Silica-alumina is widely used as a catalyst for such reactions as cracking, isomerization, and polymerization. Recently many studies of the nature of the catalytically-active sites[1-4] which are developed by the removal of chemisorbed water from the surface have been undertaken. The active sites thus generated possess acid properties; the Lewis-acid site can accept lone-pair electrons, and the Brönsted-acid site can donate a proton. It is thought that these acid sites play an important role in surface reactions. The distribution of these acid sites has been measured by various techniques, such as the indicator method[5,6] and the volumetric-base adsorption method.[7,8] However, no exact information on the nature of the surface of silica-alumina, has yet been obtained. In this work, the *n*-butylamine titration method using the Hammett indicators was employed to determine and characterize the acid properties of the surface of silica gel, alumina, and silica-alumina; the results will be discussed in relation to the heat of immersion caused by the interaction of water with acid sites. Furthermore, the spectra resulting from the diffuse reflection[9] of anthracene adsorbed on the samples from an *n*-hexane solution were measured in order to confirm the results obtained from the above experiments.

Experimental

Materials. The silica gel was prepared by the hydrolysis of ethyl ortho-silicate, which had been purified by distillation at 120—130°C. The product was washed with water by repeated decantation, kept standing overnight at 150°C, and then calcined at 600°C in air for 8 hr. Alumina was produced by hydrolyzing aluminum isopropoxide which had been previously purified by distillation under reduced pressure. The product was treated in the same way as in the case of silica gel. The silica-alumina was prepared by adding a suspension of aluminum isopropoxide in alcohol to the sol obtained by hydrolyzing ethyl ortho-silicate. The mixture was well

stirred for 3hr at 120—130°C, and then treated as above. X-Ray analysis showed that the silica gel and silica-alumina were practically amorphous and that the alumina was of the γ-type. The specific surface areas of the samples evacuated at 300°C were determined by the B.E.T. method from the nitrogen adsorption. The results are listed in Table 1. The *n*-butylamine and benzene were purified by distillation, with several pieces of metallic sodium added to remove any moisture. The anthracene and the Hammett indicators were purified by recrystallizing them twice from a hot alcoholic solution.

Measurement of Acid Properties. The silica gel, alumina, and silica-alumina were dried at 100°C, 300°C, and 500°C for 3hr *in vacuo*. These samples were then dispersed into dry benzene, and the suspensions thus obtained were titrated with a 0.5 N benzene solution of *n*-butylamine using the Hammett indicators.[5] The treatment was made in a dry-box through which nitrogen gas flowed continuously. The amount of *n*-butylamine titrated corresponds to the number of acid sites.

Heat of Immersion. The heats of immersion of the samples were measured at 25°C in water and in an aqueous solution of *n*-butylamine by using a calorimeter equipped with a thermistor.[10]

Diffuse Reflection. An oxygen-free *n*-hexane solution of anthracene was added through a breakable joint to a sample dried at 300°C. After the adsorption equilibrium had been established, the *n*-hexane was sufficiently removed through a trap cooled with liquid nitrogen. The colored sample was then transferred into a cell used for the measurement of diffuse reflection, which was then cut off. The spectra were measured using a Hitachi-Perkin-Elemr 139 spectrophotometer, equipped with an attachment for the measurement of the diffuse reflection.

Results and Discussion

Acid Properties. The acid properties of the surfaces of silica gel, alumina, and silica-alumina show different characteristics as the evacuating temperature rises.

Figure 1 shows that silica-alumina has two acid-site groups; one group includes the strong acid sites in the range of $H_0 < -3.0$, and the other, the weak acid sites in the range of $6.8 > H_0 > 3.0$, where H_0 is the Hammett function. These are scarcely no intermediate sites between $H_0 = 3.0$ and $H_0 = -3.0$, as may be seen in the figure. The strong acid sites increase with a rise in the outgassing temperature. The acid property of alumina is quite different from that of silica-alumina, as is shown in Fig. 2. When alumina is heated at 100°C, weak acid sites alone develop. However, when the sample is treated at 300°C, strong acid sites also appear and the total number of acid sites increases. On the other hand, when heated at 500°C, all of the strong acid sites disappers. The total number of acid sites of silica gel is nearly

constant, regardless of the evacuating temperature, whereas more stronger acid sites appear with a rise in the temperature, as may be seen in Fig. 3.

The acid strength of silica-alumina also changes with the alumina content. Figure 4 shows the case of silica-aluminas evacuated at 300°C. The number of strong acid sites is almost zero for pure silica gel, but it increases with the alumina content until finally it again takes a low value for pure alumina. The maximum number of weak acid sites is at the content of 10—20%. Thus, the total number of sites is maximum at a content of about 20%. The aluminum atom originally hydrated in the surface layer of silica-alumina is dehydrated by evacuation at a high temperature. The naked aluminum atom thus produced may behave as a strong acid site, while the hydrated one may act as a weak acid site.[11] As the probability that the naked aluminum atoms will appear on the surface by evacuation increases with the alumina content, it may be generally predicted that the number of strong acid sites increases, and that of weak acid sites decreases, with an increase in the alumina content. The fact that the number of strong acid sites is less for alumina than for silica-alumina seems to be due to the difference in the mechanism of the generation of acid sites between these two materials.[12]

Heat of Immersion. The heats of immersion of silica-aluminas with various alumina contents in water are shown in Fig. 5. The heat evolved increases with the alumina content, as has been reported previously.[10] The factors responsible for the generation of the heat may be considered to be as follows: (1) the property of -OH groups on the surface, (2) the hydrogen bond between the -OH group and electronegative oxygen or the nitrogen atom in such molecules as water and *n*-butylamine, and (3) the distribution of acid sites on the surface. When the samples are immersed into water, the water molecule with non-bonding electrons generally makes a co-ordinate bond with the active acid site. The strong acid site is considered to contribute to heat generation more than the weak site does. The small amount of heat for silica gel may be due to the absence of a strong acid site on its surface and also to the weak dipole-dipole interaction of a water molecule having a large permanent dipole moment with the neutral -OH group. The gradual increase in the heat with the alumina content may be due to a slow increase in the number of strong acid sites on the surface. The large heat value for alumina may be caused mainly by the strong interaction of the negatively-charged -OH group[13] with the water molecule, since the alumina has a small number of strong acid sites.

When the samples are immersed into an aqueous solution of *n*-butylamine, more heat is generated than in the above case, as may be seen by comparing Figs. 5 and 6. The difference between the heat of immersion in water and that in the aqueous solution of *n*-butylamine is shown in Fig. 7. The amount of heat at a content of about 10% is characteristically large. The amount of *n*-butylamine adsorbed from the aqueous solution on the surface of silica-alumina is shown in Fig. 8, where the adsorbed amount was determined by means of

an electrical conductivity method. The maximum amount of *n*-butylamine adsorbed is at a content of 10%, as may be seen in Fig. 8. Each of the curves in Figs. 7 and 8 bears a fairly good resemblance in shape to the curve of total acid sites shown in Fig. 4.

Diffuse Reflection. Anthracene was used as a molecular indicator because it is known that the spectra due to the interactions of anthracene with Lewis-acid site and with a Brönsted-acid site can be distinguished from each other.[14,15] A

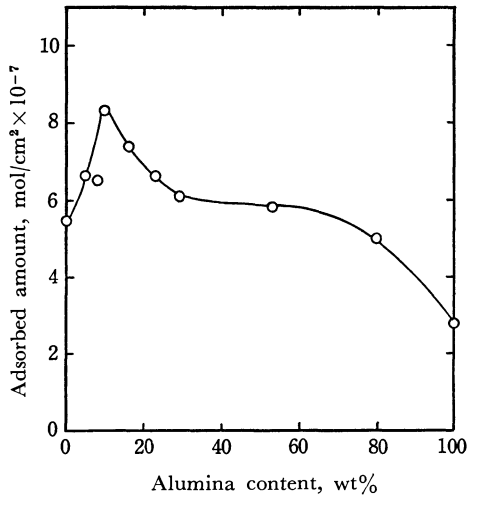

Fig. 8. Adsorbed amount of *n*-butylamine on the surface of silica-aluminas with various contents of alumina from the aqueous solution of *n*-butylamine.

degassed *n*-hexane solution of anthracene was added to a sample evacuated at 300°C through a breakable joint, the whole was allowed to stand for 1 hr, and then the *n*-hexane was removed through the other breakable joint. Upon this treatment silica-alumina turned green and alumina, palegreen, but silica gel showed no change in color. According to the observation of the color change, only the strong interaction of anthracene with the acid sites can be observed. In the measurement of diffuse reflection, alumina shows a very weak absorption at 760 mμ; this is due to the carbonium cation radical arising from electron transfer from the anthracene molecule to the Lewis-acid site. This species was confirmed by ESR measurement. Silica-alumina with a content of 80% shows an absorption at 760 mμ, stronger than in the case of alumina; this was confirmed by a study of the ESR spectra.

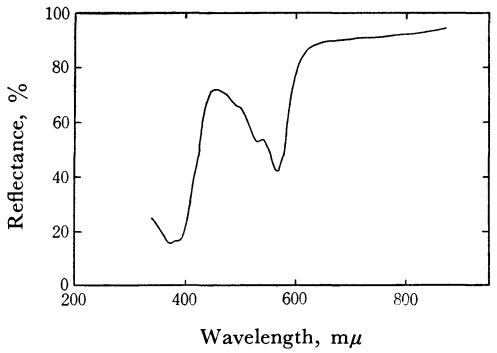

Fig. 10. Effect of water vapor on diffuse reflection spectrum of anthracene adsorbed on the surface of 10% silica-alumina.

On the other hand, silica-alumina with a content of 10% shows an absorption due to the interaction of anthracene with the Brönsted-acid site at 430 mμ in addition to that due to interaction with the Lewis-acid site at 760 mμ as Fig. 9 shows. Silica gel shows no absorption at either 760 mμ or 430 mμ.

When water molecules are adsorbed from the vapor phase through a third breakable joint, the color, the absorption bands at both 430 mμ and 760 mμ, and the ESR signal all disappear in the cases of alumina and silica-alumina, but new absorption bands at 530 mμ and 570 mμ appear in the case of silica-alumina with a content of 10%, as may be seen in Fig. 10. This new interaction is weak, since the color reverts to the original one when the system is evacuated. When anthracene is adsorbed and then water is adsorbed, it seems that water molecules squeeze themselves between the anthracene molecules and the sites on the surface. As a result, the absorption bands at 430 mμ and 760 mμ both disappear. This phenomenon suggests that the water molecule reacts with the acid sites more strongly than does anthracene, and also that the water molecule rather than *n*-butylamine is adsorbed preferentially on the sites from the aqueous solution of *n*-butylamine.

Conclusion. When silica-alumina is immersed into an aqueous solution of *n*-butylamine, the water molecule may preferentially interact with the strong acid sites and may weaken the site strength, as in the case described above. As a result, the strong acid sites may be transformed to weak ones, while the total number of the acid sites remains unchanged. If both the adsorbed amount and the heat value of *n*-butylamine depend principally on the total number of acid sites, the resemblance in shape among the curves of these three quantities (Figs. 4, 7, and 8) may be interpreted well.

Photoemission from Polycyclic Aromatic Crystals in the Vacuum Ultraviolet Region. III. Aromatic Crystals and Charge-transfer Complexes

Tomohiko HIROOKA, Masakatsu KOCHI, Jun-ichi AIHARA, Hiroo INOKUCHI and Yoshiya HARADA

The Institute for Solid State Physics, The University of Tokyo, Roppongi, Tokyo

(Received September 25, 1968)

The photoemission from various types of charge-transfer complexes, quinolinium-tetracyanoquinodimethane Q(TCNQ)$_2$ (I), dibenzophenothiazine (DBP)-dicyanodichloro-*p*-benzoquinone (DDQ)[(DBP)(DDQ)(II) and (DBP)$_2$(DDQ)(III)], trinitrobenzene (TNB)-coronene (IV), and TNB-perylene (V), and also large polycyclic aromatic hydrocarbons, violanthrene A (VI), violanthrene B (VII), coronene (VIII), pyranthrene (IX), and pyranthrone (X), was observed in the vacuum ultraviolet region. The experimental equation $Y \propto (E-E^*)^3$, where Y is the quantum yield of photoemission; E, the incident photon energy, and E^*, the threshold energy, was used to determine the ionization potential. The E^*-values, as estimated from the experimental equation, were I=4.85 eV, II 4.99, III 4.75, IV 5.62, V 5.52, VI 5.06, VII 5.13, VIII 5.58, IX 5.04, and X=5.71 eV. A band structure scheme for these organic semiconductors was introduced to analyse the emission mechanism.

In 1935, the spectral dependence of the photoemission from the naphthalene and anthracene complexes with alkali metals was observed by Suhrmann.[1] In 1963, Inokuchi and Harada[2] reported their findings on the violanthrene A complex with cesium; further, Ogino *et al.*,[3] measured the dependence of the pyrene derivatives complexes with cesium. However, the photoemission from the charge-transfer complexes, the components of which are organic substances, were not observed until recently because the wavelength region of the photoemission from them is in the vacuum ultraviolet region where measurement is difficult. On the other hand, we have already reported our findings on the current-voltage characteristics and the spectral distributions of the photoemission from polycyclic aromatic hydrocarbons.[4,5] Recently Batley and Lyons[6] reported on the photoemission from the 1,6-diaminopyrene- and the tetramethyl-*p*-phenylenediamine-complexes with various organic acceptors.

In the above previous works, two methods of determining the ionization potential of solid have been used. One was the method of obtaining the ionization potential from the threshold energy of the spectral response of the photoemission. Lyons and Morris[7] determined the threshold as the lowest detectable current. However, in this method, it is necessary for the photoemission yield to rise up abruptly at the threshold energy; this condition is not necessarily satisfied in all compounds. For instance, the bulk ionization potentials determined by Kearns and Calvin[8] by this method were too small in comparison with the values obtained by the other methods.

The second method was that of the retarding potential. Terenin and Vilessov[9] obtained the ionization potential by measuring a current-stopping potential and also a current-saturation potential. When the sample has a semiconductive character, however, it is very difficult to determine the current-stopping potential because the current becomes an asymptotic curve to the voltage axis in its neighbourhood.[10]

This paper will give the results of the photoemission from various types of charge-transfer complexes and large polycyclic aromatic hydrocarbons. Because the voltage-current characteristic of the charge-transfer complexes used in this work is intrinsic semiconductor-like and because the photoemission yield does not rise up abruptly at the threshold energy, their ionization potentials can not be determined by the above two methods. Therefore, an experimental equation will be employed in this study to determine the ionization potential.

Experimental

Materials. The materials used in the present study are shown in Figs. 1 and 2. Figure 1 shows the structural formula of the condensed aromatic hydrocarbons—violanthrene A, violanthrene B, coronene, pyranthrene and pyanthrone. Figure 2 illustrates those of the charge-transfer complexes — quinolinium-tetracyanoquinodimethane $Q(TCNQ)_2$ and dibenzphenothiazine (DBP)-dicyanodichloro-*p*-benzoquinone (DDQ); these are two different complexes with different component ratios, (DBP)(DDQ) and $(DBP)_2(DDQ)$. The other charge-transfer complexes used are trinitrobenzene (TNB)-coronene and TNB-perylene.

Sample Preparation. Except for $Q(TCNQ)_2$, the materials were deposited on a copper disc, 10 mm in diameter, by means of sublimation *in vacuo* (10^{-5}—10^{-6} mmHg). The deposited films were several microns thick. The $Q(TCNQ)_2$ complex could not be sublimed. Therefore, as it had a high electrical conductivity in the bulk state, the complex could be used as a pressed disc stuck with silver paste onto the copper disc. The pressed sample was approximately 1 mm thick.

