodium bicarbonate. By ESR and UV spectral studies, 253.7 mμ light was found to be responsible for the transannular reaction.

The origin of pyrene (IV) in coal tar was once questioned and was attributed to *m*-xylene, assuming the intermediacy of either 2,2',6,6'-tetramethylbiphenyl or [2.2]metacyclophane (I).[2] Baker and his co-workers[3] have realized the conversion of I to IV in a 60% yield by the action of palladium charcoal. They also showed hexahydropyrene was obtainable from I by treating it with aluminum chloride. As a related observation, we confirmed smooth conversion of I to 4,5,9,10-tetrahydropyrene (II) by the action of ferric chloride.[4]

Both ionic and homolytic pathways are shown to effect the transannular reaction of I. Thus, electrophilic substitution reactions, such as nitration[5,6] or halogenation reaction[5,7,8] afforded II or its 2-substituted derivatives. Noteworthy is the isolation of II, 4, 5-dihydropyrene (III) and IV from the nitration reaction mixture using benzoyl nitrate.[6] In this case both electrophilic and radical reactions are occurring as competing processes. Photochemical conversion of I to IV was first realized by Lindsay and his co-workers[9] who treated I with bromine under ultraviolet irradiation. We observed that irradiation of I with nitrosyl chloride afforded II in a good yield.[4]



I II III IV

Apart from curiosity in the origin of IV in nature, those reactions involving transannular dehydrogenation or cycloisomerization step are of considerable interest as regards the reaction mechanism and synthetic utility. Whereas some mechanistic studies on the transannular reactions initiated by electrophiles are available,[5,6,8,10,11] only limited studies have been carried out on the photochemical behavior of I.[7,9,12] Our earlier findings that the photo-aryl coupling of I induced by iodine afforded a good yield of II,[7] urged us to study the reaction further in order to find out the optimum reaction conditions and to obtain mechanistic evidence.

The photochemistry of I was examined under selected conditions using a 1-kW high-pressure mercury arc lamp. A cyclohexane solution (0.83×10^{-2} M) contained in a quartz tube was irradiated externally for 20hr under oxygen or nitrogen current. The reaction mixture was analyzed by column chromatography on alumina and the products were characterized by spectroscopic methods or by a direct comparison with the authentic samples. The results are summarized in Table 1.

TABLE 1. THE PHOTOCHEMICAL REACTIONS OF [2.2]METACYCLOPHANE (I) AND 4,5,9,10-TETRAHYDROPYRENE (II)[a]

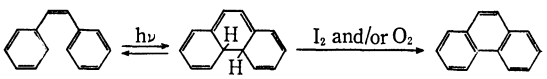
No.	Compound, mmol		Iodine mmol	Sodium bicarbonate mmol	Products, %			
					I	II	III	IV
1[b]	I	0.25			100			
2	I	0.25	0.01		17	37	8.2	trace
3	I	0.25	0.25			15	22.4	29.2
4	I	0.25	0.25	0.3		21	28.8	27.4
5	I	0.25	0.125	0.5		38.2	15.0	24.0
6	I	0.25	0.125	0.5[d]		58.4	30.0	10.2
7[b]	I	0.25	0.25	8.3		62.0	26.7	11.3
8[b,c]	I	0.25	0.25	8.3		51.4	48.6	
9	II	0.50	0.25	1.2		54.3	28.2	8.3

a) A cyclohexane solution (30 ml) contained in a quartz tube was irradiated externally with a 1-kW high-pressure mercury are lamp for 20 hr. Except for No. 1, which was carried out under oxygen, all photolysis reactions were performed under a current of nitrogen.
b) Yields are expressed in a product ratio.
c) Ultraviolet irradiation was continued for 40 hr.
d) Instead of sodium bicarbonate, sodium carbonate was used.

First, it was found that oxygen was not effective as the oxidant for the transannular dehydrogenation reaction (No. 1). The rest of the photolyses were thus performed under nitrogen. Addition of a small amount of iodine, however, was shown to lead to the formation of II and III together with a trace amount of IV (No. 2). Higher rate of conversion to pyrene was achieved by the irradiation with an equimolar amount of iodine. In this case the yield of pyrene reached 29.2% (No. 3).

As will be discussed in detail later, the initial product of the reaction is assumed to be II, of which further dehydrogenation may be responsible for the formation of III and IV. This was clearly confirmed by carrying out similar photolysis studies on II itself (No. 9). The compound was found to afford 36.5% of dehydrogenation products. Examination of the effect of base revealed that the presence of an excess of sodium bicarbonate retarded further transformation of II. Thus as high as a 62% yield of II was achieved (No. 7). The fact that only a small amount of iodine is enough to effect the reaction to a significant extent (No. 2) indicates that iodine is regenerated[13] from hydrogen iodide, which is formed in the photolytic dehydrogenation processes. Use of an equimolar amount of iodine and trapping of generated hydrogen iodide thus made this reaction highly specific one.

The photochemical transformation of *cis*-stilbene to phenanthrene[13,14] has been extensively studied and has been extended to the syntheses of phenanthrene derivatives,[15] triphenylenes,[1,16,17] polycondensed ring compounds including phenanthrene system[18-20] and heterocyclic analogs.[21,22] The reaction mechanism has been elucidated beyond doubt by trapping the intermediate compound 4a,4b-dihydrophenanthrene (V), by carrying out ultraviolet irradiation of stilbene solutions in the absence of oxygen.[14,23,24] Oxidation of V with



V

oxygen, iodine, or more effectively with the mixture of these two as the dark reaction was assumed to be the final stage of the reaction. Atomic sulfur generated from *cis*-stilbene sulfide was also found to be effective as an oxidant.[25]

It is apparent that no such mechanism formulated above is conceivable for the metacyclophane case,

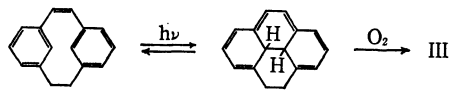
since the two benzene rings in this compound are not in conjugation. Moreover, the fact that oxygen is not effective for cycliaztion suggested that the photo-aryl coupling of I proceeded through an entirely different mechanism from that of *cis*-stilbene-phenanthrene cases.

Recently, Blaschke and Boekelheide[26] prepared [2.2]metacyclophan-1-ene (IV) and observed a photochemical equilibrium (VI⇄VII). They have



VI VII

noticed that VII is extremely sensitive to oxygen and is easily convertible to III by its presence. The cyclization step in this case is thus similar to the stilbene type and different from ours.

Kinetic studies[27] have revealed that the dehydrogenation reaction of ethylene bridge occurs much more slowly compared with the transannular cyclization step. This permits us to treat the latter process separately from the competing reactions in the initial stage of the reaction. Therefore our effort was concentrated to define the nature of the transannular reaction step.

An ESR signal appeared when a deaerated cyclohexane solution of I containing iodine was irradiated with unfiltered light of a high-pressure mercury lamp at room temperature. The signal was observed as a single line spectrum with a band width of 23 gauss. When, however, I or iodine alone was irradiated under similar conditions no such signal was observable. These facts indicated that a fairly stable radical species was formed by the irradiation of I in the presence of iodine.

It was also found that only 253.7 mμ light was responsible for the formation of the radical intermediate as revealed by the ESR studies using light with various wavelengths. This specificity was further confirmed by the UV spectra measurements under irradiation. The spectral changes under irradiation with 253.7 mμ light are shown in Fig. 1. The appearance of peaks characteristic of II occurring at 260, 268, 280, 292, 320 and 335 mμ after about 3.5hr clearly demonstrated the formation of II. At the same time, if an equimolar or more of iodine was present, the absorbance of the iodine band at 525 mμ showed a marked decrease with the progress of the reaction as shown in Fig. 1. No changes in the spectrum occurred by the irradiation with other lines. From these experiments, it was confirmed that the reaction was initiated by the light of 253.7 mμ and that the excitation of a long wave band of iodine was not effective to bring about the cyclization.

Several mechanisms are conceivable for the facile transannular reaction of I. In view of the appearance of a rather stable radical intermediate, abstraction of 8,16-hydrogen occurred most probably in a stepwise manner. Excited I could react with iodine to give a cation radical or analogous species, of which further dehydrogenation would lead to II.

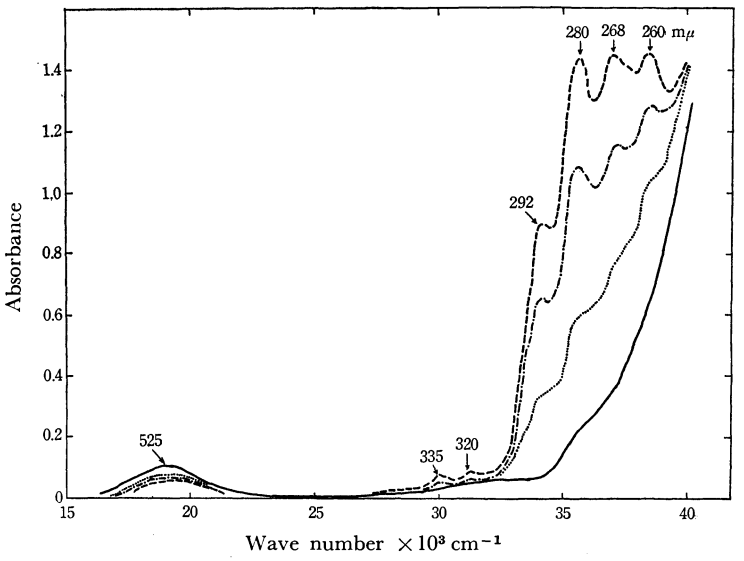


Fig. 1. Change of the absorption spectra of [2.2]metacyclophane (1.3×10^{-4} M) and iodine (0.3×10^{-3} M) in a cyclohexane solution upon irradiation for 69 (·····), 205 (-·-·-) and 330 min (----). The spectrum of the original solution is also shown (——).

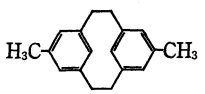
26) H. Blaschke and V. Boekelheide, *J. Am. Chem. Soc.*, **89**, 2747 (1967).

27) Details of the kinetic studies will be reported elsewhere by one of the authors (S. H.).

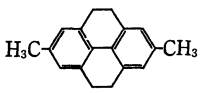
Excitation of iodine at the short wave band might also lead to a similar pathway. Since a mixture of I and iodine in cyclohexane showed a weak charge-transfer band at 280 mμ, excitiation of the complex could also be the initial step of the reaction. On the other hand, the participation of σ-complex would not be likely when one considers the instability of the iodinated aromatic compounds toward irradiation,[1,28] thus our original scheme[7] became unattractive. Although the data at hand strongly suggested the participation of iodine in the initial stage of the reaction, the choice among the absorbing species could not be achieved. The quantum yield of this reaction was found to be 0.016[27] with unfiltered light.

Obviously the cyclization is facilitated by the proximity of two benzene rings which are separated only by 2.689 Å.[29] As expected no reaction occurred when bibenzyl, an open-chain model of I, was irradiated under the conditions described above. The driving force of the reaction might be sought in the highly strained nature of the metacyclophane structure which is relieved by going into bicyclic.

5,13-Dimethyl[2.2]metacyclophane (VIII) has been shown to react similarly to give 2,7-dimethyl-4,5,9,10-tetrahydropyrene (IX).[30] The occurrence of the transannular reaction with the metacyclophane derivative, of which 5- and 13-positions are blocked by methyl groups, also excludes the possibility of the participation of the σ-complex.



VIII



IX

Boekelheide and his co-workers[31] have observed a photochemical equilibrium between *trans*-15,16-dimethyldihydropyrene (X) and 8,16-dimethyl-[2.2]metacyclophane-1,9-diene (XI). It appeared to be of interest to attempt the photocyclization

reaction with 8,16-dimethyl derivative such as XII. The hexamethyl[2.2]metacyclophane has, however, been recovered unchanged by the photolysis experiments carried out as above.[30]

Experimental

Light Sources. For preparative experiments, a 1-kW high-pressure mercury arc lamp, Wako HBC-1000, was used. Cyclohexane solutions were irradiated externally in a quartz tube under the selected conditions by being immersed in a water bucket which housed the light source. Cooling was achieved by running water.

For the measurements of the ESR and UV spectra under irradiation a 100-W Toshiba SHL-100 UV lamp was used. The specific lines were selected by using a combination of glass filters (Toshiba and Hoya filters; UV-D25, UV-29, UV-DlC, V-Y48) and nickel sulfate solution (100 g/300 m*l*).

Spectra Measurements. UV spectra were recorded with Shimadzu RS autorecording spectrophotometer or Hitachi EPU-2 spectrophotometer. ESR spectra were recorded with Japan Electron Optics Co., X-band, ESR instrument model JES-3B type. Deaerated cyclohexane solutions were used for the measurements.

The Photolysis of [2.2]Metacyclophane (I). As a typical example, details of experiment No. 7 are given below. A mixture of 50 mg (0.25 mmol) of I, 63 mg (0.25 mmol) of iodine and 70 mg (8.3 mmol) of sodium bicarbonate in 30 m*l* of cyclohexane was irradiated for 20 hr under a nitrogen current. After the reaction was over, the mixture was successively washed with water, sodium thiosulfate solution and water. After drying over magnesium sulfate, the solution was concentrated. By column chromatography on alumina using *n*-hexane as an eluent, there were isolated three fractions, which consisted of 62.0% of II, mp 138°C, 26.7% of III, mp 132°C, and 11.3% of IV, mp 150°C (in the order of elution from the column). They were characterized by NMR and IR spectra and also by a direct comparison with the authentic materials.[6]

The authors are grateful to Professor T. Morita of Gunma University for his continued interest in this work.

Organic Syntheses by Means of Metal Complexes. III.[1] Cobalt Carbonyl-catalyzed Carbonylation of β-Propiolactone

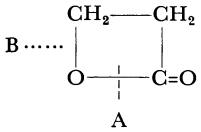
Yoichi MORI and Jiro TSUJI

Basic Research Laboratories, Toyo Rayon Co., Kamakura

(Received July 10, 1968)

It was found that the carbonylation of β-propiolactone can be carried out in the presence of dicobalt octacarbonyl. Butyrolactone and succinic acid were obtained by the reaction of β-propiolactone with carbon monoxide and hydrogen. Succinic anhydride was obtained by the reaction with carbon monoxide.

β-Propiolactone (abbreviated as PL) is a reactive compound and undergoes many reactions. Its reactions can be classified into two types. One of them proceeds through the *O*-acyl fission (A) which is possible under basic conditions. On the other hand, under acidic conditions, the *O*-alkyl fission (B) occurs.[2]



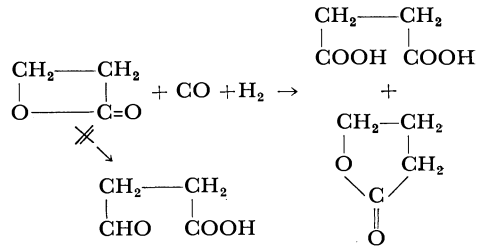
A

It seemed of interest to us to study the reaction of carbon monoxide with highly reactive PL. Carbon monoxide is also reactive and behaves as nucleophile or radical depending on the reaction conditions. It is known that carbon monoxide is activated most effectively by catalytic action of metal carbonyls, among which dicobalt octacarbonyl is well known catalyst of carbonylation of olefins and other unsaturated compounds. In addition, it catalyzes the carbonylation of epoxide which is a highly strained heterocyclic ring.[3] In view of the fact that PL is a highly strained reactive cyclic compound, the carbonylation of PL was attempted by the catalytic action of dicobalt octacarbonyl. It is known that active species in the dicobalt octacarbonyl-catalyzed carbonylation is cobalt tetracarbonyl hydride formed from dicobalt octacarbonyl and hydrogen. The cobalt hydride is strongly acidic. Therefore, it is expected that the carbonylation of PL catalyzed by dicobalt cotacarbonyl

$$Co_2(CO)_8 + H_2 \longrightarrow 2HCo(CO)_4 \qquad (I)$$

via the cobalt hydride in the presence of hydrogen should proceed through the *O*-alkyl fission, and carbon monoxide should be inserted into the *O*-alkyl bond to give a C_4 dicarbonyl compound.

Based on the above assumption, the reaction of PL with carbon monoxide and hydrogen in the presence of dicobalt octacarbonyl in benzene was attempted. In this reaction, hydrogen reacts with dicobalt octacarbonyl to give cobalt tetracarbonyl hydride (I). Once the acidic hydride is formed, then it is reasonable to assume that the *O*-alkyl fission of PL is possible to form a cobalt-alkyl complex, followed by carbon monoxide insertion to give succinic acid aldehyde as final product. However, contrary to the expectation, the product actually obtained by the reaction of PL with carbon monoxide and hydrogen was not the aldehyde. Instead, butyrolactone and succinic acid were isolated from the reaction mixture in a total yield of about 80% based on PL. The ratio of these two products changed depending on the reaction conditions. It is not easy to define which factor favors the formation of either product. The results are shown in Table 1. The result shows that the alcohol and acid were formed instead of the expected aldehyde by the ring opening reaction of PL with carbon monoxide and hydrogen.



Then the reaction of PL with carbon monoxide in the absence of hydrogen was tried. By the reaction in benzene carried out at 150°C, two products

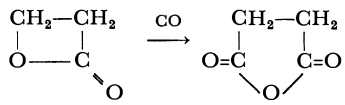
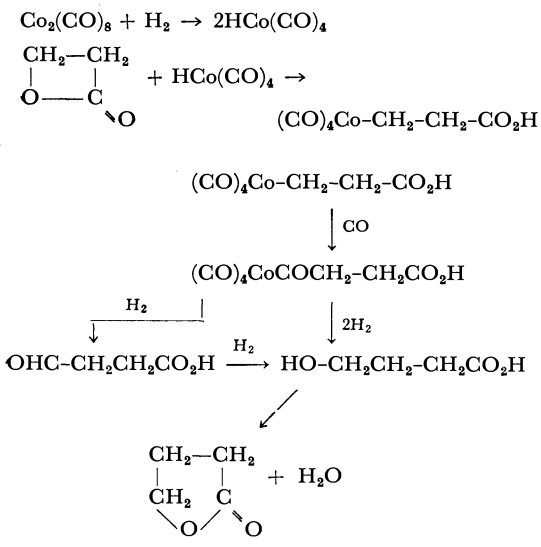
* The reactions were carried out with PL (5.75 g), solvent (30 ml) and dicobalt octacarbonyl (0.7 g) at 150°C.

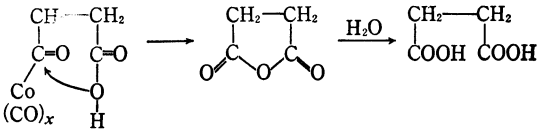
were isolated. One of them was identified as acrylic acid. Apparently acrylic acid was formed by the ring opening of PL without reacting with carbon monoxide. The other product was confirmed to be succinic anhydride. Thus carbon monoxide was inserted into the *O*-alkyl bond.



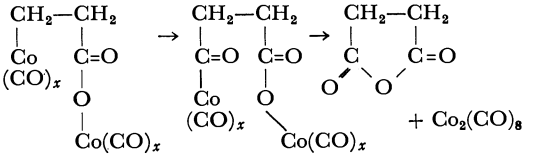
The following mechanisms are proposed for the dicobalt octacarbonyl-catalyzed carbonylation of PL. The reaction of cobalt tetracarbonyl hydride and PL gives the alkyl cobalt complex *via* *O*-alkyl fission. This is reasonable because cobalt hydride is acidic. The alkyl complex is subjected to carbon monoxide insertion to give the acyl complex. The acyl complex is split with either hydrogen or cobalt tetracarbonyl hydride to give aldehyde and dicobalt octacarbonyl. Alcohol is formed by the hydrogenation of the aldehyde or directly from the acyl complex. Then γ-hydroxybutyric acid is converted into the lactone with the liberation of water.



The formation of succinic acid can be explained by the cyclization of the acyl complex as shown below. In the presence of water formed by the lactone formation, succinic anhydride is hydrolyzed to give succinic acid.



A possible path of the formation of succinic anhydride in the absence of hydrogen is the following. In this reaction cobalt hydride is not formed and the *O*-alkyl fission reaction of PL with dicobalt octacarbonyl gives the following alkyl complex. The carbon monoxide insertion into the alkyl cobalt bond gives acyl complex which cyclizes to give anhydride and dicobalt octacarbonyl.



The possibility that the reaction proceeds through the intermediate formation of acrylic acid from PL can be ruled out by the fact that an attempted oxo reaction of acrylic acid under the similar reaction conditions did not proceed and unchanged acrylic acid was recovered almost quantitatively. Therefore the selective introduction of carbon monoxide at β-position of PL should be possible through the intermediate complex formed by the *O*-alkyl fission of PL with cobalt catalyst.

Experimental

Materials. Commercially available PL was used without purification. Dicobalt octacarbonyl was synthesized by the known method.

Reaction of PL with Carbon Monoxide and Hydrogen. Benzene (30 ml), PL (5.75 g) and dicobalt octacarbonyl (0.7 g) were mixed in a glass vessel equipped with a gas inlet capillary and the glass vessel was placed in an autoclave. Carbon monoxide

(80 atm) and hydrogen (40 atm) were charged and the reaction was carried out at 150°C for 4 hr with shaking. A pressure drop of 35 atm was observed. The solvent was removed by distillation from the reaction mixture, and butyrolactone (3.12 g, 45.5%) was isolated by distillation at 91—94°C/20 mmHg. The residue was recrystallized from ether and succinic acid was isolated (3.63 g, 38.4%). Both products were indentified with authentic samples by IR spectra.

Reaction of PL with Carbon Monoxide. Benzene (30 m*l*), PL (5.75 g) and dicobalt octacarbonyl (0.7 g) were mixed in the autoclave as shown above and allowed to react with carbon monoxide (100 atm) at 150°C for 4 hr and pressure drop of 4 atm was observed. Distillation of the reaction mixture gave acrylic acid (1.08 g, 18.8%) and succinic anhydride (2.37 g, 29%, 99°C/2 mmHg). The latter solidified on standing, mp 117—119°C.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 779—781 (1969)

Polymerization of Naphthalene and Reactions of Polynaphthalene

Hiroshi MINATO,[1]* Nobuyuki HIGOSAKI and Chieko ISOBE

Department of Chemistry, International Christian University, Mitaka, Tokyo

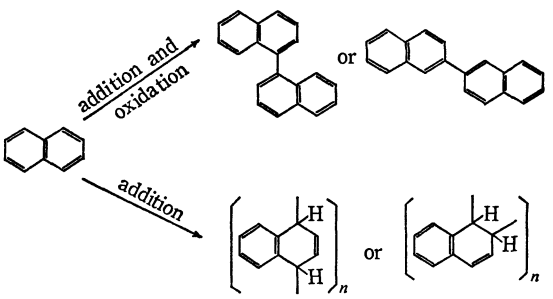
(Received July 13, 1968)

Naphthalene was polymerized by use of anhydrous aluminum chloride. The polynaphthalene formed was soluble in various organic solvents. The molecular weight determination suggested that the average degree of polymerization was six. The NMR spectrum indicated the presence of non-aromatic hydrogens, and the elemental analysis roughly corresponded with $(C_{10}H_8)_n$. The reactions of the polymer was examined such as hydrogenation, bromination, thermal dehydrogenation, chloromethylation and epoxidation.

Kovacic and his coworkers reported on the reactions of various aromatic hydrocarbons such as benzene, toluene, xylene and naphthalene with Lewis acids and oxidizing agents.[1)] From benzene, polyphenyls were obtained, which were insoluble and infusible. Naphthalene was let to react in *o*-dichlorobenzene with Lewis acids and oxidizing agents, and 1,1'-, 1,2'- and 2,2'-binaphthayls were obtained.

We have been interested in two-step polymerizations of various compounds, and have examined the possibility of performing the addition and the oxidation separately in order to obtain a soluble and fusible polymer.

It was found that benzene, toluene and xylene yields very little polymer when oxidizing agents were not present. However, it was found that naphthalene was converted into polynaphthalene in quite a good yield when it was let to react with anhydrous aluminum chloride without solvent. The results of this polymerization and the reactions of the polymer obtained will be described in this paper.



Experimental

Reagents. Naphthalene used was commercially available extra pure grade naphthalene. Anhydrous aluminum chloride used was commercially available extra pure grade.

Polymerization of Naphthalene. *Procedure A.* Naphthalene, 160 g, was ground in a porcelain mortar and placed in a 500 m*l* three-necked round-bottomed flask. Anhydrous aluminum chloride, 11 g, was also finely powdered and added. They were stirred under a nitrogen atmosphere. When the temperature was raised to 70—72°C, the mixture melted and became homogeneous. The reaction was exothermic at the first stage, and no sooner the reaction started than the color of the mixture started to darken. The reaction mixture was kept at 73—72°C for two hours. The

TABLE 1. POLYMERIZATION OF NAPHTHALENE

Procedure	Naphthalene g (mol)	Aluminum chloride, anhydrous g (mol)	Mol% $AlCl_3$	Temp. °C	Time hr	Yield g (%)
A	160 (1.25)	11 (0.0825)	6.2	73—75	2	56.0 (35.0)
B	96 (0.748)	25.5 (0.191)	20.3	80—90	2.5	81.0 (84.4)

black product was a viscous liquid at the reaction temperature and solidified at room temperature. The product was all transferred to a 1-*l* round-bottomed flask to which 500 m*l* of water was added. The naphthalene which remained unreacted was steam-distilled out to a receiver through an air condenser. The steam ditillation was continued for 4 hr. The water was discarded, and another 500 m*l* of fresh water was added to run the second distillation for four hours. The same procedure was carried out for the third distillation. After the third distillation, the black product was added in 200 m*l* of warm benzene, and the product completely dissolved. After cooling anhydrous sodium sulfate was added, and the solution was allowed to stand overnight. After the filtration of the sodium sulfate, benzene was evaporated to yield 56 g of a product. The product was a viscous tar-like substance with cohesive properties. The solubility of the product in petroleum ether was 0.154 g/100 m*l* at 27°C.

Procedure B. The procedure was the same as in Procedure A except the quantities of the reagents and the experimental conditions as Table 1 shows. Analyses of the polymers produced by two procedures indicated that the structure and the properties of these polymers were similar. The polymer produced by Procedure A was subjected to various reactions and analyses.

Purification. Naphthalene polymer, 15 g, was dissolved in 10 m*l* of benzene. The solution was added drop by drop into 200 m*l* of petroleum ether with stirring. The naphthalene polymer was dispersed to yield fine, dark brown precipitates which accumulated at the bottom of the beaker. The precipitates were filtered by use of a glass filter, dried and ground in a mortar. Brown powder, 7.0 g was obtained. The weight percent yield was 47%. Again the brown powder was dissolved in 5 m*l* of benzene, and the benzene solution was added dropwise into a 200 m*l* of stirred petroleum ether. Almost all of the substance was recovered in the second precipitation. For the investigation of the structure, further purification was tried. The polymer, 6.5 g, obtained by the above purification, was shaken three times with 100 m*l* of 5% $NaHCO_3$, three times with 100 m*l* of 5% HCl, and three times with 100 m*l* of distilled water. Anhydrous sodium sulfate was added to the benzene solution, and the solution was allowed to stand overnight. The filtered benzene solution was added dropwise to 400 m*l* of stirred petroleum ether. The benzene solution was dispersed to yield brown precipitates. The precipitates were filtered and dried. The final product obtained was 3.5 g and the percentage yield in this prification was 54%.

Results and Discussion

The Analyses of the Polymer. The NMR spectrum of the naphthalene polymer is shown in Fig. 1. The absorptions at 1.9 ppm and 2.9 ppm are due to aliphatic hydrogens. Since there are two peaks instead of one, the 1,2-dihydro-structure seems to predominate in the polymer. The 1,2-dihydro-structure has two kinds of aliphatic hydrogens and the 1,4-dihydro-structure has one kind of aliphatic hydrogen.

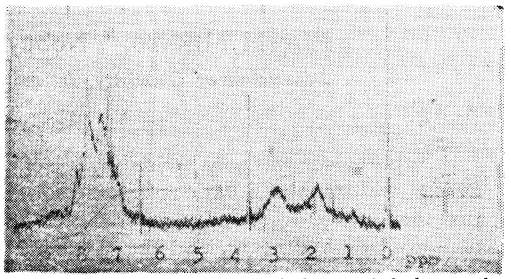

Fig. 1. NMR spectrum of the naphthalene polymer in CCl_4 (reference, tetramethylsilane: 60 Mc).

The results of the elemental analysis of the polymer is summarized in Table 2.

These results indicate the presence of some non-hydrocarbon materials, presumably aluminum chloride. The carbon hydrogen contents correspond with the formula $C_{10}H_{7.37}$. The small difference between this value and theoretical value $C_{10}H_8$ can be ascribed to the dehydrogenation of the polymer, which is likely to take place to some extent even in the absence of any oxidizing agent.

The molecular weight of the polymer was determined by an Osmometer Model 301, Microlab. The determination in chloroform showed that the molecular weight was 761. Since the molecular weight of ($C_{10}H_8$) is 769, the average degree of polymerization of this napthalene polymer is six.

In order to estimate the number of olefinic double bonds, catalytic hydrogenation of the polymer was carried out by use of platinum oxide. The benzene solution of the polymer was treated with hydrogen for three hours at 28°C/1 atm. Two determinations were carried out independently, and it was found that no hydrogen was absorbed in both cases. The failure of the hydrogenation may be ascribed to the bulkiness of the polymer molecule and the steric hindrance as to the olefinic double bonds.

The polymer was brominated with KBr-$KBrO_3$ in acetic acid according to the method of Johnson and Clark.[2] A $C_{10}H_8$ unit absorbed 0.40 bromine

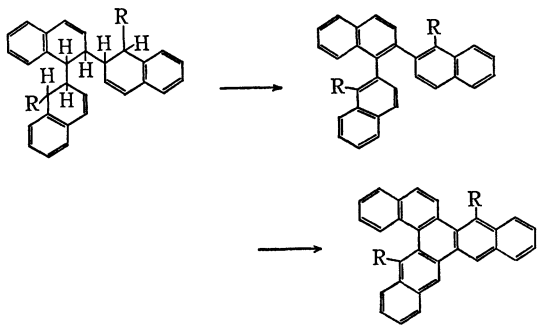
2) H. L. Johnson and R. A. Clark, *Anal. Chem.*, **19**, 869 (1947).

TABLE 2. ELEMENTAL ANALYSIS OF NAPHTHALENE POLYMER

	C%	H%	C%+H%	C%/C%+H%	H%/C%+H%
Found	92.30	5.71	98.01	94.18	5.82
Calcd for $C_{10}H_8$	93.71	6.29	100		
Calcd for $C_{10}H_6$	96.00	4.00	100		

molecule in one hour, but after several hours the absorption only increased to 0.43. Theoretically every $C_{10}H_8$ unit of the polymer should absorb 1.0 molecule of bromine.

When the naphthalene polymer was heated in air, it softened near 60°C, and the color darkened at 160—170°C. While being heated, it apparently was aromatized. At 300°C, it was rather hard solid which could be pressed or moved by a spatula. It was thermally very stable and the weight did not decrease at all when heated for 90 min at 220°C and then for 90 min at 290°C. When it was heated for 6 hr at 320°C, some dehydrogenation took place, and the elemental analysis of the polymer indicated that the structure was $(C_{10}H_{5.82})_n$. The analysis shows that some naphthalene units are bound by more than one linkage.

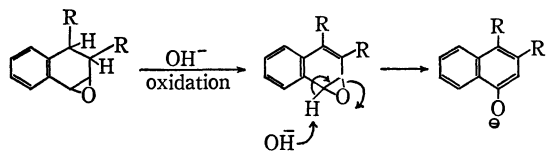


Reactions of the Naphthalene Polymer. *Oxidation with Potassium Permanganate.* The naphthalene polymer was refluxed in an alkaline potassium permanganate solution for 2 hr. The IR spectrum of the product was identical with that of the naphthalene polymer itself. The softening point (about 60°C) of the product was the same as that of the original polymer. It was, therefore, concluded that the naphthalene polymer was not oxidized with the reagent under the conditions mentioned above.

Chloromethylation. The naphthalene polymer was chloromethylated with polyoxymethylene and hydrogen chloride by the usual procedure. The chlorine analysis of the product showed 5.42% chlorine. Since the theoretical value was 20.1%, 27.0% of the initial polymer units was chloromethylated. The IR spectrum showed a new band at 1000 cm^{-1}.

Hydrolysis of the Chloromethylated Polymer. The chloromethylated polymer which was not separated from the unreacted naphthalene polymer was hydrolysed with a potassium carbonate solution. The IR spectrum of the hydrolysis product showed a new band at 1070 cm^{-1} which did not appear in the spectrum of the chloromethylated polymer, while the absorption band at 1000 cm^{-1} in the spectrum of the chloromethylated polymer greatly decreased. The absorption band at 1070 cm^{-1} was assigned to C–O of primary alcohol, and an absorption band due to O–H of primary alcohol appeared at 3400 cm^{-1}.

Epoxidation. The naphthalene polymer was epoxidized according to the method described for the epoxidation of styrene.[3] When the polymer was let to react with perbenzoic acid in benzene at 15°C, the peracid consumed for epoxidation was 71.7% at 113 hr, 78.1% at 165.5 hr and 88.1% at 573.5 hr (after the correction for blanks). In order to remove benzoic acid, the epxoidized polymer solution was treated with 5% sodium bicarbonate solution. Unexpectedly, the epoxidized naphthalene polymer was extracted into the aqueous layer after several extractions. When the alkaline solution was neutralized with hydrochloric acid, brown precipitates were obtained which were benzoic acid and phenolic polymers. Apparently the following reactions took place.



Attempts were made in order to remove benzoic acid without destruction of epoxy group, but in vain. The naphthalene polymer did not form its picrate; the sublimation of benzoic acid resulted in the destruction of the epoxy ring; the column chromatography resulted in the decomposition of the epoxy ring.

In order to have the easier separation of the carboxylic acid after the epoxidation, monoperphthalic acid was used. The rate of epoxidation was a little slower than that with perbenzoic acid, and 39.7% of the peracid was consumed after 44 hr. Phthalic acid precipitated was easily filtered.

The epoxidized naphthalene polymer was mixed with aniline-phenol-formaldehyde resin in the weight ratio of 1 : 0.43, and the mixture was heated at 160°C for 30 min. The mixture solidified completely due to the cross-linking.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 782—789 (1969)

Studies of Peptide Antibiotics. XIV. Analogs of Gramicidin S Containing D-Valine or D-Leucine in Place of D-Phenylalanine

Haruhiko Aoyagi,[1] Tetsuo Kato, Michinori Waki, Okitoshi Abe, Reiko Okawa, Satoru Makisumi and Nobuo Izumiya[2]

Laboratory of Biochemistry, Faculty of Science, Kyushu University, Hakozaki, Fukuoka

(Received July 15, 1968)

Two analogs of gramicidin S, 4,4'-D-valine- and 4,4'-D-leucine-gramicidin S (XVI-A and XVI-B), have been synthesized and tested for the antibacterial properties. The crude product obtained after the cyclization of a linear pentapeptide active ester was composed of the protected monomer and dimer. The pure protected dimer was obtained by a column chromatography of Sephadex LH-20, and the hydrogenolysis of this product in the presence of hydrogen chloride afforded the crystalline hydrochloride of XVI-A or XVI-B. These analogs were as active as natural gramicidin S; the results indicated that the aromatic side chains of the D-phenylalanines in the molecule of gramicidin S can be replaced by the aliphatic side chains without an influence for the activity.

In connection with a series of studies in this laboratory on a significance of the side chains of the amino acid residues of gramicidin S (Fig. 1)

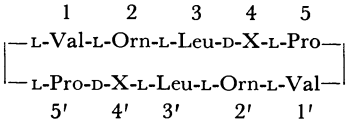

Fig. 1. Structure of gramicidin S (GS) and its analogs. X represents an amino acid residue such as Phe (GS), Val (XVI-A) or Leu (XVI-B).

to its antibacterial activity, it has been reported in the previous paper that an analog of the antibiotics was prepared in which the benzyl groups of D-phenylalanine residues in 4- and 4'-positions of the molecule were replaced by the hydrogens of glycines, and 4,4'-glycine-gramicidin S thus prepared was found to possess almost no activity toward several microorganisms.[3] From this finding, it appeared that the side chains of D-phenylalanines in the sequence of gramicidin S are of considerable importance for an exhibition of the activity. In order to investigate an effect of replacing the benzyl side chains of D-phenylalanines by the aliphatic side chains of D-valines or D-leucines, we attempted to prepare several analogs of gramicidin S. The present paper will describe the syntheses and antibacterial properties of 4,4'-D-valine- and 4,4'-D-leucine-gramicidin S besides the preparations of the cyclic pentapeptides, 4-D-valine- and 4-D-leucine-cyclosemigramicidin S.

It would be noteworthy that D-valine residue is a constituent in several natural antibiotics such as actinomycins and fungisporin, and D-leucine residue in etamycin, esperin and malformin.[4] Some peptide antibiotics such as sporidesmolide I[4] and gramicidin A[5] contain both D-valine and D-leucine as a constiuent. The closely related polymyxin B_1 or E_1 has been shown to be homodetic cyclic decapeptide wherein an amino group of the molecule is acylated with 6-methyl-octanoic acid. Of special interest in connection with the present paper was the fact that polymyxin E_1 differs from polymyxin B_1 in having an D-leucine-residue in place of the D-phenylalanine at 6-position of polymyxin B_1.[6]

Since the cyclization of H-Val-Orn(δ-Z)-Leu-Gly-Pro-ONp[7] afforded exclusively the benzyloxycarbonyl-substituted dimer through the doubling reaction,[3] the syntheses of the protected cyclic decapeptides (XIV-A and -B) were attempted by possible dimerization reaction of the pentapeptide

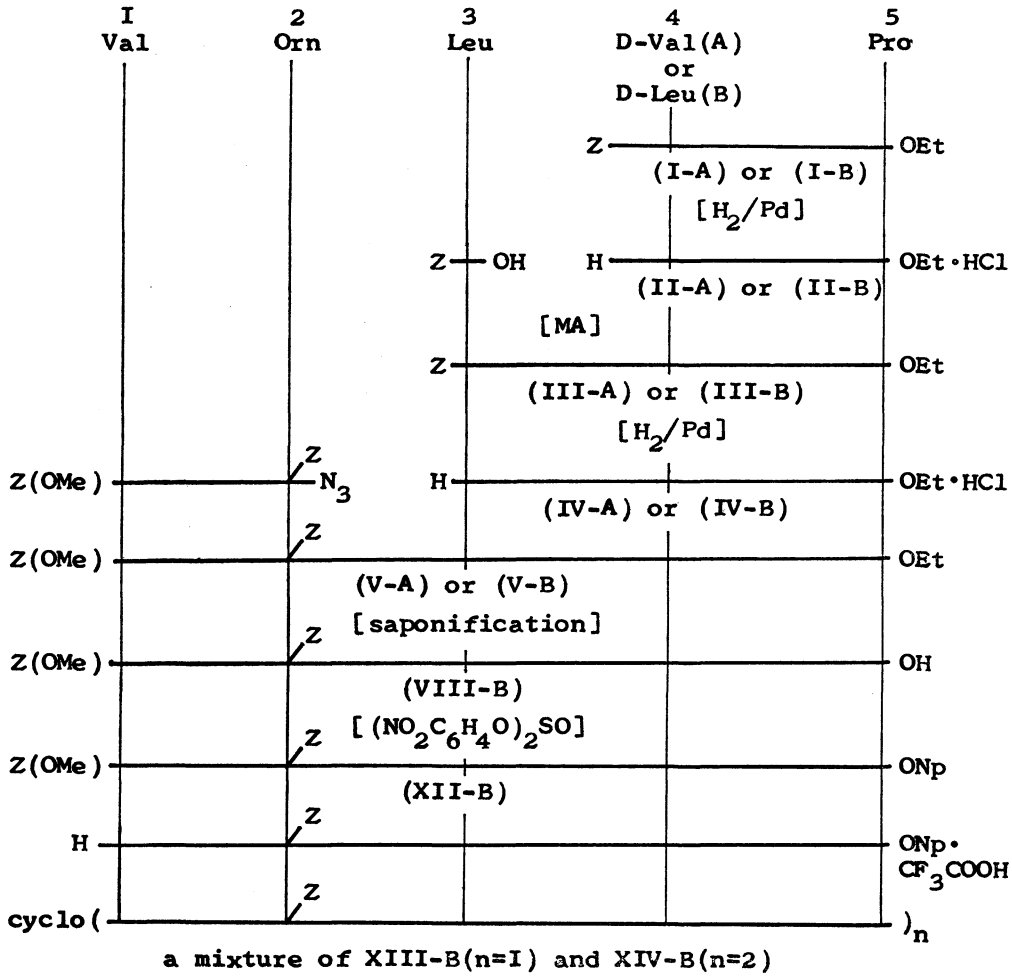

Fig. 2. Cyclization of linear pentapeptide active ester containing D-Leu.

active esters (XII-A and -B) as shown in Figs. 2 and 3. To obtain an acylpentapeptide acid (VIII-A or -B) which is a starting material for the active ester, the corresponding acylpentapeptide ethyl ester was subjected to the saponification; the reaction of the acylpeptide ester (V-B) containing D-leucine proceeded smoothly to afford the acylpeptide acid (VIII-B) in a good yield, whereas the ester (V-A) containing D-valine was found to resist for the saponification reaction. In this connection, it would be noteworthy that several investigators have reported the resistance of a peptide ester containing valine or isoleucine residue for the saponification.[8,9] Therefore, the acylpentapeptide acid (VIII-A) containing D-valine was prepared by the condensation of Z(OMe)-Val-Orn(δ-Z)-N_3 with neutral tripeptide (VII-A). Acyltripeptide acid (VI-A) which is a material for the neutral tripeptide was prepared by the saponification of acylpeptide ester (III-A) without any difficulty though the ester contained a valine residue.

The treatment of an acylpentapeptide acid (VIII-A or -B) with di-p-nitrophenyl sulfite gave an amorphous acylpeptide active ester, and its p-methoxybenzyloxycarbonyl group was removed by the action of trifluoroacetic acid. The pentapeptide active ester trifluoroacetate obtained was treated with a large amount of pyridine (concentration of the ester in pyridine, 3×10^{-3} M). After the evaporation of the reaction mixture, the residue dissolved in aqueous methanol was treated with columns of Dowex 1 and 50 to be free from the undesired products. The subsequent evaporation of the effluent yielded a semi-solid residue which was found to be a mixture of the protected monomer (XIII-A or -B) and dimer (XIV-A or -B). Attempts to separate the components in the residue by the fractional crystallization with methanol-ether failed because of no appreciable difference in solubility between

the two components.[10] The separation of the components was achieved by the use of a Sephadex LH-20 column with methanol as an eluting solvent; the protected dimer (XIV-A or -B) was obtained from the faster eluting fraction, and the monomer (XIII-A or -B) from the slower fraction (Fig. 4). The weight ratio of both components calculated

10) In the previous papers, we reported that the pure protected GS,[11] diZ-substituted [Lys$^{2,2'}$]-GS or [Dba$^{2,2'}$]-GS[12] was obtained easily by the fractional crystallization from the mixture of the protected cyclic decapeptide and pentapeptide because of the great difference between their solubilities.

Table 1. Ratio of protected monomer and dimer after cyclization of linear pentapeptide active esters

p-Nitrophenyl ester of[a]	Ratio of compounds in product[b] Z-cyclic monomer	diZ-cyclic dimer
H-Val-Orn(Z)-Leu-D-Phe-Pro-OH[11]	32	68
-Gly-[3]	0	100
-D-Val-	17	83
-D-Leu-	15	85

a) After the first compound listed, only variation of the residue will be shown.
b) The concentrations of linear pentapeptide *p*-nitrophenyl esters in pyridine were $\sim 3 \times 10^{-3}$ M.

are shown in Table 1 with the previous results related to the present paper.

To establish the structure of the protected dimer containing D-leucine derived from the linear pentapeptide active ester, a linear decapeptide active ester was cyclized to yield a benzyloxycarbonyl substituted cyclic decapeptide as shown in Fig. 5. Then the properties of the obtained crystals (XIV-B in Fig. 5) agreed well with that of the protected dimer (XIV-B in Fig. 4).

The hydrogenolysis of each of the protected peptides in the presence of an equivalent hydrogen chloride yielded a crystalline hydrochloride of the required cyclic peptide (XV-A, -B, XVI-A or -B). The antibacterial activities of these peptides toward several microorganisms were further examined (Table 2). It was found that the two cyclosemigramicidin S analogs (XV-A and -B) exhibited no antibacterial activities as same as cyclosemigramicidin S itself[11] and its analogs replaced by glycine[13] or sarcosine[14] at 5-position

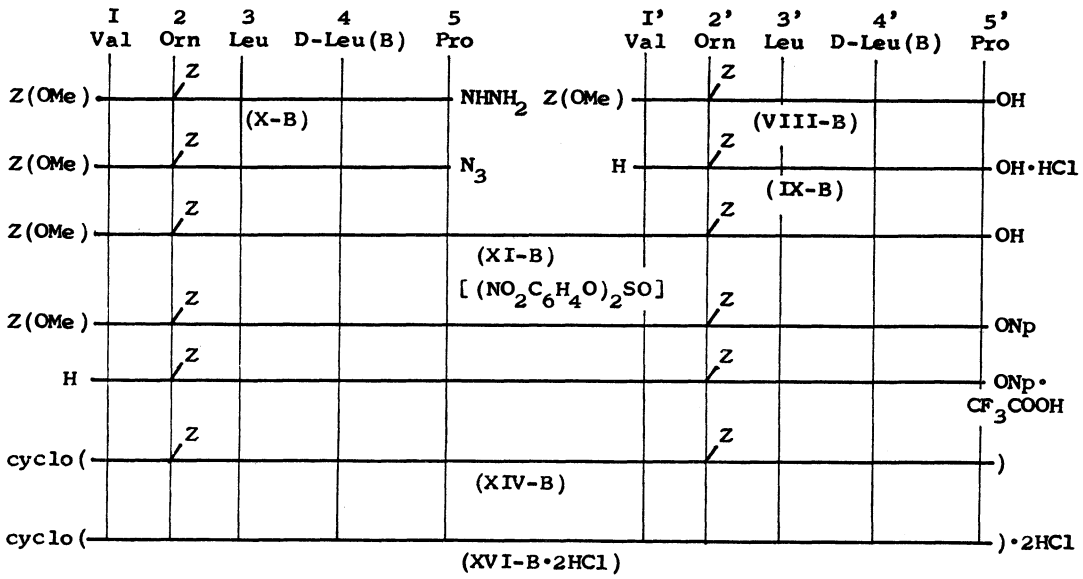

Fig. 5. Cyclization of linear decapeptide active ester.

Table 2. Inhibitory activity of the compounds on microorganisms
Minimum inhibitory concentration, $\mu g/ml$[a]

	Escherichia coli	*Proteus vulgaris*	*Staphylococcus aureus*	*Bacillus subtilis*	*Mycobacterium avium*
GS	>100	>100	5	5	>100

of the molecule. On the other hand, 4,4'-D-valine- and D-leucine-gramicidin S were as active as the natural gramicidin S against several microorganisms. The results indicated that the aromatic side chains of D-phenylalanine residues of 4- and 4'-position can be replaced by the bulky aliphatic side chains such as isopropyl and isobutyl groups without any influence in the activity.

Experimental

All melting points are uncorrected.

Z-D-Val-Pro-OEt (I-A). To a solution of benzyloxycarbonyl-D-valine[8] (5.02 g; 20 mmol) and L-proline ethyl ester *p*-toluenesulfonate[15] (6.30 g; 20 mmol) in chloroform (40 ml), there were stirred triethylamine (2.80 ml) and dicyclohexylcarbodiimide[16] (4.12 g) at 0°C. After it had been allowed to stand overnight at 0°C, the mixture was evaporated *in vacuo*, and ethyl acetate was added to the residue. After the dicyclohexylurea was filtered off, the filtrate was washed successively with 4% sodium bicarbonate, 3% hydrochloric acid and water, and dried over sodium sulfate. The filtrate was evaporated *in vacuo*; yield of oil, 3.99 g (58%); R_f, 0.95.[17]

Z-D-Leu-Pro-OEt (I-B). (a) This was obtained from oily benzyloxycarbonyl-D-leucine (6.92 g; 26 mmol) and L-proline ethyl ester *p*-toluenesulfonate (8.20 g; 26 mmol) as described above; yield of oil, 7.48 g (74%); R_f, 0.97.[17] (b) To a solution of benzyloxycarbonyl-D-leucine dicyclohexylammonium salt[18] (4.46 g; 10 mmol) and L-proline ethyl ester *p*-toluenesulfonate (3.15 g; 10 mmol) in chloroform (20 ml), there were stirred dicyclohexylcarbodiimide (2.02 g) at 0°C. After it had been allowed to stand overnight at 0°C, the mixture was treated as described above; yield, 3.06 g (78%); R_f, 0.97.[17]

H-D-Val-Pro-OEt·HCl (II-A). A solution of I-A (3.00 g; 8 mmol) dissolved in 0.48N methanolic hydrogen chloride (17.5ml) was subjected to hydrogenolysis in the presence of palladium black. The filtrate from the catalyst was evaporated to dryness *in vacuo;* yield of oil, 2.20g (99%); R_f, 0.75[17].

H-D-Leu-Pro-OEt·HCl (II-B). This was obtained from I-B (4.70g; 12mmol) as described above; yield of oil, 3.44g (98%); R_f, 0.65.[17]

Z-Leu-D-Val-Pro-OEt (III-A). Benzyloxycarbonyl-L-leucine dicyclohexylammonium salt[19] (3.57g; 8mmol) was coupled with II-A (2.23g; 8mmol) as described for the preparation of I-B (b). Yield of oil, 3.60g (92%); R_f, 0.92.[17]

Z-Leu-D-Leu-Pro-OEt (III-B). This compound was obtained from benzyloxycarbonyl-L-leucine dicyclohexylammonium salt (2.55g; 5.7mmol) and II-B (1.67g; 5.7mmol) as described above. The crude product was recrystallized from ethyl acetate - petroleum ether; yield, 2.02g (71%); mp 135°C; $[\alpha]_D^{22}$ −21.8° (*c* 1, DMF); R_f, 0.97.[17]

Found: C, 64.12; H, 8.30; N, 8.50%. Calcd for $C_{27}H_{41}O_6N_3$: C, 64.39; H, 8.21; N, 8.34%.

H-Leu-D-Val-Pro-OEt·HCl (IV-A). This was obtained from III-A (4.90g; 10mmol) as described for the preparation of II-A; yield of oil, 3.85g (98%); R_f, 0.70.[17]

H-Leu-D-Leu-Pro-OEt·HCl (IV-B). This was obtained from III-B (3.02g; 6 mmol); yield of oil, 2.44 g (100%); R_f, 0.67.[17]

Z(OMe)-Val-Orn(δ-Z)-Leu-D-Val-Pro-OEt (V-A). To a Z(OMe)-Val-Orn(δ-Z)-$NHNH_2$[20] (1.09g; 2mmol) dissolved in a mixture of acetic acid (20ml), dimethylformamide (10 ml) and 1N hydrochloric acid (4.4 ml) was added sodium nitrite (152mg) in water (1ml). After 6 min cold water (100ml) was added to the solution. The azide which precipitated was collected by filtration and washed with 4% sodium bicarbonate and water, and then dried *in vacuo*. The azide was added to a solution of IV-A (0.77 g; 2mmol) and triethylamine (0.28ml) in dimethylformamide (20 ml). The mixture was stirred for 3 days at 0°C and evaporated *in vacuo*. The precipitate which formed upon the addition of water was collected, washed successively with 4% sodium bicarbonate, 10% citric acid and water. It was recrystallized from methanol-dioxane-ether; yield, 1.17 g (69%); mp 180—183°C; $[\alpha]_D^{22}$ −10.8° (*c* 1, DMF); R_f, 0.92.[17]

Found: C, 62.49; H, 7.64; N, 9.92%. Calcd for $C_{45}H_{66}O_{11}N_6$: C, 62.33; H, 7.69; N, 9.69%.

Z(OMe)-Val-Orn(δ-Z)-Leu-D-Leu-Pro-OEt (V-B). The azide derived from Z(OMe)-Val-Orn(δ-Z)-$NHNH_2$ (3.26 g; 6 mmol) was condensed with IV-B (2.44 g; 6 mmol) and triethylamine (0.84 ml) as described above. The crude product was recrystallized from methanol - dioxane - ether - petroleum ether; yield, 4.04 g (77%); mp 142—144°C; $[\alpha]_D^{22}$ −11.0° (*c* 1, DMF); R_f, 0.88.[17]

Found: C, 62.46; H, 7.78; N, 9.76%. Calcd for $C_{46}H_{68}O_{11}N_6$: C, 62.70; H, 7.78; N, 9.53%.

Z-Leu-D-Val-Pro-OH (VI-A). To a solution of III-A (7.20 g; 14.7 mmol) in a mixture of methanol (40 ml) and dioxane (40 ml), 2N sodium hydroxide (11 ml) was added, and the solution was allowed to stand for 5 hr at 30°C. After the addition of 1N hydrochloric acid (23 ml), the solution was evaporated *in vacuo*. The oily product extracted with ethyl acetate (50 ml) and dried over sodium sulfate. The filtrate was evaporated *in vacuo*; yield of oil, 6.5 g (96%); R_f, 0.77.[17]

H-Leu-D-Val-Pro-OH (VII-A). A solution of VI-A (3.35 g; 7.3 mmol) in a mixture of acetic acid (15 ml), methanol (12 ml) and water (3 ml) was subjected to hydrogenolysis in the presence of palladium black. The

filtrate was evaporated to dryness *in vacuo*; yield of oil, 2.26 g (95%); R_f, 0.72.[17]

Z(OMe)-Val-Orn(δ-Z)-Leu-D-Val-Pro-OH (VIII-A). The azide derived from Z(OMe)-Val-Orn(δ-Z)-$NHNH_2$ (3.80 g; 7 mmol) was added to a solution of VII-A (2.35 g; 7 mmol) and triethylamine (0.98 m*l*) in dimethylformamide (50 m*l*). The mixture was stirred for 3 days at 0°C and evaporated *in vacuo*. The residue was triturated with 10% citric acid, and the precipitate was collected by filtration and washed with water. It was recrystallized from methanol - ether - petroleum ether; yield, 4.02 g (65%); mp 173—175°C; $[\alpha]_D^{22}$ −12.2° (*c* 1, DMF); R_f, 0.82.[17]

Found: C, 60.41; H, 7.30; N, 10.04%. Calcd for $C_{43}H_{62}O_{11}N_6 \cdot H_2O$: C, 60.18; H, 7.53; N, 9.84%.

Z(OMe)-Val-Orn(δ-Z)-Leu-D-Leu-Pro-OH (VIII-B). To a solution of V-B (4.41 g; 5 mmol) in a mixture of methanol (20 m*l*) and dioxane (20 m*l*), 2 N sodium hydroxide (5 m*l*) was added, and the solution was allowed to stand for 4 hr at 30°C. After the addition of 10% citric acid (75 m*l*) under cooling, the solution was concentrated *in vacuo* at a low temperature, and the precipitate was collected by filtration. This was recrystallized from methanol - ether - petroleum ether; yield, 3.34 g (78%); mp 149—151°C; $[\alpha]_D^{22}$ −20.0° (*c* 1, DMF); R_f, 0.75.[17]

Found: C, 61.53; H, 7.70; N, 9.63%. Calcd for $C_{44}H_{64}O_{11}N_6 \cdot 1/2H_2O$: C, 61.30; H, 7.60; N, 9.75%.

H-Val-Orn(δ-Z)-Leu-D-Leu-Pro-OH·HCl (IX-B). To a solution of VIII-B (3.42 g; 4 mmol) in dioxane (40 m*l*), 4.0 N hydrogen chloride in dioxane (36 m*l*) was added at room temperature. After 2 hr, the solution was evaporated, and the residue was triturated with ether. The crystals were collected with the aid of ether; yield, 2.94 g (98%); mp 163—165°C; $[\alpha]_D^{18}$ −14.0° (*c* 0.5, DMF); R_f, 0.72.[17]

Found: C, 57.63; H, 7.84; N, 11.56%. Calcd for $C_{35}H_{57}O_8N_6Cl$: C, 57.95; H, 7.92; N, 11.59%.

Z(OMe)-Val-Orn(δ-Z)-Leu-D-Leu-Pro-$NHNH_2$ (X-B). To a solution of V-B (3.52 g; 4 mmol) in dimethylformamide (15 m*l*), hydrazine hydrate (4 m*l*) was added and the solution was allowed to stand for 7 days at 30°C. The solution was then concentrated *in vacuo* to a small volume. The hydrazide which precipitated upon the addition of water was collected and recrystallized from dioxane-ether; yield, 3.01 g (87%); mp 147—149°C; $[\alpha]_D^{18}$ −20.4° (*c* 1, DMF); R_f, 0.78.[17]

Found: C, 60.50; H, 7.62; N, 12.50%. Calcd for $C_{44}H_{60}O_{10}N_8 \cdot 1/2H_2O$: C, 60.24; H, 7.71; N, 12.79%.

Z(OMe)-Val-Orn(δ-Z)-Leu-D-Leu-Pro-Val-Orn-(δ-Z)-Leu-D-Leu-Pro-OH (XI-B). The azide derived from X-B (1.04 g; 1.2 mmol) was added to a solution of IX-B (0.87 g; 1.2 mmol) and triethylamine (0.33 m*l*) in dimethylformamide (20 m*l*). The crude product was obtained as described for the preparation of VIII-A and recrystallized from ethyl acetate - petroleum ether; yield, 1.54 g (67%); mp 148—151°C; $[\alpha]_D^{18}$ −34.0° (*c* 0.5, DMF); R_f, 0.80.[17]

Found: C, 61.24; H, 7.89; N, 10.82%. Calcd for $C_{79}H_{118}O_{18}N_{12} \cdot H_2O$: C, 61.54; H, 7.85; N, 10.90%.

Z(OMe)-Val-Orn(δ-Z)-Leu-D-Val-Pro-ONp (XII-A). To a solution of VIII-A (2.04 g; 2.3 mmol) in pyridine (10 m*l*), di-*p*-nitrophenyl sulfite[21] (2.98 g; 9.2 mmol) was added. After the mixture had been allowed to stand overnight at room temperature, it was evaporated *in vacuo*. The residual solid was collected with the aid of a mixture of ether and petroleum ether; yield, 1.73 g. The *p*-nitrophenyl ester content was estimated to be 94% by measuring the optical density at 412 mμ.[22]

Z(OMe)-Val-Orn(δ-Z)-Leu-D-Leu-Pro-ONp (XII-B). The compound VIII-B (0.853 g; 1 mmol) was converted to XII-B (0.890 g) as described above in which *p*-nitrophenyl ester content was estimated to be 111%.

Mixture of *cyclo*-(Val-Orn(δ-Z)-Leu-D-Val-Pro-) (XIII-A) and *cyclo*-(Val-Orn(δ-Z)-Leu-D-Val-Pro-)$_2$ (XIV-A). The compound XII-A (1.73 g) was treated with anisole (2 m*l*) and trifluoroacetic acid (12 m*l*) at 0°C. After 20 min, the solution was evaporated, and the solid was collected with the aid of a mixture of ether and petroleum ether. The pentapeptide *p*-nitrophenyl ester trifluoroacetate thus obtained was dissolved in dimethylformamide (20 m*l*) and acetic acid (1 m*l*). The solution was added dropwise into pyridine (600 m*l*) at 55—60°C during 5 hr and the stirring was continued for additional 2 hr. The solution was evaporated, and the residue was dissolved in a mixture of methanol (25 m*l*), dioxane (25 m*l*) and water (10 m*l*). The solution was treated with columns (1.8×15 cm) of Dowex 1 (OH^- form) and Dowex 50 (H^+ form). The columns were washed with the same solvent (150 m*l*), and the combined effluent was evaporated to dryness. The residual product was collected by filtration with the aid of water and dissolved in 4 m*l* of methanol (solution A). A drop of solution A was subjected to hydrogenolysis, and the electophoresis of the hydrogenated material showed two spots.[23] Half of solution A (2 m*l*) was applied to a column (2.7×52 cm) with Sephadex LH-20, and the development continued with methanol. Elution was carried out at room temperature, at a flow rate of 30 m*l* per hr; a 3 m*l* fraction was collected. The peptide content in the fractions was determined as described previously.[11] The first peak appeared from tube numter 47 to 58, and the second, from 62 to 68. The fractions 59 to 61 contained both components. The other half of solution A was chromatographed; the first peak, 43 to 61 and the second, 64 to 72.

***cyclo*-(Val-Orn(δ-Z)-Leu-D-Val-Pro-) (XIII-A).** The fractions 62—68 and 64—72 were combined and evaporated *in vacuo*, and the product was collected by filtration with the aid of water. The crude product weighed 86 mg. It was recrystallized from methanol - ether - petroleum ether; yield, 68 mg (4.4% from VIII-A); mp 161—163°C; $[\alpha]_D^{22}$ −74.7° (*c* 0.3, DMF); R_f, 0.95.[17]

Found: C, 60.92; H, 7.97; N, 12.43%; mol wt, 704.[24] Calcd for $C_{34}H_{52}O_7N_6 \cdot H_2O$: C, 60.51; H, 8.08; N, 12.46%; mol wt, 675.

***cyclo*-(Val-Orn(δ-Z)-Leu-D-Val-Pro-)$_2$ (XIV-A).** The fractions 47—58 and 43—61 were treated as described above; yield of a crude product, 394 mg. Recrystallization from methanol - ether - petroleum ether gave 346 mg (22% from VIII-A); mp 212—214°C; $[\alpha]_D^{22}$ −137° (*c* 0.3, DMF); R_f, 0.93.[17]

Found: C, 60.38; H, 7.88; N, 12.36%; mol wt,

22) R. Schwyzer and P. Sieber, *ibid.*, **40**, 624 (1957).

23) Each of the hydrogenated materials was designated as XVII-A in this case or XVII-B in the case containing D-leucine, and the results of carboxymethylcellulose column chromatography are shown in Fig. 7.

1372.[24] Calcd for $C_{68}H_{104}O_{14}N_{12}\cdot 2H_2O$: C, 60.51; H, 8.08; N, 12.46%; mol wt. 1350.

Mixture of *cyclo*-(Val-Orn(∂-Z)-Leu-D-Leu-Pro-) (XIII-B) and *cyclo*-(Val-Orn(∂-Z)-Leu-D-Leu-Pro-)$_2$ (XIV-B). Pentapeptide *p*-nitrophenyl ester trifluoroacetate obtained from XII-B (0.887 g) was added to pyridine (200 ml) as described for the preparation of a mixture of XIII-A and XIV-A. A crude product was dissolved in 2 ml of methanol (solution B). A quarter of solution B (0.5 ml) was applied to a column (2.7×52 cm) with Sephadex LH-20 as described. The first peak appeared from tube number 35 to 49, and the second, 53 to 60. The fractions from 50 to 52 contained both components. Other three quarters of solution B were treated similarly.

***cyclo*-(Val-Orn(∂-Z)-Leu-D-Leu-Pro-) (XIII-B).** The four fractions which were eluted slower such as from 53 to 60 were pooled and treated as described for the preparation of XIII-A; yield, 59 mg. It was recrystallized from ethyl acetate - petroleum ether; Yield, 53 mg (7.6% from VIII-B); mp 167—170°C; $[\alpha]_D^{18}$ −30.6° (*c* 0.3, DMF); R_f, 0.96.[17]

Found: C, 60.36; H, 7.97; N, 11.85%; mol wt, 680.[24] Calcd for $C_{35}H_{54}O_7N_6\cdot 3/2H_2O$: C, 60.23; H, 8.23; N, 12.03%; mol wt, 698.

***cyclo*-(Val-Orn(∂-Z)-Leu-D-Leu-Pro)$_2$ (XIV-B).** *(a) From VIII-B.* The four fractions which were eluted faster such as from 35 to 49 were treated as described above; yield, 312 mg. It was recrystallized from ethyl acetate-petroleum ether; yield, 296 mg (43% from VIII-B); mp 205—208°C; $[\alpha]_D^{18}$ −108° (*c* 0.5, DMF); R_f, 0.91.[17]

Found: C, 60.67; H, 8.32; N, 12.34%; mol wt, 1343.[24] Calcd for $C_{70}H_{108}O_{14}N_{12}\cdot 2H_2O$: C, 61.02; H, 8.19; N, 12.20%; mol wt, 1378.

(b) From XI-B. The compound XI-B (0.308 g; 0.2 mmol) was treated with di-*p*-nitrophenyl sulfite (0.65 g) in pyridine (2 ml), and the acyldecapeptide *p*-nitrophenyl ester (0.33 g) was obtained as amorphous powder; its *p*-nitrophenyl ester content, 107%. The product was treated with trifluoroacetic acid (2 ml), and the decapeptide *p*-nitrophenyl ester trifluoroacetate obtained was added to pyridine (100 ml). The effluent from the Dowex 1 and 50 columns was evaporated, and the crystals were collected with the aid of water; yield, 138 mg. This was recrystallized from ethyl acetate-petroleum ether; yield, 123 mg (45% from XI-B); mp 207-210°C; $[\alpha]_D^{18}$ −110° (*c* 0.5, DMF); R_f, 0.91.[17] The mixed mp with XIV-B from VIII-B was not depressed.

***cyclo*-(Val-Orn-Leu-D-Val-Pro-)·HCl (XV-A·HCl).** A solution of XIII-A (20 mg; 0.03 mmol) dissolved in 0.01 N methanolic hydrogen chloride (3.37 ml), was subjected to hydrogenolysis in the presence of palladium black. The solution, after being filtered from the catalyst, was evaporated to dryness *in vacuo*. The crystals were collected with the aid of ether; yield of the air-dried product, 16.2 mg (92%); mp 251—254°C (decomp.); R_f, 0.80[17] and 0.97;[25] amino acid ratios in acid hydrolysate, $Val_{2.1}Orn_{1.0}Leu_{1.0}Pro_{1.1}$.

24) The molecular weight was determined on a Hitachi Osmometer, type 115, using methanol as the solvent.

25) The R_f of the paper chromatography with Toyo Roshi No. 52 refers to the *n*-butanol - acetic acid - pyridine - water (4 : 1 : 1 : 2, v/v) system.

as described for the preparation of XV-A; yield of the air-dried product, 96%; mp 275—277°C (decomp.) $[\alpha]_D^{21}$ −133° (*c* 0.3, DMF; R_f, 0.75[17] and 0.97[25]); amino acid ratios in acid hydrolysate, $Val_{1.8}Orn_{0.9}$-$Leu_{1.0}Pro_{0.9}$.

Found: C, 51.78; H, 8.68; N, 13.91%. Calcd for $C_{52}H_{94}O_{10}N_{12}Cl_2 \cdot 5H_2O$: C, 52.08; H, 8.49; N, 13.56%.

The air-dried product lost 8.9% of its weight after drying for 3 hr at 80°C and 2 mmHg. Calcd for $6H_2O$: 8.8%.

***cyclo*-(Val-Orn-Leu-D-Leu-Pro-)$_2$·2HCl (XVI-B·2HCl).** The compound XIV-B (0.04 mmol) was treated as described for the preparation of XV-A; yield of the air-dried product, 86%; mp 256—260°C (decomp.); $[\alpha]_D^{25}$ −100° (*c* 0.3, DMF); R_f, 0.73[17] and 0.95;[25] amino acid ratios in acid hydrolysate, $Val_{0.9}Orn_{1.0}$-$Leu_{2.0}Pro_{0.9}$.

Found: C, 51.72; H, 8.95; N, 13.30%. Calcd for $C_{54}H_{98}O_{10}N_{12}Cl_2 \cdot 6H_2O$: C, 51.70; H, 8.80; N, 13.40%.

The air-dried product lost 6.9% of its weight after dried for 3 hr at 80°C and 2 mmHg. Calcd for $5H_2O$; 7.2%.

Electrophoresis and Carboxymethylcellulose (CMC) Chromatography. Electrophoresis on Toyo Roshi No. 52 paper was carried out with a solvent system, formic acid-acetic acid-methanol-water (1 : 3 : 6 : 10, v/v; pH 1.8) for 2.5 hr at 600 v/30 cm. Figure 6 shows that XVI-A and XVI-B migrate toward the cathode faster than XV-A and XV-B, and that mobilities of XVI-A and XVI-B were comparable with that of gramicidin S. In CMC column chromatography, a sample (0.5-1 mg) was dissolved in 0.2—0.3 m*l* of 0.2 M pyridinium acetate containing 30% methanol (pH 5.1), the solution was applied to a column (0.9×50 cm) with CMC (Eastman No. 7796), and development was continued with the same solvent. Two-m*l* fractions were collected at flow rate of 20 m*l* per hr. The peptide content in the fractions was determined by the ninhydrin method, and the results are shown in Fig. 7.

Microbiological Assays.[26] The minimum amount of the compounds necessary for the complete inhibition of growth was determined by a dilution method using a bouillon agar medium and a synthetic medium. As is shown in Table 1, [D-Val$^{4,4'}$]- and [D-Leu$^{4,4'}$]-gramicidin S were found to be as active as natural gramicidin S against *Staph. aureus* and *B. subtilis*. Whereas cyclo-semigramicidin analogs, XV-A and -B, exhibited no antibacterial activity against the microorganisms tested.

26) We are indebted to Dr. M. Shibata of Takeda Chemical Industries, Ltd. for the assay.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 789—794 (1969)

The Decomposition of Cyclohexyl Hydroperoxide in the Presence of Cyclohexanone and a Novel Rearrangement Product

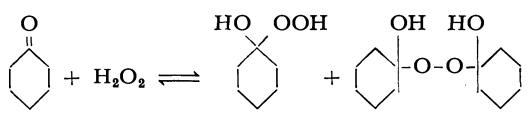
Sumio CHUBACHI, Hideo MATSUI, Kiyoshi YAMAMOTO and Sachio ISHIMOTO

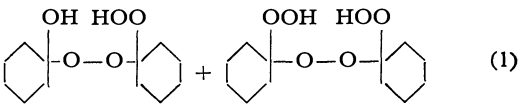
Product Development Institute of Teijin Limited, Hinode-cho, Iwakuni-shi, Yamaguchi

(Received July 18, 1968)

One of the major reaction products besides cyclohexanol from the reaction of cyclohexyl hydroperoxide with cyclohexanone was isolated and confirmed as ε-cyclohexyloxycaproic acid. The rate of formation of ε-cyclohexyloxycaproic acid was measured in excess cyclohexanone and found to follow a first order law for cyclohexyl hydroperoxide. The activation energy of 10.1 kcal/mol was found for the formation of the acid. The rate of decomposition of cyclohexyl hydroperoxide in cyclohexane was measured in the presence of various concentrations of cyclohexanone and the rates of formation of cyclohexanol and the free carboxylic acids were also measured. An adduct formation between cyclohexyl hydroperoxide and cyclohexanone followed by homolytic decomposition of the adduct was suggested to explain the experimental results.

The reaction of hydrogen peroxide with cyclohexanone has been studied by Criegee *et al.*[1] and they showed the formation of four rather stable peroxides at 40°C.





(1)

Denisov *et al.*[2] have studied the free-radical formation in the similar reaction by means of α-naphthylamine technique at 120—140°C. It is also known that alkyl hydroperoxides were strong oxidizing

1) R. Criegee, W. Schnorrenberg and J. Becke, *Ann.*, **565**, 7 (1949).

agents in the presence of alkali hydroxides and cleaved alkyl aryl ketones into corresponding aryl carboxylic acids and alkyl alcohols.[3,4] Cyclohexanone was found to be inert on treatment with *t*-butyl hydroperoxide in the presence of an alkali hydroxide.[3] On the other hand, cyclohexanone reacts readily with peracids to produce ε-caprolactone.[5,6]

This report deals with the decomposition of cyclohexyl hydroperoxide in the presence of cyclohexanone and a novel rearrangement product, namely ε-cyclohexyloxycaproic acid, $C_6H_{11}\cdot O\cdot(CH_2)_5\cdot COOH$ (I). Some kinetic investigations were carried out to estimate the reaction mechanism to this reaction and the characteristic nature of the decomposition of cyclohexyl hydroperoxide in the presence of cyclohexanone was elucidated.

Experimental

Reagents. Commercial cyclohexane and cyclohexanone were fractionated using 2 feet Vigreaux column, bp 80.7°C for cyclohexane and bp 156—156.5°C for cyclohexanone.

Cyclohexyl hydroperoxide was prepared by the following procedure. The air-oxidation of cyclohexane was carried out using an aluminum walled autoclave at 140°C for three hours by passing approximately one *l*/min of air, and the oxidate solution was concentrated by evaporating cyclohexane at a room temperature under a reduced pressure employing a water aspirator until approximately 0.3 mol/*l* of the hydroperoxide concentration was attained. The conecntrated oxidate solution was washed with an equal volume of aqueous 10% Na_2CO_3 solution to remove free acids. The amount of the hydroperoxide in the solution was determined by an iodometric titration of an aliquot of the solution. Two equivalents of NaOH as 40% aqueous solution were added dropwise to the oxidate solution with vigorous stirring at around 5°C. The precipitated salt of hydroperoxide was separated by means of a centrifuge and washed with cyclohexane several times and dried in a desiccator under the reduced pressure of 10mmHg. Dried precipitate was dissolved in the least volume of ice-water and neutralized with 50% acetic acid to pH 6. The solution was extracted with an equal volume of diethyl ether three times. The ether layer was dried and ether was evaporated at a room temperature under the reduced pressure of 3 mmHg.

Isolated cyclohexyl hydroperoxide was 85—90% pure and stored in a refrigerator. The identity of the hydroperoxide was established by an infrared and an NMR spectra. IR spectrum (Hitachi model EPI-S2) (γ_{max}, 1450, 1365, 1160, 1150, 1020, 950 and 840 cm^{-1}). NMR spectrum (Nihon Denshi model JNM 3H-60) measured at 60 Mc (2.16τ(−OOH)(singlet)(1H), 6.08τ (=CH–O–)(multiplet)(1H) and mutiplets centerd around 8.5 τ (–CH_2–)(10H)).

Methyl-ε-cyclohexyloxycaproate. A mixture of cyclohexanone and cyclohexyl hydroperoxide (1:1 molar ratio) was heated at 140°C for 2 hr in a round bottom flask. The reaction mixture was treated with an ethereal solution of diazomethane and the methyl esters of the produced acids were analyzed on the gas liquid partition chromatography, glpc, (Hitachi model KGL-2B), using a 2 m column packed with silanized kieselguhr (30—60 mesh) impregnated with 25% diethyleneglycol succinate operating at 160°C with helium as a carrier gas. A few mg of the comparatively pure unknown compound was obtained by repeated condensation of the eluted vapor corresponding to one of the two major products besides cyclohexanol and identified as methyl-ε-cyclohexyloxycaproate, $C_6H_{11}\cdot O\cdot(CH_2)_5COOCH_3$ (II).

Found: C, 68.2; H, 8.8% (F & M glpc type analyzer). Calcd for $C_{13}H_{24}O_3$; C, 58.4; H, 10.5%.

Infrared spectrum (ν_{max}, 2980, 2920, 1750, 1460, 1440, 1370, 1200, 1180, 1110, 1025 and 955 cm^{-1}). NMR spectrum (6.32τ(−$COOCH_3$)(sing.) (3H), 6.53τ (–CH_2O–)(tripl.)(2H), 7.70τ(–CH_2COO–) (tripl.)(2H), multiplets centerd around 8.5τ(–CH_2–) (16H) and multiplet around 6.35τ(=CHO–)(1H) seemed to be overlapped with the methyl singlet). The structure of the unknown compound was confirmed by the comparison with the spectra of authentic methyl-ε-cyclohexyloxycaproate. The other major product was identified as dimethyl adipate. The total carboxylate content was determined by the use of potentiometric automatic titrater (Hiranuma Sangyo model RA-1) after saponification of the reaction mixture.

Synthesis of Methyl-ε-cyclohexyloxycaproate. In a 500 m*l* round bottom flask 200 g of cyclohexanol was heated with 5.8 g (0.25 mol) of metallic sodium for several hours until homogeneous solution was obtained. ε-Chlorocaproic acid, 15.1 g (0.1 mol), was then added dropwise with vigorous stirring to the solution and heating was continued further for one hour after the addition. The excess cyclohexanol was removed under a reduced pressure and the residue was digested with 150 g of water. Unreacted alkoxide was neutralized by bubbling sufficient volume of carbon dioxide gas through the solution, which was then evaporated to dryness. The solid residue was dissolved in 100 m*l* of water, washed with ether and then acidified. The aqueous solution was extracted with ether. The ether layer was dried and treated with the ethereal diazomethane, and ether was removed to give crude methyl ester of ε-cyclohexyloxycaproic acid, which was then fractionated, bp 115°C at 2 mmHg. Yield 16.4 g (72% of the theoretical yield).

Found: C, 68.4; H, 10.5%. Calcd for $C_{13}H_{24}O_3$: C, 68.4; H, 10.5%.

The IR and NMR spectra of this compound agreed with those of the unknown compound.

Decomposition of Cyclohexyl Hydroperoxide. Thermal decomposition of cyclohexyl hydroperoxide in cyclohexane in the presence of cyclohexanone was studied in an aluminum walled autoclave at 130°C under a stream of nitrogen (1.5 *l*/min). Cyclohexane solutions (300 m*l*) containing *ca.* 0.15 mol of cyclohexyl hydroperoxide and three different concentrations of cyclohexanone were placed in the autoclave, heated to 130°C with vigorous stirring (800 rpm) and maintained at that temperature. Aliquots were withdrawn at specified

intervals through a sample outlet device. The hydroperoxide concentrations in the aliquots were determined by the iodometric titration and the total free carboxylate contents were determined by the use of potentiometric automatic titrater. The total carbonyl contents were estimated by the method described in an earlier publication.[7] Cyclohexanone and cyclohexanol contents in the aliquots were determined by glpc (Hitachi model KGL-2A), using a 3 m column packed with kieselguhr (30—60 mesh) impregnated with 25% of polyethyleneglycol 3000 operating at 140°C with helium as a carrier gas. Chlorobenzene was used as an inner standard. Since the remaining cyclohexyl hydroperoxide in the sample decomposed on glpc and also gave cyclohexanone and cyclohexanol, their amounts should be deduced from the measured values to obtain true concentrations of cyclohexanone and cyclohexanol in the samples. Glpc of 91 mmol/*l* and 183 mmol/*l* of cyclohexyl hydroperoxide solution in cyclohexane gave 52 mmol/*l* and 97 mmol/*l* of cyclohexanone and 42 mmol/*l* and 92 mmol/*l* of cyclohexanol respectively.

Results and Discussion

The decomposition of cyclohexyl hydroperoxide (100 mmol) in 1 mol of cyclohexanone at 140°C for three hours gave 3 mmol of adipic acid and 3.9 mmol of ε-cyclohexyloxycaproic acid. The total carboxylate content after saponification of the reaction mixture was 34.2 meq. There was some indication of the presence of a higher boiling substance which was revealed by glpc using a capillary column, but no dodecanedioic acid was found in the reaction mixture.

The rates of formation of ε-cyclohexyloxycaproic acid were followed at the three different temperatures, (see Table 1) and an over-all activation energy for the first order rate constants was calculated as 10.1 kcal/mol.

Table 1. Rate constants of ε-cycolhexyloxycaproic acid formation*

Temp. (°C)	$k\times10^{-6}$ (sec^{-1})
105	4.60
120	7.80
130	10.44

* Initial cyclohexyl hydroperoxide concentration is 775 mmol/kg in cyclohexanone.

The rates of decomposition of cyclohexyl hydroperoxide in the presence of three different concentrations of cyclohexanone in cyclohexane solution at 130°C were followed by iodometry, and the rates of formation of cyclohexanone, cyclohexanol and the total free acids in the reaction mixture were also measured. (see Tables 2, 3)

The rate of formation of the total free acids (expressed in meq) was found to obey the equation,

$$\frac{d(FA)}{dt} = k_1\cdot(CHPO)\cdot(ANON), \qquad (2)$$

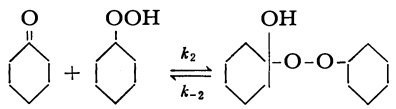
where, FA, total free acids; CHPO, cyclohexyl hydroperoxide; ANON, cyclohexanone. (see Figs. 1, 2)

It might be expected that cyclohexyl hydroperoxide forms an adduct (III) with cyclohexanone-like hydrogen peroxide.



(III) (3)

The formation of ε-cyclohexyloxycaproic acid can be explained by the probable –O–O– bond scission of the adduct followed by β-scission of α-hydroxy-

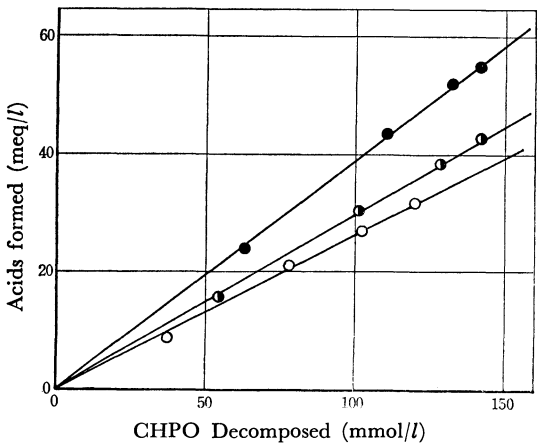


Fig. 1. Relationship between decomposed cyclohexyl hydroperoxide and free acids formed.
●, cyclohexanone 0.67 mol/l; ◑, cyclohexanone 0.38 mol/l; ○, cyclohexanone 0.22 mol/l

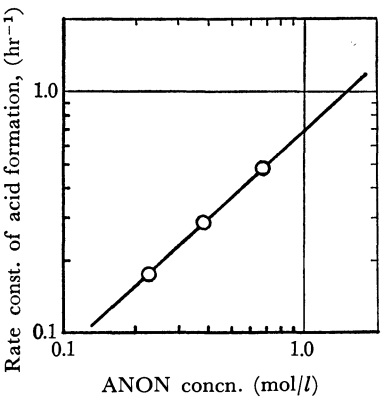

Fig. 2. Relationship between rate constants of acid formation and cyclohexanone concentrations.

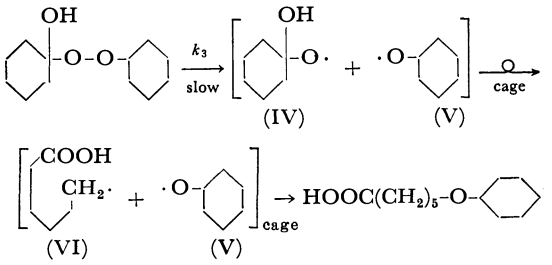
alkoxy free radical (IV) to produce a rearranged free radical (VI) and the cage recombination of the radical (VI) with incipient alkoxy radical (V).



(4)

This process may be either stepwise or a concerted one. If the whole course of the reaction scheme involved the fast pre-equilibrium of the adduct

formation and the slow decomposition of the adduct, the rate of formation of ε-cyclohexyloxycaproic acid would be expressed as follows.

$$\frac{d(CCA)}{dt} = K \cdot k_3 \cdot f \cdot (CHPO) \cdot (ANON), \quad (5)$$

where, CCA, ε-cyclohexyloxycaproic acid; K, equilibrium constant ($K=k_2/k_{-2}$); k_3, decomposition rate constant; f, fraction of radicals to form CCA.

Hence, the over-all activation energy for this reaction will be expressed by,

$$E_a = E_{k2} - E_{k-2} + E_{k3}, \quad (6)$$

where, E_{k2}, activation energy for forward reaction; E_{k-2}, activation energy for backward reaction; E_{k3}, activation energy for decomposition reaction.

Denisov *et al.*[2] reported the value of the heat of formation of the cyclohexanone-H_2O_2 adduct as 6.7 kcal/mol and value of an activation energy for the decomposition rate constant of that adduct as 16.2 kcal/mol. Thus an over-all activation energy of that process would be around 9.5 kcal/mol, which is close to that of ε-cyclohexyloxycaproic acid formation.

The β-scission of the radical (IV) will also be able to give cyclohexanone and hydroxy radical (·OH), but the recombination of hydroxy radical with the alkoxy radical (V) only produces cyclohexyl hydroperoxide and reverses the adduct formation. The main products of the decomposition of cyclohexyl hydroperoxide in the presence of cyclohexanone are clearly cyclohexanol and the carboxylic acids. (see Table 3) This is incompatible with the approximate 1 : 1 formation of cyclohexanone and cyclohexanol in the decomposition of cyclohexyl hydroperoxide on glpc.

The diffusion of the radicals (IV), (V) and hydroxy radical out of the solvent cage may cause the formation of cyclohexanol and the other acidic substances. The initial rate of the formation of cyclohexanol is expressed as

$$\left[\frac{d(ANOL)}{dt}\right]_{initial} = k_4 \cdot (ANON)^{0.51}, \quad (7)$$

where, ANOL, cyclohexanol. (see Fig. 3)

The chain reaction mechanism for the formation of cyclohexanol can be suggested by the approximate one half order dependence of the rate on cyclohexanone concentration and illustrated by the following reaction scheme.

$$\left.\begin{aligned} &\text{Adduct} \rightarrow RO\cdot + R'\cdot, \\ &R'\cdot + ROOH \rightarrow \\ &\quad ROO\cdot + R'H \text{ or } RO\cdot + R'OH, \\ &RO\cdot + ROOH \rightarrow ROO\cdot + ROH, \\ &2ROO\cdot \rightarrow 2RO\cdot + O_2, \\ &2RO\cdot \rightarrow \text{molecular products,} \end{aligned}\right\} \quad (8)$$

where, RO·, $C_6H_{11}O\cdot$; R'·, other radicals; ROOH, $C_6H_{11}OOH$.

The rate of disappearance of cyclohexyl hydroperoxide was observed to be

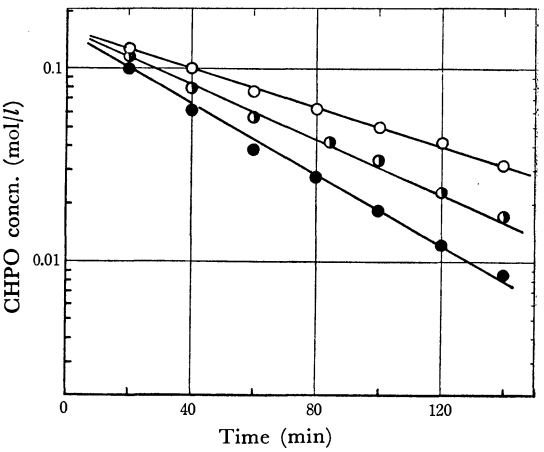


Fig. 4. Disappearance of cyclohexyl hydroperoxide in the presence of cyclohexanone.
●, cyclohexanone 0.67 mol/*l*; ◑, cyclohexanone 0.38 mol/*l*; ○, cyclohexanone 0.22 mol/*l*

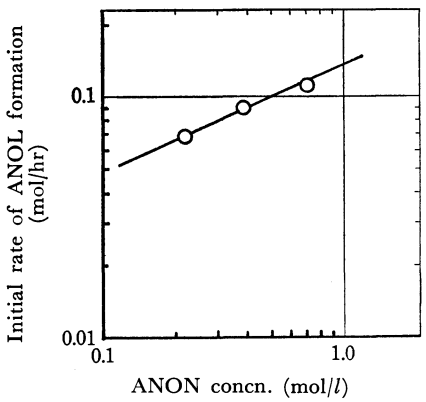

Fig. 3. Relationship between initial rates of cyclohexanol formation and cyclohexanone concentrations.

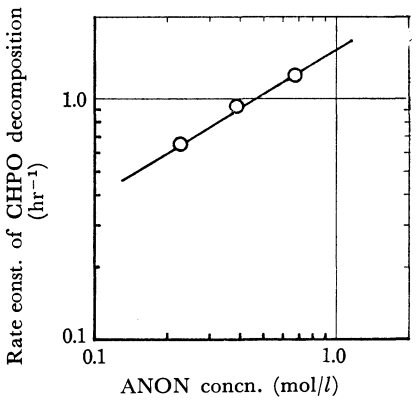

Fig. 5. Relation between decomposition rate constants of cyclohexyl hydroperoxide and cyclohexanone concentrations.

$$-\frac{d(CHPO)}{dt} = k_5 \cdot (CHPO) \cdot (ANON)^{0.67}. \quad (9)$$

(see Figs 4, 5)

The catalytic effect of the produced acids (up to 35 meq) on the rate of disappearance of cyclohexyl hydroperoxide was examined by the addition of a small amount of carboxylic acids (up to 100 mq) to the reaction mixture and found to be not very significant in our experimental condition. (see Table 4)

Table 4. Effects of acid concentration on the rate constants

Run No.	Acid conc. (meq)	k_d* (hr^{-1})	
SA-30	110±13	1.15	Caproic acid was added.
SA-29	38±12	0.93	Adipic acid was added.
SA-31	21±14	0.85	Produced acid only.
SA-21	19±15	0.84	Produced acid only.
SA-34	18±13	0.84	Produced acid only.
---- Extrapolated to zero, 0.78			

Temperature, 130°C; Cyclohexanone concentration, 0.37 mol/l.

* $-\frac{d(CHPO)}{dt} = k_d \cdot (CHPO)$

Consequently, the rate equation of disappearance of cyclohexyl hydroperoxide is considered to involve several independent terms

$$-\frac{d(CHPO)}{dt} = k_6 \cdot (CHPO) + K \cdot k_3 \cdot (CHPO) \cdot (ANON) + k_7 \cdot (CHPO)^m \cdot (ANON)^n, \quad (10)$$

where, k_6, first order rate constant for the decomposition of cyclohexyl hydroperoxide; k_7, rate constant for the induced decomposition of cyclohexyl hydroperoxide.

Farkas *et al.*[8] reported the rate constant of the disappearance of cyclohexyl hydroperoxide in cyclohexane (k_6; 0.000143 min^{-1} at 130°C). The presence of cyclohexanone is found to increase the rate of disappearance of cyclohexyl hydroperoxide (k_{obs}; $0.042+(ANON)^{0.67}$ min^{-1} at 13°C). The observed over-all rate enhancement of disappearance of cyclohexyl hydroperoxide in the presence of cyclohexanone would be the consequence of the combined effect of the terms in the Eq. (10.)

We are indebted to Teijin Limited who granted us permission of publication.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 794—797 (1969)

Photochemical Ethoxycarbonylmethylation of Benzene with Ethyl Haloacetates[1)]

Yoshiro OGATA, Teruo ITOH and Yasuji IZAWA

Department of Applied Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya

(Received July 18, 1968)

The ultraviolet light-induced reaction of ethyl haloacetate with an excess benzene gives ethyl phenylacetate (1.7%) and diethyl succinate (1.6%) as main products, while the same reaction of excess chloroacetate with benzene gives ethyl phenylacetate higher yield (optimum 78.4%). Addition of aluminum chloride to the reaction mixture using an excess benzene gives ethyl phenylacetate as a sole product (11.5%). The effect of reaction conditions on the yield is examined.

In the Friedel-Crafts reactions of ordinary carboxylic acids and esters with aromatic compounds, the carbon atom of carbonyl group is the main electrophilic site. In general, the substitution of aromatic rings by $-CH_2COOH$ (carboxymethylation) and by $-CH_2COOR$ (alkoxycarbonylmethylation) are difficult and the papers on these reactions are few.[2)] For example, the condensation of naphthalene with chloroacetic acid affording α-naphthaleneacetic acid in the presence of ferric oxide needs *ca.* 20 hrs' refluxing at 218°C.[2a)] The photo-induced reaction of this type has been

Abstr.*, **48**, 2019 (1954).

reported by Kharasch,[3] who succeeded in the carboxymethylation of benzene and cyclohexene with iodoacetic acid, but he provided no detail discussions.

The present paper describes our results on the photochemical ethoxycarbonylmethylation of benzene with ethyl chloroacetate or ethyl bromoacetate in the presence and absence of aluminum chloride.

$$C_6H_6 + ClCH_2COOC_2H_5 \xrightarrow{h\nu} C_6H_5CH_2COOC_2H_5 + HCl$$

Results and Discussion

The ultraviolet irradiation of a solution containing ethyl haloacetate and benzene gave ethyl phenylacetate (I), diethyl succinate (II) and a trace of biphenyl. These products were identified by means of GLC. The results are shown in Table 1 and Fig. 1.

g) Methanol solution.

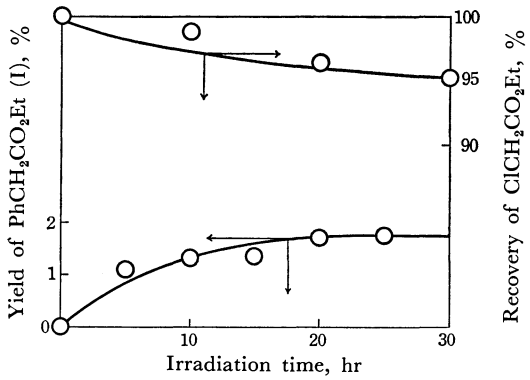

Fig. 1. Typical conversion curves for the reaction of ethyl chloroacetate with benzene.

Irradiation of a benzene solution of 0.1 M ethyl chloroacetate with high-pressure Hg lamp gave I, but in a poor yield (1.7%), while the reaction did not take place in the dark even at refluxing temperature. Almost no further photochemical reactions of I and II occurred.

Since both ethyl chloroacetate and benzene show an absorption band below 2600 Å, a low-pressure Hg lamp which emits almost exclusively 2537 Å light was used under similar conditions, but there was no appreciable effect on the yield of ethyl phenylacetate.

Irradiation at higher temperature (65°C) slightly increased the yield of ethyl phenylacetate. A slight increase in the yield of I was observed, when bromoacetate was used in place of chloroacetate probably because of the lower bond energy of C–Br than that of C–Cl, but the yield was still poor. Generally, the reaction in a solution of an excess benzene gave I in a poor yield, which may be due to the inner filter behavior of solvent benzene.

Further, the irradiation of an acetone or methanol solution of 0.1 M ethyl chloroacetate and 0.1 M benzene gave neither I nor II.

On the other hand, it was of interest to note that the irradiation of 0.1 M benzene in ethyl chloroacetate as solvent gave considerable yields of I and II as main products. In contrast to the reaction in a benzene solution, the yield of I is increased to 78.4%, while that of biphenyl also increases (Table 2). In addition, two other products were detected, neither of which has yet been identified.

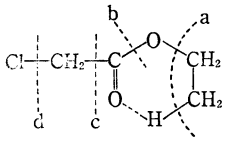
c) Immersion-type lamp.
d) Molar ratio of II to I.
e) Oxygen was added.
f) Iodine was added.

A probable primary process of this light-induced reaction may be the bond fission of excited ethyl haloacetate. The following types of bond cleavage have been considered to occur in the photolysis

3) a) N. Kharasch and L. Göthlich, *Angew. Chem.*, **74**, 651 (1962). b) N. Kharasch, P. Lewis and R. K. Sharma, *Chem. Commun.*, 435 (1967).

of alkyl esters[4]; (a) γ-H abstraction by an oxygen atom of carbonyl group and concerted alkyl-oxygen bond fission, (b) acyl-oxygen bond fission and (c) carbonyl-carbon fission. Fission of type (b) occurs mostly at shorter wavelengths (2380 Å and 1870 Å), while fissions of the types (a) and (c) take place at longer wavelength.



Since a high-pressure Hg lamp was used as the light source in the present reaction, fissions of the types (a) and (c) seem to be more probable. The formation of phenylacetate indicates the occurrence of another type of fission (d) (halogen-carbon bond fission).

The formation of diethyl succinate indicates the formation of ethoxycarbonylmethyl radical (III). In addition, hydrogen chloride was detected in the reaction products by the silver nitrate test. On the basis of these data and available postulates[3,5] of similar radical substitutions on benzene ring, probable reaction pathways to account for the observed products can be presented as follows.

$$ClCH_2CO_2Et \overset{h\nu}{\rightleftharpoons} Cl\cdot + \underset{(III)}{\cdot CH_2CO_2Et} \quad (1)$$

$$\bigcirc + \cdot CH_2CO_2Et \longrightarrow \underset{(IV)}{\bigcirc\!\!\begin{matrix}CH_2CO_2Et\\H\end{matrix}} \quad (2)$$

$$\underset{(IV)}{\bigcirc\!\!\begin{matrix}CH_2CO_2Et\\H\end{matrix}} + Cl\cdot \longrightarrow \underset{(I)}{\bigcirc CH_2CO_2Et} + HCl \quad (3)$$

$$2\cdot CH_2CO_2Et \longrightarrow \underset{(II)}{\begin{matrix}CH_2CO_2Et\\|\\CH_2CO_2Et\end{matrix}} \quad (4)$$

Scheme 1

This scheme involves a σ-complex IV as an unstable intermediate. If the hydrogen atom abstraction from IV (Eq. (3)) would be the rate-determining step, addition of oxygen or iodine as an oxidizing agent to the system should tend to increase the yield of I, but this tendency was virtually not observed; *i. e.*, the addition of oxygen, which may quench the excited chloroacetate, somewhat decreased the yield of **I**, while the addition of iodine slightly increased the yield.

Interestingly, the mixture of 0.1 M aluminum chloride with a benzene solution of 0.1 M ethyl chloroacetate gave on irradiation ethyl phenylacetate as a sole product (Table 3). The yield of I was made better than that without aluminum chloride. These improvements in selectivity and yield of I seem to indicate the participation of an ionic mechanism similar to the ordinary Friedel-Crafts reaction.

TABLE 3. THE YIELDS OF ETHYL PHENYLACETATE IN THE PHOTOCHEMICAL REACTION OF ETHYL CHLOROACETATE WITH EXCESS BENZENE IN THE PRESENCE OF ALUMINUM CHLORIDE AT 25°C[a]

c) Deposit on the wall of reaction vessel was cleaned at appropriate interval of time.

The ordinary Friedel-Crafts reaction of benzene with ethyl acetate in the dark gives acetophenone, ethylbenzene and *p*-ethylacetophenone.[6] In the similar dark reaction of benzene with ethyl chloroacetate, the formation of ethylbenzene, diethylbenzene and triethylbenzene has been reported.[7] It has been shown that the activity of halogen atom in ethyl chloroacetate was suppressed by the presence of carbonyl group. The closer the carbonyl group is located to the halogen atom, the more effective is the suppression; *e. g.*, ethyl ω-chloropropionate and ω-chlorobutyrate can react at the halogenated carbon atom in the Friedel-Crafts reaction.[7] However, the halogenated carbon atom is the reaction site in our photo-Friedel-Crafts reaction. This difference may be explained by the photo-excitation of the carbonyl group. If the carbonyl oxygen atom of the ester would gain a positive formal charge through its n–π^* excitation by irradiation, a coordination of aluminum

chloride to halogen rather than carbonyl should occur, hence the halogenated carbon atom should become the attacking site.

No spectral evidence for a coordination compound between ethyl chloroacetate and aluminum chloride has been reported, while aluminum chloride is shown to coordinate to the carbonyl oxygen atom of ethyl acetate in view of the shift of the carbonyl stretching absorption from 1741 cm^{-1} in ethyl acetate to 1622 cm^{-1} in the complex.[8] Characteristic IR absorption bands of a mixture of aluminum chloride and ethyl chloroacetate are listed in Table 4. Observed shift of ν_{C-Cl} and $\nu_{C=O}$ suggests that aluminum chloride coordinates with both halogen and carbonyl in the ground state, but the halogenated carbon atom can be the more reactive site in the n–π^* excited state of the carbonyl because of its reverse π-electron polarization to that in the ground state.

$$AlCl_3 + ClCH_2CO_2Et \xrightarrow[n-\pi^*]{h\nu} \left[\overset{\delta-}{AlCl_3}\cdots\overset{\delta+}{Cl}CH_2CO_2Et\right]$$

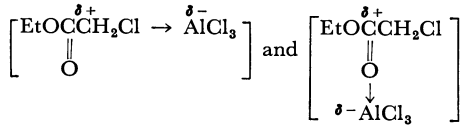
These speculations are rationalized by the photochemical formation of ethyl phenylacetate alone in the presence of aluminum chloride.

Table 4. Infrared spectra (cm^{-1}) of ethyl chloroacetate and its complex with aluminum chloride at 20°C

$ClCH_2CO_2Et$ (liquid)	$ClCH_2CO_2Et \cdot AlCl_3$	Assignment
1770	1740	$\nu_{C=O}$
1195	1215	ν_{CO-O}
1030	1025	ν_{O-Et}
570	490	ν_{C-Cl}

The participation of 1 : 1 complex between ethyl chloroacetate and aluminum chloride in this reaction is suggested by the following experiments. When the molar ratio of chloroacetate to aluminum chloride was varied, the yield of I reached to a maximum value at 1 : 1 of the molar ratio (Table 3).

On mixing ethyl chloroacetate with aluminum chloride, new absorption bands appear at 2750 Å and 3650 Å. These bands may be assigned to the complexes (Va and Vb) of ethyl chloroacetate and aluminum chloride, *i. e.*,



Va

Vb

Therefore, the excitation of these complexes (perhaps C-T complex) also might play an important role as well as the n–π^* excitation of carbonyl in this light-induced primary process, *i. e.*,

$$>C=O \xrightarrow{h\nu} >\overset{\delta-}{C}-\overset{\delta+}{O}\cdot$$

But the excitation of the C-T complexes cannot explain the selective formation of I. Therefore, it is probable that the n–π^* excitation of carbonyl group participates more than that of C-T complexes.

Experimental

Materials. Ethyl bromacetate[9] was prepared by the conventional esterification of bromoacetic acid with ethanol catalyzed by concentrated sulfuric acid, bp 158.5—159°C, ν_{max} 1730, 1185 and 1028 cm^{-1}. Ethyl chloroacetate, bp 52—53°C/21 mmHg, ν_{max} 1770, 1195, 1030 and 570 cm^{-1}, authentic ethyl phenylactate, bp 115—116°C/22 mmHg, ν_{max} 1740, 1605, 1500, 1155 and 1030 cm^{-1}, and authentic diethyl succinate, bp 108—108.5°C/19 mmHg, ν_{max} 1740, 1160 and 1030 cm^{-1}, were also prepared by the similar esterification of the corresponding acids. The IR spectra were measured by a Perkin-Elmer Model 337 spectrophotometer.

General Procedure. A Halos high-pressure 300 W Hg lamp and a low-pressure 30 W Hg lamp with a water-cooling quartz jacket were used as light sources. The reaction mixture was placed in a cylindrical quartz vessel (30×300 mm), N_2 gas being bubbled into the mixture. The vessel together with the lamp was immersed into a water bath at a distance of 5 cm.

For the immersion type irradiation, the light source was immersed in a reaction mixture in a reactor equipped with a N_2 gas inlet, a thermometer and a condenser.

The reaction mixture was irradiated for 30hr. At appropriate intervals of time, aliquots were taken out, each yield being estimated by means of GLC.

Analysis of Products. The identification of products was done by means of GLC employing a Yanagimoto Model GCG-220 operated with a column (1 m× 4 mm) packed with Silicone DC 550 (30 wt %) on Celite 545 of 80—100 mesh using H_2 as a carrier gas (40 ml/min) at 180°C or a Yanagimoto Model GCG-550 F equipped with a hydrogen-flame ionization detector, operated with a column (0.75 m×3 mm) packed with DEGS (13 wt %) on Celite 545 of 80—100 mesh using N_2 as a carrier gas (30 ml/min) at 60—180°C (6°C/min). The yields of products I and II were also estimated by means of GLC under the same conditions using *n*-butyl benzoate as an internal standard. The recovery of the ethyl chloroacetate was estimated by means of GLC operated with a column (2 m×4 mm) packed with Apiezon Grease L (3 wt %) on Celite 545 of 80—100 mesh with H_2 as a carrier gas (40 ml/min) at 80°C using anisole as an internal standard.

Nitroalkenylferrocene. II. The Condensation Reaction of Nitroolefins with Aromatic Carbonyl Compounds

Mikio SHIGA, Hiromichi KONO, Izumi MOTOYAMA and Kazuo HATA

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya, Tokyo

(Received July 30, 1968)

The condensation reactions of β-ferrocenylnitroethylene (**1**), with various aromatic aldehydes in the presence of an excess of sodium methoxide were investigated. The main products of these reactions were ferrocenylnitroalkenols (**2**), which were obtained from precursory sodium salts by the acidification of the reaction mixture. Sodium nitroalkanolate (**4**) was postulated as an intermediate in these reactions. On the other hand, the reaction of **1** with acetophenone resulted in a different condensation, one giving 1-benzoyl-2-ferrocenyl-3-nitropropane (**11**) and 1-benzoyl-2-ferrocenylethylene (**12**).

Various reactions of nitroolefins have been reported by several authors,[1-5] but most of these reports were concerned with the reaction of β-carbon of nitroolefins. With a view of getting some information on the reactivity of the α-carbon of nitroolefins, the condensation of β-ferrocenylnitroethylene (**1**)[6] with aromatic aldehydes was investigated for this paper.

The sodium salt of the nitroethylene (1) reacted with aldehyde in methanol solution at 0°C. The reaction mixture, after it had been kept stirring for 20 hr, was poured into water and the excess of aldehyde was removed with benzene. The acidification of the aqueous solution with dilute hydrochloric acid gave 3-ferrocenyl-2-nitro-1-aryl-2-propen-1-ol (**2**). The product (**2**) is considered to exist in the original reaction mixture as its sodium salt. It was found that some of the nitroalkenols are apt to decompose to give formylferrocene during the extraction of the alkaline solution with benzene. Hence, the preferred procedure for obtaining the nitroalkenols (**2**) is to pour the reaction mixture directly into dilute hydrochloric acid and then to extract it with benzene. The results of the condensation reaction are summarized in Table 1. The NMR and IR spectra of the nitroalkenols (**2**) are shown in Tables 2 and 3. The condensation reactions usually produced a small

amount of by-products, consisting of formylferrocene and two unidentified ferrocene derivatives, one of which was considered to be a dimer of **1** on the basis of its IR spectrum.

The formation of the nitroalkenol (**2**) from the nitroolefin (**1**) is interpreted as is shown in the scheme. Sodium methoxide reacts with **1** to generate a carbanion (**3**), which then attacks a carbonyl carbon on the aromatic aldehyde to form a sodium nitroalkanolate (**4**). The intermediate (**4**) is converted into the nitroalkenol (**2**), either by the action of sodium methoxide through sodium nitroalkenolate (**5**) (Course A) or by intramolecular hydrogen transfer through the sodium salt of *aci*-nitroalkenol (**6**) (Course B). Course A seems more favorable than Course B when an excess of sodium methoxide is present in the reaction mixture.

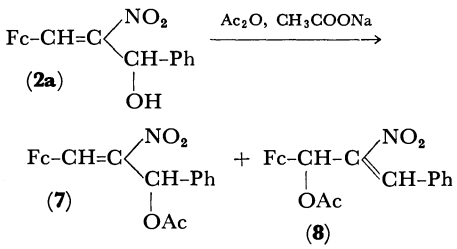
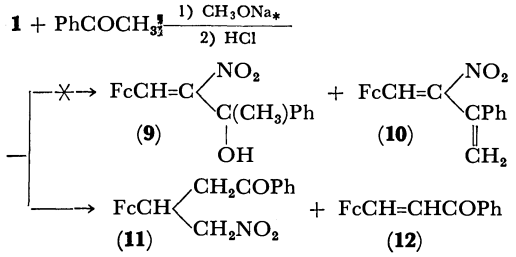
The condensation reactions which were carried out in solvents other than methanol resulted in a low yield of **2** (Table 4). The low yield is probably caused by the insufficient solubilities of the sodium salt (**3**) toward these solvents.

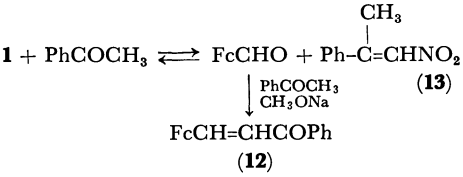
When 3-ferrocenyl-2-nitro-1-phenyl-2-propen-1-ol (**2a**) was treated with acetic anhydride and sodium acetate, two isomeric acetates were obtained. One of them, obtained in a 56% yield, was found by a study of its IR and NMR spectra to be the normal acetylation product (**7**). The other product, obtained in a 6.7% yield, was tentatively identified as the rearrangement product (**8**) from the results of its elemental analysis, but the lack of its NMR data does not permit any conclusive structural assignment.



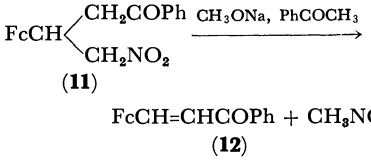
In contrast with the behavior of aldehyde, the similar reaction of the nitroethylene (**1**) with acetophenone gave quite a different result; instead of an analogous nitroalkenol (**9**) or its dehydration product (**10**), 1-benzoyl-2-ferrocenyl-3-nitropropane (**11**) was obtained as the condensation product of a carbanion generated from acetophenone with β-carbon on **1**, together with a small amount of 1-benzoyl-2-ferrocenylethylene (**12**).[7,8]



As is shown in Table 5, when a large excess of acetophenone was used (Run b), **12** was obtained in a good yield. It may be assumed that the formation of **12** is to be ascribed to the condensation of the excess acetophenone with formylferrocene, which is itself produced by the following exchange reaction between acetophenone and β-ferrocenylnitroethylene (**1**):



However, this inference is ruled out by the experimental finding that 2-phenyl-1-nitropropene (**13**) could not be detected in the reaction product. A better explanation seemingly lies in the fact that the primary product (**11**) was easily decomposed into 1-benzoyl-2-ferrocenylethylene (**12**) and nitromethane in the presence of sodium methoxide and an excess of acetophenone.



Experimental

General Procedure of Preparing Nitroalkenol (2). The reaction conditions and the products of the condensation reactions of β-ferrocenylnitroethylene with aromatic aldehydes are summarized in Table 1. A typical reaction procedure was as follows: To 1.28 g (0.005 mol) of finely-powdered β-ferrocenylnitroethylene in 7 m*l* of absolute methanol at 0°C, there were added slowly 1.35 g (0.025 mol) of sodium methoxide, which had been freshly-prepared from absolute methanol and sodium metal. Subsequently, 0.025 mol of aromatic aldehyde was added, drop by drop, into the mixture with stirring. After it had been stirred for 20 hr, the reaction mixture was poured into a mixture of 10% hydrochloric acid (100 m*l*) and benzene (30 m*l*), and then stirred for a few more minutes. The benzene layer which separated from the aqueous layer was washed three times with 50 m*l* portions of water and then dried over magnesium sulfate. After the benzene had been removed by distillation under reduced pressure, the residual blue-violet oil was dissolved in 2 m*l* of chloroform and chromatographed on alumina, using chloroform as the solvent, the chromatographic column being covered with aluminum foil in order to prevent the

7) K. Schlögl, *Monatsch. Chem.*, **88**, 601 (1957).
8) J. Boichard, J. P. Monin and J. Tirouflet, *Bull. Soc. Chim. France*, **1963**, 851.

decomposition of unstable nitroalkenol (**2**) by exposure to the light. The first fraction of the chromatography gave the starting material, and the second fraction gave a mixture of **2** and by-products as a blue-violet oil, which was then subjected to further chromatography on Florisil, using benzene as the solvent. Nitroalkenol (**2**) was obtained as a blue-violet oil from the second fraction, whereas the first and the third fraction gave by-products. The nitroalkenol (**2**) thus obtained was purified again by chromatography on Florisil.

3-Ferrocenyl-2-nitro-1-phenyl-2-propen-1-ol (2a). The condensation reaction of β-ferrocenylnitroethylene (**1**) (1.28 g) with benzaldehyde (2.6 g) gave a blue-violet oil of nitroalkenol (**2a**) (0.93 g, 52%).

Found: C, 61.81; H, 4.59; N, 4.11%. Calcd for $C_{19}H_{17}FeNO_3$: C, 62.80; H, 4.68; N, 3.85%.

3-Acetoxy-1-ferrocenyl-2-nitro-3-phenylpropene (7) and 3-Acetoxy-3-ferrocenyl-2-nitro-1-phenylpropene (8). To 400 mg of **2a** in 4 m*l* of acetic anhydride, 0.5 g of anhydrous sodium acetate was added. After it had been heated to 95°C for 3 hr, the reaction mixture was poured into 50 m*l* of water. The blue-brown solid (450 mg) which separated as a precipitate was chromatographed on Florisil, using a mixture of benzene-*n*-hexane (5 : 1) as the solvent. The starting material (**2a**) was recovered as the first fraction. After the starting material had then been completely removed, elution with chloroform gave an acetylated product (**7**), (250 mg, 50% yield as a blue-violet oil.

Found: C, 61.80; H, 4.62; N, 3.02%. Calcd for $C_{21}H_{19}FeNO_4$: C, 62.22; H, 4.62; N, 3. 45%.

A third elution, using a mixture of chloroform and a small amount of methanol as the solvent, afforded the isomeric acetate (**8**), (30 mg, 6.7% yield) as a brown solid (mp 62—64°C).

Found: C, 61.02; H, 4.57; N, 3.40%. Calcd for $C_{21}H_{19}FeNO_4$: C, 62.22; H, 4.62; N, 3.45%.

3-Ferrocenyl-2-nitro-1-(2-furyl)-2-propen-1-ol (2b). The condensation reaction of β-ferrocenylnitroethylene (1.28 g) with furfural (2.4 g) gave 0.61 g (35% yield) of nitroalkenol (**2b**).

Found: C, 58.55; H, 4.02; N, 3.35%. Calcd for $C_{17}H_{15}FeNO_3$: C, 57.79; H, 4. 24; N, 3.96%.

3-Ferrocenyl-2-nitro-1-(*p*-methoxyphenyl)-2-propen-1-ol (2c). *p*-Anisaldehyde condensed with β-ferrocenylnitroethylene to give 0.83 g (43% yield) of nitroalkenol (**2c**).

Found: C, 62.64; H, 4.44%. Calcd for $C_{20}H_{19}FeNO_4$, C: 63.61; H, 4.83%.

3-Ferrocenyl-2-nitro-1-(*p*-nitrophenyl)-2-propen-1-ol (2d). The condensation of β-ferrocenylnitroethylene (1.28 g) with *p*-nitrobenzaldehyde (3.7 g) afforded 1.17 g of crude nitroalkenol (**2d**). A small amount of the by-products could not be removed from the crude **2d** by column chromatography, but the IR spectrum of the crude product clearly showed the existence of **2d**.

1-Benzoyl-2-ferrocenyl-3-nitropropane (11). The condensation reaction of β-ferrocenylnitroethylene (1.28 g, 0.005 mol) with acetophenone (3.0 g, 0.025 mol) was carried out much like that with aldehydes. The first fraction of the chromatographic separation of the crude product on alumina gave a small amount of reddish crystals of 1-benzoyl-2-ferrocenylethylene (**12**) (mp 137—140°C, 0.07 g, 5% yield) upon elution with benzene.

The main product (**11**) was obtained as pale yellow crystals (mp 111—113°C, 1.57 g, 84% yield) by elution with chloroform. The IR spectrum of **11** showed absorption bands at 1670 cm^{-1} (C=O) and at 1549 cm^{-1} (NO_2)

Found: C, 63.80; H, 4.86; N, 3.82%. Calcd for $C_{20}H_{19}FeNO_3$: C, 63.66; H, 5.04; N, 3.71%.

1-Benzoyl-2-ferrocenylethylene (12). a) The condensation reaction described above was carried out in the presence of a large excess (9.0 g, 0.075 mol) of acetophenone. A mixture of **12** and formylferrocene was obtained as the first fraction by the chromatography of the crude product on alumina. After the removal of the formylferrocene by sublimation, **12** was obtained as reddish-orange crystals (1.35 g, 86% yield). The IR spectrum of **12** showed absorption bands at 1655 and 1676 cm^{-1} (C=O).

Found: C, 72.58; H, 5.14%. Calcd for $C_{19}H_{16}FeO$: C, 72.15; H, 5.06%.

b) Acetophenone (6.0 g, 0.05 mol) was added to a solution of **11** (0.74 g, 0.0025 mol) and sodium methoxide (0.54 g, 0.01 mol) in absolute methanol (7 m*l*). After being kept standing overnight, the reaction mixture was poured into 100 m*l* of 10% hydrochloric acid and extracted with benzene. The extract was dried over magnesium sulfate and concentrated. The chromatographic separation of the crude product on alumina gave **12** (0.51 g, 65% yield) from the second fraction.

The Wolff Rearrangement. V. Kinetic Isotope Effect of α-Diazoacetophenone*1

Yasuhide YUKAWA and Toshikazu IBATA*2

The Institute of Scientific and Industrial Research, Osaka University, Kamiyamada, Suita, Osaka

(Received August 9, 1968)

Kinetic isotope effect of the Wolff rearrangement of carbonyl-^{14}C and phenyl-1-^{14}C labeled α-diazoacetophenone was measured in *t*-butyl alcohol at 30°C, using a solution of silver benzoate in triethylamine as a catalyst. No apparent kinetic isotope effect was observed in both cases within experimental error. These results suggest that the elimination of nitrogen and the migration of phenyl group proceed in two steps in the rate-determining step.

In the previous papers of this series, we have reported the kinetic studies of the Wolff rearrangement of α-diazoacetophenone,[1] and substituent effect of substituted α-diazoacetophenones catalyzed by silver benzoate in alcohols.[2] From these results it was concluded that the rate-determining step of this reaction was that of elimination of nitrogen. In this case following two mechanisms are possible;

a) A concerted one-step mechanism in which elimination of nitrogen and migration of alkyl group proceed synchronously.

b) Two-step mechanism in which the elimination of nitrogen proceeds in the first step, followed by migration of alkyl group.

One-step mechanism

$$[\underset{\text{(I)}}{\overset{\ominus}{\text{RCOC}}=\text{N}_2—\overset{\oplus}{\text{Ag}}\text{N}(\text{C}_2\text{H}_5)_3}] \rightarrow [\underset{\text{(II)}}{\text{R}-\overset{\ominus}{\text{C}}=\text{C}=\text{O}}] + \text{N}_2 + [\text{AgN}(\text{C}_2\text{H}_5)_3]^{\oplus} \quad (1)$$

Two-step mechanism

$$[\underset{\text{(I)}}{\overset{\ominus}{\text{RCOC}}=\text{N}_2—\overset{\oplus}{\text{Ag}}\text{N}(\text{C}_2\text{H}_5)_3}] \rightarrow [\underset{\text{(III)}}{\overset{\ominus}{\text{RCOC}}—\overset{\oplus}{\text{Ag}}\text{N}(\text{C}_2\text{H}_5)_3}] + \text{N}_2 \quad (2)$$

$$[\underset{\text{(III)}}{\overset{\ominus}{\text{RCOC}}—\overset{\oplus}{\text{Ag}}\text{N}(\text{C}_2\text{H}_5)_3}] \rightarrow [\underset{\text{(II)}}{\text{R}-\overset{\ominus}{\text{C}}=\text{C}=\text{O}}] + [\text{AgN}(\text{C}_2\text{H}_5)_3]^{\oplus} \quad (3)$$

The kinetic isotope effect may be useful to distinguish these two mechanisms, in other words, to get the precise information on the transition state of this reaction. In this connection, Fry and his co-workers have studied the kinetic isotope effect of the Curtius rearrangement of phenyl-1-^{14}C, carbonyl-^{14}C and ^{15}N labeled benzazide.[3] We have studied the kinetic isotope effect of the Wolff rearrangement of α-diazoacetophenone-(carbonyl-^{14}C) (IVa) and α-diazoacetophenone-(phenyl-1-^{14}C) (IVb), when triethylamine solution of silver benzoate was used as a catalyst.

Results and Discussion

Kinetic isotope effects of the Wolff rearrangement of (IVa) and (IVb) were determined as follows; Sampling of 10 m*l* of reaction mixture at every ten minutes after the initiation of the reaction, converting the unreacted IV in each sample into a 2,4-dinitrophenylhydrazone of phenacyl chloride by the reaction with 2,4-dinitrophenylhydrazine in the presence of hydrochloric acid, burning the purified hydrazone by modified van Slyke wet-oxidation method,[4] and absorbing the carbon dioxide into an aqueous barium hydroxide solution to give barium carbonate, and counting the radio activity of the barium carbonate by G. M. counter after disk formation. The results obtained were

given in Tables 1 and 2. Radio activity of each run was constant within experimental and counting error of ±2%, and no kinetic isotope effect was observed for IVa and IVb.

One of the most important factors of kinetic isotope effect is the variation of the zeropoint energy difference between the transition state and the reaction origin of the rate-determining step by means of heavy and light isotopic compounds. In other words, the partial bond breaking and bond formation with respect to labeled atom in the transition state causes the alternation of the vibrational frequency of that bond and consequently leads to the kinetic isotope effect. Generally, when bond breaking occurs in the transition state the normal kinetic isotope effect is expected, and bond formation causes the reverse one.

It may be considered from our results, in which no kinetic isotope effect was observed in both IVa and IVb, that bond breaking or bond formation with respect to both carbonyl-C-atom and phenyl-1-C-atom of α-diazoacetophenone is not happened in the transition state. Therefore two-step mechanism is preferred. The precise model of the transition state of this reaction may be shown by VII, in which the R-CO bond length is not changed from that of V*[3] (path B). This may suggest that the bond energy effect observed in the substituent effect of para-electron releasing groups, such as *p*-methoxy and *p*-ethoxy, on reaction rate is not attributed to R-CO bond cleavage but to C-N_2 bond cleavage.

Experimental

Materials. *α-Diazoacetophenone-(carbonyl-^{14}C).* A mixture of 1.23 g (0.010 mol) of benzoic-^{14}C acid (sepcific activity 11.8 μc/mmol) and 2.5 g (0.021 mol) of purified thionyl chloride was refluxed for three hours. The excess thionyl chloride was evaporated under reduced pressure, and the last of the reagent was removed by azeotrope with two added 5 m*l* of absolute benzene. Benzoyl chloride obtained was used for diazoacetophenone formation without further purification. To 50 m*l* of etheral solution of diazomethane, prepared by the alkaline decomposition of 7.0 g (0.07 mol) of *N*-nitroso-*N*-methylurea, an etheral solution of previously synthesised benzoyl-^{14}C chloride was added drop by drop under stirring at −5°C. After standing overnight at room temperature, the ether was removed under reduced pressure at room temperature. Yellow crystals of IVa were obtained from the residue on standing in the refrigerator and purified by two recrystallization from petroleum ether. Mp 47.5—48.0°C, yield 0.85 g (58%).

α-Diazoacetophenone(phenyl-1-^{14}C). 1.11 g (0.009 mol) of commercial benzoic acid (phenyl-1-^{14}C labeled) (specific activity 18.7 μc/mmol) was chlorinated by 2.4 g (0.020 mol) of purified thionyl chloride to give phenyl-1-^{14}C labeled benzoyl chloride, according to the same method described in the previous part. IVb was obtained by the reaction of corresponding benzoyl chloride and four equivalents of diazomethane. Mp 47.5—48.0°C, yield 0.83 g (63%). The phenyl-1-labeled α-diazoacetophenone (0.83 g) was diluted isotopically by adding 1.40 g of unlabeled α-diazoacetophenone, and isotopically homogenized by two recrystallization from petroleum ether.

Specific Activity $=18.7\times0.83/(0.83+1.40)=6.96$ μc/mmol

Silver benzoate, t-Butyl Alcohol and Triethylamine. Reagent and solvents used here were prepared and purified by the method previously reported.[1]

Quantitative Determination of α-Diazoacetophenone (IV). When IV was treated with 2,4-dinitrophenylhydrazine (VIII) in alcoholic solution in the presence of hydrochloric acid, 2,4-dinitrophenylhydrazone of phenacyl chloride[5] was precipitated accompanying the evoluation of nitrogen. In order to utilize this reaction for the quantitative determination of unreacted diazoketone in the course of the Wolff rearrangement, it is ascertained that the formation of the hydrazone is almost quantitative under the same condition of the isotope effect determination reaction, as shown in Table 3.

Determination of Rate Constant and Kinetic Isotope Effect of the Wolff Rearrangement of IVa. *Determination of Reaction Rate.* To a solution of 0.813 g (5.5 mmol) of IVa (specific activity, 11.8 μc/mmol) dissolved in 100 m*l* of *t*-butyl alcohol contained in long necked reaction vessel, triethylamine (2.0 m*l*) solution of 0.100 g of silver benzoate was added at a time. After vigorous swirling, reaction vessel was immersed in the thermostated bath at 30.05±0.01°C. A 10 m*l* of alquot of the reaction mixture was pipetted into a 50 m*l* of flask containing 100 mg of VIII and 10 m*l* of concentrated hydrochloric acid and 10 m*l* of ethanol

at the intervals of ten minutes after the addition of the catalyst. The hydrazone solutions were allowed to stand overnight in the bath at 50—60°C, for the purpose of the complete precipitation of the hydrazone and aging of the crystals, then allowed to cool to room temperature, added 10 m*l* of water. Crystals of the hydrazone were collected on the precisely weighed fritted glass funnel, washed with 2 N hydrochloric acid until no yellow color of unreacted VIII-hydrochloride appeared in the filtrate, washed with distilled water and then dried for 12—15 hr at 80—90°C, and weighed.

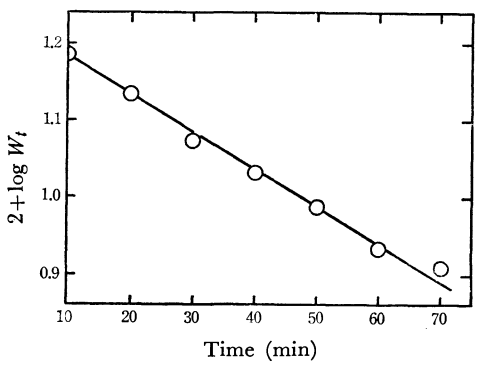

Fig. 1. The linear relationship between log W_t and time in the reaction of IVa.

The linear first-order plot was obtained between log W and time as shown in Fig. 1. The reaction rate k was calculated by the following equation,

$$k_t=2.303\times\log(W_0/W_t)$$

where W_0 and W_t were denoted the weight of the hydrazone at the time of $t=0$ and t respectively, and $t=0$ was

the time of the first pipetting.

Measurement of Kinetic Isotope Effect. The hydrazone obtained from the rate measurement of IVa (shown in Table 1, Nos. 1—7) was recrystallized four times from a mixed solvent of ethyl acetate and ethanol (3 : 1), and solvent was evaporated completely in vacuum desiccator for a few days. About 15—16 mg of purified hydrazone was oxidized by modified van Slyke wet-oxidation method, and carbon dioxide was absorbed by 10 m*l* of saturated barium hydroxide solution to give barium carbonate. Carbon dioxide and barium hydroxide solution was kept separately until oxidation was complete (at 170°C, for 4 hr), in order to homogenize the distribution of carbon fourteen in barium carbonate. Barium carbonate was made as a disk of 1.7 cm in diameter, which had infinite thickness, by filtration (using metallic filter), and radio activity of these barium carbonate samples were counted by G. M. counter after drying.

Determination of Reaction Rate and Kinetic Isotope Effect of the Wolff Rearrangement of IVb. The same procedure described in the case of IVa was used for these measurements. Reaction conditions used and results obtained were given in Table 2 (Fig. 2). It was ascertained that the degree of the contamination of the commercial benzoic acid-(phenyl-1-^{14}C) (IX) used for the synthesis of IVb by the mixing of benzoic acid-(carbonyl-^{14}C) was no more than 0.44%, comparing the radio activity of the barium cabonate obtained by direct oxidation of IX with that obtained by Schmidt rearrangement of IX.

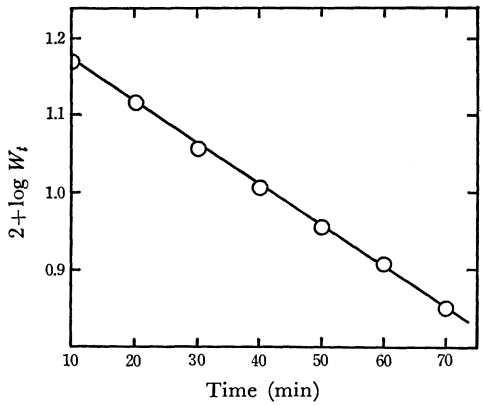

Fig. 2. The linear relationship between log W_t and time in the reaction of IVb.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 805—808 (1969)

Organic Syntheses by Means of Noble Metal Compounds. XXXVIII. Cyclohexanone Oxime Complexes of Palladium[1]

Sinzo IMAMURA, Tsunesuke KAJIMOTO, Yukishige KITANO and Jiro TSUJI

Basic Research Laboratories, Toyo Rayon Co., Kamakura

(Received August 9, 1968)

Ligand exchange reactions of palladium complexes having π-allyl and acetylacetonate as ligands with cyclohexanone oxime were carried out and the formation of several new oxime complexes was reported.

Dioximes as bidentate form stable complexes with various metals, and dimethylglyoxime is a typical example. On the other hand, monoximes do not form a stable complex, and it has been reported that an attempt to prepare a monoxime complex with nickel, iron and cobalt salts gave no stable complex.[2] Formation of stable monoxime complexes with platinum and palladium[2] has been reported briefly. We have found that monoximes form stable complexes with palladium by displacing ligands of various palladium complexes. In this paper the ligand exchange reaction of palladium complexes with cyclohexanone oxime is reported.

Results and Discussion

The formation of a stable complex by the reaction of palladium chloride with two moles of cyclohexanone oxime and its structure have already been reported.[3] The complex can be prepared more easily by treating benzonitrile complex of palladium chloride with the oxime. It was confirmed by X-ray analysis that the complex has a square planar *trans* structure (I). The preparation of the corresponding *cis* complex (II) was attempted

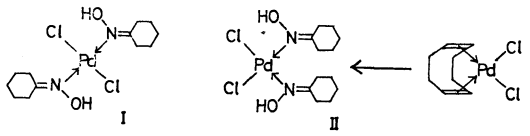
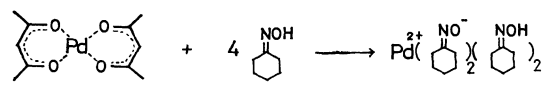
by the displacement reaction of 1,5-cyclooctadiene-palladium chloride complex with the oxime.



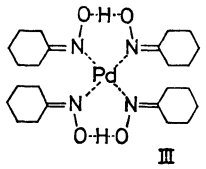
I II

Simple displacement of cyclooctadiene should presumably give the *cis* structure. The complex obtained showed the same IR and NMR spectra as those of the *trans* complex. The only difference was their melting points. The melting point of the *cis* complex, 199°C, was found to be higher than that of the *trans* complex, 184°C. In order to confirm the *cis* structure definitely, the measurement of the dipole moments of both complexes was attempted, but, owing to their low solubilities in benzene, no definite conclusion was obtained. Thus it is not certain whether the complex is really *cis* or not. The NMR spectrum of the *trans* complex is shown in Fig. 1. Two kinds of NMR signals due to the syn and anti α-methylene protons of a cyclohexanone ring are observed at τ 6.91 and τ 7.36. Saito and Nukada[4] reported that, in cyclohexanone oxime hydrochloride, only one kind of α-methylene proton signal is observed, because the paramagnetic anisotropic effect of the hydroxyimino group is eliminated due to the addition of the proton of hydrogen chloride to the lone pair electrons of the nitrogen atom. In the palladium oxime complex, the oxime coordinates to palladium atom with the lone pair electrons of the nitrogen atom, and the separation of the syn and anti proton signals is considered to be attributed to the diamagnetic anisotropic effect of palladium.

From the above mentioned complex formation, it is apparent that cyclohexanone oxime is capable of forming a stable complex with palladium. The oxime complex formation by a ligand exchange reaction of rather stable palladium complexes was attempted. The first example was palladium acetylacetonate, which is a very stable complex. A solution of palladium acetylacetonate in dichloromethane was treated with the oxime at room temperature for 3 min, and a new complex was isolated by the addition of a large amount of ether. The complex showed no IR absorption due to the carbonyl, indicating that the acetylacetone was displaced completely by the oxime. The analysis showed that the complex contained two moles of the oxime anion and two moles of the oxime.



An IR absorption band at 2350 cm^{-1} indicates the presence of hydrogen bonding.[5] The following structure (III) is possible for the complex.



III

π-Allylpalladium chloride was then treated similarly with the oxime in dichloromethane at room temperature. A new complex was isolated by the addition of a large amount of ether. The NMR and IR spectra showed that the complex still retains the π-allyl system and the reaction is not a displacement, but an addition reaction. Analysis showed that one mole of the oxime per two atoms of palladium was incorporated into the complex.

The addition of the oxime molecule by the opening of the bridged structure as shown below (IV) was an expected reaction. The opening of the bridge structure of π-allylpalladium chloride is

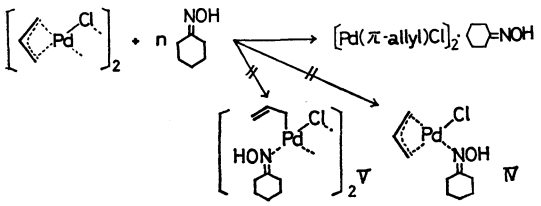
known with such a ligand as phosphine or amine. Another possibility is the opening of the π-allyl system to form σ-allyl bond (V). If these transformations take place, the complex containing one mole of the oxime per one atom of palladium should be obtained. The analysis clearly indicated that these addition reactions did not take place. Even when an excess of the oxime was allowed to react with π-allylpalladium chloride, only one mole of the oxime per mole of the dimeric π-allyl complex was incorporated.



X-Ray crystallographic studies showed that the complex has the structure shown in Fig. 2. Details of the crystallographic studies will be given in a forthcoming paper. In this complex the oxime attaches to one of the palladium atoms by opening the palladium-chlorine bond, forming an unsymmetrical complex. As for the π-allyl system the NMR spectra showed exactly the same pattern as that of the original π-allylpalladium chloride as shown in Table 1. Thus the oxime is quite different from phosphine and other ligands toward π-allyl complex.

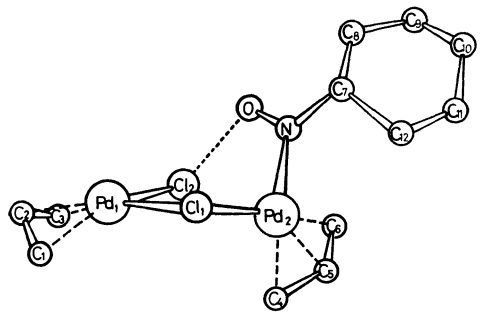


Fig. 2. Schematic drawing of $(Pd(\pi\text{-}C_3H_5)Cl)_2$-$C_6H_{10}NOH$.

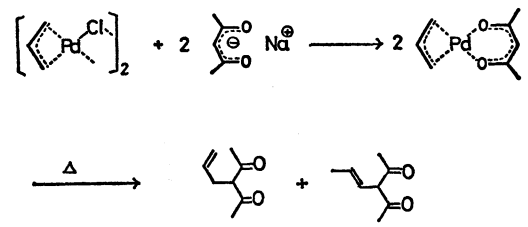
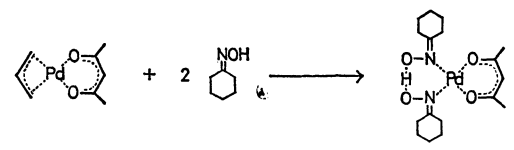
From the above experiments, it was found that coordinated acetylacetonate is displaced easily with the oxime, and the π-allyl system remained intact when treated with oxime. The reaction of the oxime with π-allylpalladium acetylacetonate was investigated, with the expectation that the acetylacetonate would be displaced. The preparation of π-allylpalladium acetylacetonate was reported by Shaw[7] by the reaction of π-allylpalladium chloride with thallium acetylacetonate. We have synthesized the same complex by treating the π-allylpalladium chloride with sodium hydroxide solution of acetylacetone.



The complex is not stable and decomposes slowly on standing. When heated at 90°C under reduced pressure, the complex decomposed to give 3-allyl-2,4-pentanedione, accompanied by 3-propenyl-2,4-pentanedione. The products were formed by the coupling of the two ligands coordinated to the palladium. A somewhat stable complex was obtained by the reaction of π-(1-ethoxycarbonyl-methyl-3-ethoxycarbonylallyl)palladium chloride with sodium acetylacetonate in benzene.

The reaction of the oxime with π-allylpalladium acetylacetonate in ether proceeded somewhat violently and yellow crystals separated. Infrared spectrum showed the presence of the acetylacetonate system in the new complex. Thus it is apparent that unexpectedly the π-allyl system was displaced with the oxime instead of the acetylacetonate system.



VI

An IR band at 2350 cm^{-1} indicates the presence of hydrogen bonding and the structure (VI) is proposed for the complex.

From the results described in this paper, it is

6) B. L. Shaw and N. Sheppard, *Chem. Ind. (London)*, **1961**, 517.

7) S. D. Robinson and B. L. Shaw, *J. Chem. Soc.*, **1963**, 4806.

apparent that the oxime coordinates to palladium to form stable complexes. Stable ligands such as π-allyl or acetylacetonate can be displaced with the oxime quite easily.

Experimental

Reaction of π-Allylpalladium Chloride with Cyclohexanone Oxime. Bis(π-allyl)palladium chloride (1.83 g) was dissolved in a minimum amount of dichloromethane, and cyclohexanone oxime (0.57 g) was added. The mixture was stirred for 3 min until a complete solution was obtained. Then, a large amount of ether was added to ensure the precipitation to give 2.13 g of a pale yellow complex. The complex was washed well with ether and then recrystallized from a mixture of dichloromethane and ether. On standing in air the complex decomposes slowly. When heated it darkens at 121—131°C and decomposes at 134°C.

Found: C, 30.27; H, 4.56; N, 2.80; Cl, 15.10%. Calcd for $C_{12}H_{21}NOPd_2Cl_2$: C, 30.09; H, 4.42; N, 2.92; Cl, 14.80%.

Reaction of palladium acetylacetonate with cyclohexanone oxime.

Reaction of Palladium Acetylacetonate with Cyclohexanone Oxime. Palladium acetylacetonate (1 g) and cyclohexanone oxime (2 g) were mixed in dichloromethane and the mixture was shaken for 3 min. Pale yellow crystals were obtained by the addition of a large amount of ether. The complex was recrystallized twice from ether-dichloromethane mixture. Mp 167°C. Found: C, 51.65; H, 7.68; N, 9.96%. Calcd for $C_{24}H_{42}N_4O_4Pd$: C, 51.75; H, 7.60; N, 10.05%.

Preparation of π-Allylpalladium Acetylacetonate. Acetylacetone (1 g) and sodium hydroxide (0.4 g) were dissolved in 10 m*l* of water and the solution was poured into a separatory funnel. Then π-allylpalladium chloride (1.83 g) and 30 m*l* of ether were added to the funnel, and the mixture was shaken for 3 min, when the complex dissolved completely. The ethereal layer was separated and the ether was evaporated. From the residue, pale yellow crystals were obtained, which were washed with water. The crystals were purified by subliming twice at 50—60°C/2 mmHg to give colorless crystals; mp 72—73°C. The complex decomposes on standing at room temperature. Found: C, 39.00; H, 4.97%; mol wt, 243. Calcd for $C_8H_{12}O_2Pd$; C, 38.97; H, 4.91%; mol wt, 246.5.

Decomposition of π-Allylpalladium Acetylacetonate. The complex (4.8 g) was heated in an oil bath at 100°C under reduced pressure (30 mmHg), and a liquid (1.2 g) was obtained at 83—90°C/30 mmHg. The liquid was purified by preparative gas chromatography to give 3-allyl-2,4-pentanedione. The structure was determined by NMR and IR spectra. Found; C, 68.71; H, 8.86%; mol wt, 139. Calcd for $C_8H_{12}O_2$: C, 68.54; H, 8.63%; mol wt, 140.18.

Preparation of π-(1-Ethoxycarbonylmethyl-3-ethoxycarbonylallyl)palladium Acetylacetonate. 1-Ethoxycarbonylmethyl-3-ethoxycarbonylallyl palladium chloride (2.55 g) and sodium acetylacetonate (0.92 g) were mixed in 20 m*l* of benzene and the mixture was stirred at room temperature for 30 min. After the reaction, benzene was removed at 2 mmHg and the residue was extracted with ether. By evaporating the ether, pale yellow crystals were obtained, which are more stable than π-allylpalladium acetylacetonate, but decomposes slowly on standing. Found: C, 44.74; H, 5.49%. Calcd for $C_{15}H_{22}O_6Pd$: C, 44.51; H, 5.48%.

Reaction of π-allylpalladium acetylacetonate with cyclohexanone oxime.

Reaction of π-Allylpalladium Acetylacetonate with Cyclohexanone Oxime. π-Allylpalladium acetylacetonate (2.46 g) was dissolved in 25 m*l* of ether, and the oxime (2.16 g) in 15 m*l* of ether was added. The mixture was shaken for 3 min. When it was warmed on a steam bath, a violent reaction was observed and yellow crystals appeared to give 2.9 g of a crude product which was recrystallized from dichloromethane and ether twice to give crystals, mp 149—150°C. Found: C, 47.45; H, 6.57; N, 6.66%. Calcd for $C_{17}H_{18}N_2O_4Pd$; C, 47.40; H, 6.55; N, 6.50%.

The authors would like to thank Mr. H. Saito for helpful discussions on the NMR spectra.

Chemical Research Laboratory, Tanabe Seiyaku Co., Ltd., Higashiyodogawa-ku, Osaka

(Received August 12, 1968)

t-Amyloxycarbonylamino acids (Aoc-amino acids) were found to be synthesizable under the conditions of the Schotten-Baumann reaction with *t*-amyl chloroformate in the presence of a water-soluble inert solvent. The procedure was applied to almost all amino acids or their derivatives; the yields of the products and their purities were satisfactory except in the cases of asparagine, glutamine, and nitroarginine. Many *t*-butyloxycarbonylamino acids (Boc-amino acids) were also synthesized successfully using the same procedure. Similarly, *t*-amyl and *t*-butyl carbazates were synthesized in satisfactory yields with these chloroformates and hydrazine hydrate. Thus, the procedure was demonstrated to be the simplest for the preparation of Aoc- or Boc-amino acids and hydrazide.

In this series of studies,[1-4] it has previously been established that *t*-amyl chloroformate (I) is a useful reagent for introducing the Aoc-group into amino acid esters in an organic solvent, and that Aoc-amino acids can be obtained conveniently by the removal of the ester groups. *t*-Amyl carbazate has also been synthesized by the condensation of reagent I with anhydrous hydrazine, and many Aoc-amino acids have been prepared with the carbazate as in the case of the standard method for the synthesis of Boc-amino acids. The Aoc-group thus introduced can be removed during peptide synthesis, as in the case of the Boc-group. The Aoc-method has already been applied to the syntheses of many peptides.[2,5-10]

As was mentioned in the first paper,[1] the introduction of the Aoc-group into free amino acid was unsuccessful with the reagent I when the reaction was carried out under the standard conditions of the Schotten-Baumann reaction. This was attributed to the instability of the reagent I in water. During repeated trials, however, it was found that the addition of an inert water-soluble organic solvent, such as tetrahydrofuran, isopropanol, or methanol, increased the rate of the acylation reaction in comparison with that of the decomposition of I. Finally, new practical conditions were established for the direct preparation of the Aoc-amino acids with the reagent I by the Schotten-Baumann reaction. The reagent I which was synthesized by the ether procedure[1] was preferable for these reactions to that prepared by the toluene method,[4] because the presence of a water-insoluble solvent in the Schotten-Baumann reaction mixture tended to increase the formation of uncertain by-products. Although this procedure was satisfactory for almost all amino acids and their side-chain derivatives, low yields and unsatisfactory purities were observed in the syntheses of Aoc-asparagine, -glutamine, and -nitroarginine, as is shown in Table 1. These phenomena may account for the partial formation of their mixed anhydrides during the reaction, which in these cases may be further transformed to the nitriles or lactams.

The synthesis of *t*-amyl carbazate[4] has been

simplified further in the present study; that is, commercially-available hydrazine hydrate (80—90%) was found to be a satisfactory material when the reagent I was slowly added to it for the coupling reaction. The yield of *t*-amyl carbazate was almost the same as that previously reported with anhydrous hydrazine.[4]

The same technique was also applied to the synthesis of Boc-amino acids and of the carbazate. Although Anderson and McGregor[11] abandoned the use of *t*-butyl chloroformate (II)[12] as a reagent for the preparation of Boc-amino acids, these Boc-derivatives were found to be synthesized similarly,

and in almost the same yields, as Aoc-derivatives (see Table 2).

One big difference between Aoc- and Boc-derivatives was in their solubilities in water. Although there was no difficulty in extracting Aoc-amino acids or hydrazide from the aqueous reaction media with ether, a strong salting-out was usually necessary to extract the Boc-amino acids or hydrazide from the aqueous reaction mixture. This difference should also be kept in mind when Aoc- or Boc-peptide derivatives are synthesized.

Experimental

All the reactions with the reagent I or the reagent II were monitored by thin-layer chromatography using Silica-gel G; the solvent system was chloroform : methanol : acetic acid (95 : 5 : 3 v/v) or *n*-butanol : acetic acid : water (4 : 1 : 1 v/v). After separation, the spots were located with ninhydrin at 100°C or with iodine vapor at room temperature.

***t*-Amyl Chloroformate (I).** Liquid phosgene was collected and measured (200 m*l*, *ca.* 2.8 mol) in a three-necked flask (capacity 5 *l*), and then a solution of *t*-amyl alcohol (176 g, 2 mol) in dry ether (3 *l*) was added to it. A solution of dry pyridine (150 g, 1.9 mol) in dry ether (1 *l*) was added slowly to the mixture at −20——30°C over a period of 90 min, taking precautions to prevent the introduction of moisture. Efficient stirring was necessary in order to obtain a homogeneous reaction. Stirring was continued for a further 30 min at the same temperature, and then the mixture was kept overnight in a deep freezer at −20°C. The precipitate thus formed was filtered off, again taking care to prevent the introduction of moisture; the filtrate was then concentrated to about 400 m*l* under reduced pressure in an ice-water bath. This solution was used as the stock solution of I without further purification. (It should be kept dry in a deep freezer and use within 10 days.)

***t*-Butyl Chloroformate (II).** Essentially the same procedure was followed with *t*-butyl alcohol (148 g, 2 mol). The final solution was used as the stock solution of II without further purification.

***t*-Amyloxycarbonyl-L-proline** (General Procedure for the Synthesis of Aoc-amino Acids). A stock solution of I (1 mol, calcd from *t*-amyl alcohol) was added slowly to a solution of L-proline (69 g, 0.6 mol) in a mixture of methanol (150 m*l*) and 2 N aqueous sodium hydroxide (600 m*l*) at 0——5°C. The mixture was agitated vigorously with a mechanical stirrer during the addition of I (over about one hour). The stirring was continued for a further 2 hr at 0°C, and then for an additional hour at room temperature. (During the reaction, the solution should be kept above pH 8 by the addition of 4 N aqueous sodium hydroxide. After the addition of I, the extent of the reaction should be checked by thin-layer chromatography; if appreciable proline remains, more reagent should be added.) Then, the reaction mixture was adjusted to pH 2—3 with 1 N hydrochloric acid, and the product was extracted with ethyl acetate (300 m*l*×1, 100 m*l*×3). The combined extract was dried over sodium sulfate. On the concentration of the dried solution, crystals were obtained which were then recrystallized from ethyl acetate and petroleum ether; yield 137 g (88%). The physical constants of the material are shown in Table 1.

***t*-Amyl Carbazate.** Reagent I (1 mol, calcd from *t*-amyl alcohol) was added, over a 3-hr period, to a suspension of 80% hydrazine hydrate (250 g, 4 mol) in ether (1 *l*) at 0——3°C. The slow addition of I and a vigorous stirring of the reaction mixture were essential to obtain a good yield. Stirring was continued at 0°C for an additional 2 hr after the complete addition of I. Then, 4 N sodium hydroxide (250 m*l*) was added to the reaction mixture, the ether layer was separated, and the aqueous layer was extracted with ether (100 m*l*×3). The ether layer and the extracts were combined, washed with a saturated solution of sodium chloride, and dried over sodium sulfate. The removal of ether from the dried solution left an oily material, which was then purified by fractional distillation under reduced pressure; yield, 83 g (57%, calcd from *t*-amyl alcohol), bp 85—86°C/4—5 mmHg. This value was essentially the same as that reported previously.[4]

***t*-Butyloxycarbonylglycine** (General Procedure for the Synthesis of Boc-amino Acids). Glycine (45 g, 0.6 mol) was dissolved in a mixture of methanol (120 m*l*) and 2 N aqueous sodium hydroxide (600 m*l*). The solution was treated with II (1 mol, calcd from *t*-butyl alcohol) following the procedure used for the synthesis of Aoc-L-proline with I. The reaction mixture was acidified to pH 2—3 with 1 N aqueous hydrochloric acid and saturated with sodium chloride; then the product was extracted with ethyl acetate (200 m*l*×2, 100 m*l*×5). The combined extract was washed with a saturated solution of sodium chloride (50 m*l*×2) and dried over sodium sulfate. The concentration of the dried solution left crystals which were then recrystallized from ethyl acetate and petroleum ether; yield, 77 g (74%). The melting point of this compound is shown in Table 2.

***t*-Butyl Carbazate.** The procedure used for the synthesis of *t*-amyl carbazate was followed with the reagent II (1 mol, calcd from *t*-butyl alcohol). The reaction product was extracted with ether (200 m*l*×2, 100 m*l*×5) after the addition of 4 N sodium hydroxide (250 m*l*) and saturation with sodium chloride. The combined ether extract was dried over sodium sulfate, and the dried solution was concentrated to a residue which was purified by fractional distillation; yield, 77 g (58%), bp 92—93°C/10 mmHg, mp 39.5—41.5°C. Reported, bp 120—122°C/15 mmHg, mp 41—42°C.[13]

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 812—820 (1969)

The Structure and the Stereochemistry of Solidagonic Acid

Shoichi KUSUMOTO, Tomomi OKAZAKI, Akio OHSUKA and Munio KOTAKE

Institute of Organic Chemistry, Faculty of Science, Osaka City University, Kita-ku, Osaka

(Received August 29, 1968)

A new bitter principle, solidagonic acid $C_{22}H_{34}O_4$, was isolated from the root of *Solidago altissima* L. It is a bicyclic diterpene carboxylic acid, having an acetoxyl group and two double bonds, and was formulated as II on the basis of chemical and spectroscopic studies. The other constituents of the root, kolavenic acid (XXIV) and kolavenol (XXVIII) were also isolated, and they were chemically correlated to II. The absolute configurations of II, XXIV and XXVIII were established by application of the octant rule on the ORD curves for some ketonic compounds derived from them.

We have previously reported[1] the isolation and structual elucidation of solidagonic acid, a bitter principle isolated from the root of *Solidago altissima* L. We now present evidences in full detail about its constitution and stereochemistry.

S. altissima L. (Compositae) is a perennial plant native to North America, and now grows all over Japan. Its root has a considerable bitter taste. Several investigations have been reported about the constituents of Solidago species,[2-4] and recently, a diterpene ketone, named solidagenone, was isolated from the root of *S. canadensis* L. and *S. giganitia*. Its structure was deduced as I from spectroscopic and chemical studies.[5] However, nothing has been reported about a bitter principle, and thus our study was undertaken.

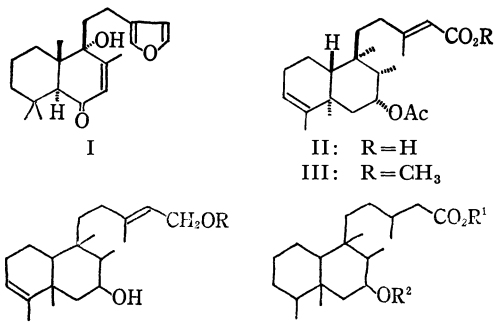

Fig. 1

Results and Discussion

An ethanol extract of the root of *S. altissima* L. was chromatographed repeatedly on silica-gel and silicic acid columns, and a bitter principle was isolated. It was a carboxylic acid and named solidagonic acid (II), $C_{22}H_{34}O_4$, mp 143—144°C, $[\alpha]_D^{12}$ −97.6°. Compound II was treated with diazomethane to give the methyl ester (III) $C_{23}H_{36}O_4$, mp 106.5°C, $[\alpha]_D^{12}$ −98.8°. Later, the method of isolation was improved and III was isolated from the dried root in about a 0.3% yield.

The IR spectrum of II indicated the presence of an ester (ν_{max}^{KBr} 1732, 1237 cm^{-1}) and an α,β-unsaturated acid (3400—2400, 1680, 1637 cm^{-1}). The UV spectra of II and III also suggested the presence of α,β-unsaturated acid (λ_{max}^{EtOH} 217.5 mμ ε 9090) and ester function (217.5 mμ, ε 15400), respectively. The NMR spectrum of II showed the presence of a carboxylic acid (δ 11.75, 1H), an acetyl group (2.00, 3H s), two tertiary methyl groups (0.97 and 1.17, each 3H s), one secondary methyl group (0.92, 3H d J=7 cps) and two olefinic methyl groups (1.59 and 2.18, each 3H slightly splitting singlet). Among them a signal at 2.18 ppm predicted the presence of the $-C(CH_3)=\dot{C}-CO_2H$ group and this was supported by the fact that the signal shifted to 1.65 ppm upon converting III to the diol (IV) by lithium aluminum hydride reduction.

Compound III absorbed 2 mol of hydrogen on catalytic hydrogenation and gave the tetrahydro methyl ester (VI), which proved to be a mixture of stereosiomers (see below). Its NMR spectrum showed the presence of one hydrogen on the carbon atom bearing the acetoxyl group (δ 4.97, 1H broad). Furthermore, calculation of the degree of unsaturation concluded that III has a bicyclic

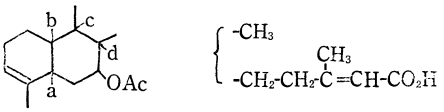
structure. The carbon skeleton of II is a decaline type since III gave 1,2,5-trimethylnaphthalene when dehydrogenated on selenium or palladium-charcoal.

When III was oxidized with one mole of monoperphthalic acid, a single monoepoxide (IX) $C_{23}H_{36}O_5$, mp 135.5—136.5°C, was obtained. It is clear from the IR and NMR spectra that the terminal α,β-unsaturated ester function remained unchanged (ν_{max}^{KBr} 1715, 1640 cm^{-1}; δ 2.41 3H d $J=1.1$ cps, and 5.53 1H broad singlet), and the other double bond was epoxidized (δ 1.15 3H s, and 2.77 1H triplet like). After introducing a methyl group into the epoxide ring, the product (XI) was dehydrogenated to afford 1,2,5,6-tetramethylnaphthalene, mp 116—117°C. Hence, one of the double bonds in II was fixed at C-3. The monoepoxide (IX) was reduced with lithium aluminum hydride to give the triol (XII) $C_{20}H_{36}O_3$, mp 120—121.5°C. When XII was acetylated with acetic anhydride and pyridine at room temperature, a monoacetate (XIII) $C_{22}H_{38}O_4$, mp 142.5—143.5°C, was obtained. This monoacetate was further acetylated at 100°C to afford an oily diacetate (XIV) (ν_{max}^{Oil} 3500 cm^{-1}; δ 1.97 6H s). Ozonolysis of XIV gave a methyl ketone (XV) $C_{20}H_{34}O_4$, mp 104—105°C, (ν_{max}^{KBr} 1705 cm^{-1}; δ 2.10 3H s). Thus, the structure of another double bond in II was confirmed as $-C(CH_3)=CHCO_2H$

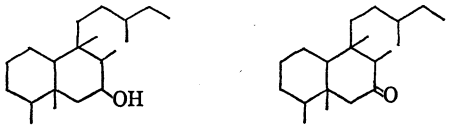
An attempt to establish the position of the acetoxyl group in II was then undertaken. Compound III was hydrolyzed with methanolic potassium hydroxide and the resultant hydroxy acid (XVI), which could not be crystallized, was oxidized with Jones reagent to furnish the keto acid (XVII) which also could not be crystallized. Therefore, XVII was esterified with diazomethane and the product was purified on a silica-gel column to give an oily keto ester (XVIII), which was chracterized as the 2,4-dinitrophenylhydrazone $C_{27}H_{36}O_6N_4$, mp 174°C. When the keto ester (XVIII) was treated with methyl magnesium bromide, an expected product could not be isolated in a satisfactory yield, probably due to further reactions initiated by the ready dehydration of the terminal allylic tertiary alcohol. Thus, this sequence of the reactions was carried out with the tetrahydro series of compounds in the following manner. A crystalline tetrahydro hydroxy acid was obtained by hydrolysis of the tetrahydro derivative (VI) mentioned above, but the yield was poor and a considerable amount of an oil, which could not be crystallized, was obtained from the mother liquor. Therefore, the product of hydrolysis was esterified with diazomethane and two methyl esters were isolated by repeated chromatography on a silica-gel column: VIIa an oil; and VIIb $C_{21}H_{38}O_3$, mp 84—87°C. These esters were hydrolyzed to the corresponding two tetrahydro hydroxy acids: VIIIa $C_{20}H_{36}O_3$, mp 99—100°C; VIIIb $C_{20}H_{36}O_3$, mp 142—144°C. Since the IR spectra of these two acids in chloroform were almost identical, they are considered to be the stereoisomers formed by catalytic hydrogenation. The hydroxy acid (VIIIb) was oxidized with Jones reagent to the keto acid (XIX) $C_{20}H_{34}O_3$, mp 82—83°C. The position of the ketone was marked with methyl Grignard reagent, and the resultant hydroxy acid (XX) was dehydrogenated on selenium to give 1,2,3,5-tetramethylnaphthalene.[6] Thus, the position of acetoxyl group in II was unequivocally defined at C-7.



XXI

Fig. 4

6) D. E. A. Rivett, *J. Chem. Soc., (C)*, **1966**, 1892.

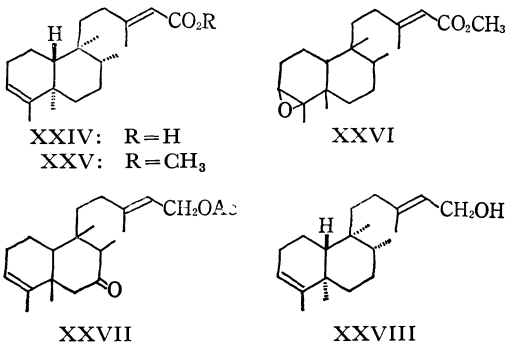


XXII XXIII

Fig. 5

The structure of solidagonic acid (II) proposed on the basis of the foregoing results should have the partial structure represented by XXI, in which the remaining tertiary methyl group and the side chain must be attached to some of the four possible positions *a*—*d*. The positions of the remaining tertiary substituents and the secondary methyl group were determined as follows. The diol (IV) gave the 7-monoalcohol (XXII) on hydrogenation over Adams catalyst in acetic acid - ethanol accompanied with hydrogenolysis of the terminal allylic alcohol. Oxidation of XXII with Jones reagent furnished the 7-ketone (XXIII) $C_{20}H_{36}O$, bp 125—133°C (bath)/1mmHg. The NMR spectrum of XXIII showed the presence of only three hydrogens adjacent to carbonyl group in the region of δ 1.8—2.7 ppm (δ 2.45 1H q J=6.7 cps, δ 1.94 and 2.28 AB type each 1H d J=12 cps). The former was assigned to the hydrogen at C-8 which coupled only with the three hydrogen atoms in the C-8 methyl group. The latter two were assigned to the C-6 methylene protons which coupled only with each other. Consequently the secondary methyl group was fixed at C-8, and it is clear that C-5 and C-9 carry no hydrogen. Although it is not possible to confirm the nature of the remaining two residues attached to C-5 and C-9, the structure represented by II is the most probable one, as judged from the NMR spectra of the two tertiary methyl groups of the various derivatives prepared (see below). Moreover, this structure is the so-called "rearranged labdane skeleton" of the type exhibited by the cascarillins,[7] and it is also reasonably explained on the basis of biogenetic considerations.[8-10] Therefore, the constitution of solidagonic acid is deduced as II.

Kolavenic acid (XXIV) was isolated from a benzene extract of the dried root as its methyl ester (XXV) $C_{21}H_{34}O_2$, bp 151—152°C/1 mmHg, $[\alpha]_D^{26}$ −60.8°. Its IR spectrum suggested the presence of an α,β-unsaturated ester group and its NMR spectrum showed the presence of two tertiary methyl groups (δ 0.76 and 1.02 each 3H s), one



XXIV: R=H
XXV: R=CH_3
XXVI

Fig. 6

secondary methyl group (0.85 3H d J=6 cps)' two olefinic methyl groups (1.60 and 2.18 each 3H) and two olefinic protons (5.15 1H m, and 5.59 1H broad singlet). The terminal $-C(CH_3)=CH-CO_2H$ group was also expected in XXIV by comparison of these spectra with those of II and III. The compound XXIV was assigned to desacetoxyl solidagonic acid as a result of the following observations: (i) XXV absorbed 2 mol of hydrogen, indicating its bicyclic nature; (ii) dehydrogenation of XXV gave rise to 1,2,5-trimethylnaphthalene; (iii) methylation of the monoepoxide (XXVI) with methyl magnesium bromide followed by dehydrogenation resulted in the formation of 1,2,5,6-tetramethylnaphthalene, indicating that another double bond is at C-3. Compound XXIV was chemically correlated with II as follows. The alcohol formed upon removal of the C-7 oxygen function by Huang-Minlon reduction of the keto acetate (XXVII) was found to be identical with kolavenol (XXVIII), which was prepared by the reduction of XXV with lithium aluminum hydride; the comparison of their IR spectra, $[\alpha]_D$ and the mixed melting point test of their 3,5-dinitrobenzoate. The structure (XXV) thus established is in accordance with the constitution proposed for methyl kolavenate which has been isolated from *Hardwickia pinata* by Dev *et al.*[10] Although direct comparison of both substances has not been possible, it is evident that XXV is identical with methyl kolavenate, since the physical properties of both derivatives are in good agreement. Consequently, XXIV and XXVIII are named kolavenic acid and kolavenol, respectively. Kolavenol itself was also isolated from the dried root as its 3,5-dinitrobenzoate.

The stereochemistry of C-8 was assigned by an examination of solvent effects on the chemical shift of the secondary methyl group in the 7-keto derivatives. Downfield shifts of 0.06 and 0.05 ppm for XXVII and XXIX respectively were observed on changing solvent from carbon tetrachloride to benzene; these values are in reasonable agreement with those for equatorial methyl groups adjacent to a ketone. The equatorial orientation of the

Fig. 7

C-8 methyl group was also supported by the fact that the starting ketodiol monoacetate (XXIX) was recovered by the treatment with alkali followed by acetylation.

The C-7 hydrogen appears as broad peaks or broad quartet-like peaks with half height width of 6—8 cps in the NMR spectra for 7-acetoxy or 7-hydroxy derivatives. These values suggest that C-7 hydrogen is in equatorial and thus the acetoxyl group should be axially oriented, since it has been demonstrated that the two adjacent carbon atoms (C-6 and 8) carry axial hydrogens.

The chemical shifts of the two tertiary methyl groups of the various derivatives prepared are summarized in Table 1. Remarkable upfield

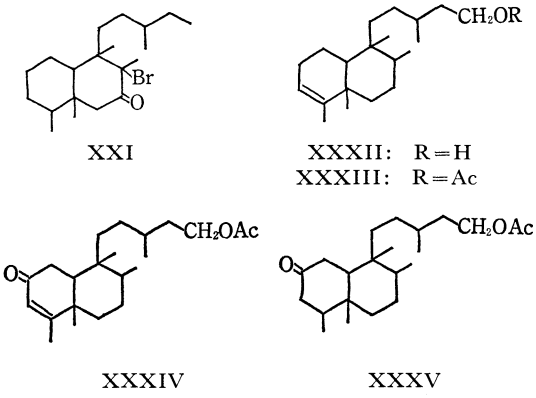
Table 1. Chemical shift (δ) of the tertiary methyl groups

Compound	Solv.	C-5 Me	C-9 Me
IV	CCl_4	1.25	0.98
IV	C_6H_5N	1.55	1.21
V	CCl_4	1.25	0.97
XXVII	CCl_4	0.95	0.71
XVI	CCl_4	1.27	1.01
XVIII	CCl_4	0.96	0.72

shifts (about 0.3 ppm) of both of these methyl groups were observed, when the C-7 hydroxyl group was converted to a ketone. Therefore, 1,3-diaxial relations are expected between the methyl groups and the C-7 hydroxyl group.[11] The signals of these methyl groups of the diol (IV) moved downward (0.30 and 0.23 ppm, respectively) when the solvent was changed from carbon tetrachloride to pyridine, in which the downfield shift due to 1,3-diaxial relationship is known to increase.[12] The acetoxyl group in II is in a sterically hindered environment. The evidences for this are based on the following observations; (i) the acetyl group in II and VI resists to alkaline hydrolysis—a period of 10 hr at refluxing temperature was required to complete the reaction in 20% methanolic potassium hydroxide, (ii) the C-7 hydroxyl group could not be acetylated readily and (iii) the triol monoacetate (XIII) was recovered on reduction of the ketodiol monoacetate (XXIX) with sodium borohydride, indicating an attack of the reagent from the opposite side of the original hydroxyl group. These observations lead to the conclusion that the two tertiary methyl groups and the acetoxyl group in II are in a 1,3,5-triaxial relation.

The allylic methyl group in the side chain of III appeared at δ 2.15 ppm in carbon tetrachloride and this signal shifted to 2.20 ppm in benzene. These values are in good agreement with those expected for the allylic methyl group which is *cis* to a carbomethoxyl group.[13]

The ring junction and the absolute configuration were determined by examination of the ORD curves of the 7-ketone (XXIII), the bromoketone (XXXI) and the 2-keto acetate (XXXV). Bromination of XXIII in carbon tetrachloride furnished a monobromoketone (XXXI) $C_{20}H_{35}OBr$,



XXI XXXII: R=H
XXXIII: R=Ac

XXXIV XXXV

Fig. 8

which must be the 8-bromide, as the quartet of the C-8 proton disappeared and the singlet of the C-8 methyl group appeared at δ 1.72 ppm in its NMR spectrum. The axial orientation of the bromine was borne out by the facts that only a little shift ($+1\ cm^{-1}$) of the carbonyl band in IR spectrum was observed on bromination,[14] and that the NMR signal of one of the C-6 hydrogens showed a downfield shift which was probably due to the 1,3-diaxial interaction with the bromine atom.[15] This assignment was also confirmed by a bathochromic shift and an increasing amplitude of Cotton effect.[16] The ORD curve of the bromoketone (XXXI) showed a more intense negative Cotton effect ($a=-79.5$) in comparison with the 7-ketone (XXIII) which showed a small negative

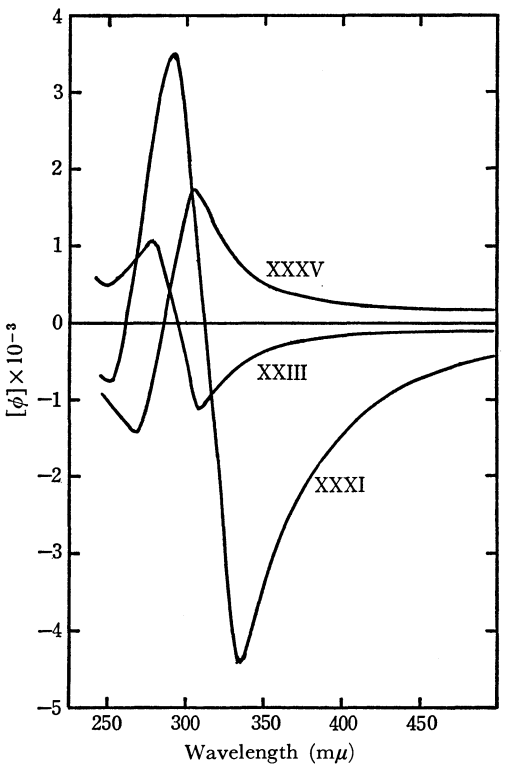

Fig. 9. ORD curves of XXIII, XXXI and XXXV.

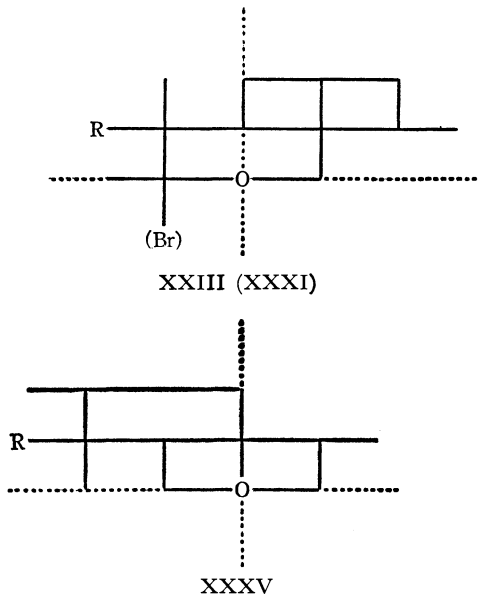

Fig. 10

Cotton effect ($a=-21.5$). Thus the bromine atom is β-oriented according to the axial haloketone rule and the absolute configuration of the B ring, except C-10, should be in the form given by II. The conjugated system in the side chain of methyl kolavenate (XXV) was reduced with metallic sodium in ethanol, and acetylation of the product afforded dihydrokolavenol acetate (XXXIII) $C_{22}H_{38}O_2$, bp 145—150°C (bath)/0.5 mmHg. Compound XXXIII was oxidized with chromium trioxide in acetic acid at 50°C to furnish an α,β-unsaturated cyclohexenone derivative (XXXIV): ν_{max}^{Oil} 1670, 1620 cm^{-1}; λ_{max}^{EtOH} 240 mμ (ε 9800); δ 1.85 3H d $J=1.2$ cps (C-4 methyl) and δ 5.56 1H d $J=1.2$ cps (C-3 proton). The newly introduced carbonyl group must be at C-2 as indicated by these spectral data. The 2-keto acetate (XXXV) $C_{22}H_{38}O_3$ was obtained by hydrogenation of XXXIV and reoxidation of the resultant saturated alcohol. The ORD curve of XXXV showed a positive Cotton effect ($a=+31.5$). Consequently, the *trans* junction of AB ring was established since the absolute configuration of the B ring, except C-10, was determined as mentioned above. Accordingly, the stereochemistry of solidagonic acid was fully established as shown by II.

Experimental

All melting points were measured on a Kofler block and are uncorrected. The NMR spectra were taken on a JEOL C-60 spectrometer in carbon tetrachloride unless otherwise stated; the signals are recorded in ppm from TMS (internal standard) as zero. All rotations were measured in 95% ethanol solution. Petroleum ether had bp 60—70°C. Merck silica-gel (0.05—0.2 mm) was used for chromatography.

Isolation of Solidagonic Acid (II). The sliced fresh root of *S. altissima* L. (11 kg) was extracted with ethanol at room temperature, the ethanol extract concentrated under reduced pressure and the residue extracted with ether. The oily residue (82 g) obtained after removing the solvent was chromatographed on silicagel (400 g) and eluted with benzene - ethyl acetate (95 : 5); 1.4 g of colorless crystals were obtained. The remaining oily portion was rechromatographed on a column of silicic acid (150 g), and eluted with benzene - ethyl acetate (98 : 2); 1.2 g of the crystals. The combined crystalline portion was recrystallized from petroleum ether to give colorless prisms: mp 143—144°C; $[\alpha]_D^{12}$ −97.6° (c 2.07); IR (KBr) 3400—2400, 1732, 1680, 1637, 1237 cm^{-1}; UV λ_{max}^{EtOH} 217.5 mμ (ε 9090); NMR 0.97, 1.17, 2.00 (each 3H s), 0.92 (3H d $J=7$ cps), 1.59, 2.18 (each 3H slightly splitting singlet), near 5.1 (2H broad peak), 5.63 (1H broad singlet), 11.75 (1H s).

Found: C, 72.88; H, 9.51%. Calcd for $C_{22}H_{34}O_4$: C, 72.89; H, 9.45%.

The methyl ester was obtained as granular crystals by esterification with diazomethane in ether and recrystallization from petroleum ether: mp 106.5°C; $[\alpha]_D^{12}$ −98.8° (c 1.80); IR (KBr) 1732, 1720, 1645, 1252, 1145 cm^{-1}; UV λ_{max}^{EtOH} 217.5 mμ (ε 15400); NMR 2.15 (3H d $J=1.2$ cps), 3.63 (3H s); NMR (in benzene) 2.20 (3H d $J=1.2$ cps).

Found: C, 73.22; H, 9.68%. Calcd for $C_{23}H_{36}O_4$: C, 73.36; H, 9.64%.

Isolation of Solidagonic Acid (III) and Kolavenic Acid (XXV) as Their Methyl Esters and of Kolavenol (XXVIII). The dried and crushed root (2.7kg) was

extracted with benzene by allowing to stand at room temperature for 4 weeks. The oily residue (90 g) obtained after removing the solvent under reduced pressure was partitioned between petroleum ether and 80% aqueous methanol.

An oil obtained by the evaporation of the solvent of the methanol-soluble fraction (36 g) was dissolved in ether and treated with an excess of diazomethane. The product was chromatographed on a silica-gel (400 g) column, and eluted with benzene, the eluate concentrated and the residue recrystallized from petroleum ether. Methyl solidagonate (III) was obtained as granular crystals (10 g), mp 106.5°C.

The petroleum ether solution, which had been extracted with 80% methanol, was again extracted with 95% methanol. An oily residue (23 g) left after removal of methanol was treated with an excess of diazomethane in ether. The resultant oil was chromatographed on a silica-gel (280 g) column and eluted with benzene. The first fraction was rechromatographed on a fresh silica-gel (100 g) column with petroleum ether - benzene (1 : 1) as a developing system. Methyl kolavenate (XXV) was obtained as a coloroess oil (8.1 g): bp 151—152°C/1 mmHg; $[\alpha]_D^{26}$ −60.8° (*c* 2.07); IR(oil) 1725, 1645, 1230, 1150 cm^{-1}; NMR 0.76, 1.02, 3.65 (each 3H s), 0.85 (3H d J=6 cps), 1.60 (3H slightly splitting singlet), 2.18 (3H d J=1.2 cps), 5.15 (1H broad), 5.59 (1H broad).

Found: C, 79.05; H, 10.87%. Calcd for $C_{21}H_{34}O_2$: C, 79.19; H, 10.76%.

The second fraction gave a small amount of III.

The third reaction was rechromatographed on a silica-gel column. Its elution with petroleum ether - ethyl acetate (95 : 5) gave an oil (0.5 g), which was treated with 3,5-dinitrobenzoyl chloride in pyridine to furnish kolavenol 3,5-dinitrobenzoate, mp 107°C. It was identified by mixed melting point with an authentic sample (prepared from methyl kolavenate) and by comparison of their IR spectra.

Reduction of III with Lithium Aluminum Hydride. A solution of III (3.5 g) in absolute ether (50 m*l*) was added dropwise to lithium aluminum hydride (1.7 g) in absolute ether (30 m*l*) with stirring, the mixture was stirred for further 4 hr under reflux, and then kept standing overnight. The reaction mixture was treated in the usual manner and the crude product was crystallized from benzene - petroleum ether, the diol (IV) was obtained as needles (2.6 g): mp 93.5—94.5°C; NMR 0.98, 1.25 (each 3H s), near 1.00 (3H d J=*ca.* 7 cps), 1.59 (3H d J=1.5 cps), 1.65 (3H slightly splitting singlet) near 3.94 (1H broad), 4.00 (2H d J=7 cps), 5.06 (1H broad) 5.31 (1H broad triplet J=7 cps); NMR (in pyridine) 1.21, 1.55 (each 3H s), 1.16 (3H d J=7 cps).

Found: C, 78.23; H, 11.16%. Calcd for $C_{20}H_{34}O_2$: C, 78.38; H, 11.18%.

Hydrogenation of III. Compound III (6.4 g) in ethanol (120 m*l*) was hydrogenated over 5% palladium-charcoal (0.6 g) at room temperature and atmospheric pressure; 2 mol of hydrogen was absorbed during 3 hr. The product (VI) (6.4 g) could not be crystallized. NMR 0.92 (6H s), 1.94, 3.60 (each 3H s), 4.97 (1H braod W_h=*ca.* 8 cps).

Dehydrogenation of III. i) A mixture of III (1.0 g) and 10% palladium-charcoal (1.5 g) was heated at 280—300°C under nitrogen for 12 hr, extracted with ether, the solvent evaporated, and a saturated solution of 1,3,5-trinitrobenzene in ethanol added to the residue; the adduct of 1,2,5-trimethylnaphthalene was obtained as orange yellow needles (80 mg), mp 158°C.

Found: C, 59.82; H, 4.68; N, 10.70%. Calcd for $C_{19}H_{17}O_6N_3$: C, 59.53; H, 4.47; N, 10.96%.

ii) Methyl solidagonate (III) (3.0 g) was heated at 270—280°C for 6.5 hr with selenium (3.0 g) under nitrogen, the reaction mixture extracted with ether, the ether extract passed through a column of alumina (20 g) and the solvent of the eluate was evaporated to dryness. A saturated solution of picric acid in ethanol was added to the residue to give 1,2,5-trimethylnaphthalene picrate as reddish orange needles (290 mg), which was recrystallized from ethanol, mp 139—140°C. This picrate was decomposed on a silica-gel column to the corresponding hydrocarbon; NMR 2.40, 2.49, 2.60 (each 3H s).

Styphnate, mp 131°C

Monoepoxide (IX). Monoperphthalic acid (0.485 g, 1.0 equiv.) in ether (22 m*l*) was added to an ether solution of III (1.0 g in 20 m*l*) under stirring in an ice bath and the reaction mixture allowed to stand for 19 hr at room temperature. The reaction mixture was washed successively with a saturated aqueous solution of sodium bicarbonate and water and then dried. The crystalline residue obtained upon evaporation of the solvent was chromatographed on a silica-gel (20 g) column. Elution with benzene - ethyl acetate (95 : 5) gave the monoepoxide (IX) (0.9 g), which was recrystallized from petroleum ether to give colorless prisms: mp 135.5—136.5°C; IR(KBr) 1729, 1715, 1640 cm^{-1}; NMR 0.90 (3H d J=7.1 cps), 0.92, 1.15, 1.19, 1.99, 3.60 (each 3H s), 2.14 (3H d J=1.1 cps), 2.77 (1H triplet like), 5.05 (1H ill resolved quartet, W_h=*ca.* 6 cps), 5.53 (1H broad singlet).

Found: C, 70.40; H, 9.30%. Calcd for $C_{23}H_{36}O_5$: C, 70.37; H, 9.24%.

Grignard Reaction of IX. A solution of IX (3.0 g) in absolute ether (80 m*l*) was added dropwise to a solution of methyl magnesium bromide (which had been prepared from 4.7 g of magnesium in 150 m*l* of absolute ether). The mixture was stirred for 6 hr under reflux, and allowed to stand overnight. The oily product was chromatographed on a silica-gel (90 g) column. Elution with benzene - ethyl acetate (85 : 15) gave the epoxydiol (X) (0.3 g), which was recrystallized from petroleum ether to give colorless prisms: mp 104.5—106°C; NMR 2.80 (1H triplet like).

Found: C, 75.45; H, 11.08%. Calcd for $C_{22}H_{38}O_3$: C, 75.38; H, 10.93%.

Successive elution of the chromatogram with benzene-ethyl acetate (7 : 3) afforded the triol (XI) (0.7 g), which was recrystallized from petroleum ether, mp 85—89°C.

Found: C, 75.69; H, 11.44%. Calcd for $C_{23}H_{42}O_3$: C, 75.36; H, 11.55%.

Dehydrogenation of XI. Compound XI (0.49 g) was heated for 8.5hr at 290—300°C with 10% palladium-charcoal (0.5 g) in a nitrogen atmosphere, the reaction mixture extracted with ether and the solvent removed. The crude oily product upon treatment with picric acid in ethanol gave the picrate (0.08 g), which was decomposed on a silica-gel column to 1,2,5,6-tetramethylnaphthalene; the recrystallized product (from ethanol), mp 116—117°C. NMR 2.41, 2.51 (each 6H s), 7.11, 7.63 (each 2H d J=9 cps).

Found: C, 91.09; H, 8.91%. Calcd for $C_{14}H_{16}$:

C, 91.25; H, 8.75%.

Picrate, mp 155—156°C.

Reduction of IX with Lithium Aluminum Hydride. To lithium aluminum hydride (1.4 g) in absolute ether (20 m*l*) was added a solution of IX (1.0 g) in absolute ether (30 m*l*) during a 30 min period with stirring at room temperature. The mixture was stirred for further 6 hr under reflux and set aside over night at room temperature. The reaction mixture was terated in the usual manner and the crude product was crystallized from benzene, the triol (XII) (0.6 g) was obtained: mp 120—121.5°C; NMR (in $CDCl_3$) 1.70 (3H slightly splitting singlet), 4.14 (2H d J=6 cps), 5.40 (1H broad triplet J=6 cps).

Found: C, 74.12; H, 11.32%. Calcd for $C_{20}H_{36}O_3$: C, 74.02; H, 11.18%.

Triol Monoacetate (XIII). Compound XII (1.0 g) dissolved in pyridine (8 m*l*) was treated with acetic anhydride (4 m*l*), and the reaction mixture set aside 17 hr at room temperature. Recrystallization from benzene gave XIII as prisms (1.0 g): mp 142.5—143.5°C; IR (KBr) 3500, 1712, 1240 cm^{-1}; NMR (in $CDCl_3$) 2.08 (3H s), 4.09 (1H ill resolved quartet), 4.59 (2H d J=7.5 cps), 5.37 (1H broad triplet J=7.5 cps).

Found: C, 72.11; H, 10.52%. Calcd for $C_{23}H_{38}O_4$: C, 72.09; H, 10.45%.

Triol Diacetate (XIV). Compound XIII (1.0 g) in pyridine (10 m*l*) and acetic anhydride (4 m*l*) was heated 100°C for 4hr. The oily product was chromatographed on a silica-gel (30 g) column. Elution with benzene - ethyl acetate (85 : 15) gave the oily diacetate (XIV) (0.85 g): IR(oil) 3500, 1740 (broad), 1230 cm^{-1}; NMR 1.97 (6H s), 5.09 (1H broad.)

Successive elution with the same solvent afforded the starting monoacetate (XIII) (0.2 g).

Ozonolysis of XIV. Ozonized oxygen was passed through a solution of XIV (0.83 g) in chloroform (14 m*l*) under ice-salt cooling for 25 min. The solvent was evaporated *in vacuo* and the oily residue was heated with 20 m*l* of water on a boiling water bath for 30 min. The neutral oil (0.6 g) obtained was chromatographed on a silica-gel (15 g) column with benzene - ethyl acetate (7 : 3) as a developing solvent. The crude methyl ketone (XV) (0.35 g) thus obtained was recrystallized from petroleum ether: mp 104—105°C; IR(KBr) 3540, 1732, 1705, 1232 cm^{-1}; NMR 1.99, 2.10 (each 3H s), 5.05 (1H quartet like W_h=*ca.* 7 cps).

Found: C, 70.75; H, 10.08%. Calcd for $C_{20}H_{34}O_4$: C, 70.97; H, 10.13%.

Keto Ester (XVIII). Compound II (1.0 g) was heated under reflux in 20% methanolic potassium hydroxide (20 m*l*) for 9.5 hr. The hydroxy acid (XVI) obtained as an oil (0.9 g) could not be crystallized after chromatography on a silica-gel column: IR(oil) 3360, 3200—2400, 1685, 1635 cm^{-1}; NMR 1.01, 1.27 (each 3H s), 4.00 (1H broad W_h=7.5 cps).

Jones reagent [a mixture of chromium trioxide (2.7 g) and concentrated sulfuric acid (2.3 m*l*) in water (10 m*l*)] (1.0 m*l*) was added dropwise to a solution of XVI (0.9 g) in acetone (30 m*l*) in an ice bath. The mixture was stirred for 2hr, diluted with water and extracted with ether. The ether solution was concentrated and treated with a solution of diazomethane in ether. Chromatography on a silica-gel (20 g) column with benzene gave the keto ester (XVIII) as an oil (0.65 g): IR(oil) 1710 (broad), 1640, 1225, 1150 cm^{-1}; NMR 0.72, 0.96 (each 3H s).

2, 4-Dinitrophenylhydrazone, mp 174°C.

Found: C, 63.22; H, 7.19; N, 10.86%. Calcd for $C_{27}H_{36}O_6N_4$: C, 63.26; H, 7.08; N, 10.93%.

Tetrahydro-hydroxy Esters (VIIa, b) and hydroxy Acids (VIIIa, b). Compound VI (7.0 g) was heated under reflux in 5% ethanolic potassium hydroxide for 8 hr. The acidic fraction was treated with an excess of diazomethane in ether for 3hr at room temperature. The oily product (6.5 g) obtained by evaporation of the solvent was chromatographed on a silica-gel (150 g) column and eluted with benzene - ethyl acetate (95 : 5). The oily hydroxy ester (VIIa) (3.6 g, a single spot on TLC) was isolated: IR (oil) 3510, 1740, 1200, 1010 cm^{-1}; IR (in CCl_4) 3680, 3500, 1745, 1200, 1010 cm^{-1}.

Successive elution with the same solvent gave a mixture of the two esters (0.8 g) and the crystalline hydroxy ester (VIIb) (1.8 g). The latter was recrystallized from petroleum ether: mp 84—87°C; IR(KBr) 3500, 1720, 1195, 1000 cm^{-1}.

Found: C, 74.69; H, 11.13%. Calcd for $C_{21}H_{38}O_3$: C, 74.51; H, 11.32%.

The IR spectra for VIIa and VIIb in carbon tetrachloride were almost iden tical.

Compound VIIa (2.2 g) was hydrolyzed for 3hr with 8% ethanolic potassium hydroxide under reflux. The hydroxy acid (VIIIa) was isolated in the usual manner and recrystallized from ptroleum ether as colorless plates (2.0 g): mp 99—100°C; IR (in $CHCl_3$) 3600, 3500, 3300—2500, 1710 cm^{-1}.

Found: C, 74.07; H, 11.24%. Calcd for $C_{20}H_{36}O_3$: C, 74.02; 11.18%.

Compound VIIb was hydrolyzed to the hydroxy acid (VIIIb), which was recrystallized from petroleum ether - benzene (8 : 2) as hexagonal plates, mp 142—144°C.

Found: C, 74.28; H, 10.97%.

The IR spectra for VIIIa and VIIIb in chloroform were almost identical.

Oxidation of VIIIb with Jones Reagent. Jones reagent (4.0 m*l*) was added to a solution of VIIIb (3.5 g) in acetone (80 m*l*) during a course of 10 min in an ice bath with stirring and the mixture was stirred for further 30 min at this temperature. The reaction mixture was treated in a usual manner and the crude product was crystallized from petroleum ether. The tetrahydro-keto acid (XIX) was obtained as needles (2.9 g), mp 82—83°C.

Found: C, 74.63; H, 10.71%. Calcd for $C_{20}H_{34}O_3$: C, 74.49; H, 10.63%.

The Reaction of XIX With Methyl Magnesium Bromide. A solution of XIX(3.5 g) in absolute ether was added dropwise to methyl magnesium bromide (which had been prepared from 1.1 g of magnesium) in absolute ether under constant stirring, the mixture heated under reflux for 6 hr, and then the reaction mixture treated as usual. The product was chromatographed on a silica-gel (60 g) column. Its elution with benzene - ethyl acetate (4 : 1) afforded the hydroxy acid (XX) (1.3 g), which was recrystallized from petroleum ether as needles: mp 128.5—130.5°C; IR(KBr) 3460, 3200—2400, 1711 cm^{-1}.

Found: C, 74.45; H, 11.36%. Calcd for $C_{21}H_{38}O_3$: C, 74.51; H, 11.32%.

Dehydrogenation of XX with Selenium. A mixture of XX (1.3 g) and selenium (1.3 g) was heated at 300°C for 10 hr under nitrogen and the reaction mixture

extracted with petroleum ether. The petroleum ether solution was passed through a column of silica-gel (20 g) to give a fraction, which on addition of a saturated solution of picric acid in ethanol, afforded the adduct (192 mg) of 1,2,3,5-tetramethylnaphthalene as orange-red crystals, mp 163—164°C. This adduct was decomposed on a silica-gel column to the corresponding hydrocarbon; NMR 2.32, 2.42, 2.54, 2.62 (each 3H s).

1,3,5-Trinitrobenzene adduct, mp 182—183°C.

Found: C, 60.67; H, 5.12; N, 10.49%. Calcd for $C_{20}H_{19}O_6N_3$: C, 60.45; H, 4.82; N, 10.58%.

7-Ketone (XXIII). Compound IV (2.6 g) in acetic acid (100 m*l*) and ethanol (50 m*l*) was hydrogenated over Adams catalyst (200 mg) at room temperature under atmospheric perssure; about 2.9 mol of hydrogen was absorbed. The oily product (2.6 g) obtained was chromatographed on a silica-gel (20 g) column and eluted with benzene. The 7-monoalcohol (XXII) was obtained as a colorless oil (1.6 g): IR(oil) 3350 cm^{-1}; NMR 3.95 (1H quartet like).