The formation of the complex was examined by means of the absorption spectra of the sublimed samples. We observed that (DBP)(DDQ) and $(DBP)_2(DDQ)$ have different absorption spectra, both of which possess a characteristic charge-transfer band near 7400Å.

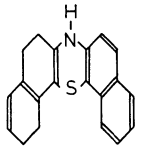
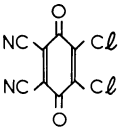
$Q(TCNQ)_2$



Dibenzophenothiazine (DBP)



Dichlorodicyano-p-benzoquinone (DDQ)

Fig. 2. The structural formulas of the charge-transfer complexes.

To observe the photoemission, a Seya-Namioka-type vacuum ultraviolet monochromator was used. The details of the apparatus have been reported previously.[4] The collector of the photoemissive cell, a glass sphere, was about 13 cm in diameter. On the inside it was coated with a conducting layer of colloidal graphite, Aquadag. The sample was placed in the centre of the cell. In order to obtain enough intensity, the slit was made 1 mm wide at the cost of resolving power. The photoemission current was amplified and observed by a Cary 31 vibrating-reed electrometer.

The spectral dependence of the photoemission yield was measured under an applied potential of 10 V, enough to gather all of the emitting electrons, and at intervals of 20Å. The saturation of the photoemission current for $Q(TCNQ)_2$ against an applied potential was very slow, but the current observed around 50V was saturated enough for us to estimate the phtoemission yield.

The current-voltage characteristics were observed by a spherical retarding method, and the photoemission current was recorded as a function of the applied voltage with a Yokogawa X-Y recorder, PRO-12. The current saturation potential, V_s, was determined by averaging the values observed at the incident wavelength of 1600Å, 1400Å, or 1200Å. In the present study, a highly accurate saturation point was obtained because the photocell used had a good spherical geometry. This observation was carried out to a precision of less than 0.03 eV.

Results and Discussion

Figure 3 shows the photoelectric yield curves of violanthrene A and violanthrene B as functions of the incident photon energy. Figure 4 shows those of pyranthrene and pyranthrone. The threshold energy, E_{th}, can be determined by extrapolation to a quantum yield of 10^{-7} electrons per incident quantum. However, as is shown in Figs. 3 and 4,

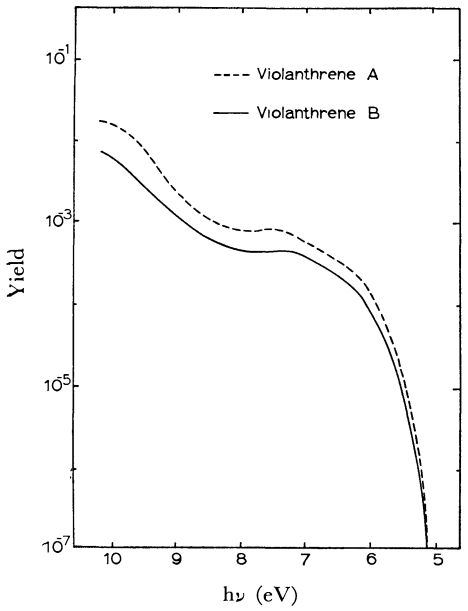


Fig. 3. The photoelectric yield curves of violanthrene A and violanthrene B.

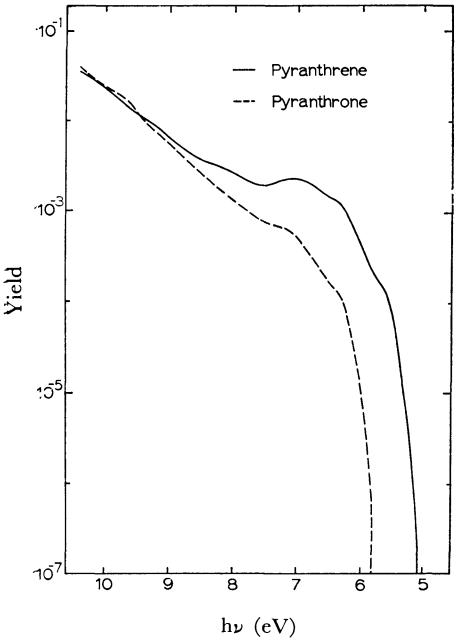

Fig. 4. The photoelectric yield curves of pyranthrene and pyranthrone.

the shapes of the rising photoemission yield curves from the threshold point are different in various compounds. For instance, violanthrene A and violanthrene B are found to have the same threshold energy by the extrapolation method described above, but the shapes of the rising photoemission yield curves are clearly different.

The spectral response patterns of the yield are very different in the two types of charge-transfer complexes used in the present study. One of them is a weak charge-transfer complex, while the other is a strong charge-transfer complex. Figure 5 shows the spectra dependence of the photoemission yield of two weak charge-transfer complexes (CT-complexes), TNB-coronene and TNB-perylene.

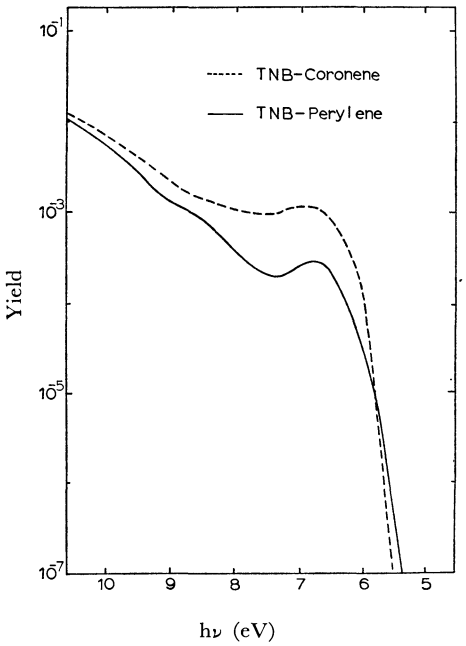

Fig. 5. The photoelectric yield curves of the weak charge-transfer complexes, TNB-coronene and TNB-perylene.

In the case of weak CT-complexes, the photoemission yield curves are almost the same as that of the donor component; for instance, the yield curve of (TNB)-coronene has a peak at about 6.7 eV corresponding to that of coronene.*1 The ionization potential of the acceptor (TNB) is estimated to be higher than that of the donor (coronene), therefore, the ionization potential of the complex can be determined by means of the threshold energy of only the donor (coronene). Figures 6 and 7 show the spectral responses of the yields of the strong charge-transfer complexes—Q(TCNQ)$_2$, (DBP)-(DDQ), and (DBP)$_2$(DDQ).

The photoemission yield curves of their separated components are shown in the same figure for comparison. In Fig. 7 the characteristic peak is observed at about 7.3 eV; this value, corresponds to

*1 This suggests that, in weak charge-transfer complexes, the two components keep their individual characteristics, so the total photoemission from complexes is almost equal to the superposition of those of the two components.

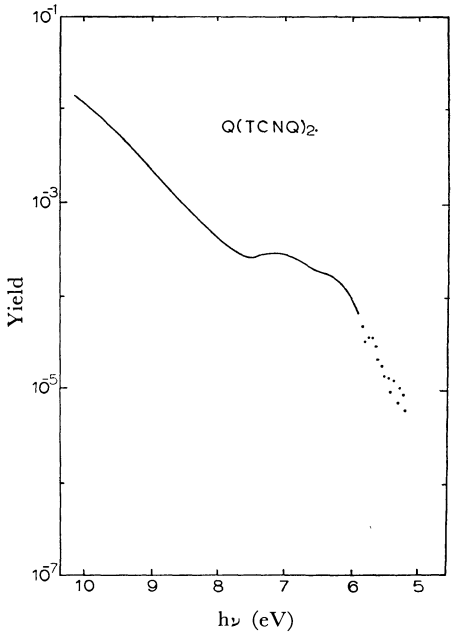

Fig. 6. The spectral response of the photoemission yield of the strong charge-transfer complex, $Q(TCNQ)_2$.

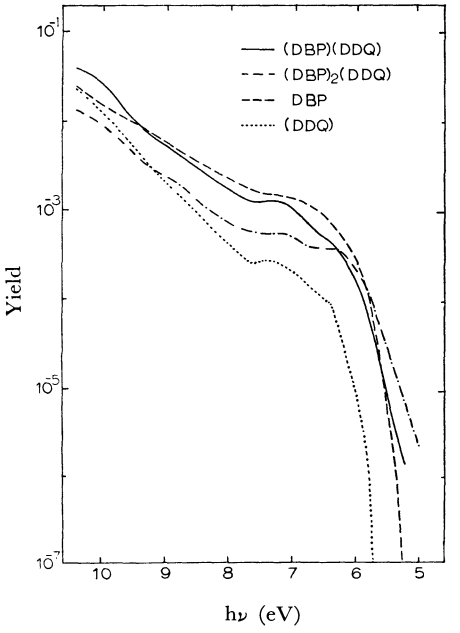

Fig. 7. The spectral response of the photoemission yield of the strong charge-transfer complexes, (DBP)(DDQ), $(DBP)_2$(DDQ) and their components.

that of the acceptor, DDQ. In $(DBP)_2$(DDQ) a new peak is observed at about 6.4 eV.

The quantum yield near the threshold energy of the strong charge-transfer complexes decreased very slowly in comparison with the other materials; therefore, the threshold energy could not be determined by the extrapolation method.

By analogy with the Fowler plot for metal, we assumed that the quantum yield in organic crystals near the threshold energy is subject to the conventional power law;*2

$$Y \propto (E-E^*)^n \qquad (1)$$

where Y is the quantum yield, E, the incident photon energy, and E^*, the threshold energy.

Figure 8 shows the spectral dependence of the photoemission yield of (DBP)(DDQ) as plotted with $n=1$, 2, and 3. This indicates that, in the lower-energy part, a cube root plot of the quantum yield becomes almost linear as a function of the incident photon energy, while in the higher-energy part the quantum yield becomes linear. The same equation, Eq. (1), was applied to the photoemission from inorganic crystals.[12] This empirical cube root law held true for all the compounds studied.

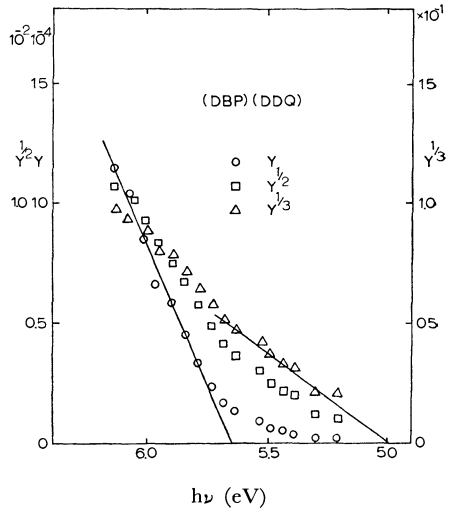

Fig. 8. The linear, square and cube root plot of the yield of (DBP)(DDQ) near the threshold energy.

*2 In inorganic semiconductors, Kane[11] proposed that the spectral yield obeys $Y \propto (E-E^*)^n$, in which $n=$ 1, 3/2, 2, and 5/2 under various conditions near the threshold energy. Gobeli and Allen[12] observed that, for an atomically-clean silicon surface, the spectral yield curve was composed of two components. One of them is the part of a linear plot of the yield which corresponds to a direct transion, while the other is the part of a cube root plot at a lower photon energy which corresponds to an indirect transition. Kane's theory was obtained assuming that the band theory can be strictly applied. However, it is doubtful whether it can be applied to organic crystals with narrow band widths.

11) E. O. Kane, *Phys. Rev.*, **127**, 131 (1962).
12) G. W. Gobeli and F. G. Allen, *ibid.*, **127**, 141 (1962).

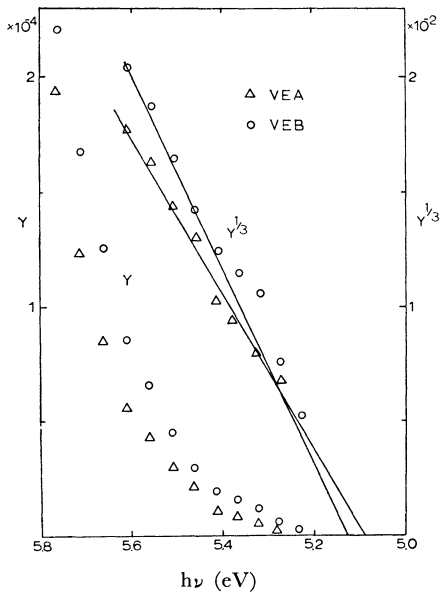

Fig. 9. The linear and cube root plot of the photoemission yield of violanthrene A and violanthrene B near the threshold energy.

Figure 9 shows the cube root plot and the linear plot of violanthrene A and violanthrene B. The difference in the photoemission yield curve near the threshold energy leads to the difference in the threshold energy, E^*.

This method can be applied to the complexes, and their threshold energy can be thus determined. For both the single component compounds and the complexes used, the cube root plot gives a straight line for the energy region of 0.3 eV—0.6 eV from the threshold energy. The E_{th} values and also the E^* values obtained by this method are given in Table 1. As this table shows, the E_{th} and E^* of single component compounds agree within the limits of 0.15 eV. Especially for the compounds which have an abrupt increase in the quantum yield near the threshold energy, the threshold energy values obtained by the extrapolation method need not be modified.

The values of the ionization potential are 0.37 eV for (DBP)(DDQ) and 0.61 eV for $(DBP)_2(DDQ)$ respectively, both values being smaller than that of the donor, DBP. If this difference is caused by any impurity which has a lower threshold energy, the quantum yield will not be subjected to the cube root law, because perhaps the impurity is only small in amount. Batley and Lyons[6] explained it as being due to the difference in polarization energy for the non-ionic complexes. For the ionic complexes they used the different explanation that the emission comes from the negative ion. The strong charge-transfer complexes in the present study have the properties between the weak charge-transfer complexes and the ionic complexes.

If we assume that the organic molecular crystals used as emitters are intrinsic semiconductors, and if a metal is used as the collector, the schematic diagram in Fig. 10 can be introduced. The Fermi level of the emitter coincides with that of the collector in thermal equilibrium. The potential difference between the vacuum level of a collector and the vacuum level of an emitter corresponds to the current saturation potential, V_s. The work function, φ, of the emitter, which corresponds to the energy difference between the vacuum level of the emitter and the Fermi level, is obtained as;

$$\varphi = \varphi_c - eV_s = 4.74 - eV_s \qquad (2)$$

where φ_c is the work function of the collector. Aquadag (colloidal graphite) is used as the collector in our study. The value of φ_c for Aquadag is 4.74 eV.[10]

Work functions can be determined independently by means of the contact potential difference method. Kotani and Akamatu[13] determined the work functions of the organic crystals using this method. Table 2 shows the work functions obtained by means of these two methods. The table indicates

that the two work functions are in fairly good agreement.

In the case of the intrinsic semiconductor, the energy difference, δ,*3 between the top of the valence band and the Fermi level is a half of the band-gap energy, $\Delta\varepsilon/2$, based on the results of the temperature dependence of the semiconduction. If we use the work functions, φ, in Table 2, the band-gap energy, $\Delta\varepsilon$, can be estimated from the following equation:

$$\Delta\varepsilon = 2(E^* - \varphi) = 2(E^* - \varphi_c + eV_s) \quad (3)^{*4}$$

In Table 3, the $\Delta\varepsilon$ values obtained in this way are compared with those found from the temperature dependence of the semiconduction. The two values are in fairly good agreement in spite of the rough assumption. This result suggests that the energy level diagram used is a good assumption.

We wish to thank Professors Yoshio Matsunaga and Junji Aoki, and Mr. Satoshi Iwashima for supplying us with the organic materials.