Jones reagent (2.0 m*l*) was added to a solution of XXII (1.6 g) in acetone (30 m*l*) in 3 min in an ice bath, stirred for further 10 min at this temperature, and the reaction mixture worked up in the usual way. Distillation of an oily product under reduced pressure afforded 7-ketone (XXIII) (1.6 g): bp 125—133°C (bath)/1 mmHg; IR(oil) 1708 cm^{-1}; NMR 1.94, 2.28 (each 1H d J=12 cps), 2.45 (1H q J=6.7 cps); ORD $[\phi]_{308}^{\text{trough}}$ −1145°, $[\phi]_{278}^{\text{peak}}$ +1007° (*c* 0.147, in CH_3OH).

Found: C, 82.07; H, 12.35%. Calcd for $C_{20}H_{36}O$: C, 82.12; H, 12.40%.

Dehydrogenation of XXV. Compound XXV (1.6 g) was heated for 10 hr with 10% palladium-charcoal (1.0 g) at 300—320°C under nitrogen and the mixture was extracted with ether. An oil (1.0 g) obtained after removal of the solvent was treated with picric acid in ethanol. Reddish brown crystalls of 1,2,5-trimethylnaphthalene picrate were recrystallized from ethanol; yield 109 mg, mp 136—138°C which was undepressed on admixture with the authentic sample.

Hydrogenation of XXV. Compound XXV (1.6 g) was dissolved in ethanol (50 m*l*) and hydrogenated over Adams catalyst (0.2 g); 2.04 mol of hydrogen was absorbed during a 2.5 hr period. The product was isolated as usual and distilled under reduced pressure: bp 135—140°C (bath)/3 mmHg; IR (oil) 1745, 1160 cm^{-1}.

Methyl Kolavenate Monoepoxide (XXVI). A solution of monoperphthalic acid (3.3 g, 1.1 equiv.) in ether (140 m*l*) was added dropwise to a solution of XXV (5.0 g) in ether (50 m*l*) with stirring in an ice bath. The mixture was set aside for 20 hr at room temperature. Working up in the usual way gave a colorless oil (5.4 g), which was chromatographed on a silica-gel (100 g) column. Elution with benzene - ethyl acetate (95 : 5) afforded the monoepoxide (XXVI) as an oil (4.55 g): IR(oil) 1720, 1645 cm^{-1}; NMR 0.69, 1.06, 1.15, 3.64 (each 3H s), 2.16 (3H d J=1.2 cps), 2.78 (1H triplet like), 5.60 (1H broad singlet).

Grignard Reaction of XXVI Followed by Dehydrogenation. A solution of XXVI (4.3 g) in absolute ether (40 m*l*) was added dropwise to an ice cold solution of methylmagnesium bromide (which had been prepared from 4.7 g of magnesium) in absolute ether (100 m*l*). The mixture was stirred under reflux for 6.5 hr and set aside overnight at room temperature. Working up in the usual way afforded an oily product (4.5 g). A mixture of this oil (2.4 g) and selenium (2.0 g) was heated at 300—320°C for 8 hr under nitrogen and after cooling extracted with ether. The ether solution was passed through a column of alumina and the solvent of the eluate evaporated. The residue was recrystallized from ethanol to give 1,2,5,6-tetramethylnaphthalene; mp 115—116°C, picrate mp 157—157.5°C.

Kolavenol (XXVIII). A solution of XXV (3.2 g) in absolute ether (50 m*l*) was added dropwise to a solution of lithium aluminum hydride (1.0 g) in absolute ether (100 m*l*) in 15 min at room temperature and the mixture refluxed for 3 hr. Working up the reaction mixture in the usual way afforded an oil (3.0 g), which was chromatographed on a silica-gel (60 g) column. Elution with benzene - ethyl acetate (95 : 5) gave kolavenol (XXVIII) as an oil (1.5 g), $[\alpha]_D^{26}$ −57.1° (*c* 2.52).

The 3,5-dinitrobenzoate derivative was prepared by treatment with 3,5-dinitrobenzoyl chloride and pyridine, and recrystallized from ethanol, mp 105.5—106.5°C.

Found: C, 66.90; H, 7.49; N, 5.94%. Calcd for $C_{27}H_{36}O_6N_2$: C, 66.92; H, 7.49; N, 5.78%.

Acetylation of IV Followed by Oxidation. Compound IV (1.0 g) was dissolved in a mixture of pyridine (8 m*l*) and acetic anhydride (4 m*l*) and set aside for 40 hr in a refrigerator. The oily product obtained in the usual way was chromatographed on a silica-gel (19 g) column to remove a small amount of the diacetate. Elution with benzene - ethyl acetate afforded the monoacetate (V) as an oil (1.1 g): IR(oil) 3500, 1740, 1235 cm^{-1}; NMR 0.97, 1.25, 1.97 (each 3H s), 3.96 (1H quartet like), 4.48 (2H d J=7.5 cps).

Compound V (1.1 g) in acetone (25 m*l*) was oxidized with Jones reagent (1.2 m*l*) in an ice bath. Working up the reaction product in the usual way and chromatography on a silica-gel column afforded the keto-acetate (XXVII) as an oil (0.85 g): NMR 0.71, 0.95 (each 3H s), 0.89 (3H d J=*ca.* 7 cps); NMR (in benzene) 0.95 (3H d J=7.2 cps).

Huang-Minlon Reduction of XXVII. A solution of XXVII (0.9 g) in triethyleneglycol (15 m*l*) containing potassium hydroxide (2.5 g) and 80% hydrazine hydrate (5 m*l*) was heated for 1 hr at 130°C, for 2 hr at 150°C and then for 1.5 hr at 210°C. The reaction mixture was extracted with ether and the ether solution was washed thoroughly with water, dried, and evaporated. The residual oil was chromatographed on a silica-gel (16 g) column and eluted with benzene - ethyl acetate (97 : 3); an oily alcohol yield 0.2 g, $[\alpha]_D^{27}$ −55.9°C (*c* 3.04). The IR spectrum of this alcohol was identical with that of kolvavenol (XXVIII) prepared from XXV.

The 3,5-dinitrobenzoate derivative, mp 105—106°C, showed no depression of melting point on admixture with authentic kolavenol 3,5-dinitrobenzoate.

Oxidation of XIII with Jones Reagent. Jones reagent (1.0 m*l*) was added to a solution of XIII (1.0 g) in acetone (20 m*l*) under stirring in an ice bath, and stirred for further 20 min at this temperature. Working up the reaction mixture in the usual way afforded the ketodiol monoacetate (XXIX) as a viscous oil (1.0 g), which could not be crystallized even after

careful chromatography on a silica-gel column. IR (oil) 3500, 1740, 1710, 1240 cm^{-1}; NMR 0.67, 0.91, 1.08, 1.98 (each 3H s), 0.87 (3H d J=6 cps); NMR (in benzene) 0.92 (3H d J=6 cps).

The Alkaline Treatment and Reduction with Sodium Borohydride of XXIX. Compound XXIX (0.7 g) was dissolved in 5% pottasium hydroxide solution in methanol (10 m*l*) and heated under reflux for 2 hr. The solution was concentrated *in vacuo* to half of its volume, diluted with water, and extracted with ether. The ketodiol (XXX) was obtained as a viscous oil (0.5 g), which could not be crystallized.

Compound XXX (0.5 g) was dissolved in pyridine (1 m*l*) and acetic anhydride (2 m*l*) and set aside overnight at room temperature. Working up the reaction mixture in the usual way afforded an oil (0.5 g), and its IR spectrum was identical with that of the starting ketodiol monoacetate (XXIX).

The ketodiol monoacetate (0.5 g) thus obtained was dissolved in methanol (15 m*l*) and sodium borohydride (0.1 g) was added in portions in an ice bath with stirring during 20 min. The mixture was stirred for 2 hr at room temperature, then acidified with acetic acid, and diluted with water to give colorless crystals. Recrystallization from benzene gave the pure crystals (0.4 g), which were found to be identical with authentic triol monoacetate (XIII) as shown by their melting point, mixed melting point and IR spectra.

Bromoketone (XXXI). A solution of bromine (0.10 m*l*) in carbon tetrachloride (4 m*l*) was added dropwise in 20 min to a solution of XXIII (0.5 g) in carbon tetrachloride (20 m*l*) at room temperature under stirring. The solution was stirred for further 30 min, and washed successively with water, aqueous sodium thiosulfate solution and water. Evaporation of the solvent gave a pale yellow oil (0.65 g), which was chromatographed on a silica-gel (14 g) column. Elution with petroleum ether - benzene (1 : 1) afforded the bromoketone (XXXI) as a colorless oil (0.5 g): IR(oil) 1709 cm^{-1}; NMR 1.72 (3H s), 2.21, 3.34 (each 1H d J=12.5 cps); ORD $[\phi]_{335}^{\text{trough}}$ −4450°C, $[\phi]_{292}^{\text{peak}}$ 3500° (*c* 0.119, in CH_3OH).

Found: C, 64.60; H, 9.59%. Calcd for $C_{20}H_{35}OBr$: C, 64.67; H, 9.50%.

Dihydrokolavenol Acetate (XXXIII). Metallic sodium (6 g) was added in portions to a boiling solution of XXV (3.1 g) in absolute ethanol (65 m*l*) during 2 hr. The mixture was kept at 100°C for 1.5 hr (during this period all sodium dissolved), cooled, diluted with water and then extracted with ether. The reddish brown oil (2.1 g) obtained on concentration was acetylated with acetic anhydride and pyridine and the product was chromatographed on a silica-gel (42 g) column with benzene as an eluting solvent. The dihydrokolavenol acetate (XXXIII) was obtained as an oil (1.9 g), which was distilled under reduced pressure: bp 145—150°C (bath)/0.5 mmHg; NMR 1.54 (3H d J=1.6 cps), 1.94 (3H s), 4.01 (2H t J=6.3 cps), 5.08 (1H broad).

Found: C, 79.13; H, 11.26%. Calcd for $C_{22}H_{38}O_2$: C, 78.98; H, 11.45%.

Oxidation of XXXIII with Chromium Trioxide. A solution of XXXIII (1.7 g) and chromium trioxide (1.4 g) in acetic acid (30 m*l*) and water (1.5 m*l*) was heated for 2 hr at 50°C. After an excess reagent was decomposed with ethanol, the solvent was evaporated *in vacuo*. An oily residue was dissolved in ether, the ether solution washed successively with water, a saturated aqueous solution of sodium bicarbonate and water, and dried. The oil obtained on evaporation of the solvent was chromatographed on a silica-gel column and eluted with benzene - ethyl acetate (9 : 1). The 2-keto-3-ene (XXXIV) was obtained as a pale yellow oil (0.5 g): IR(oil) 1738, 1670, 1620, 1235 cm^{-1}; UV $\lambda_{\max}^{\text{EtOH}}$ 240 mμ (ε 9800); NMR 1.85 (3H d J=1.2 cps), 1.96 (3H s), 4.02 (2H t J=6.3 cps) 5.56 (1H d J=1.2 cps).

2-Ketone Acetate (XXXV). Compound XXXIV (0.45 g) in ethanol (20 m*l*) was hydrogenated over Adams catalyst (40 mg) at room temperature and atmospheric pressure; 2.2 mol of hydrogen was absorbed. The product was isolated as a colorless oil (0.4 g), IR(oil) 3400 cm^{-1}.

The hydrogenation product (0.45 g) in acetone (10 m*l*) was oxidized with Jones reagent (0.5 m*l*) in an ice bath. An oily product was chromatographed on a silica-gel (14 g) column and eluted with benzene - ethyl acetate (9 : 1). The 2-ketone acetate (XXXV) was obtained as a colorless oil (0.25 g), which was distilled under reduced pressure: bp 168—173°C (bath)/0.006 mmHg; IR(oil) 1736, 1710, 1235 cm^{-1}; ORD $[\phi]_{305}^{\text{peak}}$ +1740°, $[\phi]_{268}^{\text{trough}}$ −1410° (*c* 0.116, in CH_3OH).

Found: C, 75.18; H, 10.91%. Calcd for $C_{22}H_{38}O_3$: C, 75.38; H, 10.93%.

The authors express their gratitude to Dr. Y. Hirose of the Institute of Food Chemistry for providing facility for the measurement of NMR spectra. They are indebted to Professor K. Naya of Kwansei Gakuin University for the measurement of ORD spectra.

Ultraviolet Spectral Studies in the Esters of Aroylphosphonic Acids

Ken-ichi TERAUCHI and Hiroshi SAKURAI

The Institute of Scientific and Industrial Research, Osaka University, Yamada-Kami, Suita, Osaka

(Received June 22, 1968)

The yellow color and spectral properties of aroylphosphonates are of some interest since the carbon analog benzaldehyde derivatives are colorless and since the phosphorus atom obviously acts as part of the chromophoric system.

The infrared and NMR data[1] provide evidence for a moderately strong conjugation between phosphorus of the phosphoryl group and carbon of the adjacent carbonyl group; more especially, the infrared absorptions of the carbonyl group in Compounds I—VIII (Table 2) show significantly low frequencies (50—65 cm^{-1} less than those[2] of the corresponding aldehydes). Griffin[3] and Berlin[4] have investigated the ultraviolet spectral evidence for d_π–p_π bonding in tri-2-pyrryl-, 2-(1-methylpyrryl),- 2-thienyl-, and 2-furylphosphine oxides, all of which possess a number of *para*-substituents on the aromatic ring, and in some acylphosphonates, respectively. The n–π^* transitions, however, in esters of aroylphosphonic acids have not yet been elucidated. In the present work, the n–π^* bands of Compounds I—VIII have been investigated, and an interesting correlation of the n–π^* band with Hammett substituent constants has been found.

The ultraviolet spectra of benzoylphosphonates were shown in the 320—450 mμ region (Fig. 1). In the ultraviolet and visible regions, the I—VIII benzoylphosphonates have two absorptions (Table 1); that in the 258—295 mμ region is identified as a π–π^* transition (^1A–^1L_a) on the basis of the large extinction coefficients, and the other, occurring in the 373—385 mμ region, identified as an n–π^* transition of the carbonyl group, are involving interaction with the phosphorus d-orbitals. The high intensity π–π^* bands in Compounds I—VIII underwent a bathochromic shift of from 17 to 29 mμ from those of its carbon-analog benzaldehydes.[5] Such a red shift suggests the extended conjugation that electronic excitation would produce an excited electron, one which is probably partially delocalized over the P→O group perhaps through vacant d orbitals on the phosphorus. On the other hand, the n–π^* bands in I—VIII are, of course, at much longer wavelengths. When we compare

TABLE 1. ULTRAVIOLET SPECTRAL DATA FOR AROYLPHOSPHONATES

Compound	R	R′	Transition π–π^* λ_{max}, mμ (log ε_{max})	Transition n–π^* λ_{max}, mμ (log ε_{max})
I	C_6H_5	C_2H_5	258 (4.05)	379 (1.92)
II	C_6H_5	i-C_3H_7	258 (4.11)	379 (1.91)
III	C_6H_5	n-C_4H_9	259 (4.11)	380 (2.01)
IV	C_6H_5	$CH_2CH{=}CH_2$	265 (4.31)	378 (2.18)
V	p-ClC_6H_4	C_2H_5	268 (4.10)	385 (1.97)
VI	p-BrC_6H_4	C_2H_5	271 (4.27)	385 (1.98)
VII	p-$CH_3OC_6H_4$	C_2H_5	294 (4.01)	373 (2.18)
VIII	p-$(CH_3)_3CC_6H_4$	C_2H_5	271 (4.06)	375 (2.16)

the absorption data[6] with those of the benzaldehydes, we find that the n–π^* absorption maxima of benzoylphosphonates show an average bathochromic shift of 50 mμ, suggesting that the orbital on carbon atom overlaps with a vacant d orbital on the phosphorus. Also, the extinction coefficients of benzoylphosphonates are considerably greater than those of the corresponding benzaldehydes. The n–π^* transition of I occurred at a wavelength shorter by 17 mμ in methanol than in cyclohexane (hypsochromic shift). This change follows the pattern

usually observed in carbonyl compounds in changing from non-polar to polar solvents; hence, it substantiate the identification of the spectroscopic transition as n–π^*.

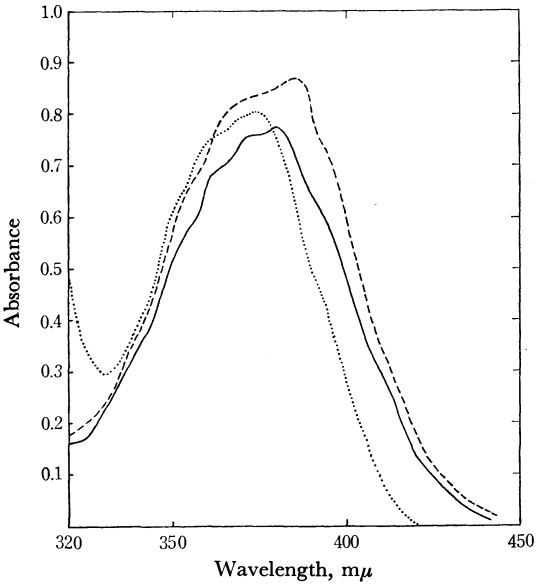

Fig. 1. The electronic spectra of I (——), 928×10^{-5} M; V (– – –), 958×10^{-5} M; and VI (·····), 533×10^{-5} M; all spectra were recorded in cyclohexane.

An interesting correlation between the wavelengths of the most intense n–π^* bands and σ's, the Hammett substituent constants, was also noted (Fig. 2). Although it is recognized that ultraviolet data, which involve both ground and excited states, cannot normally be related to Hammett substituent effects, which involve ground states only, this apparent correlation appears worthy of comment. A linear correlation of wavelengths with σ's was found for benzoylphosphonate and its *p*-*t*-butyl-, *p*-methoxy-, *p*-chloro-, and *p*-bromo derivatives. Unfortunately, no kinetic data involving Hammett correlations in *para*-substituted benzoylphosphonates have yet been reported; however, we believe that this correlation is real and significant.

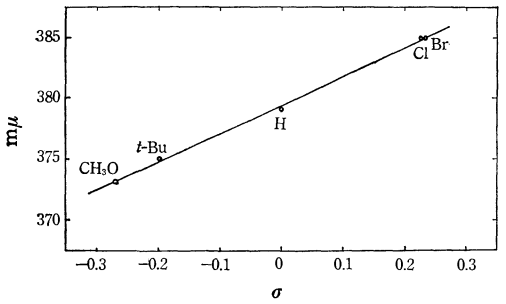

Fig. 2. Carbonyl n–π^* absorption wavelength *vs.* Hammett σ constant for *p*-substituted benzoylphosphonates.

Such a substituent effect prompts the question concerning the preferred conformation in the aroylphosphonates. The NMR data[1] suggest free rotation around the C–P bond. On the other hand, dipole-moment measurements have been reported the values of 2.93 D for I, 3.20 D for VI, and 2.64 D for V.[7]

These values of VI and V, lower and higher, respectively compared to those of the corresponding aldehydes (reported[8] as 3.70 D and 2.03 D respectively) prompt the speculation that the powerful electron inductive abilities of the methoxy and chloro functions cause a change in the electron density on the carbonyl carbon atom. The more the electron density on the carbonyl carbon increases, the more the lifetime of the conformation in which the carbonyl and phosphoryl groups are opposite might increase.

Consequently, it is conceivable that, in Compound V, the interaction of a filled nonbonding orbital on the oxygen of the phosphoryl group with the π-orbital of the carbon atom of the carbonyl group could occur to a greater extent than in Compound VI and could result in the n–π^* band at a longer wavelength. Assuming sp^2-hybridization on the oxygen of the phosphoryl group, the overlap of these orbitals is possible and is probably at a maximum when the P→O bond is perpendicular to the plane composed of the aryl ring, carbon, and phosphorus. It is also known[9] that, when there is a direct (σ-type) interaction of the π-orbital of the carbon atom of the carbonyl group with the lone-pair electron in another group, an intensification of the carbonyl n–π^* band is observed. Therefore, as is shown in Table 1, from the large intensity of the n–π^* band in Compounds I—VIII we will be able to deduce that such a direct

interaction (overlap effect) exists in benzoylphosphonates. This interactioni is supported by the findings concerning the carbonyl stretching frequency shown in Table 2. However, in view of the ultraviolet data, the p_π–d_π bonding in aroylphosphonates is apparently far less sensitive to rotation around the bond axis than is the p_π–p_π bonding such as that in α-diketones.[10] In arly sulfones, it is known that the formation of p_π–d_π bonds is independent of steric restraints because of the geometry and the large number of 3d orbitals.[11] In compounds of the R_3PO type it has been pointed out that some interaction of 3d orbitals with a π orbital of the chromophoric R group is possible, whatever the orientation of the chromophore plane with respect to the rest of the molecule.[12]

In addition, the β-keto compound diethylphosphonacetophenone has only one high intense band (λ_{max} 245 mμ, log ε 4.32), with no discrenible shoulders in the 220—450 mμ region; this shows the absence of any formation of d_π–p_π bonding.

Experimental

The ultraviolet spectra were determined in spectral-grade cyclohexane on a Hitachi EPU-2 spectrophotometer. The infrared spectra were obtained on a Hitachi EPI-S2 instrument run at a very slow speed in films of the esters of sodium chloride plates. The aroylphosphonates were synthesized by the reaction of trialkyl phosphites with acid chloride.[1] The diethylphosphonacetophenone was prepared by the methods of Borowitz *et al.*[13] Repeated distillation under reduced pressure was used to purify all the compounds needed. Tlc on a 0.25-mm thickness of silica gel, with acetone-chloroform in the volume ratio of 1 : 9, showed only one spot after development for each of the compounds examined.

Laser-induced Chemical Reaction. I. Reaction of Carbon Vapor Produced by a Pulse Ruby Laser

Ko TAKI, Pil Hyon KIM and Susumu NAMBA

The Institute of Physical and Chemical Research, Yamato-machi, Saitama

(Received July 2, 1968)

An intense laser beam is known to produce a high-temperature region when it hits the surface of a suitable target, resulting in the evaporation of the target material. This note will describe an investigation of the reaction of such a vapor with hydrocarbon.

The target material employed in this work was Shimadzu spectroscopic electrode graphite preheated under a vacuum. The laser used was a pulse ruby laser, the output energy and pulse duration of which were about 3 joules and 0.5 msec respectively.

The laser beam was focused by a lens of 30 mm focal length upon the graphite carbon in a 7-cc Pyrex cell filled with ethylene vapor. After a 10—20 pulse irradiation, the analysis was performed by gas chromatography; the principal products were acetylene, diacetylene, and vinylacetylene. The ratio of C_3 to C_4 products*1 was about 0.03—0.05. The data are listed in Table 1.

TABLE 1. YIELD OF PRODUCTS FROM THE REACTION OF ETHYLENE WITH CARBON VAPOR PRODUCED BY THE LASER BEAM

Product	Yield ($\times 10^{-6}$ mol)
Methane	0.15—0.22
Ethane	0.06—0.08
Ethylene	—
Acetylene	24.0—26.0
Vinylacetylene	0.5
Diacetylene	3.5—4.0
C_3 compounds	0.12—0.15
C_4 compounds	4.0—4.5
C_3/C_4	0.03—0.05

Ethylene: 700 Torr
Carbon consumed: 3.0—4.0 $\times 10^{-5}$ mol
Laser: 10 pulses

*1 All the reaction products were catalytically reduced by PtO_2 and hydrogen, and the propane and butane produced from C_3 and C_4 products were analysed by gas chromatography using a silica gel column; the area ratio was calibrated to the molar ratio.

There have been intensive investigations of the reaction of free carbon atoms produced by nuclear recoil reaction[1,2] and by the photolysis of carbon suboxide[3] and a carbon arc.[4] However, the reaction products and their distributions differ greatly from case to case. In the recoil reaction, it has been shown that the most common primary processes are the additions of the C atom (monoatomic carbon) to C–H and C=C bonds; the resulting adducts then undergo secondary processes. On the other hand, the carbon vapor produced in the carbon arc reacts with butenes to give spiropentane derivatives and bisethanoallene derivatives, which have been suggested to be produced from the reactions of monoatomic carbon (C_1) and triatomic carbon (C_3)[5] respectively, but no formation of acetylene has yet been found. This difference has been considered[6] to be due to the facts that the reaction conditions are not the same, and that, in a recoil reaction, free carbon atoms are apparently reaction species, while in the case of carbon vapor produced in the carbon arc the carbon atoms are complexed on the surface material.

From the fact that the products consist of C_2 and C_4 compounds in the laser-induced reaction, it seems likely that the reaction may involve the interaction of a diatomic carbon intermediate (C_2) with ethylene. There have been a few reports on the reaction of C_2, in which the diatomic carbon intermediate is the precursor of the production of acetylene[7] and other products.[8] It was considered to be highly desirable to confirm the presence of C_2 and, if possible, to observe its chemical properties. Spectroscopically, the presence of C_2 in the carbon vapor produced by laser irradiation was confirmed by the observation of the C_2 Swan bands in the vacuum system, in a hydrogen atmosphere, and in ethylene vapor. The C_2 Swan bands were also observed by Howe[9] and by Mentall and Nicholls[10] in air.

Laser-induced reactions in hydrogen, lower alkanes, butadiene, and butene-1 were also investigated.

In the reaction with hydrogen, the principal product was acetylene (about 80%, based on the carbon consumed), while no ethylene was detected, as is shown in Table 2. On the other hand, a carbon atom was produced by a recoil reaction with hydrogen[11] to produce CH, CH_2, and CH_3 radicals, these radicals undergo further reaction to produce acetylene, ethylene, and other products.

TABLE 2. YIELD OF PRODUCTS FROM THE REACTION OF HYDROGEN WITH CARBON VAPOR PRODUCED BY THE LASER BEAM

Product	Yield ($\times 10^{-6}$ mol)
Methane	0.3—0.4
Acetylene	15.0—20.0
Ethylene	0
C_3 compounds	0.1
C_4 compounds	1.0
C_3/C_4	0.1

Hydrogen: 700 Torr
Carbon consumed: $3.0—4.0 \times 10^{-5}$ mol
Laser: 10 pulses

In the reaction with a hydrogen and ethylene mixture (8 : 1), no pentene-1 was detected. As has been suggested by Wolfgang and his coworkers,[12] the addition of methyne (CH) to an ethylene molecule gives pentene-1. Therefore, the possibility that methyne was a precursor of acetylene may be excluded.

In the reaction with methane, ethane, and cyclopropane, the principal product was acetylene, and only a trace amount of ethylene was formed, as shown in Table 3. A carbon atom has been known to react with methane to produce ethylene and acetylene in an almost equivalent yield by insertion:[13,14]

$$C + CH_4 \rightarrow (CH_3\text{–}\dot{C}\text{–}H) \rightarrow C_2H_4 \text{ and } C_2H_2$$

The reaction of a carbon atom with cyclopropane should give an equivalent amount of acetylene and ethylene[13,15] *via* the carbene formed by the insertion reaction:

In the reaction with 1,3-butadiene and butene-1, neither spiropentane nor bisethanoallene derivatives are detected gas chromatographycally. Thus, monoatomic carbon is not considered to be an

Table 3. Yield of products from the reaction of methane, ethane, and cyclopropane with carbon vapor produced by the laser beam

Substrate	Methane	Ethane	C-Propane
Pressure (Torr)	700	670	680
Product ($\times 10^{-6}$ mol)			
Methane	—	2.9—4.2	2.6—2.8
Ethane	1.1	—	0.1
Ethylene	0	4.2—6.6	2.0—2.3
Acetylene	12.7—17.1	16.1—23.5	22.6—23.2
Propane	—	1.4	—
Propylene	0.31—0.41	—	14.5—16.6
C_3 products	0.5—0.7	1.4—2.7	—
C_4 products	1.8—3.9	3.6—4.0	8.8—10.0
C_3/C_4	0.1—0.4	0.4—0.7	—

Carbon consumed: $3.0—4.0\times10^{-5}$ mol
Laser: 10 pulses

important reactive intermediate in this reaction, since the product patterns are quite different from those in the reaction of the carbon atom.

The yield of C_3 compounds is higher in the reaction with ethane than with ethylene, and the C_3/C_4 ratios in the reaction with ethane and ethylene are 0.7 and 0.04 respectively. If the C_1 atom is the reaction species, C_3 compounds would be formed more easily in ethylene than in ethane.[1,13] In the recoil reaction, the ratio of C_3 compounds to C_4 compounds in ethylene vapor is 2.6.[1,2] These observations suggest that C_2 reacts with ethylene and ethane as follows:

$$C_2H_4 + C_2 \rightarrow (C_2H_4C_2)^* \begin{cases} \nearrow C_3 \text{ compounds} \\ \searrow C_4 \text{ compounds} \end{cases}$$

$$C_2H_6 + C_2 \rightarrow (C_2H_6C_2)^* \begin{cases} \nearrow C_3 \text{ compounds} \\ \searrow C_4 \text{ compounds} \end{cases}$$

In the laser-induced reaction with the mixture of H_2 and D_2 (the D_2/H_2 ratio is 1.1), the isotopic composition*2 of acetylene (C_2H_2 : C_2HD : C_2D_2) was detected to be 1 : 2.1 : 1.3 by mass spectrometrical analysis. From the highest yield of C_2HD, the mechanism of the molecular process, $C_2+H_2\rightarrow C_2H_2$ may be excluded; acetylene may be formed mainly as follows:

$$C_2 + H_2 \rightarrow C_2H + H \qquad \Delta H = -29 \text{ kcal}^{*3}$$

$$C_2H + H_2 \rightarrow C_2H_2 + H \qquad \Delta H = -10 \text{ kcal}$$

Since, in this experiment, the temperature at the surface of graphite carbon irradiated by ruby laser is estimated at 3000—4000°K[18] and since a high concentration of carbon vapor containing C_1, C_2, C_3, *etc.*[10] is produced, reaction product from C_1, C_2, and C_3 should be detected in the reaction. The methane (a small yield) actually formed in the hydrogen atmosphere might be the reaction product of C_1.

In conclusion, diatomic carbon (C_2) is considered to play the dominant role in the laser-induced reaction with olefin (ethylene) and hydrogen to produce acetylene and diacetylene.

The authors wish to acknowledge the valuable assistance of Miss K. Motegi in carrying out this work as well as to express their appreciation to Mr. S. Satooka for his mass spectrometric analysis.

*2 The isotopic composition was determined mass spectrometrically, using the published cracking pattern of C_2HD, C_2D_2, and C_2H_2.[16] The latter two of these compared well with our measured patterns of pure C_2H_2 and C_2D_2.

*3 The C_2H bond energy is from Ref. 17.

Studies of Heteroaromaticity. XXIII.[1] 1,3-Dipolar Cycloaddition Reactions of 5-Nitrofuronitrile Oxide and *m*-Nitrobenzonitrile Oxide with Benzyne

Tadashi SASAKI and Toshiyuki YOSHIOKA

Institute of Applied Organic Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya

(Received July 10, 1968)

Many papers have been published on the electrophilic addition of benzyne to nitrosobenzene,[2] acridine,[3] acetylene derivatives,[4] and on the 1,3-dipolar cycloaddition reactions of benzyne with diazoketones and acyl azides.[5] Also, several kinds of reactive dienes are known as trapping agents of benzyne.[6] However, it seems rather surprising that there has been no report which deals with its 1,3-dipolar cycloaddition reactions with nitrile oxides.

In the course of our studies on the dipolar reactivity of 5-nitro-2-furohydroxamoyl chloride,[7] we have reported that the thermal 1,3-dipolar cycloaddition procedure using hydroxamoyl chlorides has a big advantage over the corresponding nitrile oxide method, especially in the reactions with acetylenic dipolarophiles. Since benzyne is regarded as a cyclic acetylene, we attempted to apply the same procedure to benzyne. The product obtained was yellow crystals and the structure was confirmed to be 3-(5-nitro-2-furyl)benzisoxazole (I) by the elemental analyses and spectral data; the NMR spectrum in $CDCl_3$ showed signals at 1.17τ (multiplet, 1H) and 2.33 (multiplet, 3H), besides those of nitrofuran ring protons at 2.50 (doublet, 1H, J=3.8 cps) and at 2.64 (doublet, 1H, J=3.8 cps).[8] We assigned the signal at 2.33τ to H_B aromatic protons and that at 1.17τ to an H_A proton of the benzene ring. The increased deshielding of H_A compared with that of H_B is explained by the strong paramagnetic anisotropic effect of a neighbouring ether oxygen. The presence of the ultraviolet absorption maximum in ethanol at 327 mμ (ε=10300) indicates that the structure of this product is similar to 3-(5-nitro-2-furyl)-5-substituted isoxazole (II).[7]

Similar treatment of *m*-nitrobenzhydroxamoyl chloride also afforded the corresponding 3-(*m*-nitrophenyl)benzisoxazole (III) in 10% yield. These yields are much lower compared with those in the cases with diazoketones and acyl azides,[5] and these low yields may be explained by the weak electrophilicity of the nitrile oxides formed under the reaction conditions.

Whereas 1,2-dimethoxyethylene is known to be a suitable solvent[9] for the generation of benzyne by the above method, it was used in place of dichloromethane. However, the yields could not be improved so much.

The reaction path may involve the initial coordination of the electronegative oxygen of the nitrile oxide with a triple bond of benzyne to form an oxygen-carbon bonding, followed by cyclization to benzisoxazole as indicated below:

This mechanism is rather interesting when compared with that of benzonitrile oxide with nitrosobenzene[10] and of nitrosobenzene with benzyne,[2] in both of which the reactions are thought to be initiated by a carbon-nitrogen bonding, while the Diels-Alder reaction of benzyne with styrene is recently reported.[11]

Experimental[12]

3-(5-Nitro-2-furyl)benzisoxazole. 5-Nitro-2-furohydroxamoyl chloride,[7] 1.31 g (7 mmol), was dissolved in a mixture of 1 m*l* of isoamyl nitrite and 40 m*l* of dichloromethane. The solution was warmed to 55—60°C and a solution of 1.23 g (9 mmol) of anthranilic acid and 1.2 m*l* of triethylamine in 18 m*l* of acetone was added slowly to this stirred solution at the same temperature in 1 hr. The reaction mixture was refluxed for further 2 hr until the evolution of nitrogen gas had completely ceased. After the solvents were removed under reduced pressure, the residue was dissolved in chloroform and chromatographed on a silica-gel column, using chloroform as the eluent. The first fraction afforded 0.1 g (10%) of yellow crystals, mp 176°C, after recrystallization from ethanol. The main products eluted from other fractions were intractable tars.

Found: C, 57.63; H, 2.62; N, 12.12%. Calcd for $C_{11}H_6O_4N_2$: C 57.40; H, 2.63; N, 12.17%

3-(*m*-Nitrophenyl)benzisoxazole. Similarly, 10% yield of this compound was obtained, mp 176°C. UV λ_{max}^{EtOH} mμ (ε): 285 (6500), 224 (19500).

Found: C, 64.62; H, 3.35; N, 11.45%. Calcd for $C_{13}H_8O_3N_2$: C, 65.00; H, 3.36; N, 11.66%.

Organic Syntheses by Means of Metal Complexes. IV. Reduction of Nitrobenzene with Carbon Monoxide[1]

Tsunesuke KAJIMOTO and Jiro TSUJI

Basic Research Laboratories, Toyo Rayon Co., Kamakura

(Received July 10, 1968)

Carbon monoxide has been used to reduce many inorganic compounds, but its use in reduction of organic compounds has not been widely explored. This paper reports the reduction of nitrobenzene with carbon monoxide in acetic acid to give acetanilide.

There are several examples of the reduction of nitrobenzene with carbon monoxide. Formation of azobenzene from nitrobenzene and carbon monoxide has been reported.[2] Kmiecik[3] has reported the conversion of 2-nitrobiphenyl to carbazole in the presence of carbon monoxide and iron pentacarbonyl. The synthesis of urethane by the reaction of nitrobenzene and carbon monoxide in alcohols or phenols in the presence of $Rh(CO)_2$-Cl_2 and co-catalyst is known.[4] Hardy and Bennett isolated phenylisocyanate by the reaction of nitrobenzene and carbon monoxide in the presence of Rh/C-$FeCl_3$ catalyst.[5] In these reactions, carbon monoxide behaves as a reducing agent and carbon dioxide is formed. Phenylnitrene may be considered as an intermediate in these reactions.

We attempted nickel carbonyl catalyzed reduction of nitrobenzene with carbon monoxide, and confirmed the formation of acetanilide in high yield. The reaction should be carried out above 300°C, and at 285°C no acetanilide was obtained. When the reaction was done in propionic acid solution, propionanilide was obtained. Somewhat similar catalytic activities were observed with iron pentacarbonyl and dicobalt octacarbonyl. The results are shown in Table 1. Intramolecular condensa-

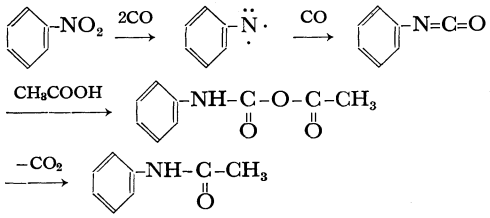
* Initial pressure at room temperature.

tion did not occur with *o*-nitrobenzoic acid in toluene solution and nitrobenzene was obtained by decarboxylation.

This reaction may be explained by the following mechanism. At first nitrobenzene is converted into phenylnitrene by giving the oxygen to carbon monoxide. Phenylnitrene is then carbonylated to produce phenyl isocyanate.



The reaction of isocyanate with acetic acid followed by decarboxylation gives acetanilide. As a related reaction, the formation of acetanilide by the reaction of phenyl thioisocyanate with acetic acid is known.[6]

Experimental

Materials. Commercially available nickel carbonyl and iron carbonyl were used without further purification. Cobalt octacarbonyl was synthesized from cobalt hydroxide by the known method.[7] Nitrobenzene was distilled before use.

Reactions of Nitrobenzene with Carbon Monoxide. Only a typical experiment is described. A stainless steel autoclave (100 ml) was charged with 9 g of nitrobenzene, 25 ml of acetic acid and 0.25 ml of nickel carbonyl. The autoclave was sealed and pressured to 100 kg/cm² with carbon monoxide, and then heated at 310°C for 90 min with stirring. After the reaction, the autoclave was allowed to cool and the reaction product was subjected to distillation. Under reduced pressure, acetanilide (6.1 g, 61%) was collected, which was identified with an authentic sample by mixed melting point determination (112°C) and infrared spectra. At the same time, formation of carbon dioxide was confirmed with a barium hydroxide solution. The other experiments were carried out similarly.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 829—831 (1969)

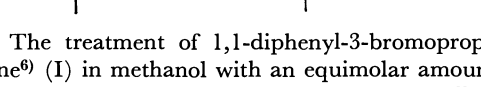
Metal Acetate- and Alcohol-catalyzed Retropropargyl Rearrangement

Fumio TODA, Masahiro HIGASHI and Katsuhiko AKAGI

Department of Industrial Chemistry, Faculty of Engineering, Ehime University, Matsuyama

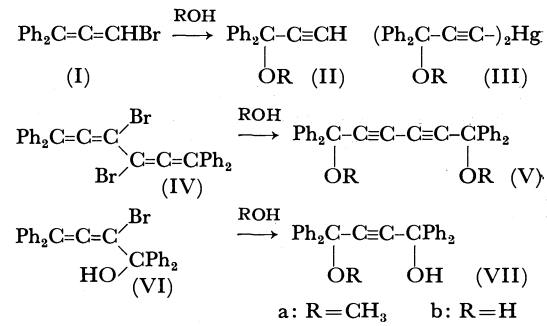
(Received July 12, 1968)

A few lithium aluminum hydride-,[1,2] cuprous bromide-,[3] potassium iodide-[3] and silver nitrate-[4] catalyzed retropropargyl rearrangements*1 (Eq. (1)) have been reported. In all these cases, however, the rearrangement was accompanied by isomerization to allene or by reduction to ethylene. It has also been reported that the alkylation of haloallene increases the proportion of the allenic isomer[5] or of the reduction product.[2] We have found that some metal acetates in alcohol and, surprisingly, alcohol itself also act as catalysts for the retropropargyl rearrangement of phenyl-substituted bromoallenes, thus affording alkoxyacetylenes in moderate yields. This is the first finding of the alcohol-catalyzed displacement of a relatively unreactive halogen atom on an unsaturated carbon.



(1)

The treatment of 1,1-diphenyl-3-bromopropadiene[6] (I) in methanol with an equimolar amount of AgOAc at room temperature for 1 hr afforded 1,1-diphenyl-1-methoxyprop-2-yne[7] (IIa) in a 71% yield. By the procedure employed for I, 1,1,6,6-tetraphenyl-3,4-dibromohexa-1,2,4,5-tetraene (IV)[8] was then reacted with methanol in the presence of twice the molar amount of AgOAc; this afforded 1,1,6,6-tetraphenyl-1,6-dimethoxyhexa-2,4-diyne (Va)*2 in a 94% yield. A similar rearrangement was observed with 1,1,4,4-tetraphenyl-3-bromobuta-1,2-diene-4-ol[9] (VI), where the reaction was faster than those of I and IV. The treatment of VI with methanol in the presence of AgOAc for 30 min at room temperature afforded 1,1,4,4-tetraphenyl-1-methoxybut-2-yne-4-ol (VIIa) in a 95% yield. The structure of VIIa was identified by comparing its mp and infrared spectrum with those of an authentic specimen prepared according to the literature.[7]



When the AgOAc-catalyzed rearrangements of I, IV, and VI were carried out in aqueous acetone, the corresponding acetylenic alcohols, IIb, Vb, and VIIb, were obtained in quantitative yields.

All of the rearrangements described above were also catalyzed by $Hg(OAc)_2$, whereas the acetates of Cu^{2+}, Zn^{2+}, Cd^{2+}, Pb^{2+}, Cr^{2+}, Co^{2+} and Ni^{2+} were all inert. The treatment of I in methanol with an equimolar amount of $Hg(OAc)_2$ afforded the mercuric acetylide IIIa, whereas the same treatment of IV gave Va. Since IIIa was easily formed by the reaction of IIa and $Hg(OAc)_2$, IIa may be produced initially. The mercuric acetylide IIIa was identical with that prepared according to the usual method.[10] In the case of VI, an unidentified mercuric compound, $C_{30}H_{23}O_3BrHg$, was obtained in a 14% yield in addition to VIIa (54% yield).

The most striking rearrangement was the alcohol-catalyzed one. After standing for a long time at room temperature, a mixture of IV and methanol afforded Va quantitatively. Although the metal acetate-catalyzed rearrangement was done for 1 hr,

*2 An authentic sample of Va was prepared by the oxidative coupling of IIa which had been obtained according to the reported method.[7]

9) F. Toda, T. Komoda and K. Akagi, This Bulletin, **41**, 1493 (1968).

10) B. B. Elsner and P. F. M. Paul, *J. Chem. Soc.*, **1951**, 893

a similar reaction without a catalyst afforded unreacted bromoallene. However, the reaction was accelerated by heating; for example, the heating of a mixture of IV and methanol under reflux for 5 hr afforded Va in a 93% yield. The heating under reflux of a solution of I in methanol for 1 hr afforded IIa and 1,1-diphenylprop-1-en-3-al (VIII) in 43 and 46% yields respectively. The latter was identical with that prepared according to the reported method.[11] The same treatment of VI in methanol afforded, quantitatively, 1,1,4,4-tetraphenyl-1,4-dimethoxybut-2-yne (IX), which was identical with that prepared according to a different method.[12] Since the treatment of VIIa in methanol containing a catalytic amount of hydrogen bromide afforded IX quantitatively, it is clear that VIIa was formed initially and that it then reacted further with methanol. The acid-catalyzed replacement of hydroxyl with the alkoxyl group will be reported in a separate paper.

Experimental*3

Silver Acetate-catalyzed Rearrangements in Methanol of Several Bromoallenes. I) A solution of I (2.71 g, 10 mmol) and AgOAc (1.67 g, 10 mmol) in methanol (100 m*l*) was stirred at room temperature for 1 hr. The reaction mixture was then decomposed with water and extracted with ether. The ether layer was washed with water and dried over sodium sulfate. The crude oil remaining after the evaporation of the solvent was distilled to afford IIa, 1.58 g (71%), bp 109°C/3 mmHg. The infrared spectrum was identical with that of an authentic sample prepared according to the literature.[7]

IV) A solution of IV (270 mg, 0.5 mmol) in methanol (10 m*l*) was treated with AgOAc (160 mg, 1 mmol) by the procedure employed for I. The crude crystals obtained by adding water to the reaction mixture were recrystallized from methanol to yield Va as colorless needles, 208 mg (94%), mp 196°C. IR: 2160 ($\nu_{C\equiv C}$) and 1090 cm^{-1} (ν_{C-O}). NMR: a multiplet centered at 2.65 (phenyl, 20H) and a singlet at 6.62τ (methyl, 6H). These spectral data were identical with those of an authentic sample prepared by the oxidative coupling of IIa.

Found: C, 87.15; H, 5.77%. Calcd for $C_{32}H_{26}O_2$: C, 86.88; H, 5.92%.

VI) A solution of VI (453 mg, 1 mmol) in methanol (10 m*l*) was treated with AgOAc (167 mg, 1 mmol) by the procedure employed for I. The curde crystals obtained by adding water to the reaction mixture were recrystallized from petroleum ether (bp 70—80°C) to afford VIIa as colorless needles, 380 mg (95%), mp 112—113°C. IR: 3350 (ν_{OH}) and 1060 cm^{-1} (ν_{C-O}).

Found: C, 85.83; H, 6.12%. Calcd for $C_{29}H_{24}O_2$: C, 86.14; H, 5.94%.

Silver Acetate-catalyzed Rearrangements in Aqueous Acetone of I, IV, and VII. A solution of the bromoallene (I, IV or VII) in 80% aqueous acetone was treated with an equimolar amount of AgOAc by the procedure employed for the rearrangement in methanol. The reaction mixture was decomposed with water and extracted with ether. The ether layer was washed with water, dried over sodium sulfate, and evaporated to dryness to give the corresponding acetylenic alcohol, IIb, VIb, or VIIb, in a quantitative yield in all cases. Each product was recrystallized from acetone to afford the corresponding complex with acetone; each product was identical with the respective authentic sample.[13]

Mercuric Acetate-catalyzed Rearrangements in Methanol of the Following Bromoallenes. I) A mixture of I (271 mg, 1 mmol), $Hg(OAc)_2$ (319 mg, 1 mmol), and methanol (10 m*l*) was stirred at room temperature for 2 hr. Crystals collected by filtration were recrystallized from benzene-petroleum ether (bp 70—80°C) to afford IIIa as colorless needles, 232 mg (72%), mp 211°C. IR: 2160 ($\nu_{C\equiv C}$), and 1185 and 1075 cm^{-1} (ν_{C-O}). NMR: a multiplet centered at 2.63 (phenyl, 20H) and a singlet at 6.64; (methyl, 6H). Those spectral data were identical with those of an authentic sample prepared according to the usual method.[10]

Found: C, 59.72; H, 4.01%. Calcd for $C_{32}H_{26}O_2Hg$: C, 59.76; H, 4.08%.

IV) The same treatment of IV for 5 hr gave Va in a 53% yield.

VI) The treatment of VI (453 mg, 1 mmol) in methanol (10 m*l*) with $Hg(OAc)_2$ (320 mg, 1 mmol) at room temperature for 30 min afforded a crystalline solid. The solid was collected by filtration, washed with methanol, and recyrstallized from acetone to yield an unidentified mercuric compound, 100 mg, (14% as $C_{30}H_{23}O_3BrHg$), mp>270°C.

Found: C, 50.11; H, 3.02%. Calcd for $C_{30}H_{23}O_3$-BrHg: C, 50.63; H, 3.23%.

The combined methanol layer was decomposed with water and extracted with ether. The ether layer was washed with water and dried over sodium sulfate. Crystals obtained by the evaporation of the solvent were recrystallized from petroleum ether (bp 70—80°C) to yield VIIa as colorless needles, 220 mg (54%), mp 112—113°C. A mixed-melting-point determination with an authentic sample prepared by the AgOAc-catalyzed reaction showed no depression.

Alcohol-catalyzed Rearrangements of Several Bromoallenes. I) A solution of I (135 mg, 0.5 mmol) in methanol (10 m*l*) was heated under reflux for 1 hr. After the addition of water, the reaction mixture was extracted with ether. The ether layer was washed with water, dried over sodium sulfate, and

Reaction of Sulfides with *t*-Butyl Hypochlorite in the Presence of Water, ^{18}O Tracer Study

Kunihiko KIKUKAWA, Waichiro TAGAKI, NORIO KUNIEDA and Shigeru OAE

Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sugimoto-cho, Sumiyoshi-ku, Osaka

(Received July 20, 1968)

It has been found that *t*-butyl hypochlorite oxidizes organic sulfides to the corresponding sulfoxides or sulfones under suitable reaction conditions, and the synthetic utility of this oxidation to prepare sulfoxide has been examined for series of sulfides.[1-4] However, the mechanistic features have not been fully explored yet. Skell and Epstein obtained sulfoxides by the oxidation of corresponding sulfides at low temperature (−78°C) and suggested the following mechanism (Eq. (1)) which involves an alkoxy sulfonium salt as the intermediate. Walling and Mintz carried out the same reaction in benzene at room temperature, and found that the stoichiometry of the reaction was not 1 : 1 with respect to both the sulfide and the reagent as

$$R_2S + t\text{-}C_4H_9OCl \rightarrow [R_2SOC_4H_9]^+Cl^- \rightarrow R_2SO \quad (1)$$

would be expected from Eq. (1), but the ratio was 1 : 2 and a high yield of sulfoxide and a mixture of products from hypochlorite were obtained. They did not observe any sulfone formation contrary to other reports,[2] and suggested a polar mechanism involving molecular chlorine and diphenyl sulfur dichloride for oxidation of diphenyl sulfide, rejecting free radical mechanisms.

During the courses of our investigation on the oxidation of organic sulfur compounds with halogenating agents, we have been interested in the fate of oxygen atom in the above oxidation. It is obvious that the oxygen atom of the sulfoxide must come from *t*-butyl hypochlorite when the reaction is carried out in non-hydroxylic solvent. Meanwhile, it has been reported that in the presence of water molecular halogen oxidizes sulfides to the corresponding sulfoxides.[5-7] In this oxidation, ^{18}O tracer experiments have demonstrated that the oxygen atom of the sulfoxide comes exclusively from water, and not from any other solvent components such as acetic acid or methanol, *etc.*[7] However, the last possibility of oxygen uptake into sulfoxide from other solvents cannot still be ruled out in some other system.[8]

Therefore, it is interesting to examine the effect of water on the above *t*-butyl hypochlorite oxidation.

Results and Discussion

Oxidation of diphenyl sulfide with an equimolar amount of *t*-butyl hypochlorite in dioxane at room temperature yielded the corresponding sulfoxide. Any intermediate, such as that isolated by Skell and Epstein[2] at low temperature, was not observed.

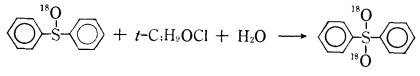
1 : 1 : 2	60	—	1.72	1.14	—
1 : 2 : 2	—	80	1.72	—	1.37
1 : 2 : 10	—	90	1.62	—	1.62

a) One gram of I in 30 m*l* of the mixture of II and III.

With twice molar amounts of hypochlorite, diphenyl sulfone was obtained as the main product. The addition of water to the reaction mixture did not change the product composition. The possibility of ^{18}O (of water) incorporation into the products was then examined. The results summarized in Table 1 shows that the ^{18}O incorporation did take place in both sulfoxide and sulfone formation. The amount of incorporation was more than 80% and approached 100% as the amount of water increased. The ^{18}O incorporation has been also examined for the oxidation of sulfoxide to the corresponding sulfone. As shown in Table 2, the oxygen atom of water was again found to be incorporated in the sulfone.

Table 2. Oxidation of diphenyl sulfoxide with *t*-butyl hypochlorite

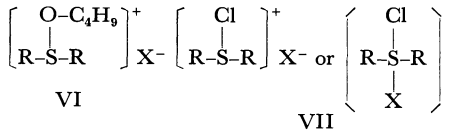


Atom % of ^{18}O in[a]		
Water	Sulfoxide	Sulfone
0.20	1.02	0.62
1.60	1.02	1.25
1.60	0.21	0.78

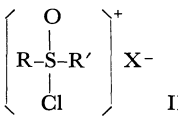
a) Mole of ratio of sulfoxide : *t*-C_4H_9OCl : H_2O = 1 : 2 : 2

The formation of ^{18}O labeled sulfoxide does not necessarily rule out the possibility that the primary product is the unlabeled sulfoxide which then undergoes an oxygen exchange reaction catalyzed by the hydrogen chloride formed.[9] Therefore, the oxygen exchange reaction of diphenyl sulfoxide was examined by adding hydrogen chloride instead of adding *t*-butyl hypochlorite, although the results in Table 2 indicate that such oxygen exchange reaction must be slow compared to the oxidation reaction. This control experiment also reveals that the oxygen exchange of a sulfoxide is negligible under these conditions (see Experimental).

The above oxidation reaction presumably proceeds through the hydrolysis of either one of the following two different intermediates, VI or VII. For the hydrolysis of VI, there are two possibilities, *i. e.* one is the attack of water on the sulfur atom giving a labeled sulfoxide, the other is the solvolysis of *t*-butyl group giving an unlabeled sulfoxide. The



VI VII



IX

attack of chloride anion on *t*-butyl group would also give an unlabeled sulfoxide. This possibility, however, is not in accord with the above experimental results. Meanwhile it is difficult to consider that the nucleophilic reaction takes place exclusively on the sulfur atom rather than on *t*-butyl group. Therefore, the more likely intermediate is VII which rapidly reacts with water to give a sulfoxide. In the absence of water *t*-butoxy anion would reacts with VII to give VI. The formation of VI and its decomposition to give the sulfoxide would be slower than the formation of VII and its hydrolysis.

The formation of the sulfone and the incorporation of ^{18}O into the sulfone with identical concentration as that of the sulfoxide seem to suggest that the chlorosulfoxonium (IX) is formed as the intermediate which upon quenching with water is converted to the sulfone.

Experimental

Materials. Dioxane was purified by treating with hydrochloric acid and with metallic sodium. Diphenyl sulfide was prepared by Friedel-Crafts reaction of benzene and elemental sulfur according to the method used by Dougherty and Hammond.[10] Diphenyl sulfoxide was prepared by the oxidation of diphenyl sulfide with hydrogen peroxide. *t*-Butyl hypochlorite was prepared by the reaction of *t*-butanol with chlorine in a sodium hydroxide solution according to the method of Leeter and Bell.[11] Diphenyl sulfoxide ^{18}O-labeled was prepared by the oxidation of diphenyl sulfoxide in a mixture of

bromine-$H_2{}^{18}O$-pyridine.[7]

Oxidation of Diphenyl Sulfoxide and Sulfone with *t*-Butyl Hypochlorite in ^{18}O Enriched Water-Dioxane. To a solution of diphenyl sulfoxide in dioxane-water was added *t*-butyl hypochlorite dropwise under stirring at 15°C. After one hour, most of the solvent was removed by concentration under reduced pressure, and water was added to the residue to give crystalline product. The properties and the purity of diphenyl sulfoxide was discussed in the previous papar.[9b] The results are shown in Tables 1 and 2.

Control Experiment. ^{18}O-Labeled diphenyl sulfoxide was treated under the same reaction conditions as in the above oxidation, except that an equimolar amount of hydrogen chloride was added in place of *t*-butyl hypochlorite.

After one hour, diphenyl sulfoxide was recovered and its ^{18}O content was assayed:

Atom % of ^{18}O: Starting sulfoxide, 0.827; recovered sulfoxide, 0.821.

Kinetics of Multidentate Ligand Substitution Reactions. V. Effects of Ammonia and Thiocyanate Ion on the Substitution Reaction of Eriochrom Black T with Nickel(II)-Ethylenediaminetetraacetate Chelate

Mutsuo KODAMA and Katsumi MIYAMOTO

Department of Chemistry, Ibaraki University, Mito, Ibaraki

(Received July 24, 1968)

In an earlier paper,[1] the substitution reaction of Eriochrom Black T (BT) with nickel(II)-ethylenediaminetetraacetate (Ni(II)-EDTA) chelate was studied spectrophotometrically. The study showed that reaction proceeds through two simultaneous reaction paths involving doubly- and completely-deprotonated BT anions. The present paper deals with the effects of ammonia, thiocyanate and bromide ions on the reaction of BT with Ni(II)-EDTA chelate. Even in the presence of ammonia or thiocyanate, Ni(II)-EDTA chelate showed the same kinetic behavior as in the absence of ammonia or thiocyanate, but the rate of reaction was reduced appreciably. This was ascribed to the fact that the concentration of normal Ni(II)-EDTA chelate, which is reactive in the present situation, is reduced by the formation of a mixed ligand chelate involving ammonia or thiocyanate.

Experimental

Reagents. The preparations of nickel(II) perchlorate and ethylenediaminetetraacetate solutions were described previously.[1] Ammonia and potassium thiocyanate were of analytical reagent grade and used without further purification. A spectrophotometric test showed that the addition of ammonia or thiocyanate did not affect the absorption curve of BT solution (pH=10.0) containing 10.0 mM ethylenediaminetetraacetate. The concentration of ammonia was determined by titrating against standard hydrochloric acid using Methyl Orange as indicator. The concentration of thiocyanate was standardized against a standard silver nitrate solution.[2]

Apparatus and Experimental Procedure. All apparatus and experimental procedures were as described previously.[3] Reactions were followed spectrophotometrically by observing the absorbance at 630 mμ. The ionic strength of sample solutions was adjusted to 0.30 by adding an appropriate amount of sodium perchlorate (ammonia system) or potassium nitrate (thiocyanate or bromide system). A pseudo first-order rate constant, k^+, was obtained from the plot of $\log(A_{HD}/(A-A_{NiD}))$ against time, t, where A_{HD}, A and A_{NiD} have the same meanings as previously.[1]

Results and Discussion

Effects of ammonia and thiocyanate on the substitution reaction of BT with Ni(II)-EDTA chelate were examined at 25°C for solutions containing an excess of ethylenediaminetetraacetate in the pH range 8.50 to 10.50. Therefore, no buffer reagent was used in this study. Even in the presence of ammonia or thiocyanate, nickel(II)-EDTA chelate shows quite the same kinetic behavior as in their absence.[1] However, as illustrated in Fig. 1, ammonia or thiocyanate appreciably reduces the rate of the substitution reaction. The reduction in the pseudo first-order rate constant, k^+,[1] increases

1) M. Kodama, C. Sasaki and M. Murata, This Bulletin, **41**, 1333 (1968).

2) F. P. Treadwell and W. T. Hall, "Analytical Chemistry," Vol. II, John Wiley and Sons, Inc., New York (1951), p. 647.

3) K. Kodama, This Bulletin, **40**, 2575 (1967).

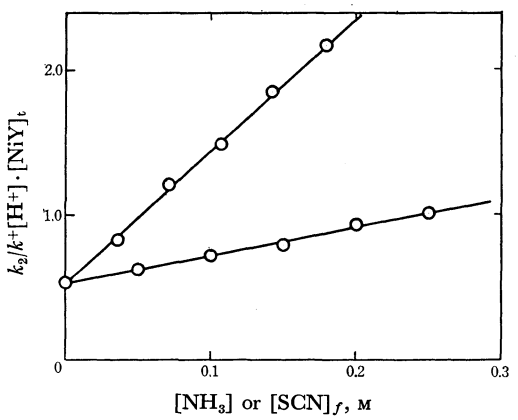

Fig. 1. The relation between $1/k^+$ and the concentration of ammonia or thiocyanate ion.
μ=0.30, 25°C, λ=630 mμ
Concentration of nickel(II)-EDTA=10.45 mM
Concentration of uncomplexed EDTA=10.0 mM

with increasing concentration of ammonia or thiocyanate. All the above facts suggest that the present reaction has the same mechanism as in the absence of ammonia or thiocyanate, but that the concentration of reactive Ni(II)-EDTA chelate in the reaction is reduced by the addition of ammonia or thiocyanate. This can be explained simply by considering the formation of a mixed ligand chelate involving ammonia or thiocyanate which is much less reactive than a normal chelate, NiY^{2-}. If the present reaction proceeded only through NiY^{2-}, the apparent rate constant, k^+, should be given by

$$k^+=\frac{k_2^+\cdot k_2}{[H^+]}\cdot\frac{[NiY]_t}{1+K^{NCS}\cdot[NCS]_f}$$

$$\text{or}\quad \frac{k_2^+\cdot k_2}{[H^+]}\cdot\frac{[NiY]_t}{1+K^{NH_3}\cdot[NH_3]_f} \qquad (1)$$

where k_2^+ and k_2 have the same meanings as in a previous paper,[1] and other notations are defined: $[NiY]_t$, the total concentration of Ni(II)-EDTA chelate; $[NCS]_f$, the concentration of uncomplexed thiocyanate, $[NH_3]_f$,[1]* the concentration of uncomplexed ammonia; $K^{NCS}=[NiY(NCS)^{3-}]/[NiY^{2-}]\cdot[NCS^-]$; $K^{NH_3}=[Ni(NH_3)Y^{2-}]/[NiY^{2-}]\cdot[NH_3]$.

The $k_2[NiY]_t/[H^+]\cdot k^+$ value was plotted against $[NH_3]_f$ or $[NCS]_f$. Results are shown in Fig. 1. The slope *vs.* intercept ratios of the linear relation in Fig. 1 were 17.1 and 3.47 for the ammonia and thiocyanate systems, respectively.

As shown in Fig. 2, the addition of ammonia or thiocyanate results in a change in the absorption curve of Ni(II)-EDTA chelate. This can be ascribed to the formation of a mixed ligand chelate involving ammonia or thiocyanate. From the increase in absorbance, K^{NCS} and K^{NH_3} were determined with

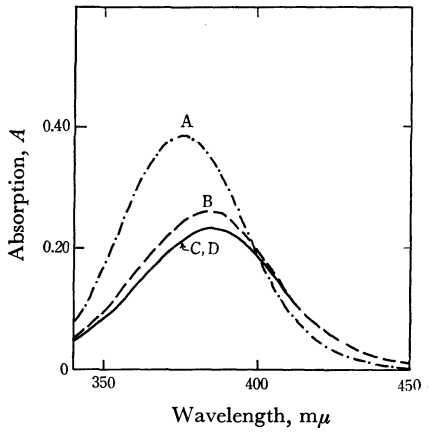

Fig. 2. Absorption curves of nickel(II)-EDTA chelate.
Concentration of nickel(II)-EDTA chelate=10.0 mM

the aid of the following relation derived thermodynamically,

$$\log\frac{A-A_{NiY}}{A_{NiYX}-A}=\log K^X+\log[X]_f \qquad (2)$$

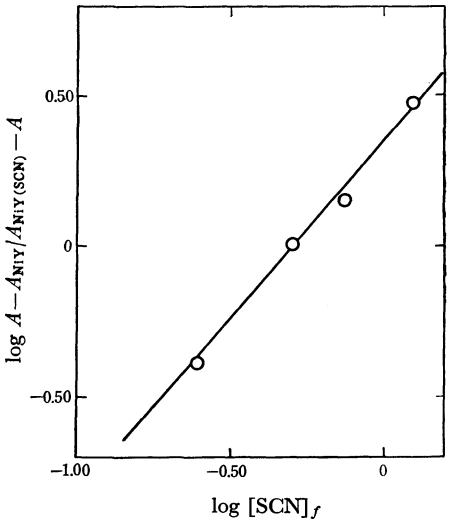

Fig. 3. Determination of K^{SCN}.
μ=2.0, pH=9.70, λ=380 mμ
Concentration of nickel(II)-EDTA=20.0 mM
Concentration of uncomplexed EDTA=20.0 mM
Concentration of thiocyanate ion ranged from 0.25 to 1.25 M

*1 Precisely, $[NH_3]_f$ means the concentration of uncomplexed ammonia.

where K^X denotes K^{NH_3} or K^{NCS} and $[X]_f$, $[NH_3]_f$ or $[NCS]_f$ and where A_{NiY} is the absorbance of a solution containing only NiY^{2-}, A_{NiyX}, the absorbance of a solution in which all Ni(II)-EDTA chelate is present in the form of NiYX, and A the absorbance of a solution containing both Ni(II)-EDTA chelate and ammonia or thiocyanate.

A typical result obtained for the thiocyanate system was given in Fig. 3 (at 380 mμ). The K^{NCS} value was estimated as 3.02 (μ=0.30) from the linear relation. In a similar way, K^{NH_3} was determined as 12.6 (μ=2.0) at 370 mμ, in good agreement with a reported value.[4]

The agreement of the slope *vs.* intercept ratio in the kinetic study with the K^X value determined strongly supports the present authors' explanation that the present reaction proceeds only through NiY^{2-}, and that the mixed ligand chelate involving thiocyanate or ammonia is essentially non-reactive.

In the d^8 octahedral system, any reaction going by the coordination number seven (pentagonal bipyramid) would inevitably lead to a considerable loss in crystal field separation energy, and hence be slow.[5] Therefore, the explanation that ammonia or thiocyanate may form the seventh bond to the nickel(II) ion in the pentagonal bipyramid reaction intermediate, thus making the Ni(II)-EDTA chelate less reactive, is impossible as far as crystal field effects are concerned.

Generally, the rate of dissociation of water from nickel(II) ion is expected to be much faster than that of ammonia. Therefore, if the formation of a Ni(II)-OH_2 bond prior to the formation of the first Ni(II)-BT bond is essentially required in the present reaction, the ammonia coordinated to the nickel(II) ion might considerably reduce the rate of reaction of BT with Ni(II)-EDTA chelate. The same explanation may also be applied to the effect of thiocyanate on the reaction. To understand the precise role of the coordinated ammonia or thiocyanate in the present exchange reaction, further systematic and advanced investigations must be undertaken. The effect of bromide ion which does not form a mixed ligand chelate with NiY^{2-} was also studied, but no practical effect observed.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 835—837 (1969)

The Complexation Reaction of 1-(Hydroxy-4-methyl-2-phenylazo)-2-naphthol-4-sulfonic Acid (Calmagite) with Divalent Metal Ions and Use as a Metallochromic Indicator

Mutsuo KODAMA and Katsumi MIYAMOTO

Department of Chemistry, Ibaraki University, Mito, Ibaraki

(Received July 31, 1968)

In previous papers,[1,2] the complexation reaction of 1-(1-hydroxy-2-naphthylazo)-6-nitro-2-naphthol-4-sulfonic acid (Eriochrom Black T, BT) with divalent metal ions in the presence of aminopolycarboxylate was studied spectrophotometrically. In the present paper, solution equilibria between 1-(hydroxy-4-methyl-2-phenylazo)-2-naphthol-4-sulfonic acid (common name, calmagite) and metal(II)-aminopolycarboxylate chelates were dealt with in the same way as in the BT system, and the use of calmagite as a metallochromic indicator in the chelatometric titrations of zinc(II), cadmium(II) and lead(II) was studied.

Apparatus and experimental procedures were those used previously.[1,2] Commercial calmagite was purified by employing the procedure proposed by Lindstrom and Diehl.[3] The C.H.N. analysis and spectrophotometric measurement showed that the purity of calmagite was 93%.

The Complexation Reaction of Calmagite. Typical absorption curves of calmagite and its metal(II) chelates were shown in Fig. 1. In copper(II)-ethylenediaminetetraacetic acid(EDTA), zinc(II)-nitrilotriacetic acid (NTA), lead(II)-NTA and cadmium(II)-*N'*-(hydroxyethyl)-ethylenediamine-*N,N,N'*-triacetic acid (EDTA-OH) systems, the exchange reaction of calmagite with metal(II)-

aminopolycarboxylate chelates proceeds very rapidly. Hence, the composition and stability constants of calmagite chelates of these metal(II) ions were determined from $\log(A_{HD}-A)/(A-A_{MD})$ *vs.* $\log[MZ]/([Z]_f\ [1+K_2[Z]_f/(a_H)])$ plots.[1,2] In nickel(II)-EDTA-OH and cobalt(II)-EDTA system, however, the reaction is very slow. Therefore, as in BT system, solution equilibria were determined from a $\log\ [(A_{HD}-A)/(A-A_{MD})[m-(A_{HD}-A)/(A_{HD}-A_{MD})]$ *vs.* $\log\ [Z]_f$ plot.[4,5] The notations here are those used previously.[1,2,4,5] Under the present experimental conditions, calmagite invariably forms chelates of a 1-to-1 composition. Results are given in Table 1. The numerical values used in the calculation of stability constants of calmagite chelates were estimated from the related con-

stants[1-3,6-8] in a solution of ionic strength 0.10 in the same way as previously.[1] On the basis of general relation between stability constant and dissociation constant, the stability constant of metal(II)-calmagite chelate would be larger than that of metal(II)-BT chelate. In contrast to this prediction, log K_{MD} values of cadmium(II) and lead(II) chelates of calmagite were slightly less than those of BT. This abnormal behavior can not be explained in a simple manner, but may partially be attributed to π-back donation, to steric interaction or other effects. It can also be mentioned here that the Irving-Williams series applies to calmagite and BT chelates of copper(II), nickel(II), cobalt(II) and zinc(II).

The Use of Calmagite as an Indicator in Chelatometric Titrations of Zinc(II), Cadmium(II) and Lead(II). Thermodynamically, because of its larger log K_{MD} value, calmagite can not be used as a metallochromic indicator in EDTA titrations of copper(II), nickel(II) and cobalt(II). In the cases of zinc(II), cadmium(II) and lead(II), as shown in Table 2, end point indices, Δ_1 and Δ_2,[9] calculated using stability constants of metal(II)-EDTA,[7] -calmagite, tartrate[10] and ammine[8] complexes, and dissociation constants of EDTA[6] and calmagite,[3] clearly suggest that calmagite can be used successfully as an indicator in EDTA titrations of zinc(II), cadmium(II) and lead(II). This prediction was examined experimentally. At the end point, the color transition from red to bluish-violet occurred sharply. Typical results are given in Table 3. Experimental equivalence points agreed well with stoichiometric ones. Aqueous solutions of calmagite and its metal(II) chelates were much more stable than those of BT, in good agreement with the findings of Lindstrom and Diehl.[3]

Radical Copolymerization of Glycidyl Dienecarboxylates with Styrene

Yoshio IWAKURA, Fujio TODA, Reiko IWATA and Yoshinori TORII

Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Tokyo

(Received July 31, 1968)

Extensive studies of the copolymerization of glycidyl acrylate and methacrylate have been undertaken by several investigators in recent years.[1-3] In connection with these works, glycidyl dienecarboxylates such as glycidyl β-vinylacrylate (GV) and glycidyl sorbate (GS) were prepared and copolymerized with styrene in benzene at 60°C, using α,α′-azobisisobutyronitrile as an initiator. The monomer reactivity ratios (r_1, r_2) were determined by the intersection method of Mayo and Lewis[4] and by the method of Fineman and Ross.[5] Then, the Q and e values of both monomers were calculated from these experimental results by means of Alfrey and Price equation.[6] These

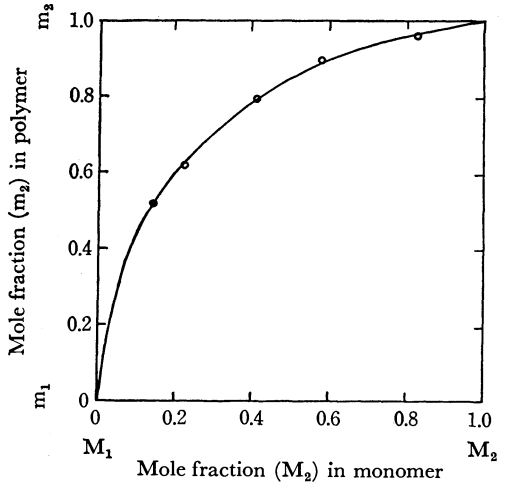

Fig. 1. Styrene - glycidyl β-vinylacrylate.

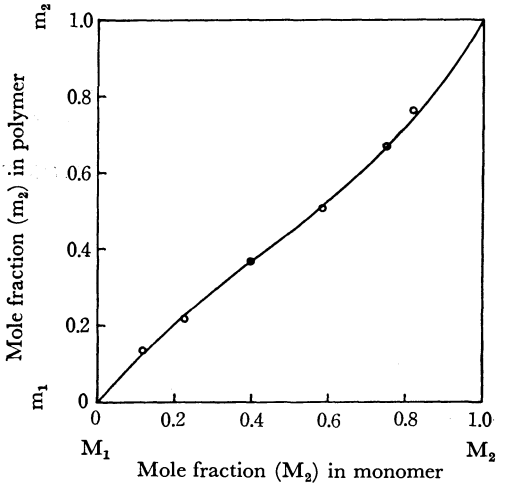

Fig. 2. Styrene - glycidyl sorbate.

values are listed in Table 1. The copolymer composition curves for GV and GS are shown in Figs. 1 and 2. It was found that the apparent rate of copolymerization of GV with styrene was somewhat slow in the region rich in charged styrene components, whereas the situation was reversed in the copolymerization of GS. The copolymer composition curve of GV shows that GV is reactive and is well-incorporated into a copolymer in the monomer mixture richer in styrene components. The copolymer composition curve of GS runs nearly along the 45° line and copolymerization will produce a copolymer possessing almost the same composition as the monomer mixture even at a high conversion.

It has been reported[7] that the replacement of the β-hydrogen of *n*-butyl acrylate by a methyl group brought about a serious decrease in the Q value from 0.50 to 0.007. The difference in Q value between GV and GS is presumably attributable to the same effect in the δ-methyl substitution system. Although the e value was also decreased by β-substitution in the case of butyl acrylate, no influence on the e value by δ-substitution in diene derivatives has been reported in the literature. The small increase in e value by δ-substitution therefore remained unexplained.

Copolymer were found to be soluble in benzene, tetrahydrofuran, dioxane, dimethylformamide, chloroform, and acetone, and insoluble in methanol, *n*-hexane, and water. The copolymers of GV containing a larger amount of GV were gummy materials, however, the other copolymers were white powder.

The infrared absorptions of $\nu_{C=O}$ and δ_{CH} of the *trans*-double bond in the copolymer appeared at 1730 and 970 cm^{-1} and at 1735 and 970 cm^{-1} in the copolymers of GV and GS, respectively. The absorption peaks arising from the phenyl ring of copolymer were exhibited at 1600, 1500, 760, and 700 cm^{-1}. The fact that the absorption maxima of the epoxide group[8] appeared at 900 and 840 cm^{-1} proved that the epoxide ring still remained unattacked in the copolymer. The epoxide contents in copolymers determined by titration corresponded substantially well to those calculated from elemental analyses.

Experimental

Synthesis of β-Vinylacrylic Acid. The procedure of Glushkov[9] was modified for the preparation of β-vinylacrylic acid. Malonic acid (250 g, 2.40 mol) was dissolved in pyridine (350 m*l*). Into the solution, kept at 75—80°C, acrolein (100 m*l*, 1.51 mol) was then added under stirring, drop by drop. The reaction mixture was stirred for 15 min, and then 75 m*l* of acrolein was added, drop by drop. After a few minutes interval, an additional 25 m*l* of acrolein was added to the mixture. After the mixture had been stirred for 30 min, it was poured onto crushed ice and acidified gradually wish 175 m*l* of concentrated sulfuric acid. Yellowish crystals were precipitated in a pulpy state by acidification. The crystals were filtered and washed with cold water. The filtrate was extracted three times with methylene chloride (each 300 m*l*), and the combined extract was dried over sodium sulfate. Yellowish crystals were obtained by the evaporation of the solvent. All the crystals were recrystallized from water, in the presence of hydroquinone as an inhibitor, to yield 66 g (28%) of the product melting at 68.5—70.5°C (lit.,[10] 72°C)

in the form of needles. Crude crystals seemed to be pure enough for the synthesis of acid chloride. Recrystallization would cause a loss of β-vinylacrylic acid by thermal polymerization.

Synthesis of β-Vinylacryloyl Chloride. β-Vinylacryloyl chloride was synthesized from β-vinylacrylic acid and thionyl chloride in a 68% yield by the method described by Alder.[11] The boiling point was 42—44°C/10 mmHg.

Synthesis of Glycidyl β-Vinylacrylate (GV). In a four-necked flask there was placed glycidol in dry tetrahydrofuran, plus a small amount of an inhibitor. Equimolar amounts of triethylamine and β-vinylacryloyl chloride, each diluted with dry tetrahydrofuran, were added separately through two dropping funnels. Care had to be taken to maintain the reaction mixture in a condition with a slight excess of amine and to keep it below 10°C with an ice bath. After the addition had been completed, the mixture was stirred for 1 hr; the resultant triethylamine hydrochloride was removed by filtration, and the filtrate was dried over sodium sulfate. The product was obtained by distillation under a high vacuum in a 44% yield. The boiling point was 72—73°C/0.4 mmHg. If the bath temperature was raised above 120°C, distillation was impossible because of the thermal polymerization of the liquid phase. IR absorption bands: ν C=O 1715, ν C=C 1640, 1600; *trans*-conjugated diene δ CH 1015; epoxide 905, 840; terminal vinyl δ CH 930 cm^{-1}. λ_{max} 245 mμ in tetrahydrofuran.

Found: C, 62.57; H, 6.61%. Calcd for $C_8H_{10}O_3$: C, 62.32; H, 6.54%.

Synthesis of Sorboyl Chloride. A 500 m*l* flask was charged with 168 g (1.5 mol) of sorbic acid. Phosphorus pentachloride (312 g, 1.5 mol) was then vigorously blended in, portion by portion, using a glass rod. The reaction mixture was liquefied within a short time as the reaction proceeded. After the addition, the hydrogen chloride thus formed was purged from the reaction mixture with an aspirator. The product was separated from phosphorus oxychloride by distillation under reduced pressure with a small amount of a polymerization inhibitor such as *N*-phenyl-β-naphthylamine and purified by redistillation to give a fraction boiling at 70—72.5°C/10 mmHg and weighing 136 g (70% yield[12]). If the bath temperature was raised to over 110°C, the contents of the reaction flask suddenly became a black resinous material.

Synthesis of Glycidyl Sorbate (GS). Glycidyl sorbate was prepared by a method analogous to that used for GV. Toluene was used as the solvent in this case. The precipitated triethylamine hydrochloride was removed by filtration. The crude filtrate showed two carbonyl absorptions at 1720 and 1740 cm^{-1} in the infrared spectrum. The absorption of a higher frequency would indicate the existence of an isomer formed by the migration of the double bond to glycidyl 3,5-hexadienoate in the course of reaction. The crude reaction mixture was then heated together with a small amount of benzylamine at 90°C for 3 hr in order to bring about isomerization to a conjugated structure. The treatment was continued until the absorption at 1740 cm^{-1} disappeared. The solution thus treated was washed successively with dilute sulfuric acid, a sodium bicarbonate solution, and water, and then dried. After the removal of the toluene, vacuum distillation was repeated three times to give GS boiling at 100—102°C/0.3 mmHg[13] in a 42% yield. λ_{max} 259 mμ in tetrahydrofuran.

Found: C, 64.53; H, 7.06%. Calcd for $C_9H_{12}O_3$: C, 64.27; H, 7.19%.

Copolymerization. Polymerization experiments were carried out at 60°C in sealed tubes (10 m*l*) under a nitrogen atmosphere and using α,α′-azobisisobutyronitrile as an initiator. About 2 g of a mixture of precisely weighed styrene and GV was diluted with benzene (5 m*l*; in the case of GS, 2 m*l*) and sealed. The solution was then kept at 60°C for 15—28 hr. The polymer solution was poured into methanol, and the precipitated polymer was collected by filtration and reprecipitated, chloroform being used as the solvent and methanol as the non-solvent. The purified polymers were dried *in vacuo*, and the composition of the copolymer was determined by elemental analyses.

Determination of Epoxide Values. About 300mg of a copolymer sample was precisely weighed and dissolved in 25 m*l* of a HCl-dimethylformamide solution in a glass-stoppered flask.[14] The solution was then kept at 60°C for 64 hr. After the solution had been cooled to room temperature, calcium carbonate (0.5 g), starch solution (1.0 m*l*), and a fluorescein solution (5 drops) were added and the mixture was titrated by a standard silver nitrate solution. The epoxide value was calculated by subtracting the blank titer obtained under the same condition but without a sample.

The epoxy contents of the copolymers are as follows:

Copolymer	From elemental analyses:	From epoxide value:
Styrene-GV	89.1 mol%	84 mol%
Styrene-GS	21.7 mol%	21 mol%

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 840 (1969)

The Near Ultraviolet Absorption Spectrum of Quinoxaline Vapor

Yoshinori HASEGAWA,*1 Yoshito AMAKO and Hiroshi AZUMI

Department of Chemistry, Faculty of Science, Tohoku University, Katahira-cho, Sendai

and Mitsuo ITO and Yoko KAIZU

The Institute for Solid State Physics, The University of Tokyo, Minato-ku, Tokyo

(Received July 31, 1968)

We have measured the n–π^* absorption spectrum of quinoxaline vapor from 20 to 200°C with absorption cells of 40 and 120 cm in length, using a Shimadzu GE-340 grating spectrograph (dispersion in the second order=1.3 Å/mm) and a Jarrell Ash 3.4 m grating spectrograph (dispersion in the second order=2.4 Å/mm).

It has been found in this spectrum,*2 just as had previously been found in the spectrum of pyrazine vapor,[1,2] that the bands consist of two systems, one broad-band system originating at 26016.7 cm^{-1} and with a prominent progression of 525.3 cm^{-1}, and one sharp-band system with a 524.7 cm^{-1} progression with strong false origins at 27496.2 and 27670.1 cm^{-1}. Each band of the sharp system has a clear-cut head on the shorter-wavelength side and degrades toward the longer wavelengths.

Contrary to the case of the pyrazine spectrum, however, we can assign the broad system as an allowed $^1A_1$–$^1B_1$ transition with the 0–0 band at 26016.7 cm^{-1} and the sharp system as a vibronic transition induced by "intensity borrowing" from the $^1A_1$–$^1A_1$ transition, on the basis of the following considerations:

(1) The broad system exhibits a spectral-band feature characteristic of the vibrational structures for an allowed electronic transition, while the sharp system is characteristic of those for a vibronically-induced transition.

(2) In the n–π^* absorption bands of pyrazine,[1,2] the sharp bands have been observed to belong to the parallel bands of a near-oblate symmetric top (the asymmetric parameter, $\kappa \approx +0.7$) and assigned as an allowed electronic transition, while the broad bands, which can be regarded as the perpendicular bands, have been assigned as a vibronic transition. On the other hand, the quinoxaline molecule can be regarded as a near-prolate symmetric top (approximately, $\kappa \approx -0.7$). As is well known,[3] the parallel bands of a prolate symmetric top have nearly the same rotational structures as have of an oblate symmetric top. Therefore, it is natural to suppose that the sharp bands of the quinoxaline spectrum correspond to the parallel bands, (in-plane polarized perpendicular to the N–N axis of the molecule) and the broad bands, to the perpendicular bands, (polarized normal to the molecular plane).

It can not be determined with certainty, however, whether the sharp bands are the "forbidden"[4] bands in the allowed $^1A_1$–$^1B_1$ transition or the electronically-forbidden bands ($^1A_1$–$^1A_2$ transition, a component of the n–π^* splitting), since no hot bands corresponding to the strong false origins at 27496.2 and 27670.1 cm^{-1} appeared at all.*3

If we can regard the two vibrational frequencies, 525.3 and 524.7 cm^{-1}, observed in the broad and sharp system respectively as belonging to one electronic transition, we might assign the sharp bands to the "forbidden" bands in the allowed $^1A_1$–$^1B_1$ transition with the 0–0 band at 26016.7 cm^{-1}. The strong false origins at 27496.2 and 27670.1 cm^{-1} may also be then assigned to 0+1479 and 0+1653 cm^{-1} respectively. It seems, however, that the 1653 cm^{-1} is too high to be a fundamental frequency of the n–π^* state. However, this frequency is unlikely to be a combination.

Although several points remain uncertain, the proposed assignment seems most probable in the light of present knowledge. The vibrational analysis will be reported in detail elsewhere.

---

Formation of 3-Butenoates from Crotonyl Chloride in the Presence of Amines

Yoshio IWAKURA, Fujio TODA, Reiko IWATA*1 and Yoshinori TORII*2

Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received August 5, 1968)

The reaction of acyl halides with alcohols is a conventional method of preparing esters.[1] In the course of applying this method to *trans*-crotonyl chloride in order to obtain unsaturated esters, which are used as monomers in vinyl polymerization, it was found that hydrogen abstraction from the β-methyl group of *trans*-crotonyl chloride occurred and that esters of vinylacetic acid (3-butenoates) were formed, possibly as a result of elimination-addition. In connection with this work, Payne has reported[2] that the dehydrochlorination of 3,3-dimethylacrylyl chloride through the use of tertiary amine occurs by 1,4-elimination to give the intermediate isopropenylketene, which is trapped in a dimeric form. The thermal isomerization of methyl *trans*-crotonate has also been investigated by Butler *et al.*[3]

The dependence of the formation of isomerized esters on various factors, such as the reaction conditions and the kinds of starting materials, was studied by determining by gas chromatography (GC) the ratio of crotonate and 3-butenoate existing in the products. The experimental results are summarized in Table 1. The structural assignment of each ester rests on the infrared and NMR spectra. The experimental results thus far examined show that the product ratio is influenced chiefly by the method of the reaction and by the kinds of reactants, such as alcohols and amines, while it is not so much influenced by the reaction time, the temperature, and the solvents. There was little difference in products ratios between the two methods of addition: 1) the simultaneous addition of acid chloride and amine into alcohol,

TABLE 1. REACTION OF *trans*-CROTONYL CHLORIDE WITH ALCOHOL

Run	Alcohol	Amine	Temp. °C	Solvent	3-Butenoate %	*trans*-Crotonate %	Method of reaction
1	MeOH	TEA	20	THF	76.7	23.3	Amine and acid chloride were added into alcohol.
2	MeOH	TEA	20	THF	74.2	25.8	Amine and acid chloride were added into alcohol, allowed to stand for 18 hr.
3	MeOH	Pyridine	20	THF	8.7	91.3	Amine and acid chloride were added into alcohol.
4	MeOH	DABCO*	20	THF	14.3	85.7	Amine and acid chloride were added into alcohol.
5	MeOH	TEA	20	THF	92.2	7.8	Acid chloride was added into amine and alcohol.
6	MeOH	TEA	−30	THF	92.2	7.8	Acid chloride was added into amine and alcohol.
7	MeOH	TEA	20	Benzene	93.9	6.1	Acid chloride was added into amine and alcohol.
8	MeOH	TEA	20	THF	79.6	20.4	Amine was added into acid chloride and alcohol.
9	*i*-BuOH	TEA	20	THF	98.3	1.7	Acid chloride was added into amine and alcohol.

TEA: Triethylamine THF: Tetrahydrofuran DABCO: Diazabicyclooctane

* On the contrary to our expectation, amount of 3-butenoate in product was small, presumably due to low solubility and basicity of its half-protonated form.

*1 Present address: Government Chemical Industrial Research Institute, Tokyo; Hon-machi, Shibuya-ku, Tokyo.

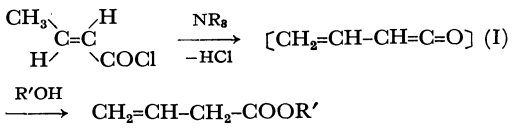
3) J. N. Butler and G. J. Small, *Can. J. Chem.*, **41**, 2492 (1963).

and 2) the addition of amine to a mixture of alcohol and acid chloride. However, by the addition of acid chloride to a mixture of amine and alcohol, that is, by a reaction under amine excess conditions, 3-butenoate was predominantly obtained possibly because of elimination-addition. It was noteworthy that a strong base such as triethylamine favored the formation of 3-butenoate, while *trans*-crotonate was mainly given by pyridine under the same reaction conditions. Isobutanol, which is rather bulky, gave a larger amount of isomerized ester than did methanol.



Several mechanisms are possible for the formation of 3-butenoate. The most probable explanation of the reaction scheme is that *trans*-crotonyl chloride is converted to an unstable vinylketene intermediate (I), which then reacts very rapidly with alcohol to give the isomerized ester. This assumption is well in accordance with the description of Payne.[2] The influence of the carbonyl group of α,β-unsaturated acid chlorides on the mobility of β-methyl hydrogen would be extended by conjugation, which has been established in the deuterium exchange reaction of such carboxylic acids as tiglic acid.[4]

Finally, 3-butenoate once formed was stable enough and had little tendency to isomerize to crotonate when the reaction mixture was kept standing at room temperature as long as amine salt did not exist in the system and *vice versa*. However, small amounts of such amines as *n*-butylamine and benzylamine assisted the migration of the double bond of isolated 3-butenoates to the stable conjugated form at elevated temperatures.

Experimental

Synthesis of Standard Materials. The methyl *trans*-crotonate and methyl 3-butenoate (methyl vinylacetate) were synthesized by the esterification of the corresponding acids in excess methanol with a small amount of a *p*-toluenesulfonic acid catalyst: bp; methyl *trans*-crotonate,[5] 120—122°C; methyl 3-butenoate,[6] 111—113°C. The methyl *cis*-crotonate[7] was obtained by courtesy of Professor T. Tsuruta of The University of Tokyo, bp 119°C.

Reaction Conditions. Equimolar amounts (0.1 mol) of alcohol, amine, and *trans*-crotonyl chloride which had been diluted appropriately were allowed to react in a solvent (40 m*l*) for 30 min at a constant temperature. The amine hydrochloride thus precipitated was removed by filtration, and the resultant filtrate was subjected to GC measurement.

Gas chromatography was carried out under the following conditions:

Column PEG 1500, 2 m; He 40 ml/min; Column Temperature 129°C; Sample 1—4 μl.

The retention times of the esters are shown in Table 2. The amounts of the esters were determined from the areas of the peaks in the GC charts. Although they were not measured, the absolute yields were thought to be good enough, since the reactions were carried out under mild conditions.

Table 2. Retention times of each ester in GC

Ester	Retention time	
	min	temp. °C
Methyl *trans*-crotonate	3.08	129
Methyl *cis*-crotonate	2.43	129
Methyl 3-butenoate	2.42	129
Isobutyl 3-butenoate	2.94	155
Isobutyl *trans*-crotonate	3.40	155

Isolation of Aplysin, Debromoaplysin, and Aplysinol from *Laurencia Okamurai* Yamada[1]

Toshi IRIE, Minoru SUZUKI and Yoshiki HAYAKAWA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo

(Received September 3, 1968)

As part of a continuing search for constituents from *Laurencia* species,[2] we have examined *L. Okamurai* Yamada (Japanese name, Mitsudesozo; Rhodomelaceae). In this paper we will report the isolation of aplysin (I),[3] debromoaplysin (II),[3] aplysinol (III),[3] laurinterol (IV),[2c] and debromolaurinterol (V)[2c] and also a new, unidentified dibromo-compound (VI) from the seaweed.

Methanol extracts of the dried seaweed were evaporated *in vacuo*, and the residue was percolated with ether. The ethereal solution was washed successively with a dilute potassium hydroxide solution, dilute hydrochloric acid, and water, and evaporated. The oily neutral fraction thus obtained was chromatographed on silica gel.

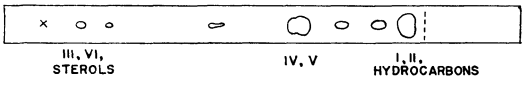

Fig. 1. TLC of the neutral fraction (silica gel, benzene).

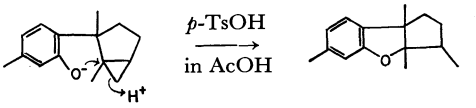
From fractions eluted with 9 : 1 *n*-hexane - benzene, there was obtained a crystalline bromo-compound (I), $C_{15}H_{19}OBr$; mp 85—86°C, $[\alpha]_D$ −85°. The UV, IR, and NMR spectra of I were superimposable upon those of aplysin, which was isolated by Yamamura and Hirata[3] from *Aplysia kurodai* (sea rat) and which was also obtained by treatment with *p*-toluenesulfonic acid of laurinterol.[2c] The identity was further confirmed by a comparison of the R_f value on TLC and by a mixed-melting-point determination with an authentic sample.

Fractions eluted with 7 : 3 *n*-hexane - benzene left a colorless oil upon the removal of the solvent; this oil was purified by rechromatography on silica gel to give a pure, oily substance (II), $C_{15}H_{20}O$, $[\alpha]_D$ −63°. The IR and NMR spectra suggest that II is debromoaplysin;[3] this is confirmed by the synthesis from debromolaurinterol (V) shown below.



V II

Benzene eluates gave a mixture of alcohols, from which cholesterol, a monobromo-alcohol (III), $C_{15}H_{19}O_2Br$, mp 157—159°C, and a dibromo-compound (VI), $C_{14}H_{20}O_5Br_2$ (M^+ 428), mp 148.5—149°C, were isolated. The compounds III and VI could be purified *via* their acetates, VII, $C_{17}H_{21}O_3Br$, $[\alpha]_D$ −26°, and VIII, $C_{16}H_{22}O_6Br_2$, mp 154—156°C, $[\alpha]_D$ −44°, respectively. Compound III was identified as aplysinol[3] by a comparison of its UV, IR, and NMR spectra with those of an authentic sample. In the IR spectrum, the new dibromo-compound (VI) showed alcoholic group(s) at ν_{max} 3500 cm^{-1}, but no carbonyl function. The IR and NMR spectra of its acetate (VIII) exhibited the presence of an acetoxyl group [ν_{max} 1755 cm^{-1}; τ 7.86 (3H, s)], four tertiary methyl groups (3H, s's at τ 8.82, 8.70, 8.54 and 8.27) (two of which could be assumed to be olefinic and/or attached to epoxide-ring carbon, judging from their chemical shifts), two protons on carbons bearing bromine atoms (τ 5.2—5.8), and a proton on a carbon bearing an acetoxyl group (τ 4.71). The structure elucidation of VI is now in progress.

The principal part of the neutral fraction was eluted with 1 : 1 *n*-hexane - benzene; it was found to consist of laurinterol (IV) and debromolaurinterol (V), which were isolated from *L. intermedia* Yamada.[2c] It is noteworthy that these bromo-compounds have been found in only one seaweed.

Experimental

Isolation. Air-dried seaweed (1.4 kg), collected at Hakata-shima, the Inland Sea of Japan, was extracted with methanol, and then the methanolic solution was concentrated *in vacuo*. The residue was percolated

with ether, and the ethereal solution was shaken with a 5% potassium hydroxide solution and then with 1N hydrochloric acid to remove the acidic and basic components. After the removal of the solvent, a neutral, brown-colored oil (30 g) was obtained; it was subsequently chromatographed on silica gel.

Aplysin (I). Fractions eluted with 9 : 1 *n*-hexane - benzene left a crystalline substance upon the removal of the solvent. Recrystallization from methanol gave colorless crystals, mp 85—86°C; $[\alpha]_D$ −85° (*c*, 1.25; $CHCl_3$); UV, λ_{max}^{EtOH} 293, 232 mμ (ε 4400, 8100); IR, ν_{max}^{Nujol} 1610, 1580, 1474, 1393, 1380, 1263, 1230, 1100, 1005, 880, 860 cm^{-1}; NMR, τ 8.90 (3H, d, J=6 c/s), 8.75 (3H, s), 8.70 (3H, s), 7.68 (3H, s), 3.48 (1H, s), 2.95 (1H, s). (Found: C, 61.16; H, 6.41%).

The IR and NMR spectra were superimposable upon those of aplysin, and the R_f value on TLC and the mixed-melting-point were the same as those of an authentic sample.

Debromoaplysin (II). Fractions eluted with 7 : 3 *n*-hexane - benzene left an oily substance, which was then purified by rechromatography over silica gel to give a pure, colorless oil, $[\alpha]_D$ −63° (*c*, 1.15; $CHCl_3$); IR, ν_{max}^{film} 1620, 1595, 1500, 1280, 1265, 1120, 1010, 950, 800 cm^{-1}; NMR, τ 8.90 (3H, d, J=6 c/s), 8.75 (3H, s), 8.70 (3H, s), 7.72 (3H, s), 3.60 (1H, broad s), 3.50 (1H, broad d, J=7 c/s), 3.20 (1H, d, J=7 c/s). (Found: C, 82.98; H, 9.20%).

The IR and NMR spectra were superimposable upon those of debromoaplysin, to be described below.

Laurinterol (IV) and Debromolaurinterol (V). From fractions eluted with 1 : 1 *n*-hexane - benzene two compounds, IV, $C_{15}H_{19}OBr$, mp 54—55°C, and V, $C_{15}H_{20}O$ (an oil) were obtained and identified as laurinterol and debromolaurinterol respectively.

Aplysinol (III). Fractions eluted with benzene gave a mixture of alcohols. This mixture was then acetylated with acetic anhydride and pyridine at room temperature. The acetylated product was chromatographed on silica gel to give a pure, colorless oil (VII); $[\alpha]_D$ −26° (*c*, 0.85; $CHCl_3$); UV, λ_{max}^{EtOH} 292, 233 mμ (ε 2600, 5100); IR, ν_{max}^{film} 1750, 1615, 1585, 1490, 1230, 1050 cm^{-1}; NMR, τ 8.93 (3H, d, J=6 c/s), 8.63 (3H, s), 8.07 (3H, s), 7.74 (3H, s), 5.83 (2H, AB-q), 3.44 (1H, s), 2.95 (1H, s).

The acetate VII was saponified with 1.5N methanolic potassium hydroxide under reflux to give the original alcohol (III) in a good yield. Recrystallization from carbon tetrachloride gave colorless crystals, mp 157—159°C; $[\alpha]_D$ −54° (*c*, 0.90; $CHCl_3$); UV, λ_{max}^{EtOH} 292, 233 mμ (ε 5400, 10200); IR, ν_{max}^{Nujol} 3240, 1582, 1490, 1230, 1157, 1102, 1056, 998, 880, 857, 840, 790 cm^{-1}; NMR, τ 8.93 (3H, d, J=6 c/s), 8.54 (3H, s), 7.71 (3H, s), 6.28 (2H, m), 3.47 (1H, s), 2.98 (1H, s).

(Found: C, 57.67; H, 6.17%).

The IR and NMR spectra were superimposable upon those of aplysinol. Aplysinol (III) has also been isolated directly from the original alcoholic mixture by careful rechromatography.

Dibromo-compound (VI). The rechromatography of the afore-mentioned alcoholic mixture led to the isolation of crystals melting at 148.5—149°C (VI); IR, ν_{max}^{Nujol} 3500, 1252, 1080, 1050, 1000, 915, 896, 823, 786 cm^{-1}. Acetate (VIII), colorless crystals, mp 154—156°C (from CCl_4), $[\alpha]_D$ −44° (*c*, 0.75; $CHCl_3$); UV, λ_{max}^{EtOH} 290 mμ (ε 180); IR, ν_{max}^{Nujol} 1755, 1403, 1225, 1082, 1050, 1032, 1012, 942, 878, 828, 790 cm^{-1}; NMR, τ 8.82 (3H, s), 8.70 (3H, s), 8.54 (3H, s), 8.27 (3H, s), 7.86 (3H, s), 7.5—8.2 (2H, m), 7.05 (1H, s), 5.2—5.9 (2H, m), 4.71 (1H, s).

Found: C, 40.65; H, 4.67%. Calcd for $C_{16}H_{22}O_6Br_2$: C, 40.86; H, 4.72%.

The saponification of VIII gave VI in a good yield.

Debromoaplysin (II) from Debromolaurinterol (V). A solution of V (51 mg) and *p*-TsOH (25 mg) in glacial acetic acid (2 ml) was heated at 50°C for 25 hr. After being cooled, the reaction mixture was extracted with ether, and the ethereal solution was washed successively with water, a 5% sodium bicarbonate solution, and a saturated sodium chloride solution, and dried over sodium sulfate. The ether was then removed, and the residual oil was chromatographed over silica gel to give a pure, colorless oil (47 mg),¶ $[\alpha]_D$ −61° (*c*, 0.74, $CHCl_3$); mass spectrum, *m/e* (rel. abund.) 216 (M^+), 202 (15), 201 (100), 187 (11), 173 (18), 160 (31). 159 (50), 145 (14), 119 (9), 91 (9), 77 (6), 55 (4), 43 (5), and 41 (8). The IR and NMR spectra were superimposable upon those of II, and the mass spectral data were identical with those of debromoaplysin reported in the literature.[3]

The authors wish to express their hearty thanks to Professor Yoshimasa Hirata, Nagoya University, for providing them with the IR and NMR spectral charts of aplysinol, and to Professor Toraya Fujiyama, Hiroshima University, for collecting the seaweed. The authors' thanks are also due to Mr. Shigezo Shimokawa and Miss Yoshiko Kishio for their NMR measurements, to Miss Yuko Imai for her measurements of the mass spectra, and to Mrs. Toyoko Toma, Faculty of Pharmaceutical Science, for her microanalyses.

SHORT COMMUNICATIONS

Conformational Dependence of P=O Stretching Vibration Frequency in Six-membered Cyclic Phosphates

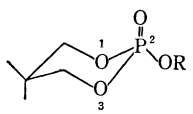
Masatsune KAINOSHO, Toshikatsu MOROFUSHI and Asao NAKAMURA

Central Research Laboratories, Ajinomoto Co., Inc., Suzuki-cho, Kawasaki

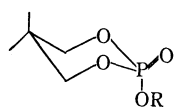
(Received December 19, 1968)

It has been reported that the P=O stretching frequency ($\nu_{P=O}$) does not show any appreciable dependency on the conformational environments of 1,3,2-dioxaphosphorinane system,[1,2] although the $\nu_{S=O}$ in six-membered cyclic sulfites is quite sensitive to the conformations.[3] NMR and dipole moment studies[4] have shown that the P=O bond is mainly at the equatorial rather than the axial position. The same conformation is also confirmed by the X-ray diffraction method[5] in the crystalline state of several phosphates.

In this communication we wish to present the unequivocal evidence of conformational dependence of $\nu_{P=O}$, which is contrary to previous reports. The infrared spectra of 5,5-dimethyl-2-oxo-2-alkoxy-(or 2-aryloxy)-1,3,2-dioxaphosphorinanes were carefully examined both in solid phase (KBr tablet) and in carbon tetrachloride solution.



α



β

In solid phase, all of the compounds examined show a symmetrical single absorption at 1284—1305 cm^{-1} which can be assigned to $\nu_{P=O}$, but in solution an extra band at 1267—1298 cm^{-1} followed by the strong absorption at 1308—1322 cm^{-1} (see Table 1). These bands are assignable to $\nu_{P=O}$ because they were shown to shift by the addtion of phenol possibly due to the formation of hydrogen bonding. The origin of this phenomenon (*i. e.* two $\nu_{P=O}$'s) is attributable to the conformational equilibrium, $\alpha \leftrightarrow \beta$. With I—V, the relative intensity of the higher frequency bands are much stronger than the lower ones, indicating that the former are equatorial and the latter are axial $\nu_{P=O}$. This assignment is compatible with the general trend that the axial stretching frequency is lower than the equatorial one.

* Preparation of these compounds will be described elsewhere.

** Liquid at room temperature.

Clearer examples are supplied by VI and VII, in which β-conformation may be expected to have a strong 1,3-diaxial repulsion between the ring hydrogens and the substituents at aryloxy groups. Thus, the intensity ratios of two bands ($\nu_{P=O_{eq}}$: $\nu_{P=O_{ax}}$) are roughly estimated as 4 : 1 and 1 : 1 for VI and VII, respectively. These ratios are in agreement with the NMR results which will be published elsewhere.

The Electron Spin Resonance of the Trinuclear Vanadyl Pyrophosphate Complex

Akinori HASEGAWA, Yoshio YAMADA and Masaji MIURA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima

(Received October 30, 1968)

An aqueous solution of the vanadyl pyrophosphate (1 : 1) complex has shown a characteristic ESR spectrum which has never been observed in any other vanadyl complexes. Yakovenko and Mustaev recently proposed $Na_2VOP_2O_7 \cdot 6H_2O$ as the molecular formula for this complex.[1] The observed spectrum (Fig. 1) can not, however, be interpreted in terms of any of the present models of a mononuclear or binuclear complex.

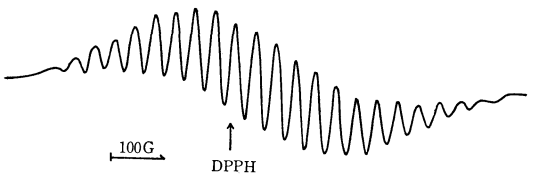

Fig. 1. ESR spectrum of aqueous solution of vanadyl pyrophosphate complex at 25°C

The molecular formula of this system, therefore, has been investigated further by various methods. The amount of water eliminated from the crystal was determined gravimetrically, and that of sodium ions, by atomic absorption spectrophotometry. The molecular weight has been measured by means of a vapor-pressure osmometer with this system. Assuming the complex to be trinuclear, its molecular weight is 1120, a value which is in good agreement with the calculated value, 1077. The results of all these measurements have definitely indicated the trinuclear formula of $[Na_2VOP_2O_7]_3 \cdot 12H_2O$.

Thus, in the trinuclear complex, exchange interaction among three vanadyl ions should be taken into account. The spin Hamiltonian is shown in the form:

$$\mathcal{H} = g\beta H \sum_{i=1}^{3} S^{(i)} + a \sum_{i=1}^{3} S^{(i)} I^{(i)} + \bar{J} \sum_{i>j=1}^{3} S^{(i)} S^{(j)}, \quad (1)$$

where $\bar{J} \gg a$ is assumed. With this assumption and the mixing of the two doublet states with the quartet state, Hudson and Luckhurst showed that the ESR transitions allowed for the quartet state to occur at:[2]

$$h\nu = g\beta H + \frac{a}{3}(m^{(1)} + m^{(2)} + m^{(3)}). \quad (2)$$

The vanadyl pyrophosphate complex may, therefore, be expected to give a spectrum composed of 22 lines and with a splitting of 36.4 gauss. This splitting is one-third of that of 109 gauss observed in vanadyl pyrophosphate (1 : 2), which shows no spin exchange.

Transitions for the two doublet states are also allowed at:

$$h\nu = g\beta H + \frac{a}{3}(m^{(1)} + m^{(2)} + m^{(3)}) \pm \frac{2a}{3}(m^{(1)2} + m^{(2)2} + m^{(3)2} - m^{(1)}m^{(2)} - m^{(2)}m^{(3)} - m^{(3)}m^{(1)})^{1/2}. \quad (3)$$

The spectrum predicted for these transitions is constructed with 144 irregularly spaced lines. As the intensity of these lines is very weak compared with that for the quartet, the quartet state appears predominantly in the spectrum of the trinuclear complex. The spectrum simulated with these assumptions shows a satisfactory agreement with that observed.

Hudson and Luckhurst, using Redfield's theory, explained the distinctive change in the spectrum of the triradical with a rise in the temperature in terms of the spin exchange interaction.[2] In the present case, however, no such change can be observed. This may be attributed to the condition $\bar{J} \gg a$. In order to estimate the value of $\bar{J}$, measurements of the magnetic susceptibility were carried out at various temperatures above 77°K.

According to Kambe's theory,[3] the effective Bohr magneton for this complex obeys the equation:

$$\mu_{eff} = \left[\frac{5\exp(-3\bar{J}/2kT) + 1}{\exp(-3\bar{J}/2kT) + 1}\right]^{1/2}. \quad (4)$$

By comparing this relation with the observed values, $\bar{J} \simeq 30$ cm^{-1} was obtained, where it must be noticed that the sign of $\bar{J}$ is the reverse of the conventional one. This value completely satisfies the condition of $\bar{J} \gg a$, a being 99×10^{-4} cm^{-1}. The large antiferromagnetic exchange interaction may suggest that the spin exchanges through the π bonds of O–P–O in pyrophosphate.

Mass Spectroscopic Detection of Methyl Radical in the Reaction of Hydrogen Atom with Ethylene

Soji TSUCHIYA, Fukusaburo ISHIHARA, Satsuki TASHIRO and Tsutomu HIKITA

Department of Fuel Technology, Faculty of Engineering, University of Tokyo, Hongo, Tokyo

(Received November 4, 1968)

It is well known[1] that the reaction of hydrogen atom with ethylene produces energy rich ethyl radicals initially, and that those stabilized by collisions with surrounding particles or a wall of a reaction vessel undergo the recombination and the disproportionation reactions. In this communication, we will describe the evidence for the existence of methyl radical, and will suggest the mechanism in a low pressure reaction with a high concentration of hydrogen atom.

Hydrogen atoms, which are produced by a microwave discharge in the mixture of 10% hydrogen in argon, are introduced to the Pyrex reaction tube with a flow velocity of 6 m/sec at 0.45 Torr, and ethylene is added *via* the inner tube that is movable to control the reaction time in the range of 1—15 msec. The reaction products are fed into a TOF mass spectrometer through a pin hole positioned at the end of the reaction tube.

The analysis of the observed mass spectrum shows that ethane and methane are the main reaction products, while butane and propane are minor ones. For example, the reaction at an initial concentrration ratio of $[C_2H_4]_i/[H]_i=5$*1 is expressed by a stoichiometric equation, $C_2H_4+2H=0.77C_2H_6+0.22CH_4+0.07C_3H_8+0.002C_4H_{10}$. In this analysis, the peak intensities of $m/e=15$ and 14 in the spectrum are in excess compared with the ones calculated from the standard mass spectral patterns of the above products. In order to decide what product contributes to the $m/e=15$ peak, the ionization efficiency curve was observed as shown in Fig. 1. The appearance potential is 5.90 eV lower than the ionization potential of argon atom, *i. e.*, 15.76−5.90=9.86 eV. This value is fairly in agreement with that of methyl radical, 9.843 eV.[2] The same experiment to ascertain the existence of ethyl radical was also made. The appearance potential of the $m/e=29$ peak is equal to the ionization potential of ethylene, because the $m/e=29$ peak corresponds to the parent ion of isotopic ethylene $^{13}C^{12}CH_4$. Hence, the concentration of ethyl radical is too small to be detected.

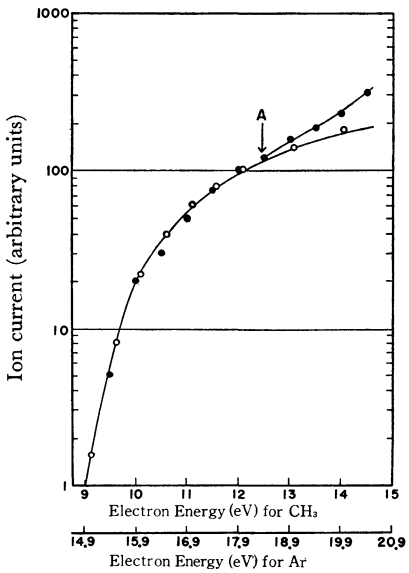

Fig. 1. Ionization efficiency curve of methyl radical in the reaction products.
●: that of CH_3^+ ion from CH_3 radical,
○: for A^+ ion from argon atom; point A shows the beginning of the contribution of CH_3^+ ion from methane in the products.

From the above results, the following reactions are concluded to be dominant in the present condition.

$$C_2H_4 + H \rightleftarrows C_2H_5^* \longrightarrow C_2H_5 \quad (1)$$
$$C_2H_5 + H \longrightarrow C_2H_6 \quad (2)$$
$$\longrightarrow 2CH_3 \quad (3)$$
$$CH_3 + H \longrightarrow CH_4 \quad (4)$$

A very small concentration of ethyl radical is considered due to the fact that the rates of reactions (2) and (3) are much larger than that of (1), and moreover that the collision frequency to stabilize an energy rich ethyl radical is small. The existence of a detectable amount of methyl radical means that reaction (4) is not very fast compared with the reaction (1). The details of the study on the kinetics will be published in the near future.

*1 This value is estimated from the relation, $[C_2H_4]_i/([C_2H_4]_i-[C_2H_4]_f)\alpha$, where $[C_2H_4]_f$ is the final concentration of ethylene at the end of the reaction, and α is the stoichiometric ratio of the reaction.

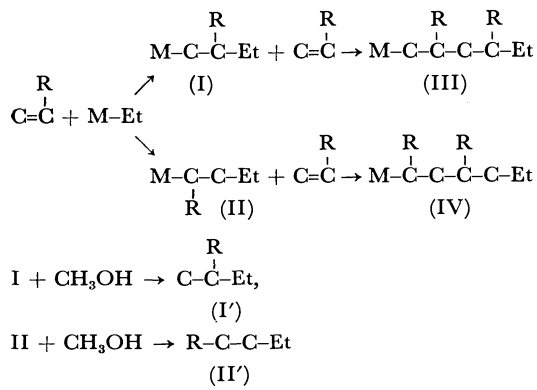
A Mechanism of the Syndiotactic Polymerization of α-Olefin

Yoshinobu TAKEGAMI and Toshimitsu SUZUKI

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Kyoto

(Received December 5, 1968)

In connection with the initiation step of the polymerization of α-olefin, the insertion reactions of olefins into metal-ethyl bond in Ziegler-type catalysts were studied.[1] An olefin was reacted with a catalyst in a high concentration, and then, after a certain reaction time, the catalyst mixture was decomposed by methanol. The insertion processes of an olefin into a metal-ethyl bond may be formulated as follows:



The hydrocarbons thus liberated were identified by gas-liquid chromatography.

The catalyst system containing titanium gave exclusively a metal alkyl (I), which was related to the isotactic polymerization of α-olefins. Unlike as in the titanium system, propylene was polymerized to a syndiotactic polymer with a vanadium catalyst at a low temperature.[2]

The method described in a former paper[1] was used in this vanadium catalyst system. However, in the case of propylene, neither metal alkyl (I) nor (II) were detected at a low temperature. Butene-1 and higher olefins could not be polymerized with this catalyst.[3] Pentene-1 could be reacted with vanadium tetrachloride and diethylaluminum chloride catalysts. After methanolysis, *n*-heptane (from metal alkyl (II)) and a small amount of 3-methylhexane (from metal alkyl (I)) were obtained. The results are summarized in Table 1. At −70°C, where the syndiotactic polymerization of propylene proceeded, almost ten times as much (II) as metal alkyl (I) was obtained. The fact that the yield of the metal alkyls decreased with the reaction time indicates that the second step of the insertion of pentene-1 into metal alkyls (I) and (II) occurred slowly.

Recently Zambelli *et al.*[4] succeeded in copolymerizing ethylene and butene-1 with a syndiospecific catalyst, and they obtained an almost alternating copolymer. This may be explained, in our opinion, by the consideration that the insertion of butene-1 into a sterically-hindered secondary metal alkyl bond is difficult, while ethylene is easily inserted into the secondary metal alkyl bond and forms the primary metal alkyl bond again.

According to this mechanism, almost every experimental result with the syndiospecific catalyst can be clearly explained.

1) A bulky olefin, such as butene-1 or pentene-1, can not be polymerized, for the steric hindrance of the alkyl substituent attached closely to vanadium interrupts the coordination of the approaching monomer.

2) The syndiotacticity in the case of the polymerization of propylene is caused by the monomer attack on the secondary metal alkyl bond from the less hindered site.

3) The addition of anisole to the reaction system increases the tendency of the insertion reaction to the secondary metal alkyl bond, as is shown in Table 1.

Photocycloaddition of Propionaldehyde to Ethyl Vinyl Ether[1]

Kensuke SHIMA and Hiroshi SAKURAI

The Institute of Scientific and Industrial Research, Osaka University, Suita-shi, Osaka

(Received December 6, 1968)

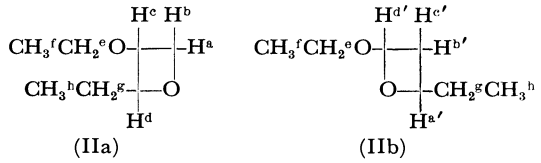
It has been reported that aliphatic aldehyde add to highly-alkylated olefins, such as tri- and tetramethylethylene, to give oxetanes photochemically.[2] However, in the cases of 1-olefins (*e. g.*, 1-hexene or 1-octene) ketones (I) are mainly formed by the radical chain mechanism.[3]

$$R_1CHO + R_2CH{=}CH_2 \xrightarrow{h\nu} R_2CH_2CH_2COR_1 (I)$$

The photoreaction of aliphatic aldehydes with electron-deficient olefins also gives ketones.[4]

In this communication, we wish to report on the photochemical formation of oxetanes from propionaldehyde and ethyl vinyl ether.[5] A solution containing 70 g of ethyl vinyl ether and 32 g of propionaldehyde was irradiated, using a 350-W high-pressure mercury lamp and a Pyrex filter, at 20°C under nitrogen for 20 hr. After the subsequent evaporation of the unreacted materials, a fraction boiling at 60—70°C/27 mmHg was collected; yield, *ca.* 10 g.[6] It contained two main products (more than 85%) and several minor products.[7] A mixture of the two main products (in almost a 1 : 1 ratio) was isolated using a preparative VPC; bp 64°C/27 mmHg, n_D^{28} 1.4133. Found: C, 64.50; H, 11.08%; mol wt,[8] 133. Calcd for $C_7H_{12}O_2$: C, 64.58; H, 10.84%; mol wt, 130.

The structure IIa was assigned on the basis of spectral data. The IR spectrum showed a strong band at 970 cm^{-1} (oxetanes) and neither hydroxyl nor carbonyl absorptions. The NMR spectrum showed resonances at τ 5.3—6.2 (4H, complex multiplet), τ 6.68 (2H, quartet, H^e), τ 8.40 (2H, quintet, H^g), τ 8.88 (3H, triplet, H^f), and τ 9.12 (3H, triplet, H^h).[9] Four hydrogens on the oxetane ring appear at τ 5.3—6.2. If the oxetanes had the structure IIb, $H^{d'}$ would be present in the lower field due to the adjacent two oxygens and would have an appreciably different τ value from those of $H^{b'}$ and $H^{c'}$.[10] On the other hand, if they had the structure IIa, all of the four hydrogens on the ring would be in the α-position relative to the oxygens and would be expected to give complex multiplets because of their similar τ values and because of the complex coupling between them. On the basis of these data, two these oxetanes were confirmed to be *cis*- and *trans*-isomers of IIa.



(IIa) (IIb)

Generally, one cannot obtain oxetanes in the photoaddition of aliphatic aldehydes to 1-olefins. This is mainly because of the slow rate of the formation of oxetanes compared with that of the formation of free radicals. It is well established that the formation of oxetanes proceeds *via* the attack by the electrophilic oxygen atoms of the $n\pi^*$ triplet states of carbonyl compounds on olefins with electron-donating groups. Therefore, oxetanes are easily obtained in the photoaddition of propionaldehyde to ethyl vinyl ether. In this case, very few ketones are formed. This may be due to the high probability of polymerization in ethyl vinyl ether. The orientation of the resulting oxetanes is that to be expected from a consideration of the more stable biradical intermediate. It is interesting that 1-olefins, with an electron-donating substituent, give mainly oxetanes upon the photoaddition of aliphatic aldehydes.

10) The NMR spectra of oxetanes show the α-hydrogen to oxygen at 5.0—6.0τ; the presence of additional α-oxygen to $H^{d'}$ further lowers its value, while the β-hydrogen to oxygen on the ring occurs at 6.4—7.4τ. D. R. Arnold, R. L. Hinman and A. H. Glick, *Tetrahedron Letters*, **1964**, 1425.

Intrinsic Viscosity of Rigid Complex Molecules*1

Keishiro TSUDA

Textile Research Institute of Japanese Government, Kanagawa-ku, Yokohama

(Received December 16, 1968)

The intrinsic viscosity of a molecule consisting of n elements is expressed in terms of the hydrodynamic force $\boldsymbol{F}_l$ exerted on solvent by an element l as[1)]

$$[\eta] = -\frac{N_0}{M\eta_0\dot{\varepsilon}}\sum_{l=1}^{n}\langle(\boldsymbol{F}_l\cdot\boldsymbol{e}_x)(\boldsymbol{R}_l\cdot\boldsymbol{e}_y)\rangle. \tag{1}$$

Here N_0 is the Avogadro number, M the molecular weight of the solute, η_0 the solvent viscosity, $\dot{\varepsilon}$ the rate of strain, and $\boldsymbol{R}_l$ the position of the indicated element l relative to the molecular center of mass. $\boldsymbol{e}_x$ and $\boldsymbol{e}_y$ are the unit vectors in the x and y directions, respectively. Hence, the unperturbed velocity of the solvent at the point $\boldsymbol{R}_l$ is defined by

$$\boldsymbol{v}_l^0 = \dot{\varepsilon}(\boldsymbol{R}_l\cdot\boldsymbol{e}_y)\boldsymbol{e}_x. \tag{2}$$

The hydrodynamic force $\boldsymbol{F}_l$ is then written as

$$\boldsymbol{F}_l = -\zeta(\boldsymbol{v}_l^0 - \boldsymbol{u}_l) - \zeta\sum_{s=1}^{n}{}'\boldsymbol{T}_{ls}\cdot\boldsymbol{F}_s, \tag{3}$$

where ζ is the friction constant of a single element, $\boldsymbol{u}_l$ the velocity of element l, and the sum extends over 1 to n, but l, with respect to s. $\boldsymbol{T}_{ls}$ represents the Oseen interaction tensor which is defined by

$$\boldsymbol{T}_{ls} = \frac{1}{8\pi\eta_0 R_{ls}}\left(\boldsymbol{I} + \frac{\boldsymbol{R}_{ls}\boldsymbol{R}_{ls}}{R_{ls}^2}\right), \tag{4}$$

where R_{ls} is the distance between elements l and s.

For a solute molecule of rigid structure, we have

$$\boldsymbol{u}_l = (\dot{\varepsilon}/2)[(\boldsymbol{R}_l\cdot\boldsymbol{e}_y)\boldsymbol{e}_x - (\boldsymbol{R}_l\cdot\boldsymbol{e}_x)\boldsymbol{e}_y]. \tag{5}$$

Equation (3) may then be rewritten in the form

$$\boldsymbol{F} = -(\dot{\varepsilon}/2)\zeta\boldsymbol{a}_\beta - \zeta\boldsymbol{T}\cdot\boldsymbol{F}, \tag{6}$$

or in its equivalent form,

$$-(1/\dot{\varepsilon})\boldsymbol{a}_\alpha\cdot\boldsymbol{F} = (\zeta/2)\boldsymbol{g}_{\alpha\beta} + (\zeta/\dot{\varepsilon})\sum_\nu\boldsymbol{a}_\alpha\boldsymbol{a}^\nu\boldsymbol{T}\boldsymbol{a}_\nu\boldsymbol{F}, \tag{7}$$

with the abbreviations,

$$\begin{aligned}\boldsymbol{F} &= \sum_l\boldsymbol{F}_l, \quad \boldsymbol{T} = \sum_l\sum_s\boldsymbol{T}_{ls},\\ \boldsymbol{a}_\beta &= \sum_l[(\boldsymbol{R}_l\cdot\boldsymbol{e}_x)\boldsymbol{e}_y + (\boldsymbol{R}_l\cdot\boldsymbol{e}_y)\boldsymbol{e}_x],\\ \boldsymbol{a}_\alpha &= \sum_l(\boldsymbol{R}_l\cdot\boldsymbol{e}_y)\boldsymbol{e}_x, \quad \boldsymbol{g}_{\alpha\beta} = \boldsymbol{a}_\alpha\cdot\boldsymbol{a}_\beta.\end{aligned} \tag{8}$$

Further, Eq. (7) is transformed to

$$\eta_{\alpha\beta} = (1/2)\zeta\boldsymbol{g}_{\alpha\beta} - \zeta\sum_\nu\boldsymbol{T}_\alpha{}^\nu\eta_{\nu\beta} \tag{9}$$

with

$$\begin{aligned}\eta_{\alpha\alpha} &= -(\zeta\boldsymbol{a}_\alpha/\dot{\varepsilon})[-(\dot{\varepsilon}/2)\boldsymbol{a}_\alpha - \boldsymbol{T}\cdot\boldsymbol{F}],\\ \eta_{\alpha\beta} &= -(\zeta\boldsymbol{a}_\alpha/\dot{\varepsilon})[-(\dot{\varepsilon}/2)\boldsymbol{a}_\beta - \boldsymbol{T}\cdot\boldsymbol{F}],\\ \eta_{\beta\alpha} &= -(\zeta\boldsymbol{a}_\beta/\dot{\varepsilon})[-(\dot{\varepsilon}/2)\boldsymbol{a}_\alpha - \boldsymbol{T}\cdot\boldsymbol{F}],\\ \eta_{\beta\beta} &= -(\zeta\boldsymbol{a}_\beta/\dot{\varepsilon})[-(\dot{\varepsilon}/2)\boldsymbol{a}_\beta - \boldsymbol{T}\cdot\boldsymbol{F}].\end{aligned} \tag{10}$$

Multiplying Eq. (9) by $g^{\gamma\alpha}$, summing the result over α, and using the relation,

$$\sum_\alpha(\eta^{-1})^{\gamma\alpha}\eta_{\alpha\beta} = \delta_\beta^\gamma, \tag{11}$$

we obtain

$$(1/2)(\eta^{-1})^{\alpha\beta} = (g^{\alpha\beta}/\zeta) + T^{\alpha\beta}. \tag{12}$$

Substituting Eq. (12) into Eq. (1), and taking the average over all possible orientations of the solute molecule, we obtain

$$\begin{aligned}[\eta] &= (N_0/M\eta_0)\langle\eta_{\alpha\beta}\rangle\\ &= \frac{N_0}{6M\eta_0}\left(\sum_{l=1}^{n}\zeta R_l^2\right)\left\{1 + \frac{\zeta}{8\pi\eta_0\sum_{l=1}^{n}R_l^2}\sum_{l=1}^{n}\sum_{s=1}^{n}\left\{\frac{R_lR_s\cos\alpha_{ls}}{R_{ls}}\right.\right.\\ &\quad + \frac{1}{10R_{ls}{}^3}[4R_lR_s(R_l^2 + R_s^2)\cos\alpha_{ls}\\ &\quad \left.\left. - R_l^2R_s^2(1 + 7\cos^2\alpha_{ls})]\right\}\right\}\end{aligned} \tag{13}$$*1

with

$$|\boldsymbol{R}_l| = R_l, \quad |\boldsymbol{R}_s| = R_s, \quad (\boldsymbol{R}_l\cdot\boldsymbol{R}_s) = R_lR_s\cos\alpha_{ls}. \tag{14}$$

Let us now show some results obtained by applying the so-called *shell model*[2)] in evaluation of Eq. (13). The first example is a spherical molecule of radius r, whose surface is covered by a number of small spherical elements being in contact with one another. In the limit that the number of small elements approaches infinity while their size tends to zero, the above Eq. (13) yields the Einstein equation,

$$[\eta] = (5N_0/2M)(4\pi r^3/3). \tag{15}$$

The second example is a tetrahedral contact arrangement of four identical spheres which may be regarded as a model of hemoglobin molecule. Thus each sphere may be regarded as a myoglobin molecule. The shell model calculation of Eq. (13) yields

$$[\eta](\text{hemo})/[\eta](\text{myo}) = 1.28. \tag{16}$$

This result is to be compared with the experimental values of $[\eta]$, 4 and 3.6 (cc/g) for hemoglobin,[3,4)] and 3 (cc/g) for myoglobin.[3)] The agreement between theory and experiment seems satisfactory.

More details of the theory will be published later with various applications to other biopolymers and flexible chain polymers.

A Possible Role of Diarylmethanes as the Intermediate for the Disproportionation of Methyl Groups in the Jacobsen Reaction[1]

Hitomi SUZUKI, Yukio TAMURA and Akira SERA

Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto

(Received January 9, 1969)

Pentamethylbenzene (I)[2] and chlorotetramethylbenzenes (CTB)[3] are known to undergo disproportionation, in contact with concentrated sulfuric acid, to yield hexamethylbenzene (II) and chloropentamethylbenzene (III), respectively. Under suitable conditions, however, an appreciable amount of diarylmethanes (DAM) has been isolated from these reaction mixtures. Thus, CTB (16.9 g) stirred with sulfuric acid (98 g) for 55 hr at room temperature gave III (5.4—6.3 g) and a higher-melting crystalline product (0.8—1.4 g). The latter was defined as dichloroheptamethyldiphenylmethane (DHD) by analysis ($C_{20}H_{24}Cl_2$), mass spectra (*m/e*: 334(M^+), 319 (M^+–CH_3), 299(M^+–Cl); very strong rearrangement-dissociation peaks characteristic for *o*-methylated DAM at 180 ($C_{11}H_{13}Cl^+$) and 166 ($C_{10}H_{11}Cl^+$)),[4] infrared spectra and PMR spectra (Table 1). Chlorodurene and chloroprehnitene mainly gave a single DAM (IV and VII, respectively), but chloroisodurene yielded an intimate mixture of two isomers (V and VI), where V was the major component. Their structures have been established by the independent syntheses, with the exception of VI, to which the orientation has been allocated on spectral evidences. These DAM were slightly soluble in sulfuric acid, and, when dissolved in methylcyclohexane and stirred with sulfuric acid for a prolonged period, they could slowly be converted into CTB, chlorotrimethylbenzenesulfonic acids and some unidentified, high-melting substances. Besides these products, however, isomeric DHD with substituent groups at 2,2′,6,6′-positions have been found to yield some III under the same conditions, in accord with the findings that DAM are cleft by acid catalyst to give a benzyl cation,[5] which abstracts the hydride ion to be reduced to the corresponding hydrocarbon.[6]

Although an attempt to isolate a definite DAM from the reaction mixture of I has failed due to a complicated character of the by-product, both 2,2′,3,3′,4,4′,5,5′,6- and 2,2′,3,3′,4,4′,5,6,6′-nonamethyldiphenylmethanes have been found to behave similarly toward sulfuric acid, giving I, a little II and tetramethylbenzenesulfonic acids accompanied by amorphous substances. These results may be taken to suggest a possibility of the arylalkyl cation-alkylation mechanism[7] to play some role in the intermolecular migration of methyl groups in the Jacobsen reaction.

Selective Homogeneous Hydrogenation of 3-Oxo-1,4-diene Steroids with a Ruthenium Complex as Catalyst

Shigeo NISHIMURA and Kiyoshi TSUNEDA

Department of Industrial Chemistry, Tokyo University of Agriculture and Technology, Koganei, Tokyo
Chemical Research Laboratory, Teikoku Hormone Manufacturing Co., Ltd., Shimosakunobe, Kawasaki

(Received January 17, 1969)

Recently, an excellent example of selective homogeneous hydrogenation has been described in the reduction of 3-oxo-1,4-diene steroids to the corresponding 3-oxo-4-enes using chlorotris(triphenylphosphine)rhodium as catalyst.[1,2] Although the hydrogenation with this catalyst seems to proceed quite selectively, it usually does not stop at 3-oxo-4-enes and further hydrogenation to saturated ketones may occur with prolonged reaction period.[1-3]

We have investigated the hydrogenation of 1,4-androstadiene-3,17-dione (I) with a ruthenium complex prepared from hydrated ruthenium chloride and triphenylphosphine,[4] and found that the hydrogenation with this complex is also applicable to the selective reduction of I to 4-androstene-3,17-dione (II). The hydrogenation proceeds rather readily at below 50°C under a high pressure of hydrogen. In contrast to the hydrogenation with the rhodium complex, II was practically not hydrogenated further with this ruthenium complex. A small amount of androstane-3,17-dione (III), the most part of which was the 5α isomer, was produced along with II. The yield of II decreased with elevation of the reaction temperature, although the rate of hydrogenation increased greatly. A noteworthy feature of this hydrogenation is that the selectivity for the formation of II varies considerably with the pressure of hydrogen, as shown in Table 1. Thus, a high yield of II may be obtained by hydrogenating at a relatively low temperature and under a high hydrogen pressure. In a typical run, 750 mg of I was hydrogenated with 150 mg of the catalyst in 15 m*l* of benzene at 40°C under the hydrogen pressure of 125 kg/cm^2 for 10 hr.

Table 1. Effect of hydrogen pressure on the selectivity of hydrogenation of 1,4-androstadiene-3,17-dione (I)[a]

Hydrogen pressure (kg/cm^2)	Reaction time (hr)	% of I converted	Composition of hydrogenated product (%)[b]	
			II	III
10	1.5	12.3	66.4	33.6
30	1.5	19.4	78.9	21.1
50	1.5	26.2	85.8	14.2
100	1.5	45.1	89.5	10.5
162	1.5	64.8	92.5	7.5

a) I (300 mg) was hydrogenated with 300 mg of the ruthenium complex in 60 m*l* of benzene at 50°C.

b) II: 4-androstene-3,17-dione.
III: androstane-3,17-dione, the most part of which was the 5α isomer. The product was analyzed by gas chromatography after evaporation of the solvent followed by extraction with methylcyclohexane.

The product was 94% of II and 6% of III, and contained no starting material, as analyzed by gas chromatography. After the solution was passed through alumina and the solvent removed, recrystallization of the soiid residue from acetone - hexane gave 640 mg of almost pure II, mp 165—169°C, $[\alpha]_D^{22}$ +189 (chloroform). Its infrared spectrum was identical in all respects with that of an authentic sample of II. Under similar conditions, 17β-hydroxy, 17β-acetoxy and 17β-acetyl derivatives of 1,4-androstadien-3-one were also hydrogenated to the corresponding 4-en-3-ones with high selectivity as in the case of I.

Analysis of the product during the course of hydrogenation of I showed that the ratio of the II to III formed was nearly constant throughout the reaction. This indicates that III was produced from I simultaneously with II. A further evidence for this is that a very prolonged hydrogenation of II gave a small amount of III which was a mixture of 5β and 5α isomers. A probable course of the formation of III seems to be the one *via* 5α-androst-1-ene-3,17-dione, which was found to be hydrogenated readily to III under the conditions in which II did not hydrogenate.

Further studies on this hydrogenation are in progress.

Delayed Fluorescence of the DNA-Acridine Dye Complexes in a Frozen Aqueous Solution

Yukio KUBOTA*, Yasuo FUJISAKI* and Masaji MIURA**

*Department of Chemistry, Yamaguchi University, Yamaguchi

**Department of Chemistry, Faculty of Science, Hiroshima University, Hiroshima

(Received December 16, 1968)

In order to obtain further information regarding the energy transfer between the DNA base-dye molecules and between dye-dye molecules in the DNA-acridine dye complexes, the luminescence of the complexes was measured under various conditions by using a Hitachi MPF-2A fluorescence spectrophotometer with an attachment for phosphorescence measurements.[1]

Figures 1 and 2 show typical results obtained for the DNA-proflavine complexes. In the presence of proflavine, the DNA phosphorescence with a peak about 460 mμ diminishes and two new peaks appear; the emissions around 580 mμ and 495 mμ may be ascribed, respectively, to the phosphorescence (P) and delayed fluorescence (DF) of the dye bound to DNA.

The DF observed at a high P/D*1 value seems to be due to the excitation energy transfer from the DNA triplet state to the dye singlet state, as was first suggested by Isenberg *et al.*,[2] in view of the facts that its excitation spectrum is identical with that of the DNA phosphorescence, that the absorption spectra of the complexes overlap to a great extent with the phosphorescence spectrum of DNA, and that the intensity of DF varies proportionally to the intensities of P of DNA and the dye. The intensity of DF decreases with a decrease in the P/D value; this decrease is especially remarkable in the case of denatured DNA.

On the other hand, the DF at a low P/D value appears to be a result of the triplet-triplet annihilation of the dyes, for its excitation spectrum is identical with that of the P of the dye and the intensity of DF is proportinal to the square of the intensity of the P of the dye.[3,4] This type of DF, newly observed in the DNA-dye complexes, becomes remarkable with a decrease in the P/D value. The DF at neither high nor low P/D values decays exponentially. The values of the half-life of DF, an order of 10—60 msec, depend on the P/D value and on the kind of acridine dye. A similar phenomenon of DF was also observed in the cases of acridine orange, acridine yellow, and acriflavine, except that DF due to the photoionization of the dye was additionally observed in the DNA-acriflavine complexes.[5] Further study of the mechanism of DF is in progress.

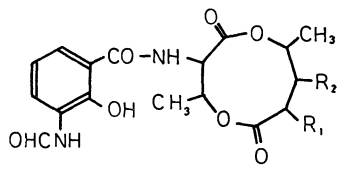
The Total Synthesis of Dehexyl-deisovaleryloxy-antimycin A_1

Mitsuhiro KINOSHITA and Sumio UMEZAWA

Department of Applied Chemistry, Faculty of Engineeering, Keio University, Koganei-shi, Tokyo

(Received January 23, 1969)

Antimycin A is a complex of at least four closely related antifungal antibiotics (A_1—A_4) produced by *Streptomyces* spp., and the structures of antimycin A_1 (Ib) and A_3 (Ic) were elucidated by van Tamelen *et al.*,[1] Birch *et al.*,[2] Yonehara *et al.*,[3] and Harada *et al.*[4] The most striking characteristic of the structure of antimycin A is its dilactone ring linked *via* an amide bond to 3-formamidosalicylic acid.



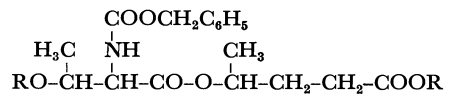
Ia Ib Ic

R_1: H n-C_6H_{13} n-C_4H_9
R_2: H i-C_4H_9COO i-C_4H_9COO

We wish to record the total synthesis of dehexyl-deisovaleryloxy-antimycin A_1 (Ia) which differs from natural antimycin A in that the acyloxy and alkyl substituents of the dilactone ring are replaced by hydrogen atoms.

N-Benzyloxycarbonyl-*O*-*t*-butyl-L-threonine[5] was condensed with *t*-butyl γ-hydroxyvalerate[6] using *N*,*N*′-dicyclohexylcarbodiimide (DCCI) in pyridine to afford *t*-butyl γ-(*N*-benzyloxycarbonyl-*O*-*t*-butyl-L-threonyloxy)valerate (II): $[\alpha]_D^{19}$ −4° (*c* 2, ethanol); yield 42%.

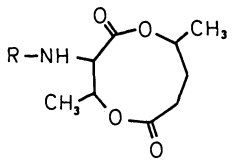
Treatment of II with trifluoroacetic acid gave γ-(*N*-benzyloxycarbonyl-L-threonyloxy)valeric acid



II III

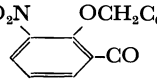
R: t-C_4H_9 H

(III): $[\alpha]_D^{21}$ −16° (*c* 2, ethanol); yield 85.5%. The hydroxycarboxylic acid (III) was cyclized with trifluoroacetic anhydride in benzene (concentration of III in benzene: 4×10^{-2}M) at 75°C for 16 hr to afford colorless crystals of *N*-benzyloxycarbonyl-4-amino-1,5-dimethyl-3,7-dioxo-2,6-dioxacyclononane (IV): mp 105—107°C; $[\alpha]_D^{21}$ +14° (*c* 2, ethanol); MW 335.140 (MS); ν_{max}^{KBr} 3320, 1745, 1693 and 1539 cm^{-1}; yield 32.5%.



IV V

R_1: $C_6H_5CH_2OCO$ O_2N $OCH_2C_6H_5$



The benzyloxycarbonyl group was removed and the resulting free amino dilactone was *N*-acylated with *O*-benzyl-3-nitrosalicylic acid *N*-hydroxysuccinimide ester to yield *N*-(*O*-benzyl-3′-nitrosalicyloyl)-4-amino-1,5-dimethyl-3,7-dioxo-2,6-dioxacyclononane (V): mp 188—189.5°C; $[\alpha]_D^{28}$ +20° (*c* 2, tetrahydrofuran); ν_{max}^{KBr} 3200, 1743, 1645 and 1532 cm^{-1}; yield 72.4%. Hydrogenation of V over palladium black in methanol, followed by *N*-formylation with 98% formic acid and DCCI afforded dehexyl-deisovaleryloxy-antimycin A_1 (Ia): mp 154—155°C; $[\alpha]_D^{19}$ +70° (*c* 1, chloroform); λ_{max}^{MeOH} 226 (log ε 4.62), 320 mμ (log ε 3.93); $\nu_{max}^{CHCl_3}$ 3435, 1747, 1706, 1647, 1614, and 1531 cm^{-1}; yield 56%. The synthetic product Ia completely inhibited the growth of *Piricularia oryzae* in a concentration of 0.39 mcg/ml by dilution method using bouillon.

Chemiluminescent Reaction between Polyphenols and Ozone in Acetic Acid

Ryôjirô IWAKI

Chemical Laboratories, Hitotsubashi University, Kunitachi-shi, Tokyo

and Isao KAMIYA

Department of General Education, Nagoya University, Chikusa-ku, Nagoya

(Received May 6, 1968)

The chemiluminescence of polyphenols with ozone in acetic acid was investigated in the presence and in the absence of rhodamine B. The emission intensity in the presence of rhodamine B (I_M) was about 100—500 times as large as that in the absence of the dye (I_P). From the measurement of the emission intensity *vs.* the reaction time, it was found that the time required to attain the peak intensity of I_M is almost equal to that required to attain the peak of I_P at equal concentration of polyphenol. A similarity was found in the spectral distributions of I_M and the fluorescence emission of rhodamine B determined under comparable conditions. Rhodamine B was scarcely decomposed for the production of the enhanced emission; this lent support to the conclusion that the enhancement effect of rhodamine B is due to an energy-transfer from an excited species produced by the oxidation of polyphenols to the dye. Determining the changes in the absorption spectra during the luminescent reaction, we also found that the emission results not from the decomposition of polyphenols but from the decomposition of an intermediate compound. On the basis of these results, a reaction scheme was proposed. If the increment of the total light emitted by the enhancement effect, (Δ), is defined as:

Δ=(Total light emitted in the polyphenol+rhodamine B system)−(Total light emitted in polyphenol alone)−(Total light emitted in rhodamine B alone),

the scheme gave the following equation:

$$\Delta = A[\mathrm{R}]_0 \ln(1+[\mathrm{P}]_0/A[\mathrm{R}]_0) \qquad (1)$$

where $[\mathrm{R}]_0$ and $[\mathrm{P}]_0$ are the initial concentrations of rhodamine B and polyphenols respectively. A is the parameter, depending upon the experimental conditions. The values of Δ calculated from Eq. (1) were in fairly good agreement with the measured values.

In connection with the study of the ozonolysis of aromatic compounds, we are interested in the chemiluminescent reaction between ozone and such polyphenols as hydroquinone, resorcinol, catechol, pyrogallol, phloroglucinol, and gallic acid. However, little is yet known as to the mechanism for the chemiluminescent reaction because of the low photon yield.

In 1960, Bersis[1] showed that the emission intensity of the polyphenol chemiluminescence was remarkably enhanced in the presence of rhodamine B. Recently, Kamiya and Iwaki[2] have found that the emission from the reaction of eosin with hydrogen peroxide in an alkaline solution is enhanced by adding uranin. On the basis of kinetic studies, a mechanism involving an energy-transfer from an excited intermediate species*1 produced by the oxidation of eosin to uranin was postulated. Similar effects have been observed by several investigators: Kautsky and Zocher[3] found the effect of rhodamine dyes in the chemiluminescence of siloxen ($Si_6H_3O_6$) with potassium permanganate, and Vasil'ev[4] observed a similar effect of anthracene derivatives in the chemiluminescent autoxidation of hydrocarbon. In all of these reports, an energy-transfer mechanism was postulated to explain the enhanced emission. The present experimental results lend support to the postulation.

The spectral distribution of the enhanced emission agreed with that of the fluorescence emission

of the added fluorescer, which was scarcely decomposed in the production of the enhanced emission.

As has been pointed out by Vasil'ev[5] and by Kasha[6], it is very suggestive that the behavior of excited species in an extremely weak chemiluminescent reaction can be investigated by means of the enhancing technique. In practice, several investigators[7] have carried out studies of weak chemiluminescent reactions by adding suitable fluorescers.

In the present paper, we will describe several experimental results supporting the theory that the enhancement effect of rhodamine B upon the emission of polyphenol chemiluminescence is caused by an energy-transfer excitation. The mechanism for the reaction, based on the kinetic results on the emission intensity, the emission spectra, and the changes in the absorption spectra during the luminescent reactions, will also be discussed.

Experimental

Original concentrated solutions of polyphenols (2.4×10^{-3} mol/l) and rhodamine B (1.6×10^{-3} mol/l) in acetic acid were diluted by adding acetic acid before they were used. Rhodamine B was recrystallized from a 60—70% aqueous ethanol solution. Analytical-grade polyphenols were used without further purification.

Reaction was initiated by introducing ozonized air produced in a Siemens ozonizer. Air was supplied by using a small rotary compressor, to which a manometer and a flowmeter were attached to control the pressure and the flow rate. The air was freed from carbon dioxide by granulated potassium hydroxide and dried by silica gel. Ozonized air was freed from the oxides of nitrogen (if any) by passing it through an aqueous solution of sodium hydroxide. The emitted light was detected with a photomultiplier tube (Toshiba MS9SY) coupled with a linear amplifier, and the output current was lead to a pen-recorder, so that the curves of the emission intensity *vs.* the reaction time could be recorded. Care was taken to keep constant the temperature (30°C) in the ozonizer and in the reaction vessel. The spectra of both the chemiluminescence and fluorescence were measured at 30°C, as has been described in a preceding paper.[8]

The absorption spectra of the reaction systems were measured with a Shimadzu SV-50-type recording spectrophotometer after the dissolved ozone had been removed by passing the systems through nitrogen gas. The concentrations of reactants and products were determined photometrically with a Shimadzu QR-50-type spectrophotometer.

Results

Curves of Emission Instensity *vs.* Reaction Time. The curves of the emission intensity *vs.* the reaction time measured in the rhodamine B system (I_R - t curve), in the gallic acid system (I_P - t

curve), and in the gallic acid system in the presence of rhodamine B (I_M - t curve) are given in Fig. 1, where (x-y-z) refers to the system composed of x m*l* of the polyphenol solution, y m*l* of the rhodamine B solution, and z m*l* of acetic acid. These results indicate that: (1) In both emissions, with and without enhancing, the emission rises to a maximum value (I_{max}) after a period of induction, and then slowly decreases.

(2) In the two systems of equal initial concentrations of polyphenol, the I_{max} of the I_M - t curve is almost 100—500 times as large as that of the I_P-t curve, but the time required to attain the I_{max} (τ) of I_M is nearly equal to that needed to attain that of I_P.

(3) Both values of I_{max} and τ increase with an increase in the concentration of polyphenol.

The curves of the emission intensity measured in resorcinol systems are given in Fig. 2. Similar curves were obtained in catechol systems. Figure 2 shows that the emission characteristics are apparently similar to those in gallic acid, but are not so intense.

Figure 3 shows the emission characteristics measured in hydroquinone systems, demonstrating that I_M - t curves have two emission peaks while I_P- t curves have only one peak. It may be noted that the time required to attain the first peak of the I_P - t curve is almost equal to the time required to attain the I_{max} of I_P - t curve in each pair with equal concentrations of polyphenol.

Similar curves were obtained in the pyrogallol and phloroglucinol systems, but the emission is more intense than that in the hydroquinone system.

The effect of the rhodamine B concentration upon the emission intensity was measured in both the gallic acid system and the hydroquinone system. The results, shown in Figs. 4 and 5 respectively, indicate that the values of I_{max} increase with an increase in the concentration of rhodamine B, but the values of τ hardly vary if the polyphenol concentration is ketp constant.

Figure 6 shows the effect of the rhodamine B concentration upon the I_R - t curve, demonstrating that the induction period is neither so long nor so varied after the change in the initial concentration of rhodamine B as that found in polyphenol chemiluminescence.

Chemiluminescence Spectra. The chemiluminescence spectra were determined in gallic acid and pholoroglucinol system containing rhodamine B, and were compared with the fluorescence spectrum of rhodamine B determined under comparable conditions. As may be seen in Fig. 7 (the gallic acid system) and Fig. 8 (the phloroglucinol

system), similar chemiluminescence and fluorescence spectral distributions were obtained, indicating that the excited singlet of rhodamine B is the emitting species.

Changes in Absorption Spectra of Polyphenol in the Region between 250 mμ and 450 mμ during the Luminescence Reaction. The absorption spectrum of hydroquinone in acetic acid was changed during the oxidation with ozone, as is shown in Fig. 9. The peak at 291 mμ decreased, and simultaneously a new band at about 250 mμ appeared to reach a maximum, which was then decreased by oxidation. The changes can be attributed to both the decomposition of hydroquinone and the formation of an intermediate compound. Figure 10 shows the plots of $\log D_{291}$

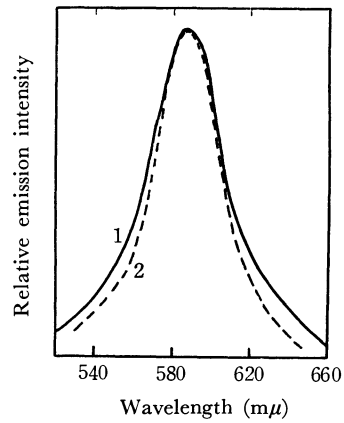

Fig. 8. Chemiluminescence spectrum in phloroglucinol - rhodamine B system and fluorescence spectrum of rhodamine B.

(absorbance at 291 mμ) against the reaction time. The plots on the straight line indicate that the decomposition of hydroquinone from the initial stage of the reaction is first order with respect to the polyphenol concentration. The plots of D_{250} *vs.* reaction time are shown in Fig. 11. It is demonstrated that the decomposition processes are not so simple because the time required to attain the maximum concentration of the intermediate compound increases with an increase in the initial concentration of hydroquinone.

Figure 12 shows the changes in the absorption spectrum of gallic acid during the oxidation with

ozone. The results show that the peak at 272 mμ decreases without the appearance of a new absorption peak. However, the changes in the absorbance at 340 mμ (D_{340}), shown in Fig. 13, strongly suggest the formation of an intermediate compound. The plots of log D_{272} *vs.* the reaction time, given in Fig. 14, demonstrate that the decomposition of gallic acid at the initial stage is also first order with respect to the polyphenol concentration.

Decomposition Rate of Rhodamine B. Figure 15 shows the changes in the concentration of rhodamine B during the luminescent reaction in hydroquinone-rhodamine B systems. It is important and interesting to see that rhodamine B hardly decomposes at all until the hydroquinone decreases upon its oxidation with ozone to a low concentration; this means that the enhanced

emission does not result from the decomposition of the dye. The decomposition-curves of rhodamine B measured in other polyphenol-systems are shown in Fig. 16; they demonstrate that all of the polyphenols retard the decomposition of rhodamine B as hydroquinone does.

Discussion

The experimental results apparently indicate that the enhancement effect of rhodamine B upon the chemiluminescence of polyphenols is caused by an energy-transfer from an excited species produced by the reaction of polyphenols to the dye.

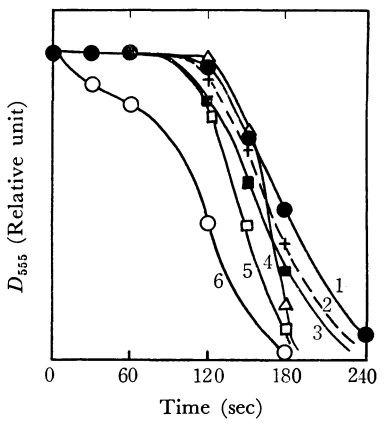

Fig. 16. The concentration of rhodamine B as a function of the reaction time in the several systems of various polyphenols. Initial concentrations of polyphenol and rhodamine B are 2.2×10^{-3} mol/l and 1.6×10^{-4} mol/l, respectively.
1: Catechol, 2: Hydroquinone,
3: Resorcinol, 4: Phloroglucinol,
5: Pyrogallol, 6: Gallic acid

The I_M - t curves with the changes in the concentrations of gallic acid and of the intermediate compound are compared in Fig. 17. It is found that the I_M - t curve does not agree with the decomposition curve of hydroquinone, but does agree with that of the intermediate compound except for the initial stage. This fact indicates that the polyphenol chemiluminescence arises not from the

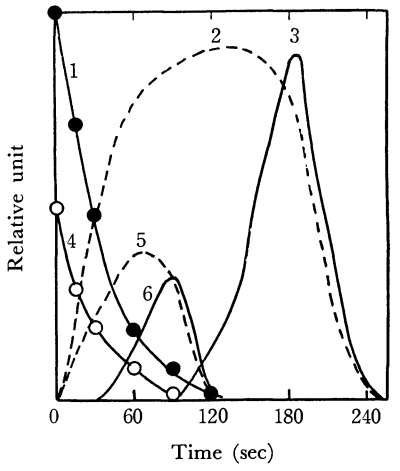

Fig. 17. Comparison between I_M - t curve and concentration curve of gallic acid or intermediate compound in gallic acid systems.
1: $[P]$ - t curve (9-1-0)
2: D_{340} - t curve (9-0-1)
3: I_M - t curve (9-1-0)

5: D_{340} - t curve (3-0-7)
6: I_M - t curve (3-1-6)

decomposition of the gallic acid but from the decomposition of the intermediate. The discrepancy for the initial stage in the two curves can be explained by the argument that the decomposition of the intermediate is retarded by polyphenol, as is that of rhodamine B. This argument is supported by the experimental findings to be described below.

A solution of polyphenol was pre-treated for a short duration with ozone in order to lower the concentration of polyphenol; then nitrogen gas was bubbled into it to remove the dissolved ozone. After rhodamine B had been added to the pre-treated solution, ozone was again passed into the solution to initiate the luminescent reaction. The curves of the emission intensity *vs.* the reaction time measured in such pre-treated solutions of gallic acid and hydroquinone are shown in Figs. 18 and 19 respectively. These figures show that the induction periods for the luminescent reactions were shortened by the pre-treatment. Moreover, when small amounts of the polyphenols were added again to the pre-treated solution, the emission was observed after a long induction period, as is shown by dotted curves in Figs. 18 and 19.

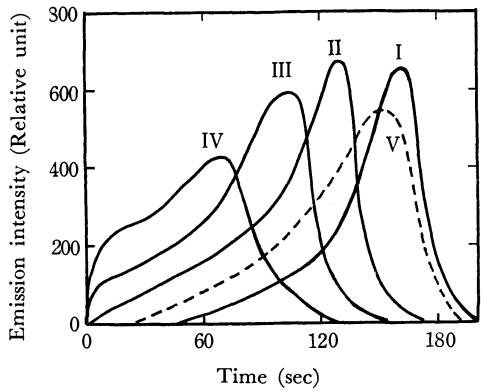

Fig. 18. I_M - t curves measured in gallic acid systems, pre-treated with ozone.
I: non-treated, II: treated for 30 sec, III: 60 sec, IV: 120 sec, V: A small amount of gallic acid was added after pre-treated for 120 sec.

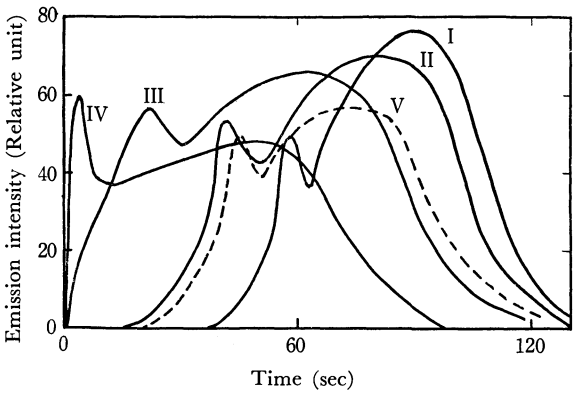

Fig. 19. I_M - t curves measured in hydroquinone systems, pre-treated with ozone.
I: non-treated, II: treated for 30 sec, III: 45 sec, IV: 60 sec, V: A small amount of hydroquinone was added after pre-treated for 60 sec.

As is shown in Fig. 3, the first peak of the I_M - t curves and the peak of the corresponding I_R - t curves are found at the same reaction time. In view of the finding that the polyphenols do retard the decomposition of rhodamine B, it seems liekly that the first peak of the I_M - t curve is to be attributed to the enhanced emission due to an energy-transfer (say, I_{PR}-emission), and the second peak, to the luminescent decomposition of rhodamine B (say, I'_R-emission).

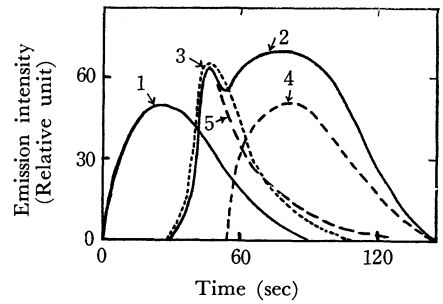

Fig. 20. Curves of I_R, I_M and I_P and shematic curves of I'_R- and I_{PR}-emission in hydroquinone systems.
1: I_R (0-1-9), 2: I_M (5-1-4), 3: I_P (5-0-5)$\times$ 100, 4: I'_R-emission, 5: I_{PR}-emission

If the curve of the I'_R-emission is assumed to be described by the parallel displacement of the I_R - t curve measured for rhodamine B alone, so as to fit the decay part with the I_M - t curve measured in the polyphenol - rhodamine B system, the schematic curve of I_{PR} - emission can be obtained graphically by subtracting the curve of the I'_R-emission from the I_M - t curve. Figure 20 shows the curves of the I'_R-emission and the I_{PR}-emission described in this way, together with the I_P - t curve measured in polyphenol alone. We can see in Fig. 20 that the curve of I_{PR}-emission is very similar to the I_P - t curve.

Two peaks did not appear in the I_M - t curves for gallic acid. This is probably due to the fact that the I'_R-emission falls upon the I_{PR}-emission as a result of the weak retardation for rhodamine B decomposition.

Reaction Scheme

On the basis of the results, the following mechanism seems plausible for the luminescent reaction:

At the initial stage, polyphenol (P) is oxidized with ozone to produce an intermediate compound

(M):

$$P \xrightarrow{O_3} M \qquad [I];\ \text{reaction rate: } k_1.$$

The polyphenol concentration [P] at the reaction time t is given by:

$$[P] = [P]_0 \exp(-k_1 t) \tag{1}$$

where $[P]_0$ is the initial concentration of polyphenol. Taking account of the fact that M does not decompose until [P] becomes small value of $[P]' = [P]_0\exp(-k_1 t')$, we have:

$$[M] = [P]_0\{1-\exp(-k_1 t')\} \tag{2}$$

when $t \leqq t'$. Assuming that t' is nearly equal to τ (the time required to attain I_{max}), the values of [P]' can be calculated from $[P]' = [P]_0\exp(-k_1\tau)$ by using the values of τ measured in hydroquinone systems for various $[P]_0$ and k_1 values; these values are tabluated in Table 1. The values of [P]' are almost constant, which indicates that our presumption is plasusible.

Table 1. The values of [P]' calculated from the equation, $[P]' = [P]_0\exp(-k_1\tau)$ in hydroquinone systems

$[P]_0$ (mol/l)	k_1 (sec^{-1})	τ (sec)	[P]' (mol/l)
2.4×10^{-4}	0.032	17	1.4×10^{-4}
7.2×10^{-4}	0.032	34	2.4×10^{-4}
1.2×10^{-3}	0.032	48	2.6×10^{-4}
1.7×10^{-3}	0.032	60	2.5×10^{-4}
2.2×10^{-3}	0.032	72	2.2×10^{-4}
2.4×10^{-4}	0.045	15	1.2×10^{-4}
7.2×10^{-4}	0.045	27	2.1×10^{-4}
1.2×10^{-3}	0.045	37	2.3×10^{-4}
1.7×10^{-3}	0.045	45	2.2×10^{-4}
2.2×10^{-3}	0.045	52	2.1×10^{-4}

For the sake of simplicity, we may write the production of an excited species (S*) in the following first-order reaction with respect to the concentration of the intermediate compound:

$$M \xrightarrow{O_3} S^* \qquad [II];\ k_2.$$

Thus, when $t>t'$, [M] is given by:

$$[M] = [\{(k_1-k_2)[P]_0 + k_2[P]'\}\exp(-k_2 T) - k_1[P]'\exp(-k_1 T)]/(k_1-k_2) \tag{3}$$

where $T=t-t'$.

S* is deactivated by fluorescence processes or by non-radiative processes:

$$S^* \longrightarrow S + h\nu \qquad [III];\ k_3.$$
$$S^* \longrightarrow S \qquad [IV];\ k_4.$$
$$S^* + M \rightarrow S + M \qquad [V];\ k_5.$$
$$S^* + P \rightarrow S + P \qquad [VI];\ k_6.$$

In the systems involving rhodamine B (R), the processes of energy-transfer from S* to R take place:

$$S^* + R \rightarrow S + R^* \qquad [VII];\ k_7.$$

R* is deactivated by the fluorescence process:

$$R^* \longrightarrow R + h\nu' \qquad [VIII];\ k_8.$$

Although other non-radiative processes of deactivation also take place, our discussion is limited to the process VIII because of the high efficiency of the fluorescence emission of R. The intensity of emission resulting from the energy-transfer (I_{PR}) is given by:

$$I_{PR} = k_8[R^*] = k_7[S^*][R] \tag{4}$$

where [R] is the rhodamine B concentration.

By the steady-state approximation, $d[S^*]/dt=0$, and assuming that $k_5=k_6=k_q$ and $k_3+k_4 \ll k_7[R]+k_q([M]+[P])$, [S*] is given by:

$$[S^*] = k_2[M]/\{k_7[R] + k_q([M] + [P])\} \tag{5}$$

From Eqs. (3), (4), and (5), I_{PR} is given by:

$$I_{PR} = \frac{k_2k_7[R][\{(k_1-k_2)[P]_0+k_2[P]'\}\exp(-k_2T)-k_1[P]'\exp(-k_1T)]}{(k_1-k_2)k_7[R]+k_q[\{(k_1-k_2)[P]_0+k_2[P]'\}\exp(-k_2T)-k_2(P)'\exp(-k_1T)]} \tag{6}$$

The values of Δ (the increment in the total light emitted by the enhancement effect) is defined as:

$$\Delta = \int_0^\infty (I_M - I_P - I_R)dT \tag{7}$$

Using the relations: $I_M = I_{PR} + I'_R$ and $I_M \gg I_P$, and assuming that $\int I_R dT = \int I'_R dT$ and $[R]=[R]_0$ (the initial concentration of rhodamine B), Eq. (7) becomes:

$$\Delta = \int_0^\infty I_{PR}dT = (k_7/k_q)[R]_0\ln\{1+[P]_0/(k_7/k_q)[R]_0\} \tag{8}$$

Equation (8) is reduced to the following convenient form:

$$\Delta = A[R]_0\ln(1+[P]_0/A[R]_0) \tag{9}$$

where $A=k_7/k_q$. Table 2 illustrates the values of Δ measured by using the graphical integration of I_M-t curves and I_R-t curves and the values calculated from Eq. (9) by using a suitable parameter A. The calculated values are in fairly good agreement with the measured values in every polyphenol systems.

A similar chemiluminescence emission and the enhancement effect of rhodamine B were observed

in the solutions of aminophenols and phenylenediamine in acetic acid, but neither emission nor enhancement effect was observed in the phenol, aniline, nitrophenol, and nitroaniline system. The enhancement effect upon the polyphenol chemiluminescence emission was also observed when anthracene was added in place of rhodamine B, but no enhancement effect was observed in the presence of methylene blue. Further investigation is necessary to elucidate these phenomena.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 864—870 (1969)

A Study on Electron Spin Resonance of the Complex between Metal Ions of Group II and *o*-Quinone Anion*[1]

Keiji KUWATA and Yasuhiro SHIMIZU

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka

(Received July 12, 1968)

An electron spin resonance study on the complex formation between *o*-quinone anion and metal ions of group II was undertaken, and the change in *g*-factor and proton hyperfine splittings of *o*-quinone anion by the complex formation were examined in detail. The change in *g*-factor was closely related to both the change in the unpaired electron distribution and the change in energy difference between lone pair orbital of oxygen and unpaired electron orbital. The stabilization of the quinone anion against its coupling reaction was seemed to be related to the shift in *g*-factor by complex formation. The interaction between quinone anion and metal ions was deduced to be partly ionic. An open shell SCF calculation with CI for the free quinone anion was carried out in order to discuss the electronic spectra of the complex.

Besides the electron spin resonance study on the complexes of paramagnetic metal ions, such study on the complex between free radicals or radical ions and diamagnetic metal ions is also efficient in the investigations into the nature of the interaction between ligands and metal ions.

It is well known that the mixture of poly-phenol and alkaline earth metal ion yields green colored complex, and this fact was applied to the qualitative analysis of these ions. During this reaction, a kind of complex between *o*-quinone anion and the metal ions is thought to be produced.

Eaton[1)] studied on the effect of complex formation of *o*-quinone anion with diamagnetic ions of group II and III by the ESR spectra, and found the change in proton hyperfine splitting of the ligand, and the appearance of additional hyperfine splittings due to the nuclear magnetic moment of metal ions in the cases of Y^{3+} and La^{3+} ions.

Since *g*-factor of the ESR spectrum is closely related to the change in the lone pair orbital of oxygen atom in semiquinone anion, it is useful to examine the effects of complex formation of both *g*-factor and proton hyperfine splitting for the investigation into the nature of interaction between ligand and metal ion.

The present work was undertaken in order to examine the change in *g*-factor of *o*-quinone anion and also to reexamine the change in hyperfine splittings in detail, and to make a theoretical discussion on the nature of the interaction between ligand and metal ion.

An attempt to analyze the electronic spectra of *o*-quinone anion was made using an open-shell SCF method of Pople and Nesbet with CI. The effects of complex formation on the reactivity of *o*-quinone anion were also studied.

Experimentals

o-Benzoquinone was prepared by the oxidation of catechol.

The electron spin resonance spectra were measured using a home-made X-band spectrometer of 455-kc/sec field modulation and with a 30 cm electromagnet of

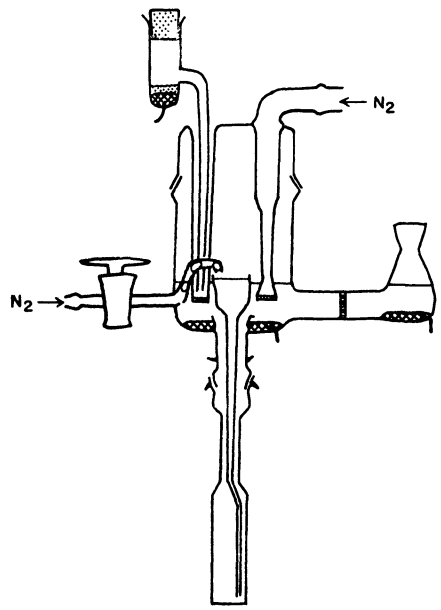

Fig. 1. The electrolytic reduction cell for the measurements of electronic absorption spectra.

1) D. R. Eaton, *Inorg. Chem.*, **3**, 1268 (1964).

Japan Electron Optics Laboratory Co. The samples for ESR and UV measurements were prepared as follows. In the case of quinone anions with alkali metal ions, the radicals were prepared using a flow system at a flow rate of about 0.5 ml/sec. In the case of quinone anions with alkaline earth metal ions, three different methods were used: a) the flow method at a flow rate of about 3 ml/min, b) aerial oxidation by shaking the dilute ammonia solution of hydroquinone in contact with air, and deaeration of the solution, c) the electrolytic reduction, the cell for which is shown in Fig. 1.

The electronic absorption spectra were measured using a Hitachi spectrophotometer model EPS-2, under the same condition as that for the measurement of ESR spectra.

For magnetic field calibration, peroxylamine disulfonate was used as a reference with a dual mode (H_{014}) ESR cavity. ^{14}N hyperfine splitting constant and g-factor of peroxylamine disulfonate were taken to be 13.0 G and 2.00550, respectively.[2]

Calculation of Spin Density and g-Factor in Quinone Anion. Hückel MO method and McLachlan's method[3] were used for the calculation of spin density for free and complex quinone anion. In addition, the iterative simple MO method,[4] and the open-shell SCF MO method of Pople and Nesbet[5] with CI were used for free quinone anion.

In the iterative method, the coulomb integrals and the exchange integrals were repeatedly modified according to the values of the total charges and bond orders under the assumption that coulomb and exchange integrals were proportional to the electronegativity of the atom and to the overlap integral between atoms, respectively. The iteration was repeated until the mutual consistency of the assumed set with the calculated set was achieved.

The variation of g-factor in complex quinone anions was analyzed on the basis of theory given by Stone.

Writing the nth molecular orbital ϕ_n as linear combination of atomic orbitals, $\phi_n=\sum_k \chi_k^{(n)}$, where $\chi_k^{(n)}$ is an (un-normalized) atomic orbital on atom k, and using second order perturbation theory with neglecting differential overlap integral, Stone had derived the following expression for g-factor:[6]

$$g_{zz} = 2.00232 + 2\sum_{n\neq p} \frac{\sum_k \langle \chi_k^{(p)}|l_{kz}|\chi_k^{(n)}\rangle \sum_{k'}\zeta_{k'}\langle \chi_{k'}^{(n)}|l_{k'z}|\chi_{k'}^{(p)}\rangle}{E_p - E_n} \quad (1)$$

where l_{kz} is the z-component of angular momentum about the kth atom, ζ_k is the spin orbit coupling constant for the kth atom, E_p is the energy of the odd electron orbital and E_n is the energy of the nth molecular orbital in the molecule.

For the case of quinone anion, Δg can be divided into three parts as follows:

$$\Delta g = g - g_e = \Delta g_{hc} + \Delta g_{co} + \Delta g_n$$

where Δg_{hc}, Δg_{co} and Δg_n are the contributions to Δg from the parts of C-C and C-H σ-orbitals of the skeleton, CO σ-orbitals, and the oxygen lone-pair orbitals, respectively.

In the present study, the iterative simple MO method and the modified extended Hückel MO method were used for π-system and for CO σ-bond, respectively. For simplicity, the bonding between SP^2 hybrid orbital of carbon atom and 2P atomic orbital of oxygen atom was taken as CO σ-bonding. With the above-mentioned orbitals, Δg was calculated using Eq. (1).

Δg_{hc} was estimated from the following equation,[6]

$$\Delta g_{hc} = \sum_i^{\text{carbon}} \rho_i(24.7 - 19.3\Lambda) \times 10^{-5} \quad (2)$$

where Λ is the coefficient of the odd-electron orbital energy, $\alpha+\Lambda\beta$, and ρ_i is the odd-electron density on the ith carbon.

Δg_n could be estimated on the basis of the $n\rightarrow\pi^*$ transition process in quinone anion, so that the contribution from ith lone-pair orbital to Δg_n was given by the following equation, derived from Eq. (1).

$$\Delta g_n{}^i = \frac{2}{3}\frac{\langle \chi_z^{(p)}|l_y|\chi_x^{(n)}\rangle\zeta_O\langle \chi_x^{(n)}|l_y|\chi_z^{(p)}\rangle}{E_p - E_n} = \frac{2}{3}\frac{\zeta_O\rho_O}{E_p - E_n} \quad (3)$$

here, the subscripts x, y and z represent the x, y and z-components of the quantities, respectively, ρ_O is the spin density on oxygen atom and E_p-E_n is the $n\rightarrow\pi^*$ transition energy.

Results

Whereas the hyperfine coupling constants in ESR spectra and the stability of p-benzoquinone anion were not affected by the presence of metal ions, o-benzoquinone anion was fairly affected under the same condition.

The alkali metal ions did not change the hf coupling constants, but slightly increased its signal intensity of the ESR spectrum. Notable effects of the presence of metal ions were seen in the case of alkaline earth metal ions. The coupling constants and g-factor were changed in accordance with the cation species.

Observed hyperfine splittings and g-factors for o-quinone anion are listed in Table 1, together with spin densities derived from experimental proton hyperfine splitting constants using McConnell's relationship: as, $a=Q\cdot\rho$. Here Q was chosen to be 23 gauss.

In addition to the primary o-quinone anion the spectrum which had been attributed to secondary radical was observed in methanol. The latter radical was identified with 4, 5-dimethoxy benzosemiquinone anion radical formed through the substitution of 4 and 5 position of o-quinone anion by methoxy groups.[1]

The observed electronic absorption spectra of

complex radical using an electrolytic reduction are shown in Fig. 2. Three peaks at 370—380 mμ (I), 400—440 mμ (II) and 650—700 mμ (III) were assigned to the complex o-quinone anion radical.

The contour plots of spin densities calculated varying the coulomb integral of oxygen in Hückel MO method and McLachlan's method are shown in Fig. 3.

The spin densities and the odd-electron orbital energy of quinone anion calculated by the iterative simple MO method were as follows.

$$\rho_1 = 0.173,\ \rho_3 = 0.018,\ \rho_4 = 0.104,\ \rho_7 = 0.205,$$

and $E_p = \alpha + 0.574\beta$. $\beta = -2.39$ eV

The unrestricted SCF calculation was carried out until the spin densities became mutually consistent to three decimal places, and the result is shown diagrammatically in Fig. 5, together with the experimental values.

The bonding and antibonding orbitals of a C–O σ-bond were obtained: as,

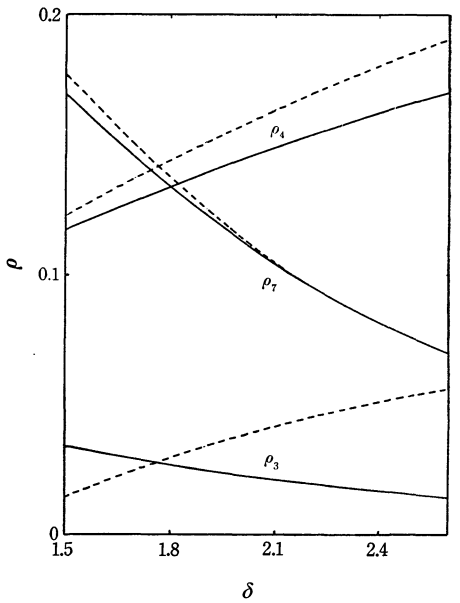

Fig. 3. The contour plots of calculated spin densities.
—— by Hückel MO, ---- by McLachlan's method, in which λ was taken to be 1.2. The axis of abscissa represents δ in coulomb integral $\alpha_O = \alpha + \delta\beta$.

$$\phi^b_{CO} = 0.549\chi_{sp^2} + 0.708\chi_p \quad E^b_{CO} = -22.46\text{ eV}$$

$$\phi^a_{CO} = 0.851\chi_{sp^2} - 0.783\chi_p \quad E^a_{CO} = 2.46\text{ eV}$$

Accordingly, Δg_{hc} and Δg_{co} for the free quinone anion were estimated to be 3.3×10^{-5}, -41.1×10^{-5}, respectively. In aqueous solution, g-factor of the free quinone anion was 2.00467, so that to have such value, the contribution from the lone-pair orbitals, Δg_n should be 273×10^{-5}, and the absorption band for $n\rightarrow\pi^*$ transition was estimated to be at *ca.* 662 mμ using Eq. (3).

Discussion

Hyperfine Coupling Constants of the Complex Radical. As shown in Table 1, hyperfine coupling constants for the ring protons at ortho position decreased as those of meta position increased. The contour plots of calculated spin densities using Hückel MO treatment showed that ρ_4 increased as the δ increased whereas the spin density ρ_3 (at position 3) decreased. Here δ denotes the coefficient of coulomb integral of oxygen atom, $\alpha_O=\alpha+\delta\beta$. This tendency was consistent with that of the change in experimental spin density, accordingly the effect of chelation on the spin density seemed to be equivalent to the value of coulomb integral of oxygen atom where assuming it to be more negative.

Fraenkel *et al.*,[7] showed that McLachlan's method led to an excellent agreement between the observed proton hyperfine splittings and the calculated ones for free *o*-quinone anion, where $\lambda=1.2$, $\alpha_O=\alpha_B+2.1\beta$ and $\beta_{CO}=\beta_{CC}$ were taken as molecular parameters. And in their calculation, while ρ_4 was positive, ρ_3 was negative.

As shown in Fig. 3, McLachlan's method, however, led to such result that not only ρ_4 but also the absolute value of ρ_3 (in this case, ρ_3 was negative) increased as the δ increased. Thus the McLachlan's method was seemingly unsuitable to analyze the experimental result. The present result possibly showed that ρ_3 and ρ_4 were both positive.

In general, spin polarization has a tendency to enhance the spin density at the position where high spin density would be expected by Hückel MO calculation, while it would diminish the spin density at the position where low spin density would be expected by Hückel MO calculation. In fact such tendency was observed so far as ρ_3 and ρ_4 were concerned.

The semiempirical parameter λ in McLachlan's method controls the amount of spin polarization in the radical. If λ is taken to be less than 0.3, the effect of spin polarization still remains small, both ρ_3 and ρ_4 remain positive in the case of δ value less than 2.3 and the tendency of decrease in a_3 and increase in a_4 as δ increases is evident. The turning point of spin density ρ_3 from positive to negative depends on not only λ but δ, *e. g.*, with $\lambda=0.5$, the turning point was at $\delta=1.9$.

On varying the counter ions in the sequence of NH_4^+, Ba^{2+}, Sr^{2+}, Ca^{2+}, Mg^{2+}, ρ_3 decreased, whereas ρ_4 increased. The observed values of ρ_3 and ρ_4 correlated smoothly with electronegativity of the metal atom as shown in Fig. 4, or in other expression the coulomb integral of oxygen in the complex quinone anion seemed to correlate to the electronegativity of metal ion changed. It is noted here that this sequence agreed with the sequence of the stability of the complex quinone anion in solution. This is discussed again in later section.

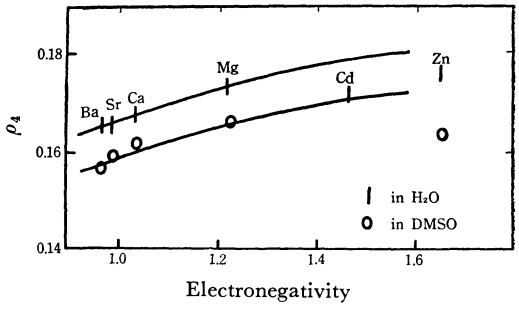

Fig. 4. The relationship between the observed spin density on position 4 and the Pauling's electronegativity of metal atom.

As to the solvent effects, a fact that the complex radical was more stable in DMSO than in water was found. And this was understood by the difference in electrostatic interactions as follows. The dielectric constant of water is larger than that of DMSO, thus in water the radical ion has weaker interaction with metal ion, or the dissociation constant of the complex should be larger than in DMSO. The difference in electrostatic interaction could also relate to the difference in the amount of increase in δ. Figure 4 shows that the oxygen atom had larger value of δ in water than in DMSO, or in other word, in the solvent of larger dielectric constant the value of δ became larger.

***g*-Factor of Complex Radical.** The solvent effect on *g*-factor of diphenyl nitric oxide has been treated as a perturbation of increase in coulomb integral of the oxygen atom through the hydrogen-bonding between solute and solvent.[8] On the other hand, in the present case the addition of metal ion to the oxygen atoms of quinone anion made the coulomb integral of oxygen atom more negative and thus affected on *g*-factor of the anion. Although both the lone pair orbitals of oxygen atom and C-O σ-bond would be likely affected, as the first step of approximation, an assumption that σ-system remains unchanged in the complexes was made. Then the effect of complex formation on *g*-factor could be regarded as a perturbation only on π-electron system. The effect of a change in α_o on the spin density on the rth atom ρ_r, the odd-electron orbital bond order between rth and sth atoms P_{rs} and the odd-electron orbital energy E_p will be expressed using atom-atom polarizability as follows.

TABLE 2. *g*-FACTORS FOR COMPLEX QUINONE ANIONS

	Mg^{2+}	Ca^{2+}	Sr^{2+}	Ba^{2+}	Zn^{2+}	Cd^{2+}	NH_4^+
$g_{obs.}$	2.00423	2.00433	2.00435	2.00400	2.00389	2.00347	2.00467
$g_{calc.}$	2.00416	2.00448	2.00454	2.00461	2.00408	2.00420	2.00467
$(g_{obs.}-g_{calc.})\times 10^{+5}$	7	−15	−19	−61	−19	−73	−0

With the molecular orbital calculated by the interative method, these quantities are as follows.

$$\left.\begin{aligned}
\delta E_p &= \rho_7\delta\alpha_7 + \rho_8\delta\alpha_8 = 0.4096\times\delta\alpha_O \\
\delta\rho_1 &= \pi^p{}_{1,7}\delta\alpha_7 + \pi^p{}_{1,8}\delta\alpha_8 = 0.1376\times\delta\alpha_O/\beta \\
\delta\rho_3 &= \pi^p{}_{3,7}\delta\alpha_7 + \pi^p{}_{3,8}\delta\alpha_8 = -0.0184\times\delta\alpha_O/\beta \\
\delta\rho_4 &= \pi^p{}_{4,7}\delta\alpha_7 + \pi^p{}_{4,8}\delta\alpha_8 = 0.0936\times\delta\alpha_O/\beta \\
\delta\rho_7 &= \pi^p{}_{7,7}\delta\alpha_7 + \pi^p{}_{7,8}\delta\alpha_8 = -0.2128\times\delta\alpha_O/\beta \\
\delta P_{17} &= \pi^p{}_{17,7}\delta\alpha_7 + \pi^p{}_{18,8}\delta\alpha_8 = 0.0224\times\delta\alpha_O/\beta
\end{aligned}\right\} \quad (4)$$

Here, the same notation as that in the reference was used.[8]

The effect of complex formation on *g*-factor could be divided into three parts as mentioned in the preceding section, that is to say, $\delta\Delta g_{hc}$, $\delta\Delta g_{co}$ and $\delta\Delta g_n$, which could be expressed by the amount of change in α_o.

$$\left.\begin{aligned}
\delta\Delta g_{hc} &= 1.1\times10^{-5}\times\delta\alpha_O/\beta \\
\delta\Delta g_{co} &= 9.3\times10^{-5}\times\delta\alpha_O/\beta
\end{aligned}\right\} \quad (5)$$

$$\begin{aligned}
\delta\Delta g_n &= \frac{4}{3}\frac{\zeta_O(\rho_O+\delta\rho_O)}{E_p+\delta E_p-E_n} - \frac{4}{3}\frac{\zeta_O\rho_O}{E_p-E_n} \\
&= -140.7\times10^{-5}\times\delta\alpha_O/\beta \\
&\quad -72.9\times10^{-5}\times(\delta\alpha_O/\beta)^2
\end{aligned}$$

Using Eq. (4), the increase in coulomb integral of oxygen atom could be estimated by the deviation of observed hyperfine coupling constants for complex quinone from that for free quinone anion, thus the change in $\delta\Delta g$ was calculated using Eq. (5). Calculated values of *g*-factor are listed in Table 2 together with observed ones.

As seen in Table 2, a trial to explain the variation of *g*-factor of complex quinone anion by considering only about the change in π-system was not necessarily carried out successfully. In the cases of Ba^{2+} and Cd^{2+} there was fairly large disagreement between $g_{cal.}$ and $g_{obs.}$, so that it seemed necessary to consider some additional contributions coming from the change in σ-system.

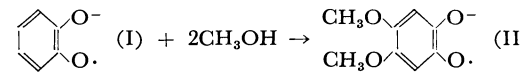
The contributions from Δg_{hc} and Δg_{co} were estimated to be 3.3×10^{-5} and -41.1×10^{-5}, respectively, and these values are so small that they can be disregarded as compared with Δg_n: the contribution from lone pair orbital.

If the addition of metal ion to oxygen atoms of quinone anion stabilizes lone pair orbital energies of oxygen atoms, the difference between lone pair orbital energy and unpaired electron orbital energy will be enhanced and as a result, the estimated value of *g*-factor will decrease as expected from Eq. (3). Therefore, it may be reasonable to take the difference between the observed value and the calculated one of *g*-factor in Table 2 as the measure of stabilization in lone pair orbital energy of oxygen atom.

The quantity, $g_{obs.}-g_{calc.}$, increased with the stabilization of E_n, so that in this study among the ions of IIa and IIb group elements, the stabilization of lone pair orbital energy was found to increase in the order of $Ba^{2+}>Sr^{2+}>Ca^{2+}>Mg^{2+}$ and $Cd^{2+}>Zn^{2+}$, respectively.

As a conclusion, following mechanisms of the variation of *g*-factor were approved. The change in distribution of unpaired electron in complex quinone anion coming from the increase in coulomb integral of oxygen is partly the origin of the variation of *g*-factor, and the change in energy difference between lone pair orbital of oxygen and unpaired electron orbital is also responsible for the variation of *g*-factor.

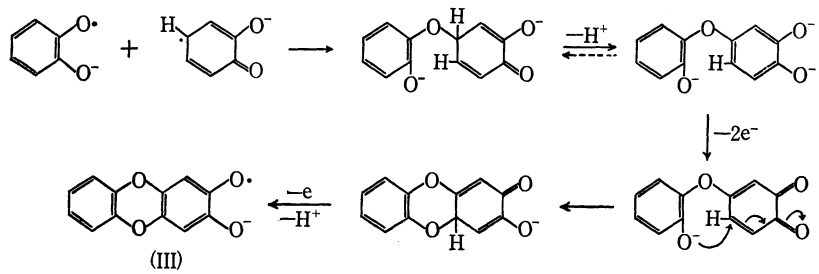
Reactivity and Structure of Complex Quinone Anion. Using the alkaline methanol as a solvent for *o*-quinone anion-metal ion system, the spectrum for a secondary radical superimposing on that of primary radical was observed and the secondary radical had been identified as a methoxylated radical (II). This secondary radical was formed by a reaction of primary radical (I) with methanol[1] in the presence of metal ions as catalyst.



It was shown in Hückel MO treatment that the complex formation brought about the increase in unpaired electron density at position 4 and 5, and also the decrease in total π-electron density at these positions. As a result, the increase in unpaired electron density would make the radical reaction favorable at these positions, and the decrease in total π-electron density would make the negatively charged species more easily to attack at these position too.

The nature of the attacking species was not known at the present stage of experiment, however, it may be suggested that the attacking species is radical or has neagtive charge.

On the other hand, in the absence of metal ions, when the spectrum of *o*-quinone anion in alkaline solution was recorded, the gradual appearance of a triplet spectrum superimposed on the center of original spectrum was observed. This triplet



(III)

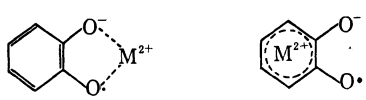
spectrum was assigned to dibenzo-1,4-dioxin-2,3-quinone anion (III) which was formed through dimerization of *o*-quinone anion.[9]

In this study, however, dimer anion was not observed in the presence of alkaline earth metals. This is probably due to the restriction against dimerization reaction for the complex quinone anion, since oxygen atoms in the complex anion are hindered by a metal ion and are prevented to react with another anion. Upon the addition of various metal ions, the stability of complexed anion against such dimerization reaction increased as the ability of enhancing δ in the coulomb integral of oxygen increased, thus the interaction between oxygen atoms of quinone anion and metal ion played an important role in the selectivity of reaction.

The hyperfine splitting due to the metal nuclei had been observed,[1] and this shows confirmatively that metal ion has an interaction with *o*-quinone anion and the unpaired electron flows into the metal ion, but this amount is estimated to be very small.

For the complex quinone anion, following two structures are possible. a) Metal ion is in the plane of benzene ring and attaches to two oxygen atoms of the quinone anion. b) Metal ion is located above the benzene ring and interacts with whole of the π-electrons of benzene ring.

(a) (b)



(IV) (V)

In the latter case, the metal ion makes coulomb integrals of all carbon atoms more negative, and this is equivalent to the decrease in δ in coulomb integral of oxygen atoms, and this effect does not agree with experiment, or it will give the wrong tendency in the variation of unpaired electron distribution. Thus, it could be suggested that the *o*-quinone anion-metal complex takes the structure of the former case (a).

Energy Levels of *o*-Quinone Anion. The studies on the electronic spectra of *o*-benzoquinone were reported already,[10] and such an approximate information about the energy levels of the anion tha one or two absorption bands seemingly appear in the wavelength region of 500—800 mμ was derived.

For the detailed discussion on the electronic state of the anion, a calculation based on unrestricted SCF-MO method (UHF) was performed, and three absorption bands in visible region were expected. The energies of the allowed transitions and the oscillator strengths for those transitions are shown in Fig. 5.

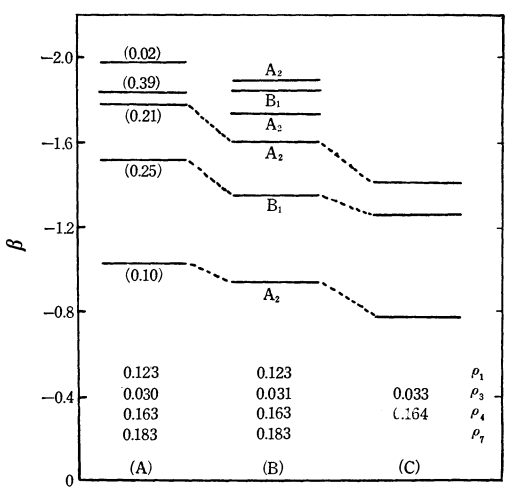


Fig. 5. The spin density and the excitation energy of free quinone anion. (A) by open shell SCFMO (B) by open shell SCFMO-CI. (C) observed values. The numerals in the parentheses indicate the calculated oscillator strengthes.

While the experimental value of oscillator strength could not be determined because of the difficulty in determination of the concentration of the anion, the relative intensities of observed spectra were compared with the calculated oscillator strength, and three observed absorption bands at 370—380 mμ, 400—440 mμ, and 650—760 mμ were assigned to $\pi \rightarrow \pi^*$ transitions.