Mössbauer Effect of ^{119}Sn in Molecular Complexes of Tin(IV) Chloride with Several Aromatic Compounds

Sumio ICHIBA, Mitsuo MISHIMA*1 and Hisao NEGITA

Department of Chemistry, Faculty of Science, Hiroshima University, Hiroshima

(Received October 4, 1968)

The Mössbauer spectra of molecular complexes of tin(IV) chloride with some oxygen-containing aromatic compounds, such as hydroxybenzaldehydes and cinnamic acid, were investigated. Most of these complexes show the quadrupole splitting resulting from the addition of aromatic molecules to tin(IV) chloride, although in some cases broad absorption curves are observed. The isomer shifts of these complexes are 0.25—0.45 mm/sec, much smaller than that of tin(IV) chloride itself. These values are almost the same as those of the complexes of tin(IV) chloride with aliphatic compounds. From these results, the bond nature and structures of these complexes, which had not previously been studied, were discussed in some detail.

In a previous paper[1] dealing with the ^{119}Sn Mössbauer effect in the molecular complexes of tin (IV) chloride with some aliphatic compounds, it was shown that the spectra for most of the complexes were doublets caused by the quadrupole splitting, and that the isomer shifts of the molec-

ular complexes with respect to SnO_2 were in the range from 0.30 to 0.45 mm/sec.

In the present work, the 1 : 2 molecular complexes of tin(IV) chloride with some aromatic compounds have been investigated by Mössbauer spectroscopy. The structures of these complexes have not been investigated. However, the preparations of most of the complexes have been reported by Pfeiffer[2,3] and by Rosenheim *et al.*[4]

In the molecular compolexes of tin(IV) chloride (electron acceptor) with oxygen-containing aromatic compounds (electron donor), there are two possibilities in the way of coordination, unlike the aliphatic compounds, because the oxygen-containing aromatic molecule has two parts serving as electron donors, *i. e.*, the benzene ring and the oxygen-containing group. In the complex of tin(IV) chloride with benzaldehyde, for example, the chlorine atom in tin(IV) chloride may be bonded to the benzene ring of benzaldehyde through its π-electron, but it is equally, or even more, likely that the oxygen atom of the aldehyde group will be coordinated to the tin atom in tin(IV) chloride directly through the lone-pair electrons of the oxygen, as in the case of aliphatic compounds reported previously. In the former case the chlorine atoms around the tin atom remain in the tetrahedron form in complexing, whereas in the latter case they change to an octahedron.

The purpose of the present study is to clarify the difference between the aliphatic and aromatic complexes and to explain, on the basis of the Mössbauer parameters, how tin(IV) chloride is bounded to the aromatic compound in the complex.

Experimental

Preparation of Molecular Complexes. The tin(IV) chloride and all the aromatic compounds were obtained commercially. All the complexes except that of tin(IV) chloride with cinnamyl alcohol were prepared by a method similar to those described by Pfeiffer[2,3] and by Rosenheim and Levy.[4] That is, the complexes were formed by dropping tin(IV) chloride (1/20 mol) into ice-cooled petroleum ether, chloroform, or a benzene solution of an aromatic compound (1/10 mol); they were then dried over silica gel in a vacuum desiccator.

The complex of tin(IV) chloride with cinnamyl alcohol was prepared by adding tin(IV) chloride (1/20 mol) to petroleum ether in which cinnamyl alcohol (1/10 mol) was suspended. Brown nonhygroscopic crystallines with a mp of 82 °C were thus obtained. All the complexes except that of tin(IV) chloride with ethyl cinnamate were purified by sublimation under a reduced pressure of 4—7 mmHg. The complexes were identified by their melting points; the results are summarized in Table 1, along with the literature values.

Table 1. Melting points of $SnCl_4$-complexes

a) Refs. 2, 3.
b) Melting point could not be measured on account of thermal decomposition.

Measurements. The measurements were made as previously.[1] The activity at a given velocity was accumulated until it reached about 10^5 counts in order to reduce the statistical errors. The γ-ray radiation source was tin(IV) oxide containing 1 mCi ^{119m}Sn. The source was used at room temperature, whereas the absorber was cooled with liquid nitrogen. The thickness of the absorber was about 15 mg/cm^2 for Sn. X-rays were cut off by a palladium foil attached to the absorber.

Results and Discussion

The results are given in Table 2. The isomer shift, δ, and the quadrupole splitting, 2ε, of the complexes are presented in the first and second columns respectively. The third column gives the half-width, $R_{1/2}$, which was defined in the previous paper.[1] The isomer shift is referred to tin(IV) oxide at room temperature. A positive value means that the source and the absorber are approaching each other, while a negative value means that they are moving apart. When the splitting due to the quadrupole interaction was

observed, the average line position was taken as the δ-value. All the values of δ and 2ε are given in mm/sec.

Isomer Shift. In Table 2 the values of the isomer shift for all the complexes of $SnCl_4$ with oxygen-containing aromatic compounds fall in a range from 0.25 to 0.45 mm/sec. There is no appreciable difference between the δ-values for the complexes with oxygen-containing aliphatic compounds reported previously[1] and those with oxygen-containing aromatic compounds. The values are appreciably smaller than those of tin(IV) chloride, which are 0.7 ± 0.08,[5] 0.78 ± 0.1,[6] 0.8 ± 0.05,[7] and 0.9 ± 0.1[8] with respect to tin(IV) oxide. This means that tin(IV) chloride-complexes have a lower s-electron density at the tin nucleus than does tin(IV) chloride itself. In other words, the formation of the 1 : 2 complex of tin(IV) chloride with an oxygen-containing organic compound results in a decrease in the s-electron density at the tin nucleus.

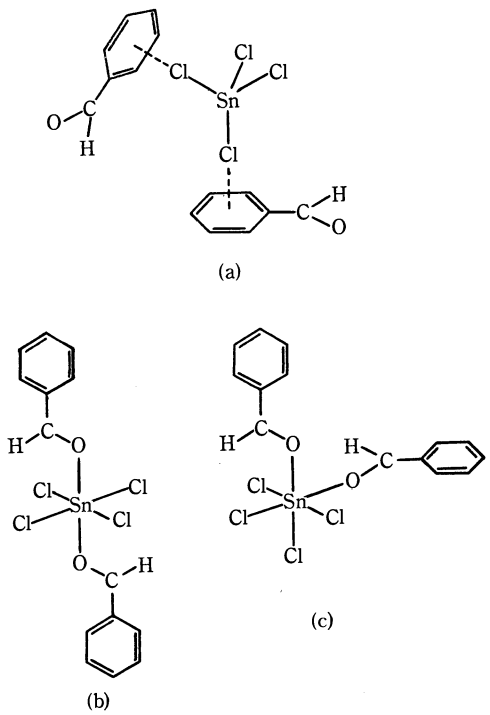

Fig. 1. Bond structures of $SnCl_4$-benzaldehyde complex.

In forming the molecular complex, it is assumed that the coordination of aromatic molecules to tin(IV) chloride permits two bond-structures, as has been mentioned above. For instance, the possible bond-structures of the complex of tin(IV) chloride with benzaldehyde are shown in Fig. 1; in (a) the π-electrons are transferred from the benzene ring to the chlorine atom of tin(IV) chloride, while in (b) and (c) the lone-pair electrons of the oxygen atom are transferred to the tin atom. In the (a) bond-structure the tetrahedral arrangement of the chlorine atoms around the tin atom is preserved, but in the structures (b) and (c) it changes to an octahedron of the *trans*- or *cis*-form.

The electron configuration outside the krypton core of a neutral tin atom is $(4d)^{10}(5s)^2(5p)^2$. In tin(IV) chloride, chlorine atoms are coordinated to the tin atom in a tetrahedral form so that the hybrid bond of the tin atom is sp^3. If the Sn–Cl bond in tin(IV) chloride is completely covalent, as has been discussed in a previous paper,[1] its s-electron character is 0.25. However, the bonds character was deduced to be approximately 40% ionic from the pure quadrupole resonance due to ^{35}Cl[9] and the Mössbauer effect of ^{119}Sn.[8,10]

If the complex has the structure (a), electrons will transfer from the benzene ring of the benzaldehyde to the chlorine atom of tin(IV) chloride. Consequently, the chlorine atom in the complex may be more ionic than that of tin(IV) chloride itself. However, the electron transferred to the chlorine atom may not influence the electron density at the tin nucleus very seriously, since it affects indirectly through the chlorine atom.

On the other hand, in the complex of the bond-structure (b) or (c) the electron-donor atom is the oxygen atom and the acceptor atom is the tin atom in tin(IV) chloride. That is to say, oxygen atoms are directly coordinated to the tin atom, and then oxygen atoms occupy a *cis*- or *trans*-position and the arrangement of atoms around the tin atom is hexacoordinated. Lone-pair electrons of the oxygen atom of the aldehyde group contribute directly to the electron core of the tin atom of tin(IV) chloride and sp^3d^2 hybrid orbitals are formed around the tin atom. If the ligand atoms are completely hexacoordinated, *i. e.*, if the Sn–O and Sn–Cl bonds are entirely equivalent and completely covalent, the s-electron character of the bonds is 0.17. Therefore, the s-electron density at the tin nucleus may be expected to be larger in the complex of the bond-structure (a) than in the complex of the bond-structure (b) or (c). Thus, the complex of the bond-structure (a) should show a larger isomer shift than the complex of the bond-structure (b) or (c). The isomer shifts of the complexes

between tin(IV) chloride and oxygen-containing aromatic compounds are 0.25 to 0.45 mm/sec, considerably smaller than that of tin(IV) chloride itself; these shifts do not differ appreciably from those of the complexes of tin(IV) chloride with aliphatic compounds, 0.31—0.45 mm/sec. Accordingly, the complex of tin(IV) chloride with aromatic compounds is considered to have the bond-structure (b) or (c). It is uncertain at this stage which of the bond-structures, (b) or (c), is the more probable, for other experimental data is lacking.

Quadrupole Splitting. With the exception of the complexes of tin(IV) chloride with *p*-hydroxybenzaldehyde and with cinnamyl alcohol, small quadrupole splittings were observed for all the complexes. A pair of clearly-split lines were observed in two complexes, those with benzoic acid and with ethyl cinnamate. The spectrum of the complex with benzoic acid is shown in Fig. 2 as an example. When the value of $R_{1/2}$ was below 2 mm/sec, only a broad absorption curve was observed. The value of the quadrupole splitting was found by analysing the curve, assuming that the component lines were of a Lorentzian type with a half-width of 1.50 mm/sec.

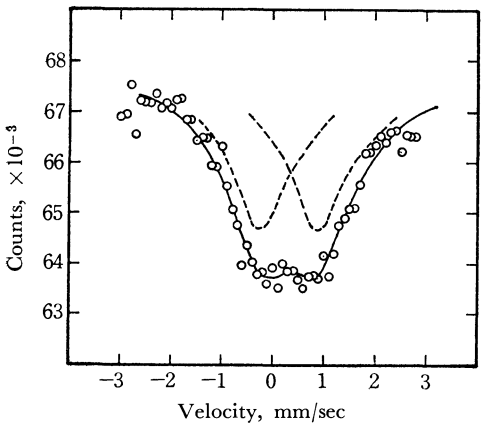

Fig. 2. Mössbauer spectrum of $SnCl_4 \cdot 2C_6H_5COOH$.

In Table 2, it is interesting to note that the complex with *p*-hydroxybenzaldehyde has no quadrupole splitting, though the complex with *o*-hydroxybenzaldehyde has. This is obviously due to the difference of the molecular structures of the ligands. However, the crystal structures of these complexes have not yet been established. Since the difference in the quadrupole splitting is caused by the relative positions of the OH- and CHO-groups, or the ortho- and para-positions, it is significant to consider how the two isomers are coordinated to the tin atom and how they give rise to the electric field gradient around the tin nucleus.

In the hexacoordinated complex of tin(IV) chloride with *p*-hydroxybenzaldehyde, the OH-groups are coordinated to the tin atom; therefore, the CHO-groups are free from the coordination, being separated from the tin atom or *vice versa*. However, it is more probable that the OH-groups are coordinated, for the complex with benzaldehyde shows splitting. On the other hand, in the complex with *o*-hydroxybenzaldehyde, the non-coordinated group at the ortho-position is very close to the tin atom and so necessarily causes an electric field gradient of some extent at the tin nucleus. Thus, the difference between the relative positions of the OH- and CHO-groups is reflected in the quadrupole splitting.

Small quadrupole splittings are also observed in the complexes with aromatic molecular ligands containing a carbonyl group with which the organic molecules are attached to the tin atom. According to Greenwood and Ruddick,[11] quadrupole interactions in tin(IV) compounds are observed only when there is an imbalance in subsidiary π-interactions.

In the spectrochemical series, carbonyl is ranked as a strong π acceptor and Cl^-, as a strong π donor. This difference in ligand ability will be enough to cause the imbalance in the π-interactions between the π orbitals of the ligands and the d_π orbitals of the central tin atom in the complex. Thus, small quadrupole splittings are observed in the complexes with benzaldehyde, benzoic acid, *etc.*, whereas no quadrupole splitting is observed in the complexes with *p*-hydroxybenzaldehyde and cinnamyl alcohol. This is because the *p*-hydroxybenzaldehyde and cinnamyl alcohol are attached to the tin atom by means of OH-groups which have little or no π-bonding abilities and which do not give rise to an electric field gradient at the tin atom. The small variation in the splitting values results from the inductive effects of the neighbouring groups of the carbonyl coordinated to the tin atom.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 1490—1493 (1969)

The Heat of Immersion of Ferric Oxide in Water

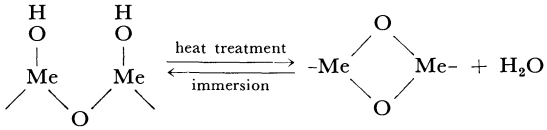
Tetsuo MORIMOTO, Noriko KATAYAMA, Hiromitu NAONO and Mahiko NAGAO

Department of Chemistry, Faculty of Science, Okayama University, Tsushima, Okayama

(Received October 17, 1968)

Four kinds of ferric oxide (α-Fe_2O_3) which differ in origin and history have been used for measurements of the surface area, the water content, and the heat of immersion in water. Two cases have been discovered; in one there appears a maximum in the plot of the heat of immersion against the pretreatment temperature according to the origin of the sample, but in the other a maximum does not appear. The heavy hydration treatment carried out prior to the immersion measurements raises the value of the heat of immersion in water, but it has no serious effect on the heat of surface hydration calculated therefrom, as in the case of TiO_2. The average value of the latter was 11.3 kcal/mol H_2O.

Measurements of the heat of immersion have been made on various kinds of insoluble metal oxides in water as well as in organic liquid, and it has been brought to light that the surface hydroxyl groups on metal oxides more or less affect the wetting phenomena.[1,2] Most plots of the heat of immersion in water against the pretreatment temperature show a maximum. This heat-of-immersion anomaly has been explained in terms of the overlapped effect of the chemisorption (the formation of surface hydroxyl groups) and the physical adsorption of water. The surface hydroxyl groups can be removed gradually by heating *in vacuo*, and can be reproduced immediately after immersing the surfaces into water, when the temperature of pretreatment is relatively low. However, when the pretreatment temperature is higher than a limited degree, the rate of the reproduction of the surface hydroxyl groups is remarkably delayed. Thus, the heat treatment at elevated temperatures results in a stabilization of the surface oxide structure made by the reaction:



Usually the maximum in the plot of the heat of immersion *vs.* the pretreatment temperature has been reported to appear in the temperature range from 300°C to 600°C with various kinds of oxides, such as SiO_2,[3,4] Al_2O_3,[5] TiO_2,[6,7] and ZnO.[8]

It has been a question for the present authors whether or not the maximum of the heat-of-immersion curve appears with every kind of metal oxide.