Figure 5 also shows the result obtained by considering on configuration interaction among twenty

10) S. Nagakura and A. Kuboyama, *J. Am. Chem. Soc.*, **76**, 1003 (1954); A. Kuboyama and K. Wada, This Bulletin, **38**, 1709 (1965).

low lying excited doublet states. Since the wave function obtained here was not true eigenfunction of $S=1/2$ state, we should use the annihilation operator and remove the components of higher spin states. The wave function obtained after applying annihilation operator, however, does not satisfy the condition of energy minimum, on the contrary. Even if the higher spin states are excluded, the drastic change of spin density distribution will not be expected because those states are lying in high energy states and the effect from those states will be small. For that reason, only single determinant wave function was used at the starting point. In this CI calculation, we also made an approximation, in which the singly excited states had the same form as those in closed-shell SCF-MO.

In open-shell SCF-MO, electron correlation is already partly included so that the configuration interaction in UHF has different significance from that in restricted HF.

In this study, the result that the configuration interaction scarcely affected on the spin density, whereas it considerably affected on the transition energy was also shown.

The weak absorption band for $n\rightarrow\pi^*$ transition, the energy of which estimated to be approximately 1.8—3.7 eV from the observed values of g-factor using Eq. (3), might be masked by the strong π-π^* transition bands in this region.

The authors wish to express their thanks to Professor Kozo Hirota for his encouragement throughout this work.

Appendix

An Unrestricted SCF MO-CI Calculation of *o*-Quinone Anion. In the closed shell Hartree-Fock wave function, the repulsion between electrons is not accounted for properly because electrons affect each other through their instaneous potentials, not just by their average potentials. The antisymmetry of the wave function itself acts as if there would be a rather strong repulsion between particles with the same spin at small distances, but further correlative effects associated with particles having different spins cannot be treated properly.

On the other hand, in the open shell SCF MO, the orbitals associated with different spins will automatically try to arrange themselves in such a way that particles having antiparallel spins will tend to avoid each other due to their mutual repulsion.

In the present study, the unrestricted Hartree-Fock method (UHF) of Pople and Nesbest was used for free *o*-quinone anion. The ground state wave function was described by:

$$\Psi_g = |\phi_1\bar{\phi}_1\phi_2\bar{\phi}_2\cdots\phi_n\bar{\phi}_n\phi_{n+1}| \tag{6}$$

where $N(=2n+1)$ is the number of π-electrons. The molecular orbitals given by the linear combination of atomic orbitals were chosen to minimize the electronic energy.

$$E=\sum_{i}^{\alpha+\beta}H_i+\frac{1}{2}\sum_{i}^{\alpha+\beta}\sum_{j}^{\alpha+\beta}J_{ij}-\frac{1}{2}\left(\sum_{i}^{\alpha}\sum_{j}^{\alpha}+\sum_{i}^{\beta}\sum_{j}^{\beta}\right)K_{ij}$$

In the calculation of H_i, J_ij and K_ij, the coulomb repulsion integrals, $(\mu\mu|\mu\mu)$ and $(\mu\mu|\nu\nu)$, and the core integrals, α and β were evaluated by the semiempirical procedure analogous to that of Pariser and Parr.[11]

The core integrals were calculated from the next equations:

$$\alpha_\mu=-w_\mu-\sum_{\mu\neq\nu}(\mu\mu|\nu\nu)$$

$$\beta_{CC}=-\frac{17.464}{r^6_{CC}}\text{eV},\quad \beta_{CO}=-\frac{8.8086}{r^6_{CO}}\text{eV}^{12)}$$

where w_μ and $(\mu\mu|\nu\nu)$ were the valence state ionization potential and the coulomb repulsion integral under the neutral electron distribution.

It was assumed that the free *o*-quinone anion was planer and that the ring part and r_{CO} of the radical had the same molecular dimension as that of benzene and 1.23Å, respectively. The one-center coulomb repulsion integral $(\mu\mu|\mu\mu)$ and the two-center coulomb repulsion integral $(\mu\mu|\nu\nu)$ were evaluated from the same procedure as that in Harada's paper.[13]

The best result of calculation, in which core integrals were calculated assuming that each atom of the molecule was neutral but repulsion integral was modified by the result of the iterative simple MO method, is given in Fig. 5.

The configuration interaction between the ground state and the singly excited states in the same spin state as the ground state was considered.

The singly excited states were represented by Slater determinants of the form under our approximation.

$$\left.\begin{aligned}
\psi^{(\mathrm{I})}_{i\rightarrow k}&=|\cdots\phi_i\phi_k\phi_0|(2\alpha\alpha\beta-\alpha\beta\alpha-\beta\alpha\alpha)/\sqrt{6}\\
\psi^{(\mathrm{II})}_{i\rightarrow k}&=|\cdots\phi_i\phi_k\phi_0|(\alpha\beta\alpha-\beta\alpha\alpha)/\sqrt{2}\\
\psi_{i\rightarrow o}&=|\cdots\phi_i\phi_0\bar{\phi}_0|\\
\psi_{o\rightarrow l}&=|\cdots\phi_i\bar{\phi}_i\phi_l|
\end{aligned}\right\} \tag{7}$$

The electronic ground state function was approximated by a linear combination of doublet functions, (6) and (7).

$$\Phi=\sum_i A_i\psi_i$$

Effect of Potassium Promoter on Iron Oxide Catalysts for Dehydrogenation of Ethylbenzene to Styrene

Katsue SHIBATA and Tadamitsu KIYOURA

Central Research Laboratory, Toyo Koatsu Industries, Inc., Kuden, Totsuka-ku, Yokohama

(Received July 17, 1968)

The catalytic activity and the sintering property of iron oxide catalysts with and without potassium additives have been studied. The potassium oxide acts as a promoter and is effective under given conditions in increasing the activity of the catalyst from four to ten times. The effects of the promoter can be classified thus: (1) Structural promoter: The increase in the apparent bulk density and the shrinkage of the catalyst tablet upon calcination during the preparation of the catalyst are prevented by potassium additives. The differences in the specific surface area and in the pore volume of the catalyst between with and without potassium promoter are slight. These effects on iron oxide appear to be caused largely by the formation of $K_2Fe_{22}O_{34}$. (2) Synergetic promoter: The potassium promoter changes the apparent energy of activation of the dehydrogenation reaction from 28 to 43 kcal/mol. The increase in the catalytic activity is due to the increase in the pre-exponential factor. The increase in the factor can be explained in terms of the higher concentration of the active center produced by the interaction of the potassium promoter with iron oxide. (3) Selectivity promoter: The formation of benzene by a side reaction is retarded by potassium additives.

Alkali metal oxide, especially potassium oxide, is extensively used as a promoter in many catalytic reactions, such as water gas shift, ammonia synthesis, and the dehydrogenation of organic compounds. It is well known that the potassium oxide reduces the amount of carbon deposit on the catalyst surface and causes the deposited carbon to be removed by steaming. In examining an iron oxide catalyst used for the dehydrogenation of butene to butadiene, Kearby[1] has described the characteristics of the potassium promoter. Lee and Holmes[2] studied the relations between the catalytic activity and electronic properties of alkali and alkaline earths promoting iron oxide for the dehydrogenation of ethylbenzene to styrene. However, the effect of alkali on an iron oxide catalyst for the dehydrogenation of organic compounds has not been clarified completely. The present paper describes some results of our study of the promoter action of potassium oxide on the iron oxide catalyst used for the dehydrogenation of ethylbenzene to styrene. The results of our experiments show that potassium acts as both a structural and a synergetic promoter. In addition, the formation of benzene is retarded by potassium oxide additives.

Experimental

Materials. The ethylbenzene was of a reagent grade and was obtained from the Wako Pure Chemicals Company; its purity, tested by gas chromatography, was superior to 99.5%, the remaining part being benzene and toluene. The ferric nitrate and potassium carbonate were reagent-grade chemicals and were used without further purification.

Catalyst Preparation. *Catalyst A*: Ferric hydroxide, prepared by the addition of an aqueous solution of ammonia to a solution of ferric nitrate, was decomposed to ferric oxide at 500°C in air. The ferric oxide powder and a suitable amount of potassium carbonate was mixed by hand grinding in an agate mortar, and then compressed into tablets under a pressure of 100 kg/cm^2. The tablet was calcined at 930°C in an electric furnace for two hours in the presence of air, and then crushed into granules.

Catalyst B: The compressed tablet of the ferric oxide powder without potassium additives was calcined in an electric furnace for two hours at 900°C in air. The calcined tablet was then crushed into granules and impregnated with a suitable amount of an aqueous potassium carbonate solution.

For both Catalyst A and Catalyst B, the fraction passing through a 1.5-mm sieve but not a 1.0-mm sieve was chosen for the activity and apparent-bulk-density mesurements.

Activity Measurements. The catalytic activity was measured with a differential reactor, with the conversion of ethylbenzene being kept below 5%. The distributions of the by-products, benzene and toluene, were measured with an integral reactor.

Preheated ethylbenzene and a 9/1 mol ratio of steam were fed into a stainless-steel reactor (10 mm i.d.) at 1 atm, and the reactor effluent was analyzed by gas chromatography. A thermocouple junction for measuring the reaction temperature was located at a center

1) K. K. Kearby, *Ind. Eng. Chem.*, **42**, 295 (1950).
2) E. H. Lee and L. H. Holmes, Jr., *J. Phys. Chem.*, **67**, 945 (1963).

of the catalyst bed in a stainless steel tube (1.6 mm o.d.) inserted through the bottom of the reactor.

Apparent Bulk Density. A weighed amount of the catalyst granules was placed in an ordinary glass cylinder and then the cylinder was shaken till the granules showed a constant volume.

Shrinkage of the Tablet of the Catalyst. The shrinkage of the tablet (0.5 cm long by 1.00 cm diameter before calcination) by calcination in the process of catalyst preparation was measured by an ordinary micrometer after the tablet had been cooled to room temperature. The maximum variation between samples heated in this way was less than 2%.

X-Ray Diffraction. X-Ray powder diffraction diagrams were recorded by a X-ray diffractometer (Geigerflex). As a X-ray radiation source, vanadium-filtered chrome radiation was used.

Specific Surface Area and Total Pore Volume. The specific surface area was obtained by applying the B. E. T. method to the adsorption isotherm of nitrogen at −196°C. The total pore volume was obtained from the amount of nitrogen adsorbed at the relative pressure of 0.98 in the adsorption of nitrogen at −196°C.

Results and Discussion

Sintering of the Iron Oxide during Catalyst Preparation. The apparent bulk density of the granules of Catalyst A with various concentrations of potassium additives is shown in Fig. 1. The

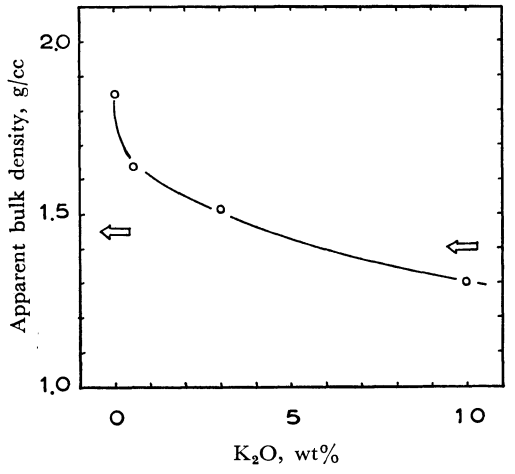

Fig. 1. Apparent bulk density of the iron oxide catalyst with various content of potassium oxide. The arrows indicate the apparent bulk density of catalyst before calcination.

concentration of potassium additives is indicated as a weight percentage of the potassium oxide. The apparent bulk densities of these catalysts before calcination ranged from 1.40 to 1.45 g/cc; after calcination, in the course of preparing a catalyst at 930°C for two hours, the value increased to 1.85 g/cc without potassium additives. The increase in the apparent bulk density upon calcination diminishes progressively with an increase in the concentration of potassium oxide. When the concentration of potassium reaches above about 3%, the apparent bulk density of the catalyst after calcination becomes lower than that of the uncalcined catalyst. Figure 2 shows the effect of the

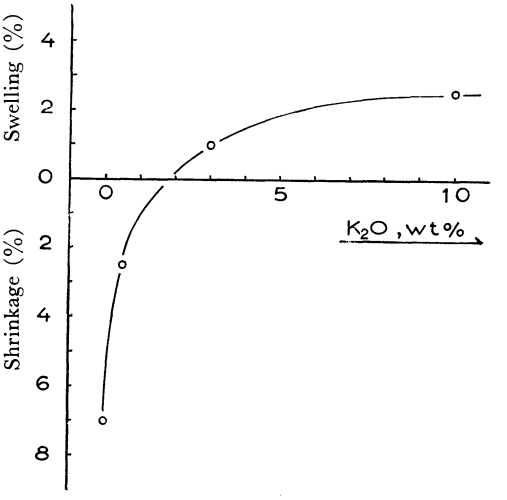

Fig. 2. Shrinkage or swelling of the Catalyst A by calcination in the process of catalyst preparation.

concentration of potassium oxide on the shirnkage or swelling of the Catalyst A tablet in the course of the catalyst preparation. The shrinkage and swelling of the tablet are indicated as changes in the diameter (1.00 cm before calcination). The shrinkage of the tablet without potassium additives is about 7%, whereas a swelling of the tablet is observed when the concentration of potassium oxide reaches above 3%. As is shown in Fig. 3, the

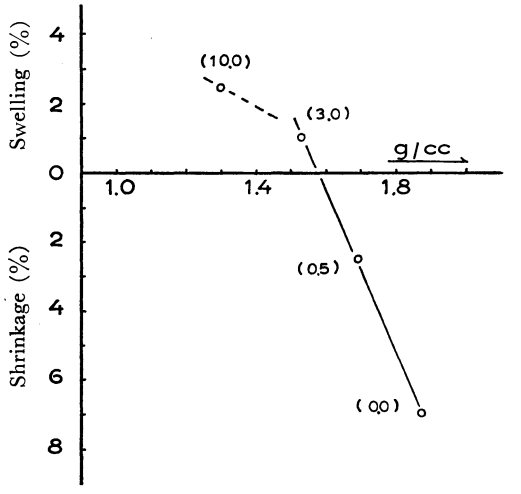

Fig. 3. Relation between apparent bulk density and shrinkage or swelling of the Catalyst A. The numerals in parentheses are the weight percent of potassium oxide.

relation of the shrinkage or swelling to the apparent bulk density is linear except when the concentration of potassium oxide is above 3%. The Table 1 illustrates the specific surface area and the total pore volume of the catalyst with and without a potassium promoter.

Table 1. Surface area and pore volume of the catalyst

	Surface area m^2/g	Pore volume cc/g
Fe_2O_3 uncalcined	28	0.33
Fe_2O_3 calcined	2.5	0.20
Fe_2O_3-K_2O (3 wt%) uncalcined	29	0.33
Fe_2O_3-K_2O (3 wt%) calcined	3.0	0.18

The difference between the specific surface area and the pore volume of the catalyst with and without a potassium promoter is slight. The effect of a potassium promoter in preventing the sintering of the catalyst appears to be caused largely by the formation of $K_2Fe_{22}O_{34}$. The specific gravity of $K_2Fe_{22}O_{34}$ is 4.24,[3,4] whereas that of ferric oxide is 5.13,[5] and it has been reported that $K_2Fe_{22}O_{34}$ is obtained by the calcination of a mixture of ferric oxide and potassium carbonate.[6] X-Ray diffraction diagrams of the iron oxide catalyst with and without potassium additives are shown in Fig. 4. The diagram of iron oxide with potassium additives is essentially the same as that of $K_2Fe_{22}O_{34}$ reported by other workers.[4,7,8] The weight percentage of K_2O in $K_2Fe_{22}O_{34}$ is 5.06; this value is near to the composition where the deviation from the linear relation was observed, as is shown in Fig. 3. The composition of the Catalyst A may be $K_2Fe_{22}O_{34}\cdot nFe_2O_3$ when the content of K_2O is lower than 5.06 wt%; above this concentration the composition may be $K_2Fe_{22}O_{34}\cdot mK_2O$.

Activity Measurements of Catalyst A. To test the stability of the catalyst, the variation of the conversion with the time was tested. After a rapid initial fall of the conversion with the time during the first two hours after ethylbenzene was fed in, the catalyst came to a steady state and the conversion remained constant. The samples used for analyzing the reaction products were withdrawn

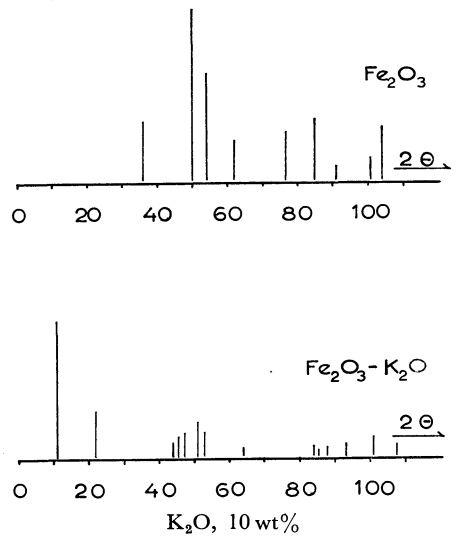

Fig. 4. X-Ray powder diffraction diagrams of iron oxide catalyst with and without potassium promoter. (Radiation: Cr$K\alpha$)

two hours after the start of feeding. Figure 4 shows the temperature dependence of the rate of the dehydrogenation of ethylbenzene using a differential reactor. The reaction rates per unit volume of the catalyst, r, were determined from the $r=(F/V)\cdot X$ relation, where F represents the feed rate of ethylbenzene into the reactor in g-mol per sec, where V represents the volume of the catalyst in ml, and where X represents the fraction of ethylbenzene converted to styrene. The styrene made from the gas-phase reaction in the empty reaction vessel was subtracted from the total conversion. As is shown in Fig. 5, the potassium

oxide acts as a promoter and is, under given conditions, effective in increasing the activity of the catalyst from four to ten times. The activity of the catalyst is not so sensitive to the potassium oxide concentration in the range from 0.5 to 10.0 wt%, although the rate of dehydrogenation increased slightly with an increase in the concentration of potassium oxide. The apparent energies of activation were obtained from the slopes of the straight lines shown in Fig. 5; they were found to be 28 kcal/mol without potassium additives and 43 kcal/mol with them. Within the limits of experimental error the energy of activation was the same for all the iron oxide catalysts with potassium promoters. The interaction of the potassium promoters with iron oxide is assumed to give an active center which is less reactive than iron oxide without the promoter. The high activity of the potassium-promoted catalyst is caused by a high pre-exponential factor, which compensates for the high activation energy. The increase in the pre-exponential factor can tentatively be explained in terms of the higher concentration of the active center, as the difference between the specific surface area of the catalyst with and without a potassium promoter is slight. It was concluded that the promotion of the iron oxide catalyst by potassium is not only structural but also synergetic in nature. This conclusion was rendered certain by the discovery of the change in the activation energy, since the structural promotion should not alter the temperature coefficient. This conclusion is also supported by the results of the experiments using Catalyst B.

Table 2 shows the distribution of the two by-products, benzene and toluene, together with that of the main product, styrene. These results were measured with an integral reactor.

TABLE 2. DISTRIBUTION OF PRODUCTS
(Reaction temp., 600°C)

Catalyst	Benzene (mol%)	Toluene (mol%)	Styrene (mol%)
Fe_2O_3	2.4	0.55	12.5
Fe_2O_3-K_2O (0.5 wt%)	1.5	2.2	63.9
Fe_2O_3-K_2O (3.0 wt%)	1.1	2.6	65.5
Fe_2O_3-K_2O (10.0 wt%)	1.2	4.3	68.0

As is shown in Table 2, the addition of potassium decreased the catalytic activity of the benzene formation, in spite of the fact that the potassium increased the catalytic activity of the dehydrogenation reaction. Generally, alkylation and dealkylation are catalyzed by an acid. The acidity on iron oxides, if any, must be neutralized by the addition of potassium compounds. Therefore, it is natural to think that the decrease in the activity of benzene formation is mainly due to the neutralization of the acidity of the catalyst by a potassium promoter, rather than to a retardation by the styrene formed.

The formation of toluene increases with an increase in the concentration of potassium oxide. This increase in the activity of toluene formation is partly due to the increased yield of styrene, as the toluene is mainly produced from styrene.

Activity Measurement of Catalyst B. Figure 6 shows the temperature dependence of the rate of the dehydrogenation on Catalyst B. The procedure and the experimental conditions were the same as those of the experiments using Catalyst A. The potassium carbonate-impregnated catalyst showed a drastic change in catalytic performance, displaying sharp increases in the rate of the formation of styrene. The activity of these catalysts was insensitive to the potassium oxide content in the range from 0.5 to 3.0 wt%. The apparent energies of activation were found to be 28 kcal/mol without potassium additives and 46 kcal/mol with them. The high activity of the catalyst with a potassium promoter is caused by a high pre-exponential factor, which compensates for the high activation energy. The increase in the pre-exponential factor is due to the increase in the concentration of the active center which is newly-produced by the interaction of the potassium promoter with iron oxide.

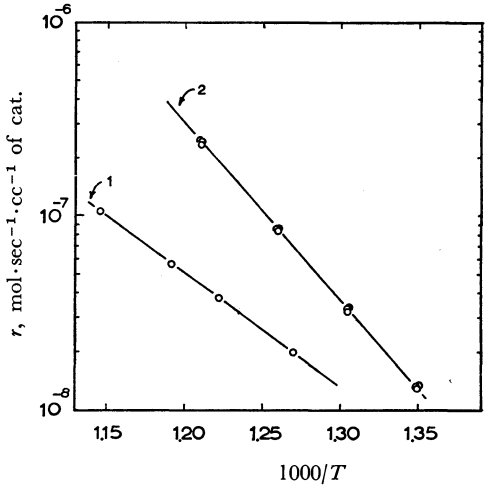

Fig. 6. The effect of temperature on the rate of ethylbenzene dehydrogenation on Catalyst B.
1, Fe_2O_3; 2, Fe_2O_3-K_2O (0.5—3.0 wt%)

As may be seen from the method of preparing Catalyst B, potassium carbonate was impregnated to the calcined iron oxide, and the calcination process was carried out in the absence of potassium carbonate; accordingly, in the case of Catalyst B the effect of the potassium promoter is to enhance the intrinsic activity of the iron oxide catalyst.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 875—880 (1969)

Extraction of Hydrochloric Acid by Tri-*n*-octylamine in Benzene

Takashi KOJIMA, Hiroshi FUKUTOMI and Hidetake KAKIHANA

Research Laboratory of Nuclear Reactor, Tokyo Institute of Technology, Meguro-ku, Tokyo

(Received July 27, 1968)

The equilibria involved in the extraction of HCl by tri-*n*-octylamine (TOA) in benzene have been investigated as a function of the HCl and TOA concentrations. Two distinctly different extractions were observed for two different acidity ranges. From the extraction in the low acidity range (<0.001 M HCl), it has been found that two complexes of TOA·HCl and $(TOA\cdot HCl)_2$ are formed in the organic phase and that the equilibrium constants for the two reactions,

$$TOA(org) + \tfrac{1}{2}H^+(aq) + Cl^-(aq) = TOA\cdot HCl(org)$$

and

$$2TOA(org) + 2H^+(aq) + 2Cl^-(aq) = (TOA\cdot HCl)_2(org),$$

are $K_{11}=(1.51\pm0.02)\times10^4$ and $K_{22}=(2.92\pm0.07)\times10^9$ respectively. For higher concentrations of HCl>3 M, it seems probable that two major complexes of $(TOA\cdot HCl)_2HCl$ and $(TOA\cdot HCl)_3(HCl)_2$ besides the monomer and the dimer, and three minor complexes of $(TOA\cdot HCl)_2(HCl)_2$, $(TOA\cdot HCl)_3HCl$, and $(TOA\cdot HCl)_3(HCl)_3$ are formed in the organic phase.

Since Smith and Page[1] extracted various weak and strong acids with a chloroform solution of methyl-di-octylamine, the extraction of various metal ions from acid solutions by high-molecular-weight amines has been studied and used for various separation processes and analytical techniques. Several reviews[2-4] of this kind of work have been published. On the other hand, although many studies on the extraction mechanism have been reported, in all of these studies except a few,[5-6] the amine salts have been assumed to be monomeric and the possibility of the aggregation of amine salts has been neglected or disregarded.

Since Allen[7] tried to explain the insensitivity of the activity of TOA and di-decylamine sulfates and bisulfates to change in their concentrations by assuming them to form large colloidal aggregates, systematic investigations of the aggregation of several amine salts in the organic phase have been carried out using the methods of light scattering,[8] freezing-point lowering,[9-10] vapor-pressure lowering,[11-12] and two-phase e.m.f. titration.[13] Although it has been found that the amine salts tend to aggregate in an inert solvent with a low dielectric constant, there are still many contradictions in the quantitative treatment of the extraction equilibria.

The main purpose of the work reported here has been to evolve a quantitative description of the extraction equilibria and to find the composition of aggregates of the amine salt in the organic phase. In the present paper, a study of the extraction of HCl from an aqueous solution by TOA in benzene will be reported.

Experimental

Reagents. TOA (supplied by the Kao Saop Co., Tokyo) was purified by vacuum distillation (10 mmHg, and 190—200°C). The other chemicals used were of an analytical grade and were used without further purification. Laboratory-distilled water was used.

Solutions. The TOA solutions were prepared volu-

metrically from TOA and benzene. Aqueous solutions of hydrochloric acid were prepared by the dilution of 12 M HCl. The ionic strengths of HCl solutions with low concentrations (<TOA concentration) were adjusted with 1 M NaCl in order to keep the mean activity coefficient of HCl in the aqueous phase constant, while no such adjustments were made to solutions with high HCl concentrations (>1 M).

Procedure and Analysis. The TOA solutions were shaken in the extraction tubes with equal volumes of HCl aqueous solutions for 15 min. After centrifuging, suitable aliquots of the aqueous phase and of the organic phase were pipetted out for the determination of HCl concentrations. For the extraction of HCl from a solution of a low acidity, the activities of hydrogen ions in the aqueous phase were measured with a pH meter (Radiometer PHM4c, Copenhagen), the concentrations of HCl extracted into the organic phase were determined from the difference in the HCl concentrations of the aqueous phase before and after the equilibrium. For the extraction of HCl from highly-acidic solutions, the concentrations of HCl in the aqueous phase and in the organic phase were determined titrimetrically by the use of a standard base in an 80% ethanol aqueous solution with a mixed indicator of thymol blue and phenolphthalein. Corrections for the excess HCl extracted by benzene itself were made for the extractions with concentrations higher than 8 M HCl.

The concentrations of TOA solutions were determined titrimetrically by measuring the concentration of HCl which was extracted by shaking with a 1 M HCl aqueous solution. All the experiments were performed in a room with the temperature controlled at 25±1°C.

Results and Discussion

It is convenient to present our results in two parts, since two distinctly different extractions were

observed the two different acidity ranges.

(I) Extraction of HCl the in Low-acidity Range. Since it has been found that the ionic dissociation of amine salts is practically negligible in the low dielectric diluents,[14] a general expression for the extraction of HCl by TOA in benzene can be written by:

$$l\overline{\mathrm{TOA}} + m\mathrm{H}^+ + m\mathrm{Cl}^- = \overline{(\mathrm{TOA})_l(\mathrm{HCl})_m} \quad (1)$$

where the upperlined species are those in the organic phase.

The application of the law of mass action to Eq. (1) gives Eq. (2) on the assumption of ideal behavior in the organic phase:

$$\overline{[(\mathrm{TOA})_l(\mathrm{HCl})_m]} = K_{lm}[\overline{\mathrm{TOA}}]^l(\mathrm{H}^+)^m(\mathrm{Cl}^-)^m \quad (2)$$

where brackets denote the concentration, and parentheses, the activity.

Since the ionic strength in the aqueous phase is adjusted with 1 M NaCl, Eq. (2) is replaced by:

$$\overline{[(\mathrm{TOA})_l(\mathrm{HCl})_m]} = K'_{lm}[\overline{\mathrm{TOA}}]^l(\mathrm{H}^+)^m \quad (3)$$

where:

$$K'_{lm} = K_{lm}(\mathrm{Cl}^-)^m{}_{1\,\mathrm{M\ NaCl}} \quad (4)$$

Using Eq. (3), the following equations can be obtained from the material balance:

$$\overline{[\mathrm{TOA}]}_\mathrm{T} = \overline{[\mathrm{TOA}]} + \sum\sum lK'_{lm}[\overline{\mathrm{TOA}}]^l(\mathrm{H}^+)^m \quad (5)$$

$$\overline{[\mathrm{HCl}]}_\mathrm{T} = \sum\sum mK'_{lm}[\overline{\mathrm{TOA}}]^l(\mathrm{H}^+)^m \quad (6)$$

where $\overline{[\mathrm{TOA}]}_\mathrm{T}$ is the total concentration of TOA and where $\overline{[\mathrm{HCl}]}_\mathrm{T}$ represents that of HCl in the organic phase. Using Eq. (5) and Eq. (6) we can introduce the average number of HCl combined with TOA, Z:

$$Z = \frac{\overline{[\mathrm{HCl}]}_\mathrm{T}}{\overline{[\mathrm{TOA}]}_\mathrm{T}} = \frac{\sum\sum mK'_{lm}[\overline{\mathrm{TOA}}]^{l-1}(\mathrm{H}^+)^m}{1 + \sum\sum lK'_{lm}[\overline{\mathrm{TOA}}]^{l-1}(\mathrm{H}^+)^m} \quad (7)$$

The results of Z and $\log(\mathrm{H}^+)$ for TOA concentrations ranging from 1.25% to 10% by volume are given in Table 1. Plots of Z *vs.* $\log(\mathrm{H}^+)$ are shown in Fig. 1. As may be seen by comparing it with Eq. (7), the disagreement between the plots of Z *vs.* $\log(\mathrm{H}^+)$ for different TOA concentrations indicates that the complexes of $l>1$ are formed.

The concentrations of free amine, $\overline{[\mathrm{TOA}]}$, which can not be determined directly, are obtained as follows. Considering the correlation between Eq. (5) and Eq. (6), the following partial differential equation can be obtained:

$$\left(\frac{\partial \ln b}{\partial \ln a}\right)_B = -\left(\frac{\partial A}{\partial B}\right)_a = -\left\{Z + \left(\frac{\partial Z}{\partial \ln B}\right)_a\right\} \quad (8)$$

where $a=(\mathrm{H}^+)$, $b=\overline{[\mathrm{TOA}]}$, $A=\overline{[\mathrm{HCl}]}_\mathrm{T}$, and $B=\overline{[\mathrm{TOA}]}_\mathrm{T}$.

The integration of Eq. (8) at the B constant gives:

$$\log(b/B) = -\left[\int\left\{Z + \left(\frac{\partial Z}{\partial \ln B}\right)_a\right\}\mathrm{d}\log a\right]_B \quad (9)$$

The values of b determined from graphical integration in Eq. (9), using the values of a, B, and Z in Table 1, were found to be identical with $(B-A)$ regardless of B, as is shown in Fig. 2. This finding leads to the conclusion that the value of $\sum\sum(l-m)K'_{lm}b^la^m$ is equal to zero, *i.e.*, $l=m$.

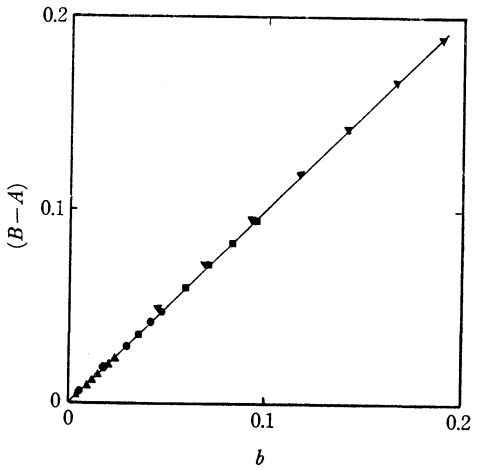

Fig. 2. The comparison between $(B-A)$ and b determined from graphical integration in Eq. (9) using the data in Table 1 where $A=\overline{[\mathrm{HCl}]}_\mathrm{T}$, $B=\overline{[\mathrm{TOA}]}_\mathrm{T}$ and $b=\overline{[\mathrm{TOA}]}$.

14) C. Kraus, *J. Phys. Chem.*, **60**, 129 (1956).

Accordingly, Eq. (6) can be rewritten as:

$$A = BZ = \sum lK'_{ll}\, u^l \qquad (10)$$

where $u=ab$ and where $b=(B-A)$. The values of K'_{ll} may be easily determined with the values of BZ and u. The plots of BZ/u *vs.* u give a straight line, as is shown in Fig. 3. This relationship corresponds to the coexistence of two reactions:

$$\overline{\mathrm{TOA}} + \mathrm{H^+} + \mathrm{Cl^-} = \overline{\mathrm{TOA{\cdot}HCl}} \qquad (11)$$

$$2\overline{\mathrm{TOA}} + 2\mathrm{H^+} + 2\mathrm{Cl^-} = (\overline{\mathrm{TOA{\cdot}HCl}})_2 \qquad (12)$$

The values of the equilibrium constants of these reactions have been calculated using the computer program LETAGROP[15] on the data presented in Table 1; the values of $K'_{11}=(9.90\pm0.11)\times10^3$ and $K'_{22}=(1.26\pm0.03)\times10^9$ have also been obtained. By substituting these values into Eq. (4), the values of:

$$K_{11} = (1.51 \pm 0.02) \times 10^4$$

$$K_{22} = (2.92 \pm 0.07) \times 10^9$$

were determined, in which the mean activity coefficient of a 1 M NaCl aqueous solution[16] was used as the activity coefficient of the chloride ion.

The value of $K_{11}=(1.51\pm0.02)\times10^4$ is in good agreement with the corresponding equilibrium constants of $(1.4\pm0.4)\times10^4$ and $(1.3\pm0.3)\times10^4$ when these is no ionic medium and a 2 M LiCl

aqueous solution at 25°C respectively, as reported by Newman and Klotz.[17]

The equilibrium constant, $\bar{\beta}_2$, of the dimer formation expressed by the equation:

$$2\overline{\text{TOA}\cdot\text{HCl}} = \overline{(\text{TOA}\cdot\text{HCl})_2} \qquad (13)$$

was calculated from $\bar{\beta}_2 = K_{22}/K^2_{11}$; the value of $\bar{\beta}_2 = 12.9 \pm 0.5$ was obtained. This value is in close agreement with that of log $\bar{\beta}_2 = 1.1$ (at 25°C) for tri-laurylamine (TLA) chloride in benzene obtained from the measurement of the vapor-pressure lowering by Markovits and Kertes,[18] but it is different from that of $\bar{\beta}_2 = 53$(at 25°C) for TLA chloride in benzene obtained by Scibona *et al.*,[19] using the same method.

(II) Extraction of HCl in the High-acidity Range. As may be seen in the extraction of HCl in the low acidity range, Z values approch unity at $(H^+) \simeq 0.001$ regardless of the TOA concentration, and the relationship of $Z=1$ seems to be satisfied until 3 M HCl. When the concentration of HCl is, however, above 3 M, the Z values increase with the HCl and TOA concentrations; this means that more acid was extracted into amine than corresponds to the 1 : 1 composition. The results are listed in Table 2. The activities of HCl in Table 2 were calculated using the mean activity coefficient.[20] The plots of $(Z-1)$ *vs.* log(HCl) are shown in Fig. 4.

Since the free amine concentrations at high HCl concentrations are supposed to be negligible in view of the values of $K_{11} = (1.51 \pm 0.02) \times 10^4$ and $K_{22} = (2.92 \pm 0.07) \times 10^9$, the expression for the extraction of HCl can be written as:

$$l\overline{\text{TOA}\cdot\text{HCl}} + n\text{HCl} = \overline{(\text{TOA}\cdot\text{HCl})_l(\text{HCl})_n} \qquad (14)$$

Hence, the following equations can be derived from the material balance:

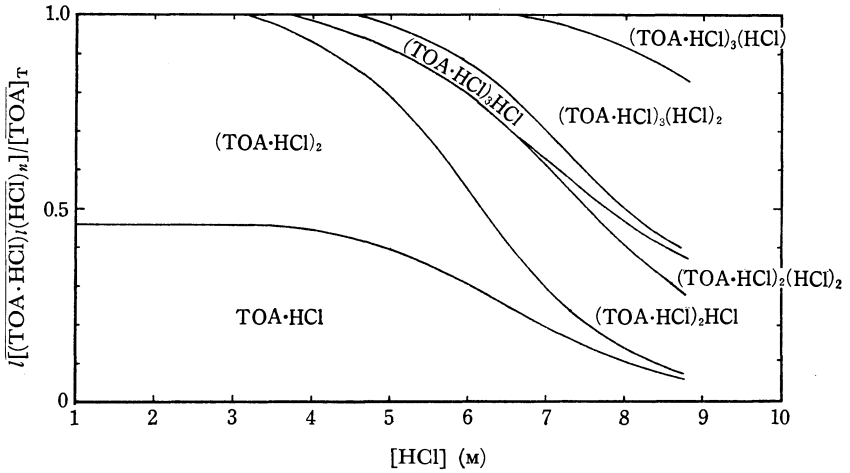

Fig. 5. $l[(\overline{TOA\cdot HCl})_l(\overline{HCl})_n]/[\overline{TOA}]_T$ plotted against [HCl] at $[\overline{TOA}]_T$= 0.1 M. The curves were determined from the material balance using $\bar{\beta}_2$= 12.9 and the values of $\boldsymbol{K}_{ln}$ in Table 4.

$$[\overline{TOA}]_T = [\overline{TOA\cdot HCl}] + 2\bar{\beta}_2[\overline{TOA\cdot HCl}]^2 + \sum\sum l\boldsymbol{K}_{ln}[\overline{TOA\cdot HCl}]^l(HCl)^n \quad (15)$$

$$[\overline{HCl}]_T - [\overline{TOA}]_T = (Z-1)[\overline{TOA}]_T = \sum\sum n\boldsymbol{K}_{ln}[\overline{TOA\cdot HCl}]^l(HCl)^n \quad (16)$$

where $\boldsymbol{K}_{ln}$ is the equilibrium constant of Eq. (14) given by:

$$\boldsymbol{K}_{ln} = \frac{[(\overline{TOA\cdot HCl})_l(\overline{HCl})_n]}{[\overline{TOA\cdot HCl}]^l(HCl)^n} \quad (17)$$

The values of $[\overline{TOA\cdot HCl}]$, which can not be measured directly, are determined as follows. From Eq. (15) and Eq. (16),

$$\left(\frac{\partial \ln b}{\partial \ln a}\right)_B = -\left\{(Z-1) + \left(\frac{\partial(Z-1)}{\partial \ln B}\right)_a\right\} \quad (18)$$

where $a=(HCl)$, $b=[\overline{TOA\cdot HCl}]$, and $B=[\overline{TOA}]_T$.

By integration at the B constant, Eq. (18) becomes:

$$\log(b/b_0) = -\left[\int_{a=a_0}^{a}\left\{(Z-1) + \left(\frac{\partial(Z-1)}{\partial \ln B}\right)_a\right\} d\log a\right]_B \quad (19)$$

where a_0 is the value of a at $Z=1$ and b_0, the value of b at $a=a_0$, which is given by:

$$b_0 = \frac{-1+\sqrt{1+8\bar{\beta}_2 B}}{4\bar{\beta}_2}$$

The values of $b(a,Z-1)_B$ are shown in Table 3; they were determined by graphical integration in Eq. (19) using the data in Table 2. In order to evaluate the values of $\boldsymbol{K}_{ln}$, it is convenient to introduce a new parameter:

$$\boldsymbol{K'}_l = \sum_{n=1}\boldsymbol{K}_{ln}a^n \quad (20)$$

The substitution of Eq. (20) into Eq. (16) yields:

$$A_a = \sum_{l=1} l\boldsymbol{K'}_l b^l \quad (21)$$

where A_a represents the values of $(Z-1)B$ at the a constant.

The method of least squares was used to evaluate the values of $\boldsymbol{K}_{ln}$ fitted to the data in Table 3. Although several combinations of l and n have been tried, the data can be best fitted in with the presence of five species of $(TOA\cdot HCl)_2HCl$, $(TOA\cdot HCl)_2(HCl)_2$, $(TOA\cdot HCl)_3HCl$, $(TOA\cdot HCl)_3(HCl)_2$, and $(TOA\cdot HCl)_3(HCl)_3$. The equilibrium constants for Eq. (14) are given in Table 4. The curves shown in Fig. 3 were determined from the material balance using the values of $\boldsymbol{K}_{ln}$ in Table 4.

As may be seen in Fig. 3, the calculated values of $(Z-1)$ are in good agreement with the experimental values. When the total concentration of TOA and the concentration of HCl in the aqueous phase are given, it should be possible to calculate the concentration of each complex in the organic phase. As an example of the calculation, a graph of $l[(\overline{TOA\cdot HCl})_l(\overline{HCl})_n]/[\overline{TOA}]_T$ against [HCl] at $[\overline{TOA}]_T$=0.1 M is mapped in Fig. 5. From Fig. 5 it may be seen that, besides the monomer and the dimer, the two species of $(TOA\cdot HCl)_2HCl$ and $(TOA\cdot HCl)_3(HCl)_2$ are the major complexes, while the other three species of $(TOA\cdot HCl)_2(HCl)_2$, $(TOA\cdot HCl)_3HCl$ and $(TOA\cdot HCl)_3(HCl)_3$ are the minor complexes.

The authors are deeply grateful to Dr. Erik Högfeldt(Royal Institute of Technology, Stockholm) for performing the LETAGROP calculation and for his stimulating discussions. Thanks are also due to the Kao Soap Co. for its gift of tri-*n*-octylamine.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 881—886 (1969)

The Crystal and Molecular Structure of Bis-(N,N'-π-cyclopentadienyl cobalt)-di-*tert*-butyl Urea, $(\pi\text{-}C_5H_5Co)_2(N\text{-}t\text{-}C_4H_9)_2CO$

Yoshiki MATSUURA,*1 Noritake YASUOKA, Tatzuo UEKI,*2 Nobutami KASAI,*3 and Masao KAKUDO

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamada-Kami, Suita, Osaka

(Received July 27, 1968)

The crystals of $(\pi\text{-}C_5H_5Co)_2(N\text{-}t\text{-}C_4H_9)_2CO$ are orthorhombic, and the space group is *Fdd*2, with $a=9.10_1$, $b=17.97_3$, $c=23.61_6$ Å, and $Z=8$. The crystal structure was determined with use of Mo$K\alpha$ counter data, the final R being 0.063 for 578 non-zero reflections. The molecules has a C_2 symmetry, and the carbonyl group lies exactly on the two-fold axis. Unexpectedly, the molecule has the local structure of N,N'-di-*t*-butyl urea, two nitrogen atoms being bridged to two cobalt atoms. The two crystallographically independent Co–N bonds are 1.942 and 1.951 Å, which are equal within the limits cf experimental error. Two cobalt atoms are directly bonded to each other at a distance of 2.371 Å, which is shorter than that of 2.47 Å found in $(CO)_6Co_2(C_2Ph_2)$.

Many polynuclear organometallic compounds which involve metal-metal bonds have been found, and some of them contain nitrogen or sulfur atoms bridging between the metal atoms. The bridge nitrogen or sulfur atoms in these complexes may stabilize the metal-metal bonds.

The $(\pi\text{-}C_5H_5Co)_2(N\text{-}t\text{-}C_4H_9)_2CO$ complex was prepared according to the following reaction[1] (Table 1).

Both complexes, III and IV, are presumed to take trigonal bipyramidal sturctures,[1] having three cobalt atoms in the equatorial plane. Compound II was not identified as N,N'-di-*t*-butyl urea until the structure analysis of the complex I had been completed. According to such recent spectrochemical studies as IR, NMR, and mass spectra, the two structures shown in Fig. 1 have been proposed for the complex I.[1]

To determine the exact structure of this compound involving the feature of coordination around the cobalt atom, the crystal structure analysis of the complex I, $(C_5H_5Co)_2(N\text{-}t\text{-}C_4H_9)_2CO$, was undertaken by means of X-ray diffraction.[2]

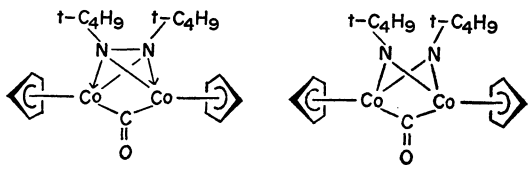

Fig. 1. Two proposed structures for the complex I.

Experimental

The crystal is dark green and has a needle-like shape elongated along the *c* axis. The melting point is 165—168°C, and around this temperature the crystal sublimes appreciably.

The approximate cell dimensions were determined by taking Weissenberg photographs with nickel-filtered Cu$K\alpha$ radiation. The space group was uniquely determined as *Fdd*2 from the following systematic absences

hkl; $h + k \neq 2n$, $k + l \neq 2n$;

$0kl$; $k + l \neq 4n$ and

$h0l$; $l + h \neq 4n$

The precise determination of the unit cell dimensions and the collection of the intensity data were carried out by the use of a G. E. XRD-5 diffractometer equipped with a single crystal orienter.*4 Zirconium-filtered Mo$K\alpha$ radiation (λ=0.7107 Å) was used. The crystallographic data of this compound are listed in Table 2.

TABLE 2. CRYSTALLOGRAPHIC DATA OF $(\pi\text{-}C_5H_5Co)_2(N\text{-}t\text{-}C_4H_9)_2CO$

Orthorhombic	$M = 418.1$
$a = 9.10_1$ Å	$Z = 8$
$b = 17.97_3$ Å	$D_m = 1.46$ g·cm^{-3}
$c = 23.61_6$ Å	$D_x = 1.44$ g·cm^{-3}
$V = 3862.9$ Å	Space Group $Fdd2$

Within the limits of $2\theta \leqq 45°$, 641 independent reflections were obtained, but of these 83 were too weak to be measured.

The crystal used had dimensions of 0.10×0.12×0.10 mm. The linear absorption coefficient, μ, was 18.0 cm^{-1}. No correction for absorption was made because of the negligibly small variation in the transmission of X-rays over the observed angular range, while the corrections for Lorentz and polarization factors were made in the usual way.

Structure Determination

As may be seen in Table 2, the unit cell contains eight molecules. Since the general position in the $Fdd2$ space group is sixteen-fold, the whole molecule should possess a C_2 symmetry and the carbonyl group must lie on the two-fold axis.

The position of the cobalt atom was easily found from a three-dimensional Patterson function. A three-dimensional electron density distribution based on the phase of the cobalt atom revealed the positions of all the light atoms other than hydrogen. The positions of these atoms were also confirmed by the minimum function method.

The refinements of the positional and thermal parameters of the 13 non-hydrogen atoms were carried out by means of the least-squares procedure. The first three cycles with isotropic temperature factors for all atoms except hydrogen gave the discrepancy factor of R=0.11 for non-zero reflections. The next three cycles, of a similar refinement, with an anisotropic temperature factor for only the Co atom, gave R=0.083, while five more cycles with anistorpic temperature factors for all the atoms reduced the R to 0.063 (0.093 for all reflections). The quantity minimized was $\sum w(\Delta F)^2$. Throughout the refinement procedure, the following weighting scheme was applied:

$w = 1.0$ for $F_o \geqq 29$, and

$w = 0.2$ for $F_o < 29$ (marked by asterisks in Table 5).

The final atomic coordinates, together with their estimated standard deviations, are listed in Table 3. The thermal parmeters are shown in Table 4,

* "Equivalent isotropic temperature factor"; obtained by averaging $4\beta_{11}/a^{*2}$, $4\beta_{22}/b^{*2}$, and $4\beta_{33}/c^{*2}$.

carried out on a IBM 7090 computer through the 'UNICON' project and a NEAC 2200 computer of this University with programs written by Dr. Tamaichi Ashida. The atomic scattering factors used in the calculations were taken from those of Hanson and his co-workers.[3]

Results and Discussions

The skeleton of the molecule is shown in Figs. 3 and 4, as viewed along the *b* and *c* axes respectively.

Instead of the previously proposed structure, the complex takes an unexpectedly unique structure. The ligand molecule forms a urea-like structure. The two nitrogen atoms bridge to the two cobalt atoms, and the cobalt atoms are also bonded to each other. These bridge nitrogen atoms are themselves bridged by the carbonyl. Such a urea-like local structure formed in this molecule may be closely related to the formation of *N,N'*-di-*t*-butyl urea during the preparation of this compound; this complex may be regarded as an intermediate in the formation of the above-mentioned urea in the reaction between $(t\text{-}C_4H_9N)_2S$ and $\pi\text{-}C_5H_5Co(CO)_2$ (Table 1). As has been stated before, the whole molecule has a C_2 symmetry, and the carbonyl lies exactly on the two-fold axis. As can be seen in Figs. 3 and 4, there are approximately two verticalmirror planes, perpendicular to each other in the molecule, and the molecule has a quasi-C_{2v} symmetry.

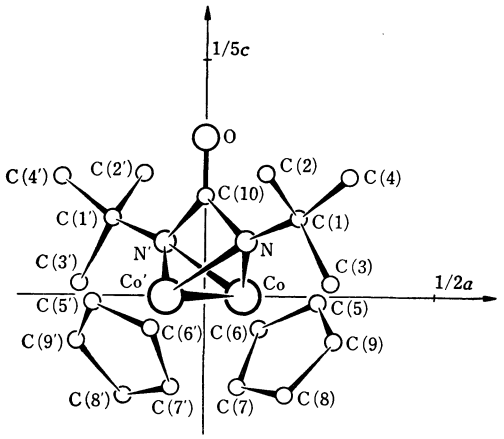

Fig. 3. The molecular structure of $(\pi\text{-}C_5H_5Co)_2\text{-}(N\text{-}t\text{-}C_4H_9)_2CO$.

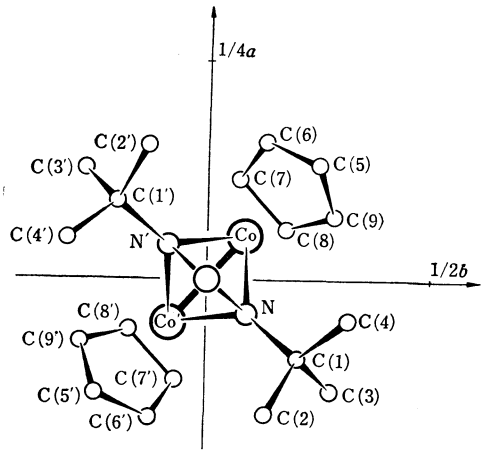

Fig. 4. The skeleton of the molecule; viewed down along the *c* axis.
The molecule has a quasi-C_{2v} symmetry.

The intramolecular bond lengths and angles are summarized in Table 6. In this table, the numbering of atoms is the same as in Figs. 3 and 4.

The Co–Co distance of 2.371 Å is shorter than

that of 2.47 Å found in $(CO)_6Co_2(C_2Ph_2)$.[4] Such a shortening suggests that the metal-metal bond in this complex may be stabilized by the bridge nitrogens.

All the Co–N bonds, in which two pairs of crystallographically equivalent bonds are included,

(I)

(II)

have the same distances within the limits of experimental error. These four Co–N bonds are in an essentially equal bonding state as a result of the resonance between two canonical structure I and II. The Co–N distances are similar to or somewhat shorter than those found in a number of cobalt-ammine complexes.[5]

The local features of the urea-like part of this compound are listed in Table 7 and compared with those of the urea.

It seems that the considerably shorter C–O distance, the longer C–N distance, and the smaller NCN angle of this molecule can be interpreted as being mainly due to the strong interaction among the nitrogen and cobalt atoms bound together.

Table 7. The local features of the urea-like part in comparison with urea

The five carbon atoms of the cyclopentadienyl ring lie almost exactly on a plane; the maximum deviation from the plane being 0.003 Å. The equation of the least-squares plane in terms of rectangular coordinates is:

$$-0.52227X - 0.59808Y + 0.60790Z - 2.64618 = 0,$$

where $X=ax$, $Y=by$, and $Z=cz$.

The carbon atoms in the ring show a marked anisotropy in temperature factors, and these atoms have relatively large "equivalent isotropic temperature factors," as shown in the last column of Table 4. The electron-density distribution of the five carbon atoms of the cyclopentadienyl ring given in Fig. 2 shows a smearing of the electron density along the cyclopentadienyl ring which is similar to that in the ferrocene molecule. From these facts, it may be concluded either that the cyclopentadienyl ring is moving somewhat as a hindered rotator or that there exists an orientational disorder of the rings in the crystal. The

	C(2)-C(3^{iii})		3.87 Å
	C(2)-C(8^{iii})		3.70 Å
	O-C(3^{iii})		3.73 Å
Code for superscript:			
i	$0.25-x$,	$0.25+y$,	$0.25+z$;
ii	$0.25+x$,	$0.25-y$,	$0.25+z$;
iii	$-0.25+x$,	$-0.25-y$,	$0.25+z$

plane of each cyclopentadienyl ring is at a distance of 1.704 Å from the cobalt atom.

Figure 5 shows the crystal structure viewed down the c axis. There are seven rather short intermolecular atomic contacts of less than 4.0 Å, the shortest one is 3.70 Å between C(2) and C(8^{iii}) (Table 8). All the other intermolecular distances are far longer than the sum of the van der Waals radii. The sublimation of this crystal around the melting point may be explained by this loose packing of the molecules.

The authors are very grateful to Professor Sei Otsuka and his co-workers of this University who gave them precious specimens.

K-Band Electron Paramagnetic Resonance of Sulfur Monoxide in the Gaseous Phase

Hiromichi UEHARA

Sagami Chemical Research Center, Sagamihara-shi, Kanagawa

(Received August 2, 1968)

Four K-band electron paramagnetic resonance transitions of $^3\Sigma^-$ $^{32}S^{16}O$ in the gas phase have been observed. One of these occurs between the Zeeman levels of the $K=1$, $J=0\rightarrow K=0$, $J=1$ states and three between the Zeeman levels of the $K=2$, $J=2\rightarrow K=3$, $J=2$ states. The analysis of the spectra has led to the g values of g_s^e, g_l^e, and g_r (in accordance with the notation by Tinkham and Strandberg). Knowledge of the rotational magnetic moment gave the equilibrium internuclear distance of $R_e=1.48101\pm0.00006$ Å.

Two electric dipole EPR transitions of $^3\Sigma^-$ $^{32}S^{16}O$ in the gas phase were first detected by McDonald.[1] Subsequently, another two transitions were observed by Daniels and Dorain[2] and another one by Carrington, Levy and Miller.[3] These five lines occur between levels characterized by $K=1$ and $J=1$ and by $K=2$ and $J=1$, and are observable by using a conventional X-band spectrometer. Several other transitions are expected to be detected at the K-band frequencies. In the present study, four K-band transitions of $^3\Sigma^-$ $^{32}S^{16}O$ were observed among the Zeeman levels of $K=1$, $J=0\rightarrow K=0$, $J=1$ and $K=2$, $J=2\rightarrow K=3$, $J=2$.

Recently, detailed analyses of the X-band spectrum were carried out by Daniels and Dorain[4] and by Carrington, Levy, and Miller[5] using the theory of the oxygen molecule presented by Tinkham and Strandberg.[6,7] Since the sign of the g value of the rotational magnetic moment, g_r, is different between their results, it would be desirable to analyze the K-band spectra independently of the X-band lines, in order thus to determine the sign of g_r. In this study, the g values of the electron spin, the orbital, and the rotational magnetic moments were determined by means of the K-band data. The rotational magnetic moment gave the equilibrium

internuclear distance, R_e, by the use of the equilibrium *interatomic* distance, r_e, obtained by Amano, Hirota and Morino.[8]

Experimental

A modified Japan Electron Optics Laboratory ESR spectrometer with a 100 kHz field modulation was used in conjunction with a 12-in electromagnet yielding a maximum field of 10000 G. The K-band experiments were performed with a cylindrical TE_{012}-mode detection cavity, the parallel endplates of which were replaced by some with 8 mm-i.d. holes and with collars to prevent any leakage of the cavity radiation. A cavity with a 7.5-mm-o.d. quartz flow tube inserted was adjusted to resonate at 24.9 GHz. The magnetic field was measured with a Hewlett-Packard 5245 L electronic counter by counting the proton magnetic resonance frequency of the water contained in a probe just outside the detection cavity. The field measurements were corrected for the small field differential that existed between the cavity center and the position of the magnetometer probe. The microwave frequencies were determined with reference to the transition frequencies of the atomic hydrogen observed simultaneously with those of SO. The required g factor was taken from the work of Beringer and Heald.[9] A trace amount of hydrogen was added to the oxygen upstream of a microwave discharge cavity in order to generate the atomic hydrogen.

Sulfur monoxide was produced by mixing the product of a microwave discharge in the oxygen gas with carbonyl sulfide at a point just upstream from the detection cavity and was pumped through a quartz flow tube whose inner diameter was 6.5 mm into a K-band spectrometer detection cavity. The gaseous flow through the tube was maintained by means of a Tokuda 500-*l*/min mechanical pump. A waveguide-type discharge cavity was placed 20 cm upstream from the detection cavity and was powered by a Toshiba 2M89 magnetron operated at a frequency of 2450 MHz.

The observation of the SO lines in the K-band region was difficult compared with that in the X-band region. This difficulty was mainly caused by the restriction on the maximum flow rate because of the small size of the flow tube through the K-band cavity. Moreover, the adhesions of sulfur and sulfuric acid inside the flow tube decreased the spectrometer sensitivity and shifted the resonant frequencies, though the sulfur coating was slight at a low partial pressure of carbonyl sulfide. In this study, the partial pressure of carbonyl sulfide was about 3×10^{-2} mmHg, and that of oxygen was about 2×10^{-1} mmHg. Sulfuric acid was formed because of the grease used. By the use of Dow-Corning silicone grease, the sulfuric acid became scarcely discernible. The flow tube was washed with detergent before each measurement. This procedure was indispensable to avoid large noises caused by the free electrons introduced into the spectrometer cavity.

Description and Analysis of the Spectra

Four transitions, $K,J,M=1,0,0\rightarrow0,1,-1$, $2,2,1\rightarrow3,2,2$, $2,2,2\rightarrow3,2,1$, and $2,2,2\rightarrow3,2,2$, were observed in the K-band region. These transitions are shown in Fig. 1. The position of each line was determined as follows: immediately after a transition of SO was measured, a transition of the atomic hydrogen and again the same transition of SO were successively recorded. The frequencies thus determined are listed in Table 1. The experimental uncertainty in the magnetic field is the difference between the two measurements of the field value of a transition of SO plus the error for

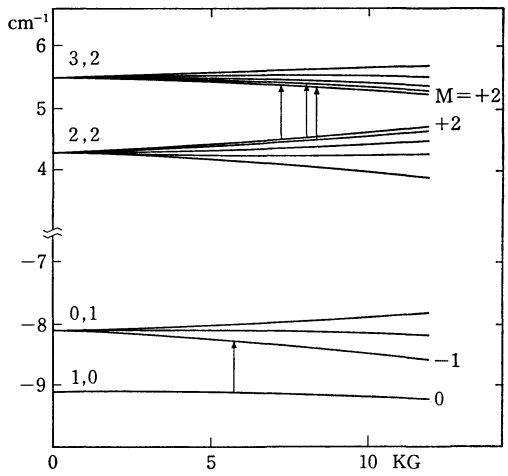

Fig. 1. An energy-level diagram of the magnetic-field splitting of the $K,J=1,0$; $0,1$; $2,2$ and $3,2$ levels of $^{32}S^{16}O$. The observed transitions are indicated.

reading the position of a peak. The designated uncertainty in the microwave frequency is based on an estimated error in measuring the position of a peak of atomic hydrogen. Under optimum conditions the strongest band of the 1,0,0→0,1,−1 transition was observed at a 1-sec time constant with a signal-to-noise ratio of 100. The microwave frequency used was 24.9 GHz. The slight difference in microwave frequency for each measurement was due to the slight difference in the position of the quartz-flow tube inserted in the spectrometer cavity. The 2,2,1→3,2,1 and 2,2,1→3,2,0 transitions could not be detected.

The observed spectra were analysed according to the thory of molecular oxygen proposed by Tinkham and Strandberg.[6,7] Recently, Kayama and Baird[10] have shown that several modifications of the theory proposed by Tinkham *et al.* are indispensable. Therefore, we follow the formulation by Tinkham and Strandberg so as not to conflict with the theory of Kayama and Baird. The modifications given by Kayama and Baird will be discussed later. The effective Hamiltonian for $^3\Sigma^-$ molecules were derived[6,7] as:

$$\begin{aligned}\mathscr{H} &= P_R^2/2M + \frac{1}{2}M\omega_e^2R_e^2\xi^2 + b\xi^3 \\ &+ B\mathfrak{R}^2 + \frac{2}{3}\lambda(3S_z^2 - \boldsymbol{S}^2) + \mu\mathfrak{R}\cdot\boldsymbol{S} \\ &+ (g_s^e - g_r)\beta HS_z + g_l^e\beta H\sum_{g=x,y}\phi_{zg}S_g \\ &+ g_r\beta HM, \end{aligned} \tag{1}$$

where:

$$B = B_N - B'',\ \lambda = \lambda' + \lambda''\ \text{and}\ \mu = \mu' + \mu''.$$

Since the Hamiltonian (1) is integrated over the electron coordinates, the ξ dependence of the parameter λ as well as B must be taken into account:

$$B = B_e(1 - 2\xi + 3\xi^2),\quad \lambda = \lambda_e + \lambda_{(1)}\xi + \lambda_{(2)}\xi^2. \tag{2}$$

No similar expansion for the parameter, μ, was found to be necessary for this experiment. The meanings of the various notations used above are the same as those given by Tinkham and Strandberg, except that the gyromagnetic ratios, g_s^e, g_l^e, and g_r, are opposite in sign.

The analysis was carried out by setting up a secular equation of $\mathscr{H}$ with respect to Hund's Case b wavefunctions. The matrix elements off-diagonal in the vibrational quantum number, v, were eliminated by the Van Vleck transformation. This procedure shows that large vibration-dependent terms can be taken out by defining the v-dependent constants, λ_v and B_v, as in the (3) equations:

$$\left.\begin{aligned} B_v &= B_e[1 + (2v+1)(3\varepsilon + 12b\varepsilon^3B^{-1})], \\ \lambda_v &= \lambda_e - 6(2v+1)b\varepsilon^3B^{-1}\lambda_{(1)}, \end{aligned}\right\} \tag{3}$$

although higher-order centrifugal distortion terms cannot be eliminated in this way.

The matrix elements in Hund's Case b representation have been given in Eqs. (52) and (60) of TS I and Eq. (24) in TS II. The elements with $\Delta K = \pm 2$ and $\Delta J = 0, \pm 1$, which are introduced by the term $g_l^e\,\beta H\sum_{g=x,y}\phi_{zg}S_g$ and which are not listed in TS II, are given in the $(K', J', M|\mathscr{H}_{ml}|K, J, M)$ form as:

$$\left.\begin{aligned} &(J-1,J,M|\mathscr{H}_{ml}|J+1,J,M) = \\ &\quad -g_l^e\beta HM/\{(2J+1)[J(J+1)]^{1/2}\} \\ &(J-2,J-1,M|\mathscr{H}_{ml}|J,J,M) = \\ &\quad -g_l^e\beta H[(J^2-1)(J^2-M^2)]^{1/2}/ \\ &\quad \{(2J-1)[J(2J+1)]^{1/2}\}, \\ &(J-1,J-1,M|\mathscr{H}_{ml}|J+1,J,M) = \\ &\quad -g_l^e\beta H[(J^2-1)(J^2-M^2)]^{1/2}/ \\ &\quad \{(2J+1)[J(2J-1)]^{1/2}\} \end{aligned}\right\} \tag{4}$$

where:

$$\mathscr{H}_{ml} = g_l^e\beta H\sum_{g=x,y}\phi_{zg}S_g. \tag{5}$$

The required 19-dimensional matrix for a given value of M was diagonalyzed by using an IBM 7090 computer. The values of field-free parameters used in this study were: $B_{v=0}=21523.6$, $\lambda_{v=0}=158256$, $\mu_{v=0}=-168.5$, and $\lambda_{(1)}=2.1\times10^5$, in units of megahertz. They were obtained by Amano, Hirota, and Morino[8] by analyzing the microwave spectra of $^{32}S^{16}O$.

The computation was made point by point for various values of the field H and of the g values, g_s^e, g_l^e, and g_r. The most probable g values obtained by fitting the K-band $^{32}S^{16}O$ resonances are given in Table 2. The quoted errors reflect the experimental uncertainties both in the magnetic field and in the microwave frequency. The experimental and calculated EPR results are shown in Table 1.

Discussion

It may be seen from Table 1 that the observed EPR transitions in the K-band region can be explained by the theory of Tinkham and Strandberg. Table 2 indicates that the g values, g_s^e, g_l^e, and g_r, obtained in the present study are almost in agreement with those given by Daniels and Dorain. The negative sign of g_r proposed by Carrington, Levy, and Miller[5] does not describe the observed K-band spectra.

All this while the theory of Tinkham and Strandberg was followed. As has been mentioned above, Kayama and Baird pointed out that the contribution of $^1\Sigma_g^+$ to the $^3\Sigma_g^-$ ground state of O_2 cannot be ignored. They re-examined the theory of Tinkham *et al.* by the use of the "true microscopic" spin-orbit interaction Hamiltonian and modified the results given in TS I and II. Their results

TABLE 2. g VALUES OF SO

g Value	Present study	Daniels and Dorain[4]	Carrington, Levy and Miller[5,a]
g_s^e	2.00199 ± 0.00010	2.00197 ± 0.0001	2.0023
g_l^e	0.00364 ± 0.00020	0.00371 ± 0.0005	0.0040 ± 0.0003
g_r	0.00011 ± 0.00007	0.00019 ± 0.0002	-0.00020 ± 0.00020

a) g Values listed here are all opposite in sign to those of Carrington, Levy and Miller.[5]

revealed that, first, the value of λ'' should be given by the sum of λ''_{Π} and λ''_r, where λ''_{Π} is the contribution to λ'' from the $^3\Pi_g$ symmetry state and λ''_r from the $^{2S+}\Pi^1{}_g$ ($S=0$, 2) and $^{2S+1}\sum_g^+$ ($S=0$, 1, 2) states, and, second, as a result of the mixing of the $^1\sum_g^+$ state with the $^3\sum_g^-$ ground state, the λ_v, μ, and g_l^e parameters in Eqs. (1) and (3) should be interpreted as $\tilde{\lambda}_v$, $\tilde{\mu}$, and $\tilde{g}_l^e$, which depend on the state-mixing as expressed by:

$$\left.\begin{aligned}\tilde{\mu} &= \mu + 2\alpha\left(B_v - \frac{1}{2}\mu\right),\\ \tilde{\lambda}_v &= \lambda_v - \frac{2}{3}\alpha(2\lambda_v + \zeta_v) + \alpha\left(B_v - \frac{3}{2}\mu\right)\\ \tilde{g}_l^e &= g_l^e - \alpha g_s^e,\end{aligned}\right\} \quad (6)$$

where 2α represents the $^1\sum_g^+$ character in the ground state and ζ, the contribution to λ'' from the $^1\sum_g^+$ state.

In the case of sulfur monoxide, there is no g or u symmetry, and the physical interpretation of the parameters introduced by Kayama and Baird must be different from that for the oxygen molecule. Nevertheless, the (6) equations seem valid phenomenologically and we shall not discuss this difference any further. In these circumstances, such physical interpretations of the λ and μ paramters as those given by Daniels and Dorain seem meaningless unless the correct estimates of ζ and μ' or α are made. It is more proper to express the molecular constants, μ' and μ'' in the following form, including α as a parameter:

$$\left.\begin{aligned}\mu' &= -0.0004 + 1.4\alpha \pm 0.0003\\ \mu'' &= -0.0052 - 2.9\alpha \pm 0.0003\ \mathrm{cm^{-1}}.\end{aligned}\right\} \quad (7)$$

Kayama and Baird[10] estimated the 2α value of oxygen to be $(3.0—4.0)\times10^{-4}$. The 2α value for sulfur monoxide should be of the same order of magnitude as that for oxygen. Therefore, the second-order contrubution, $-2Bg_l^e$, constitutes the main part of μ. In fact, the fact that the value, $-2Bg_l^e=-0.0052\pm0.0003\ \mathrm{cm^{-1}}$, determined from the electron resonance is almost equal to the value of $\mu=-0.0056\ \mathrm{cm^{-1}}$ determined through microwave spectroscopy provides a welcome check on the consistency of the electron resonance and the microwave spectra, as was pointed out by Carrington, Levy, and Miller.[5]

The contribution of the electronic mass to the rotational constant is:

$$B'' = B(g_r - g_r^n) = 0.00027 \pm 0.00005\ \mathrm{cm^{-1}}. \quad (8)$$

This leads to the value of $0.721087\pm0.000055\ \mathrm{cm^{-1}}$ of B_{Ne}, the rotational constant of the bare nuclei, when the B_e value of $0.720817\pm0.000005\ \mathrm{cm^{-1}}$ obtained by Amano, Hirota, and Morino is used. The B'' value of $0.00027\ \mathrm{cm^{-1}}$ is a correction of 370 ppm (parts per million). The usual procedure of using atomic rather than nuclear masses reduces this correction 270 ppm, leaving 100 ppm. The equilibrium internuclear distance, R_e, was estimated to be 1.48101 ± 0.00006 Å by using the nuclear masses and the latest values of the universal constants. The difference of 0.00007 Å between r_e and R_e is somewhat larger than the experimental errors. Carrignton, Levy, and Miller[5] concluded that the internuclear distance R_e coincided with the interatomic distance r_e within the limits of experimental error. The contradiction between the two experiments occurs mainly from the different signs of the values obtained for g_r. Most molecules will have $g_r>0$ because the electronic contribution slightly outweighs that of the bare nuclei.[11] A sizable correction of the electronic contribution must be made for the rotational constant, B_e, in order to determine the internuclear distances to the full accuracy of the data. The correction of +370 ppm for B_e in the sulfur monoxide in the present study is of reasonable order of magnitude compared with the correction of +400 ppm in the oxygen molecule.[6]

The author wishes to express his gratitude to Professor Yonezo Morino for his encouragement throughout this work. His thanks are also due to Dr. K. Kayama for helpful suggestions on improving the experimental accuracy.

Basicity of Dimethyl Sulfoxide in an Aqueous Solution as Measured by the Spectrophotometric Indicator Method

Goro WADA

Department of Chemistry, Nara Women's University, Nara

(Received August 10, 1968)

The basic nature of dimethyl sulfoxide (DMSO) has been known in water, and so has its pK_a value, which varies somewhat according to the measuring methods. In the present work, a spectrophotometric method employing thymol blue and *o*-nitroaniline as indicators was applied; the thermodynamical pK_a° value of DMSO was determined to be -1.04 at 25°C. Since there is no dependence of pK_a° upon the temperature, the proton transfer from water to DMSO in water is likely to be athermal.

The nature of dimethyl sulfoxide (DMSO) as a solvent for acid-base equilibria and for other chemical reactions has been well investigated, and the results have been well collected.[1,2] On the other hand, the quantitative basic strength of DMSO as a base itself in an aqueous solution was first found by potentiometric titration by Nylén[3] in 1941, who established that the pK_a° value of DMSO at 20°C was zero, where pK_a° was defined as the thermodynamical dissociation constant of the SH^+ acid, the protonated form of DMSO. Recently, Streuli[4] and Andersen *et al.*[5] determined the pK_a° value to be 1.0 and 0.911 respectively, by similar potentiometric titrations using perchloric acid as the titrant and acetic anhydride as the solvent. More recently, by measuring the chemical shifts of the methyl groups of DMSO as a function of the sulfuric acid concentration, Haake and Cook[6] determined the basicity of DMSO to be -2.7; this value shows a lower basicity than the values previously obtained.

The pK_a° values observed are thus widely scattered between -2.7 and $+1$. The present work was undertaken to estimate it by a method different from those previously adopted. A spectrophotometric method employing two acid-base indicators, thymol blue and *o*-nitroaniline, was applied; it gave -1.04 as pK_a° value, a value which lies nearly at the center between the two extreme values previously determined.

Experimental

Commercial DMSO was distilled twice under reduced pressure of oxygen-free nitrogen.[7] Anhydrous sodium perchlorate was prepared by recrystalizing a crude wet source from water and drying it to an anhydrous state at a temperature not higher than 300°C. The ionic strength of the solutions presently being investigated, μ, was controlled with this salt. The perchloric acid, thymol blue, and *o*-nitroaniline were used without further purification.

For the measurements of the optical densities of solutions, a Beckman spectrophotometer, Model DU, was used with a thermostated cell compartment and quartz cells with light paths of 1 cm and 10 cm.

Results with Thymol Blue

Ionization Constant and Molar Extinction Coefficients of Thymol Blue. The spectra of thymol blue (thymolsulfonephthalein) at various hydrogen ion concentrations in aqueous solutions are shown in Fig. 1. The figure indicates that the absorption peak at 544 mμ is due to the acid form of the indicator (represented by HIn), while the two absorption peaks at 433 and 335 mμ are due to the base form of the indicator (In^-). Another absorption of the acid form appearing with a peak at 395 mμ (shown by a broken line in Fig. 1) overlaps with the bottom part between the two absorption bands of the base form. Isosbestic points occur at 486 mμ and somewhere between 375 and 390 mμ.

Since the observed absorbance at 540 mμ can be approximately attributed only to the acid form of thymol blue, the molar extinction coefficient of

7) J. Menashi, W. L. Reynolds and G. Van Auken, *Inorg. Chem.*, **4**, 299 (1965).

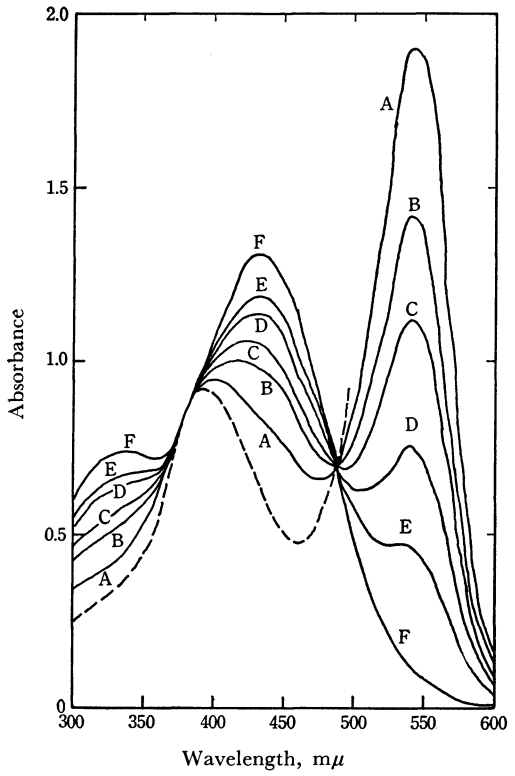

Fig. 1. Absorption spectra of thymol blue at various hydrogen ion concentrations, $[HIn]_0 = 1\times10^{-4}$ M.
A : $[H^+]=0.040$ M, B : 0.020 M, C : 0.013 M
D : 0.0067 M, E : 0.0033 M, F : 10^{-7} M
Broken line : acid from.

the acid form at 540 mμ, ε_A^{540}, can easily be estimated to be 3.13×10^4 $M^{-1}cm^{-1}$, by assuming that of the base form, ε_B^{540}, to be zero.

From the absorbances at 540 mμ at various hydrogen ion concentrations, the respective concentrations of HIn and In^- can be ascertained. Therefore, the ionization constant of the indicator, defined as $K_{HIn}=[H^+][In^-]/[HIn]$, at 25°C is calculated to be $(2.21\pm0.12)\times10^{-2}$ M.

At 540 mμ, ε_A^{540} is so complicatedly affected by the addition of even a small amount of DMSO to the aqueous solution that this wavelength seems less suitable than 433 and 335 mμ for the present purpose of measuring the K_a of the protonated DMSO.

When the solution is neutral, thymol blue may be considered to be completely in the base form.*1 This fact enables us easily to obtain the molar extinction coefficients of the base form, ε_B's. At some acid concentrations, on the other hand, the apparent absorbance of the solution, A, is the sum of those due to the two forms, as is expressed by:

$$A = \varepsilon_A[HIn] + \varepsilon_B[In^-] \quad (1)$$

when either 433 mμ or 335 mμ is employed for the measurement. With the help of the K_{HIn} value, the following data were obtained on the extinction coefficients:

$$\left.\begin{aligned} \varepsilon_A^{433} &= 6.11\times10^3\ M^{-1}\,cm^{-1} \\ \varepsilon_A^{335} &= 2.71\times10^3\ M^{-1}\,cm^{-1} \\ \varepsilon_B^{433} &= 1.31\times10^4\ M^{-1}\,cm^{-1} \\ \varepsilon_B^{335} &= 7.36\times10^3\ M^{-1}\,cm^{-1} \end{aligned}\right\} \quad (2)$$

The ε_A's of thymol blue in an aqueous solution at both 433 and 335 mμ are indifferent to the presence of DMSO at concentrations as high as $[S]_0=0.6$ M within the limits of experimental error, while it was found that the absorption spectrum of the base form of thymol blue has a slight tendency to be lowered in the 350—480 mμ region and raised in that of 300—350 mμ with an increase in the concentration of DMSO at the rates expressed empirically as:

$$\left.\begin{aligned} \varepsilon_B^{433} &= (1.31-0.029[S]_0)\times10^4\ M^{-1}\,cm^{-1} \\ \varepsilon_B^{335} &= (7.36+0.114[S]_0)\times10^3\ M^{-1}\,cm^{-1} \end{aligned}\right\} \quad (3)$$

Calculation of K_a of Protonated DMSO. Since the total concentration of the indicator, $[HIn]_0$, is represented by:

$$[HIn]_0 = [HIn] + [In^-] \quad (4)$$

the following expression can be obtained by combination with Eq. (1):

$$A = \frac{\varepsilon_A[H^+]+\varepsilon_B K_{HIn}}{[H^+]+K_{HIn}}[HIn]_0 \quad (5)$$

When DMSO is added to water to make its total concentration $[S]_0$, with $[HIn]_0$ and $[HClO_4]_0$ kept constant, $[H^+]$ will decrease to $[H^+]'$ due to the protonation of DMSO and, at the same time, ε_B will vary according to Eq. (3). Consequently, A will also alter to A'. By putting the observed A' and calculated ε_B values into Eq. (5), the decrease in the hydrogen ion concentration can be obtained; it is equivalent to the concentration of the protonated DMSO, $[SH^+]$. Since $[S]=[S]_0-[SH^+]$, the value of K_a can easily be calculated. The change in the absorbance caused by the addition of DMSO, $A'-A$, was generally so small compared with A itself that differential spectrophotometry had better be adopted, taking a solution of the indicator in the absence of DMSO as the reference solution.

At comparatively high $[S]_0$ values, the activity of water in the system, a_{H_2O}, is no longer equal to unity but is, rather, reduced to an extent which is assumed to be approximately proportional to its mole fraction in the system. Such a consideration was taken into account in the course of the calculation of K_a.

The values of K_a calculated at various acid and DMSO concentrations at $\mu=0.55$ M and 25°C are listed in Table 1; they give an averaged value

*1 Since thymol blue is dibasic, "the base form" used here must be "the neutral form".

TABLE 1. K_a VALUES AT VARIOUS ACID AND DMSO CONCENTRATIONS AT $\mu=0.55$ M AND 25°C BY USE OF THYMOL BLUE AS AN INDICATOR

0.16	433	—	5.9	5.6	4.3	5.3
	335	5.9	4.5	4.8	4.5	4.0

Mean 4.7±0.5

TABLE 2. K_a VALUES MEASURED WITH THYMO BLLUE AT VARIOUS TEMPERATURES AT $[S]_0=0.3$—0.7 M, $[HClO_4]_0=0.06$—0.12 M AND $\mu=0.55$ M

T, °C	K_a, M
15	4.5±0.6
25	4.7±0.5
35	4.5±0.6

$K_a=4.7\pm0.5$ M. Table 2 summarizes the averaged K_a values measured in the same way as before at various temperatures; this table indicates that there is almost no variation in K_a with a change in the temperature.

Results with *o*-Nitroaniline

Ionization Constant and Molar Extinction Coefficients of *o*-Nitroaniline. The spectra of *o*-nitroaniline in both the acid and base forms are shown in Fig. 2. Only the base form exhibits a broad absorption band, with a peak at 410 mμ, while the acid form has a maximum absorption at 265 mμ in the ultraviolet region, where the base form has a considerable absorption, too.

Since molecular *o*-nitroaniline is a kind of base, the acid and base forms may be better represented by HIn^+ and In respectively. Then, the ionization constant of the indicator is defined as $K_{In}=[H^+][In]/[HIn^+]$. As to the mass and absorption balances with respect to the indicator, the following two equations are maintained:

$$[In]_0 = [HIn^+] + [In] \quad (6)$$

$$A = \varepsilon[In]_0 = \varepsilon_A [HIn^+] + \varepsilon_B[In] \quad (7)$$

where ε stands for the apparent molar extinction coefficient of the indicator. From these relations, ε is expressed as a function of $[H^+]$:

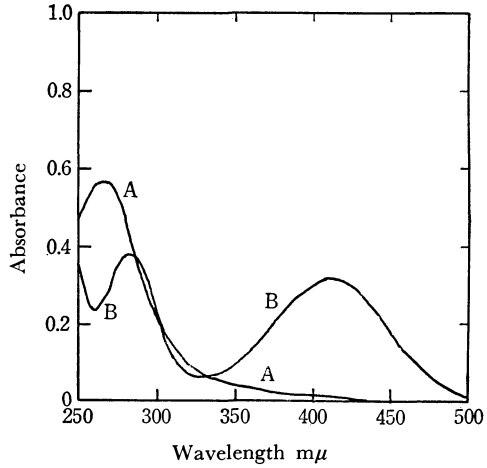

Fig. 2. Absorption spectra of *o*-nitroaniline at $[In]_0=1\times10^{-4}$ M.
A : acid form, B : base form

$$\frac{1}{\varepsilon-\varepsilon_A} = \frac{1}{\varepsilon_B-\varepsilon_A}\left(1+\frac{[H^+]}{K_{In}}\right) \quad (8)$$

If ε_A is negligibly small as compared with ε_B, Eq. (8) is reduced to:

$$\frac{1}{\varepsilon} = \frac{1}{\varepsilon_B} + \frac{[H^+]}{\varepsilon_B K_{In}} \quad (9)$$

This is clearly the case when 380, 410, or 440 mμ is employed for the measurement. The plots of $1/\varepsilon$ *versus* $[H^+]$ at $\mu=0.55$ M and 25°C yield good straight lines at the respective wavelengths, as is shown in Fig. 3, which reveal $\varepsilon_B^{440}=3.48\times10^3$, $\varepsilon_B^{410}=4.47\times10^3$, $\varepsilon_B^{380}=3.16\times10^3$ $M^{-1}cm^{-1}$, and $K_{In}=1.27$ M on the average. The latter value

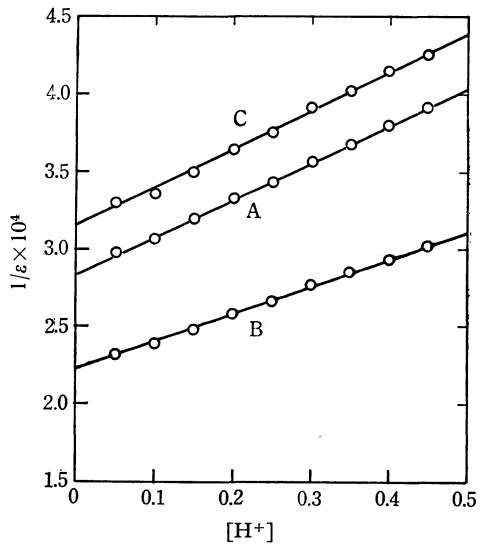

Fig. 3. Linearities of $1/\varepsilon$ of *o*-nitroaniline solution against $[H^+]$ at $\mu=0.55$ M, 25°C.
$[In]_0=1\times10^{-4}$ M, A: 440 mμ, B : 410 mμ, C : 380 mμ

agrees fairly well with the $K_{In}=1.55$ M measured in very concentrated perchloric acid.[8]

In a way quite similar to the case of thymol blue, the ε_B's of *o*-nitroaniline at 440 and 410 mμ were found to be affected by the addition of DMSO, thus:

$$\left.\begin{aligned}\varepsilon_B^{440} &= (3.48+0.138[S]_0)\times 10^3\ M^{-1}\,cm^{-1}\\ \varepsilon_B^{410} &= (4.47+0.113[S]_0)\times 10^3\ M^{-1}\,cm^{-1}\end{aligned}\right\} \quad (10)$$

although ε_B^{380} is almost independent of $[S]_0$.

Calculation of K_a of Protonated DMSO. As in the case of thymol blue, a slight change in A, and, therefore, in ε, upon the addition of DMSO at constant $[HClO_4]_0$ and $[In]_0$ values, observed by means of the differential spectrophotometry, results from the changes in $[H^+]$ and in ε_B (in the case of 440 or 410 mμ) according to Eq. (9). The decrease in $[H^+]$ corresponds to the occurrence of SH^+; this enables us to determine K_a. The calculated results of K_a are summarized in Table 3. The averaged value of K_a at $\mu=0.55$ M and 25°C is found to be 4.6±0.5 M; this value is in good agreement with the results obtained with thymol blue.

Table 3. K_a values at various acid and DMSO concentrations at $\mu=0.55$ M and 25°C by use of *o*-nitroaniline as an indicator

$[HClO_4]_0$ M	λ mμ	$[S]_0$ M 0.2	0.3	0.4	0.5	0.6	0.7
0.3	440	—	4.5	4.8	5.0	5.0	4.8

	380	4.8	4.0	3.7	4.0	3.9	3.9

Mean 4.6±0.5

Discussion

The averaged value of K_a as measured by both indicators is 4.7±0.5 M; namely, $pK_a=-0.67$ at $\mu=0.55$ M and 25°C. Through the approximate Debye-Hückel relation:

$$pK_a^\circ = pK_a - 0.5\sqrt{\mu} \quad (11)$$

the thermodynamical basicity strength of DMSO is estimated to be $pK_a^\circ=-1.04$. This pK_a° value is less basic than the values found by the potentiometric titration[4,5] and more basic than that found by the chemical-shifts method.[6] As to the acidic nature, on the other hand, DMSO is an extremely weak acid which yields the CH_3-SO-CH_2^- anion, with a supposed acid dissociation constant of 10^{-31}.[2] In fact, the practical preparation of this anion (methylsulfinyl carbanion) is possible only under very severe conditions.[9]

The fact that the pK_a values of DMSO vary according to the alteration of the measuring methods, namely, about 1 by the potentiometric titration, −1 by the spectrophotometric method and −2.7 by the chemical shifts of the protons, indicates that there may be some variation in the extent of the association between a proton and a DMSO molecule in water. The method of the chemical shifts measures only the closest combination between them, while the electrochemical method finds more associated molecules of DMSO with protons, including those in looser combination. The spectrophotometry discriminates the protonated DMSO from the unprotonated by a way intermediate between the two other methods.

According to the values in Table 2, there is no dependence of K_a upon the temperature; therefore, the enthalpy change associated with the $S+H_3O^+ \rightleftharpoons SH^+ + H_2O$ reaction seems to be zero. This means that the protonation energies of water and DMSO are nearly equal to each other in water.

The experimental part of the work was carried out at the Department of Chemistry, University of Minnesota, U. S. A. The author's sincere thanks are due to Professor Warren L. Reynolds for his helpful discussion.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 894—897 (1969)

Fragmentation of the Excited Isobutane Ion Produced by Charge Transfer from the Nitrogen Molecule Ion

Tetsuo MIYAZAKI, Tadahiko KOHAMA, Kenji FUEKI and Zen-ichiro KURI

Department of Synthetic Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya

(Received August 12, 1968)

The radiolysis of the N_2-*iso*C_4H_{10} (0.0153 mol/mol of N_2) mixture has been studied by using such ion scavengers as ammonia and sulfur hexafluoride. It was found that the $C_3H_7^+$ ion is formed by the fragmentation of the excited isobutane ion produced by the charge transfer from the nitrogen ion. Although nitrogen is an effective quencher of the excited ion, the yield of the $C_3H_7^+$ ion is constant over the pressure range from 0.66 to 130 atm. It has been concluded that the excited isobutane ion produced by the charge transfer with 5 eV excess energy decomposes very fast and that it can not be deactivated by nitrogen of 130 atm, while it has been reported by other authors that the excited isobutane ion with 1.2 eV excess energy can be deactivated below 1 atm. This difference in the characters of the excited isobutane ions can be explained by the previously-proposed mechanism of the fragmentation.

The fragmentation of the excited ion has been explained by the quasi-equilibrium theory,[1] which is based on the fundamental assumption that the randomization of excitation energy among oscillators occurs before the dissociation of the excited ion.

We concluded in a previous study[2] of the effect of density in the radiolysis of butanes that excited ions can be classified into two types, M^{+*} and M^{+**}. The M^{+*} ion decomposes slowly and can be collisionally deactivated by an increase in the pressure. The M^{+**} ion decomposes in a time of one vibration and can not be deactivated even in the liquid phase. In order to obtain further details on the mechanism, studies[3,4] have been made of the ionic fragmentation in the liquid-phase radiolysis of hydrocarbons, and the following new mechanism of the fragmentation of M^{+**} ion has been proposed[5]: The M^{+**} ion is the electronically-excited ion, and the electronic excitation energy spreads over all the C–C bonds in a molecule prior to its fragmentation. The ion decomposes instantaneously in one vibration at a bond where the mean excitation energy per C–C bond exceeds its bond energy.

The present work studies the effect of pressure on the fragmentation of the excited isobutane ion produced by the charge transfer from the nitrogen ion; the previously-proposed mechanism of the fragmentation is confirmed.

Experimental

The isobutane was supplied by the Takachiho-Shoji Co.; its gas chromatographic analysis showed the presence of 5×10^{-4}% C_2H_6 as an impurity. The ammonia and sulfur hexafluoride were both of high purity and were used without further purification. The nitrogen was 99.99% pure.

The samples were irradiated with γ rays from ^{60}Co at a dose rate of 2.26×10^5 rad/hr and with a total dose of 1.13×10^5 rad at room temperature. The energy absorbed in nitrogen was measured by Fricke dosimetry.

The reaction at a nitrogen pressure of 0.66 atm was carried out in a 350 cc glass cylinder, while those at nitrogen pressures above 1 atm were carried out in a stainless-steel autoclave (45 cc). The products were analyzed by a Hitachi K 53 gas chromatograph equipped with a flame ionization detector (activated alumina column, 2 m, 100°C).

Results and Discussion

Sensitization by Nitrogen. The *G*-value of propane in the radiolysis of N_2(100 atm)-*iso*C_4H_{10} (0.0153 mol/mol of N_2) mixtures amounts to 46 if the value is expressed by the number of product molecules per 100 eV directly absorbed on isobutane. Since the $G(C_3H_8)$ value is 2—3 in the radiolysis of pure isobutane,[2] it may be reasonable to consider that most of the propane in the radiolysis of N_2-*iso*C_4H_{10} mixtures is formed by the sensitization of nitrogen. A similar sensitization was previously

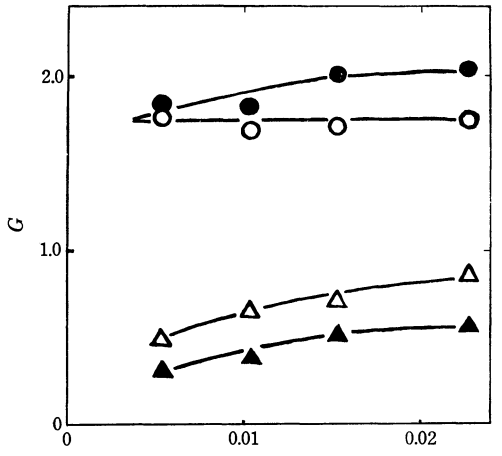

Fig. 1. Effect of increasing concentration of isobutane on the nitrogen sensitization at constant nitrogen pressures of 0.66 and 100 atm.
—●— C_3H_8 at 0.66 atm of N_2
—○— C_3H_8 at 100 atm of N_2
—▲— C_3H_6 at 0.66 atm of N_2
—△— C_3H_6 at 100 atm of N_2

found in the radiolysis of the N_2 - n-C_4H_{10} system.[6] Therefore, the G-values of products are expressed in this paper by the number of product molecules per 100 eV absorbed on nitrogen. The effect of an increase in the concentration of isobutane on the yields of propane above a 0.0153 mol ratio of isobutane suggests that the sensitization by nitrogen may be completed above this concentration (Fig. 1).

Mechanism of Nitrogen Sensitization. The ionic processes of the sensitization were studied by using ammonia as a scavenger of the carbonium ion and sulfur hexafluoride as an electron scavenger. The effect of ammonia on the radiolysis of N_2 (100 atm) - $iso C_4H_{10}$ (0.0153 mol/mol of N_2) - SF_6 (0.003 mol/mol of N_2) mixtures is shown in Fig. 2. Since the neutralization reaction of the stable butane ion ($C_4H_{10}^+$) is suppressed by the presence of sulfur hexafluoride, the reactions of the excited butane ion, such as reactions (3) and (4), can be studied by the addition of ammonia.[3,4] The marked decrease in propane and the increase in propylene upon the addition of ammonia is due to the following reactions of the $C_3H_7^+$ ion with ammonia:

$$N_2 \rightsquigarrow N_2^+ + e \quad (1)$$

$$N_2^+ + i\text{-}C_4H_{10} \rightarrow C_4H_{10}^{+**} + N_2 \quad (2)$$

$$C_4H_{10}^{+**} \rightarrow C_3H_7^+ + CH_3 \quad (3)$$

$$C_3H_7^+ + i\text{-}C_4H_{10} \rightarrow C_3H_8 + C_4H_9^+ \quad (4)$$

$$C_3H_7^+ + NH_3 \rightarrow C_3H_6 + NH_4^+ \quad (5)$$
$$\searrow\ C_3H_7NH_3^+ \quad (6)$$

The similar phenomenon was also observed in the gas-phase radiolysis of the n-butane-ammonia system.[7] Since the ionization potential of nitrogen is 15.6 eV, and since that of isobutane is 10.6 eV,

7) T. Miyazaki and S. Shida, This Bulletin, **38**, 2114 (1965).

the $C_4H_{10}^{+**}$ ion formed by the charge transfer from the nitrogen ion has an excitation energy of 5 eV, much higher than the bond energy of the C–C bond (0.61 eV).