This paper will report that two cases have been discovered with α-Fe_2O_3; in one a maximum appears in the plot of the heat of immersion *vs.* the pretreatment temperature, but in the other a maximum does not appear. We have also investigated the effects of hydration treatment on the heat of immersion of α-Fe_2O_3 in water, and on the heat of surface hydration calculated therefrom.

Experimental

Materials. The samples used in the present work are four kinds of α-Fe_2O_3. One of them is the α-Fe_2O_3 presented by the Nippon Bengara Co.; it was prepared by calcining $FeSO_4 \cdot 7H_2O$ at 800°C for 7 hr. This original sample was treated several times with 0.1 N nitric acid in order to remove the basic impurities, and then with 0.1 N ammonia water in order to remove the acidic impurities; then it was washed with distilled water, and finally, by means of electrodialysis, cleaned of electrolytes. The conductivity of supernatant liquid was thus brought to a limiting value. The resultant sample was dried at 110°C for 8 hr in an oven (sample C). Another kind of sample was prepared by the calcination of α-FeOOH (goethite) for 5 hr at 800°C in air; this sample had been made by the oxidation of ferrous sulfate with hydrogen peroxide. This was thoroughly washed with distilled water, and then dried at 110°C for 8 hr in an oven (sample G).

8) T. Morimoto, M. Nagao and M. Hirata, *Kolloid-Z. u. Z. Polymere*, **225**, 29 (1968).

A part of each sample (C and G) was immersed in hot water at 80°C for 3 days to prepare a highly-hydrated sample, which was then dried as before (samples CH and GH).

Surface-area Measurements. The specific surface areas of the samples were measured by applying the BET theory to the nitrogen adsorption data obtained at the temperature of liquid nitrogen, assuming the cross-sectional area of a nitrogen molecule to be 16.2 Å^2.

Heat-of-immersion Measurements. The calorimeter and the technique for the heat-of-immersion measurement were the same as have been described previously.[5,8] The measurement was carried out at 25°C. The sample was treated in an ampoule at a desired temperature for 4 hr in a vacuum of 10^{-5} Torr before the heat-of-immersion measurements. As the heat of breaking of the ampoule was found to be 0.28 J, this was calibrated for the heat-of-immersion data.

Water-content Measurements. The water content of α-Fe_2O_3 was measured by the successive-ignition-loss method[5,8] by using an all-glass apparatus equipped with an oil manometer. As the gases other than water vapor were found to be present in the gas phase evolved at higher temperatures, they were determined by the technique described previously.[7] For instance, the gases other than water vapor which were evolved at 300, 600, and 800°C amounted to 0.10, 0.23, and 0.27 molecules/100 Å^2 for the sample GH. The water-content values given in Fig. 2 are those free from these quantities.

Results and Discussion

The specific surface area of α-Fe_2O_3 is given in Fig. 1 as a function of the temperature of pretreatment. The data show that the surface area of these samples remains unchanged up to about 500—600°C; with a further rise in the temperature, it decreases sharply, indicating a remarkable sintering.

In Fig. 2 the water content of α-Fe_2O_3, represented in OH's/100 Å^2, is plotted against the temperature of pretreatment. Much as in the cases of the other oxides,[5,7,8] the water content of α-Fe_2O_3 decreases steeply until about 400°C, and then it does so very slowly. The hydration treatment has a considerable effect upon the water content, which becomes larger in the sample subjected to a heavy hydration procedure, as was seen in the case of TiO_2.[7]

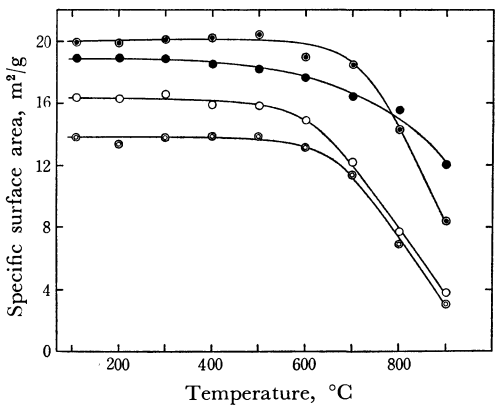

Fig. 1. Dependence of the specific surface area of α-Fe_2O_3 on pretreatment temperature.

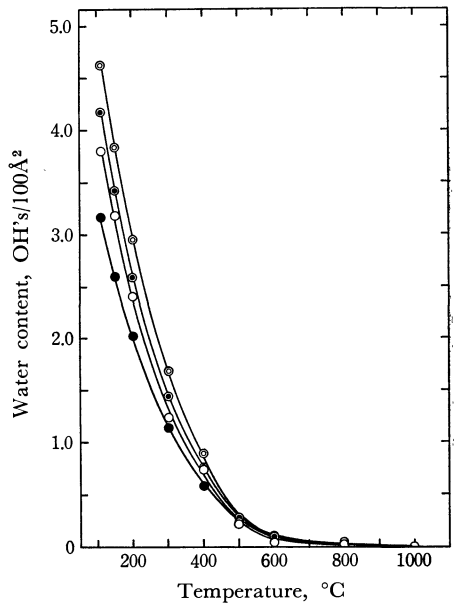

Fig. 2. Water content of α-Fe_2O_3 at various temperatures.
○, C; ◎, CH; ●, G; ⊙, GH

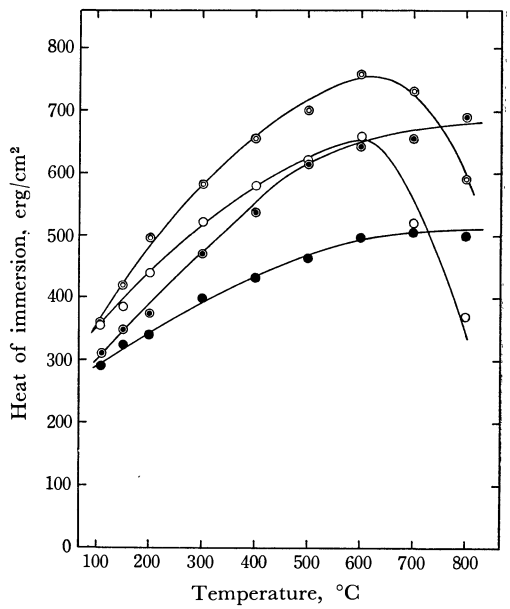

Fig. 3. Dependence of the heat of immersion of α-Fe_2O_3 in water on pretreatment temperature.
○, C; ◎, CH; ●, G; ⊙, GH

Figure 3 shows the relation between the heat of immersion of α-Fe_2O_3 in water and the temperature of pretreatment. It may be seen from Fig. 3 that the heat-of-immersion value is greater in the sample with a large water content resulting from a heavy hydration procedure.

The heat of immersion of the samples C and CH increases initially with a rise in the temperature of pretreatment; it reaches a maximum at 600°C, and then decreases slowly. Such maxima in the heat-of-immersion curve have been reported with such oxides as SiO_2,[3,4] Al_2O_3,[5] TiO_2,[6,7] and ZnO.[8]

On the other hand, the features of the heat-of-immersion curve of the samples G and GH are quite different from those of the former two samples; at first it increases to 600°C, as in the cases of the samples C and CH, but after that the heat-of-immersion value remains almost unchanged, unlike as in the latter cases, and thus no maximum appears. We have never encountered such a situation in which one sample of a substance reveals, and another one does not reveal, a maximum in the heat-of-immersion curve.

The appearance of the maximum in the plot of the heat of immersion of metal oxide in water against the temperature of pretreatment has been explained in terms of the overlapped effect of the chemisoprtion and physical adsorption of water.[3-8] As the temperature of pretreatment rises, the surface hydroxyl groups on metal oxides can be increasingly removed by condensation dehydration.[9,10] When the surfaces thus treated are immersed in water, rehydroxylation will occur on the dehydrated sites. At the same time, the additional heat of reaction will be released together with the heat evolution due to physical interaction between the solid surfaces and the water molecules. At temperatures higher than that of a maximum point, the rehydroxylation on the oxide surface is delayed by the stabilization of the surface oxide structure;[3,5] the higher the temperature, the greater the stabilization. Thus, the contribution of rehydroxylation heat decreases at extremely high temperatures, resulting in a depression of the observed heat of immersion. The fact that the heat-of-immersion curve of the samples G and GH does not reveal a maximum, but only a slow break at almost the same temperature as that of the maximum in the cases of the samples C and CH, indicates that the stabilization of the oxide structure of these samples is not remarkable. The weak stabilization of oxide structure permits a partial rehydroxylation.

Previously the water vapor adsorption isotherms have been investigated on the samples CH and GH.[11] This investigation showed that the amounts of water chemisorbed on the sample CH were 7.59 and 6.73 OH's/100 Å^2 when treated at 600°C and 800°C respectively, whereas on the sample GH it was 7.91 OH's/100 Å^2 in either case. This implies that when the sample is treated at 800°C, the rehydroxylation is incomplete with the sample CH, whereas with the sample GH it is complete; at the same time, this finding substantiates the stabilization theory accounting for the heat-of-immersion anomaly. However, the reason why it is difficult for the stabilization of surface oxide structure to occur on the sample GH has not yet been solved; it may depend on the crystal properties of the sample, which are decided by the origin and the history of the sample.

We can obtain the heat of surface hydration by assuming the complete rehydroxylation of dehydrated sites in the range of lower temperatures of pretreatment than the maximum point. Figure 4 represents the plots of the heat of immersion against the water content of α-Fe_2O_3. The same plotting can be made also for the samples G and GH, as is shown in Fig. 4. The slopes of these plots indicate the heat of formation of surface hydroxyl groups, that is, the heat of surface hydration; the results are tabulated in Table 1.

It can be seen from Table 1 that the heat of surface hydration is almost the same for every sample, being 11.3 kcal/mol H_2O on the average,

irrespective of the origin and the history of the sample. This value of heat of surface hydration is quite small compared with the value, 24.2 kcal/mol H_2O, which was obtained for α-Fe_2O_3 by Healey *et al.*[12] by combining the heat-of-immersion data and the water adsorption data. At any rate, neither the preparation nor the hydration treatment of the sample has any serious effect on the heat-of-surface-hydration value, as was in the case with TiO_2.[7] The hydration treatment rather affects the value of the heat of immersion itself, as may be seen in Fig. 3. Thus, it is reasonable to consider that the hydration treatment causes the increased physical interaction between the surfaces of α-Fe_2O_3 and the water molecules, much as with the previous consideration in the case of TiO_2.[7]

Nonequilibrium Thermodynamics of the Relaxing System Subject to Multinomial Distribution

Kenji ISHIDA

Department of Applied Chemistry, Ibaraki University, Hitachi, Ibaraki

(Received October 17, 1968)

It has been shown that the relaxation process in a system of noninteracting particles in contact with a heat bath, on the assumption that the system is in local equilibrium, can be described by the Markov process homogeneous in time, and that the solution of the Markov process is a multinomial distribution. The nonequilibrium thermodynamics for such a relaxing system was formulated by means of the stochastic entropy production which can be derived by the probabilistic version of classical entropy production. As a sepcial case, the stochastic nonequilibrium thermodynamics for the relaxing system of identical harmonic oscillators was discussed.

The theory of nonequilibrium thermodynamics is applicable to the description of relaxation phenomena in a physical system. As an example, there is an energy transfer between two sub-systems at different temperatures. We consider here a homogeneous system of noninteracting particles immersed in a heat bath. Although the system and the heat bath are thermally insulated as a whole, they are closed to each other so that energy is exchangeable but not so matter. The temporal behavior of the system, which has been initially prepared in a nonequilibrium state, is the relaxation to an equilibrium state through weak interaction with the heat bath. If, furthermore, the heat bath is assumed to be sufficiently large compared with the relaxing system, the former always remains in the equilibrium state characterized by a time-independent temperature $T(\infty)$ throughout the relaxation process. Both relaxing system and heat bath fill the same space with a constant volume, but they are maintained respectively at different temperatures $T(t)$ and $T(\infty)$ at any time t in the course of the relaxation process. According to the theory of nonequilibrium thermodynamic[1,2] the entropy production $\mathrm{d}_i S(t)/\mathrm{d}t$ in the whole system may be written in the form

$$\mathrm{d}_i S(t)/\mathrm{d}t = \{1/T(t) - 1/T(\infty)\}\mathrm{d}U(t)/\mathrm{d}t \qquad (1)$$

where $U(t)$ is the internal energy of the relaxing system. This thermodynamic equation is valid for the nonequilibrium system, in which the existence of local equilibrium is assumed.[3,4] The local equilibrium is one of fundamental postulates in the theory of nonequilibrium theormodynamics and will also play an important role in the present study. For the concept of local equilibrium to be applied without any justification to the stochastic version of (1), we propose that the relaxation in the system where the local equilibrium prevails at each point in the space might, in general, be expected to be a Markov process homogeneous in

time.[5] If, then, the transitions between energy states of particles in the relaxing system are described by a Markovian master equation with time-independent transition probabilities, the nonequilibrium thermodynamics of the relaxing system may be formulated by the procedure analogous to the stochastic theory of nonequilibrium thermodynamics of chemical kinetics discussed previously.[6]

Stochastic Entropy Production

If the relaxing system consists of N noninteracting particles and the probability for a particle to be found in an energy state ε_l at time t is denoted by $p_l(t)$, the mean energy of the relaxing system, $<E(t)>$, is given by

$$<E(t)> = N\sum_l \varepsilon_l p_l(t) = N<\varepsilon(t)> \quad (2)$$

where $<\varepsilon(t)>=\sum_l \varepsilon_l p_l(t)$ is the mean energy for one particle, because we have assumed the normalization $\sum_l p_l(t)=1$. Since the thermodynamic function $U(t)$ corresponds to $<E(t)>$, the statistical expression of $\mathrm{d}U(t)/\mathrm{d}t$ becomes

$$\mathrm{d}U(t)/\mathrm{d}t = N\sum_l \varepsilon_l \mathrm{d}p_l(t)/\mathrm{d}t \quad (3)$$

under the condition that the volume of the relaxing system is constant. Substituting Eq. (3) into Eq. (1), we obtain

$$\mathrm{d}_i S(t)/\mathrm{d}t = \boldsymbol{k}N\sum_l \{\beta(t)-\beta(\infty)\}\varepsilon_l \mathrm{d}p_l(t)/\mathrm{d}t \quad (4)$$

where $\boldsymbol{k}$ is Boltzmann's constant and the parameter $\beta(t)=1/\boldsymbol{k}T(t)$ has been introduced. In order to reform Eq. (4) into a statistical-thermodynamic expression, it is necessary to find the physical distribution law available to $p_l(t)$.

To do so, first of all, we define $P(n_0, n_1, \cdots, n_l, \cdots; t)\equiv P(\boldsymbol{n}; t)$ to be the probability that at an arbitrarily fixed time t the numbers of particles in the states of energies $\varepsilon_0, \varepsilon_1, \cdots, \varepsilon_l, \cdots$ are $n_0, n_1, \cdots, n_l, \cdots$, respectively. Since, however, the relaxing system assuming local equilibrium is governed by the Markov process homogeneous in time, we can obtain the Markovian master equation for the joint probability distribution $P(\boldsymbol{n}; t)$

$$\mathrm{d}P(\boldsymbol{n}; t)/\mathrm{d}t = \sum_{l'}{}' \sum_l{}' \lambda_{ll'}\{-n_l P(\boldsymbol{n}; t) + (n_l+1)P(\boldsymbol{n}', n_l+1, n_{l'}-1; t)\} \quad (5)$$

where $\lambda_{ll'}$ is the transition probability from ε_l to $\varepsilon_{l'}$ in unit time and the prime of $\sum'$ and $\boldsymbol{n}'$ indicates the omission of the term of $l=l'$. When the initial probability distribution is a multinomial distribution, the solution is also given by the multinomial distribution[7,8]

$$P(\boldsymbol{n}; t) = \{N!/\prod_l n_l!\}\prod_l \{p_l(t)\}^{n_l} \quad (6)$$

where $p_l(t)$, as it has been defined in regard to Eq. (2), denotes the probability for a particle to be found in the energy state ε_l at time t. It has been proved in Refs. 7 and 8 that the unique stationary solution $P(\boldsymbol{n}; \infty)$ exists independently of initial conditions. It can be concluded, therefore, that the multinomial distribution is preserved at all times throughout the Markovian relaxation process. For the system subject to such a stationary probability distribution, Nagasako has given the probabilistic proof that $p_l(\infty)$ can be expressed by the physical distribution law[9]

$$p_l(\infty) = g_l \exp[-\beta(\infty)\varepsilon_l]/\sum_l g_l \exp[-\beta(\infty)\varepsilon_l] \quad (7)$$

where g_l denotes the degeneracy.

Once local equilibrium is established, we can use the method of analysis for a nonequilibrium system with small deviations from equilibrium. We then have the Taylor series expansion of $p_l(t)$ in powers of $\beta(t)$ with only the first-order term

$$p_l(t) = p_l(\infty) + (\partial p_l/\partial\beta)_\infty\{\beta(t)-\beta(\infty)\} \quad (8)$$

because $p_l(t)$ is considered to include $\beta(t)$ as a variable. Since, however, $p_l(t)$ is differentiable with respect to $\beta(t)$, it follows that

$$(\partial p_l/\partial\beta)_\infty = \partial p_l(\infty)/\partial\beta(\infty) = -(\varepsilon_l - <\varepsilon(\infty)>)p_l(\infty)$$

where we have used Eq. (7). We thus obtain as the alternative expression of Eq. (8)

$$p_l(t) = p_l(\infty)[1-\{\beta(t)-\beta(\infty)\}(\varepsilon_l - <\varepsilon(\infty)>)] \quad (8')$$

Substituting Eq. (7) into Eq. (8') and using the approximation $1-\{\beta(t)-\beta(\infty)\}\varepsilon_l = \exp[-\{\beta(t)-\beta(\infty)\}\varepsilon_l]$, we find

$$p_l(t) = \frac{g_l \exp[-\beta(t)\varepsilon_l]}{\sum_l g_l \exp[-\beta(\infty)\varepsilon_l]} + \frac{g_l \exp[-\beta(\infty)\varepsilon_l]}{\sum_l g_l \exp[-\beta(\infty)\varepsilon_l]}\{\beta(t)-\beta(\infty)\}<\varepsilon(\infty)>$$

By using the similar approximations

$$\exp[-\beta(\infty)\varepsilon_l] = \exp[-\beta(t)\varepsilon_l]\{1+[\beta(t)-\beta(\infty)]\varepsilon_l\}$$

and

$$\sum_l g_l \exp[-\beta(\infty)\varepsilon_l] = \sum_l g_l \exp[-\beta(t)\varepsilon_l]\{1+[\beta(t)-\beta(\infty)]<\varepsilon(\infty)>\}$$

the above equation can be transformed to

$$p_l(t) = \frac{g_l \exp[-\beta(t)\varepsilon_l]}{\sum_l g_l \exp[-\beta(t)\varepsilon_l]} \times [1-\{\beta(t)-\beta(\infty)\}^2(\varepsilon_l - \langle\varepsilon(\infty)\rangle)\langle\varepsilon(\infty)\rangle]$$

9) N. Nagasako, This Bulletin, **35**, 179 (1962).

To the same linear approximation as Eq. (8), we finally obtain

$$p_l(t) = g_l \exp[-\beta(t)\varepsilon_l]/\sum_l g_l \exp[-\beta(t)\varepsilon_l] \quad (9)$$

For the relaxing system governed by the multinomial distribution (6), that is to say, the Maxwell-Boltzmann distribution (9) characterized by a time-dependent parameter $\beta(t)$ is also approximately preserved throughout the relaxation process. The nonequilibrium system in which the distribution law (9) is held for $0 \leq t \leq \infty$ has been called the canonically invariant system by Andersen *et al.*[10] They have investigated under what conditions a relaxing system is canonically invariant and have formulated the nonequilibrium thermodynamics for this system.

We can, however, derive the stochastic expression for the thermodynamic equation (1) on the postulate that the Markovian master equation (5) is a mathematical description of the relaxation process of the system in local equilibrium. From Eqs. (4), (7) and (9) we obtain

$$\begin{aligned} \mathrm{d}_i S(t)/\mathrm{d}t &= -\boldsymbol{k}N \sum_l \mathrm{d}p_l(t)/\mathrm{d}t \ln[p_l(t)/p_l(\infty)] \\ &= -\boldsymbol{k} \sum_l \mathrm{d}<n_l(t)>/\mathrm{d}t \ln[p_l(t)/p_l(\infty)] \end{aligned} \quad (10)$$

which is none other than the stochastic expression of Eq. (1). Of course, the non-negativity of entropy production, $\mathrm{d}_i S(t)/\mathrm{d}t \geq 0$, must also be satisfied for Eq. (10).[11] The integration of Eq. (10) becomes

$$\begin{aligned} S(t) &= -\boldsymbol{k} \sum_l <n_l(t)> \ln[p_l(t)/p_l(\infty)] + S_e \\ &= -\boldsymbol{k} <\ln \Pi_l [p_l(t)/p_l(\infty)]^{n_l}> + S_e \end{aligned} \quad (11)$$

where S_e denotes the value of the entropy at equilibrium. This equation shows that for the relaxing system the entropy is also correlated with the probability for a microscopic state of its system. If, on the contrary, we begin with Eq. (11) as the definition of the stochastic entropy for a relaxing system, we obtain the entropy production (1) through the distribution laws (7) and (9). Since the mean $<>$ in Eq. (10) is operated with respect to the probability distribution $P(\boldsymbol{n}; t)$, equation (11) may be written as

$$S(t) = -\boldsymbol{k} \sum_{\boldsymbol{n}} P(\boldsymbol{n}; t) \ln \frac{P(\boldsymbol{n}; t)}{P(\boldsymbol{n}; \infty)\Omega} \quad (12)$$

where we have set $S_e = \boldsymbol{k} \ln \Omega$. It should be noted, here, that the probability distribution is in form invariant on the assumption of local equilibrium. It is also possible to develop the nonequilibrium satatistical thermodynamics on the basis of the Eq. (12), which is called the Gibbs entropy postulate.[12]

Relaxation Equations

To obtain a better understanding of relaxation phenomena, we now return to the alternative equation of Eq. (1),

$$\mathrm{d}_i S(t)/\mathrm{d}t = 1/T(\infty)\{\beta(t)/\beta(\infty) - 1\} \mathrm{d}<E(t)>/\mathrm{d}t \quad (1')$$

Taking $1/T(\infty)\{\beta(t)/\beta(\infty) - 1\}$ as force, we see that the corresponding flux is $\mathrm{d}<E(t)>/\mathrm{d}t$. We then have, as a phenomenological relation,

$$\mathrm{d}<E(t)>/\mathrm{d}t = L/T(\infty)\{\beta(t)/\beta(\infty) - 1\} \quad (13)$$

where L is called the phenomenological coefficient. On the other hand, it follows from $\mathrm{d}<E(t)>/\mathrm{d}t = \sum_l \varepsilon_l \mathrm{d}<n_l(t)>/\mathrm{d}t$ and Eq. (A. 2) that the rate of energy change is given by

$$\mathrm{d}<E(t)>/\mathrm{d}t = N \sum_l{}' \sum_{l'}{}' \varepsilon_l \{\lambda_{l'l} p_{l'}(t) - \lambda_{ll'} p_l(t)\}$$

where $\langle n_l(t) \rangle = N p_l(t)$ has been used. We then have

10) H. C. Andersen, I. Oppenheim, K. E. Shuler and G. H. Weiss, *J. Math. Phys.*, **5**, 522 (1964); *J. Chem. Phys.*, **41**, 3012 (1964).

11) If we rewrite Eq. (10) in the form

$$\mathrm{d}_i S(t)/\mathrm{d}t = -\boldsymbol{k} \sum_l \mathrm{d}<n_l(t)>/\mathrm{d}t \ln [<n_l(t)>/<n_l(\infty)>] \quad (A.1)$$

and substitute the rate equation derived from Eq. (5)

$$\mathrm{d}\langle n_l(t)\rangle/\mathrm{d}t = \sum_{l'}{}' \{\lambda_{l'l}\langle n_{l'}(t)\rangle - \lambda_{ll'}\langle n_l(t)\rangle\} \quad (A.2)$$

into Eq. (A.l), we have

$$\mathrm{d}_i S(t)/\mathrm{d}t = -\boldsymbol{k} \sum_l{}' \sum_{l'}{}' \{\lambda_{l'l} <n_{l'}(t)> - \lambda_{ll'} <n_l(t)>\} \ln [<n_l(t)>/<n_l(\infty)>] \quad (A.3)$$

Since, however, this equation is symmetric with respect to l and l', we also have

$$\mathrm{d}_i S(t)/\mathrm{d}t = -\boldsymbol{k} \sum_{l'}{}' \sum_l{}' \{\lambda_{ll'} <n_l(t)> - \lambda_{l'l} <n_{l'}(t)>\} \ln [<n_{l'}(t)>/<n_{l'}(\infty)>] \quad (A.3')$$

The summation of Eqs. (A.3) and (A.3') leads to

$$\begin{aligned} \mathrm{d}_i S(t)/\mathrm{d}t = -\frac{1}{2} \boldsymbol{k} \sum_l{}' \sum_{l'}{}' \lambda_{ll'} <n_{l'}(t)> \{\lambda_{l'l}/\lambda_{ll'} - <n_l(t)>/<n_{l'}(t)>\} \\ \times \ln\{[<n_l(t)>/<n_{l'}(t)>]/[<n_l(\infty)>/<n_{l'}(\infty)>]\} \end{aligned} \quad (A.4)$$

Using the relation

$$\lambda_{l'l} <n_{l'}(\infty)> = \lambda_{ll'} <n_l(\infty)>$$

which is satisfied at equilibrium, we finally obtain

$$\begin{aligned} \mathrm{d}_i S(t)/\mathrm{d}t = -\frac{1}{2} \boldsymbol{k} \sum_l{}' \sum_{l'}{}' \lambda_{ll'} <n_{l'}(t)> \{<n_l(\infty)>/<n_{l'}(\infty)> - <n_l(t)>/<n_{l'}(t)>\} \\ \times \ln\{[<n_l(t)>/<n_{l'}(t)>]/[<n_l(\infty)>/<n_{l'}(\infty)>]\} \end{aligned} \quad (A.5)$$

Since $(y-x)\ln(x/y) \leq 0$ for any real numbers $x > 0$ and $y > 0$, it is concluded that $\mathrm{d}_i S(t)/\mathrm{d}t \geq 0$, where the equality holds for equilibrium state.

12) See Ref. 4, p. 126.

$$\mathrm{d}<E(t)>/\mathrm{d}t = \frac{1}{2}N\sum_{l}{}'\sum_{l'}{}'(\varepsilon_l-\varepsilon_{l'}) \times\{\lambda_{l'l}p_{l'}(t)-\lambda_{ll'}p_l(t)\}$$

The derivation is exactly analogous to that of Eq. (A.4). Substituting the linear approximation Eq. (8) into this equation and using the detailed balance $\lambda_{l'l}p_{l'}(\infty)=\lambda_{ll'}p_l(\infty)$, we obtain

$$\mathrm{d}<E(t)>/\mathrm{d}t = \frac{1}{2}N\beta(\infty)\sum_{l}{}'\sum_{l'}{}'\lambda_{l'l}(\varepsilon_l-\varepsilon_{l'})^2p_{l'}(\infty) \times\{\beta(t)/\beta(\infty)-1\}$$

We thus see by comparison of this equation with Eq. (13) that

$$L = N/2\boldsymbol{k}\sum_{l}{}'\sum_{l'}{}'\lambda_{l'l}(\varepsilon_l-\varepsilon_{l'})^2p_{l'}(\infty) \tag{14}$$

from which it follows that $L\geq 0$.

Let us now derive the relaxation equations for $<E(t)>$ and $\beta(t)$. The mean energy $<\varepsilon(t)>$ for particle is obtained through Eq. (8), namely,

$$<\varepsilon(t)> = <\varepsilon(\infty)>-\beta(\infty)\{\beta(t)/\beta(\infty)-1\} \times(<\varepsilon^2(\infty)>-<\varepsilon(\infty)>^2)$$

From this we obtain for the relaxing system

$$\beta(t)/\beta(\infty)-1 = -(1/\beta(\infty)\sigma_E{}^2)(<E(t)>-<E(\infty)>) \tag{15}$$

where the fluctuation of total energy, $\sigma_E{}^2=\langle E^2(\infty)\rangle-\langle E(\infty)\rangle^2=N(\langle\varepsilon^2(\infty)\rangle-\langle\varepsilon(\infty)\rangle^2)$, is connected with the specific heat at constant volume, C_v, by the relation $\sigma_E{}^2=\boldsymbol{k}T^2(\infty)C_v=-(\partial\langle E(t)\rangle/\partial\beta(t))_{v,\infty}$. From Eqs. (13) and (15), we find the following relaxation equations.

For energy:

$$\mathrm{d}<E(t)>/\mathrm{d}t = -(1/\tau)(<E(t)>-<E(\infty)>) \tag{16}$$

For temperature:

$$\mathrm{d}\beta(t)/\mathrm{d}t = -(1/\tau)\{\beta(t)-\beta(\infty)\} \tag{17}$$

where the relaxation time τ is given by

$$\tau = \sigma_E{}^2/L\boldsymbol{k} = T^2(\infty)C_v/L$$

System of Harmonic Oscillators

To illustrate the nonequilibrium thermodynamics of a relaxing system in weak interaction with a heat bath, we now consider the system of N independent and identical harmonic oscillators whose vibrational relaxations are described by the Markov processes with Landau-Teller transition probabilities in contact with a heat bath.[13] As it will be shown below, this system is a typical one of canonically invariant systems. Let the initial probability distribution $P(\boldsymbol{n}^0;0)$ at a temperature $T(0)$ be given by the multinomial distribution

$$P(\boldsymbol{n}^0;0) = (N!/\prod_j n_j{}^0!)\prod_j\{p_j(0)\}^{n^0j} \tag{18}$$

where $p_j(0)$ denotes the probability for an oscillator to be found on a vibrational level j at time $t=0$, $n^0{}_j$ is the number of such oscillators and $\sum_j n^0{}_j=N$. It follows then that at any time t the probability distribution $P(\boldsymbol{n};t)$ is also multinomial,

$$P(\boldsymbol{n};t) = (N!/\prod_j n_j!)\prod_j\{p_j(t)\}^{n_j} \tag{19}$$

In both Eqs. (18) and (19), the probability $p_j(t)$ for $0\leq t\leq\infty$ takes the familiar form

$$p_j(t) = \exp[-j\theta(t)](1-\exp[-\theta(t)]) \tag{20}$$

where $j=0, 1, 2,\cdots$. The time-dependent parameter $\theta(t)$ is given by

$$\theta(t) = \ln\frac{\mathrm{e}^{\theta(\infty)}(1-\mathrm{e}^{-\theta(0)})-(1-\mathrm{e}^{\theta(\infty)-\theta(0)})\mathrm{e}^{-ct}}{(1-\mathrm{e}^{-\theta(0)})-(1-\mathrm{e}^{\theta(\infty)-\theta(0)})\mathrm{e}^{-ct}} \tag{21}$$

where $T(0)$ and $T(\infty)$ in $\theta(0)=h\nu/\boldsymbol{k}T(0)$ and $\theta(\infty)=h\nu/\boldsymbol{k}T(\infty)$ are the temperature at the initial and equilibrium states, respectively, and the reciprocal of $c>0$ denotes the relaxation time (*cf.* Eq. (27)). If we introduce conventionally the relation

$$\theta(t) = \boldsymbol{h}\nu/\boldsymbol{k}T(t) \tag{22}$$

where $\boldsymbol{h}$ is Planck's constant and ν the vibrational frequency of oscillator, we can regard $T(t)$ as the effective temperature of the relaxing system at time t. Since Eq. (19), together with Eq. (20), preserves its form all the time during the relaxation process, the relaxing system is exactly of canonical invariance.