The effect of sulfur hexafluoride on the radiolysis of N_2(100 atm) - *iso*C_4H_{10}(0.0153 mol/mol of N_2) mixtures is shown in Fig. 3. Propane increases upon the addition of sulfur hexafluoride, while propylene decreases. The results in Table 1, however, show that propylene does not decrease upon the addition of sulfur hexafluoride in the nitrogen sensitization at 10 and 40 atm, while propane increases. Therefore, the variations in the yields of propane and propylene upon the addition of sulfur hexafluoride may be due to the different mechanisms. One possible mechanism of the slight increase in propane may be as follows:

TABLE 1. EFFECT OF PRESSURE OF NITROGEN ON THE FRAGMENTATION OF ISOBUTANE[a)]

	Pressure of N_2, atm					
	0.66	10	40	70	100	130
	isoC_4H_{10}[b)] system					
C_3H_8	2.01	2.15	2.26	2.22	1.71	1.88
C_3H_6	0.51	0.42	0.55	0.70	0.71	0.89
	isoC_4H_{10}[b)]-SF_6[c)] system					
C_3H_8	2.08	2.36	2.46	2.41	2.06	2.11
C_3H_6	0.60	0.49	0.52	0.45	0.42	0.51
	isoC_4H_{10}[a)]-SF_6[c)]-NH_3[d)] system					
C_3H_8	0.79	0.87	0.89	0.89	0.47	0.52
C_3H_6	0.99	1.19	1.28	1.35	1.21	1.02

a) Yields are expressed as the number of product molecules per 100 eV absorbed in nitrogen.
b) Concentration of *iso*C_4H_{10} is 0.0153 mol/mol of N_2.
c) Concentration of SF_6 is 0.003 mol/mol of N_2.
d) Concentration of NH_3 is 0.003 mol/mol of N_2.

$$N_2 \rightsquigarrow N_2^+ + e \quad (1)$$
$$\rightsquigarrow N_2^* \quad (7)$$
$$N_2^+ + e \rightarrow N_2, 2N \text{ or } N_2^* \quad (8)$$
$$N_2^+ + i\text{-}C_4H_{10} \rightarrow C_4H_{10}^{+**} + N_2 \quad (2)$$
$$e + SF_6 \rightarrow SF_6^- \quad (9)$$

If the recapture of electrons by nitrogen (reaction (8)) is notable even at 10 atm of nitrogen, the reaction (8) is retarded in the presence of sulfur hexafluoride by reaction (9) and reaction (2) is facilitated.

Another possible mechanism of the increase in propane may be as follows: As an excited agron reacts with sulfur hexafluoride,[8)] a highly-excited nitrogen molecule may react with sulfur hexafluoride in a similar fashion to form the nitrogen molecule ion; therefore, the yield of N_2^+, that is, that of $C_4H_{10}^{+**}$, increases upon the addition of sulfur hexafluoride:

$$N_2^* + SF_6 \rightarrow N_2^+ + SF_6^- \quad (10)$$

Effect of Pressure on the Fragmentation of the Excited Butane Ion. The yields of the $C_3H_7^+$ ion are obtained by using the results in Table 1 and the following relationship[4)]:

$$G(C_3H_7^+) = G(C_3H_8) \text{ in the } N_2\text{-}iso C_4H_{10}\text{-}SF_6 \text{ system} - G(C_3H_8) \text{ in the } N_2\text{-}iso C_4H_{10}\text{-}SF_6\text{-}NH_3 \text{ system}$$

$G(C_3H_7^+)$ shows a constant value of 1.55, even if the pressure of nitrogen varies from 0.66 to 130 atm (Fig. 4). In the mass spectrum of isobutane upon the bombardment of electrons with 14—15 eV energy, the fraction of $C_3H_7^+$ amounts to 65% of all the ions.[9)] Taking $W(N_2)$ as 36.3 eV, it may be expected that $G(C_3H_7^+)=1.79$ in the fragmentation of isobutane by nitrogen sensitization. The $G(C_3H_7^+)$ obtained in the sensitization is obviously in agreement with the mass spectrometric value.

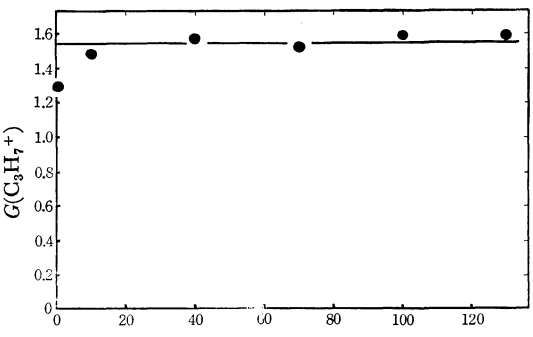

Fig. 4. Effect of pressure of nitrogen on the yields of $C_3H_7^+$ ion formed by the fragmentation of excited isobutane ion.

It has been reported[10)] that nitrogen acts as an efficient quencher of the fragmentation of the excited butane ion which is formed by the photoionization at 1048 A (11.8 eV), and that the quenching cross section of nitrogen is a seventh that of butane. As is shown in Fig. 4, the yield of the $C_3H_7^+$ ion is constant and the following deactivation reaction of the excited isobutane ion does not occur, even at 130 atm of nitrogen:

$$C_4H_{10}^{+**} + N_2 \rightarrow C_4H_{10}^+ + N_2 \quad (11)$$

It may be concluded that the excited isobutane ion with 5 eV excess energy decomposes very fast, probably in the period of one vibration, before the collisons with nitrogen. On the contrary, Ausloos *et al.*[9)] reported that the excited isobutane ion with 1.2 eV excess energy decomposes slowly and is

8) H. Hotop and A. Niehaus, *J. Chem. Phys.*, **47**, 2506 (1967).
9) S. G. Lias and P. Ausloos, *ibid.*, **48**, 392 (1968).
10) P. Ausloos and S. G. Lias, *ibid.*, **45**, 524 (1966).

collisionally deactivated by isobutane of 0.033 atm, which corresponds to a nitrogen pressure of 0.23 atm.

This large difference in the rates of fragmentation of the excited isobutane ions can be explained by the following proposed mechanism[5]: When the ion is highly excited and when the mean excitation energy per C–C bond exceeds its bond energy, the excited ion decomposes in one vibration. When the ion is little excited and when the mean excitation energy per C–C bond does not exceed its bond energy, the excited ion decomposes slowly according to the quasi-equilibrium theory. Since there are three C–C bonds in the isobutane ion, the mean excitation energy per C–C bond of the ion with 5 eV excess energy will be 1.7 eV, higher than the C–C bond energy (0.61 eV), and that of the ion with 1.2 eV excess energy will be 0.4 eV. Consequently, the former excited ion may decompose quickly, in one vibration, while the latter may do so more slowly because of the time lag needed for the accumulation of the excitation energy in a particular bond.

Infrared Spectra of Partially Deuterated Acetamide

Toyozo UNO, Katsunosuke MACHIDA and Yutaka SAITO

Faculty of Pharmaceutical Sciences, Kyoto University, Sakyo-ku, Kyoto

(Received August 17, 1968)

The infrared spectra of orthorhombic crystals of CH_3CONH_2, CD_3CONH_2, and their *N*-deuterated and partially *N*-deuterated samples have been recorded in the region between 4000 and 400 cm^{-1}. The bands due to the *trans*- and *cis*-NHD species have been assigned by comparing the spectra of various samples containing the NH_2, ND_2 and NHD species in different proportions. In the spectra of the 50% *N*-deuterated samples, the absorption bands near 1530 and 1360 cm^{-1} have been assigned to the amide II and III modes, respectively, of the *trans*-NHD species characteristic of the *trans* conformation of the –CONH– group, and those near 1480 and 1400 cm^{-1} to the NH in-plane deformation and the CN stretching modes, respectively, of the *cis*-NHD species. These assignments were confirmed by the normal coordinates analysis of eight isotopic species of acetamide based on the Urey-Bradley force field.

The hydrogen atoms in the amide group of acetamide are easily substituted by deuterium atoms by the exchange reaction with heavy water. If a mixture of water and heavy water is used in the exchange reaction, the resulting samples should contain the molecular species involving the NH_2, ND_2 and NHD groups. This report presents the assignment of infrared absorption frequencies of the NHD species of acetamide and *C*-deuterated acetamide obtained by this partial *N*-deuteration. As shown in Fig. 1, there are two geometrical isomers of the NHD species arising from the planarity of amide group. Molecular vibrations of these NHD species are of interest because of their structure involving the biochemically important –CONH– group. Our attention was drawn to this point first by observing a strong band near 1520 cm^{-1} in the infrared spectra of incompletely deuterated primary amides and noticing an analogy between this band and the amide II band of *trans*-*N*-monosubstituted amides.

It is well known that the conformation of the C=O and the NH bonds is an important factor determining the vibration modes and frequencies of the –CONH– group. The amide II and III frequencies arising from the coupling between the CN stretching and the NH in-plane deformation vibrations are observed only for the trans conformation.[1] Miyazawa has calculated the normal vibrations of the hypothetical *cis* form of *N*-methylacetamide using the Urey-Bradley force constants which reproduce the observed frequencies of the *trans* form, and has obtained almost pure CN stretching and the NH in-plane deformation vibrations instead of their coupled vibrations.[2] Since the *trans*- and *cis*-isomers of the NHD species in the present study have exactly the same force field with each other, they are expected to afford experimental evidences of the change of vibrational modes given rise to by the purely geometrical effect on the –CONH– group.

Experimental

Commercially available acetamide was purified by the crystallization from ether and ethanol solutions. *C*-Deuterated acetamide was prepared by the reaction between NH_3 gas and CD_3COCl, in ether at −20°C, and was purified by the same way as acetamide. For the preparation of CD_3COCl, commercially available CD_3COOD (Merk AG. Darmstadt) was treated with benzoyl chloride according to Bender's method.[3] These NH_2 compounds were converted into the corresponding ND_2 compounds by the exchange reaction with heavy water. The partially *N*-deuterated samples were prepared by using mixtures of water and heavy water in various proportions.

The infrared spectra were recorded on Koken DS 301 infrared spectrophotometer equipped with sodium chloride (4000—700 cm^{-1}) and potassium bromide (700—400 cm^{-1}) prisms. The measurement was made for the orthorhombic crystal obtained by the crystallization from molten liquid[4] between two potassium bromide plates or between two sodium chloride plates. The crystal form of the partially *N*-deuterated samples prepared in the same way was confirmed to be orthorhombic from the absorptions of the NH_2 species contained in the samples. The absorptions of the ND_2 species in the partially *N*-deuterated samples were then used to identify the crystal form of the almost completely *N*-deuterated samples. It was also found from the comparison of infrared spectra that the orthorhombic crystal was converted into the trigonal crystal on mulling with Nujol or hexachlorobutadiene.

Results and Discussion

A detailed assignment of the infrared absorption bands of acetamide, *C*-deuterated acetamide and their ND_2 species have been given by Suzuki on the basis of the normal coordinates analysis of the a′ vibrations.[5] Although the crystal spectra reported by Suzuki are those of the trigonal form, most of his assignments for the NH_2 and ND_2 species are applicable to the presently investigated orthorhombic form because the infrared absorptions of these two forms are not seriously different from each other.[6] The trigonal form is better than the orthorhombic one to prevent the sample from atmospheric water and to maintain the orginal concentration of the *N*-deuterated species, since the Nujol and hexachlorobutadiene mulls can be prepared more quickly than the crystal film. For investigating the spectral change around 1500 cm^{-1} on successive *N*-deuteration, however, the orthorhombic form was found to be more appropriate since it showed much sharper absorption bands in this region than the corresponding bands of the trigonal form. In Figs. 2—5, the infrared spectra of orthorhombic form of acetamide and *C*-deuterated acetamide obtained from a equimolar mixture of

water and heavy water are shown together with the spectra of the corresponding NH_2 and ND_2 species. We assumed that this mixture gave approximately rise to the deuteration of 50% of amide hydrogen atoms in the whole sample and the resulting crystal included the NHD species in the maximum concentration attainable. The absorption bands due to the NH_2 and ND_2 species appearing in the spectra of this 50% *N*-deuterated samples can be differentiated from those due to the NHD species by referring to the spectra of the NH_2 and ND_2 species. Observed frequencies and assignments are listed in Table 1.

4000—1800 cm^{-1}. The strong bands near 3300 and 2400 cm^{-1} observed for the 50% *N*-deuterated sample of acetamide are assigned to the NH and ND stretching vibrations, respectively, of the NHD compounds. The appearance of these NX (X=H or D) stretching frequencies between the symmetric and antisymmetric NX_2 stretching frequencies is to be expected from the removal of the vibrational coupling between two equivalent NX bonds. The ND stretching band consists of two peaks attributable to the *trans*- and *cis*-NHD species, but the NH stretching band does not show any splitting. A broad band near 2800 cm^{-1} observed for orthorhombic acetamide disappears on *N*-deuteration but does not disappear on *C*-deuteration.

1800—1200 cm^{-1}. In the region between 1700 and 1600 cm^{-1} where the C=O stretching and the NH_2 bending frequencies are expected, the orthorhombic crystal of acetamide shows a strong absorption band consisting of a peak at 1640 cm^{-1} and a

shoulder at its high frequency side. Since the assignment of both the peak and the shoulder to fundamentals was found to be necessary from a slight high frequency shift of the apparent absorption maximum on 50% *N*-deuteration, we divided the whole absorption of acetamide into two Lorenz type components, and estimated the position of the unobserved peak of the high frequency component to be 1665 cm^{-1} (Fig. 3-A). Similarly, the high frequency component of the corresponding absorption of *C*-deuterated acetamide was estimated to be 1655 cm^{-1} (Fig. 3-B).

Each of 50% *N*-deuterated samples of acetamide and *C*-deuterated acetamide shows clearly two bands at 1530 and 1328 cm^{-1} attributable to the NHD species. From analogy in the conformation between the *trans*-NHD species and *trans*-*N*-monosubstituted amides, it is conceivable that the CN stretching and the NH in-plane deformation vibrations of the *trans*-NHD species couple appreciably with each other and give rise to the amide II and III bands at 1530 and 1327 cm^{-1},

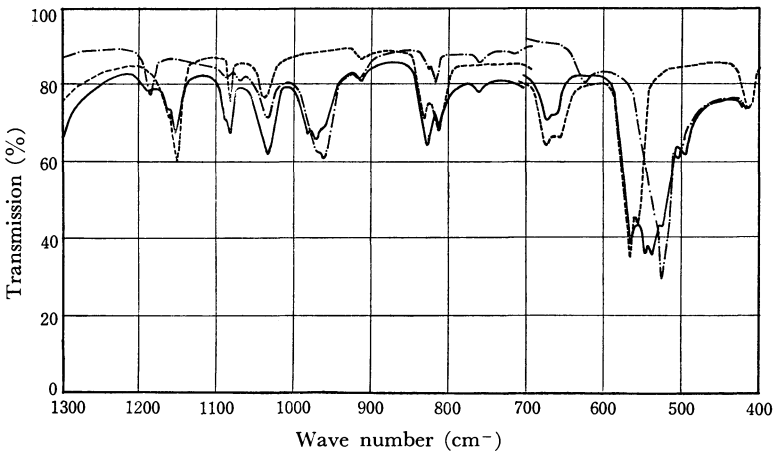

Fig. 5. Infrared spectra of *C*-deuterated acetamide in the region between 1300 and 400 cm^{-1}.

respectively. The frequencies of these bands are comparable with the amide II and the amide III frequencies (1566 and 1301 cm^{-1}, respectively) of *N*-methylacetamide[2] crystal at +15°C. The absorption bands due to the *cis*-NHD species may be found from analogy to *cis*-*N*-monosubstituted amides, for which the coupling between the CN stretching and the NH in-plane deformation vibrations is not appreciable. Supposedly, the NH in-plane deformation frequencies of *cis*-CH_3CONHD and *cis*-CD_3CONHD are not far from the corresponding frequency of diketopiperazine crystal (b_u: 1443 cm^{-1}).[7] For each of 50% *N*-deuterated samples of acetamide and *C*-deuterated acetamide, we observed an absorption band near 1480 cm^{-1} assignable to the NH in-plane deformation vibration of *cis*-NHD species. The intensity change of this absorption on the progress of *N*-deuteration was not obvious for *cis*-CH_3CONHD because of the overlap of the CH_3 degenerate deformation band at 1453 cm^{-1}. It was recognized clearly, however, for *cis*-CD_3CONHD which did not show any interfering fundamental in this region.

1200—400 cm^{-1}. For both acetamide and *C*-deuterated acetamide, most of the bands observed between 1200 and 700 cm^{-1} for the 50% *N*-deuterated samples appear also in the spectra of either the NH_2 or ND_2 species. This result seems to contradict with the fact that the ND in-plane deformation (amide III') mode of both *trans*- and *cis*-NHD species has an intrinsic frequency around 1000 cm^{-1} and is likely to couple with other modes having similar intrinsic frequencies. The normal coordinate analysis discussed in the following section ascertained, however, that the absorptions due to the NHD species overlap considerably with those due to the NH_2 or the ND_2 species.

As seen in Fig. 4, the NCO deformation band of acetamide at 586 cm^{-1} splits into four bands on 50% *N*-deuteration. This fact suggests that the NCO deformation frequencies of the NH_2, ND_2, *trans*-NHD and *cis*-NHD species are different from one another. The middle two bands observed at 568 and 556 cm^{-1} can be assigned to the NHD species. Similar splitting on 50% *N*-deuteration are observed for the NCO deformation band at 566 cm^{-1} of *C*-deuterated acetamide in Fig. 5 and for the CC' deformation band at 466 cm^{-1} of acetamide in Fig. 4.

Normal Coordinate Analysis

On assigning the infrared absorption bands of CH_3CONHD and CD_3CONHD from analogy with *N*-monosubstituted amides, we assumed that the vibrational modes of the –CONH– group were not much affected by the change in the *N*-substituent atom from carbon to deuterium. In order to verify this assumption, we carried out the normal coordinate analysis of the eight isotopic species of acetamide formed by the combination of the CH_3 and CD_3 groups with the NH_2, *trans*-NHD, *cis*-NHD and ND_2 groups. The ***G*** matrices were set up by using the structural parameters based

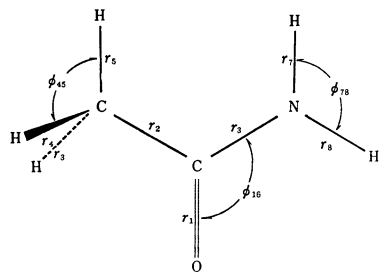

Fig. 6. Molecular structure and internal coordinates of acetamide.

on Hamilton's X ray study[4] as shown in Table 2. The description of the internal coordinates is shown in Fig. 6, and the internal symmetry coordinates are listed in Table 3. A simple Urey-Bradley force field was employed first but an interaction constant between the two NH stretching coordinates in the NH_2 group, P(NH–NH), was introduced after several trial calculations. The stretch-stretch interaction constant of this type was first introduced for methyl group[8] and water[9] as a supplementary

constant in the Urey-Bradley force field. In the present calculation, this force constant was preferred to the repulsion constant F(HNH) in fitting the NH_2 asym. and sym. stretching frequencies simultaneously. The force constants other than K(NH) and K(CH) were initially taken from Suzuki's work.[5] At the first step of the force constant refinement, only the frequencies of the NH_2 and ND_2 species and the frequencies higher than 1200 cm^{-1} of the NHD species were taken into account, and the values of K(NH), K(CH), K(CO), K(CN) and K(CC) were adjusted by referring to the Jacobian matrix elements. The stretching constants as well as the bending and repulsion constants concerned with hydrogen atoms were refined next by the least squares method for these frequencies. After this refinement, the absorption frequencies below 1200 cm^{-1} attributable to the NHD species were assigned to the vibrational modes of either the *trans* or *cis* species by referring to the calculated frequencies. This assignment was checked by the product rule and independently by the sum rule for isotopic molecules,[10] by as-

suming the unobserved CC' deformation frequencies for CD_3COND_2 and *trans*- and *cis*-CD_3CONHD to be the same as the calculated frequencies. The theoretical product rule ratios were obtained from the calculated frequencies. Both the product rule and the sum rule are well satisfied by the assigned frequencies as seen in Table 4. Then at the final step, we added the interaction constant P(NH–NH) with the initial value of zero, fixed the repulsion constant F(HNH) to zero, and refined all other force constants simultaneously to obtain a converged set. The force constants used in the final calculation are shown in Table 5 together with their dispersions. Tables 6—9 show the frequencies calculated from these force constants, the corresponding observed frequencies and the potential energy distributions. The agreement between the calculated and the observed frequencies are quite excellent throughout all isotopic species. It is seen from Table 7 that the coupling between the NH in-plane deformation and the CN stretching vibrations takes place only for the *trans*-NHD species just as shown by the calculation for *N*-methylacetamide.[1)]

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 905—908 (1969)

Some Experiments on the Triplet State Mechanism of the Spectral Sensitization of Poly(vinyl cinnamate) and Its Application for Searching New Sensitizers*[1]

Minoru TSUDA

Government Chemical Industrial Research Institute, Tokyo, Hiratsuka, Kanagawa

(Received August 17, 1968)

The spectral sensitization of poly(vinyl cinnamate) is considered to occur by the triplet energy transfer from sensitizer to the cinnamoyl group of the polymer. The triplet state mechanism is useful for finding new sensitizers. Some new sensitizer were found on the basis of the theory, and the results may verify the mechanism.

Ultraviolet light irradiation on poly(vinyl cinnamate) reduces the solubility of the polymer according to the dose of light. The main response of cinnamic acid and its esters to photons is believed to be their dimerizations. The dimerization of cinnamoyl groups attached to polymers results in crosslinking of the polymer, which produces the insolubilization of the polymer.

The photosensitivity of poly(vinyl cinnamate) is limited to wavelengths shorter than 340 mμ, but the addition of some organic compounds confers sensitivity on the portion of the spectrum absorbed by those compounds;[1,2] hence, these compounds are spectral sensitizers. The experimental fact that the better sensitizers are aromatic nitro compounds and aromatic cabronyl compounds, suggests that the energy transfer may occur from the triplet state (T-state) of sensitizers to that of the cinnamoyl group (Fig. 1). The proposed mechanism clearly explained the experimental results on the sensitivities of mixed sensitizers which have different lowest triplet levels.[3] In the present paper we will report a search for new sensitizers based on the T-state mechanism; this will be a test for the mechanism.

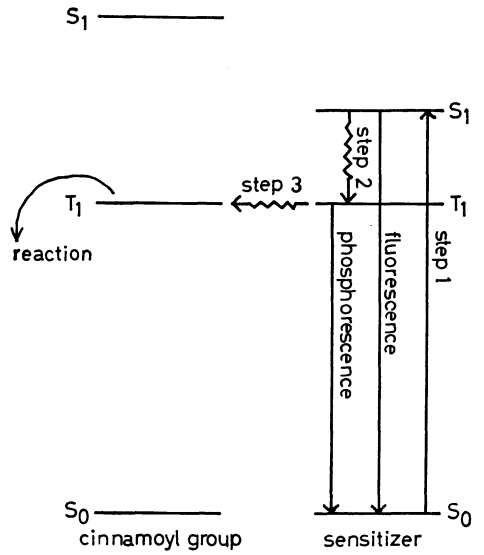

Fig. 1. Energy transfer diagram in spectral sensitization of poly(vinyl cinnamate).

*1 Presented at the International Conference on Photochemistry, Tokyo, August 28, 1965. This paper is a part of the Doctoral Thesis submitted by the author to the University of Tokyo, 1966.

Experimental

Poly(vinyl cinnamate) was prepared by the method reported in previous papers.[4] The polymer was purified by precipitation in methanol.

2,6-Dichloro- and 2,6-Dibromo-*N*,*N*-dimethyl-4-nitroaniline. Br_2(3.7 g) or Cl_2(0.92 g) was added into a methanol (200 ml) solution of *N*,*N*-dimethyl-4-nitroaniline (1.7 g), and the solution was refluxed for 2.5 hr. A large portion of methanol was distilled off, and crystals formed on standing. Recrystallized from ethanol.

Br-Derivative: mp 113.5—114.5°C. Found: C, 29.55; H, 2.40; N, 8.79; Br, 50.88%. Calcd for $C_8H_8N_2O_2Br_2$: C, 29.66; H, 2.49; N, 8.65; Br, 49.33%.

Cl-Derivative: mp 106—107°C. Found: C, 40.72; H, 3.71; N, 11.54; Cl, 29.71%. Calcd for $C_8H_8N_2O_2Cl_2$: C, 40.88; H, 3.43; N, 11.92; Cl, 29.71%.

***N*-Acetyl-4-nitro-1-naphthylamine.** 4-Nitro-1-naphthylamine (2 g) dissolved in acetic anhydride (70 ml) was heated at 100°C for 2 hr. On cooling crystals formed, which were recrystallized from ethanol.

4) M. Tsuda, *Makromol. Chem.*, **74**, 174, 183 (1964).

Mp 191.5—192°C. Found: C, 62.75; H, 4.44; N, 11.85%. Calcd for $C_{12}H_{10}N_2O_3$: C, 62.60; H, 4.38; N, 12.16%.

***N*-Benzoyl-4-nitro-1-naphthylamine.** 4-Nitro-1-naphthylamine (1.88 g) dissolved in methyl ethyl ketone (75 m*l*) and benzoyl chloride (1.55 g) were added to 10% aqueous NaOH solution (75 m*l*), and then vigorously agitated for 20 min. After standing, the upper layer was separated and methyl ethyl ketone was distilled off. The residue was recrystallized from ethanol. Mp 238—238.5°C. Found: C, 69.97; H, 4.37; N, 9.55%. Calcd for $C_{17}H_{12}N_2O_3$: C, 69.84; H, 4.14; N, 9.59%.

Other Substances. Guaranteed grade substances from Tokyo Kasei Co., Ltd. were recrystallized. Their melting points agreed with the literature values.

Sensitometry. Gray scale method proposed by Minsk *et al.*[7] was used. The gray scale used was a Kodak Step Tablet No. 2 calibrated by densitometer. The light source was a super high pressure mercury arc lamp (Toshiba SHL-100 UV). Picramide was used as a standard, assuming a relative sensitivity of 400.

Spectroscopy. Emission spectra were measured by a Hitachi EPM-2S type spectrometer, and absorption spectra were measured by Shimadzu IV-50 type spectrometer.

	F	0

P: phosphorescence, F: fluorescence

Emission Spectra and Sensitivity

Sensitizers of poly(vinyl cinnamate) may be phosphorescent. It is known that some compounds with similar structures to sensitizers do not sensitize. It was found that they do not phosphoresce but fluoresce as shown in Table 1. The failure to sensitize is easily understood in terms of the T-state mechanism, because, when step 2 in Fig. 1 does not occur, fluorescence only is observed and not phosphorescence.

Heavy Atom Effect

When heavy atoms are introduced into a molecule, step 2 of Fig. 1 is favored by the increase of the spin-orbit interaction. Therefore, we can expect an increase in the sensitizing effect of a sensitizer by the introduction of heavy atoms. At the same time the intensity of phosphorescence of the molecule is expected also to increase.

N,*N*-Dimethyl-4-nitroaniline is a sensitizer having a moderate sensitizing effect. It emits both fluorescence and phosphorescence rather strongly. Therefore, if heavy atoms are introduced into the molecule, we should obtain new sensitizers having

a strong sensitizing effect and showing strong phosphorescence. Phosphorescence spectra of *N,N*-dimethyl-4-nitroaniline (H), and its 2,6-dichloro (Cl), and 2,6-dibromo (Br) derivatives are shown in Fig. 2. The shapes of the spectra are very similar to each other.

It is noticed that the intensity of phosphorescence increases remarkably by replacing H with Cl, or with Br, and the sensitizing effect also increases as expected (Table 2).

Table 2. Heavy atom effect on sensitizers

Sensitizer	Relative sensitivity
	137
	561
	797

As the sensitizing effects are measured by the gray scale method using a super high pressure mercury are lamp as a light source, it may be considered that the exposure is due mainly to 365, 405 and 436 mμ lines considering the absorption spectra of these three sensitizers. The ratio of the intensities of these active lights emitting from the light source is 2.25 : 1 : 2.04, and the transmittances of the gray scale at those wavelengths are 55, 79, and 82%. With those corrections the relative yields of phosphorescence at these three wavelengths are obtained. The sum of the relative yields of phosphorescence at these three wavelengths plotted as the abscissa of Fig. 3 *vs.* the relative sensitivity as the ordinate produced a straight line. The relative sensitivity of the sensitizer is directly proportional to the relative yield of its phosphorescence within the limits of experimental error.

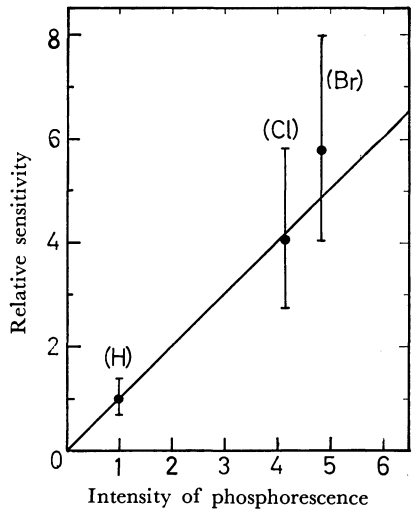

Fig. 3. Relationship between phosphorescence yields and relative sensitivities.

Energy of Triplet State

From the T-state mechanism, the sensitizing effect should be observed only when the energy of T_1 of the sensitizer is equal to or larger than that of the cinnamoyl group (Fig. 1). Therefore, there are some compounds which have not sensitizing effects in spite of their strong phosphorescence. For example, 4-nitro-1-naphthylamine phosphoresces strongly,[5] and its chemical structure is similar to 4-nitroaniline and α-nitronaphthalene (both are strong sensitizers), but it has no sensitizing effect.

Compounds having similar chemical structures may have a constant value of the gap between the peaks of their absorption spectra and the 0–0 bands of their phosphorescence spectra. The values are, for example, about 6000 cm^{-1} for the analogues of 4-nitroaniline and about 10000 cm^{-1} for the analogues of 4-nitrodiphenyl as shown in Table 3. Using this phenomenon, we may expect to change a non-sensitizer, 4-nitro-1-naphthylamine, into a sensitizer.

The peak of the absorption spectrum of 4-nitro-1-naphthylamine shifts toward the shorter wavelength region by *N*-acylation; so, the energy of

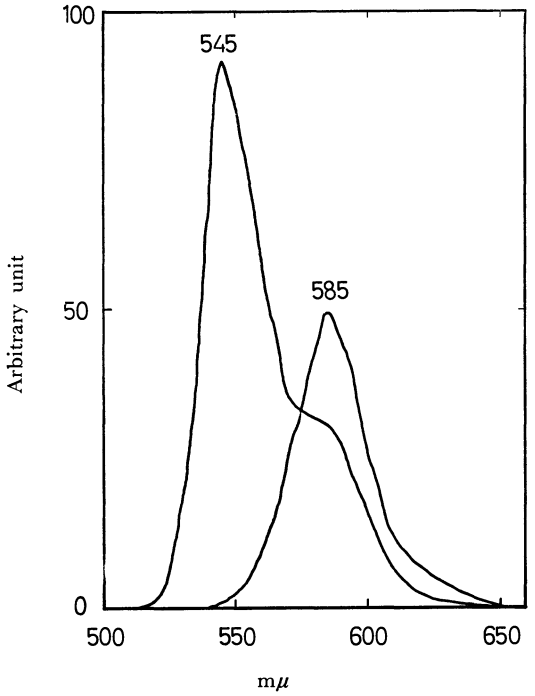

Fig. 4. Phosphorescence spectra of 4-nitro-1-naphthylamine (peak: 585 mμ) and *N*-acetyl-4-nitro-1-naphthylamine (peak: 545 mμ).
Conditions in measurements are different.

T_1 of the *N*-acylated derivative may increase, and get into the sensitizing region. *N*-Acetyl-4-nitro-1-naphthylamine and *N*-benzoyl-4-nitro-1-naphthylamine have really been found to have a strong sensitizing effect (Table 4). The phosphorescence spectra of 4-nitro-1-naphthylamine and its *N*-acetyl derivative are shown in Fig. 4. *N*-Acetyl-4-nitro-1-naphthylamine emits far stronger phosphorescence than 4-nitro-1-naphthylamine though Foster reported[5] that the latter phosphoresces strongly. The excitation spectra of both of them measured under the same conditions are shown in Fig. 5.

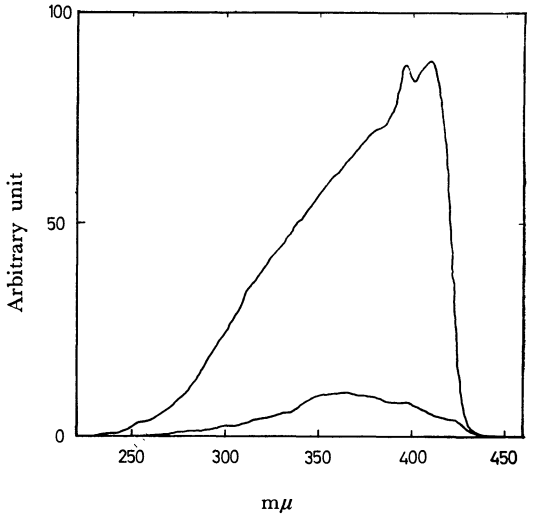

Fig. 5. Excitation spectra of 4-nitro-1-naphthylamine and *N*-acetyl-4-nitro-1-naphthylamine at the same conditions.
Analizer was set at the peak of Fig. 4. Figures of abscissa are the wavelength of excitation light. Conditions: *N*-acetyl-4-nitro-1-naphthylamine 0.944 mg/cc; 4-nitro-1-naphthylamine 0.957 mg/cc; Exciter slit width 3.5 mμ.

Conclusion

It is shown that some deductions from the T-state mechanism agree well with experimental facts. This strongly supports that the spectral sensitization of poly(vinyl cinnamate) occurs by the triplet energy transfer from sensitizers to the cinnamoyl group of the polymer. The theory is also useful for finding new sensitizers.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 909—913 (1969)

Photochemistry of Acetanilide. IV. The Photochemical Reactions in the Vapor Phase and Rigid Matrixes

Haruo SHIZUKA[1] and Ikuzo TANAKA

Laboratory of Physical Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received August 21, 1968)

The photolysis of acetanilide in the vapor phase at 2537 Å and 120°C has been studied by means of mass spectrometry, gas chromatography, and spectrophotometry. In the vapor phase, no such rearrangements of acetanilide as in the liquid phase occurred, only the decomposition of acetanilide. Carbon monoxide and ethane were formed as the main products, and the ratio of carbon monoxide to ethane was about 2. The quantum yield of the predissociation for the N–C bond of acetanilide in the vapor phase was estimated to be 0.28 from the data of the quantum yields for the formations of carbon monoxide and ethane. A small amount of methane and traces of hydrogen and benzene were also detected. The reaction scheme of acetanilide in the vapor phase at 2537 Å and 120°C has been proposed. On the other hand, the photochemical reactions of acetanilide in the rigid matrixes (MP, ME, and EPA) at −196°C and in the PVA sheet at room temperature have also been carried out by the use of a spectrophotometer and an ESR spectrometer. In the rigid matrixes at −196°C, the photochemical rearrangements did not occur, only the back reaction resulting in the distortional structure of acetanilide; this mechanism can be explained by the stiffness of the solvent cage. The cage effect on the photochemical reaction of acetanilide is also discussed.

In previous papers[2-4] on the photochemistry of acetanilide in the liquid phase, it has been shown that the photochemical rearrangement occurs due to the predissociation through the intersystem crossing ${}^3\sigma_0(\text{N–C}) \leftarrow S_1(\pi\pi^*)$, resulting in the fission of the N–C bond and the liberation of anilino and acetyl radicals and, subsequently, the recombination reactions between the pair radicals in a solvent cage.

In the liquid phase, in cyclohexane, for example, the cage effect on the recombination reactions which consist of the back reaction, *o*- and *p*-rearrangements is sufficiently large (the recombination ratio ≈ 0.9).[4] On the other hand, in the vapor phase where the solvent effect may be neglected,[5] it is expected that the recombination reactions do not occur, only the decomposition of acetanilide. However, the vapor pressure of acetanilide at room temperature is very low. In order to obtain a sufficient pressure for the vapor-phase photolysis, acetanilide should be heated at 120°C. Acetanilide does not decompose at 120°C without the radiation of UV light.

On the other hand, it is also interesting to investigate the photochemical reactions of acetanilide in rigid matrixes (MP, ME, and EPA) at −196°C and in a PVA sheet at room temperature, since the solvent cage consisting of these rigid matrixes may be expected to be very stiff.

This paper will report the photolysis of acetanilide in the vapor phase at 2537 Å and 120°C and the photochemical reaction of acetanilide in the rigid matrixes (MP, ME, and EPA) at 2537 Å and −196°C, and in PVA sheet at 2537 Å and room temperature; it will also include a discussion of the reaction schemes in these photochemical reactions.

Experimental

Materials. The acetanilide, ethanol, and ether were the same reagents as have been described in the previous papers.[2-4] The methanol was a Kantokagaku Co. G. R. product. The isopentane was a Tokyo Kasei G. R. product and was purified by passing it through silica gel and by distillation. The polyvinyl alcohol (PVA) was a Koso Chemical Co. G. R. product ($\overline{p} \sim 1500$).

Light Source and Actinometry. A low-pressure mercury lamp with a Vycor glass filter was used as the 2537 Å radiation source. Actinometry was carried out by in the same way as has been described in a previous paper.[2] The light intensity at 2537 Å was 7.85×10^{13} photons sec^{-1} in the vapor-phase photolysis.

Reaction Procedure and Analysis in the Vapor Phase. The cylindrical quartz reaction cell was 10 cm long and 4.3 cm in diameter and had a ground joint and a breakable seal. About 20 mg of acetanilide was put into the reaction cell. After degassing, the reaction cell was sealed off from the vacuum system, which was free from mercury in order to avoid mercury photosensitization. The reaction cell was then heated to 120°C by an electric heater (the vapor pressure of the acetanilide at 120°C was 1.4 Torr), and then the sample was irradiated at 2537 Å.

Acetanilide (mp 115°C, bp 305°C) did not decompose at 120°C without the radiation of UV light. After irradiation, the products were introduced from the reaction cell into the system for analysis. The mixture of noncondensable products at −196°C (carbon monoxide, methane, and hydrogen) was collected into the gas burette of the Toepler gauge and analysed by a mass spectrometer after its quantity had been measured.

The volatile compounds which are condensable in liquid nitrogen (−196°C) were trapped into a LeRoy still. C_2 compounds, such as ethane, ethylene, and acetylene, were then separated from the products with higher boiling points by vacuum distillation, and were collected into the Topeler gauge. After the measurement of their quantities, the mixture was transferred into a small tube with a rubber septum at one end. The C_2 compounds were analyzed by gas chromatography with a silica gel +5% squalane column (2 m long, at 70°C) and with an active-charcoal column (3 m long, at 160°C). The C_n compounds ($n \geq 3$), such as biacetyl and benzene, which had been trapped in the LeRoy still at −150°C, were also transferred into a small tube with a rubber septum at one end. The C_n compounds were analyzed by gas chromatography by means of a dinonyl phthalate column (1 m long, at 70°C) and with a dioctyl phthalate column (1 m long, at 86°C).

The residues of nonvolatile products at room temperature were resolved in ethanol and were measured with a spectrophotometer.

Reaction Procedure and Analysis in Rigid Matrixes. The photochemical reactions of acetanilide were carried out in degassed rigid solvents (MP, EPA, and ME)*1 at 77°K and in polyvinyl alcohol (PVA) sheet*2 at room temperature. The ultraviolet and visible absorption spectra were taken with a Shimadzu SV 50A spectrophotometer. In the photochemical reaction at −196°C, a quartz Dewar flask designed for the spectrophotometry was used as the reaction cell. ESR measurements were also made in degassed rigid solvents (methylcyclohexane and ethanol) at −196°C after irradiation with 2537 Å for 30 min by the use of a JES 3110 X.

In order to disperse acetanilide homogeneously into a PVA sheet (0.17 mm thick), it was immersed in an aqueous solution of acetanilide and then dried at 70°C. The spectral change of the acetanilide in the PVA sheet upon the irradiation at 2537 Å was measured.

*1 MP, methylcyclohexane : isopentane=2 : 1; EPA, ether : isopentane : ethanol=1 : 1 : 1; ME, methanol : ethanol=1 : 1.

*2 PVA sheet was preheated at 80°C. See Y. Tanizaki and S. Kubodera, *J. Mol. Spectry.*, **24**, 1 (1967).

Results and Discussion

Photolysis of Acetanilide in the Vapor Phase. The data on the photolysis of acetanilide in the vapor phase at 2537 Å and 120°C are presented in Table 1 and in Figs. 1 and 2. Table 1 shows the reaction products in the photolysis at a very low conversion (less than 1%).

TABLE 1. REACTION PRODUCTS IN THE PHOTOLYSIS OF ACETANILIDE

Product	Relative yield
CO	100
CH_4	1.4
H_2	Trace
C_2H_6	48
	Trace

Carbon monoxide and ethane were obtained as the main products, the ratio of carbon monoxide to ethane was about 2. The amount of methane was about 1.4% that of carbon monoxide. Traces of hydrogen and benzene were also detected, but ethylene, acetylene, biacetyl, and the rearrangement products (*o*- and *p*-amino acetophenones) were not observed.

Figure 1 shows the time dependence of the product formations for carbon monoxide and ethane as a function of the irradiation time. The quantum yields for the formations of carbon monoxide and ethane were 0.28 and 0.14 respectively.

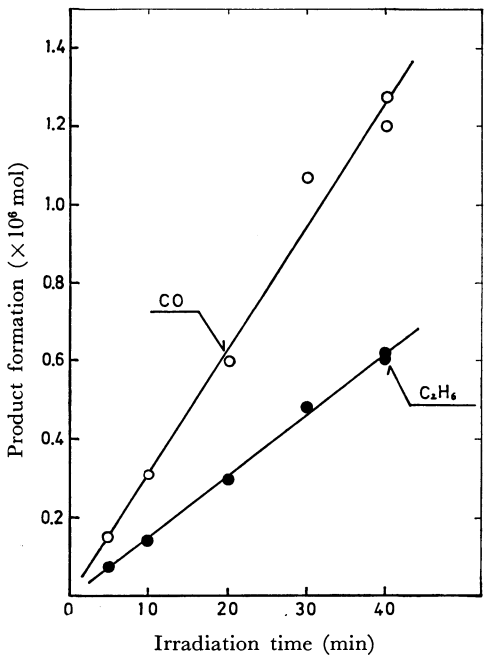

Fig. 1. Time dependence of product formations.

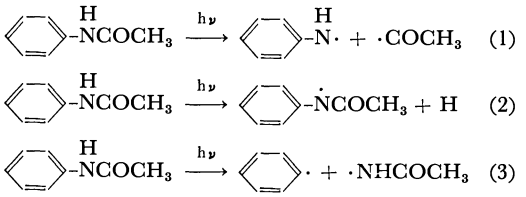
Figure 2 shows the spectral change in acetanilide in this photolysis; no rearrangement of acetanilide occurs in the vapor phase at 2537 Å, judging from the absence of any characteristic absorption bands of *o*- and *p*-amino acetophenones.[2]

Several reactions may be considered as the primary dissociation step in the photolysis of acetanilide:



(1)

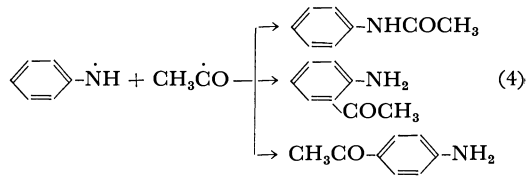
(2)

(3)

The experimental results on the formations of ethane and carbon monoxide as the main products give very strong evidence for the acetyl radical formation (Eq. (1)). The acetyl radical is known to decompose rapidly and exclusively to the methyl radical and to carbon monoxide above 100°C.[6] All the acetyl radicals formed here by Eq. (1) may, therefore, be assumed to decompose to methyl radicals and carbon monoxide molecules.

The formation of ethane can be explained by the recombination reaction between methyl radicals, and that of a small amount of methane, by the hydrogen-atom abstraction of the methyl radical. When a trace of NO (~0.1 Torr) was added to acetanilide, the formation of ethane was efficiently reduced. This result indicates that the methyl radical is formed in the photolysis of acetanilide and is scavenged by NO.

As has been described above, the rearrangement products of acetanilide were not observed in the vapor-phase photolysis. This means that no recombination reactions between anilino and acetyl radicals, such as the back reaction, *o*- and *p*-rearrangements (Eq. (4)), occurred because of the absence of a solvent cage in the vapor phase.



(4)

In view of the quantum yields for the formation of carbon monoxide and ethane, the dissociation quantum yield of acetanilide in the vapor-phase photolysis at 2537 Å and 120°C was estimated to be ~0.28, which is almost the same value as that obtained in the liquid phase (0.25).[4] It may be assumed that the predissociation by the intersystem crossing $^3\sigma_0(\mathrm{N\text{–}C}) \leftarrow S_1(\pi\pi^*)$ occurs in the vapor phase as well as in the liquid phase.

Thus, the reaction scheme of the photolysis of acetanilide in the vapor phase at 2537 Å and 120°C may be represented as follows:

$$S_0 + h\nu \longrightarrow S_2(\pi\pi^*) \quad (5)$$

$$S_2(\pi\pi^*) \xrightarrow{k_{IC}} S_1(\pi\pi^*) \quad (6)$$

$$S_1(\pi\pi^*) \xrightarrow{k_S} S_0 \quad (7)$$

$$S_1(\pi\pi^*) \xrightarrow{k_F} S_0 + h\nu' \quad (8)$$

$$S_1(\pi\pi^*) \xrightarrow{k_C} T_1(\pi\pi^*) \quad (9)$$

$$S_1(\pi\pi^*) \xrightarrow{k_{dis}} \dot{\phi}\text{-}\dot{N}H + \dot{C}OCH_3 \quad (10)$$

$$\dot{C}OCH_3 \xrightarrow{k_1} \dot{C}O + \dot{C}H_3 \quad (11)$$

$$2\dot{C}H_3 \xrightarrow{k_2} C_2H_6 \quad (12)$$

$$\dot{C}H_3 + RH \xrightarrow{k_3} CH_4 + R\cdot \quad (13)$$

Photochemical Reaction of Acetanilide in the Rigid Matrix. Figures 3(a) and 3(b) show the changes in the UV spectra of acetanilide in MP and ME degassed rigid matrixes at 2537 Å and −196°C respectively. In both cases, absorption band II decreased with the lapse of the irradiation time. The spectral change in acetanilide in the EPA rigid matrix is similar to that in ME. The absorption bands of the anilino radical (3088 Å) and the cation radical (4288 Å) which were observed in the photolysis of aniline[7] did not appear in the case of acetanilide. However, if the reaction cell was warmed up to room temperature after irradiation for 40 min in a MP rigid matrix, the spectral change of acetanilide was scarcely observed in a MP solution. Similar results were also obtained with a ME rigid matrix.

In order to detect the anilino and acetyl radicals, or the cation radical of acetanilide, ESR measurements of acetanilide in the rigid matrixes (degassed methyl cyclohexane and ethanol) at 2537 Å and −196°C were carried out, but no significant ESR signals were observed. The absence of the anilino radical and of the cation radical of acetanilide may be explained as follows:

1) The intersystem crossing $^3\sigma_0(\text{N–C}) \leftarrow S_1(\pi\pi^*)$, which produces anilino and acetyl radicals becomes less feasible at low temperatures due to the temperature dependence of the crossing probability. The acetyl radical can not escape from a solvent cage nor rearrange to the *o*- or *p*-position of the anilino radical. The only possible reaction is the back reaction, because the solvent cage in a glass at a low temperature is quite stiff.

2) The ionization potential of acetanilide (9.07 eV)[3] is larger than that of aniline (7.70 eV).[8]

From these results and considerations, it may be concluded that the spectral change in acetanilide in the rigid matrix at 2537 Å and −196°C was not caused by the *o*- and *p*-rearrangements, but by the back reaction between the pair radicals, resulting in the distorted structure of acetanilide (S_0'), which had only a little π-electron-conjugated system between anilino and acetyl groups. Equations (14) and (15) show the reaction scheme of the photochemical reaction of acetanilide in the rigid matrix at 2537 Å and −196°C.

$$S_1(\pi\pi^*) \xrightarrow{k_{dis}} (\dot{\phi}\text{-}\dot{N}H + \dot{C}OCH_3)\dagger \quad (14)$$

$$(\dot{\phi}\text{-}\dot{N}H + \dot{C}OCH_3)\dagger \longrightarrow S_0' \quad (15)$$

†: a stiff solvent cage.

When the reaction cell was warmed to room temperature, S_0' turned back to the ground state of acetanilide, S_0.

The photochemical reaction of acetanilide in

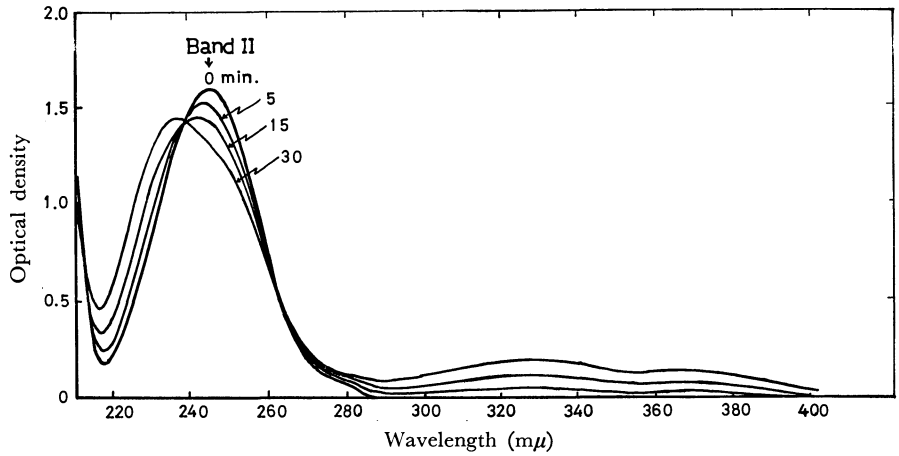

Fig. 4. Spectral change of acetanilide in PVA sheet at 2537 Å and room temperature.

the PVA sheet was observed by spectrophotometry at 2537 Å and at room temperature, as is shown in Fig. 4. Absorption band II decreased and new peaks at 325 and 365 mμ, which correspond to the *o*- and *p*-amino acetophenones respectively, appeared with an increase in the irradiation time. It is assumed that a pair of radicals can rearrange because the PVA matrix at room temperature contains an amorphous structure.

Table 2 shows the quantum yields for the formations of *o*- and *p*-amino acetophenones at 2537 Å in PVA, ethanol, and ME.

Table 2. The quantum yields at 2537 Å in PVA, ethanol, and ME

Solvent	Temp. °C	Quantum yield (Φ)		
		Φ_o	Φ_p	Φ_o/Φ_p
PVA	Room temp.	0.003_8	0.001_6	2.4
Ethanol[a)]	20	0.01_7	0.01_4	1.2
Ethanol	− 70	0.005_1	0.002_1	2.4
ME	−196	0	0	—

a) See Footnote 3.
Φ_o and Φ_p are the quantum yields for the formations of *o*- and *p*-amino acetophenones respectively at 2537 Å.

The quantum yields in the PVA sheet at room temperature decreased considerably in comparison with that in ethanol at 20°C. It seems that the back reaction in the PVA matrix is more predominant than the *o*- and *p*-rearrangements because the solvent cage in the PVA matrix is stiffer than that in ethanol at 20°C. The quantum yields in ethanol at −70°C were smaller than those in ethanol at 20°C. The dependence of the quantum yield in ethanol on the temperature from 20 up to 50°C has previously been described.[3,4)] The viscosity of ethanol in this range of temperature does not change very much, but it increases significantly at lower temperatures (*e.g.*, −70°C).[9)] Therefore, in addition to the effect of the activation energy (E_{dis} ~1.5 kcal/mol in ethanol)[4)] of the photochemical reaction of acetanilide, the cage effect becomes more important at lower temperatures because of the increasing stiffness of the solvent cage.

The ratios of Φ_o/Φ_p in PVA at room temperature and in ethanol at −70°C were about twice that of ethanol at 20°C. This indicates that the dependence of the *p*-rearrangement on the stiffness of the solvent cage is larger than that of the *o*-rearrangement because in a stiff solvent cage the *p*-positions of the anilino radical and the acetyl radical are separated by a longer path.

Conclusion

In the vapor phase at 2537 Å and 120°C, the decomposition of acetanilide took place, forming carbon monoxide and ethane ($CO/C_2H_6 \approx 2$) as the main products, instead of rearrangement. In the rigid matrix at −196°C, the rearrangements do not occur either, only the back reaction. These differences in the photochemical reaction of acetanilide are mainly caused by the cage effect on the recombination reactions between anilino and acetyl radicals formed by the intersystem crossing $^3\sigma_0$ (N–C)←$S_1(\pi\pi^*)$.

The authors are greatly indebted to Associate Professor Yuji Mori of the Tokyo Institute of Technology for his generous and very helpful discussions concerning this paper.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 914—918 (1969)

Solubility of Chlorine in Mixed Solutions of HCl and $CuCl_2$

Fumio HINE and Shusei INUTA

Training Institute for Engineering Teachers, Kyoto University, Uji, Kyoto

(Received August 23, 1968)

The solubility of chlorine in a mixed solution of HCl and $CuCl_2$ under various conditions of concentration, temperature, and partial pressure was determined. The concentration of chlorine in a solution as the sum of Cl_2 and Cl_3^- was found to be proportional to the partial pressure of chlorine in the gas phase; its slope decreased with an increase in the concentration of cupric ions due to the salting-out effect.

The recovery of chlorine from waste HCl is an attractive prospect, but the design engineer in this field requires data on systems consisting of HCl and Cl_2. The present authors have previously reported on the solubility of Cl_2 in concentrated HCl.[1)]

The HCl cell with the oxygen-depolarized cathode developed by Hine *et al.*,[2)] the so-called "Kyoto Process," contains a mixture of HCl and $CuCl_2$ in order to increase the reaction rate at the cathode represented by:

$$4H^+ + O_2 + 4e = 2H_2O \qquad (1)$$

where the cupric ions form a chloride complex such as $CuCl_3^-$ in concentrated HCl.[3)] The solubility of chlorine is, therefore, affected by the concentration of cupric chloride in the solution.

Experimental

The apparatus for vapor-pressure measurements reported by Smith *et al.*[4)] was modified.[5)] The temperature was controlled within a range of ± 0.1 °C; it caused a minor variation in the vapor pressure, but this variation was less than 3 mmHg at 90°C, for example.

The equipment and the flow sheet used for solubility measurements were the same as have previously been described.[1)]

The chlorine gas diluted with nitrogen to be sent to the measurement cell was exactly analyzed, and its moisture and temperature were brought to equilibrium before measurement.

The chlorine dissolved in the solution was titrated by iodometry. Since cupric ions in the solution also reacted on KI, the balance, total amount of KI consumed minus the amount of KI for Cu^{2+}, was taken. The cupric ions were also examined by iodometry. The compositions of the solutions examined are listed in Table 1.

Results and Discussion

Since the pressure of water vapor was not negligible in comparison with the total pressure, it was determined as a function of the temperature and of the composition of the solution. The data obtained are listed in Table 2, while an example of Dühring diagram of a system consisting of HCl and $CuCl_2$ is shown in Fig. 1. The logarithm of the vapor pressure is linear to the reciprocal temperature, $1/T$, as is shown in Fig. 2; therefore, the latent heat seems to be independent of the tempera-

ture between 30 and 90°C.

The solubilities of chlorine at various temperatures and concentrations were plotted against the partial pressure of chlorine. As the example in Fig. 3 shows, it is clear that the following Henry equation can be applied:

$$S_m = H_m \cdot p_{Cl_2} \tag{2}$$

where: S_m: the solubility of chlorine in a mixed solution mol/l
H_m: Henry's coefficient mol/l·atm
p_{Cl_2}: the partial pressure of chlorine atm

The Henry coefficient decreases with an increase in the concentration of cupric ions as is listed in Table 3. However, the slope of the logarithm of the H_m *vs.* $1/T$ curve is independent of the cupric ions, as is shown in Fig. 4. Therefore, the enthalpy change upon the dissolution of chlorine in a mixture of HCl and $CuCl_2$ is equal to that in a solution of HCl.[6]

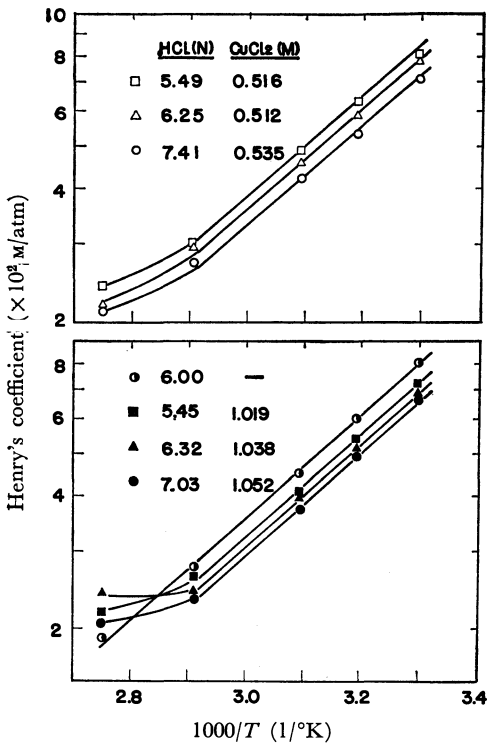

Fig. 4. Henry's coefficient at various conditions of temperature and concentration.

Let us discuss the single solution of HCl first. It is well known that a part of the chlorine forms trichloride complex ions, Cl_3^-, in a chloride solution, and that the other part may dissolve as its molecule, Cl_2.

The total amount of chlorine in HCl, as the sum of Cl_3^- and Cl_2, is a linear function of the HCl concentration and of the partial pressure in the gas phase, as has been described in a previous report,[1] that is,

$$S = H \cdot p_{Cl_2} = (\alpha x + \beta) p_{Cl_2} \tag{3}$$

where: S: the solubility of chlorine mol/l
$H = \alpha x + \beta$: Henry's coefficient mol/l·atm
x: the concentration of Cl^- mol/l
p_{Cl_2}: the partial pressure of Cl_2 atm
α and β: coefficients

Because the system consisting of Cl_2, Cl^-, and Cl_3^- is in a state of equilibrium, the concentration of Cl_3^- is proportional to x as follows:

$$(Cl_3^-) = K \cdot p_{Cl_2} \cdot x \tag{4}$$

where K is the equilibrium constant and where ( ) shows the concentration. Therefore, the concentration of Cl_2 can be represented by the balance of S minus (Cl_3^-); it is also linear to the concentration of Cl^- as follows:

$$(Cl_2) = [(\alpha - K)x + \beta] p_{Cl_2} \tag{5}$$

The effects of the electrolyte on the solubility of gas as its molecule have been studied by many authors[7,8] as the "Salting-Out Effect." They reached the important conclusion that a linear relationship exists between the logarithm of the solubility and the concentration of electrolytes in a solution.

At relatively low concentrations of HCl and in water, the data obtained at 25°C by Sherrill *et al.*[9] agree with Eq. (6), as is shown in Fig. 5.

6) See Eq. (12) in Ref. 1.
7) A. E.. Markham and K. A. Kobe, *Chem. Revs.*, **28**, 519 (1941).
8) H. Hikita, *Kagaku Kogaku (J. Chem. Eng. Japan)*, **23**, 537 (1959).
9) M. S. Sherrill and E. F. Izzard, *J. Am. Chem. Soc.*, **53**, 1667 (1931).

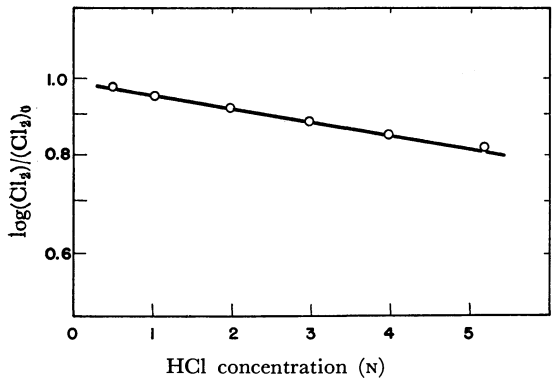

Fig. 5. Concentration of Cl_2 in HCl solution at 1 atm.

That is,

$$\log \frac{(Cl_2)}{(Cl_2)_0} = -kx \qquad (6)$$

where $(Cl_2)_0$ is the solubility of Cl_2 in pure water and where k is a constant and is very small (about 0.0183). Accordingly, the first approximation;

$$(Cl_2) = (Cl_2)_0 \cdot (1 - 2.303kx) \qquad (7)$$

is allowable with a variation of less than 2%. It is essentially the same as Eq. (5).

Zimmerman *et al.*[10] found the equilibrium constant, K, in Eq. (4) or (5) to be 0.01 at 25°C using the spectroscopic method; this value is in good agreement with that of Sherrill.[9] The relationship between K and T has been discussed in the previous report,[1] where the salting-out effect was not considered. Because the slope of the log K *vs.* $1/T$ curve is independent of the concentration of HCl, the value of K and, hence, that of $\alpha - K$ in Eq. (5) at various temperatures between 30 and 90°C can be predicted to be as listed in Table 4.

TABLE 4. K AND $(\alpha - K)$ (in mol/l·atm)

Temperature (°C)	$K \times 10^2$	$-(\alpha - K) \times 10^2$
30	0.845	0.215
40	0.620	0.186
50	0.462	0.158
70	0.273	0.093
90	0.172	0.067

With these values, the concentrations of Cl_2 and Cl_3^- shown in Fig. 6 are obtained. The solid line with open points shows the sum of chlorine dissolved at $p_{Cl_2} = 1$ atm; the data at 25°C, with the closed point, are quoted from the paper by Sherrill *et al.*[9] The thin line represents the concentration of Cl_2 predicted by Eq. (5) at a partial pressure of 1 atm. The closed points with the thin line are also based on Sherrill's data. Accordingly, the concentration of Cl_3^- can be evaluated as the balance of the two lines.

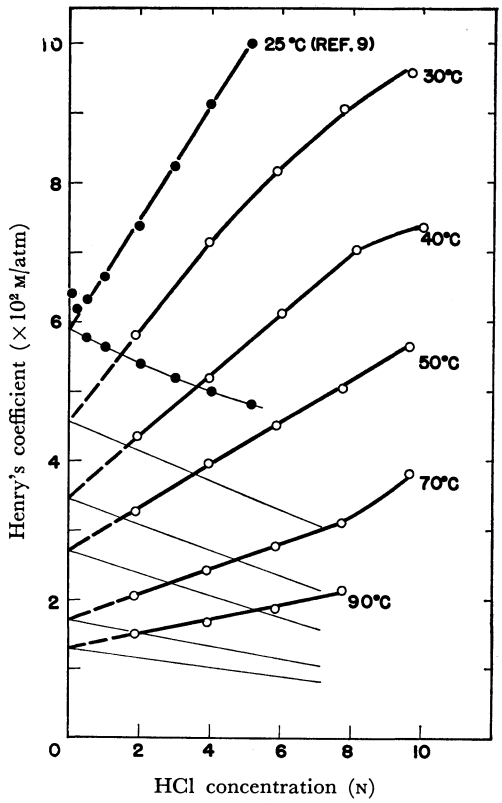

Fig. 6. Henry's coefficient as various conditions of temperature and HCl concentration.

The effect of cupric chloride on the solubility of chlorine in a mixture of HCl and $CuCl_2$ was also examined. The data obtained are shown in Fig. 7, where the ordinate is the Henry coefficient or the solubility at $p_{Cl_2} = 1$ atm and where the abscissa is the concentration of $CuCl_2$ in HCl. The concentrations of Cl_2 and Cl_3^- can be calculated by the procedure described above; the results are listed in Table 5, together with the Henry coefficients.

Now we may consider the mixed solution. It is well known that cupric ions form a chloride complex with HCl as follows:

$$CuCl_2 + Cl^- = CuCl_3^- \qquad (8)$$

This is according to Hine *et al.*,[8] who obtained the coordination number of the complex ion by means of EMF measurements. Therefore, the concentration of Cl^- in the solution decreases with an increase in the cupric ions; that is,

$$(Cl^-) = x - y \qquad (9)$$

where y is the concentration of cupric chloride in mol/l. By substituting this into Eq. (4), the next equation can be obtained:

$$(Cl_3^-) = K \cdot p_{Cl_2}(x - y) \qquad (10)$$

10) G. Zimmerman and F. C. Strong, *ibid.*, **79**, 2063 (1957).

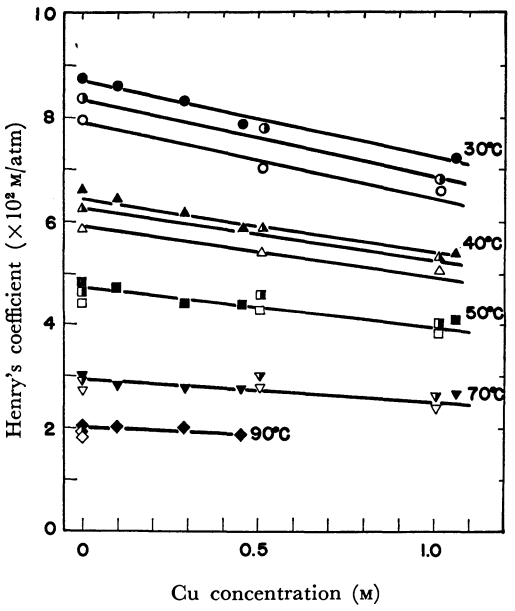

Fig. 7. Henry's coefficient at various conditions of temperature and concentrations of HCl and $CuCl_2$.
Closed point (●): 7.23 N HCl
Semi-closed point (◑): 6.25 N HCl
Open point (○): 5.49 N HCl

Table 5. Solubility of chlorine in 7.23 N HCl at $p_{Cl_2}=1$ atm (mol/l)

Temperture (°C)	$H\times10^2$	$(Cl_2)\times10^2$	$(Cl_3^-)\times10^2$
30	8.80	3.03	5.77
40	6.65	2.13	4.52
50	4.87	1.57	3.30
70	3.02	1.05	1.97
90	2.06	0.81	1.25

We may assume that (Cl_2) decreases with an increase in the concentration of cupric ions due to the salting-out effect, and that it can be represented by the following equation:

$$(Cl_2) = (a - by)p_{Cl_2} \tag{11}$$

where a and b are constants (a should be equal to $(\alpha-K)x+\beta$ because (Cl_2) is represented by Eq. (5) at $y=0$). Accordingly, the solubility of chlorine as the sum of Cl_2 and Cl_3^- can be formulated as follows:

$$S_m = (Cl_3^-)+(Cl_2) = [(\alpha x+\beta)-(K+b)y]p_{Cl_2} \tag{12}$$

From Eqs. (2), (3) and (12), we have:

$$b = \frac{H - H_m}{y} - K \tag{13}$$

Equation (13) represents the salting-out effect due to cupric chloride in the HCl solution on the solubility of chlorine; the data obtained are shown in Fig. 8. The logarithm of b is linear to $1/T$ with the slope of 2.

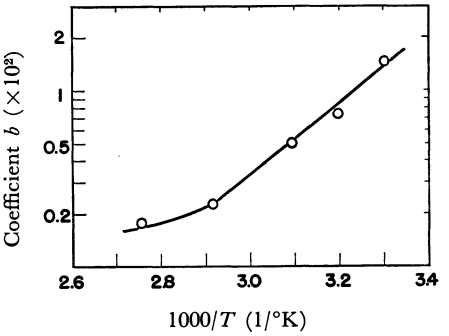

Fig. 8. The coefficient b as a function of temperature.

Equation (11) is an approximation of the next equation:

$$\log\frac{(Cl_2)}{(Cl_2)_0} = -k_m y \tag{14}$$

where k_m is a coefficient. As is shown in Fig. 7, k_m, and, hence, b in Eq. (11) are small and are functions of the temperature.

Summary

The vapor pressure of the aqueous solution consisting of HCl and $CuCl_2$ was measured. The solubility of chlorine in the same solution at a partial pressure of chlorine lower than 1 atm and at 30—90°C was also determined. The enthalpy change upon the dissolution of chlorine in the mixed solution was equal to that in a solution of HCl alone. Henry's Law was found to hold good in this case as well as in pure HCl, while the Henry coefficient decreases with decrease in the HCl concentration and increase in the $CuCl_2$ concentration because of the salting-out effect.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 919—922 (1969)

Fluorescence Lifetime of Acridine in Water-Organic Solvent Mixtures

Hiroshi KOKUBUN*1

Research Institute of Applied Electricity, Hokkaido University, Sapporo

(Received August 23, 1968)

Fluorescence lifetime of acridine has been measured in water-ethanol and water-glycerol mixtures of different composition at 25°C. Remarkable decrease in lifetime value was found as the amount of organic component increases. The lifetime of 10.3 ns was obtained for the aqueous solution. The lifetimes in glycerol and in ethanol were determined as 3.2 and 0.7_2 ns, respectively. The observed ratio of the lifetime in the mixture to the lifetime in water, τ/τ_0, has the same functional dependence on solvent composition as the ratio of fluorescence yield, ϕ/ϕ_0. These quenching phenomena by organic molecules have been interpreted as due to the solvent effects upon the radiationless transition rate. Both static and dynamic mechanisms of quenching are not applicable in the present cases of solvent quenching.

Fluorescence properties of organic compounds in solution are frequently affected by a number of factors depending on the interaction with the solvent molecule. The interaction may be hydrogen-bonding, dipolar forces and so on. Acridine is one of the compounds whose fluorescence quantum yield is strongly dependent on the nature of the solvent. At room temperature acridine emits fluorescence only in the presence of hydroxylic molecule such as water, ethanol or acetic acid.[1] However, when the hydroxylic molecule is such that, like phenol or aniline, the proton donating group X–H is conjugated with an aromatic part, the activation of fluorescence does not occur.[2] The quantum yield of the fluorescence differs considerably from solvent to solvent even when active hydroxylic solvent is employed.

Bowen *et al.*[3,4] found a remarkable reduction of the fluorescence yield of acridine with increasing amount of organic component in water-organic solvent mixtures. For example, in the ethanol solution the quantum yield of the fluorescence is less than 1/10 of that in the aqueous solution. The organic solvent mixed with water shows an effective quenching upon the fluorescence. According to them, the enhanced fluorescence in water-containing solvents is due to the occurrence of the rapid hydrogen-bonding formation between the excited acridine and water, while in the ground state the hydrogen-bonding is negligible. However, this view can be easily ruled out, since the spectroscopic study shows that acridine in the ground state forms the hydrogen-bonded complex with ethanol and other protic molecule substances at rather low concentration of donor molecule.[1,2] In protic solvent acridine may be completely hydrogen-bonded with solvent molecule.

On the other hand, Porter and Vander Donckt[5] explained the low fluorescence yield in ethanol as due to a participation of photoreduction processes in the first singlet excited state. Our recent investigation shows that the contribution of photochemical reaction to the radiationless processes of excited acridine is of minor importance.[6]

For the purpose of establishing the mechanism for this interesting behavior of the fluorescence, measurements have been made of the fluorescence lifetime of acridine dissolved in water-glycerol and water-ethanol mixtures of various compositions. Comparative study of lifetime with spectroscopic and or fluorophotometric study can afford the decisive clue to resolve the mechanisms involved. For example, Schmillen[7] has successfully discriminated the static and dynamic mechanisms of the fluorescence quenching for several dyes.

Experimental

Absorption spectra were measured with a Hitachi EPS-II spectrophotometer. Fluorescence spectra were recorded on a modified Hitachi EPU spectrophotometer. Excitation light source was Ushio USH-100 high pressure mercury lamp combined with Toshiba UV-D1A and UV-35 filters. The spectral calibration factors of this photometer were obtained by the method of

Lippert *et al.*[8] and were applied to the raw data. Lifetime measurements were made with a phasefluorometer modulated at 10.7 MHz. This device is similar to that reported by Müller *et al.*[9] except for slight simplification and working frequency. The excitation light source was the same as employed in spectral measurements. The delaylines were calibrated with the aid of a standard signal generater and a frequency counter.

Acridine was recrystallized twice from 1 : 1 ethanol-water mixture. G. R. grade glycerol was distilled under reduced pressure prior to use. G. R. grade 99.5% ethanol was used without further purification. In order to avoid the protonation in the excited state,[10] the mixtures were prepared from the aqueous 0.02 N alkaline solution and the organic solution. The concentration of acridine was kept less than 10^{-5} mol/*l* for all solutions prepared, so that the system is free from the undesired concentration quenching. The effect of dissolved oxygen was examined for several solutions, and it was found that the oxygen quenching is negligible. The present results are those for the aerated solutions.

Results and Discussion

Results of lifetime measurements are presented in Fig. 1. As the amount of ethanol or glycerol increases, the lifetime decreases rapidly and then approaches a limiting value for both mixtures. The lifetime in the aqueous solution is 10.3 ns. The limiting values of 3.2 and 0.7_2 ns were obtained respectively for glycerol- and for ethanol-water mixtures. The value for the aqueous solution is close to the value of 13.8 ns obtained by Schmillen,[11] but is not in good agreement. The value of 2.3 ns for 50% ethanol solution is in complete agreement with that obtained by Birks and Dyson.[12] Berlman's value of 0.9 ns[13] for ethanol solution agrees well with the present result. No other literature value which can be compared with the results of the present work is vavailable.

The most striking feature of the present results for ethanol-water mixtures is that the ratio in lifetime, τ/τ_0, as a function of solvent composition is in good agreement with that of quantum yield, ϕ/ϕ_0, obtained by Bowen *et al.*[4] at 18°C except for the small deviation due to the different working temperature and experimental errors. The subscript 0 stands for the values in the aqueous solution. For glycerol-water mixtures the fit of τ/τ_0 curve to that of ϕ/ϕ_0 obtained by Bowen and Sahu[3] is less satisfactory. However, since they did not take into account the effect due to the protonation in the excited state, their results can not be compared strictly with the present results. Hence, it may be considered that the relation, $\tau/\tau_0=\phi/\phi_0$, holds also for glycerol-water mixtures.

In the usual way of interpreting the quenching mechanism, it is a reliable criterion for dynamic quenching that the ratios of quantum yield fit those of lifetime especially for low quecnher concentration. If this is the case, quenching process can be described by the Stern-Volmer equation

$$\phi_0/\phi = \tau_0/\tau = 1 + k\tau_0[Q], \qquad (1)$$

where k and [Q] are the rate constant of quenching process and the quencher concentration, respectively. For both mixtures studied remarkable deviations from the above equation were found as

shown in Fig. 2. In these mixtures, especially for glycerol-water mixtures, strong variation in viscosity might be a cause of the deviations found, since dynamic quenching is a diffusion controlled process. However, no significant relation was found between the apparent quenching constant obtained by the formal application of the Stern-Volmer equation and the viscosity of the corresponding solution. The transient effect is another conceivable factor which causes deviation from the Stern-Volmer equation. Deviation due to this effect is always upward. For glycerol-water mixtures deviation from linearity is contrary to the expected direction. For ethanol-water mixtures it is as expected. However, the value of the slope extrapolated to pure water is almost zero. This means that the dynamic part scarecely contributes to the entire quenching process. Furthermore, the very fact that τ/τ_0 coincides with ϕ/ϕ_0 even for the mixtures rich in organic component (*i. e.*, large quencher concentration), implies a negation of the participation of the dynamic mechanism in quenching process, since the quantum yield measurement detects both dynamic and transient contributions, while the lifetime measurement by phase shift method detects only dynamic contribution. Thus, in every respect it is conclusive that the dynamic collisional mechanism does not participate in the present quenching phenomena.

An alternative is the static quenching, in which the formation of non-fluorescent associate between fluorescer and quencher is an essential origin of quenching. In this case the fluorescence can be emitted only from the free molecule, and the quencher does not affect the decay process of the emitting molecule. No change in lifetime is expected. In the present case, however, we should consider an associate of lower fluorescence yield, *i. e.*, hydrogen bonded acridine with ethanol or glycerol, instead of completely non-fluorescent associate. The number of emitting species is two at least, if the static mechanism is involved in the present system. Although the lifetime to be observed should vary with quencher concentration, τ/τ_0 can in no way be identical with ϕ/ϕ_0. Furthermore, as shown in Fig. 3, the fluorescence spectrum of acridine shifts merely to blue continuously and becomes better structured gradually with the increasing amount of organic component. There is no evidence that the observed fluorescence spectra consist of two components. Hence the static mechanism in a simple form was also excluded.

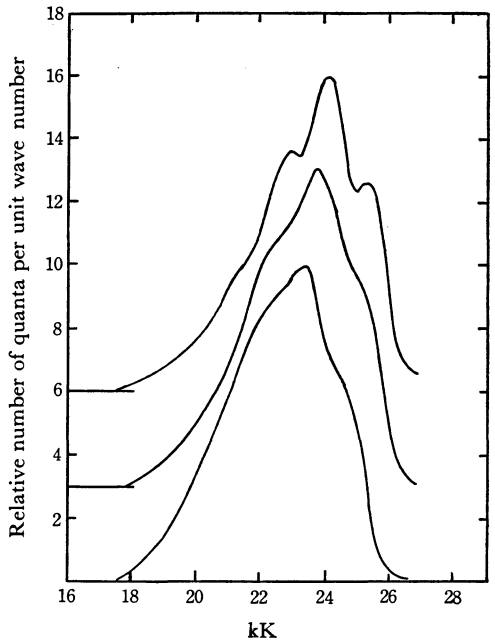

Fig. 3. Fluorescence spectrum of acridine.
Upper: in ethanol
Middle: in 50% ethanol
Lower: in water

Thus it appears that the present result is interpretable only in terms of the solvation in mixed solvents. In the aqueous solution acridine is solvated by water, and all the sites for solvation may be occupied by water molecules. By mixing an organic component into water, the organic molecules replace the water molecules on the solvation sites. This causes the changes in τ and ϕ which are given by

$$\tau = \frac{1}{k_f + k_q} \tag{2}$$

$$\phi = \frac{k_f}{k_f + k_q} \tag{3}$$

respectively. k_f is the rate constant for radiative process, and k_q is that for nonradiative.

Since the absorption intensity of acridine is practically constant in all the solutions studied, k_f can be regarded as constant throughout. Hence, it is clear that the reductions in τ and ϕ are attributed to the increase in k_q. This leads to $\tau/\tau_0 = \phi/\phi_0$ consistent with the experimental finding.

For convenience we write k_8 as a sum of two components,

$$k_q = k_{q0} + k_q(\varphi), \tag{4}$$

where k_{q0} is a radiationless rate constant in the aqueous solution and $k_q(\varphi)$ is the increment of radiationless rate constant upon addition of organic component as a function of volume fraction of organic solvent, φ. Assuming that the $k_q(\varphi)$ is proportional to the concentration, a, of the organic molecules on the acridine surface, we get

$$\frac{k_q(\varphi)}{k_{q\infty}} = \frac{a}{a_\infty} \tag{5}$$

where subscript ∞ describes the quantities for the state completely solvated by the organic molecules. For simplicity, only the first solvation sphere is considered. By means of the similar

procedure as in the treatment of monomolecular-layer adsorption isotherm, we get

$$\frac{a}{a_\infty} = \frac{\phi}{B + \varphi} \tag{6}$$

where B is a constant. Combining Eqs. (2), (4), (5) and (6), we get

$$\frac{\tau}{\tau_0 - \tau} = \frac{B}{k_q \tau_0 \varphi} + \frac{1}{k_{q\infty}\tau_0}. \tag{7}$$

This kind of treatment was first applied by Lippert and Moll[14] to the shift of fluorescence maximum of certain stilbene derivatives in organic mixed solvent.

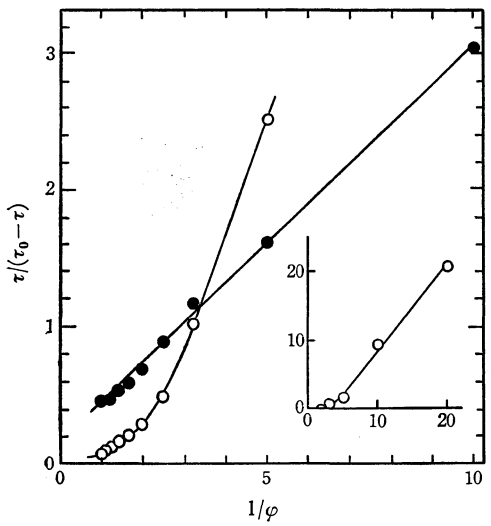

Fig. 4. $\tau/(\tau_0-\tau)$ *vs.* $1/\varphi$ plots.
—○—: Ethanol —●—: Glycerol

Plots of $\tau/(\tau_0-\tau)$ *vs.* $1/\varphi$ are given in Fig. 4. For water-glycerol mixtures the fit to Eq. (7) is quite satisfactory. However, for water-ethanol mixtures the deviation from Eq. (7) is appreciable. What kind of factors are responsible for such a discrepancy between ethanol and glycerol remain inexplicable. Taking the complex nature of these mixtures into account, no further attempt was made to find an equation of better fit.

Thus, the quenching action of organic solvent upon the acridine fluorescence has been interpreted as due to the enhanced radiationless transition produced by solvent effect. The mechanisms based on the simple collision involving two molecules and on the complex formation with definite composition have been completely precluded.

The present experimental data do not discriminate whether intersystem crossing or internal conversion is a dominant cause for the present significant radiationless process. According to Bowen *et al.*[4] the temperature dependence of k_q is well described by an Arrehnius equation for ethanol-water mixtures. The activation energy decreases with increasing ethanol fraction; from 6.59 kcal in 10% ethanol to 4.75 kcal in 50% ethanol solution. That the internal conversion requires activation energy of several kcal is highly improbable, since the density of states is very high. Furthermore, with the above fairly large activation energy the radiationless transition should be inhibited at moderate low temperature. These considerations suggest the minor importance of the internal conversion in the radiationless transitions at the first singlet excited state of acridine.

Although the position of the singlet n–π^* state is not known, it lies above ^1L_a π–π^* state[15] and may be dependent on the solvent composition. It is expected that the organic component lowers the energy of the $(n\text{–}\pi^*)^1$ state. This might be the origin of the solvent dependence of activation energy. The intersystem crossing through the $(n\text{–}\pi^*)^1$ state to the second $(\pi\text{–}\pi^*)^3$ state seems to be most probable.

In connection with present result, the author's attention was called to the work of Medinger and Wilkinson.[16] They found a remarkable deviation from the Stern-Volmer plots in the quenching of 9-phenylanthracene fluorescence in liquid paraffin by bromobenzene. They interpreted this deviation as a result of decreasing activity factor due to very high quencher concentration. However, it seems probable that the quenching by bromobenzene is not a collisional process. High quencher concentration decreases the viscosity of the solution appreciably, nevertheless the deviation from the Stern-Volmer equation is opposite as in the present acridine-glycerol-water system.

Changes in absorption and fluorescence spectra are very small, hence k_f is safely assumed to be practically constant. Equation (7) is easily modified for variables F/F_0 and [B] as follows:

$$\left(\frac{F_0}{F} - 1\right)^{-1} = \frac{C}{k_{q\infty}\tau_0[\mathrm{B}]} + \frac{1}{k_{q\infty}\tau_0} \tag{8}$$

where F/F_0 is the ratio of fluorescence intensity with the presence of bromobenzene to that without quencher, [B] is bromobenzene concentration and C is a constant. The values of F/F_0 found in literature were applied in Eq (8) and a straight line was obtained. Thus, the bromobenzene quenching is explained by the solvent effect upon the radiationless process.

Semi-Empirical ASMO SCF Method for the Valence Electron System. The Electronic Structures of Protonated Pyridinium and Diazinium Cations

Hiroshi KATO, Hajime KATÔ,*1 Hideyuki KONISHI and Teijiro YONEZAWA

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received August 26, 1968)

Using a semi-empirical ASMO SCF method for valence electron systems previously proposed by the present authors, the valence shell electronic structures of various protonated azines are investigated. The compounds treated in the present paper are monoprotonated pyridinium, mono-, and diprotonated diazinium cations. The calculated results show that quite large charge redistributions on both σ and π electron systems in these cations take place in the protonation, while about a 0.7 e charge migrates to the attached protons. As to the transition energies, the lowest π–π^* transitions exhibit slight red shifts, while the n–π^* transitions would be expected to cause large blue shifts by means of protonation. Several models for protonated cations are compared, and the configuration where the proton is situated on the bisector of the CNC(N) angle and in the molecular plane is shown to be the most stable one. The changes in Fock's operators upon protonation are also briefly discussed.

Numerous experimental and theoretical studies of the effect of protonation or hydrogen bonding on the electronic structures of nitrogen heterocycles have been presented in the past decade.[1] Mataga and Mataga treated the protonated pyridinium cation and pyrazinium diion by a semi-empirical SCF method for π electron systems and showed that their calculation were successful in accounting for the electronic spectra of these ions.[2] However, their method is based on the π-approximation and the σ-electronic systems are not taken into account explicitly; that is, the core attraction of the adding proton is considered as a prameter of the perturbation in the π electron systems. Recently, calculations including the π electrons in the compounds containing the nitrogen atoms have been made by several authors, but these treatments have not discussed the electronic spectra and the positions of the added protons.[1g,1,j]

In the present paper, the protonated cations of pyridine and three diazines are calculated by the semi-empirical ASMO SCF method for all valence electron systems previously proposed by the present authors.[3] The changes in the σ and π electronic distributions, the stabilization of the orbitals, and the shift of the electronic transitions caused by the protonation are discussed. Further, the location of the adding proton and the changes in the Fock's operators are investigated. The compounds studied in the present paper are monoprotonated pyridinium and mono- and diprotonated diazinium cations.*2 As to the geometries of these cations, it is assumed that the added proton is situated on the bisector of the CNC angle and in the molecular plane of the compound, which has the same configuration as the free molecule.*2,4,5) The N–H$^+$ bond distance is taken as 1.032 Å, as in the NH_4^- ion, throughout this procedure.[2,5]

Results and Discussion

The Change in the Charge Distribution. The calculated atomic populations of an atom A,

* The notation, +1 and +2 indicate to the mono and diprotonated species, respectively. The number for Q_H refers to the position linked with the hydrogen atom.

** The notation, Q_A refers to the atom population of carbon and nitrogen atom, and Q_H to the hydrogen atom. The notation Δ indicates the difference between the values in cation and neutral compound.

*** The protonated nitrogen atom in the monocation.

Q_A and the differences in the charges, ΔQ_A's, in the cation and its neutral molecule are compared in Table 1, where a plus sign indicates an increase in the charge and a minus sign, a decrease in the charge, by protonation. The π atomic orbital (AO) populations and their differences are also listed in the same table, together with σ charge's.

It may be seen from the table that a considerable quantity of the charges migrate to the added proton from the other atoms in the cations, and that the positive charges delocalize in all the positions of the compound. The atomic population of the added proton is equal to the sum of the net charges of the other atoms of its cation. The ratios which

are given by the sum of the ΔQ_A's with regard to nitrogen, carbon and hydrogen atoms respectively divided by the atomic population of the proton, are considered to be a measure of the contribution of the transferred charge to the proton from the corresponding atoms. These ratios for the nitrogen, carbon, and hydrogen atoms are listed in Table 2. The results in Table 2 indicate that the charges on the protons in these cations are transferred from all the atoms in the cation; in the monocations, the nitrogen and hydrogen atoms play a important role in the electron transfer, while in the diions, the contribution of the carbon atoms relatively increases. The π electron distributions are also greatly affected by the protonation; for example, the negative charges concentrate on the π AO of the protonated nitrogen atom, and the other carbon atoms almost all bear slightly positive charges. The σ electron redistribution may also be seen in Table 2. Namely, the σ electron populations of the carbon atoms show an alternation of the sign of charge, and at the nearest neighbor carbon its σ electron population increases largely in the cation.

The variations in the AO populations of the nitrogen atoms may be seen in Table 3, where the notation p_n indicates the lone pair 2p AO of the nitrogen atom. The protonation has a remarkable effect on the populations of the p_n and p_π AO's of the nitrogen atom; that is, the p_π AO loses a considerable charge, about 0.7 e, and the p_π AO gains a large negative charge. As a whole, the positive charge on the protonated nitrogen atom is not very large.

Changes in The Total and MO Energies. The proton affinities of these compounds are given as the change in the total energies of the systems, between before and after protonation.[3] The calculated values are collected in Table 4, together with the observed pK_a values and the hydrogen bonding energies.[1e],*3 Unfortunately, there are no observed data on the proton affinities of these compounds; however, the obtained values may be considered slightly large, in view of the observed values for benzene, about 7 eV, and for NH_3, 8 eV.[6] The values given in the table indicate that the order of the proton affinities for the monoprotonation agree with those of the observed pK_a values

*3 It is noticable that it is necessary to compare the calculated values of proton affinity with those observed in the gas phase, but if the changes in the entropy terms and in the solvent effects by the protonation in these compounds, are constant or are negligibly small, the above comparison is not so unreasonable.

and hydrogen bonding energies, while those for the diprotonation do not. Further, the stabilization energies due to monoprotonation are found to be about twice as large as those of the protonation to a monoprotonated compound. Thus, it may be concluded that the monoprotonations in these diazines occur more easily than do the diprotonations.

The changes in the molecular orbital (MO) energies upon protonation in pyridine are shown in Fig. 1. The pair of MO's in Fig. 1 connected with the arrow line belong to the same irreducible representation and have similar charge distributions. The orbital energy (ε) and the energy difference between these MO's, *i. e.*, the stabilization energy, $\Delta\varepsilon$, are given in Fig. 1. By protonation, all the MO's in a free compound are stabilized about 6 eV; the stabilization of the lone-pair MO (n in Fig. 1) is the largest, 10.12 eV, where the electrons in the MO (n^* in Fig. 1) in cation are mainly localized on the N–H^+ σ bond. That is, this large stabilization is due to the nitrogen lone pair in the n MO participating in the formation of the N–H^+ bond in the n^* MO. Some crossings of energy levels are seen in Fig. 1; particularly a σ MO belonging to the same symmetry as the n MO in free pyridine comes to exist in the higher-energy region in the cation. This result will be discussed in the next section in connection with the transition energy.

Transition Energy. The calculated transition energies obtained by considering the configuration interactions of limited numbers of configurations for various cations are summarized in Table 5, together with those for free molecules which have already been given in Ref. 4. The symmetry shown in this table indicates an irreducible representation of transitions in free and diprotonated compounds; these notations in the case of monoions correspond to the states in which the charge distributions are similar to those of the free and di-

protonated compounds. As may be seen from the table, the lowest π–π^* transitions show a slight red shift, and the n–π^* transitions,*4 a large blue shift, upon protonation. As was pointed out above, the σ–π^* transitions in the dications which belong to the same symmetries as the n–π^* transitions in the parent molecules appear in the lower-energy regions. It is hoped that these σ–π^* transitions in these ions will be identified experimentally. The observed values for lower π–π^* transitions in pyridinium and pyrazinium cations[2] are also listed in the same table. The agreements between the calculated and observed values are fairly satisfactory.*5 The values of the oscillator strength for several π–π^* transitions in several ions were calculated; these values are given in Table 5. The results indicate that the lowest π–π^* transitions in ions are generally intensified by protonation; this finding is in accordance with the experimental results.[2]

The Orientation of Adding Protons. In the present treatment, it is assumed that the proton is situated in the direction of the lone-pair orbital of a nitrogen atom and lies on the molecular plane of a compound. Here, let us investigate the orientation of adding protons. At first, the proton in the pyridinium cation is oriented above the molecular plane, as is shown in Fig. 2. The calculated total energies for various out-of-plane angles, θ, are given in Table 6. The values in this table indicate that the configuration with $\theta=0°$ is the most stable. From the obtained potential curve, the N–H$^+$ bending force constant is calculated to be 0.352 md/Å, compared with the observed value, 0.535 md/Å, in the NH_4^+ ion.[7] Thus, our results seem to be fairly reasonable.

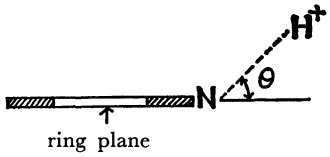

Fig. 2. The orientation of added proton in pyridinium cation.

Table 6. The configuration energies, ΔW for various θ values

θ	0°	30°	55°
ΔW	0	0.32	1.05

The next calculations are made on the monoprotonated pyridazinium cation, in which the proton is located on the vertical bisector of the N–N bond and is on the moleculer plane (B form). The configuration adopted in the previous sections was referred to the A form. These two configurations are shown in Fig. 3. The total energy obtained for the A form is more stable than that for the B form by about 2.8 eV. This destabilization for the B form is mainly due to the lack of any interaction between the proton and the MO which is constituted from the two nitrogen lone pairs and the anti-bonding type between these two lone pairs. This suggestion is supported by the following consideration. In Table 7 are collected the computed atomic dipole and its bond orders of the nitrogen atoms in pyridazine and its various cations.

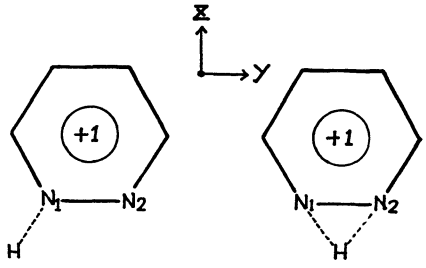

Fig. 3. The two forms in pyridazinium monoion.

Table 7. The atomic dipole values (in unit of debye) and its bond order of nitrogen atom in pyridazine and its ions

		$P_{s_NY_N}$	$P_{s_Nz_N}$	$\mu_A(D)$*
Parent	N_1	−0.137	−0.326	1.33

Monoion B	N_1	−0.151	−0.193	0.92
	N_2	0.151	−0.193	0.92
Monoion A	N_1	0.068	0.011	0.26
	N_2	0.151	−0.342	1.41
Diion	N_1	−0.011	−0.006	0.03
	N_2	0.011	−0.006	0.03

* $\mu_A=[(D_N P_{s_NY_N})^2+(D_N \cdot P_{s_N \cdot z_N})^2]^{1/2}$

$D_N=-e\int \chi_{s_N} r \chi_{p_rN} d\tau \quad (r=x,y,z)$

The listed values show that the large atomic dipoles in the free molecule are diminished by diprotonation. In the monoprotonated ions, the atomic dipole of the protonated nitrogen atom becomes very small and that of the non-protonated nitrogen becomes, inversely, stronger in the A form, whereas in the B form the atomic dipoles of both the nitrogen atoms have considerably large values and are directed toward the outsides of the N–H$^+$ bonds. The magnitudes of the atomic dipoles may be considered to represent the remaining ability of the corresponding lone pair for the bond forma-

*4 The n^*–π^* one in ion in Table 5 refers to the n–π^* transition in a free molecule.