Substituting Eq. (20) into the general formula (10) of stochastic entropy production, we obtain

$$\mathrm{d}_iS(t)/\mathrm{d}t = \boldsymbol{k}N\{\theta(t)-\theta(\infty)\}\sum_j j\,\mathrm{d}p_j(t)/\mathrm{d}t \tag{23}$$

or

$$\mathrm{d}_iS(t)/\mathrm{d}t = \boldsymbol{k}\sum_j j\{\theta(t)-\theta(\infty)\}\mathrm{d}<n_j(t)>/\mathrm{d}t \tag{23'}$$

where $\langle n_j(t)\rangle=Np_j(t)$ is the mean number of oscillators on vibrational level j. Since, however, the mean energy of oscillator is given by

$$\langle\varepsilon_v(t)\rangle = \left\{\frac{1}{2}+\sum_j j\,p_j(t)\right\}\boldsymbol{h}\nu \tag{24}$$

it follows that for the total energy

$$(1/\boldsymbol{h}\nu)\mathrm{d}<E_v(t)>/\mathrm{d}t = N\sum_j j\,\mathrm{d}p_j(t)/\mathrm{d}t \tag{25}$$

Thus, the thermodynamic expression of Eq. (25) becomes

$$\mathrm{d}_iS(t)/\mathrm{d}t = \{1/T(t)-1/T(\infty)\}\mathrm{d}<E_v(t)>/\mathrm{d}t \tag{26}$$

which represents the entropy production due to the energy transfer between the system of oscillators and the heat bath. We must here point out the following. The microscopic reversibility for the transition probabilities between adjacent vibrational energy levels has been assumed in the derivation of the Markovian master equation, from which the probability distribution (19) has been obtained. From a macroscopic point of view, we may reckon for such a statement to correspond to the assumption of the existence of local equilibrium such as

13) E. W. Montroll and K. E. Shuler, *J. Chem. Phys.*, **26**, 454 (1957). See also Refs. 8 and 10.

we have already emphasized.

If we apply $\sum_j jp_j(t) = \exp[-\theta(t)](1-\exp[-\theta(t)])^{-1}$ and Eq. (21) to the right-hand side of Eq. (25), we get the relaxation equation of exponential type, after straightforward algebra,

$$d<E_v(t)>/dt = -c(<E_v(t)> - <E_v(\infty)>) \quad (27)$$

which holds rigorously for any time t. It can be easily seen from Eq. (21), however, that the relaxation process of temperature $T(t)$ is not of exponential type but so near equilibrium.[14]

On the other hand, taking the logarithm of Eq. (20), we have

$$j\{\theta(t)-\theta(\infty)\} = \ln(<n_0(t)>/<n_0(\infty)>) - \ln(<n_j(t)>/<n_j(\infty)>)$$

where $p_0(t) = 1-\exp[-\theta(t)]$ and $p_0(\infty) = 1-\exp[-\theta(\infty)]$ have been used. If we set $d\langle n_j(t)\rangle/dt = v_j$ and define the affinity A_j for the transition between two vibrational energy levels 0 and j by

$$A_j = kT(\infty)\{\ln(<n_0(t)>/<n_0(\infty)>) - \ln(<n_j(t)>/<n_j(\infty)>)\} \quad (28)$$

we obtain from Eq. (23) the entropy production in the form of the sum of products of affinities and rates

$$d_iS(t)/dt = (1/T(\infty))\sum_j A_jv_j \quad (29)$$

This may be also interpreted as the entropy production due to the irreversible processes corresponding to the changes of the internal parameter j.[15]

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 1497—1503 (1969)

Spectroscopic Behavior of Würster's Blue Perchlorate and *N*-Ethylphenazyl Crystals

Tadayoshi SAKATA and Saburo NAGAKURA

The Institute for Solid State Physics, The University of Tokyo, Roppongi, Minato-ku, Tokyo

(Received October 19, 1968)

The electronic absorption spectra of Würster's Blue perchlorate and *N*-ethylphenazyl in solid were measured at various temperatures ranging from 48°K to 300°K. In both cases, strong bands due to the charge-transfer between the half occupied orbitals of respective component radicals were observed in near infrared region. This assignment of these bands was supported by the polarized absorption measurement carried out with the Würster's blue perchlorate single crystal. The charge-transfer band of solid Würster's blue perchlorate was found to increase its intensity with decreasing temperatures; in particular, the increasing tendency became predominant below the phase transition point (186°K). The similar tendency was also observed for solid *N*-ethylphenazyl. The temperature dependence of the band was found to be closely related with the population of triplet excitons determined from the measurement of magnetic susceptibility or paramagnetic resonance. The separation J between the ground singlet state and the thermally accessible triplet state was determined from the analysis of the temperature dependence of the charge-transfer band to be 235 cm^{-1} and 320 cm^{-1} for Würster's blue perchlorate and *N*-ethylphenazyl, respectively.

The electronic absorption spectra of Würster's blue perchlorate (WBP) and *N*-ethylphenazyl (EP) have been studied extensively with their solutions.[1-3] In solution the spectra due to the monomers were observed at room temperature, but at low temperature new bands characteristic of the dimers were found in the near infrared region. Hausser and Murrell[2] interpreted them as the charge-transfer band between the half occupied orbitals of component radicals. From temperature and concentration dependencies of electronic absorption spectra, the enthalpy change due to the dimer formation was determined by Ooshika *et al.*[1] and by Hausser[3] to be about 5—8 kcal/mol and 2 kcal/mol for WBP and EP, respectively.

Hausser measured the static magnetic susceptibility of solid EP at three temperatures and found that the value becomes lower with decreasing

temperatures.[2,3]

The paramagnetic resonance of the single crystal of WBP has been studed by McConnel *et al.*[4] They found the paramagnetic resonance signal due to triplet excitons for the WBP crystal below the orthorhombic (room temperature form) - monoclinic (low temperature form) phase transition point at 186°K. Furthermore, the sudden decrease in paramagnetic susceptibility was observed by several authors[5] with WBP at this point. These facts show that the cations form dimers in the WBP crystal of the low temperature (monoclinic) form resulting in the ground singlet state and the excited triplet state.[4] These two states may be thought to be brought about by the exchange interaction between the two cations in the monoclinic crystal. The singlet-triplet separation J was estimated to be $246\pm20\ cm^{-1}$ by McConnell *et al.* from the temperature dependence of ESR intensity.[4]

Under these circumstances, we have undertaken to study in detail the optical properties of the WBP and EP crystals at various temperatures in addition to their magnetic properties. One of our main purpose is to clarify the existence of the triplet exciton from electronic absorption measurements at various temperatures ranging from 50°K to 300°K.

Experimental

WBP and EP were prepared and purified by the same methods as described in Refs. 6 and 7, respectively. The purified sample of EP was kept at −70°C because it was fragile at room temperature.

A Cary recording spectrophotometer model 14 M was used for the measurements of electronic absorption spectra of solutions and solid samples. The solid films for absorption measurements were prepared by coating powdered samples on quartz plates by a stainless steel spatula. The solid samples prepared in this way were shown to be suitable for the measurements of absorption spectra in the near infrared and visible regions. The reliability of this method was checked by comparing the spectra of solid thin films with those observed with single crystals by the aid of a microspectrophotometer. For example, the electronic absorption spectra of tetracyanobenzene and of the naphthalene-tetracyanobenzene complex observed by the present method agree well with those observed with the respective single crystals.[8] Absorption measurements at low temperatures were made by using ordinary glass Dewar vessels containing liquid helium or liquid nitrogen as refrigerant.

A spectrophotometer attached with a microscope and a Roschen type polarizer[9] was used for the polarized absorption measurement of a single crystal.

ESR spectra were measured with a Hitachi X band spectrometer with 100kc field modulation.

Results and Discussion

Polarized Absorption Spectra of WBP. The electronic absorption spectra of the solid WBP measured at various temperatures are shown in Fig. 1. In this figure, the spectra of the ethanol solution of WBP measured at various temperatures are also shown for the purpose of comparison. Figure 1 shows that the absorption spectra of the solution and solid samples at room temperature are similar to each other[10] except for the fact that the latter exhibits a weak absorption in the near

10) The absorption bands in solid show the red shift of about 700 cm^{-1} compared with the corresponding bands of the solution.

infrared region longer than 700 mμ. This weak band observed for the solid sample is intensified with decreasing temperatures and its maximum wavelength corresponds well to the charge-transfer band of the radical dimer observed by Hausser[2,3] with the solution at low temperature. Therefore, it can be regarded as the band caused by the charge-transfer interaction between the WB cations in crystal.

In order to give an additional support to this interpretation, we measured the polarized absorption spectrum of the single crystal of WBP at room temperature. The results are shown in Fig. 2. The actual measurements were made by light polarized parallel to the a′ and c′ direction of the crystal shown in Fig. 3. The used crystal is a flat plate and shows the straight extinction under a polarizing microscope. This means that at least one crystal axis is on the observed plane, because the room temperature form of WBP is orthorhombic.[4] Furthermore, from the X-ray diffraction experiment,

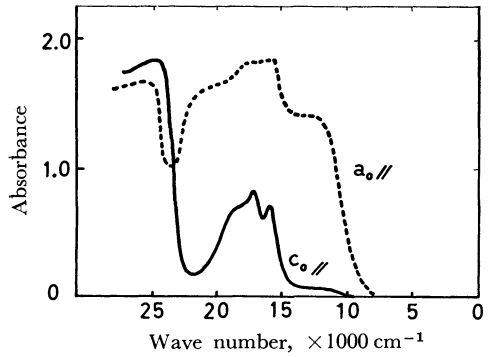

Fig. 2. Polarized absorption spectrum of the single crystal of WBP at room temperature.

the a′ c′ plane was determined to be the a_0c_0 plane.*1. On the basis of the crystal structure shown in Fig. 3, let us consider the polarization of the band near 600 mμ which can be assigned to the $^2B_{3g} \rightarrow {}^2B_{1u}$ transition of the free radical cation whose transition moment is parallel with its long molecular axis connecting the two nitrogen atoms.[11,12] This band can be expected to split into the two components parallel to a_0 and c_0 axes with the intensity ratio of $I_{//a_0} : I_{//c_0} = [\tan(90°-37.5°)]^2 : 1 = 1.7 : 1$, in the approximation of the oriented gas model. According to our measurement, this band has the maximum and minimum intensities in the directions parallel to the a′ and c′ axes, respectively, and the dichroic ratio was determined to be $I_{//a'} : I_{//c'} = 2.2 : 1$. This means that a′ and c′ axes correspond to a_0 and c_0 axes, respectively.

As is clearly seen in Fig. 2, the characteristic band which appears in the wavelength region longer than 700 mμ has the transition moment parallel to the a′ (a_0) direction. This seems to support the interpretation that the band is accompanied by the charge-transfer between the half occupied orbitals of the component radicals, in view of the fact that the line connecting their centers is parallel to a′ (a_0) axis.

Temperature Dependence of Charge-Transfer Band. *a) WBP.* In order to check the variation of the absorption spectrum above and below the phase transition point at 186°K, we measured the absorption spectrum of solid WBP at various temperatures ranging from 48°K to 300°K. The results are shown in Fig. 1. From this figure it is concluded that with lowering temperature the charge-transfer band increases its intensity and other bands due to the excitation within the radical

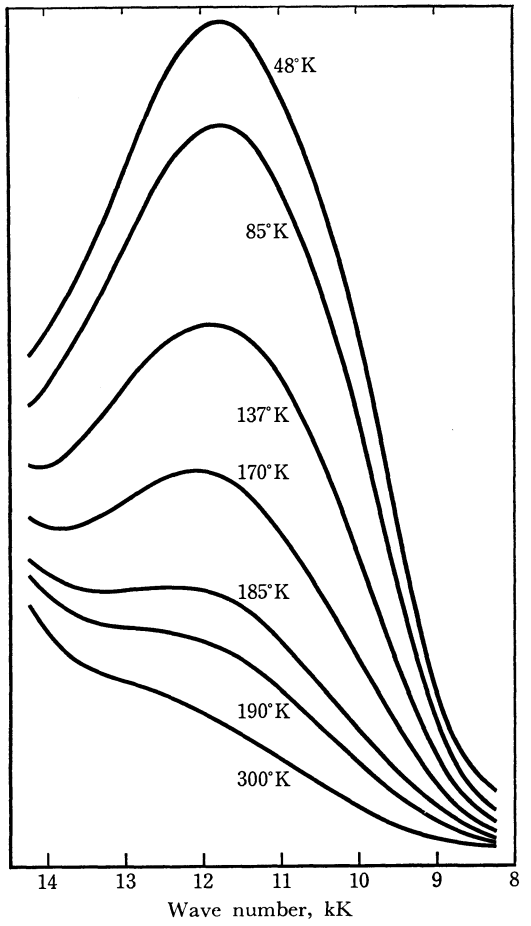

Fig. 4. The charge-transfer band of WBP at various temperatures.

cation leave their intensities almost unaltered, though their peaks shift by 700—800 cm^{-1} by changing the temperature from 300°K to 48°K.

We measured very carefully and precisely the temperature dependence of the intensity of the charge-transfer band, with the result shown in Fig. 4. This figure clearly shows that the intensity increase becomes suddenly remarkable below phase transition point. Since the dimer may be the unit in the WBP crystal below the phase transition point,[4] the observed sudden increase in absorption intensity may be thought to be due to the radical dimer formation. The details of this point are discussed in the later part in comparison with the temperature dependence of the magnetic properties.

The charge-transfer band of the WBP crystal shifts to longer wavelengths by about 1000 cm^{-1} than that of the dimer in solution. The same tendency was observed for EP. This shift may be explained qualitatively by considering the interaction between the induced transition dipoles of adjacent dimers.

b) EP. The electronic absorption spectra of EP in ethanol-ether solution and in solid are shown in Fig. 5. Concerning the solution spectrum, there appears no absorption in the near infrared region at room temperature, but at low temperature a charge-transfer band due to the dimer appears at 800 mμ.[3] The spectrum of solid EP well coincides as a whole with that of dimer in solution, although the charge-transfer band in the former appears at 900 mμ and therefore shifts by 1600cm^{-1} to lower frequencies compared with that in the latter.

The absorption spectrum of solid EP was measured at various temperatures ranging from 300°K to 55°K with the result shown in Fig. 6. The charge-transfer band of solid EP greatly increases its intensity with lowering temperature and this intensity increment becomes saturated at about 50°K. This temperature dependency is similar

13) As is clearly seen in Figs. 5 and 6, the charge-transfer band is composed of two peaks in the solid sample of EP, while the solution spectrum shows only one peak. This splitting may be due to either Davydov splitting or vibrational structure.

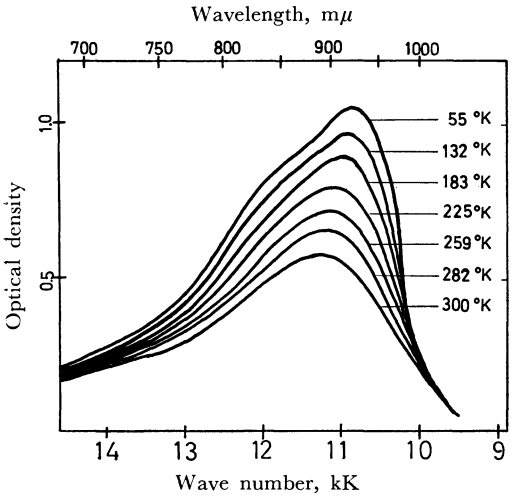

Fig. 6. The charge-transfer band of EP at various temperatures.

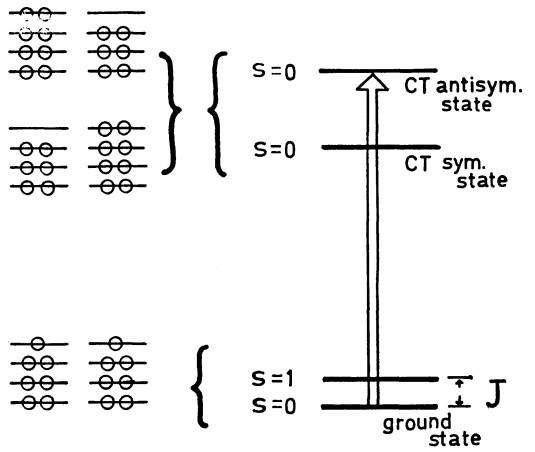

Fig. 7. Energy diagram and configurations of a radical dimer.

to that observed for the low temperature form of WBP crystal. This suggests that dimers are the unit in the EP crystal as well as in the WBP crystal below the phase transition point.[14]

The Relation Between the Temperature Dependence of Charge-Transfer Band and Magnetism. Now let us consider the reason why the charge-transfer band increases remarkably its intensity with the decreasing temperature for the WBP crystal below the phase transition point and for the EP crystal. This anomalous phenommenon can be explained by considering the existence of the thermally accessible triplet excitons in these crystals.

As described above, the radical dimer may be considered to be the unit of the structure in these crystals.[15] In the radical dimer a singlet state and a triplet state may be caused as the result of the exchange interaction between the two radical monomers of the doublet state. In the cases of WBP and EP the singlet state may conceivably be lower than the triplet state; that is to say, the ground state is singlet and the triplet excited state exists above it with the energy separation J whose magnitude is of the same order as the thermal energy kT.

The singlet triplet separation J may be considered, as in general, to be originated from the exchange interaction between two unpaired electrons in the half occupied orbitals of the component radicals. Furthermore, above the triplet state of the radical dimer, there exists the charge-transfer state which corresponds to the electron transfer between the half occupied orbitals of the component radicals. The energy diagram of this dimer is schematically shown in Fig. 7. The dimer is assumed to have a center of symmetry, as is thought to be the case in WBP and EP. When the dimer has a center of symmetry, there are two charge-transfer states, a symmetric one and an antisymmetric one; the latter is higher than the former[2] and the transition from the ground singlet state to the latter is allowed for the sandwich type dimer.

Since the charge-transfer band is observed in the near infrared region for both WBP and EP, the energy separation between the charge-transfer state and the singlet ground state may be considered to be small. From this it may be inferred that the mixing of these two states stabilizes the singlet ground state and contributes to some extent to the singlet triplet separation J.[16] However, from an analogy with the case of the hydrogen molecule the main contribution to J might be considered to be still the exchange interaction between the two unpaired electrons.[17]

On the basis of the energy level diagram shown in Fig. 7, we consider the mechanism of the temperature dependence of the absorption intensity. When a dimer is in the ground singlet state, the transition to the antisymmetric charge-transfer state is allowed, but when a dimer is in a thermally accessible triplet state the transition is forbidden from the spin multiplicity. Furthermore, as is clear from the electron configuration shown in Fig. 7, the corresponding charge-transfer triplet state does not exist. Therefore the intensity of the charge-transfer band may be considered to be propor-

14) The EP crystal has no phase transition between room temperature and 50°K.

15) The situation is the same for the solid samples with which the temperature dependence of the absorption intensity was actually measured, because they are composed of the micro crystals.

tional to the number of dimers in the ground singlet state. Neglecting the interaction between dimers, the populations of the ground singlet and excited triplet states may be assumed to follow the Boltzmann distribution law. When J is of the order of magnitude of thermal energy kT, the intensity of the charge-transfer band may be expected to be strongly dependent on temperature and the change in the charge-transfer band intensity with temperature may be regarded as the measure of the number of dimers in the thermally accessible triplet state (see Fig. 8). When we consider the crystal which is an assembly of dimers, their excited states must be replaced by a exciton traveling among them. However, the preceding discussion may still be approximately applicable.

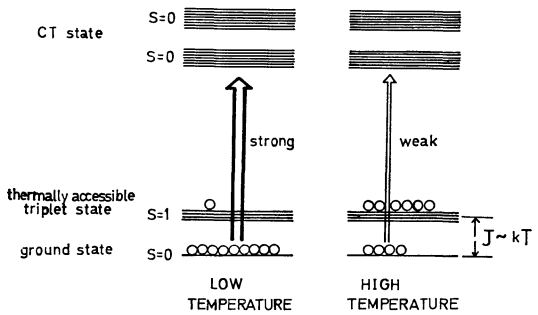

Fig. 8. A schematic explanation of the temperature dependence of charge-transfer band intensity in the solid. An arrow shows an allowed charge-transfer transition. Circles represent schematically the number of dimers of each state.

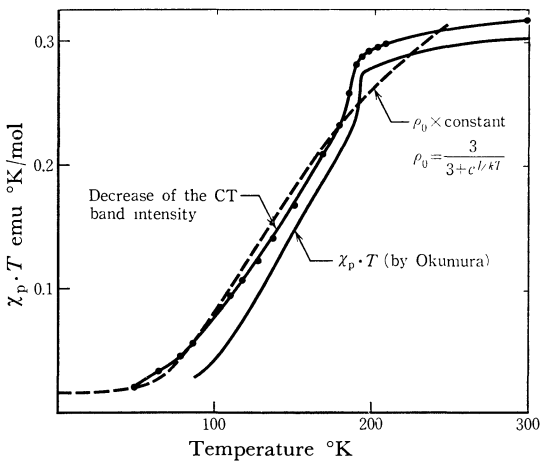

Fig. 9. Intensity of the charge-transfer band and magnetic susceptibility of WBP.

In order to make sure of the above discussion, we have undertaken to compare quantitatively the temperature dependency of the charge-transfer band intensity with that of magnetic susceptibility. The result of WBP is shown in Fig. 9. The curve showing the temperature dependence of the intensity (A) of the charge-transfer band is satisfactorily parallel with that plotting $\chi_p \cdot T$ against T measured by Okumura,[5a] where $\chi_p \cdot T$ values are known to represent the population of the dimer in the excited triplet state.[18] This means that our explanation on the temperature dependence of the charge-transfer band is correct.

The intensity of the charge-transfer band of the WBP crystal varies, though to much smaller extent than in the low temperature phase, in the room temperature phase in which WB cations are equally spaced. This seems to suggest that there exists antiferromagnetic interaction between spins on the WB cation radicals and the probability of neighboring cations having antiparallel spins decreases in higher temperatures.

Neglecting the interaction between dimers as the first approximation, the population of the triplet state ρ_0 can be represented as follows:

$$\rho_0 = 3/(3 + e^{J/kT})$$

By combining the above equation with the observed temperature dependence of the absorption intensity of the charge-transfer band, J is obtained to be $\sim 235\ \mathrm{cm}^{-1}$. This value of J agrees well with that obtained from the analysis of ESR data by McConnell ($J = 246 \pm 20\ \mathrm{cm}^{-1}$).[4]

The same consideration was applied to the solid EP and the value of J was evaluated to be $320 \pm 20\ \mathrm{cm}^{-1}$ from the temperature dependence of charge-transfer band. We also measured paramagnetic resonance spectra of the solid EP to check this value. The transition of $\Delta M = \pm 2$ was observed in addition to the ordinary transition of $\Delta M = \pm 1$.

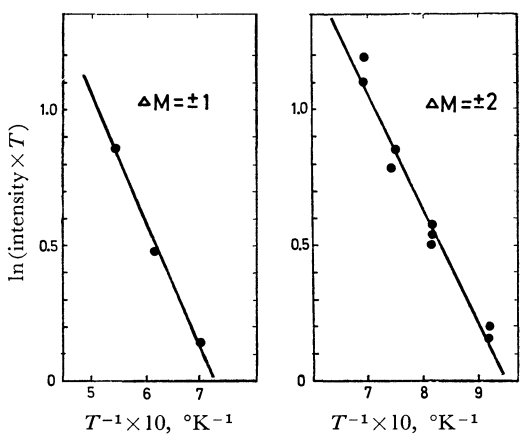

Fig. 10. Temperature dependence of paramagnetic resonance spectra of solid EP. Intensity is in arbitrary unit.

18) In connection with the above discussion, it may be added that we are not concerned with the absolute value of the population of the triplet state but only with its temperature dependence. Therefore, only the parallelism between the A-T and $\chi_p \cdot T$-T curves is important in Fig. 9. The similar parallelism can also be obtained by the use of Duffy's data[5b] instead of Okumura's data.

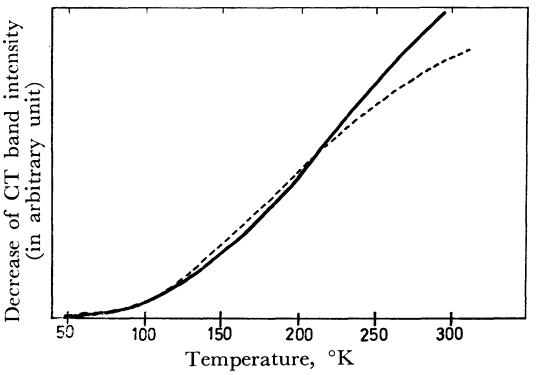

Fig. 11. Temperature dependence of the charge-transfer band intensity of solid EP. A solid line shows the decrease in the charge-transfer band intensity from the saturated value at 50°K. A dashed line represents the relation between $k\rho_0(J=320\ \mathrm{cm^{-1}})$ and T; k is a constant determined in such a way as $k\rho_0$'s fit well to the observed intensity decreases in low temperature region.

The ESR intensity I was measured at various temperatures with the results given in Fig. 10. This figure shows that a linear relationship is satisfied between $\ln IT$ and $1/T$. From the temperature dependence of paramagnetic resonance spectra, $J=330\pm20\ \mathrm{cm^{-1}}$ was obtained for $\Delta M=\pm1$, and $J=300\pm40\ \mathrm{cm^{-1}}$ for $\Delta M=\pm2$. These values agree well with the value obtained from the charge-transfer band.

As is clearly seen in Fig. 11, the experimental curve of the charge-transfer band intensity are somewhat off from the first order theoretical curve. This discrepancy becomes predominant at higher temperatures both for WBP in the low temperature phase and for EP. The reason for this discrepancy may be considered to be as follows:

1) The change in the intermolecular distance by thermal expansion.

2) The phonon induced interaction between triplet excitons.[19,20]

3) The exchange interaction between dimers.[21,22]

We also measured the temperature dependence of the other salts, especially of Würster's red perchlorate, paraphenylenediamine perchlorate and paraphenylenediamine bromide. As to these salts, such a remarkable intensity change in electronic absorption spectra as that observed with WBP and EP could not be found. This fact seems to correspond to the findings that these salts are diamagnetic at room temperature. The value of J seems to be large for these salts compared with kT.

Recently, Pott, Kommandeur *et al.*[23-26] suggested that the phase transition of WBP to be a disproportionation

$$2\ \mathrm{TMPD^+} \rightleftharpoons \mathrm{TMPD} + \mathrm{TMPD^{2+}}$$

(high temperature phase) (low temperature phase)

From our experimental results, however, this mechanism can be rejected

As is clearly seen in Fig. 1 showing the absorption spectrum of solid WBP, the 600 mμ band with vibrational structure corresponding to the $^2B_{3g}\rightarrow{}^2B_{1u}$ transition of the monopositive ion leaves its intensity and shape unaltered below the phase-transition point,[27] with the small blue shift of peak wavelengths by 700—800 $\mathrm{cm^{-1}}$ at most. This means that WB cations themselves do not suffer a large change by the phase transition and that the change in the weak interaction between WB cations is the cause of the phase transition. At least the above-mentioned observation can not be explained at all by the disproportionation mechanism by which the dipositive cation and the neutral molecule are produced below the phase-transition point.

Furthermore, the following fact may be added as a supplementary support to our opinion that the disproportionation mechanism by Pott, Kommandeur *et al.* is wrong. According to their mechanism, the singlet-triplet separation caused by the interaction between the half-occupied orbitals belonging to the neighboring WBP cations must amount to $\sim$1.5 eV (the difference between the transition energy of the charge-transfer band and the J value). This value seems to be too large judging from the distance between the two cation radicals and therefore from the magnitude of the overlap integral between the two orbitals.

The authors would like to express their sincere thanks to Professor J. Tanaka of Nagoya University for his kind advice and discussion. Their thanks are also due to Dr. H. Hasegawa and Dr. T. Maruyama of Japan Electron Optics Laboratory Co., Ltd. for the measurement of temperature dependence of the ESR signal due to $\Delta M=\pm2$ transition.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 1504—1509 (1969)

Moderator Effects on the Reactions of ^{82}Br Activated by the Isomeric Transition with Gaseous Methyl Bromide

Jiro OKAMOTO and Enzo TACHIKAWA

Division of Chemistry, Japan Atomic Energy Research Institute, Tokai-Mura, Ibaraki

(Received October 22, 1968)

^{82}Br obtained *via* the (I. T.) process has been reacted with methyl bromide. In the gaseous phase, only $CH_3{}^{82}Br$ and $CH_2{}^{82}BrBr$ are observed as major products, whereas in the solid phase other products, such as $CH^{82}BrBr_2$ and $C_2H_5{}^{82}Br$, have also been observed. Moderator experiments using He or Xe indicate that the formations of both $CH_3{}^{82}Br$ and $CH_2{}^{82}BrBr$ involve the reactions of the energetic ^{82}Br atom. This is in great contrast to the early observations of the Br_2-CH_4 system, where the ionic as well as the energetic reactions of ^{82}Br play a role in the formation of the C-^{82}Br bond. Comparisons of these results with those found in the reactions of the ^{80}Br obtained *via* the (n, γ) process suggest that the Br atom obtained *via* the (n, γ) process is more electronically excited than that from the (I. T.) process. The kinetic analysis of the present results gives the following relative α-values: α_{He}, 1.0; α_{Xe}, 8.8; α_{CH_3Br}, 10.3. It is suggested that, during the cooling-down process of ^{82}Br, a high inelasticity is involved in the collision of ^{82}Br, even with monatomic molecules.

Investigations of the recoil halogen atom reaction have included studies designed to find out more about both the primary physical state and the chemical process, and the mechanisms of chemical stabilization following these processes.[1-5]

Predominant among the subjects of interest is the relative importance of the kinetic energy and of the charge in determining the chemical reaction of the recoil atom. Definitive evidence[6] exists that the energetic reaction and also the ionic reaction sometimes play important roles in a gaseous-phase reaction of the halogen atom activated by the (n, γ) process, only part of which atom is positively charged.[7,8]

A high charge on the Br atom is developed as a consequence of the Auger process following the isomeric transition. It is postulated that this highly positive charge is partially neutralized by electron transfer from the remainder of the molecule, thus causing a repulsive force between the charged bromine atom and the remainder of the molecule.[9] The studies using a charge spectrometer indicate that free bromine atoms resulting from a molecular explosion show a charge distribution ranging up to $+14$.[10] The electron affinity of such a highly charged bromine is so high that its subsequent reaction is an electron pick-up from its surroundings.[11] Therefore, the important consideration is whether or not the Br^{+1} is reduced before reacting.