*5 Recently, the second-lowest π–π^* transition energy in the pyridinium cation was estimated to be about 6 eV by Nishimoto (private communication). Our value may be somewhat smaller, as in the case of free molecules (see Ref. 4).

7) I. Nakagawa and S. Mizushima, This Bulletin, **28**, 589 (1955).

tion; so, in the B form, the nitrogen lone pairs still possess considerably strong bonding abilities, in spite of protonation. This is one reason for the lower stabilization of the B form. Accordingly, it may be concluded that, in the most stable configurations of these cations, the proton is situated on the bisector of the C=N–N angle and on the molecular plane, a position compatible with our assumed configurations in previous sections. This fact may be evidence that the nitrogen lone pairs in these compounds can be described approximately as sp^2 hybrids.

The Change in Fock's Operator. Lastly, let us examine the effect of protonation on the Fock's operators. The Fock's operator of the rth diagonal element is represented as follows:

$$F_{rr} = H_{rr} + G_{rr} \tag{1}$$

where H_{rr} is the electron-core interaction terms and G_{rr} is the electron-electron interaction term. With the superscript 0 denoting the free molecule and $+$, the monprotonated species, the differences in the quantities in Eq. (1) between the free and protonated compounds are given by:

$$\left.\begin{aligned} \Delta F_{rr} &= F_{rr}^{+} - F_{rr}^{0} \\ \Delta H_{rr} &= H_{rr}^{+} - H_{rr}^{0} \\ \Delta G_{rr} &= G_{rr}^{+} - G_{rr}^{0} = \Delta G_{rr}^{\sigma} + \Delta G_{rr}^{\pi} \end{aligned}\right\} \tag{2}$$

where ΔG_{rr}^{σ} and ΔG_{rr}^{π} represent the contributions to the electronic interactions between the other σ and π electrons, and the electron in the rth AO, respectively.

For example, the values of Fock's operators for the π AO's and the valence AO's in a nitrogen atom in pyridine and its cation are listed in Table 8. In the table, the ΔH_{rr} values are equal to the core-attraction energies to the rth AO due to the attached proton, and the ΔG_{rr} values are the changes in the electron interaction energies upon the redistribution which is caused by protonation. Here, $\Delta G_{rr}<0$ means the decrease in the electron-repulsion term and $\Delta G_{rr}<0$ is the increase in its term by protonation. From the table, it may be seen that the absolute values of ΔF_{rr} of the π AO's of the C_1 and C_2 positions (the number is the same in Table 1) do not become as much smaller as the values in C_3, contributed by the negative values of ΔG_{rr} terms. Further, it may be noticed that these negative ΔG_{rr} values are mainly contributed from the σ electronic terms. As to the ΔG_{rr} value in the nitrogen π AO, it is found to be nearly equal to zero; this shows that the redistributions in π and σ electrons around this AO result in mutual cancellation, in spite of the large increase in this AO population, as is shown in Table 1. Finally, it may be noticed that the redistributions in σ electron parts cannot be neglected in treating only the π electron systems in this type of cation.

TABLE 8. THE CHANGES OF FOCK'S OPERATOR (eV) BY PROTONATION IN PYRIDINE

The Photoconductivity of the Titanium Dioxide Crystal

Takeaki IIDA and Hiroshi NOZAKI

The Institute of Industrial Science, The University of Tokyo, Roppongi, Minato-ku, Tokyo

(Received September 4, 1968)

The photoconductivity of titanium dioxide (rutile type) synthesized by the flame-fusion method was studied. The photoconductivity spectra showed three peaks. The first is the maximum response around the edge of the fundamental absorption of rutile; the second is the peak at 630 mμ (1.98 eV), and the third is the broad-band spectra in the near infrared region of 1.0—1.9 μ. From the facts that Fe is found by chemical analysis to be a major impurity in rutile, that the peak at 630 mμ is enhanced by the increase in Fe concentration from 0.006 mol% to 0.02 mol%, and that the infrared quenching band of photoconductivity is observed at 1.23 μ (1.01 eV) in Fe-doped rutile, it is concluded that this peak at 630 mμ results from the excitation of the electron from the Fe^{3+} level. The broad-band spectra at 1.0—1.9 μ are enhanced by the reduction and are decreased by the oxidation of the crystal, so these excitation spectra are ascribed to lattice defects originating from the non-stoichiometry of TiO_2. These defects have much influence on the photoconductivity of rutile, *i. e.*, on the relation between the photocurrent and the electrical applied field, and on the change the photocurrent *versus* the time.

Titanium dioxide has a conduction band consisting of 2p orbitals of O^{2-}. In the case of rutile, the energy gap of the forbidden band is 3.01 eV—3.05 eV.[1] When titanium dioxide is exposed to the gap light of 420 mμ, it responds quickly to the irradiation with a considerable amount of photocurrent. It is generally considered that a material which has a d-conduction band cannot become a good photoconductor. The reason for this has not yet been clarified and the photoconductivity mechanism of the d-conduction band has not been studied in detail. In view of these points, the photoconductivity of titanium dioxide has many interesting problems. The photoconductivity of the rutile crystal was studied by Cronemeyer.[1] He reported that the photoconductivity spectra of rutile has a maximum response at a wavelength of around 400 mμ. However, he has not mentioned the detailed phenomena of photoconductivity of rutile. Therefore, we have studied the photoconductivity of titanium dioxide in detail, using a single crystal of rutile synthesized by the flame-fusion method. For this report we have studied the photoconductivity spectra for pure rutile, for Fe-doped rutile, and for slightly-reduced rutile, the relation between the photocurrent and the electrical applied field, the change in the photocurrent *versus* the time, and the infrared quenching of photoconductivity for Fe-doped rutile.

Experimental

The single crystal of titanium dioxide was synthesized by the flame-fusion method using highly purified titanium dioxide powder which had been made by firing ammonium-titanil-sulfate at 1000°C. The crystal structure and the direction of the *c*-axis were identified by X-ray deflection. The single crystal was chemically analyzed by spectral analysis. Original crystals grown in an oxyhydrogen flame did not have the stoichiometric composition. Therefore, the crystal was annealed in oxygen gas at 1000°C for 20 hr, and then cooled very slowly to room temperature. The resistivity of this rutile was around 10^{12} Ω cm. After the surface of single crystal plate had been polished with alumina powder to a mirror flatness, the electrodes were attached to this plate by the following procedures. Two parallel zones of silver paste, separated by 5 mm, were painted on one side of the plate, and the sample was heated at 500°C for one hour. Then silver was slightly diffused on the crystal surface, and the electrodes were fixed securely on the surface.

The photoconductivity was measured by the following methods: the sample was mounted on a copper block with silver paste and fixed on the measurement cell. After the air in the cell had been evacuated, the copper block was cooled with liquid nitrogen. The sample was exposed through a quartz window to the monochromic light produced by a monochromator of Carl Zeis, using a 500-W tungsten lamp as the light source. An electric field of 6×10^2 V/cm was applied to the sample, and the photocurrent was measured with an electrometer of the Keithley 610 B type. The infrared quenching spectra of the photoconductivity were measured by the double-beam method; that is, the first excitation light of 400 mμ, which was made by using an interference filter of VV-40 (this filter transmits between 350 mμ and 450 mμ), and the second excitation light of infrared, made by the monochromator, were irradiated on the sample simultaneously, and then the quenching of the photocurrent was measured.

1) D. C. Cronemeyer, *Phys. Rev.*, **87**, 876 (1952).

Results

The general photoconductivity spectra of the rutile crystal are shown in Fig. 1. The maximum of the response is located at the wavelength of 420 mμ at 300°K, but it shifts to 410 mμ at 77°K. The small peak at 630 mμ is observed at any temperature and always has a good reproducibility. The broad response spectrum is observed in the near infrared region of 1.0—1.9 μ at 77°K, but this peak greatly decreases with the increase in the temperature.

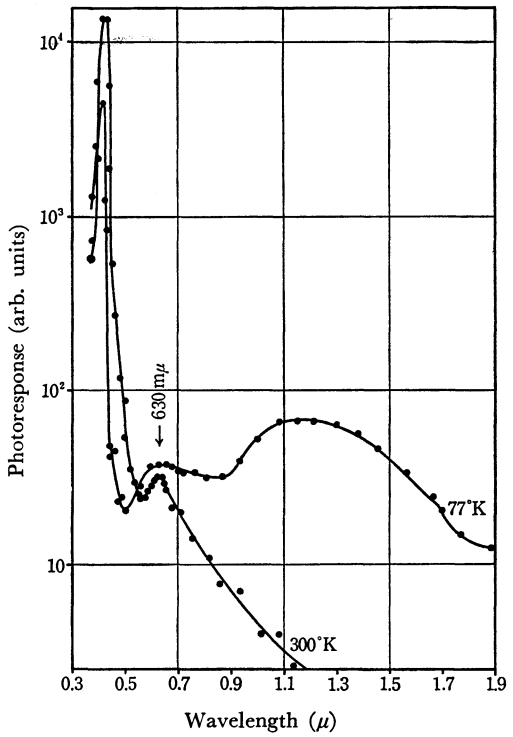

Fig. 1. Photoconductivity spectra for a rutile synthesized by the flame-fusion method.

Chemical analysis of the sample showed that the iron impurity is the major impurity; aluminium, nickel and cobalt are not detected. Therefore, we produced a single crystal doped with 0.02 mol% of iron and measured the photoconductivity spectra. As is shown in Fig. 2, in this sample the peak at 630 mμ is observed clearly, and it is enhanced by the increase in Fe concentration from 0.006 mol% to 0.02 mol%. The broad excitation spectra at 1.0—1.9 μ also appear in the Fe-doped sample, and it can be noticed that the dependence of these broad spectra on the temperature is same as in the case of undoped rutile.

If the rutile crystal is heated at 400°C under the reduced air pressure of 10^{-2} mmHg, the broad response spectra at 1.0—1.9 μ are greatly enhanced. The photoconductivity spectra of slightly-reduced

—●—●— TiO_2 : Fe (0.02 mol%)

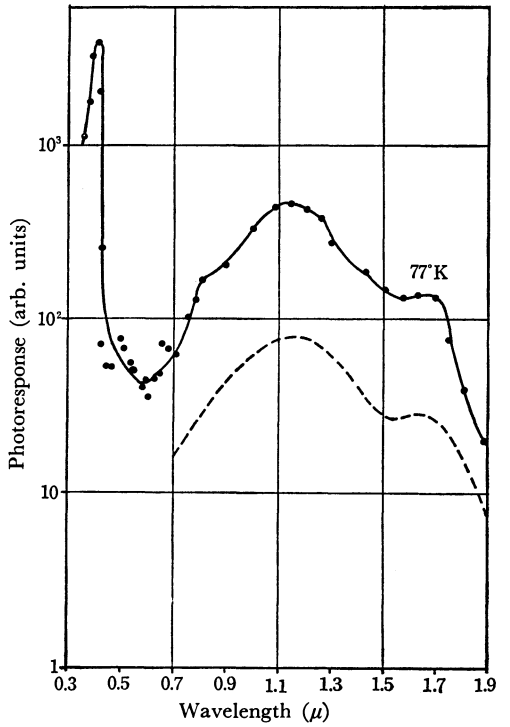

Fig. 3. Photoconductivity spectra for the reduced rutile. The dotted line represents the infrared absorption spectra of the reduced rutile which were reported by Cronemeyer.[2]

rutile, the resistivity of which is around $10^7\ \Omega$ cm, are shown in Fig. 3. It can be noticed that two peaks are found in the broad excitation spectra. One is at 1.2 μ, and the other is at 1.7 μ. The dotted line represents the infrared absorption spectra of reduced rutile measured by Cronemeyer.[2] From these curves it can be recognized that these two peaks, at 1.2 μ and at 1.7 μ, coincide with two peaks of the infrared absorption spectra.

The photocurrent dependencies of rutiles on electrical fields are shown in Fig. 4, using the light of

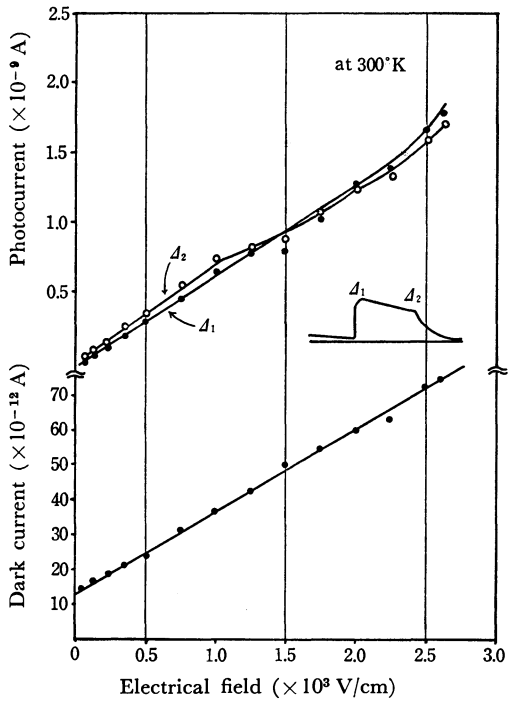

Fig. 4. Photocurrent and dark current dependencies on the electrical field. The notations of Δ_1 and Δ_2 mean the photocurrent measured two seconds and ten seconds respectively after the turn-on of the excitation light.

410 mμ as the excitation beam. The photocurrent increases proportionally to the applied field up to the field strength of 2×10^3 V/cm. The notations Δ_1 and Δ_2 represent the photocurrent measured two seconds and ten seconds respectively after the turn on of the excitation light. The saturation of the photocurrent does not appear even at the field of 2.6×10^3 V/cm. On the contrary, the dark current is exactly proportional to the applied field.

The changes in the photocurrent of a rutile with the time are shown in Fig. 5. As can be seen from the figure, the photocurrent increases rapidly with the time at first, and then it gradually saturates. If these excitations are repeated several times, the

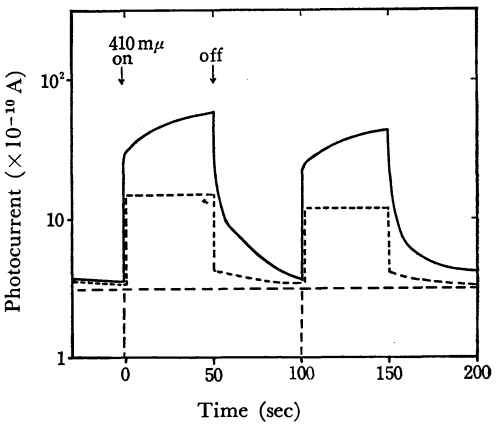

Fig. 5. The change in the photocurrent *versus* the time. The dotted line represents the change in the Fe-doped rutile.

absolute value of the photocurrent decreases gradually. In the case of an Fe-doped rutile, the shape of the photocurrent rather resembles that of the rectangular wave.

In Fig. 6, the infrared quenching spectrum of the photoconductivity of an Fe-doped rutile measured at 77°K by the double-beam method is shown. The infrared quenching band due to the hole trapped at the Fe impurity is observed at 1.23 μ. The dotted line represents the case of pure rutile. This spectrum does not have a quenching band. The degree of infrared quenching is represented by the notation of δ, which is an arbitrary statement of the difference between the full line and the dotted line.

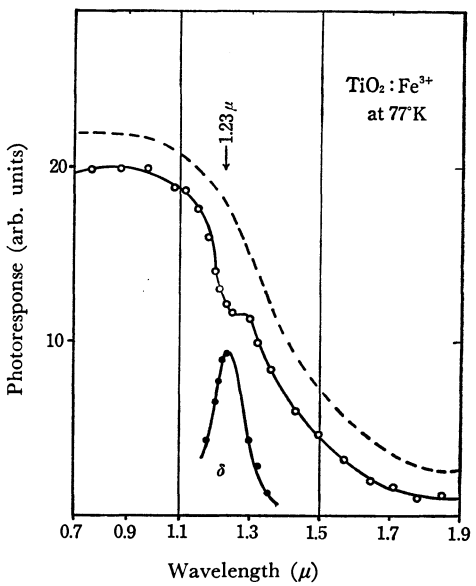

Fig. 6. Infrared quenching spectrum of the photoconductivity for the Fe-doped rutile measured at 77°K.

Discussion

The analysis of the conduction mechanism of 3d band is quite complicated because the character of the 3d conduction band has not yet been clarified. Generally speaking, most compounds which are composed of transition elements do not have a photoconductivity. Titanium dioxide has the 3d conduction band of Ti^{3+}, but it has a good response to photoconductivity. This means that the 3d conduction band does not hinder the photoconductivity and that an excited electron can move considerably freely in the 3d conduction band. As a matter of fact, the single crystal produced by the flame-fusion method has many imperfections in its lattice, such as oxygen vacancies[3,4] and interstitial Ti^{3+} ions.[5] These centers become traps or recombination centers, and they have rather more influence on the photoconductivity of titanium dioxide than does the 3d conduction band.

The photoconductivity spectra have three peaks, between 300 mμ and 2.0 μ, as shown in Fig. 1. The first maximum, around 410 mμ, is referred to the edge of the fundamental absorption of rutile, the second small peak, at 630 mμ, has been little influenced by the temperature, while the third peak, at 1.0—1.9 μ, decreases considerably if the temperature increases to 300°K. These latter two maxima may be ascribed to lattice defects in the rutile crystal. Here let us consider what kind of lattice defects exist in the rutile.

It may be said, from Fig. 2, that the peak at 630 mμ results from the excitation of the electron from the Fe impurity to the conduction band of rutile. As a matter of fact, it is very difficult to make a single crystal of rutile containing less than 0.0001 mol% of an iron impurity. Therefore, it can be understood that all the photoconductivity spectra of a single crystal synthesized by the flame-fusion method have a peak of Fe impurity at 630 mμ, and that this impurity acts as a recombination center for the electron and the hole. The ESR measurement for the Fe-doped rutile has been performed by Carter and Okaya.[6] From their ESR results it is clear that Fe occupies the Ti site as a trivalent ion. The ground state of the free Fe^{3+} ion is ^6S. The crystal field of the Ti site is the rhombic field of D_{2h},[7] and the state of ^6S splits into three levels in this crystal field.[8] We can say, from the results of photoconductivity spectra, that the ground state of the Fe impurity lies 1.98 eV (630 mμ) below the conduction band.

From the facts that the broad excitation spectra at 1.0—1.9 μ are enhanced by the reduction and are decreased by the annealment of the crystal in oxygen gas, it may be said that these spectra are due to the lattice defects caused by oxygen deficiency in the rutile crystal. The two peaks, at 1.2 μ and 1.7 μ, ofslightly-reduced rutile coincide with the two peaks of the infrared absorption of reduced rutile as measured by Cronemeyer.[2] He has explained that these two peaks correspond to the ionization energy of two electrons captured by the oxygen vacancy. On the other hand, the measurement of ESR for reduced rutile was performed by Chester,[4] Yamaka[7] and Date,[9] and they concluded that the ESR signal at the g-value of 1.98 is the signal of the interstitial Ti^{3+} ion. Considering these results, we cannot easily deduce defect models with reference to these spectra. The only thing we can say is that the single crystal synthesized by the flame-fusion method has many defects caused by the nonstoichiometry of TiO_2, and that these defects are excited by the light at 1.0—1.9 μ.

Therefore, it is expected that these defects should have much influence on the photoconductivity of rutile. The facts that the photocurrent depends linearly on the electrical field applied up to 1.0×10^3 V/cm, while over that the linear proportionality is not maintained, and the fact that the saturation of the photocurrent at a certain applied field is not observed are general tendencies of a semiconductor which has shallow traps; these facts can be interpreted by saying that the photocurrent observed is due not only to the initial photocurrent but also to the secondary photocurrent caused by the shallow traps.

On the other hand, the linearity of the dark current *versus* the applied field shown in Fig. 4 ensures us a good ohmic contact between the sample and the silver electrodes.

The change of the photocurrent of the rutile *versus* the time, shown in Fig. 5, may be interpreted as follows. The first rise in the photocurrent corresponds to the initial photocurrent, while the next gradual rising process is to be ascribed to the secondary photocurrent resulting from the effect of shallow traps. It the curve of the photocurrent of the Fe-doped rutile *versus* the time (Fig. 5), the effect of the secondary photocurrent does not appear. As we have mentioned above, Fe acts as a recombination center. It might be said that Fe has so large a capture cross-section for the electron and the hole that the effect of shallow traps is very small in the process of the photoconductivity in the Fe-doped rutile.

The impurity center of Fe can also capture a free

hole from the valence band. If this Fe is excited by the irradiation of the infrared region, the hole captured in Fe is excited to the valence band and it recombines with a free electron in the conduction band, thereby decreasing the photoconductivity. This phenomenon is called the infrared quenching of the photoconductivity. As is shown in Fig. 6, the infrared quenching band appears at 1.23 μ (1.01 eV) in rutile doped with 0.02 mol% of Fe. Therefore, we can find that the energy difference between the impurity level of Fe and the valence band is 1.01 eV. This value agrees with the result obtained from the photoconductivity spectra shown in the second figure.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 933—942 (1969)

The Electronic Structures of Unstable Intermediates. Benzyne and Hetarynes

Teijiro YONEZAWA, Hideyuki KONISHI and Hiroshi KATO

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received September 4, 1968)

A semi-empirical SCF MO method for valence electron systems, a modification of our previous method made by introducing the zero-differential overlap approximation except for the one-center exchange integrals, is presented. The results calculated for benzene, pyridine, pyrimidine and thiophene, the parent molecules of benzyne and hetarynes, using this modified method are compared with those obtained by the other calculations and experiments. The unstable intermediates treated in the present paper are benzyne, pyridynes, pyrimidyne and thiophynes. The unknown bond lengths of benzyne and hetarynes are estimated by a semi-empirical relation given in the present treatment. The nature of the carbon-carbon triplet bonds of benzyne and hetarynes is studied on the basis of the bond lengths and the total π bond orders for these bonds. The charge distributions and excitation energies of benzyne and hetarynes, and the chemical reactivity of some hetarynes are also discussed. The lowest triplet states of these intermediates are shown to be close to the singlet ground states.

In our previous series of papers[1-5] a semi-empirical SCF MO treatment for all valence electron systems was presented; this treatment has been shown to be useful in elucidating the electronic structures of various molecules. In the present paper the zero-differential overlap approximation, except for the one-center exchange integrals, is introduced into our previous method[1-5] in order to simplify its procedure and at the same time to make it applicable to large molecular systems.*1 Using this modified method, the electronic structures of benzyne and hetarynes are calculated, and the interatomic distances of these unstable intermediates estimated by a semi-empirical relation. The character of the triple bonds and the ground states of benzyne and hetarynes are discussed.[6]

Theoretical

The molecular orbital (MO) is taken as a linear combination of all the valence atomic orbitals (AO's) centered on the atoms of a molecule. Introducing the zero-differential overlap approximation, except for the one-center exchange integrals, the diagonal elements of the Fock's operator for a closed-shell molecule are given by:

$$F_{rr} = H_{rr} + \frac{1}{2}P_{rr}(rr|rr) + \sum_{r'(\neq r)}^{\text{on A}} P_{r'r'}\left[(rr|r'r') - \frac{1}{2}(rr'|rr')\right] + \sum_{\text{B}(\neq\text{A})} \sum_{s}^{\text{on B}} P_{ss}(rr|ss)$$

(r belonging hereafter to the A atom) (1)

5) H. Kato, H. Konishi, H. Yamabe and T. Yonezawa, *ibid.*, **40**, 2761 (1967).

*1 The present method differs in the parametrizations of the diagonal and off-diagonal core integrals and one and two-center repulsion integrals from the CNDO method of Pople *et al.* (Ref. 17). Recently, Bene and Jaffé treated benzene, pyridine, and diazines by means of a modified CNDO method (J. D. Bene and H. H. Jaffé, *J. Chem. Phys.*, **48**, 1807 (1968)).

6) Some of these results were reported in a preliminary communication: T. Yonezawa, H. Konishi and H. Kato, This Bulletin, **41**, 1031 (1968).

where $(rr|ss)$ and $(rr'|rr')$ are the two-center Coulomb and one-center exchange repulsion integrals respectively; where $\sum_{r'(\neq r)}^{\text{on A}}$ denotes the summation over all the valence AO's of the A atom except for the rth AO, and where the diagonal core integrals, H_{rr}, are given as follows:[1,5]

$$H_{rr} = U_{rr} + \sum_{B\neq A} (B|rr) \tag{2}$$

$$U_{rr} = -I_r - (N_r - 1)(rr|rr) - \sum_{r'(\neq r)}^{\text{on A}} N_{r'}\left[(rr|r'r') - \frac{1}{2}(rr'|rr')\right] \tag{3}$$

$$(B|rr) = -\sum_{s}^{\text{on B}} N_s(ss|rr) \tag{4}$$

where I_r is the valence state ionization potential of the rth AO and where N_r denotes the number of the valence electrons occupying the rth AO in the valence state. For the valence p AO, U_{rr} is taken as the average value fort he P_x, P_y, and P_z AO's on the same atom.

The off-diagonal elements of the Fock's operator are written in either of two ways, according to whether they are concerned with one-center or two-centers:

$$F_{rr'} = -\frac{1}{2}P_{rr'}\left[(rr|r'r') - 3(rr'|rr')\right]$$

($r \neq r'$, but both on the same atom) (5)

$$F_{rs} = H_{rs} - \frac{1}{2}P_{rs}(rr|ss)$$

($r \neq s$, on different atoms) (6)

where H_{rs} is the core resonance integral, which is given by the following two equations;

$$H_{rs} = -\frac{1}{2}KS_{rs}(I_r + I_s)$$

($r \neq s$, belonging to the adjacent atoms) (7)

$$H_{rs} = 0$$

(otherwise, but $r \neq s$)

where S_{rs} is the overlap integral between the rth and the sth AO's and where K is a constant taken to be 0.8 in the present calculation. This value will be discussed in the later part of this section. The overlap integrals are calculated with the Slater-type AO's, where the exponent values adopted are those obtained by Clementi and Raimondi[7] (shown in Table 1).

Table 1. Slater exponents (ζ_r) and valence state ionization potentials (I_r) of AO's and electron repulsion integrals

		ζ_r[a]	I_r,[b] eV	$(rr\|rr)$,[c] eV	$(rr'\|rr')$,[d] eV

b) J. Hinze and H. H. Jaffé *J. Am. Chem. Soc.*, **84**, 540 (1962).
c) Evaluated from the values of I_r and E_r of Ref. b by Eq. (8).
d) Ref. 9.

The one-center Coulomb repulsion integrals are approximated as follows:

$$(rr|rr) = I_r - E_r \tag{8}$$

where E_r is the valence-state electron affinity of the rth AO. The one-center and two-center Coulomb repulsion integrals are calculated by the Ohno approximation:[8],*2

$$(rr|ss) = \frac{1}{2}(1/\sqrt{R_{rs}^2 + 1/(rr|rr)^2} + 1/\sqrt{R_{rs}^2 + 1/(ss|ss)^2}) \tag{9}$$

where R_{rs} is the distance between the atoms to which the two AO's blong.

The one-center exchange integrals are evaluated by the Slater-Condon parameters estimated by Hinze and Jaffé.[9] These values are listed in Table 1, together with the values of I_r and $(rr|rr)$.

For the geomtries of the treated molecules except for benzyne and hetarynes, the data compiled in Ref. 10 are used. An initial set of MO coefficients is obiained by putting F_{rr} as equal to $-I_r$ and by reducing F_{sr} to the H_{rs} term only. The iteration procedure is carried out until the variation in every MO energy remains within 0.001 eV.

Choice of Parameters. The value of K in Eq. (7), which is determined so that the lower calculated

π–π^* transition energies of benzene fit the observed values, is 0.8. The π–π^* transition energies calculated with this value are cited in Table 2, together with the experimental values. This value is adopted throughout these calculations.

Results and Discussion

In this section, some calculated quantities of benzene, pyridine, pyrimidine, and thiophene, the parent molecules of the intermediates treated in this paper, will first be compared with those obtained by other methods of calculation and by other experiments. Second, an empirical relation between the calculated "bond energy" and the bond length will be presented in order to make it possible to estimate the unknown bond lengths of the intermediates. Finally, the electronic structures and configuration of benzyne and hetarynes will be discussed.

Benzene, Pyridine, Pyrimidine, and Thiophene. In Table 3, the occupied MO energies for benzene calculated by the present method are compared with the results of Schulman and Moskowitz[11] and with the experimental ionization potentials assigned by Lindholm and Jonsson.[12] In general, the values of the MO energies of the present calculations are lower than the others. However, the sequence of MO's obtained by our treatments is fairly consistent with the others.

For pyridine, our MO energies are in better agreement with those calculated by Clementi[13] and with the ionization potential measured by the photoionization experiment of Al-Joboury and Turner[14] than is the case with benzene, as is shown in Table 4. The highest occupied (HO) orbital is a nonbonding (n) one in our calculation; this is incompatible with the finding of Clementi[13] and the experimental assignment by Al-Joboury and Turner.[14,15]

and thiophene, are presented in Table 5. The n orbital of thiophene, localizing mainly on the sulfur atom, is more stable than the higher π orbitals.

The transition energies were calculated for various types of excitations. The calculated values of the π–π^* and n–π^* types for pyridine, pyrimidine, and thiophene are given in Table 6, together with the experimental values. The configuration interactions, including all the π–π^* and n–π^* singly-excited states, are, further, taken into account. When the configuration interactions are considered, a fair agreement between the calculated and observed transition energies and oscillator strengths is observed. The energies of the first π–π^* transitions,

$^1A_1 \rightarrow {}^1A_1$, in pyridine and pyrimidine do not agree with the experimental results. These transitions in pyridine and pyrimidine can be correlated with the $^1A_{1g} \rightarrow {}^1B_{1u}$ transition in benzene, the transition energy of which is also in poor agreement with the experimental results, as may be seen in Table 2.

a) y is taken as C_2 rotation axis; z is taken perpendicular to plane of a molecule.

These discrepancies may partly be attributed to the evaluation of the two-center Coulomb repulsion by Ohno approximation.[8)] The lowest n–π^* transition energy in thiophene is calculated to be larger than those in pyridine and pyrimidine, and it is also larger than some π–π^* transition energies in thiophene. The fact that the n–π^* transition in thiophene has never been observed may be evidence supporting the present results.

The AO-charge densities for pyridine calculated by the present method are compared with those obtained by Clementi[13)] in Table 7. The formal charge on the nitrogen atom becomes -0.426 in the present calculation, while it was obtained as -0.229 by Clementi.[13)] It may be noted that the large negative charge on the nitrogen atom in the present results is supplies mainly by the σ electrons rather than by the π electrons (the $2p_z$ orbitals in Table 7). The AO-charge densities for pyrimidine and thiophene are also given in Table 8. The $2p_\pi$ AO-charge and atomic charges of the nitrogen atom in pyrimidine are both larger than those in pyridine. This trend for the π charges in two compounds coincides with the finding of McWeeny and Peacock.[16)] The formal charge of the sulfur atom in thiophen, in spite of a considerably large positive value of the $3p_\pi$ net charge, is negative as a result of the back-donation of the σ electrons.

The molecular dipole moments are given approximately by the vector sum of the moment, μ_Q, derived from the net atomic charge and by the atomic dipole moment, μ_{atom}.[17)] The z components in the appropriate Cartesian coordinate are given in Debye units by using Slater-type AO's:

$$\mu_Q(z) = 4.8030 \sum_{A}^{atoms} Q_A z_A$$

$$\mu_{atom(z)} = -\sum_{A}^{atoms} D_n(A) \cdot P_{ns(A)np_z(A)} \times [\zeta_s(A) \cdot \zeta_p(A)]^{n+1/2} \Big/ \left[\frac{\zeta_s(A)+\zeta_p(A)}{2}\right]^{2n+2}$$

where z_A is the z coordinate of the A atom given in units of Å, where $P_{ns(A)np_z(A)}$ is the bond order between the ns and np_z AO's of the A atom, where ζ_s and ζ_p are the orbital exponents for the s and p atomic orbital functions, and where $D_n(A)$ is the constant which is common to the nth row elements, *i. e.*, for $n=2$ and $n=3$, $D_2=7.3370$ Debye and $D_3=10.2718$ Debye. The calculated dipole moments for pyridine and pyridimidine are in fair agreement with the experimental values shown in Table 9. The large calculated dipole moment for thiophene shows that there is still some room for improvement.

Relation Between Bond Length and E_{AB}. A bond length-bond order relation is usually used to estimate the unknown bond lengths in a π electron approximation.[18] The σ electron contribution is considered to be a constant for every bond in these treatments. In the present paper, a graphical procedure to estimate the bond length of a bond by considering all the valence electrons explicitly is proposed. For this purpose, we utilize the total electronic energy, E_{AB}, of the AB bond as given in Eq. (10) instead of the bond order:

$$E_{AB} = \sum_{r}^{\text{on A}} \sum_{s}^{\text{on B}} P_{rs}(H_{rs}+F_{rs}) \qquad (10)$$

Here $\sum_{r}^{\text{on A}}$ denotes the summation over all the valence AO's belonging to the A atom. We first plot the E_{AB} values *vs.* the observed carbon-carbon bond lengths, R_{AB}, for some typical molecules (for example, C_2H_6, C_2H_4, C_6H_6, and C_2H_2) and also for pyridine, pyrimidine, and thiophene. As may be seen in Fig. 1, a fairly smooth curve can be drawn, and this curve may then be used to predict the lengths of a bond as a semi-empirical relation according to π electron theory. The curves for carbon-nitrogen and carbon-sulfur bonds are obtained similarly (Figs. 2 and 3). These semi-empirical curves will be employed to estimate the bond lengths of benzyne and hetarynes in the next section.

Benzyne and Hetarynes. Benzyne is also called dehydrobenzene and is known to be a typical unstable intermediate on the basis of many experimental results.[19] The electronic structure of benzyne has been discussed from several points of

view by several authors,[20-24] but the electron interation has never explicitly been taken into account in these treatments. Hetarynes and benzyne analogues derives from heteroaromatic compounds, such as 3,4-pyridyne,[25,26] 4,5-pyrimidyne,[25,27] and 2,3-thiophyne,[28] may also be supposed to be unstable intermediates. Calculations on these intermediates and their isomers are performed using the semi-empirical SCF MO method presented in this paper.

Benzyne and hetarynes are so unstable that no information on their geometrical structures has ever been obtained by any experiments. An attempt to estimate the bond lengths of benzyne was made by Coulson by means of a π electron calculation of the Hückel type.[20] He used a semi-empirical bond length-bond order relation. In the present paper, we will use other semiempirical curves relating the bond lengths to the E_{AB}[6]

(Figs. 1—3).

First, the geometry of the parent molecule with two hydrogen atoms eliminated is adopted for that of an intermediate, and calculation is carried out; secondly, all the bond lengths except for the carbon-hydrogen bonds are estimated at each iteration by using the relation shown in Figs. 1—3. In the course of these iterations, the planarity of a molecule and minimum changes in the bond angles were assumed. The iteration is repeated until a self-consistency within 0.01 Å between the input and the output bond lengths is established.

The SCF bond lengths of the carbon-carbon, the carbon-nitrogen, and the carbon-sulfur bonds in benzyne and hetaynes are shown, together with those of their parent molecules for the sake of comparison, in Fig. 4. The bonds from which the two hydrogen atoms are removed become shorter by about 0.1 Å than parent molecules and take values intermediate between those of the double and triple bonds. For benzyne, the bond lengths estimated by Coulson[20] are also presented in Fig. 4. The present results differ from those of Coulson to some extent. The value of the shortest bond by Coulson is very close to that of the triple bond in acetylene, while our shortest bond is not so short.

The π charge densities for benzyne and hetarynes are presented in Table 10. The variations in the π-charge densities from their parent molecules are not very large except for the C_5 position in 4,5-pyrimidyne.

The values of the π and π' bond orders for benzyne, hetarynes, and their parent molecules in Table 11 show that the shortest bonds of benzyne and hetarnes have quite large $P_{\pi'\pi'}$ values, values which are rather larger than the $P_{\pi\pi}$ values. The total π bond order, the sums of $P_{\pi\pi}$ and $P_{\pi'\pi'}$ for these bonds range from 1.3 to 1.7. From the findings on the bond lengths and the total π bond orders for the shortest carbon-carbon bonds of benzyne and hetarynes, these bonds seem to be normal triple bonds, which may have slightly different bond characters.

It may be noted that all the HO orbitals of

benzyne and hetarynes except for 3,4-thiophyne and the lowest vacant (LV) orbitals of all the intermediates are highly localized on the carbon atoms from which the two hydrogen atoms are removed. We calculated the partial atomic dipole, d_i, of the ith carbon atom of the triple bond in these MO's. The absolute values of the d_1 and d_2 vectors the α and β angles of the orientation of the partial atomic moment from the C_1–C_2 axis (in Fig. 5) are given in Table 12. The large absolute values of d_1 and d_2 show that the electrons of these MO's are considerably localized at these carbon atoms and that the centers of the negative charge are far from the atom. The values of α and β, which are about 120°, indicate that the HO and LV MO's of benzyne and hetarynes may be described approximately as a linear combination of non-bonding sp^2-type hybrids of the carbon atoms, as has been pointed out by Ingold and King[29] for the excited bent acetylene.

It is well known that benzyne and hetarynes react as intermediates with nucleophilic reagents in the elmination-addition reaction of some substituted benzene and heterocyclic compounds.[19,25] The reactions of hetarynes with nucleophilic reagents generally afford two kinds of isomeric products. The main product of isomers may be predicted from the charge distributions in the LV orbitals of hetarynes. The absolute values of the partial atomic dipole moments in Table 12, which represent the relative strengths of the σ electron-donating power of each carbon atom of the triple bond, can be employed in the present case. From

the present calculation, the more reactive sites may be predicted to be as follows: the 4 site for 3,4-pyridyne; the 2 site for 2,3-pyridyne; the 4 site for 4,5-pyrimidyne and the 2 site for 2,3-thiophyne. The only experimental results available for comparison are for 3,4-pyridyne[26] and 4,5pyrimidyne.[25] The reactions of 3-chloro and 3-bromopyridine with lithium piperidide and piperidine give 3- and 4-piperidinopyridine in the 48 : 52 ratio.[25] For the case of 4,5-pyrimidyne, only 4-piperidinopyrimidine was obtained under the same conditions.[25] These experimental results support the predictions based on the present calculations.

Some molecular orbital energy levels of benzyne are illustrated in Fig. 6, combined with those of benzene. The HO and LV orbitals of benzyne are σ-type orbitals (mentioned above), which become unstable because they lack the two hydrogen atoms. The energy changes of the π orbitals are small. The occupied π orbitals of benzene become slightly stable, and also the degeneracy is removed. The other occupied σ-type orbitals of benzyne are more unstable than the corresponding σ orbitals of benzene. Analogous situations also occur in the case of each hetaryne.

The transition energies of benzyne and hetarynes have been calculated, and the configuration interactions further considered among a limited number of singly-excited configurations.[30] The calculated lowest singlet transitions in benzyne and hetarynes, shown in Table 13, are all σ–σ^* type transitions, from the HO to the LV levels. As the experimental value for benzyne, the value of 4.9 eV assigned to the π–π^* transition with the oscillator strength of magnitude of 0.1—0.2[31] has been reported. This energy of the transition is near the value of the lowest singlet π–π^* transition for benzene; this is also shown by the present calculations. The calculated lowest transition energies of the n–π^* type for hetarynes indicate the blue shifts referred to the corresponding ones of their parent molecules (*cf.* Table 6). In addition, the larger shift in 2,3-pyridyne than in 3,4-pyridyne can be recognized. This result may be due to the stronger interaction between the lone pair on the heteroatom and the non-bonding sp^2-type hybrids on the carbon atoms, which are situated nearer each other in the case of 2,3-piridyne than in that of 3,4-pyridyne. A similar tendency is found in the cases of 2,3-thiophyne and 3,4-thiophyne.[32]

A benzyne structure with a triplet state in its ground state was long ago discussed by Müller and Röscheisen,[33] but it was pointed out to be unlikely by Huisgen.[22] In the present calculations, the lowest triplet transitions for benzyne and hetarynes are π–π^*-type transitions. The calculated values for these transitions in Table 13 are extraordinarily small, but they are not negative; therefore, the lowest triplet states of benzyne and hetarynes may lie very close to the ground states, which should be the singlet state.[34]

We are grateful to Professor I. Tabushi for his kind discussion and also to the computation centers of both Tokyo University and Kyoto University, where the present calculations were carried out.

30) The following numbers of configurations, which consist of two groups of AO's (n, π and HO; LV and π^*), are considered: 16 for benzyne; 20 for pyridynes; 24 for pyrimidyne; 15 for thiophynes.

32) In the present calculations, 3,4-pyridyne and 3,4-thiophyne become more stable than 2,3-pyridyne and 2,3-thiophyne respectively, while 2,3-thiophyne has been pointed out by Wittig to be more stable than 3,4-thiophyne (Ref. 28). This disagreement may be attributed to the total energy of the isomers of pyridynes and thiophynes obtained by the point-charge approximation for the core-core repulsion energy.

Heat of Immersion of Titanium Dioxide in Water. I. The Effect of the Hydration Treatment of Titanium Dioxide

Tetsuo MORIMOTO, Mahiko NAGAO and Teiji OMORI

Department of Chemistry, Faculty of Science, Okayama University, Tsushima, Okayama

(Received September 19, 1968)

On anatase and rutile, three samples which differ in the extent of hydration treatment have been prepared, and the surface area, the water content, and the heat of immersion have been measured. The hydration treatment of the sample increases the water content of the sample and lowers the sintering temperature. These facts suggest that the condensation dehydration of surface hydroxyl groups from the facing surfaces of contacting particles is effective for sintering. The plot of the heat of immersion *vs.* the pretreatment temperature shows a maximum at about 400°C, and the heat of immersion is larger in the sample subjected to heavy hydration treatment. The heat of surface hydration, calculated from the plot of the heat of immersion *vs.* the water content, does not vary with the hydration treatment; it averages 25.2 and 19.0 kcal/mol H_2O for anatase and rutile respectively.

It has been clarified that, on the surfaces of metal oxides, there exist hydroxyl groups which have a great influence on such surface chemical properties as surface electrification, hydrophilicity, adsorbability, and catalytic action. Recently, investigations have been made of the chemical properties of the surface hydroxyl groups themselves from the following two points of view: first, the temperature at which the surface hydroxyl groups start to desorb *in vacuo*,[1,2] and second, the rate at which the surface hydroxyl groups are formed.[3,4] These properties seem to depend on the nature of the substrate oxides. The same situation may also be expected in properties other than those just described.

The value of the heat of immersion of metal oxides is affected by the combination of solid and liquid, and by the origin and the history of the solid. So far it has been discovered that the particle size of the powdered sample and the heat treatment of the sample performed just before the calorimetric measurement greatly influence the heat of immersion, and that these circumstances make it impossible to consider the heat-of-immersion value as inherent in the solid substance.[5,6] Of course, the coatings on the solid surface modify the oxide surface properties.[7] Of these factors, the pretreatment of the sample at elevated temperatures serves to modify the surface properties by removing the surface hydroxyl groups. Most plots of the heat of immersion in water against the pretreatment temperature reveal a maximum.[6,8-11] The appearance of the maximum has been explained in terms of the cooperative effect of the formation of surface hydroxyl groups and the physical adsorption of water on them. By analyzing the heat of immersion, therefore, we can obtain the heat of surface hydration, that is, the heat of the formation of surface hydroxyl groups.

In the present paper the heat of immersion of titanium dioxide in water has been measured in order to investigate the effects of the hydration treatment of the samples on the heat-of-immersion value obtained and on the heat of surface hydration calculated therefrom. As a result, it has been found that the hydration treatment has a great influence on the sintering of particles, and that it causes the heat-of-immersion value to vary considerably, while it scarcely affects the heat of surface hydration.

Experimental

Materials. Both the samples used in the present work, anatase and rutile, presented by the Teikoku Kako Co., had been made from titanium sulfate and were free from coatings. These original samples were treated repeatedly with 0.1 N nitric acid to remove basic impurities, and with 0.1 N ammonia water to remove acidic impurities, and then washed with distilled water; finally, the method of electrodialysis was used to clear them of electrolytes as completely as possible. The resulting samples were dried at 110°C for 10 hr in an oven (AI and RI).

A part of each sample (AI and RI) was treated at 800°C for 4 hr in air, and then exposed to saturated water vapor for 5 days at room temperature (AII and RII).

Another part of each sample (AI and RI) was further immersed in hot water at 80°C for 3 days in order to prepare a highly-hydrated sample (AIII and RIII). The samples AII, AIII, RII, and RIII were finally dried at 110°C for 10 hr as before.

Surface-area Measurement. The specific surface area of the samples was determined by applying the BET theory to the nitrogen adsorption data, assuming the area of a nitrogen molecule to be 16.2 Å^2.

Heat-of-immersion Measurement. The heat of immersion was measured at 25°C by means of a calorimeter equipped with a thermistor as the temperature-sensing element, as has been described previously.[10,11] Prior to the measurement, the glass ampoule containing the sample was treated at a desired temperature in a vacuum of 10^{-5} Torr for 4 hr, sealed off *in vacuo*, and then set in the calorimeter. The technique of the measurement of the heat of immersion was the same as has been described previously.[10,11] It has been pointed out that the heat treatment of titanium dioxide *in vacuo* leads to a partial reduction of the sample, leaving nonstoichiometric and gray-colored surfaces on the sample.[12,13] In the present investigation also, a slight color-change of the sample appeared upon pretreatment at elevated temperatures, but the sample was used for the heat-of-immersion measurement in this state.

Water-content Measurement. In a usual atmosphere water molecules are adsorbed on the surface of titanium dioxide both physically and chemically. The physically-adsorbed water can be removed fairly easily *in vacuo*, even at room temperature, whereas the chemisorbed water can be removed only gradually by heating at higher temperatures. Thus, the water contents at various temperatures were determined by the successive ignition-loss method.[10,11] Since the amount of water expelled above 1000°C was found to be negligible, the water contents at various temperatures were calculated cumulatively by the summation of the amount of water evolved at each temperature, assuming the water content at 1100°C to be zero. In these procedures a small amount of gases other than water vapor was found to be evolved at higher temperatures. This was eliminated from the water-content data in the following way. All the gases evolved at an elevated temperature were trapped in a bulb kept at the temperature of liquid nitrogen, and then measured volumetrically at room temperature after the reevaporation of the trapped gases, using an all-glass apparatus[3] equipped with an oil manometer in order to measure sensitively the minute vapor pressure of water. Next, a part of the gases was retrapped at −72°C. When the gas contained only water vapor, all the gas could be retrapped at −72°C. However, in the gases expelled from the sample at temperatures higher than 300°C, a detectable amount of gases remained uncondensed at −72°C. In such cases, only the condensed gas was again determined in the same way as before, after removing the uncondensed gases by the evacuation of the system. The latter value is illustrated in Fig. 2 as the amount of the water content. The gases other than water which were evolved included, for example, 0.09, 0.18, and 0.29 molecules/100 Å^2 at 300, 400, and 600°C respectively, for the sample RI.

Results and Discussion

In Fig. 1 the specific surface area of titanium dioxide is represented as a function of the temperature of pretreatment. The surface areas of the samples of RI, RII, and AII are almost constant up to 800°C, after that they decrease steeply, indicating the occurrence of sintering. The sintering starts at 700°C with AI, whereas it begins at 600°C with AIII and RIII.

Figure 2 shows the relation between the water content and the temperature of pretreatment, where the former is represented in OH's/100 Å^2. The water content of the rutile obtained is quite small over the whole range examined, as is shown in Fig. 2. This may be explained as follows: the surface hydroxyl groups on rutile can be more easily removed by heating *in vacuo*, and therefore the water content of rutile at 250°C to 400°C is unexpectedly less than those of α-Fe_2O_3 or ZnO.[2]

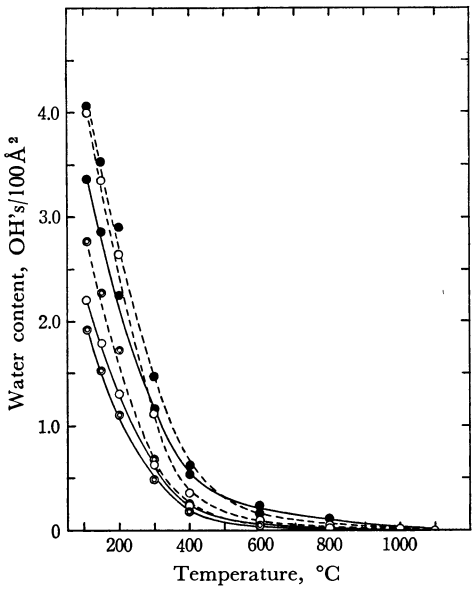

Fig. 2. Water contents of TiO_2 at various temperatures.
—— anatase: ○, AI; ◎, AII; ●, AIII
---- rutile: ○, RI; ◎, RII; ●, RIII

Also, it may be seen from Fig. 2 that the water contents on anatase seems to be slightly less than those on rutile; this may suggest that the surface hydroxyl groups on anatase can be removed as easily as, or more easily than, those on rutile. Furthermore, the water content is the greatest on the samples subjected to heavy hydration treatment in hot water, whereas it is the least on samples exposed to the saturated water vapor after 800°-treatment. In conclusion, the water contents of anatase and rutile decrease in the order: AIII>AI>AII and RIII>RI>RII.

A comparison of Fig. 1 with Fig. 2 leads to an interesting conclusion. On the samples AII and RII, which were once treated at 800°C and then exposed to the saturated water vapor at room temperature, the sintering due to retreatment does not occur below 800°C, but it occurs remarkably over 800°C, as may be expected. On the other hand, the water content of the samples AIII and RIII subjected to heavy hydration procedure in hot water is the largest, and their sintering starts at a lower temperature, 600°C. The temperature at which the sintering of the samples starts rises in the order: AIII<AI<AII and RIII<RI<RII, corresponding to the order of decrease in the water content.

In the present case, the sintering may be initiated by the condensation dehydration of hydroxyl groups from the facing surfaces of contacting particles.[14] The fact that the sintering of the sample with the larger water content starts at a lower temperature seems to support this supposition. When the condensation dehydration occurs from two contacting surfaces facing each other, there is a possibility that a part of the surface hydroxyl groups will be closed into the inner surfaces thus produced. Thus, it is reasonable to consider that it is difficult to remove such surface hydroxyl groups even at elevated temperatures, as is shown in Fig. 2.

The heat of immersion of titanium dioxide is given in Fig. 3 as a function of the temperature of pretreatment. These data show a maximum similar to the results of Wade and Hackerman.[6] The pretreatment temperature at which the maximum appears is about 400°C in the present study, whereas it was between 300°C and 350°C in their experiments. It may be seen from Fig. 3 that the value

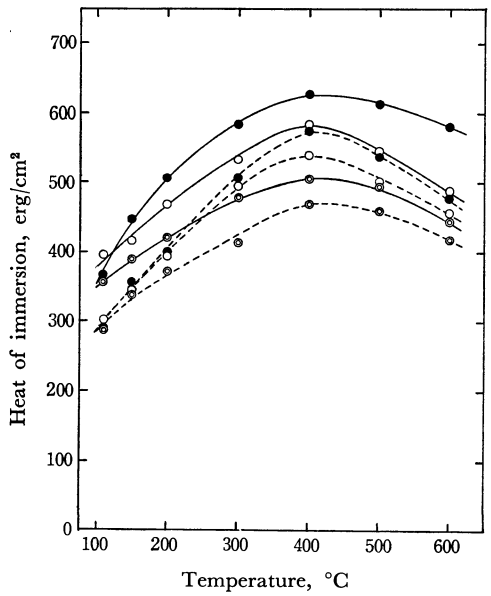

Fig. 3. Dependence of heat of immersion of TiO_2 in water on pretreatment temperature.
—— anatase: ○, AI; ◎, AII; ●, AIII
---- rutile: ○, RI; ◎, RII; ●, RIII

of the heat of immersion varies with the extent of hydration treatment, while in the experiments of Wade and Hackerman it was dependent on the size of the particles used. The heat-of-immersion value decreases in the order: AIII>AI>AII and RIII>RI>RII, parallel with the order of water content.

The heat-of-immersion anomaly, the terms of which imply the appearance of a maximum in the plot of the heat of immersion *vs.* the pretreatment temperature, has been explained as a cooperative effect of the chemisorption and physical adsorption of water: in the range of the steep increase in the heat of immersion, the reversible rehydroxylation (chemisorption of water to form surface

14) P. J. Anderson and P. L. Morgan, *Trans. Faraday Soc.*, **60**, 930 (1964).

hydroxyl groups) occurs on the site dehydrated by the pretreatment at elevated temperatures.[6,8-11] In the range of temperatures higher than the maximum point of the heat of immersion, the reversible rehydroxylation is delayed by the stabilization of the surface oxide structure, so the additional heat evolution by this reaction within the period of the heat-of-immersion measurement (less than 10 min) is decreased.

If we assume that the energy of the physical interaction on the immersion of a powdered sample in water is constant over the whole range of pretreatment temperatures, and that the appearance of the peak of the heat of immersion results from the additional heat evolution by the chemisorption of water, it may be said, as is shown in Fig. 3, that the contribution of the physical interaction varies considerably with the extent of hydration treatment and is larger on a sample which is subjected to a heavy hydration procedure and which is, therefore, rich in water. In general, three kinds of forces may be considered to be concerned with the contribution of the physical interaction on immersing a solid in a liquid: (1) the interaction between the polar surface and the dipole of the liquid molecule, (2) the effect of the induced dipole of the molecule, and (3) the effect of the dispersion force. Since titanium dioxide is known to be one of the most polar substances, it is valid to consider that the first of these three factors is most effective in the present case, being largely influenced by the surface hydroxyl groups.

Figure 4 shows the plots of the heat of immersion against the water content in the range of a steep increase in the heat of immersion in Fig. 3. As has been discussed above, in this range the physical adsorption and the chemisorption of water occur simultaneously, and the slope of this plot implies the energy of formation of a hydroxyl group (heat of surface hydration). The heats of surface hydration obtained are tabulated in Table 1; it is found that the variation in the heat due to the extent of hydration treatment is small, the average value being 25.2 and 19.0 kcal/mol H_2O for anatase and rutile respectively. Thus far the heat of surface hydration has been reported for several metal oxides: 16.1,[8] 3.5—6.5,[9] and 4.66[15] for SiO_2, 15.8 and 9.60 for α- and γ-Al_2O_3,[10] and 23.1 for ZnO.[11] The present data on TiO_2 are found to be comparable with those on ZnO.

The Chromium(III) Complexes with Anthranilicdiacetic Acid*[1]

Takeshi TOMITA, Eishin KYUNO and Ryokichi TSUCHIYA

Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa

(Received April 18, 1968)

The following chromium(III) complexes containing the anthranilicdiacetic acid (ATDA) were prepared: $[Cr(atda)^*(H_2O)_2]\cdot 3H_2O$ (reddish-violet) (I), $K[Cr(OH)(atda)(H_2O)]$ (bluish-violet) (II), $[Cr(atda)(phen)^*]\cdot 3H_2O$ (red) (III), $[Cr(atda)(dipy)^*\cdot 2H_2O$ (red) (IV), $[Cr(atda)(en)^*]\cdot 2H_2O$ (red) (V) and $K[Cr(atda)(acac)^*]$ (violet) (VI). From the results of electronic spectra, molar conductivities, chemical and thermal analyses and IR spectra, it was concluded that the Complexes I, II and VI belong to the $[CrO_5N]$, and III, IV and V belong to the $[CrO_3N_3]$ type. ATDA in all these complexes obtained was found to behave only as a quadridentate ligand. The values of the effective magnetic moments were found to be 3.7—3.9 B. M., nearly equal to the spin-only values of the tervalent chromium.
(* atda, phen, dipy, en and, acac are the basic forms of anthranilic acid, *o*-phenanthroline, 2,2'-dipyridyl, ethylenediamine and acetylacetone respectively.)

The syntheses of the chromium(III) complexes with ammoniatriacetic acid (ATA)[1] and with its derivatives, ammoniapropionicdiacetic acid (APDA)[2] and ammoniaisopropionicdiacetic acid (AIPDA)[3] in the solid state have been reported and the coordinating structures of these complexes both in a solid state and in an aqueous solution have been discussed in previous papers. On the other hand, there are few papers on the synthesis of the complexes with the carboxylmethyl derivatives of the anthranilic acid as the aromatic amino acids.

The formation constants in aqueous solution may serve as an important guide for preparing metal coordination compounds. A series of stabilities of the complexes with anthranilic acid and its derivatives have been given by Young *et al.*,[4] who pointed out that the effect of attaching acetic groups to the amino nitrogen upon the stability is seen to grow up in the sequence: anthranilic acid < anthranilicmonoacetic acid < anthranilicdiacetic acid. It may be due to the fact that the number of the chelate rings increases as the carboxylmethyl groups are introduced step by step to anthranilic acid.

In this study, the authors took the anthranilicdiacetic acid (abbreviated as ATDA) as the ligand relating to ATA, but differing from it in that ATDA contains the aromatic ring, and studied the chromium(III) complexes with this ATDA.

The present work was undertaken, i) to prepare the single- and mixed-ligand complexes containing ATDA, ii) to find out how ATDA could behave towards a chromium(III) ion in complex formation, and iii) to discuss their structures based on the comparison with those of the corresponding ATA complexes.

Experimental

Syntheses. *1) Anthranilicdiacetic Acid Hydrochloride* (ATDA·HCl), $C_{11}H_{11}NO_6\cdot HCl$. Anthranilicdiacetic acid hydrochloride was prepared by the reaction of excess monochloroacetic acid with anthranilic acid in the presence of alkali hydroxide solution enough to neutralize the above acids.[4]

2) Anthranilicdiacetatodiaquochromium(III) Trihydrate, $[Cr(atda)(H_2O)_2]\cdot 3H_2O$ (I). To two liters of aqueous solution of 20 g of chromium(III) chloride hexahydrate, 20 g of anthranilicdiacetic acid hydrochloride was added. After the mixture was heated on a boiling water bath for about two hours, the color of the solution gradually turned from green to violet. Evaporating the resulting solution for one hour, the solution was stood at room temperature overnight. Reddish-violet needle crystals precipitated were filtered, and then recrystallization was done in water. Yield, about 12 g. The compound is poorly soluble in both water (M/200) and ethanol.

Found: Cr, 13.08; C, 33.83; H, 4.46; N, 3.46; H_2O, 23.5%. Calcd for $[Cr(C_{11}H_8NO_6)(H_2O)_2]\cdot 3H_2O$: Cr, 13.30; C, 33.68; H, 4.62; N, 3.57; H_2O, 23.0%.

Other complexes newly prepared in the present study were derived from this I as a starting material.

3) Potassium Hydroxoanthranilicdiacetatoaquochromate(III), $K[Cr(OH)(atda)(H_2O)]$ (II). To a solution of 5 g of the Complex I, potassium hydroxide solution was added to adjust the solution to pH 8 and the mixture

was heated on a water bath. After cooling it to room temperature, bluish-violet powder was precipitated and then filtered. The recrystallization was achieved from water. The solubility of this compound in water was about 5 g per liter.

Found: Cr, 13.68; C, 36.66; H, 2.71; N, 3.70%. Calcd for $K[Cr(OH)(C_{11}H_8NO_6)(H_2O)]$: Cr, 13.83; C, 35.11; H, 2.93; N, 3.72%.

4) Anthranilicdiacetato - o - phenanthrolinechromium(III) Trihydrate, $[Cr(atda)(phen)]\cdot 3H_2O$ (III). Five grams of I and 2.5 g of *o*-phenanthroline monohydrate were added to 200 m*l* of water. Heating the mixture on a boiling water bath, pH of the solution was controlled at 8 by dropping the alkali hydroxide solution into it. The color of the solution turned to dark-red from violet in the reaction process. After cooling the solution at 0°C overnight, the red compound was crystallized out. It was filtered and fully washed with water and ethanol. Recrystallization was carried out from the diluted hydrochloric acid solution. Yield, about 1 g. The complex is a little soluble in water.

Found: Cr, 9.74; C, 52.37; H, 4.19; N, 7.97; H_2O, 10.1%. Calcd for $[Cr(C_{11}H_8NO_6)(C_{14}H_{10}N_2)]\cdot 3H_2O$: Cr, 10.03; C, 53.28; H, 4.28; N, 8.14; H_2O, 10.4%.

5) Anthranilicdiacetato-2,2'-dipyridylchromium(III) Dihydrate, $[Cr(atda)(dipy)]\cdot 2H_2O$ (IV). Two grams of 2,2'-dipyridyl were dissolved in 400 m*l* of I solution placed on a boiling water bath. The pH of the mixture was adjusted to about 8 and concentrated for about an hour. After cooling it to 0°C, red crystalline compound was precipitated and was recrystallized from water. Yield, about 1.5 g.

Found: Cr, 10.27; C, 51.07; H, 4.50; N, 8.66; H_2O, 7.8%. Calcd for $[Cr(C_{11}H_8NO_6)(C_{12}H_8N_2)]\cdot 2H_2O$: Cr, 10.52; C, 51.01; H, 4.08; N, 8.50; H_2O, 7.3%.

6) Anthranilicdiacetatoethylenediaminechromium(III) Dihydrate, $[Cr(atda)(en)]\cdot 2H_2O$ (V). Five grams of I were dissolved in 400 m*l* of water and 4 g of ethylenediamine dihydrochloride was added to it. The alkali hydroxide solution was poured drop by drop until a suitable pH was attained and the solution was concentrated to 100 m*l* on a boiling water bath. When the solution was cooled to 0°C, a small amount of red crystals was precipitated. It was filtered and recrystallized from methanol. Yield, about 0.5 g.

Found: Cr, 12.88; C, 39.25; H, 5.32; N, 10.51; H_2O, 9.3%. Calcd for $[Cr(C_{11}H_8NO_6)(C_2H_8N_2)]\cdot 2H_2O$: Cr, 13.05; C, 39.20; H, 5.06; N, 10.60; H_2O, 9.1%.

7) Potassium Anthranilicdiacetatoacetylacetonatochromate(III), $K[Cr(atda)(acac)]$ (VI). Five grams of I were dissolved in 400 m*l* of water, and 4.7 g of potassium acetylacetonate was added. The mixture was warmed on a water bath and then heated in a flask equipped with a reflux condenser for two hours in order to prevent the vaporization of acetylacetone during the reaction. After the solution was concentrated to 200 m*l*, the mixed solution was placed in a desiccator. If the crystal of trisacetylacetonatochromium(III) as the impure substance was deposited, it should be excluded by filtration. When the desired violet powder was precipitated, it was collected on the filter. The recrystallization was carried out from the concentrated aqueous solution. The complex is very soluble in water. Yield, about 0.5 g.

Found: Cr, 11.66; C, 43.71; H, 3.49; N, 2.97%. Calcd for $K[Cr(C_{11}H_8NO_6)(C_5H_7O_2)]$: Cr, 11.50; C, 43.65; H, 3.43; N, 3.18%.

Apparatus. The molar conductivity, the visible, UV and IR spectra, reflectance spectra and the magnetic susceptibility were measured with a Yokogawa Universal Bridge BV-Z-13A, a Hitachi EPS Spectrophotometer, a Jasco DS-301 IR Spectrophotometer, a Hitachi EPU-2A Spectrophotometer equipped with the standard Hitachi Reflectance Attachment and a Gouy Balance, respectively. The quantity of the crystal-water contained in these complexes was estimated from TGA curves measured with a Shimadzu Thermano Balance.

Results and Discussion

Behaviors toward Ion Exchangers and Molar Conductivities. The behaviors of the complexes newly prepared in the present work toward ion exchangers and their molar conductivity data measured in the 1×10^{-3} molar aqueous solution are shown in Table 1. Both the Complexes II and VI were adsorbed by Cl-form exchanger and their molar conductivities were 89.1 and 92.2 mho cm^{-1} respectively. This suggests that both complexes are 1 : 1 valency type and negatively charged electrolytes. All other complexes were adsorbed by neither Na- nor Cl-form exchanger, indicating that all exist as nonelectrolyte state.

Visible and UV Absorption Spectra. The electronic spectra of the Complexes I, II, IV and

Complex	$\nu_1(10^{13}/sec)$	$(\log \varepsilon_1)$	$\nu_2(10^{13}/sec)$	$(\log \varepsilon_2)$	$\nu_3(10^{13}/sec)$	$(\log \varepsilon_3)$
I	54.9 (56.6)*	(1.93)	75.8 (75.6)	(1.94)		
II	54.1 (56.3)	(1.88)	74.5 (75.2)	(2.03)		
III	57.7 (57.7)	(1.87)	76.9 (76.0)	(2.18)	101.4	(4.02)
IV	57.7 (58.8)	(1.83)	76.7 (76.0)	(2.14)	97.4	(4.02)
V	58.8 (60.9)	(1.83)	79.8 (80.1)	(1.94)		
VI	56.9 (58.7)	(1.96)	78.3 (77.5)	(2.31)	90.9	(3.87)

* The numerals under parentheses indicate the absorption peaks measured by means of the diffuse-reflectance method.

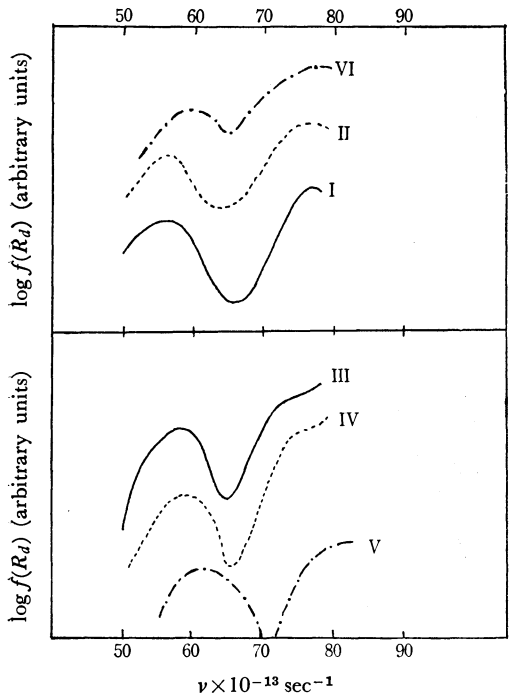

Fig. 2. Absorption spectra measured by the diffuse-reflectance method.
R_d: relative reflectance index

VI measured in aqueous solution and those of the Complexes III and V in DMF and methanol respectively are shown in Fig. 1, and all their absorption spectra obtained by diffuse-reflectance method in the solid state are in Fig. 2. The numerical data of their absorption maxima are summarized in Table 2.

It can be seen from Figs. 1 and 2 that every absorption spectrum in the solution closely coincides with the corresponding one in the solid state. It may indicate that all the complexes concerned exist in analogous form both in solution and in the crystalline state without any decomposition.

It has already been reported that the complexes, $NH_4[Cr(OH)(ata)(H_2O)]\cdot 2H_2O$[1] and $NH_4[Cr(OH)(aipda)(H_2O)]\cdot 4H_2O$,[3] corresponding to the Complex II, easily give rise to conversion to $NH_4[Cr(OH)(ata)(H_2O)_2]$ and $NH_4[Cr(OH)(aipda)(H_2O)_2]$ respectively as soon as dissolved in water and, at the same time, the color changes from purple in the crystal to green in aqueous solution, due to the liberation of nitrogen in ligands from coordination. Taking into account the result that the absorption maxima of II are larger than those of the corresponding ATA and AIPDA complexes cited above, it may be concluded that II is more stable than the ATA and AIPDA complexes.

Complexes III, IV and VI give the characteristic bands probably assigned to 2,2'-dipyridyl, *o*-phenanthroline and acetylacetone coordinated, respectively. When the aqueous solution of V was allowed to stand for several hours, a distinct frequency shift of the absorption peaks to lower wavelength region was observed, probably being attributed to the gradual aquation taking place in the complex.

The conclusion that the nitrogen atom of ATDA always coordinates to chromium(III) ion even in aqueous solution in the complexes concerned in this work, differing from that in the corresponding ATA and AIPDA complexes, may be supported by the information given above.

IR Spectra. The predominant peaks appearing in IR spectra on the complexes obtained are summarized in Table 3. With all complexes, the characteristic bands assigned to the stretching $\nu_{C=C}$ in benzene ring of atda are found near 1600 cm^{-1} and the bands for carboxyl groups of atda coordinated to chromium are shown within the wave number region of 1600—1700 cm^{-1}. By comparing these wave numbers with those observed in ATDA non-coordinated to chromium, 1730 cm^{-1}, it can be deduced that all the carboxyl groups in ATDA in every complex prepared in this work participate in coordination to the metal ion.

TABLE 3. IR DATA (cm^{-1})*

Complex	ν_{O-H}	ν_{N-H}	$\nu_{C=O}$	$\nu_{C=C}$
$atdaH_3$			1680, 1730	1600
I	3320		1620, 1675	1600
II	3240		1660, 1680	1600
III	3380		1675, 1700	1600
IV	3500		1665, 1695	1600
V	3440	3200, 3270	1630, 1680	1600
VI			1665, 1695, 1560	1605, 1530

* Measured in Nujol mull state.

As is indicated in Table 3, Complexes I—V have O–H stretching band and, above all, V shows two band peaks due to N–H stretching vibration rising from ethylenediamine. Complex VI gives two characteristic peaks owing to the acetylacetone coordinated, as is cited in literature.[5]

Magnetic Susceptibility. The effective magnetic moments of the complexes evaluated from the magnetic susceptibility measurement at room temperature are listed in Table 4. All the complexes show the normal magnetic moments, 3.7—3.9 B. M., which are nearly equal to the spin-only values calculated for tervalent chromium.

Thermogravimetric Measurement. The thermogravimetric curves for the complexes are shown in Fig. 3. It can be seen that all the complexes are gradually dehydrated up to about 130°C and then decomposed at about 230—300°C, except for the Complex I which loses stepwise three moles of the crystal-water and then two moles of the coordinated water up to 160°C.

TABLE 4. MAGNETIC MOMENT OF THE COMPLEXES

Complex	Magnetic moment (B. M.)	(Temp. °C)
I	3.76	(18.0)
II	3.80	(19.2)
III	3.80	(29.5)
IV	3.81	(30.0)
V	3.76	(21.3)
VI	3.90	(20.0)

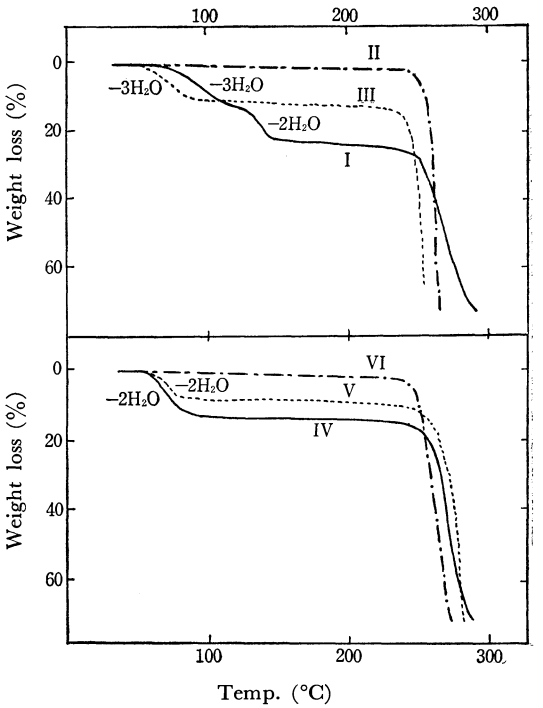

Fig. 3. Thermogravimetric curves.

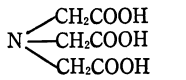
Discussion on the Structures. The configuration of the ligands, ATA, APDA and ATDA, are sketched in Fig. 4. When ATA behaves toward chromium as a quadridentate ligand, it forms three five-membered chelate rings. However, since there are some steric strains on nitrogen atom, it can be easily left from coordination to chromium, acting as a terdentate one.

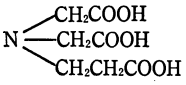
In the case of APDA, which is formed by introducing a methylene group into ATA, it can make one six-membered and two five-membered rings. Owing the such configuration, the steric strain focused on the nitrogen atom is, to some extent, reluxed, but one of the carboxyl groups is, in

5) J. P. Collman, R. A. Moss, H. Maltz and C. C. Heindel, *J. Am. Chem. Soc.*, **83**, 531 (1961).

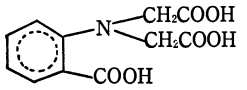
reverse, given the tendency to dislocate from coordination, differing from ATA. In short, both ATA and APDA can behave as terdentate ligands, the former acting without coordination of nitrogen atom and the latter having one of the free carboxyl group.



ATA (pK_3, 9.75)



APDA (pK_3, 9.96)



ATDA (pK_3, 7.75)

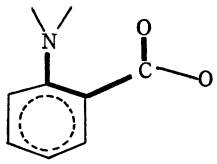


Fig. 4. The configurations of ATDA and related ligands.

On the other hand, ATDA behaves as a quadridentate ligand in all complexes treated in the present study; *i. e.*, it should be emphasized that all the four terminal atoms in the ligand, one nitrogen atom and three oxygen atoms, coordinate to the central metal ion even in an aqueous solution, although APDA sometimes behaves as terdentate ligand despite the fact that it has the analogous skeleton as ATDA. The reason for such difference will be attributed to the presence of the aromatic ring in ATDA. The available resonating interaction among one of the three carboxyls and the tertiary nitrogen group through the benzene ring may result in the shortening of the bond distances (shown by heavy lines in Fig. 4) with some extra stabilization energies and, therefore, the greater chelating power will be generated.[6] Thus, ATDA always behaves as a quadridentate ligand without the easy dissociation of the nitrogen atom from the coordination and without the formation of free carboxyl group even in solution, quite differing from ATA and APDA.

The difference of pK values among these three ligands (shown in Fig. 4) may allow an explanation for such coordinating characteristics in them as mentioned above. For example, the result that even one of the carboxyl groups in ATDA can not be easily released from the central metal in solution may be due to the smaller pK value in it.

In contrast to this stereochemical standpoint, the solubility sequence in water of each starting complex in the syntheses of a series of the mixed complexes, such as $NH_4[Cr(OH)(ata)(H_2O)] > [Cr(OH)(apdaH)(H_2O)] > [Cr(atda)(H_2O)_2]$, may play an important part in their preparation.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 952—955 (1969)

Volumetric Determination of the Iodide Ion with Mercury(II) Ethylenediaminetetraacetate Using Mercury(II)-Methylthymolblue as an Indicator

Toshiaki NOMURA

Department of Chemistry, Faculty of Science, Shinshu University, Asahi, Matsumoto

(Received May 9, 1968)

After 5 m*l* portions of 1×10^{-4} M methylthymolblue (MTB or H_2Me^{4-}) and mercury(II) nitrate solutions had been added to an iodide sample solution adjusted to pH 7.3—8.8, it was diluted to about 50 m*l* with water. This solution was titrated with a 1×10^{-2} M standard mercury(II) ethylenediaminetetraacetate (Hg-EDTA or HgY^{2-}) solution until it turned blue from greenish yellow. The iodide-ion content was calculated by applying the volume of the standard Hg-EDTA solution on the calibration curve determined with solutions of known iodide-ion contents. The iodide ion reacts with HgY^{2-} and with greenish-yellow $HgMe^{4-}$ to form colorless $[HgY(I)]^{3-}$ and blue $[HgMe(I)]^{5-}$ complexes respectively. The $[HgMe(I)]^{5-}$ complex reacts subsequently with the iodide ion to form mercury(II) iodide and greenish-yellow H_2Me^{4-}. It has been found that, except when an excess amount of the iodide ion existed, the $[HgMe(I)]^{5-}$ complex is the most stable among these mixed ligand complexes and mercury(II) iodide. Therefore, the iodide ion can be titrated directly with a Hg-EDTA solution by using $HgMe^{4-}$ as an indicator according to the following equation:

$$HgI_2 + H_2Me^{4-} + HgY^{2-} \rightarrow [HgMe(I)]^{5-} + [HgY(I)]^{3-} + 2H^+$$

Mercury(II) reacts with ethylenediaminetetraacetate (EDTA) to form mercury(II) ethylenediaminetetraacetate (Hg-EDTA or HgY^{2-}), which has no absorption in the visible region. Hg-EDTA reacts further with the iodide ion to form a colorless mixed ligand complex $[HgY(I)]^{3-}$, which does not react with the excess iodide ions any more.[1]

$$HgY^{2-} + I^- \rightarrow [HgY(I)]^{3-} \quad (1)$$

Mercury(II) reacts with colored methylthymolblue (MTB or H_2Me^{4-}) to form mercury(II)-methylthymolblue (Hg-MTB or $HgMe^{4-}$),[2] which has a color similar to that of MTB, and then further reacts with the iodide ion by means of the formation of a blue-colored mixed ligand complex $[HgMe(I)]^{5-}$:[3]

$$HgMe^{4-} + I^- \rightarrow [HgMe(I)]^{5-} \quad (2)$$

The $[HgMe(I)]^{5-}$ complex reacts subsequently with the iodide ion to form mercury(II) iodide and MTB, as the following equation shows:

$$[HgMe(I)]^{5-} + I^- + 2H^+ \rightarrow HgI_2 + H_2Me^{4-} \quad (3)$$

in the way similar to that in which the cyano mixed ligand complex $[HgMe(CN)]^{5-}$ reacts with the cyanide ion to form mercury(II) cyanide and MTB:[4]

$$[HgMe(CN)]^{5-} + CN^- + 2H^+ \rightarrow Hg(CN)_2 + H_2Me^{4-} \quad (4)$$

The order of the stability constants of these iodo mixed ligand complexes and mercury(II) iodide is:

$$[HgMe(I)]^{5-} > [HgY(I)]^{3-} > HgI_2$$

except when excess iodide ions are present in the solution.[5]

When an iodide-ion solution containing a small amount of $HgMe^{4-}$ is titrated with a Hg-EDTA solution, the reaction proceeds as follows.

When a small amount of $HgMe^{4-}$ is added to the iodide-ion solution before the titration, mercury(II) iodide and greenish-yellow H_2Me^{4-} are formed as in Eq. (5), since the excess iodide ions are present:

$$HgMe^{4-} + 2I^- + 2H^+ \rightarrow HgI_2 + H_2Me^{4-} \quad (5)$$

In the begining of the titration of this solution with the Hg-EDTA solution, the free iodide ion reacts with HgY^{2-} to form the $[HgY(I)]^{3-}$ complex as Eq. (1). After the excess iodide ions have been consumed by the Hg-EDTA, the (6) reaction begins and the blue color of $[HgMe(I)]^{5-}$ appears.

$$HgI_2 + HgY^{2-} + H_2Me^{4-} \rightarrow [HgY(I)]^{3-} + [HgMe(I)]^{5-} + 2H^+ \quad (6)$$

1) S. Komatsu and T. Nomura, *Nippon Kagaku Zasshi (J. Chem. Soc. Japan, Pure Chem. Sect.)*, **88**, 63 (1967).

2) N. Iritani and T. Miyahara, *Bunseki Kagaku (Japan Analyst)*, **12**, 1183 (1963).

5) T. Nomura and S. Komatsu, unpublished work.

Therefore, the iodide-ion contents in a solution can be titrated with a Hg-EDTA solution, using Hg-MTB as an indicator, if one considers the point at which the color changes from greenish yellow to blue as the end point of the titration.

As a representative method of the volumetric determination of iodide ions, Volhard's method (suitable for a 0.1 M iodide concentration)[6] and iodometry with hypochlorite (suitable for a 0.01 M iodide concentration)[7] have been reported. However, the present, newly-proposed method is especially suitable for the determination of about 0.01 M iodide. It is satisfactorily simple and reproducible.

Experimental

Reagents. All reagents were of an analytical grade and were used without further purification.

Methylthymolblue (MTB) Solution of 1×10^{-4} M. The stock solution of 1×10^{-3} M was prepared by dissolving 390 mg of Dotite MTB in a small amount of water, followed by the addition of 250 m*l* of methanol and by the exact dilution to 500 m*l* with water. This solution was stored in a brown glass bottle.[8] The working solution of 1×10^{-4} M was prepared by dilution with water.

Mercury(II) Nitrate Solution of 1×10^{-4} M. The stock solution of mercury(II) nitrate was prepared by dissolving 3.35 g of mercury(II) nitrate in a small amount of concentrated nitric acid and water, followed by dilution to 1 *l* with water. The precise concentration of this solution was obtained through titration with a 0.01 M standard EDTA solution, using Cu-PAN as an indicator.[9] The working solution of 1×10^{-4} M ($F=1.052$) was prepared by dilution with water.

Standard Iodide Ion Solution of 1×10^{-2} M. The stock solution was prepared by dissolving 16.6 g of potassium iodide and by then diluting to 1 *l* with water. The precise concentration of this solution was determined through titration with Volhard's method.[6] The working solution of 1×10^{-2} M ($F=1.000$) was prepared by dilution with water.

Standard Mercury(II) Ethylenediaminetetraacetate (Hg-EDTA) Solution of 1×10^{-2} M. This solution was prepared by the dissolution of 6.07 g of Dotite Hg-EDTA and by subsequent exact dilution to 1 *l* with water.

Buffer Solutions. Buffer solutions with definite pHs were prepared by properly mixing 0.2 M disodium hydrogenphosphate and 0.2 M potassium dihydrogenphosphate solutions.

Apparatus. The titration of the iodide ion solutions was carried out with a 1/20 graduated microburette. A Hitachi-Horiba M-4-type pH meter was used for the measurement of the pH values.

Procedure. Sample solutions containing up to 30 mg of iodide ions were adjusted to pH 7.3—8.8 with a buffer solution, to which a 5 m*l* portion of both a 1×10^{-4} M MTB and a mercury(II) nitrate solution were added; then they were diluted to about 50 m*l* with water. This solution (greenish yellow) was titrated with a 1×10^{-2} M standard Hg-EDTA solution until the color changed from greenish yellow to blue. The iodide-ion content was calculated by applying the titrated volume of the standard Hg-EDTA solution to the calibration curve obtained from solutions of known iodide-ion contents.

Results and Discussion

$HgMe^{4-}$ Indicator. The molar ratio of mercury(II) to MTB to form $HgMe^{4-}$ is 1 : 1, as has previously been mentioned.[2] Therefore, these reagents should be added to an iodide solution at a 1 : 1 molar ratio. However, because mercury(II) nitrate is insoluble in methanol and MTB is insoluble in water, it is difficult to make a solution which contains the reagents in a 1 : 1 molar ratio in a methanol-water mixture. Although it has been found that these reagents dissolve together in an aqueous buffer solution adjusted at pH 7.0, this solution can not be maintained for a long time because of its unstability. Therefore, each reagent solution should kept separately and added to the sample solution at every titration.

The Amount of Mercury(II) Nitrate Solution. In order to examine the suitable ratio of the mercury-(II) nitrate solution to the MTB solution, various amounts of a mercury(II) nitrate solution and 5 m*l* of a MTB solution were added to an iodide solution which had been adjusted to pH 7.5 and which contained 6.345 mg of iodide ions. The mixture was then diluted to about 50 m*l* with water. This solution was titrated according to the procedure described in the Experimental section. Below 1 m*l* of a mercury(II) nitrate solution, the end point was not clear because the weak blue color of the

mixed ligand complex was contradicted by the strong greenish-yellow color of the excess MTB. In the region from 2 m*l* to 5 m*l* of a mercury(II) nitrate solution, the end point was clearly observed despite the excess MTB giving a greenish-yellow color to the solution. From 5 m*l* to 15 m*l* of the mercury(II) nitrate solution, the end point was also clear in spite of the appearance of a yellow-green color just before the end point. However, the amount of the standard Hg-EDTA solution required in the titration was decreased in inverse proportion to the amount of the mercury(II) nitrate solution added. This situation is shown in Fig. 1. Therefore, the amount of the mercury(II) nitrate solution should be kept definite throughout a series of titrations.

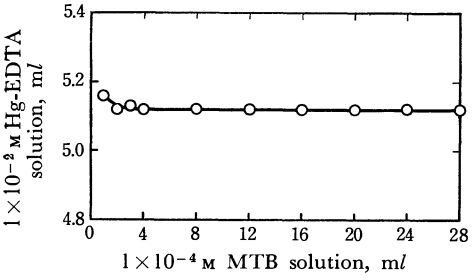

Fig. 2. Amount of MTB solution as an indicator.
6.345 mg of iodide ion, 5 m*l* of 1×10^{-4} M mercury(II) solution, pH 7.5.

The Amount of the MTB Solution. For the same purpose as in the preceding paragraph, various amounts of a MTB solution and 5 m*l* of a mercury(II) nitrate solution were added to the iodide solution under conditions identical to those described above, and this solution was treated similarly. When up to 1 m*l* of the MTB solution was added, the end point could not be determined because scarcely no color change in the solution could be observed. In the range from 6 m*l* to 15 m*l* of the MTB solution added, the greenish-yellow color of the excess MTB remained after the end point had been reached. However, the end point was clearly observed. Over 15 m*l*, however, the end point was not clear because of the strong greenish-yellow color of the excess MTB remaining after the end point. These results are shown in Fig. 2. Therefore, when 5 m*l* of a mercury(II) nitrate solution of 1×10^{-4} M is added, 2 m*l* to 15 m*l* of the MTB solution of 1×10^{-4} M should be added to the iodide sample solution before titration.

As a result of the above examination, the amount of a mercury(II) nitrate solution should be between 2 m*l* and 15 m*l* and the amount of the MTB solution should be from a half to 3 times that of the mercury(II) nitrate solution. In the following experiments, 5 m*l* portions of both mercury(II) nitrate and MTB solutions of 1×10^{-4} M were used.

Effect of pH. After a solution containing 6.345 mg of iodide ions had been adjusted to various pH values with buffer solutions, the solution was treated with the above procedure. The results are shown in Fig. 3. Up to pH 6.7, the end point

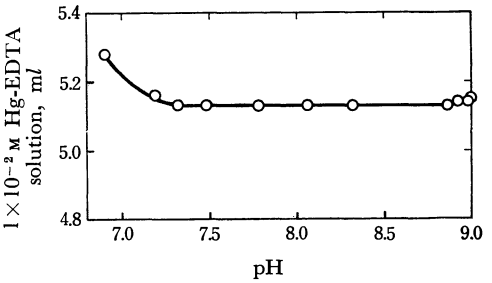

Fig. 3. Effect of pH.
Each 5 m*l* of 1×10^{-4} M MTB and mercury(II) solutions, 6.345 mg of iodide ion.

could not be detected because the yellow of MTB did not change; that is, the mixed ligand complex did not form. Between pH 6.9 and 7.1, the end point could be detected with difficulty. The color change from greenish yellow to blue was very clear between pH 7.3 and 8.8. Furthermore, an identical amount of the standard Hg-EDTA solution was necessary in this pH range. Above pH 8.9, the blue color of MTB in the high-pH region made the end point unobservable. Therefore, the titration should be performed between pH 7.3 and 8.8.

Effect of Standing Time. The interval between the preparation of a sample solution and titration with a standard Hg-EDTA solution was changed in order to study the effect of the standing time. No effect was observed, however, even at titration after 60 min. Therefore, the titration was carried out after a few minutes.

Calibration Curve and Reproducibility of Analytical Results. It is common, in a titration, for the quantity of an ion present in an unknown sample solution to be calculated by multiplicating the Titer by the volume of the standard solution required (titer). In the present method, however, because the standard Hg-EDTA solution contains free mercury(II), the Titer can not be calculated from the volume of the Hg-EDTA solution required to titrate a known amount of iodide ions. If the quantity of iodide ions were calculated with the usual Titer method, any error in the analytical results might be increased in proportion to the difference between a titer and the volume of the standard solution required to determine the Titer. In this experiment, therefore, a calibration curve was made by a procedure which proposed to express the relationship between the iodide-ion content and the volume of the 1×10^{-2} M standard Hg-EDTA solution required (titer). The reap-

Table 1. Reappearance of titer (m*l*) with the proposed procedure

Iodide ions added (mg)	0.317	0.635	1.269	2.538	6.345	12.69	19.04	25.38	31.73
1	0.12	0.41	0.92	1.99	5.13	10.34	15.57	20.83	26.08
2	0.15	0.42	0.94	2.00	5.13	10.33	15.59	20.87	26.12
3	0.15	0.41	0.94	1.99	5.12	10.33	15.61	20.84	26.09
4	0.15	0.41	0.93	1.98	5.12	10.32	15.57	20.83	26.10
5	0.16	0.42	0.93	2.00	5.13	10.33	15.58	20.82	26.10
Standard deviation	0.0063	0.0063	0.0077	0.0077	0.0063	0.0063	0.016	0.017	0.013
Variation coefficient (%)	4.21	1.54	0.83	0.39	0.12	0.06	0.10	0.08	0.05

pearance of titers on the calibration curve was examined; the results are shown in Table 1. The calibration curve is linear from a 0.3 to a 32 mg iodide ion content.

A minor additional comment is necessary regarding this titration. If the sample does not contain any iodide ions at all, the greenish-yellow color of the solution does not change to blue. Therefore, it is recommended that a preliminary test for the presence of iodide ions be made by means of the addition of 5 m*l* of a 1×10^{-4} M iodide solution to the sample. When no iodide is present in the sample, the color of the solution is blue before any of the standard solution is dropped in.

Effect of Diverse Ions. A solution containing 6.345 mg of iodide ions and various foreign ions was titrated by means of the proposed procedure. The results are shown in Table 2. The results that differed more than $\pm2\%$ from the expected volume of the standard Hg-EDTA solution were taken as the criterion for the interference.

The interference of such anions as CN^-, S^{2-}, SCN^-, and Br^- in this titration can be interpreted as originating as follows. The cyanide ion reacts with Hg-EDTA to form mercury(II) cyanide and EDTA, S^{2-} reacts with mercury(II) to form mercury(II) sulfide, and SCN^- and Br^- react with Hg-EDTA or Hg-MTB to form mixed ligand complexes. Cations, such as Co^{2+}, Ni^{2+}, Cu^{2+}, Mn^{2+}, Zn^{2+}, Ca^{2+} and Ag^+, also interfere, since these cations react with MTB to form metal-MTB complexes.

These interfering ions should be separated or masked properly when this procedure is used. A method of separation employing ion-exchange resin has been reported by Takiura *et al.*[10] for anions, and by the author for cations.[8]

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 956—960 (1969)

Determination of a Small Amount of Iodide by Atomic Absorption Spectrophotometry Using a Cadmium Hollow Cathode Lamp

Takahiro KUMAMARU

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima

(Received June 8, 1968)

A new application of atomic absorption spectrophotometry to the determination of iodide has been proposed. The method is based on solvent extraction into nitrobenzene of the colorless ion-pair formed between tris(1,10-phenanthroline)cadmium(II) and the iodide anion, and the subsequent determination of the cadmium concentration in the extract by atomic absorption in an air-acetylene flame at the 2288 Å cadmium line. The absorbance due to cadmium in the extract shows a linear relationship to the concentration of iodide over the range from 4×10^{-6} to 4×10^{-5} M initially present in the aqueous solution. The optimum conditions for the determination of iodide have been established, and the extraction efficiency and the effect of other anions have also been studied.

Since the resonance lines for most nonmetallic elements occur in the vacuum ultraviolet region, it has been impossible to determine these elements directly by atomic absorption spectrophotometry. Indirect determinations of nonmetals can, however, be readily performed with conventional atomic absorption apparatus. One of these methods is based on the stoichiometric formation of ion-pairs with a cationic metal ion chelate; these ion-pairs can then be isolated and determined by atomic absorption, the results being related quantitatively to the associated nonmetal.

It has been found that iodide anions can be extracted into nitrobenzene if the aqueous solution contains an excess of tris(1,10-phenanthroline)-cadmium(II) cations, and it is possible to determine the iodide by spraying the nitrobenzene solution into the flame of an atomic absorption spectrophotometer, with a cadmium hollow cathode lamp used as the light source. A brief preliminary study of this method has already been reported.[1] The present paper will present a detailed quantitative study undertaken to establish a new application of atomic absorption spectrophotometry. This proposed method for iodide is rapid and accurate, and it is different from the previously known colorimetric methods, which are based on the catalytic action of iodide,[2,3] the starch-iodide reaction,[3] triiodide formation,[3] and red-colored ion-pair formation between the iodide ion and the tris-(1,10-phenanthroline)iron(II) chelate cation.[4]

Indirect methods for the determination of nitrate,[5] pentachlorophenol[6] and phthalic acid,[7,8] based on the same principle, have recently been reported.

Experimental

Apparatus. The atomic absorption was measured with a Hitachi Model EPU-2 spectrophotometer and a Hitachi Model 0420 atomic absorption attachment equipped with a cadmium hollow cathode lamp. An air-acetylene flame was burned with a water-cooled 9-cm slot burner. The pH values were measured with a Hitachi-Horiba Model H-5 pH meter. The shaking for extraction was carried out with an Iwaki Model KM shaker equipped with time control. The gamma ray counting of ^{131}I was performed with an Aloka Model PSM 801 γ-ray spectrometer equipped with a 1 1/2''$\phi\times$1'' NaI(Tl) crystal.

Reagents. All the chemicals used were of an analytical reagent grade.

A phenanthroline-cadmium(II) sulfate solution was prepared by dissolving 1.28 g of cadmium sulfate ($3CdSO_4\cdot8H_2O$) and 3.17 g of 1,10-phenanthroline ($C_{10}H_8N_2\cdot H_2O$) in dilute sulfuric acid and by then diluting the mixture to a volume of 1000 ml with water. The resulting solution (pH 3) is 5.0×10^{-3} M in tris-(1,10-phenanthroline)cadmium(II) sulfate. A cadmium solution for continuous variation plots was prepared by

the suitable dilution of a cadmium sulfate stock solution (1.0×10^{-2} M) which had been standardized by EDTA titration. A standard stock solution of 1.0×10^{-2} M iodide was prepared from potassium iodide dried at 110°C. The concentration of iodide ions was determined by conventional argentometry. The iodide standard solution for the experiment was prepared by diluting an aliquot of this stock solution with water to give a concentration of 1.0×10^{-4} M. A radioactive iodide solution was also prepared from sodium iodide-^{131}I, which had been obtained from the Japan Radioisotope Association. To make the solution pH 5, a 0.5 M potassium dihydrogenphosphate-disodium hydrogenphosphate solution was employed.

Procedure. Tris(1,10-phenanthroline)cadmium(II) iodide was extracted into nitrobenzene; the organic extract was then aspirated directly into the atomic absorption spectrophotometer.

Five milliliters of the phenanthroline-cadmium(II) sulfate solution (5.0×10^{-3} M), 5 m*l* of a 0.5 M phosphate buffer solution (pH 5), and a measured volume of 15 m*l* or less of the sample solution were placed in a 100-m*l* separatory funnel, and, finally, the aqueous phase volume was adjusted to 25 m*l* with water. After 10 m*l* of nitrobenzene had been poured in, the funnel was shaken for 1 min. The two phases clearly separated within 20 min after the end of the shaking. The organic phase was then dried with 1 g of anhydrous sodium sulfate.

The absorption due to cadmium in the organic phase was then determined with the atomic absorption spectrophotometer against a reagent blank used as a reference, and expressed as the initial concentration of iodide in the aqueous phase, based on stock iodide solution used as standards. The instrument-operating conditions included analysis at the wavelength of 2288 Å, a slit width of 0.4 mm, and a lamp current of 7.5 mA (cadmium lamp). The flow rates of gases for the air-acetylene flame were 8.0 *l*/min of air and 1.6 *l*/min of acetylene. The burner height was adjusted to make the light beam pass 6 mm above the tip of the burner.

Results and Discussion

Atomic Absorption Spectrophotometric Variables. *Lamp Current.* Figure 1 shows the effect of the lamp current in the absorption of cadmium. From five series of results, it can be seen that a low lamp current gives the higher absorbance for the cadmium 2288 Å. However this cadmium hollow cathode lamp could not be used with a current less than 5 mA because of its low light intensity. Therefore, the preferable lamp current was decided to be 7.5 mA.

Air-acetylene Flame. The effects of the variation in the air-acetylene mixture on the absorption were also studied. The results are shown in Fig. 2. For convenience, the gas-flow rates were adjusted so that the burner consumes 8.0 *l*/min of air and 1.6 *l*/min of acetylene in subsequent investigations. Under these flame conditions, it was found that the optimum height for the passage of the light beam from the hollow cathode tube through the reducing flame was 5 to 8 mm above the tip of the burner; higher and lower passage of light gave slightly poorer sensitivities.

Variables of Extraction. *Solvent.* Various kinds of commercially-available organic solvents were tested for the extraction: *n*-butyl alcohol, isoamyl alcohol, isopropyl ether, ethyl acetate, *n*-butyl acetate, methyl isopropyl ketone, methyl isobutyl ketone, chloroform, carbon tetrachloride, 1,2-dichloroethane, cyclohexanone, benzene, chlorobenzene, and nitrobenzene. Only nitrobenzene extracted phenanthroline-cadmium(II) iodide selectively from the aqueous solution. Moreover, nitrobenzene is a suitable solvent for atomic absorption spectrophotometry because it gives a stable flame during the combustion and a higher

sensitivity of measurement.

The extraction percentage of iodide was then determined by the radioactive tracer method using an ^{131}I-labeled iodide solution. One milliliter of each phase was taken after extraction, and the radioactivities of gamma rays were measured with a scintillation counter. The results are shown in Table 1. When the phenanthroline-cadmium(II) chelate cations are absent in the aqueous phase, iodide ions were negligibly extracted into nitrobenzene (~200 cpm).

TABLE 1. EXTRACTION PERCENTAGE

Sample No.	Net cpm (^{131}I)		Extraction percentage, %
	Aqueous phase	Organic phase	
1	7475±89	72760±427	90.7±0.7
2	7513±89	72495±426	90.7±0.7

Organic phase: 10 m*l*, Aqueous phase: 25 m*l*
Initial concentration of iodide: 4.0×10^{-5} M
Initial concentration of tris(phenanthroline)cadmium(II): 1.0×10^{-3} M
pH: 5; buffered with phosphate

pH. The effect of pH on the extraction was studied by extracting the iodide anions from a series of aqueous solutions buffered in the pH range from 2 to 9. In Fig. 3, Curve 2 was obtained by the subtraction of the absorbance in Curve 1 (no iodide) from the total observed absorbance in the sample. The pH variations between 3.5 and 5.5 had practically no effect on the results if the absorbance of the reagent blank was subtracted from the total absorbance at each pH. In the subsequent experiments, the pH of the aqueous phase was adjusted to nearly 5 with a phosphate buffer. The change in the concentration of the phosphate buffer had a negligible effect on the extraction.

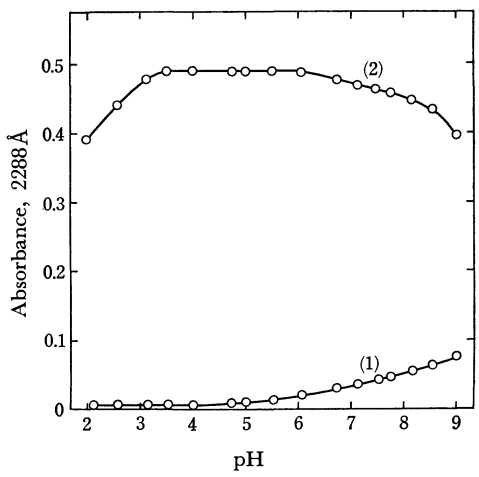

Fig. 3. Effect of pH.
(1) Reagent blank; Absorbance was measured against nitrobenzene.
(2) 4.0×10^{-5} M iodide; Correction in absorbance was made for the reagent blank.

Phenanthroline-Cadmium(II) Sulfate Concentration. As can be seen in Fig. 4, the absorbance of the nitrobenzene phase approached a limit when the chelate concentration was more than 6×10^{-4} M and when the iodide concentration was kept at

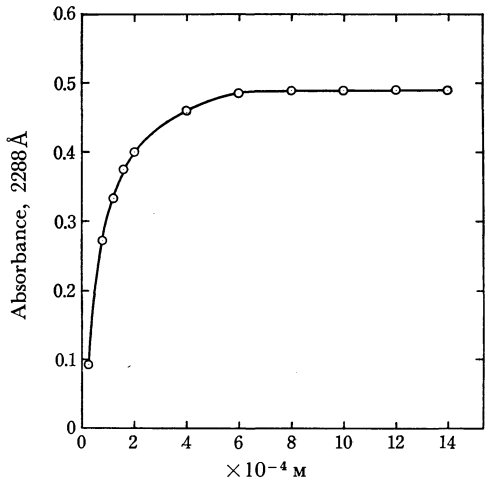

Fig. 4. Effect of chelate concentration on net absorbance for 4.0×10^{-5} M iodide.

4.0×10^{-5} M in the aqueous phase. An excess of at least 15-fold in molar quantity of the phenanthroline chelate to iodide was necessary for quantitative recoveries. Thus the chelate concentration was usually kept at 1.0×10^{-3} M.

Shaking Time. The shaking time for the extraction was varied from 0.5 to 15 min, while the other variables were kept constant. These variations in the shaking time showed that shaking for longer than a 0.5 min did not improve the extraction. Hence, 1 min was employed as the period for the extraction.

Calibration Curve. The standard procedure was decided upon the basis of the above results. The calibration curve was obtained by using varying amounts (1—10 m*l*) of the standard iodide solution (1.0×10^{-4} M). The absorbance due to cadmium in the organic phase showed a linear relationship to the tested concentration range from 4×10^{-6} to 4×10^{-5} M of iodide initially present in the aqueous phase, as is shown in Fig. 1 (Curve 2). This indicates that the high sensitivity of atomic absorption spectrophotometry for cadmium allows the determination of such low concentrations of iodide.

Precision. The reproducibility of the present method was estimated from the results of 10 sample solutions, each 4.0×10^{-5} M in iodide. The average

absorbance was 0.490, and the standard deviation was 0.003 absorbance unit (*i.e.* there was a relative error of 0.6%).

Influence of Diverse Ions. The effect of a series of anions on the extraction of the phenanthroline-cadmium(II) iodide into nitrobenzene was examined. Table 2 shows the degree of interference of diverse ions added to the solution containing iodide in 2.0×10^{-5} M.

Concentration of iodide: 2.0×10^{-5} M

It is of interest that the halides, when listed in the order of increasing interference with this method, are fluoride, chloride, and bromide, while the oxyacids and the peroxyacids of the halogens are listed, on the contrary, as iodate, bromate and chlorate, and periodate and perchlorate. One rather strange observation was that periodate appeared to interfere in a negative direction when present in a molar quantity lower than 1/10 the level of iodide. A possible reason for this low recovery may be its oxidation effect on iodide ions. Above this amount of periodate, there appeared an increase in the absorbance with an increase in the periodate; this increase might be caused by interference through the extraction of periodate ions with phenanthroline-cadmium(II). Large amounts of phosphate and sulfate, which were present in the reagent solution used, and carbonate, borate, fluoride, and iodate did not interfere with the determination of iodide, while perchlorate and chlorate, even when 1/10 the molar quantity of iodide was present, gave positive errors.

Composition of Extracted Species. In order to examine the composition of the extracted species, continuous variation plots were made in two series of extraction. As for the determination of the chelate formation ratio of phenanthroline to cadmium(II), the concentration of iodide and the total concentration of cadmium(II) and phenanthroline were both kept constant at 2.0×10^{-4} M, and then the extraction was carried out as in the procedure described above with a series of aqueous solutions containing a varying mole ratio of phenanthroline to cadmium(II). The resulting curve [Fig. 5 (Curve 1)], in which the reagent

Total concentration of tris(phenanthroline)-cadmium(II) and iodide: 1.6×10^{-4} M.
phen=1,10-phenanthroline

blank was subtracted, shows the ratio of phenanthroline to cadmium in the extracted species balances at 3; this indicates that the cationic tris(1,10-phenanthroline)cadmium(II) chelate may take part predominantly in the extraction of the iodide ion as the counter ion. Similar plots to confirm the composition of the tris(1,10-phenanthroline)-cadmium(II) iodide are shown in Fig. 5 (Curve 2). This suggests that a 1 : 2 associated ion-pair is formed in the nitrobenzene phase between the tris(1,10-phenanthroline)cadmium(II) cation and the iodide anion; thus the chemical formula of the extracted species can probably be represented as

[Cd(1,10-phenanthroline)$_3$]·I_2.

The author wishes to express his thanks to Professor Yuroku Yamamoto for his kind guidance and encouragement throughout this work, and also wishes to thank Mr. Yuzuru Otani for his technical assistance in this work.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 960—968 (1969)

Some Thermal Properties of Metal Chelates of *o*-Acylphenols and of Their Ketimine Derivatives*[1]

Seiichiro MATSUMOTO,*[2] Hiroshi KOBAYASHI and Keihei UENO

Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Fukuoka

(Received July 20, 1968)

The beryllium chelates of 2-hydroxy-3-methylacetophenone, 2-hydroxy-3-isopropylisobutyrophenone and 2-hydroxyacetophenone, and the copper- and nickel chelates of the ketimine derivatives of 2-trifluoroacetylphenol and 2-hydroxyisobutyrophenone in addition to the above *o*-acylphenols were synthesized. The thermal stability and relative volatility of these chelate compounds, measured by means of a thermogravimetric method, were found to be strongly increased by introduction of bulky alkyl or trifluoromethyl groups.

In relation to the application of gas-chromatography to the analysis of metal chelates, the great numbers of volatile metal chelates of β-diketones,[1] and of *N*-alkylsalicylaldimines[2] have been synthesized, and especially concerning the homologues of β-diketone, the correlation between the molecular structure of ligands and the volatility of their metal chelates has been intensively investigated.[3] Although no conclusive general rules governing the volatility of metal chelates have been attained yet, an observation has been made that introduction of trifluoromethyl or *t*-butyl group into a β-diketon skeleton strongly increased the volatility of its metal chelates. Except on the β-diketone homologues, however, very few works have been made on volatility of metal chelates and its correlation to the molecular structures of the ligands.

In the hope of obtaining a new type of volatile metal chelates, we synthesized the metal chelate compounds containing aromatic nuclei fused to the chelate rings in a molecule, *e. g.*, metal chelates of salicylaldehyde and of *o*-acylphenols, and investigated their volatilities and thermal stabilities in relation to the effects of aromatic nuclei, and of alkyl groups attached closely to the chelate ring.

Results and Discussion

The new ligands synthesized in the present work are 2-hydroxy-3-isopropylisobutyrophenone (I), 2-hydroxyisobutyrophenone (II), and 2-trifluoroacetylphenol (III). In addition to the above, salicylaldehyde (IV), 2-hydroxyacetophenone (V) and 2-hydroxy-3-methylacetophenone (VI) are used as ligands in order to make a comparison with the new ones. The structures of these ligands are shown in Fig. 1.

The new *o*-acylphenols, I, II and III, were synthesized by Fries rearrangement reaction from corresponding phenol acylates, accompanied by formation of isomeric *p*-acylphenols.

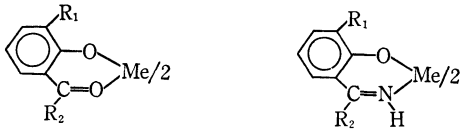
Infrared spectrum of I shows a broad diffused band at 3500—2500 cm^{-1} in good contrast with the sharp strong hydroxy band of the isomeric *p*-acylphenol observed at 3310 cm^{-1}. The character and position of this band allow it to be assigned to the stretching vibration of hydroxy group involved

in intramolecular hydrogen bond with carbonyl group sited at *ortho*-position. This is in good agreement with the observation of carbonyl band of I at 1630 cm^{-1} which is at a position of lower wave number as compared with that of the *p*-substituted isomer at 1650 cm^{-1}. 1,2,3-Tri-substituted phenyl moiety in I is ascertained by the nuclear magnetic resonance spectrum, in which three protons on an aromatic nucleus show themselves in a typical ABX pattern ($\delta_A=7.30$ ppm, $\delta_B=7.55$ ppm, $\delta_X=6.70$ ppm, $J_{AX}=J_{BX}=8$ cps, $J_{AB}=2$ cps); a quite similar pattern is observed also concerning three protons in aromatic ring of VI.

Infrared spectra of II and of III also show respectively a broad diffused band assigned to a hydroxy group in an intramolecular hydrogen bond and a band assigned to a lowered carbonyl stretching frequency in comparison with that of each *p*-substituted isomer. The spectra of II and of III reveal respectively a strong band characteristic to *o*-disubstituted benzene ring at about 750 cm^{-1}, and the presence of this band, together with the intramolecular hydrogen bond between the hydroxy and the carbonyl group, indicates *ortho*-acylphenol structures of II and III, which are also ascertained by their abilities of chelate formation with metal ions.

As observed in Figs. 2 and 3, characteristic resemblance to each other in the ultraviolet spectra of all these ligands also indicates that these ligands have the same arrangement of chromophores on a benzene nucleus.

Metal chelates of the *o*-acylphenols were prepared by using beryllium(II), copper(II) and nickel(II) salts. Beryllium ion gave 1 : 2 (metal ion : ligands) chelate compounds (VII) for I, V and VI as shown in Fig. 4, attempts to prepare complexes of III and of IV being unsuccessful. On the other hand, in the cases of copper(II)- and ncikel-(II) ions, usual procedures trying to prepare the complexes of an *o*-acylphenolate afforded, contrary to our intentions, 1 : 2 chelate compounds in which the ligands coordinated in the forms of ketimine derivatives as VIII in Fig. 4. The ketimines



(VII) (VIII)

Fig. 4. The structures of the metal chelates.

seem to arise on the process of chelate formation from the *o*-acylphenols and ammonia added into the reaction media to adjust its pH. Attempts to prepare *o*-acylphenolato-chelate compounds have been unsuccessful.

Thermogravimetric curves of the metal chelates described above are shown in Figs. 5, 6 and 7.

Although a rigorous discussion of volatility of a compound necessitates vapor pressure data at various temperatures and other thermodynamic data, the thermogravimetric method employed in the present work, roughly approximate though it may be, is a convenient procedure for the measurement of thermal stability of a compound and its relative volatility. Results of preliminary experiments on subliming behaviors of the chelates under reduced pressures indicated that the beryllium chelates of I, V and VI were readily sublimed at 150°C/0.5 mmHg, and that the copper- and nickel ketimine chelates of I and III were sublimed at

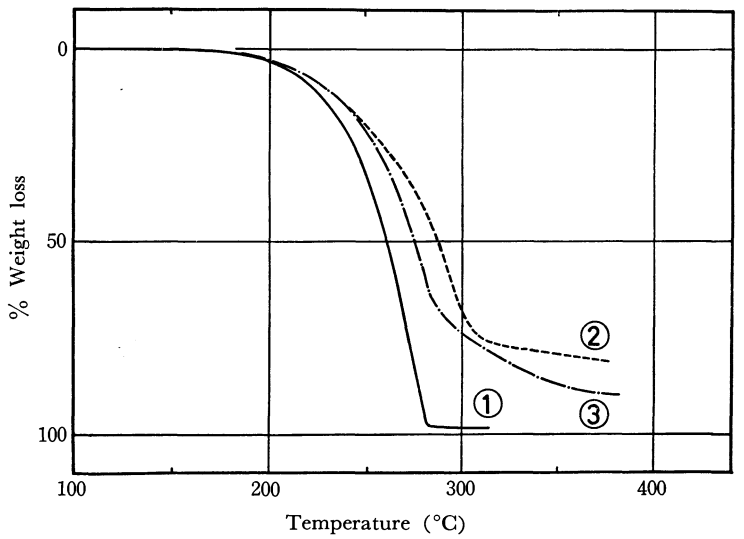


Fig. 5. Thermogravimetric curves of the beryllium chelates: Curve 1 for that of I, 2 for of V, and 3 for of VI, respectively.

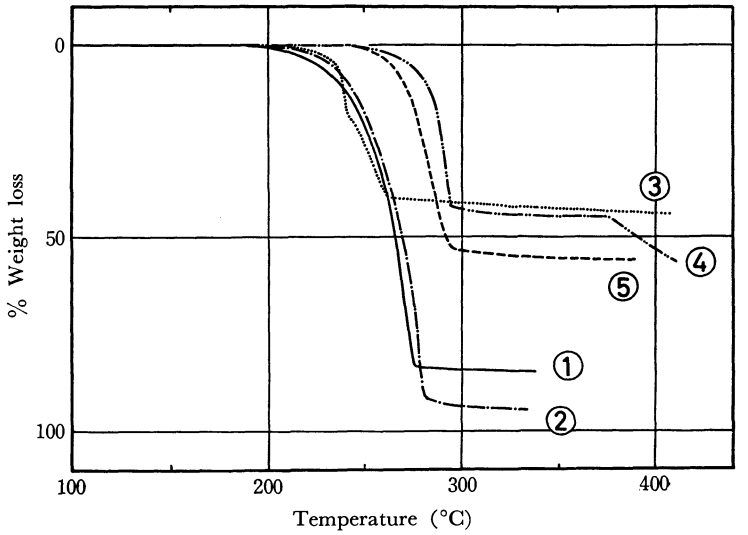

Fig. 6. Thermogravimetric curves of the copper chelates of the ketimine derivatives : Curve 1 for that of I, 2 for of III, 3 for of IV, 4 for of V and 5 for of VI, respectively.

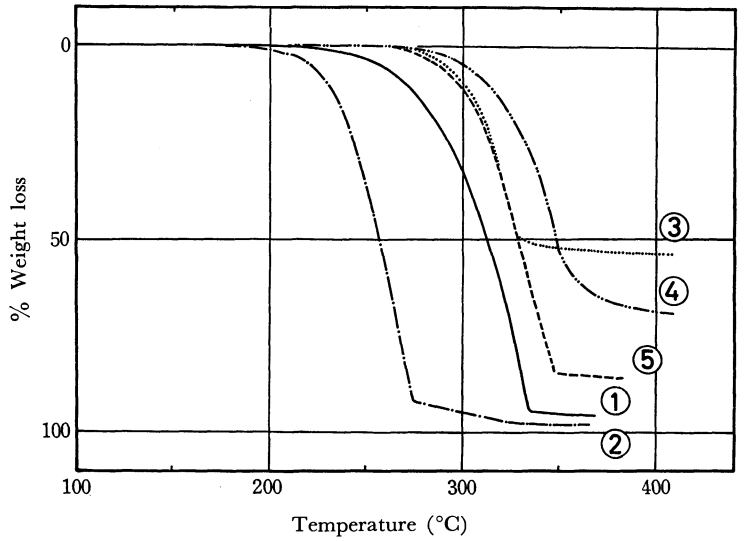

Fig. 7. Thermogravimetric curves of the nickel chelates of the ketimine derivatives : Curve 1 for that of I, 2 for of III, 3 for of IV, 4 for of V, and 5 for of VI, respectively.

about 160°C/0.4 mmHg without any decomposition, while those of IV, V and VI were less sublimable or the sublimation was accompanied with their thermal decomposition.

In the thermogravimetric experiments of these chelate compounds except those of IV, there was observed the deposition of crystalline substances onto the inner wall of the tubular glass part of the apparatus in the initial stage of the weight decrease, and the deposited substance in each experiment was confirmed to be the respective original one intact by infrared spectral comparison. This means that the initial weight decrease is not due to decomposition but to sublimation of the chelate compounds.

Thermogravimetric curves show that the introduction of a methyl group into V to give VI results in slightly easy vaporization of the chelates, and that replacing the methyl groups in VI with isopropyl groups to give I lowers the temperature where vaporization of the chelates begins and subsequently decreases their thermal decomposition as seen in Fig. 5. Thus, among the beryllium chelates only that of I could vaporize completely at a lower temperature without any thermal decomposition. Similar tendencies are observed on the ketimine chelates of copper and of nickel as seen in Figs. 6 and 7; the copper chelate of IV

begins to decompose at about 200°C and no vaporization is observed, the behavior of the nickel chelate also being not far different. Introduction of methyl- or isopropyl groups in the position adjacent to the donor groups in IV to give V, VI or I, makes their chelate compounds increasingly volatile as well as thermally stable, although the vaporization was still accompanied with slight thermal decomposition.

On the other hand, the introduction of trifluoromethyl group lowers the temperature at which vaporization of the complexes begins, as well as suppressing thermal decomposition, as observed in the complexes with the chelating agent III, which shows no thermal decomposition within the temperature range studied here.

Thus, as far as volatility is concerned, the *o*-acylphenols seem to show similar tendencies as those observed in the β-diketones; namely the more crowded groups around the donor atoms in a ligand make its chelate compound more volatile and more stable thermally, and in addition, the introduction of perfluoroalkyl groups into a ligand also makes its metal chelate strongly volatile as well as

thermally stable.

Ultraviolet spectra of the ligands given in Figs. 2 and 3 show that replacing a formyl group with an acyl group (IV→V, *etc.*) causes a characteristic shift on the spectra, although different acyl groups give no significant differences, and the introduction of an alkyl group into the aromatic nucleus (V→VI, or II→I) causes the bathochromic effect, which is still not so intensive as that observed with trifluoromethyl on III. Trifluoromethyl group causes not only strong bathochromic but also hyperchromic effects which are apparent by a comparison of the spectrum of III with that of V.

General features of visible spectra of the copper- and of the nickel ketimine chelates given respectively in Figs. 8 and 9 indicate that they are of a square planar configuration[4] and, although their molecular weights have not been determined, they seem to be all monomeric. Comparisons of their spectra reveal that introduction of alkyl groups into the ligands gives also very little effects on the electronic spectra of their metal complexes, while trifluoromethyl group causes a strong bathochromic shift.

Increased volatility of the chelate compound containing bulky alkyl groups, therefore, seems to be ascribed not to electronic effects by the alkyl groups, but mainly to their steric effects; namely the bulky alkyl groups sterically hinder the polar, or polarizable moieties such as aromatic, and chelate ring from being intermolecularly close to each other, so that consequent intermolecular forces among the chelate molecules seem to decrease to a large extent.

On the other hand, with respect to trifluoromethyl group, the nickel ketimine chelate of III is much more volatile than that of I, and therefore, bulkiness of the ligand or congestion around the central metal ion can not be only a responsible factor for the volatility. In preliminary solubility measurements in chloroform, which is known as one of the nonpolar solvents, the copper ketimine chelate of III has much less solubility than those of I, II, V and VI, though comparable with that of IV. The electronic spectrum of the copper ketimine chelate of III shows the strong red-shift, and the increased volatility of this chelate compound, therefore, must be ascribable not only to steric effects but also particular electronic effects of a trifluoromethyl group.

Whole mechanism of the increased volatility observed here should be very complicated and there remains much to be elucidated.

Experimental

Apparatus and Procedures. All melting points measured are uncorrected. The ultraviolet and visible spectra were measured with a Hitachi EPS-2 recording spectrophotometer, by using *n*-hexane as the solvents for the ligands and chloroform for the metal chelates respectively. The infrared spectra were measured with a JASCO DS-301 recording spectrophotometer. The nuclear magnetic resonance spectra were recorded with a Varian A-60 operating at 60 Mc, by using tetramethylsilane as the internal reference and carbon tetrachloride as the solvent. Thermogravimetric curves were obtained with a Shimadzu automatic recording thermobalance TB-10B under atmospheric pressure. A sample (about 40 mg) was held in a nitrogen stream (flow rate; about 60 ml/min) and heated at a rate of 5°C per minute. Temperatues were measured by alumel chromel thermocouples which were calibrated by the melting points of benzoic acid, succinic acid and anthraquinone.

Synthesis of the Ligands. *2-Hydroxy-3-isopropylisobutyrophenone (I).* 2-Isopropylphenyl isobutyrate[5] (14.7 g) was added dropwise into a suspension of aluminum chloride (10.9 g) in carbon disulfide (20 m*l*) with stirring for 30 min. The mixture was heated with gentle refluxing for an additional hour. After the solvent was distilled, which took about two hours, the temperature of the reaction mixture was gradually raised to 170°C during 30 min, and the mixture was heated keeping this temperature for subsequent 40 min. After cooled to room temperature, the resulting mixture was decomposed with aqueous hydrochloric acid (*ca.* 5 N) and steam-distilled. An organic layer separated from the aqueous distillate was taken into 500 m*l* of ether, and the ethereal solution was washed with 2 N aqueous sodium hydroxide (500 m*l*). The remaining ether layer afforded oily 2-hydroxy-3-isopropylisobutyrophenone (5.3 g) boiling at 109.0—111.0°C/2 mmHg. Found: C, 75.66; H, 8.82%. Calcd for $C_{13}H_{18}O_2$: C, 75.69; H, 8.80%. IR (liquid film): a broad band spreading over during 3500 and 2600 cm^{-1}, a triplet at 2982, 2950, and 2880 cm^{-1}, a sharp carbonyl band having some shoulders at 1632 cm^{-1}, and a sharp singlet at 746 cm^{-1}. NMR (*c* 0.77 M): a doublet at 1.17 and 1.28 ppm (12 protons), a multiplet spreading from 3.0 to 3.8 ppm (2 protons), a triplet centered at 6.70 ppm splitted with 8 cps of *J*-value (1 proton), two quartets (2 protons) centered at 7.30 and 7.55 ppm respectively, each of which is splitted into a quartet with two *J*-values (2 and 8 cps), and a singlet at 12.80 ppm (1 proton). Attempts to prepare a semicarbazone derivative were unsuccessful.

The residue remaining in a still-pot upon the steam-distillation gave the colorless crystals melting at 98.5—99.9°C (from petroleum ether). This crystalline compound was also separated from the alkaline washings after acidified (*ca.* 1 g). Found: C, 75.73; H, 9.01%. Calcd for $C_{13}H_{18}O_2$: C, 75.69; H, 8.80%. IR (potassium bromide disc): a strong band at 3310 cm^{-1}, a doublet at 2974 and 2880 cm^{-1}, a sharp carbonyl band at 1651 cm^{-1}, a prominent doublet at 1608 and 1585 cm^{-1}, and a strong sharp band at 819 cm^{-1}. Semicarbazone is readily formed, mp 199.0—203.0°C. This crystalline compound, though seemed to be 3-isopropyl-4-hydroxyisobutyrophenone, was not confirmed.

2-Hydroxyisobutyrophenone (II). Phenyl isobutyrate[6]

4) C. J. Ballhausen, "Introduction to Ligand Field Theory," McGraw-Hill, New York, N. Y. (1962).

5) A. Spassow, *Ber.*, **75**, 779 (1942).

6) E. H. Man, F. W. Swamer and C. R. Hauser, *J. Am. Chem. Soc.*, **73**, 901 (1951).

(40 g) was added dropwise into a suspension of aluminum chloride (37.3 g) in carbon disulfide (40 ml) with stirring. The mixture was heated in the similar way just as described above. The resulting mixture was decomposed with aqueous hydrochloric acid, and steam-distilled. An organic layer separated from the aqueous distillate was taken into ether, dried and distilled to give a fraction boiling at 79.3—79.5°C/3.5 mmHg (yield: 16.1 g, 40% of the theoretical). IR (liquid film): a broad band spreading over between 3400 and 2600 cm^{-1}, a triplet at 2980, 2940, and 2870 cm^{-1}, a carbonyl band at 1645 cm^{-1}, and two strong bands at 822 and 754 cm^{-1}. Analysis was satisfactory as the metal chelate derivatives, *vide infra*.

2-Trifluoroacetylphenol (III). Phenyl trifluoroacetate[7] (57 g) was added dropwise into a suspension of aluminum chloride (46 g) in carbon disulfide (60 ml) with stirring at room temperature for an hour. The mixture was heated with gentle refluxing for an additional hour. After the solvent was distilled out, which took one and half hour, the temperature of the reaction mixture was gradually rasied to 115°C during 15 min, and the mixture was cooled to 90°C, being kept at this temperature for one and half hour. The resulting mixture, after cooled to room temperature, was decomposed with aqueous hydrochloric acid, and steam-distilled. An organic layer separated from the aqueous distillate was taken into ether, and the ethereal extract was evaporated off. A residual oil was treated with copper acetate and ammonia in aqueous ethanol, giving a copper ketimine chelate (VIII) of the trifluoroacetylphenol (35 g). The ketimine chelate was decomposed with aqueous hydrochloric acid, giving a free ligand, which was extracted with ether, and was rectified to give an oily fraction boiling at 92°C/55 mmHg (yield: 23.8 g, 42% of the theoretical). Found: C, 50.65; H, 2.78%: Calcd for $C_8H_5O_2F_3$: C, 50.54; H, 2.65%. IR (liquid film): a broad band at 3240 cm^{-1}, a carbonyl band at 1684 cm^{-1}, three strong sharp bands at 1155, 950, and 755 cm^{-1}. NMR (*c*, 0.7 M): a triplet at 6.88, 7.03, and 7.17 ppm, a quartet having fine structures at 7.53, 7.67, 7.80, and 7.94 ppm, and a singlet at 11.12 ppm.

Semicarbazone derivative melting at 185.3—188.8°C (from aqueous ethanol). Found: C, 43.60; H, 3.27; N, 16.88%. Calcd for $C_9H_8N_3O_2F_3$: C, 43.73, H, 3.26; N, 17.00%.

From the fraction which did not form a copper ketimine chelate, a small amount of a seemingly *p*-substituted isomeric compound was separated, which was recrystallized from benzene to give colorless needles melting at 105.5—106.0°C. Found: C, 50.48; H, 2.80%. IR (potassium bromide disc): a sharp peak at 3480 cm^{-1} a carbonyl band at 1687 cm^{-1}, and four strong sharp bands at 1160, 951, 855, and 766 cm^{-1}.

2-Hydroxy-3-methylacetophenone (VI).[8,9] It was obtained from *o*-cresyl acetate in a similar manner to that of the ligand II, with accompanied by the *p*-substituted isomer: bp 91.7—91.9°C/5 mmHg. Semicarbazone derivative: mp 240.8—42.6°C.[9] NMR: two singlets at 2.20 and 2.51 ppm (3 protons each), a triplet centered at 6.54 ppm splitted with 7 cps of *J*-value (one proton), two doublets having fine structures, centered at 7.1 and 7.4 ppm respectively, each of which is splitted with 7 cps of *J*-value (one proton each), and a singlet at 12.18 ppm (one proton).

Salicylaldehyde (IV). used here was a commercially available one.

2-Hydroxyactophenone (V) was synthesized from phenyl acetate in a standard procedure, boiling at 113.5—113.8°C/33 mmHg.

Synthesis of the Metal Chelates of Copper and of Nickel. Salicylaldimine chelates of copper and of nickel were synthesized as following. A bis(salicylaldehydato)metal chelate (the copper chelate; 0.50 g, the nickel chelate; 0.50 g), which was prepared according to Tyson and Adams,[10] was added into 10% aqueous ammonia (90 ml for the former chelate and 70 ml for the latter, respectively) and the resulting suspension was stirred at room temperature until the color of the precipitates was changed, which took about an hour. The precipitates, collected by filtration, was washed with methanol, dried and recrystallized from an appropriate solvent. (Yield; 0.50 g for the copper chelate, and 0.41 g for the nickel chelate, respectively). The ketimine chelates of copper and of nickel were synthesized in either of the following procedures.

(A) Into an aqueous alcoholic solution of an ammine metal complex, which was prepared from the aqueous solution of the corresponding metal ion and ammonia in alcohol, was added an alcoholic solution of two moles of an *o*-acylphenol, and the solution was left to stand for a required period of time. Resulting precipitates, collected by filtration, was washed with ammonia and alcohol successively, dried and recrystallized from an appropriate solvent.

(B) Into an aqueous solution of a metal acetate, two moles of an *o*-acylphenol was added, and then alcohol was added so that the mixture made just a homogeneous solution. An appropriate amount of 28% ammonia diluted with alcohol was added into the above solution, and it was left at room temperature until the metal ketimine chelates were precipitated. The resulting precipitates were treated in the similar way just as described above. The details of the amounts of the reagents, the yields and the properties of the chelates are tabulated in Tables 1, 2, 3, and 4.

Synthesis of the Beryllium Chelates. *Bis(2-hydroxy-3-methylacetophenonato)beryllium(II)*. 2-Hydroxy-3-methylacetophenone (1.51 g) dissolved in methanol (5 ml) and 3% methanolic ammonia (8 ml) were added successively into a mixture of a 50% aqueous solution of beryllium nitrate (0.88 g) and methanol (10 ml).

The resulting mixture, after refluxed for several hours, was evaporated to dryness under reduced pressure. The residual solid was dissolved in chloroform, washed with water, and again solidified by evaporation of the solvent. The second solid was recrystallized from petroleum ether to give yellow grains (740 mg) melting at 163.9—65.6°C. Found: C, 70.32; H, 6.04%. Calcd for

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 968—972 (1969)

Spectrophotometric Studies of Ethyl Xanthate Complexes in Aqueous Solutions

Michio NANJO and Taro YAMASAKI

Research Institute of Mineral Dressing and Metallurgy, Tohoku University, Katahira-cho, Sendai

(Received July 22, 1968)

The stability constants of ethyl xanthate complexes of cadmium(II), zinc(II), nickel(II), and cobalt(II) were determined spectrophotometrically in aqueous solutions. Complexes with the 1 : 1 composition, $M(EX)^+$, were found in all cases; the stability constants of these metal complexes were calculated to be 1.2×10^4, 5.2×10, 4.4×10, and 1.1×10 for $Cd(EX)^+$, $Zn(EX)^+$, $Ni(EX)^+$, and $Co(EX)^+$ respectively at an ionic strength of 1.0 and at 25°C. These values were then compared with the stability constants of other metal complexes.

Potassium or sodium ethyl xanthate (KEX or NaEX) has been employed as a flotation agent for sulfide minerals because it gives hardly soluble metal salts in water. Thus, a large number of investigations have been conducted into the behavior of metal xanthates. However, there has been no report on the complex formation reaction between xanthate and metal ions in aqueous solutions. This may be due to the easy formation of insoluble metal xanthates and to the instability of the xanthate ion (EX^-) in an acidic solution. Majima[1] described the formation of soluble complexes, $Pb(EX)_2$, $Ni(EX)_3^-$, and $Co(EX)_3^-$, but his work was limited to studies in acetone-water solutions (1 : 1). In our previous paper[2] we have reported on the formation and properties of a tetracoordinate complex, $Cd(EX)_4^{2-}$, which was formed by the reaction of the cadmium(II) ion with an excess of EX^- in aqueous solutions.

This investigation was undertaken to examine whether other complexes could be formed by varying the concentration ratios of species of metal ions to EX^-.

The 1 : 1 complexes, $M(EX)^+$ (M: Pb, Cd, Zn, Ni, Co), were found to be formed by 3 methods, the spectrophotometric, kinetic, and solubility methods, in aqueous solutions.

This paper will deal with the spectrophotometric studies; the studies by other methods will be discussed in a subsequent paper.[3]

Experimental

Materials. KEX was prepared according to the usual method and was recrystallized three times from ethyl alcohol and ethyl ether. The product was identified by means of its UV and IR spectra. Perchlorates of cobalt, nickel, and lead were prepared by mixing the metal carbonates with perchloric acid and were then recrystallized twice from water. All the other chemicals were of a guaranteed grade and were used without further purification.

Measurements. A Hitachi recording spectrophotometer, Model EPS-3, and a Shimadzu spectrophotometer, Model QR-50, were used for the measurement of the UV absorption spectra. A Toa Model HM-5A pH meter was used for the pH determination. The

ionic strength was adjusted to 1.0 by sodium perchlorate, and both the absorbance and the pH were measured at 25°C. This equilibrium measurement was performed at pH 5—7 in order to avoid the decomposition of EX^-.

Results and Discussion

Reaction with the Cadmium(II) Ion. The absorption spectra of a KEX solution recorded in the absence and in the presence of an excess of cadmium(II) ions are presented in Fig. 1. The absorption maxima were found at 226 mμ and 301 mμ. On the addition of cadmium ions a decrease in the absorbance was observed around 301 mμ, but there was no shift in the maximum.

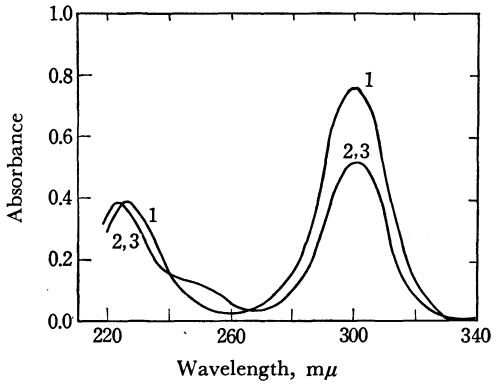

Fig. 1. Absorption spectra of KEX solutions (4.18×10^{-5} M) in the presence of 0.02 M acetate buffer and $CdSO_4$. The contents of $CdSO_4$ are 1) 0, 2) 4.75×10^{-3} and 3) 9.50×10^{-3} M respectively.

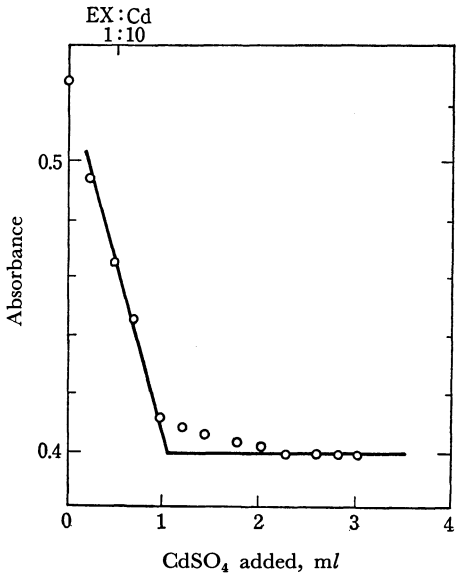

Fig. 2. Photometric titration curve of KEX solution (1.09×10^{-5} M) with $CdSO_4$ (1.02×10^{-2} M) at 301 mμ.

A slight blue shift was observed in the band of 226 mμ, and a new weak absorption band appeared in the region between 240 and 260 mμ; the isosbestic points were also observed at 240 and 265 mμ.

The photometric titration curve of a cadmium sulfate solution with a KEX solution at 301 mμ is given in Fig. 2. In Fig. 2, a plateau of absorbance with an intensity of about 70% of the original absorbance of EX^- was obtained. These changes in the absorption spectrum indicate the formation of a complex before the precipitation of bis-(ethylxanthogenato)cadmium(II), $Cd(EX)_2$, starts (K_{sp}: 2.6×10^{-14} or 5.6×10^{-15}).[4,5]

The composition of the complex was determined by employing the continuous variation method[6] in the presence and in the absence of 0.02 M of an acetate buffer solution. In this system, the mole-ratio method is not applicable because of the instability of the complex ion formed. The differences in absorbance, Δd, between the observed values, d, in a 1 cm cell and the values d_0, calculated by assuming that no complex is formed, were plotted against the mole fractions of EX^-; the results are shown in Fig. 3. The minimum value of Δd lies at a ratio of 0.5; this indicates the formation of a 1 : 1 complex.

The stability constant of the complex was calculated by using the Rose-Drago method.[7] This

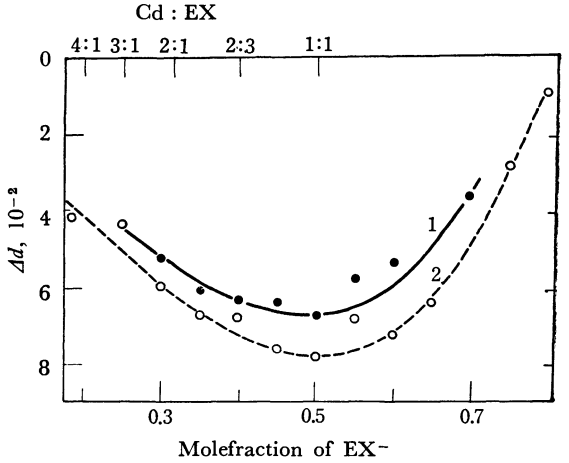

Fig. 3. Continuous variation method. 1) In the absence of acetate buffer, $[EX^-]_t+[Cd^{2+}]_t = 8.0\times10^{-5}$ M. 2) In the presence of 0.02 M acetate buffer, $[EX^-]_t + [Cd^{2+}]_t/1.2 = 8.0\times10^{-5}$ M, on the assumption of $1+K_{CdOAc}[OAc^-] = 1.2$.

5) I. A. Kakovsky, "Second International Congress of Surface Activity," Vol. IV, ed. by J. H. Schulman, Butterworth Scientific Publications, London (1957), p. 225.

6) M. Otomo, This Bulletin, **36**, 137, 889 (1963).

method is applicable when an absorption band of a ligand overlaps with that of a complex, as is shown in Fig. 1. Generally, the equation for the equilibrium is given as follows:

$$M^{2+} + EX^- \overset{K_1}{\rightleftarrows} M(EX)^+. \quad (1)$$

The concentration equilibrium quotient for this reaction can be written as follows:

$$K_1 = [M(EX)^+]/[M^{2+}][EX^-]. \quad (2)$$

The absorption of metal ions at a given wavelength was negligibly small compared with that of the complex and EX^-; therefore, the observed absorbance, d, may be expressed as follows:

$$d = \varepsilon_{EX^-}[EX^-] + \varepsilon_{M(EX)^+}[M(EX)^+], \quad (3)$$

and:

$$d_0 = \varepsilon_{EX^-}[EX^-]_t. \quad (4)$$

The substitution of $[EX^-]$ and $[M(EX)^+]$ from Eq. (3) into Eq. (2) will give the following equation:

$$K_1^{-1} = (d_0-d)/(\varepsilon_{EX^-}-\varepsilon_{M(EX)^+}) - ([EX^-]_t+[M^{2+}]_t) + (\varepsilon_{EX^-}-\varepsilon_{M(EX)^+})([EX^-]_t[M^{2+}]_t)/(d_0-d). \quad (5)$$

In Eq. (3) it is assumed that there are at most two absorbing species which obey Beer's law in the concentration range employed. The isosbestic points observed in Fig. 1 show that two absorbing species are present in the solution and that, as Fig. 2 shows, their absorptions obey Beer's law.

The values of K_1 are plotted against $\varepsilon_{Cd(EX)^+}$ in Fig. 4. This procedure is equivalent to solving a simultaneous equation for all possible pairs (K_1 and $\varepsilon_{M(XE)^+}$) of data. The curves show that they intersect at one point and that there is only one complex ion in the solution. From Fig. 4, K_1 was determined to be 1.2×10^4 in the absence of an acetate buffer, and 1.8×10^4 in the presence of a 0.02 M acetate buffer, the formation of the acetatocadmium(II) complex being taken into consideration.[8,9]

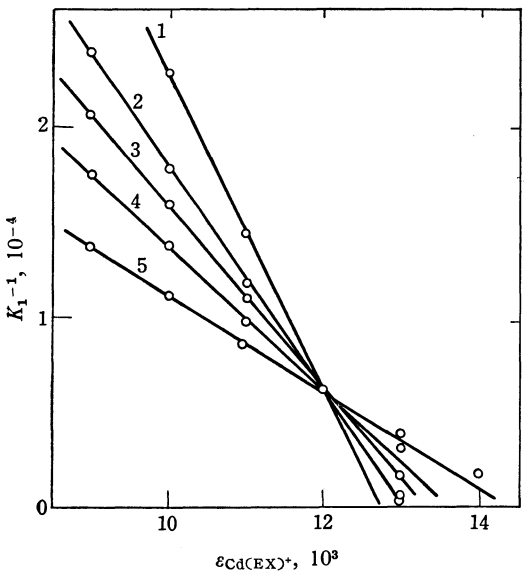

Fig. 4. Rose-Drago's plots at 301 mμ. Each sample solutions contain KEX (3.97×10^{-5} M), 0.02 M acetate buffer and 1) 5.71×10^{-4}, 2) 3.18×10^{-4}, 3) 2.84×10^{-4}, 4) 1.88×10^{-4} and 5) 9.50×10^{-5} M of $CdSO_4$, respectively.

Reaction with Zinc(II) Ions. The experiments were carried out in a 0.2 M acetate buffer solution to prevent the acid decomposition of EX^-. The absorption spectra are shown in Fig. 5. The shapes of the spectra are little different from those of cadmium. The maxima around 301 mμ and 226 mμ show a blue and a red shift respectively, and no new absorption band due to the complex ion could be observed. The isosbestic points were also obtained at 256, 294, and 326 mμ. The absorption of the complex ion obeys Beer's law in an excess of zinc ions. From the Rose-Drago plots, K_1 was determined to be 5.2×10 at 301 mμ, the formation of acetatozinc(II) complex besides the 1 : 1 complex being taken into consideration in a 0.2 M acetate buffer solution.[8] The stability constant employed was 4.6. ($K_{Zn(OAc)^+}$).

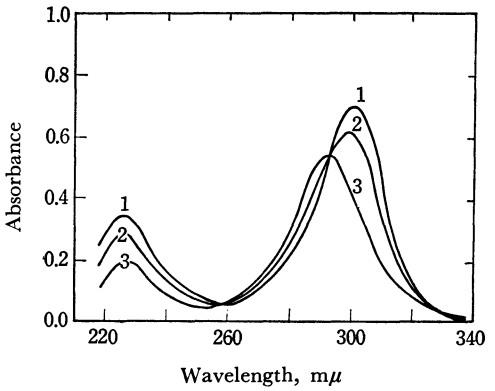

Fig. 5. Absorption spectra of KEX solutions (4.04×10^{-5} M) in the presence of 0.2 M acetate buffer and $Zn(ClO_4)_2$. The contents of $Zn(ClO_4)_2$ in each sample are 1) 0, 2) 4.17×10^{-2} and 3) 1.39×10^{-1} M, respectively.

Reaction with Nickel(II) Ions. The absorption spectra recorded showed a pronounced difference from those of cadmium and zinc, as may be seen in Fig. 6. The isosbestic points were also observed at 285 and 314 mμ, and a new absorption band was obtained around 280 mμ. The absorption band around 301 and 226 mμ showed a red and a blue shift respectively.

8) N. Tanaka and K. Kato, This Bulletin, **33**, 417, 1412 (1960).

9) I. Szilard, Dissertation, ETH, Zürich.

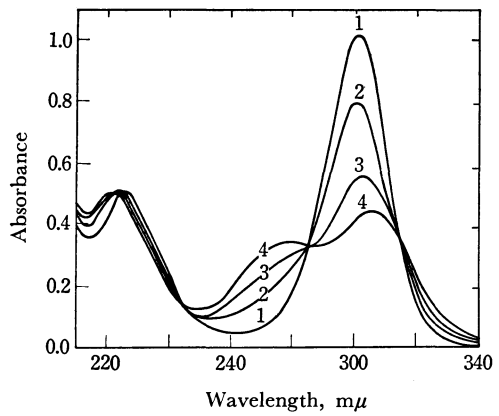

Fig. 6. Absorption spectra of KEX solutions (1.20×10^{-5} M) in the presence of 1) 0, 2) 1.10×10^{-2}, 3) 5.50×10^{-2} and 4) 2.75×10^{-1} M of $Ni(ClO_4)_2$ using 50 mm cells.

Reaction with Cobalt(II) Ions. The sample solution was deairated to protect the cobalt(II) complex from oxidation by air. The absorption spectra are similar in appearance to those of zinc. The band around 301 mμ exhibited a red shift, while the band around 226 mμ showed a blue shift. The isosbestic points were also observed at 240, 288, and 320 mμ, and K_1 was determined to be 1.1×10.

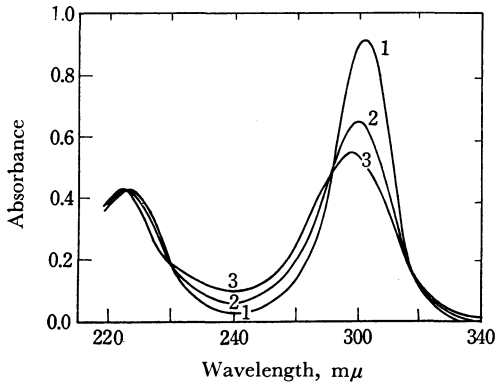

Fig. 7. Absorption spectra of KEX solutions (5.06×10^{-5} M) in the presence of 1) 0, 2) 5.68×10^{-2} and 3) 2.27×10^{-1} M of $Co(ClO_4)_2$ in each sample solutions, respectively.

Reaction with Lead(II), Copper(II), and Magnesium(II) Ions. The dissociation of bis-(ethylxanthogenato)lead(II), $Pb(EX)_2$, was so small that all attempts to obtain K_1 by the Rose-Drago method resulted in failure. The absorption spectra observed in an excess of lead(II) ion are presented in Fig. 8. In the case of copper also, the Rose-Drago method could not be employed because of the formation of dixanthogen, $(C_2H_5O\text{-}CSS)_2$, and ethylxanthogenatocopper(I). However in an large excess of copper(II) ions (10^{-3}—10^{-1} M, $[EX^-]_t=6\times10^{-6}$ M), a well-defined absorption spectra was obtained (Fig. 8). The absorption maxima were observed at 258, 283, 327, and 383 mμ, and the band at 283 mμ obeyed Beer's law ($[EX^-]_t$: 3×10^{-6}—3×10^{-5} M). Those absorption bands may be related to the formation of ethylxanthogenatocopper(II) ($Cu(EX)^+$), because the shape of the spectrum differs markedly from that of dixanthogen and the solubility of ethylxanthogenatocopper(I) has been reported to

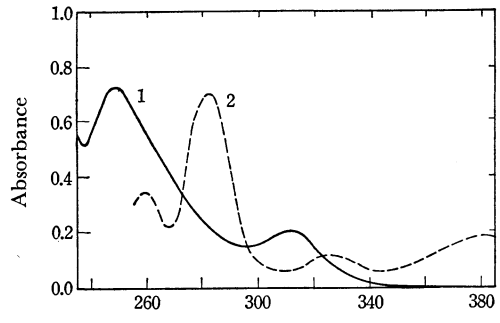

Fig. 8. Absorption spectra of 1) KEX solution (5.0×10^{-5} M) in the presence of 1.34×10^{-3} M of $Pb(ClO_4)_2$ at pH 1.5 and 2) KEX solution (6.55×10^{-6} M) in the presence of 1.24×10^{-1} M of $Cu(ClO_4)_2$ at pH 1.8, using 100 mm cells.

be very low[5] (K_{sp}: 5.2×10^{-23}). A further study by the present authors is in progress; it will be discussed in the near future.

The magnesium(II) ion caused no change in the absorption spectra of EX^-. We failed to prove the formation of any complex by a reaction between magnesium and EX^-.

These results are summarized in Table 1.

Table 1. Stability constants of 1 : 1 complexes 25°C, $\mu=1$ ($NaClO_4$)

Metal ion	K_1
Cd(II)	$(1.2\pm0.1)\times10^4$
	$(1.8\pm0.2)\times10^4$ a)
Zn(II)	$(5.2\pm0.1)\times10$ b)
Ni(II)	$(4.4\pm0.3)\times10$
Co(II)	$(1.1\pm0.1)\times10$
Mg(II)	no complex formed

a) In the presence of 0.02 M acetate buffer.
b) In the presence of 0.2 M acetate buffer.

From the kinetic data,[3] the value of K_1 for $Pb(EX)^+$ was determined to be $(2.5\pm0.4)\times10^4$. The order of K_1 decreases in the series as follows:

$$Pb > Cd \gg Zn > Ni > Co > Mg.$$

10) D. P. Mellor and L. Maley, *Nature*, **159**, 370 (1947).

The Mellow-Maley series,[10] Mg<Mn<Fe<Cd<Zn<Co<Pb<Ni<Cu<Pd, which holds for oxygen and nitrogen ligands, is a direct consequence of their ionization potentials and ionic radii. In the case of Cr(II) and Cu(II), a factor of Jahn-Teller is added to them.

On the other hand, cadmium(II) and lead(II) behave differently toward sulfur of a soft-base compound like EX^-, but they do not belong to the first raw transition series. For these two metal ions the possibility of some degree of L→M π-bonding in the complexes has been pointed out by Irving and Fernelius.[11]

It appears probable that lead(II) and cadmium(II) complexes are stabilized by the π-bonding and do not obey the Mellor-Maley series, because this series was proposed without taking the π-bonding into consideration.

The absorption spectra of EX^- in the presence of an excess of cadmium(II) and lead(II) ions showed a band around 250 mμ which could not be observed in the case of other metals. The absorbance of the ethylxanthogenatolead(II) ion around 250 mμ is stronger than that of cadmium. From these observations and the fact that the stability of the lead complex is highest, the new absorption band around 250 mμ may be explained as a reflection of the L→M π-bonding.

The question whether these absorption bands arose from n–π^* or π–π^* transition in the complexes was not resolved by these studies, but the studies to explain the shift of the absorption bands of EX^- due to the complex formation are in progress by the authors from the view-point of the metal-sulfur bond character, as has been proposed by Pearson.[12]

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 972—976 (1969)

Acid Decomposition of Metal Xanthate Complexes and Their Stability Constants

Michio NANJO and Taro YAMASAKI

Research Institute of Mineral Dressing and Metallurgy, Tohoku University, Katahiracho, Sendai

(Received July 22, 1968)

The formation of 1 : 1 complexes was confirmed by means of the kinetic method. The acid decomposition of xanthate was delayed by the addition of metal ions because of the decrease in the concentration of ethyl xanthic acid in an equilibrium. By using the rate equation, the stability constants were found to be $(1.0\pm0.2)\times10^4$, $(1.7\pm0.4)\times10$ and $(2.5\pm0.4)\times10^4$ for $Cd(EX)^+$, $Zn(EX)^+$, and $Pb(EX)^+$ respectively.

The behavior of xanthates in solutions has been the subject of numerous investigations because of the complexity of the system.[1-6] Alkali metal xanthates are especially known to be quite unstable in an acidic aqueous solution. This instability of xanthates presents a problem both in research and in the plant operation of mineral flotation with reference to the actual concentration of xanthates remaining in the pulp solution.

The acid decomposition of xanthates has been studied by several investigators. By using a UV spectrophotometer, Iwasaki and Cooke[1] were led to an important implication as to the mechanism of the acid decomposition in the low pH range, where the decomposition is extremely rapid. Majima[2] obtained the same results by using a UV spectrophotometer.

However, there have not yet been any reports that metal ions in the pulps of mineral flotation affect the acid decomposition of xanthate, which is also present in the solution. It should be emphasized that the plant operation of mineral flotation is not conducted in pure water but in

solution, and that the products obtained from xanthate ions with metal ions probably affect the flotation behavior also.

The present paper will show that such metal ions as cadmium, lead, and zinc delay the acid decomposition of potassium ethyl xanthate (KEX) in the low pH range. The reaction can be quantitatively explained by the complex formation between metal ions and the ethyl xanthate ion (EX^-) prior to the rate-determining step.

Experimental

Materials. The KEX and metal perchlorates were prepared and recrystallized by the usual method. All the other chemicals were of a guaranteed grade and were used without further purification. The sodium acetate-acetic acid buffers were prepared by mixing a solution of sodium carbonate and acetic acid.

Procedure. The kinetic measurements were made in 0.2 M buffer solutions or in a concentrated perchloric acid solution. The ionic strength was adjusted to 1.0 with sodium perchlorate through all the measurements. The KEX was dissolved in a dilute sodium hydroxide solution (pH 10—11) to prevent the solution from any acid decomposition before measurements started; then the solution was pipetted into 100 m*l* measuring flasks in which metal ions, sodium perchlorate and sodium acetate - acetic acid buffers or perchloric acid had previously been placed, and the flasks were kept in a thermostat at the temperature of 25°C. The sample solution was then transferred quickly to a quartz absorption cell.

The decomposition of EX^- is easily influenced by the temperature of the solutions,[1-c] so the cell chamber was kept at 25°C by means of a thermostating water jacket.

The decomposition rates were determined by following the absorbance at 301 mμ or 270 mμ employing a Shimadzu Model QR-50 spectrophotometer.

A Toa Model HM-5A pH meter was used for the pH measurements.

Results and Discussion

KEX is readily soluble in water. On dissolving, KEX is dissociated into K^+ and EX^-. Under some conditions, EX^- can be hydrolyzed. Hydrolysis will lead to the formation of xanthic acid:

$$R\text{-}O\text{-}C(S)S^- + H_2O \rightleftarrows R\text{-}O\text{-}C(S)SH + HO^- \quad (R=C_2H_5) \qquad (1)$$

Such a reaction involving ionic combination is known to be extremely rapid.[7] Xanthic acids are very unstable compounds and decompose rapidly into carbon disulfide and alcohols:

$$R\text{-}O\text{-}C(S)SH \rightarrow CS_2 + ROH \qquad (2)$$

The hydrolysis of xanthate anios occurs much faster than does the decomposition of xanthic acid. Consequently, the rate of decomposition depends on the concentration of xanthic acid alone, and anything which affects the hydrolysis of the xanthate anion, such as the concentration of hydrogen ions and metal ions, affects the concentration of xanthic acid in equilibria.

The decomposition rate equation was obtained by Iwasaki and Cooke[1] spectrophotometrically as follows:

$$d[EX^-]_t/dt = -k_3[HEX] = -k_3[EX^-]_t/(1+K_a/[H^+]) \equiv -k_H[EX^-]_t \qquad (3)$$

where $[EX^-]_t$ means the total concentration of the ethyl xanthate species, $[EX^-]_t=[HEX]+[EX^-]$, K_a is a dissociation constant of HEX, and k_3 express a monomolecular decomposition rate constant.

The formation of species other than EX^- and HEX results in a decrease of the concentration of HEX in equilibrium.

By assuming the formation of a stable and water-soluble metal xanthate complex ion, $M(EX)^+$, in place of a insoluble metal xanthate, $M(EX)_2$, in the presence of an excess of metal ions, the decomposition rate equation can be expressed as follows:

$$H^+ + EX^- \overset{\text{fast}}{\rightleftarrows} HEX + M^{2+} \overset{\text{fast}}{\rightleftarrows} M(EX)^+ + H^+$$
$$\downarrow \text{slow}$$
$$EtOH + CS_2 \qquad (4)$$

Since the absorbance at a given wavelength measures the total concentration of EX^-, HEX, and $M(EX)^+$, the decomposition rate may be expressed as follows:

$$d[EX^-]/dt + d[HEX]/dt + d[M(EX)^+]/dt = d([EX^-] + [HEX] + [M(EX)^+])/dt = -k_3[HEX] \qquad (5)$$

By using the dissociation constant of HEX, K_a, and the stability constant of the metal xanthate ion, K_1, Eq. (5) can be rewritten in terms of the total concentration of ethyl xanthate species:

$$d[EX^-]_t/dt = -k_3[HEX] = -k_3[EX^-]_t/(K_a/[H^+]+1 + K_1\cdot K_a\cdot[M^{2+}]/[H^+]) \equiv -k_M[EX^-]_t. \qquad (6)$$

or $$-d\ln[EX^-]_t/dt = k_3/(K_a/[H^+] + 1 + K_1\cdot K_a\cdot[M^{2+}]/[H^+]) \equiv k_M. \qquad (7)$$

were $K_1=[M(EX)^+]/[M^{2+}][EX^-]$

Upon integrating, we have:

$$\log([EX^-]_{t_1}/[EX^-]_{t_2}) = \log(\text{absorbance, } d_1)/(\text{absorbance, } d_2) = k_M(t_2-t_1)/2.303 \qquad (8)$$

Generally, the absorbance for ternary components is represented as follows:

$$d = \varepsilon_{EX^-}[EX^-] + \varepsilon_{HEX}[HEX] + \varepsilon_{M(EX)^+}[M(EX)^+] \qquad (9)$$

where ε_{EX^-}, ε_{HEX}, and $\varepsilon_{M(EX)^+}$ are the molar extinction coefficents of the ethyl xanthate ion, ethyl

7) M. Eigen, *Discussions Faraday Soc.*, **17**, 194 (1954).

xanthic acid, and the complex ion respectively. The absorption of the metal ion is negligibly small at any given wavelength. In the $pH > 1 + pK_a$ range, in which the pK_a is that of HEX ($pK_a = 1.34$),[8] scarcely any undissociated xanthic acid remains in the solution; therefore, the second term in Eq. (9) is negligibly small and the equation may be written as follows:

$$d = \varepsilon_{EX^-}[EX^-] + \varepsilon_{M(EX)^+}[M(EX)^+]. \quad (10)$$

Ethyl xanthic acid is known[3] to have an absorption maximum at 270 mμ ($\varepsilon = 10670$), and the spectrum recorded shows only a weak absorption at 301 mμ ($\varepsilon = 117$). As has been shown in a previous paper,[9] almost all the spectra have an absorption near 300 mμ. Bearing the above facts in mind, the absorbance at 301 mμ may, therefore, be attributed to the total of all the xanthate species except HEX in the high pH range, and the constants for the apparent pseudo first-order rates, k_H and k_M, can easily be obtained from the slope of the logarithm of the absorbance against the time by using Eq. (8). The measurements were made under the conditions of $[EX^-]_t \ll [M^{2+}]_t$ and $[EX^-]_t \ll [H^+]_t$, for which $[H^+]$ and $[M^{2+}]$ were kept constant during the decomposition. When a sodium acetate - acetic acid buffer is used to adjust the pH values, $[M^{2+}]$ is given approximately as follows, taking the formation of acetatometal complexes into consideration:

$$[M^{2+}] = [M^{2+}]_t/(1 + K_{MOAc} \cdot [OAc^-]), \quad (11)$$

in which K_{MOAc} represents the stability constants of acetate complexes.[10,11]

Decomposition in the Presence of an Excess of Cadmium Ions. The absorption spectra of the aqueous solutions of KEX in the presence and in the absence of an excess of cadmium(II) ions were given in a previous paper.[9] The change in the absorption spectra during the acid decomposition in the presence of an excess of cadmium(II) ions is shown in Fig. 1. As can be seen in Fig. 1, an isosbestic point was observed at 216 mμ. There was also a new band at 206 mμ which appeared when recording was done seprately in the higher-frequence region of the spectra. Carbon disulfide is known to absorb at this wavelength. This indicates that

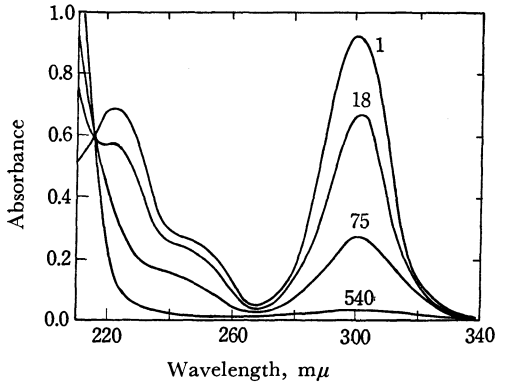

Fig. 1. Absorption spectra of KEX solution (4.32×10^{-5} M), decomposing in the presence of $CdSO_4$ (3.40×10^{-4} M) at pH 0.7. Figures on the curves indicate the standing time of sample solutions in minutes.

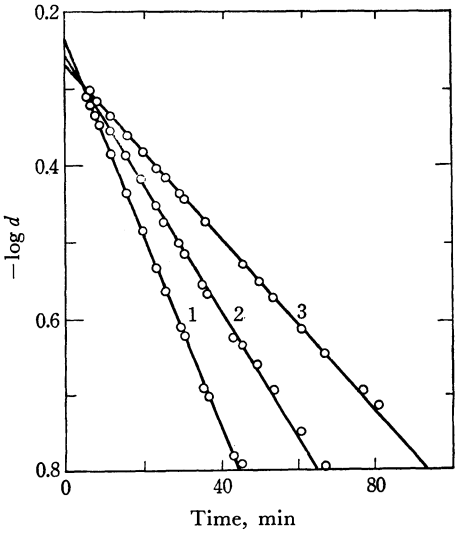

Fig. 2. First order rate plots of an acid decomposition of KEX solution (4.12×10^{-5} M) in the presence of 1) 1.43×10^{-4} M, 2) 2.85×10^{-4} M and 3) 4.75×10^{-4} M of $CdSO_4$ at pH 3.1.

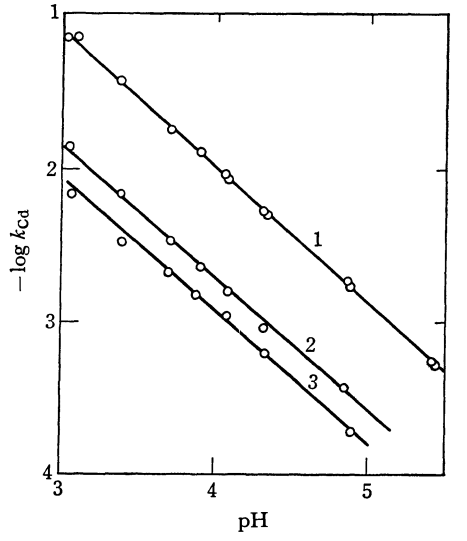

Fig. 3. Relation of pH with $\log k_H$ and $\log k_{Cd}$ in the presence of 0.2 M acetate buffer and 1) 0, 2) 4.8×10^{-4} M, and 3) 9.5×10^{-4} M of Cd(II) ion.*

* Cd(II) ion concentration was kept constant taking the formation of $Cd(OAc)^+$ ion at various pH ranges in consideration.

8) B. Toernell, *Svensk Paperstidn*, **69**, 658 (1966); *Chem. Abstr.*, **66**, 37303 g.

9) M. Nanjo and T. Yamasaki, This Bulletin, **42**, 968 (1969).

the isosbestic point arises from the formation of carbon disulfide and from the decomposition of ethyl xanthate species, and that no other side reactions covered in Eq. (4) occur.

There was no reverse reaction after the decomposition was completed under the conditions employed. Examinations were made at pH 3—5. The first-order plots are given in Fig. 2, the slope may be seen to have been influenced by the pH and by the concentration of cadmium(II) ions. The values of k_H and k_{Cd} were determined from Fig. 2, and the logarithms of k_H and k_{Cd} were plotted against pH (Fig. 3). As can be seen from Fig 3, the slope of the line of k_H was determined to be -0.92, and that of $\log k_3/K_a$, to be 1.69. The slope of k_M was also given as -0.92 at various concentrations of cadmium(II) ions.

These relations demonstrate that our initial assumption of the decomposition mechanism (Eq. (4)) is essentially reasonable; K_1 was also determined to be 1.0×10^4 by using Eq. (12), which was derived from Eqs. (3) and (6) under the condition of $pK_a<pH$:

$$(k_H/k_M) - 1 = [M^{2+}]\cdot K_1, \qquad (12)$$

and $[M^{2+}]$ is calculated by Eq. (11).

In a 0.2M acetate buffer solution, $CdOAc^+$ is the predominant species formed by the reaction of cadmium(II) and acetate ions,[10] ($K_{CdOAc^+}=10$).[11]

Decomposition in the Presence of an Excess of Zinc(II) Ions. The absorption spectra of the zinc(II) complex was given in a previous paper.[9]

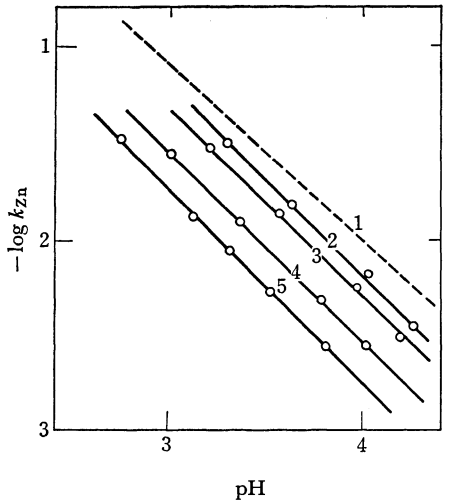

Fig. 4. Relation of pH with $\log k_{Zn}$ in the presence of 0.2 M of acetate buffer and 1) 0, 2) 3.21×10^{-2} M, 3) 6.42×10^{-2} M, 4) 1.61×10^{-1} M and 5) 3.21×10^{-1} M of $Zn(ClO_4)_2$.

10) N. Tanaka and K. Kato, This Bulletin, **33**, 417, 1412 (1960).

11) I. Szilard, Dissertation, ETH, Zürich.

The isosbestic point was found at 216 mμ by the acid decomposition, and nearly the same plots were obtained as those shown in Fig. 3; this indicates a complex formation between zinc(II) and EX^-. The slope of k_{Zn} was determined to be -0.99 (Fig. 4). The zinc(II) ion is less effective in decreasing the decomposition rate than the cadmium(II) ion, which shows that $Zn(EX)^+$ is a less stable ion than that of cadmium.

Decomposition in the Presence of an Excess of Lead(II) ions. The absorption spectra of the lead(II) complex has also been presented in a previous paper[9]; they differed markedly from those of cadmium and zinc. Therefore, kinetic measurements were conducted in highly concentrated solutions of lead(II) ion and perchloric acid in order to avoid the precipitation of $Pb(EX)_2$ and to get the proper conditions for carring out the examinations. In the very low pH range, the formation of HEX should be taken into consideration, so the absorption bands at 270 mμ and 301 mμ were used separately to plot the first-order lines. The resulting values k_{Pb} were the same. This indicates that the absorption spectra are due to the complex ion, which is a very stable ions. The relation between $\log k_{Pb}$ and $\log[Pb^{2+}]_t$ is shown in Fig. 5. The relation between $\log k_{Pb}$ and $\log[H^+]_{add}$ is also represented in Fig. 6, which is derived from Fig. 5. From Figs. 5 and 6, the slopes were determined to be -1.2 and -0.8——-1.0 respectively. These values indicate that, under the present experimental conditions, the

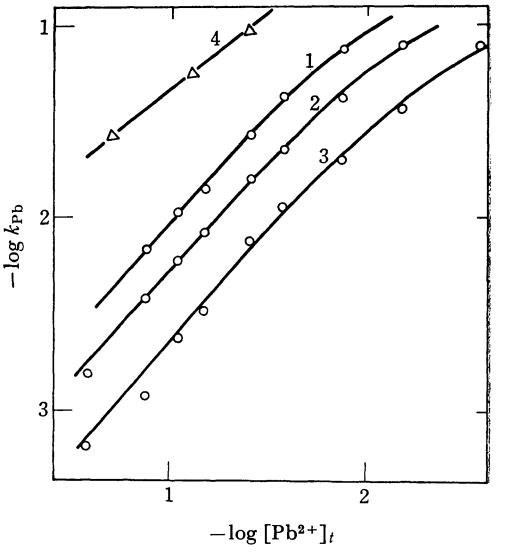

Fig. 5. Relation of $\log[Pb^{2+}]_t$ with $\log k_{Pb}$ in the presence of 1) 5.24×10^{-1} M, 2) 3.00×10^{-1} M and 3) 1.20×10^{-1} M of $HClO_4$.
Curve 4) shows the relation of $\log[Cd^{2+}]_t$ with k_{Cd} in the presence of 3.00×10^{-1} M of $HClO_4$ for the comparison with the curve 2).

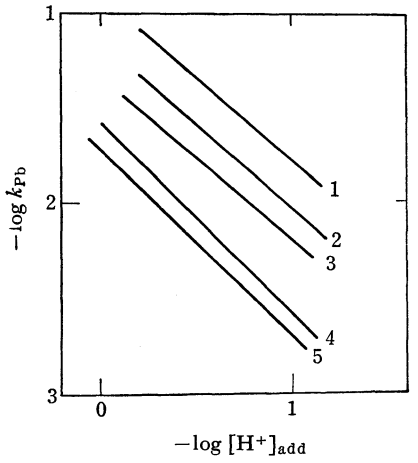

Fig. 6. Relation of $\log [H^+]_{add}$ with $\log k_{Pb}$ in the presence of 1) 1.34×10^{-2} M, 2) 2.68×10^{-2} M, 3) 4.02×10^{-2} M, 4) 6.70×10^{-2} M and 5) 9.38×10^{-2} M of $Pb(ClO_4)_2$.

formation of the complex is the predominant reaction and that the third term of the denominator of Eq. (6), $[M^{2+}]\cdot K_1\cdot K_a/[H^+]$, is larger than the other terms.

In the case of cadmium(II) and zinc(II), the relations between $\log k_M$ and $\log [M^{2+}]$ are not of the first order. They show that the curves are the same as those in Fig. 5 when there is a low concentration of lead(II) ions.

By using Eq. (7), K_1 was calculated from Fig. 5 to be 2.5×10^4; this indicates that the ethylxanthogenatolead(II) complex is more stable than the cadmium(II) complex.

These results are summarized in Table 1. The K_1 values calculated by the kinetic method are in good agreement with those by the spectroscopic method.[9]

Table 1. Stability constants of 1:1 complexes 25°C, $\mu=1(NaClO_4)$

Metal ion	K_1
Pb(II)	$(2.5\pm0.4)\times10^4$
Cd(II)	$(1.0\pm0.2)\times10^4$
Zn(II)	$(1.7\pm0.4)\times10$

The kinetic method is especially useful when the equilibrium method cannot be applied because of the formation of such hydroxides as $Pb(OH)_2$ and $Zn(OH)_2$ in a neutral pH range. Thus, the formation of 1 : 1 complexes is established.

One of the authors (M. N.) wishes especially to thank Professor Nobuyuki Tanaka, Department of Chemistry, Tohoku University, for his many helpful discussions and suggestions during this spectrophotometric and kinetic work.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 976—980 (1969)

The Synergistic Effect in Solvent Extraction. The Effect of Carboxylic Acid on the Solvent Extraction of Europium(III) with Benzoyltrifluoroacetone

Tsunenobu SHIGEMATSU, Masayuki TABUSHI, Masakazu MATSUI and Takaharu HONJYO

Institute for Chemical Research, Kyoto University, Uji, Kyoto

(Received July 25, 1968)

The effects of carboxylic acids, such as formic, chloroacetic, acetic, propionic, butyric and caproic acid, on the extraction of europium with benzoyltrifluoroacetone were studied. The extraction is enhanced by the adduct formation between metal chelates and carboxylic acids in the organic phase, while it is hindered by the formation of metal-complex ions with anions of carboxylic acids in the aqueous phase. Caproic acid acts as an organic Lewis base and shows the synergism, but formic and chloroacetic acids have a masking effect. Acetic acid, propionic acid, and butyric acid behave both as synergists in the organic phase and as masking agents in the aqueous phase. Caproic acid forms more stable adducts than does *n*-hexyl alcohol, and the composition of the chelate adduct is estimated to be $Eu(BFA)_3 \cdot 2CH_3(CH_2)_4COOH$.

As a general procedure for the extraction of metal chelates, a suitable buffer solution is added to the aqueous phase in order to minimize the pH change during the extraction. However, the use of a buffer solution sometimes causes an abnormal distribution of metals as a result of the synergistic effect and the masking effect.

Acetic acid enhances the extraction of thorium

with TTA,[1,2] but inhibits the extraction of lanthanum with TTA[3] or that of uranium[4] and europium[5] with benzoyltrifluoroacetone; it was also observed that the slope of log D *vs.* pH plots decreased upon the addition of acetic acid.[5]

In the present research, the effect of such carboxylic acids as formic, chloroacetic, acetic, propionic, butyric, and caproic acid on the extraction of europium with benzoyltrifluoroacetone in benzene was studied, and the extraction behavior was explained by the adduct formation of the carboxylic acid molecules with europium chelates in the organic phase, and by the complex formation of the acid anions with europium ions in the aqueous phase.

Experimental

Materials. The europium-152, 154 was obtained from the Radiochemical Center, Amersham. The radioisotope was purified by extracting it with 0.05 M benzoyltrifluoroacetone in benzene at pH 5, by back-extracting into 0.1 M perchloric acid, and by evaporating almost to dryness. The residue was dissolved with 0.1 M perchloric acid to make a stock solution. The benzoyltrifluoroacetone was obtained from the Dojindo Co., Ltd. The sodium perchlorate was prepared by adding sodium carbonate to perchloric acid and by subsequent recrystallization from water. All the other reagents were of the G. R. grade and were used without further purification.

Procedure. The experimental procedures were almost the same as have previously been described.[5] Ten milliliters of an aqueous solution containing a few ppm europium ions, 0.1 M sodium perchlorate, and carboxylic acid in a given concentration were shaken with 10 m*l* of 0.05 M benzoyltrifluoroacetone in benzene for one hour at 25±1°C: Each of the carboxylic acids except caproic acid was added in the aqueous phase; caproic acid was added to the organic phase. Aliquots (2 m*l*) of the two phases were pipetted into test tubes, and the distribution ratio of europium was estimated from the gamma counts, as measured with a NaI(Tl) well-type scintillation counter. The pH of the aqueous layer was measured again after the extraction. The partition of the carboxylic acids, such as acetic, propionic, butyric, and caproic acid, between benzene and water was estimated by titrating an aqueous solution containing 0.1 M or 1 M carboxylic acid with a standard sodium hydroxide solution before and after shaking with benzene. The pH of the aqueous layer during the distribution measurement was near 3; therefore, more than 99% of the carboxylic acids may exist in the neutral form. As will be described below, formic acid and chloroacetic acid did not act as synergists, but only as masking agents in the aqueous phase; therefore, the partition was not measured in these cases.

Theoretical

When the predominant species in the organic phase are MR_3, $MR_3{\cdot}HA$, $MR_3{\cdot}2HA$, $\cdots$, and when those in the aqueous phase are M^{3+}, MA^{2+}, MA_2^{+}, $\cdots$, the distribution ratio of the metal is written as follows:

$$D^* = \frac{\sum_0^m [MR_3 \cdot mHA]_o}{\sum_0^n [MA_n^{(3-n)+}]} \tag{1}$$

where M stands for the metal; MR_3, for the chelate with a chelating agent, HR, and HA, for a carboxylic acid, and where [ ] and [ ]$_o$ indicate the concentration of the relevant chemical species in the aqueous and organic phases respectively.

By introducing the distribution ratio in the absence of the carboxylic acid, D, the equation can be reduced to;

$$\frac{D^*}{D} = \frac{1+\sum_1^m \beta_m [HA]_o{}^m}{1+\sum_1^n k_n [A^-]^n} \tag{2}$$

or;

$$\log D^* - \log D = \log \{1+\sum_1^m \beta_m [HA]_o{}^m\} - \log \{1+\sum_1^n k_n [A^-]^n\} \tag{3}$$

where β_m is the overall stability constant of the adducts formal between the metal chelate and the carboxylic acid, and where k_n is that of the metal complexes with the carboxylic anion; these stability constants are expressed as:

$$\beta_m = \frac{[MR_3 \cdot mHA]_o}{[MR_3]_o [HA]_o{}^m} \tag{4}$$

$$k_n = \frac{[MA_n^{(3-n)+}]}{[M^{3+}][A^-]^n} \tag{5}$$

When the acid dissociation constant of the carboxylic acid, K_A, the partition coefficient of the acid in molecular form, K_d, and the dimerization constant in the organic phase, K_p, are known, the concentration of the monomer species in the organic phase, $[HA]_o$, and of the anionic species in the aqaqueous phase, $[A^-]$, are given from the total concentration of the carboxylic acid, C_{HA}, by the following equations:

$$[HA]_o = \frac{-K_b \sqrt{K_b^2 + 8K_d^2 \cdot K_p C_{HA}}}{4K_d \cdot K_p} \tag{6}$$

$$[A^-] = \frac{K_A(-K_b + \sqrt{K_b^2 + 8K_d^2 \cdot K_p C_{HA}})}{4K_d^2 \cdot K_p \cdot [H^+]} \tag{7}$$

where:

$$K_d = \frac{[HA]_o}{[HA]}, \quad K_p = \frac{[(HA)_2]_o}{[HA]_o^2}$$

and:

$$K_b = 1 + \frac{K_A}{[H^+]} + K_d$$

If the largest portion of the carboxylic acid is distributed into the organic phase, the concentration of the monomer species is obtained by the following equation:

$$[HA]_o = \frac{-1+\sqrt{1+8K_pC_{HA}}}{4K_p} \quad (8)$$

Results and Discussion

The effect of acetic acid on the extraction of europium with benzoyltrifluoroacetone is shown in Fig. 1. With an increase in the concentration of acetic acid, the extraction must be carried out in the higher pH region, and the log D *vs.* pH plot curves concavely. The effect of other carboxylic acids are shown in Fig. 2 (formic and chloroacetic acid), Fig. 3 (propionic acid), Fig. 4 (*n*-butyric acid), and Fig. 5 (caproic acid). Caproic acid enhances, while formic and chloroacetic acid hinder, the extraction. In these cases, the log D *vs.* pH plots are parallel to that obtained in the absence of the carboxylic acids. Propionic acid and *n*-butylic acid increase the extractability in the lower pH region, but decrease the extractability in the higher pH region, indicating convexly-curved log D *vs.* pH plots. Figure 6 presents the change in the distribution ratio of europium as a function of the caproic acid concentration. As is shown in the figure, a straight line with a slope of 1 is obtained when the log D^*/D values are plotted against log C_{HA}, but the slope becomes 2 if they are plotted against log $[HA]_o$. This fact indicates that two moles of caproic acid react with one mole of europium benzoyltrifluoroacetonate to form the $MR_3 \cdot 2HA$-type adduct in benzene, although it is not clear whether caproic acid reacts as the monomer or as the dimer. The overall stability constant of the adduct was esti-

mated to be $\log \beta_2 = 5.20$. From this value, it may be expected that caproic acid forms more stable adducts with europium benzoyltrifluoroacetonate than does *n*-hexyl alcohol ($\log \beta_2 = 3.10$). In the cases of acetic, propionic, and *n*-butyric acid, some correlation may be observed between the bend point of the $\log D$ *vs.* pH plots and the pK_A value of the carboxylic acid, and between the strength of the synergistic effect and the

partition ratio (including K_d and K_p) of the acid. In order to examine why the curious extraction behavior resulted from the distribution equilibrium expressed by Eq. (1), the rough theoretical extraction curves were obtained from the equations described above by introducing various constants of carboxylic acids, which are summarized in Table 1. The K_d and K_p values of *n*-butyric acid were lacking; K_p was assumed to be the same as the values of acetic and propionic acid, and K_d was estimated from the partition of 1M *n*-butyric acid (Ex=72.7%). The extractabilities of acetic and propionic acid obtained experimentally in the present research

a) Ref. 6, b) Ref. 7.
c) The value was assumed to be the same with that of acetic and propionic acid.
d) The value was estimated from the K_p value[c] and the extractability[g].
e) The values were assumed from β_2 of caproic acid.
f) The values were assumed from the data presented by Ref. 7.
g) The extractability was used for calculating the K_d value.[d]

were in good agreement with those calculated from the K_d and K_p values previously reported.[6] Also, in the partition of 0.1M *n*-butyric acid, the extractability obtained experimentally agreed well with that derived from the asumed K_d and K_p values. The β_2 values of these acids were uncertain, so $\log \beta_2=5$ was used, the data of caproic acid being referred to. The k_1 and k_2 values used were based on the data in the literature.[7]

Typical calculated extraction curves are indicated in Fig. 7, along with the experimental curves. Since many of the equilibrium constants were roughly estimated, and since the concentration was used instead of the activity in the calculation, the resulting curves were, of course, mere approximations. However, they may not be very wrong, for the vertical scale is logarithmic. Both the extraction curves, those calculated and those experimentally obtained, show a similar shape in each carboxylic acid; this fact indicates that the extraction behavior of europium benzoyltrifluoroacetonate in the presence of carboxylic acid can be explained by Eq. (1). For formic and chloroacetic acid, the first term of Eq. (3) is negligible and only the masking effect appears, while the second term can be neglected and the synergism is observed in the case of cap roic acid.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 981—984 (1969)

The Yields of Photonuclear Reactions Leading to the Production of Beryllium-7 with Bremsstrahlung up to 60 MeV

Yoshinaga OKA, Toyoaki KATO and Akira YAMADERA

Department of Chemistry, Faculty of Science, Tohoku University, Katahira-cho, Sendai

(Received July 25, 1968)

Beryllium, boron, carbon, oxygen, and fluorine targets with natural isotopic compositions were irradiated by bremsstrahlung with four maximum energies, 30, 45, 55 and 60 MeV, and the yields of ^{7}Be from each of these targets were determined by means of chemical separation and gamma-ray spectrometric measurements. The yields were obtained relative to the yield of the $^{12}C(\gamma, n)^{11}C$ reaction at each bremsstrahlung energy. The possible reaction pathways leading to the production of ^{7}Be were discussed. The exponential decrease in the yield value against the difference in mass between the target and the product nuclei was observed.

Knowledge of the magnitude and energy dependences of photonuclear reaction yields is basic to an understanding of the interaction of high-energy photons with nuclei. In a previous work,[1] the yields of a number of radioactive nuclei produced by (γ, xnyp) reactions on titanium and vanadium targets have been determined with bremsstrahlung up to 60 MeV. ^{7}Be decays with a half-life of 53 days upon K-capture with a 477 keV gamma-ray, accompanied by a 10.3 per cent in the decay processes.[2] These properties support the idea of obtaining some evidence of the occurrence of high-energy processes in light nuclei through measuring the ^{7}Be activities. ^{7}Be has been observed as a spallation product in a number of high-energy processes with charged particles.[3-7]

Several investigators[8-13] have also shown that ^{7}Be can be produced with high-energy photons from various light elements. However, many of their reports have been only about brief examinations.

In this work, beryllium, boron, carbon, oxygen, and fluorine targets with natural isotopic compositions were irradiated by bremsstrahlung with four different maximum energies, 30, 45, 55 and 60 MeV, and the yields of ^{7}Be from each of these targets were determined by means of gamma-ray spectrometric measurements. The yields were taken relative to the yield of the $^{12}C(\gamma, n)^{11}C$ reaction at each bremsstrahlung energy. The possible reaction pathways leading to the production of ^{7}Be were discussed. The exponential decrease in the yield value against the difference in mass between the target and the product nuclei has also been observed.

Experimental

Target Materials. Target materials of beryllium in the form of metallic flakes, boron in powder form, a carbon spectrograph rod, silica and lithium fluoride were used. All the materials were of a high purity. A definite amount of each sample (100—500 mg) was wrapped in a thin aluminum foil and then made into a small disk 7 mm in diameter and 3 mm thick.

Irradiation. The linear electron accelerator of the Tohoku University was the bremsstrahlung source. The electron beam, accelerated by the "High Current" accelerating section of the machine,[14] produced bremsstrahlung in a platinum converter 3 mm thick located 3 cm from the beam-exit window. Over the energy range investigated, the average beam current was at least 30 μA, measured at the position of the converter by using a current monitor. The targets were set in a water-cooled target holder on the bremsstrahlung beam axis immediately behind the converter. Irradiations were terminated within 1 to 3 hr. The bremsstrahlung

14) The peak current was at least 100 mA with energies up to 100 MeV. In many cases, the pulse repetition was 200 pps, with a pulse width of 3 μsec.

flux was monitored using a thin sheet of gold (10 μ thick, 7 mmϕ) adjacent to the sample.

Radiochemical Separation. To obtain the ^{7}Be spectrum without any contamination by undesirable activities in the irradiated sample, a chemical separation was necessary for all targets except beryllium. After irradiation, each target was dissolved along with 20 mg of a beryllium carrier, and then subjected to separation procedure. Boron powder was dissolved with nitric acid, and silica was dissolved with hydrofluoric acid. Wet oxidation by potassium iodate in a mixture of sulfuric and condensed polyphosphoric acids[15,16] was efficient in decomposing the carbon targets after they had been finely pulverized in a agate mortar. From these solutions, beryllium hydroxide was precipitated by the addition of aqueous ammonia and subsequent centrifuging. The hydroxide was dissolved with a small amount of nitric acid, and beryllium was extracted as its acetylacetonate into chloroform in the presence of EDTA at a pH of 7. The organic layer was back-washed twice, and then evaporated to dryness. The residual organic substances were decomposed by fuming with a sulfuric and perchloric acid mixture. The beryllium hydroxide was again precipitated from this solution by the addition of aqueous ammonia, and then ignited to obtain beryllium oxide.[17] The final oxide was packed in a small glass tube with an internal diameter of 4 mm for the determination of the chemical yield and for the gamma-ray counting.

Radioactivity Measurements. For the measurements of the gamma-ray spectra, a 3'' dia.$\times$3'' NaI(Tl) detector coupled to an 800-channel pulse-height analyzer made by the Tokyo Shibaura Electric Co., Ltd. was employed. Typical gamma-ray spectra are shown in Fig. 1. In each case, the dacay curve followed in the area under the 477 keV photopeak showed a half-life of 53 days, corresponding to the literature value of ^{7}Be.[2] The initial photopeak activity was obtained and used to determine the reaction yield.

Yield Determination. A yield was defined as the production rate of ^{7}Be per atom of a target nucleus when a standard amount of the bremsstrahlung radiation with a given maximum energy was passed through the target during the irradiation period. From the initial activity of the ^{7}Be, the corresponding saturation rate was computed and then normalized for bremsstrahlung intensity, which was measured by the amount of ^{196}Au activity in a gold foil irradiated together with the target. After correcting for chemical yield,[18] counting efficiencies, branching ratio, and internal conversion electrons, the data were expressed in the form of yields. These yields were expressed relative to that of the

17) In the case of ^{7}Be obtained from boron, the present procedure was insufficient for the complete removal of undesired activities; however, these activities could be removed by copper sulfide scavenging before the final hydroxide precipitation.
18) 50—70%.

$^{12}C(\gamma, n)^{11}C$ process, which was measured by the amount of 0.511 MeV gamma-rays arising from the annihilation of the positrons in a standard carbon disk irradiated together with the target.

Results and Discussion

Reaction Path. Beryllium and fluorine are the single-isotopic elements, and the natural isotopic abundances of the most abundant isotopes for carbon and oxygen are 98.893 and 99.759% respectively. Thus, it has been assumed for the sake of simplicity that each of these elements consists entirely of its most abundant isotope. Boron has the natural composition of two isotopes: ^{10}B(19.61%) and ^{11}B(80.39%). The competitive reactions take place on these two isotopes. Table 1 lists the possible nuclear reactions leading to the production of ^{7}Be in the energy region covered in this experiment, together with their calculated mass thresholds.[19] In many cases, ^{7}Be can be formed through several different reaction pathways. At an excitation energy up to 30 MeV, almost all of the ^{7}Be comes from ^{10}B *via* the (γ, t) process, and at this energy, ^{7}Be can be formed from carbon only by the $(\gamma, \alpha n)$ reaction on ^{12}C. For the production of ^{7}Be from ^{16}O, the only pathwhy which has a mass threshold below 45 MeV is the $(\gamma, 2\alpha n)$ reaction, and it may be seen that this reaction is the most probable pathway over the energy range investigated. All of the reactions leading to the photoproduction of ^{7}Be from the parent ^{19}F have threshold energies greater than 45 MeV.

Reaction Yield. The results obtained in this experiment are summarized in Table 2. The numbers in brackets indicate the number of determinations which were made. The errors in these results are less than 5%. For the $^{12}C(\gamma, n)^{11}C$ reaction, the resonance peak lies below 30 MeV, and the yield curve exhibits a slight increases with an increase in the energy.[20,21] The yields of the reactions investigated here appear likely to be strongly energy-dependent. Since ^{7}Be can be formed through competitive reactions on mixed boron targets, except in the irradiation at 30 MeV, the reaction yields were expressed with preference to the per atomic weight of the target element instead of per mole of the target nucleus. The yields are shown in Fig. 2, plotted against the difference in mass between the target and product nuclei at excitation energies of 30, 45 and 60 MeV. For a given energy, the exponential decrease in the reaction yield *versus* the difference in mass is shown. The gradient of the logarithm of the yield against the difference in mass increases as the excitation energy decreases.

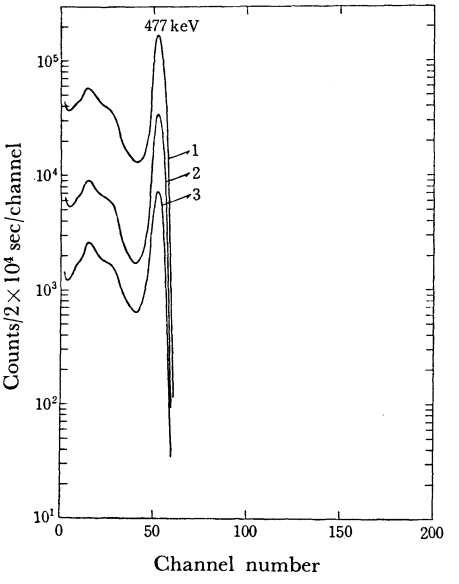

Fig. 1. Gamma-ray spectra of ^{7}Be.
1: Carbon 1.76 g, 32.1 days after irradiation
2: Beryllium 47 mg, 37.5 days after irradiation
3: Boron 77 mg, 49.4 days after irradiation
Irradiation: 60 MeV (45 μA), 3 hr
Measurement: 3″dia.×3″NaI(Tl), source distance=8 cm

Walker *et al.*[22] measured the reaction yields for the production of ^{18}F from ^{19}F to ^{32}S targets with 240 MeV bremsstrahlung, and found their exponential decrease when plotted against the number of emitted nucleons.

A similar tendency has been shown in various works of proton-induced spallation reactions,[23-25] and a possible mechanism which would result in this behavior has also been considered. When the total reaction cross-section is distributed among many of the product nuclei, a yield generally favors the product nuclide which is close to the line of the stable nuclei on the isotopic chart. If this is the case, the yield shows the exponential decrease against the difference in mass, as has been determined here. The foregoing presentation may prove useful in a general consideration of photonuclear properties in the energy region up to 60 MeV.

For analytical purposes, the lower limits of detection for beryllium and for boron under the present experimental conditions[26] can be estimated to be 2 and 10 μg respectively. Obviously, these limis of detection will be reduced by a higher bremsstrahlung intensity and by lengthening the time of irradiation.