In the ^{82}Br-CH_4 system,[3] $CH_3{}^{82}Br$ is formed by the hydrogen substitution reaction of the energetic ^{82}Br atom, while $CH_2{}^{82}BrBr$ is formed *via* the ion-molecule reaction of $^{82}Br^{+1}$. The ionization potential of methyl bromide is 10.6 eV,[12] which is lower than that of bromine by 1.2 eV. This suggests the ionic reaction of ^{82}Br is less significant in an atmosphere of methyl bromide.

The present paper is concerned with a detailed study of the reaction of the ^{82}Br obtained *via* the (I. T.) process with methyl bromide. Two reactions which are conceivable for the energetic ^{82}Br atom can be written for this compound as Eqs. (1) and (2):

$$^{82}Br + CH_3Br \rightarrow CH_3{}^{82}Br + Br \quad (1)$$

$$^{82}Br + CH_3Br \rightarrow CH_2{}^{82}BrBr + H \quad (2)$$

The isolation of these hot reaction products in other reactions, such as ionic or thermal, is possible

through moderator and scavenger methods. The abstraction of the hydrogen or bromine atom in methyl bromide must also be considered as a possible reaction. However, experimental means are not available for tracing these reactions.

A series of experiments on the rigid phase,[1,13] indicative of a high yield of organically-bound ^{82}Br, have promoted a search for such a rigid phase in the present system.

Experimental

Materials. The bromine was obtained from the Kanto Chemical Company. Methyl bromide form the Tokyo Kasei Co. was purified several times by vacuum distillation techniques: gas chromatography showed no impurity greater than 0.01%. Helium and Xenon supplied by the Nihon Sanso Co. and the Takachiho Chemical Co., were used directly without additional purification (the listed purities are 99.999 and 99.995% respectively).

Sample Preparation and Irradiation. The preparation of samples followed the routine procedures used in our previous work for gas-phase bromine hot-atom chemistry.[3] A quartz capillary containing Br_2 was gas irradiated in a pneumatic tube of a Cp-5-type reactor in JAERI for 5 min. Then it was quickly inserted into a Pyrex ampoule filled with the required gases. About 10—20% of the ^{82m}Br formed during the irradiation decayed in the Pyrex ampoule, the ^{82}Br freshly formed was made to react with methyl bromide.

Radio-gas Chromatography. The organic products were separated using a dioctyl sebacate column (15% in weight) 3m long and 6mm in inside diameter. The temperature of the operation was 95°C. A short glass column containing pottasium ferrocyanide was placed before the separation column in order to isolate any inorganic bromides, such as $H^{82}Br$ or $Br^{82}Br$, formed in the reaction system. Otherwise, a gradual elution of these from the column would interfere with a precise radioactive assay of the organic bromide. Elution gas was introduced into a G-M counter in conjunction with a scaler and printer for radioactivity measurements of each product. For the determination of the absolute yields of the individual products, the total bromine activity was measured with a gamma-ray scintillation counter (a 2″+2″ well-type NaI(Tl) scintillator at 20 cm), after a complete decaying-out of the ^{80}Br (about 48 hr after irradiation).

Correction and Experimental Errors. All of the data obtained have been corrected for decays of ^{82m}Br and ^{82}Br according to the reported half-lives of 6.1 min[14,15] and 35.4hr respectively. A consideration of the kinetic energy of the ^{82}Br atom achieved by the Auger process following the isomeric transition of ^{82m}Br shows that the recoil loss of ^{82m}Br into the wall can be neglected in the pressure range studied.[11]

In most cases, the activity in $CH_3{}^{82}Br$ or $CH_2{}^{82}BrBr$ was large enough to reduce the standard deviation of counting to a small percentage. The relative short half-life of ^{82m}Br, is however, responsible for the most serious error in the absolute yields. A ninety-one percent radioactive neutron capture by ^{81}Br results in ^{82m}Br. At the end of a 5-min irradiation, 71% of the ^{82m}Br produced is still alive.

However, this is reduced to 10—20% upon the mixing of ^{82m}Br with methyl bromide, as the transit from the reactor to the laboratory and the following sample processing usually take 10—15 min. The yields of individual products constitute only a small percentage of the total ^{82m}Br produced originally. Therefore, the accuracy of these experiments is usually limited to 5%, except in a few cases in which the counting error was greater than normal.

Results

Samples were dipped into liquid nitrogen for varying periods of time (Δt) after the mixing of ^{82m}Br with methyl bromide. Such a method makes it possible to follow the reactions occurring in both the gaseous and solid phases in a series of experiments. In Table 1 the yields of the products are listed in connection with the Δt. The decrease in

the yields with the time is just the opposite of the increase found in the Br_2-CH_4 system.[3] This observation implies that a homogeneous mixing of the Br_2 and CH_3Br is also attained on the solidification of the mixture and the chemical reaction of the ^{82}Br from (I. T.) with methyl bromide proceeds. By contrast, in the Br_2-CH_4 system the solidification of a mixture has a clumping effect on bromine, so that bromine atoms undergoing a nuclear transformation are surrounded by an envelope of molecular bromine. Further chemical reaction of ^{82}Br with methane should thus be prevented. These two kinds of observations have also been made in solid-liquid intersystems.[7]

In the following gaseous experiments, the quantitative measurements of $CH^{82}BrBr_2$ and $C_2H_5{}^{82}Br$ were not successful, simply because of their small yields (less than 0.2%). Thus, we weighted the quantitative measurements only for the products, $CH_3{}^{82}Br$ and $CH_2{}^{82}BrBr$.

* Part of the sample is lost during the sample processing.

Table 2 shows the dependences of the two major products on the pressure of methyl bromide, in the constant presence of 5 cmHg Br_2 as a scavenger. The observed increases in yields with the total pressure are considered to originate as follows: 1) with pressure, recoil loss into the wall is reduced; concomitantly, the amount of ^{82}Br reacted in the gaseous phase increases; 2) both products are formed *via* a ion-molecule reaction of $^{82}Br^{+1}$; 3) the primary products, $(CH_3{}^{82}Br)^*$ and $(CH_2{}^{82}BrBr)^*$, are highly excited, and their unimolecular decomposition reactions compete greatly with collisional deactivations as the pressure increases. The recoil energy of the ^{82}Br from (I. T.) is most in the range of 100 eV,[9] and the recoil loss of ^{82}Br into the wall is well below the experimental uncertainty in the pressure range studied. Thus, the first possibility above may be excluded.

One method to differentiate one possibility from the others is through the sensitivities of the reacting species to the addition of moderators. The dependency of the yields upon the mole fraction of helium or xenon added as a inert moderator has been measured. The results are shown in Figs. 1 and 2, where the yields are plotted as a function of the mole fraction of the moderator. In all the samples 5 cmHg of Br_2 is present as a scavenger, while the total pressure was always kept at 51±1 cmHg.

Discussion

The most striking feature of the formation of the main products, $CH_3{}^{82}Br$ and $CH_2{}^{82}BrBr$, is their great sensitivity to the presence of the moderating gas. Behavior of this kind can be understood if they formed by the energetic reaction of the ^{82}Br atom, not by the thermal ionic ^{82}Br atom. The ease with which $^{82}Br^{+1}$ is neutralized to the ^{82}Br neutral atom is dependent upon the

ionization potential of the colliding partner in the system. As the ionization potential of methyl bromide is 10.6 eV, lower than that of Br (11.84 eV), the neutralization of Br^{+1} in collision with methyl bromide is energetically very much favored. Allowing this, the subsequent reaction of $^{82}Br^{+1}$ in collision with methyl bromide will be a discharging.

Although other minor products, such as $CH^{82}BrBr_2$ and $C_2H_5{}^{82}Br$, could not be measured quantitatively, their yields are so small that they can explain only a small percentage of the total organic products at most. Within this limitation, the ^{82}Br from (I. T.) reacts with methyl bromide as a hot ^{82}Br, and $CH_3{}^{82}Br$ and $CH_2{}^{82}BrBr$ are formed through the *^{82}Br for Br* and *^{82}Br for H* reactions, as has been shown in Eqs. (1) and (2).

On the other hand, previous experiments have shown that the ^{82}Br from (I. T.), in an atmosphere of methane and in the presence of Br_2 as a scavenger, reacts with methane *via* ionic as well as energetic reactions.[3,16] However, the ionization potential of methane is higher than that of Br, and the charge transfer reaction between Br^{+1} and CH_4 is calculated to be endothermic by *ca.* 1.3 eV. The different reactivities in ^{82}Br in these systems thus, leads to the following qualitative interpretations for the reaction mechanisms of ^{82}Br from (I. T.): if the ionization potential of a reactant is lower than that of Br, ^{82}Br can well be neutralized to a neutral ^{82}Br atom and reacts *via* energetic reactions. However, in a system in which the reactant has a higher ionization potential than does Br, part of the ^{82}Br may react *via* ion-molecule reactions prior to the complete neutralization. The higher the endothermicity of the neutralization reaction, $Br^{+1}+M \rightarrow Br+M^{+1}$, the more significant become the ionic reactions.

Rack and Gordus[17] have reported that the reactions of a ^{80}Br atom activated by $^{79}Br(n, \gamma)^{80}Br$ with CH_4 require only a kinetically-excited ^{80}Br atom in spite of the fact that originally at least 18% of the ^{80}Br atoms were positively charged.[18] It is, however, very likely that charge transfer will occur in a collision of Br^{+1} with CH_4 if the ion is electronically excited[18,19] in a state sufficiently high to overcome the endothermicity of the charge transfer reaction. If this is the case, the difference in the reaction mechanisms of Br atoms from different nuclear reactions can be connected with the electronic state of atoms when they are born. Thus, it may be suggested that the recoil atom resulting from the (n, γ) process is more likely to be electronically-excited than that resulting from the (I. T.) process. This discussion will have one feature in common with the results of Rack and Gordus[6,7] on the reaction of ^{128}I from $^{127}I(n, \gamma)^{128}I$ with methane, where reactions required electronically-excited ions as well as atom or ions of kinetic energy. However, the final answer to this problem must await more information concerning the physical state of the recoil atom obtained from other types of experiments.

Unimolecular Decompositions. The above discussions assist the interpretation of the results shown in Table 2 in terms of the competition between the decomposition and the collisional stabilization of the excited $(CH_3{}^{82}Br)^*$ and $(CH_2{}^{82}BrBr)^*$. These are formed by substitution reactions of hot ^{82}Br with sufficient internal excitation energy to cause secondary decomposition. Thus, the fate of the excited molecules is either stabilization by collisional deactivation with their surrounding molecules or unimolecular decomposition. The increase in the pressure serves to stabilize with an increase in the collision frequency.

Some information on the decomposition reactions of these excited molecules has been provided by studies of recoil tritium reaction. Rowland and his collaborators[20-23] have extensively studied the unimolecular decomposition reaction of internally-excited molecules formed by the substitution reaction of the recoil tritium atom. It is reasonable to assume that the chemical reaction range of the substitution reaction of the recoil T or ^{82}Br atom is not different enough to alter the decomposition paths of the resulting excited molecule.[24] Thus, very possibly the subsequent reaction of $(CH_3{}^{82}Br)^*$ or $(CH_2{}^{82}BrBr)^*$ will be:

$$(CH_3{}^{82}Br)^* \rightarrow CH_3 + {}^{82}Br$$

$$(CH_2{}^{82}BrBr)^* \rightarrow CHBr + H^{82}Br$$

$$\text{or} \quad CH^{82}Br + HBr$$

Factors Affecting the Yields. The higher yield in the solid phase is due simply to the combination of the ^{82}Br atom with the radicals formed by the radiation chemistry in the system.[11,25,26]

the absence of γ-radiation from a nuclear reactor. Alternatively, electrons emitted by the ^{82}Br atom as a result of internal conversion and Auger transitions produce a high localized concentration of radicals so close to the atom that their reactions with the atom are not precluded by the Br_2 scavenger, whereas in the gas phase these radicals can easily be scavenged.

One of the most important conclusions to be drawn from the present experiments is that the total organic yield *via* a hot reaction is less than 10%. This is parallel to the observations on other recoil halogen atom reactions[27,28] and is consistent with the proposal of Rowland *et al.*[28] They ascribed the fact that these yields are lower than those in the recoil tritium reaction to the ease with which a recoil atom can change direction in response to a newly-available chemical potential. The halogen atom, heavier than the tritium atom, may very well be hindered by such bond formation; a substantially lower yield than in the corresponding tritum system will result. Although corrections for the secondary decompositions of excited molecules sholud be made in quantitative discussions, such corrections are unlikely to alter the qualitative conclusion.

Kinetic Theory. One of the assumptions involved in the Estrup-Wolfgang kinetic theory[29,30] is that the initial energy of recoil atom is sufficiently high for the atom to have made number of collisions in order to attain the statistical distribution of energies for the atoms in the reaction range. Qualitatively this assumption is plausible. In the isomeric transition of ^{80m}Br in the molecular bromine, the resulting ^{80}Br atoms show a charge spectrum ranging up to +11, with a maximum between +4 and +5.[10] The average kinetic energy of the Br arom achieved from the molecular explosion of Br_2 can thus be estimated[9] to be over 100 eV. Since precise information on the kinetic energy spectrum of ^{82}Br is not available, this could serve as a reasonable approximation.

The developed equation is given in:

$$\frac{-1}{\ln(1-P)} = \frac{\alpha_{\text{react}}}{I} - \frac{\alpha_{\text{mod}}}{I}\left(\frac{1-f}{f}\right),$$

where P is the total probability (organic yield) of a hot atom combining in any hot product and where I is the corresponding total reactivity integral. α_{react} and α_{mod} are the average logarithmic energy loss per collision for reactant and moderator respectively. f, the collision fraction, is computed using:

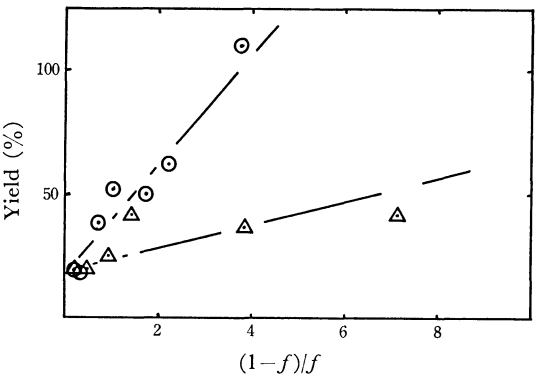

Fig. 3. Kinetic plotts of the total yields of products in moderated reactions of ^{82}Br with methyl bromide.
△: He moderator ⊙: Xe moderator

Table 3. Relative values of average logarthmic energy loss per collision, α, for collision of Br atom

system		
He-CH_3Br-Br_2	$\alpha_{He}/\alpha_{CH_3Br}$	0.27±0.03
Xe-CH_3Br-Br_2	$\alpha_{Xe}/\alpha_{CH_3Br}$	1.2±0.1
	α_{Xe}/α_{He}	4.5±0.5

$$f = \frac{X_{CH_4}S_{CH_4}}{\sum X_i S_i}.$$

Here X_i is the mole fraction of the ith molecule, and S_i is the collision cross-section for the Br-ith molecule collision. A plot of $-1/\ln(1-P)$ *versus* $(1-f)/f$ gave straight lines for the results in both He and Xe moderators as is shown in Fig. 3. The following values are obtained: (He) slope 4.8± 0.5, intercept 18±2, (Xe) slope 22±2, and intrecept 18±2. The relative values of α obtained from the intercept/slope values in Fig. 3 have been summarized in Table 3. For the calculation of S, the diameters used for individual products[31] are: He, 2.2(Å); Xe, 4.9(Å); Br, 4.2(Å), Br_2, 8.4(Å), and CH_3Br, 5.4(Å). The above graphical analysis has been carried out on the basis of the sum of the yields of $CH_3{}^{82}Br$ and $CH_2{}^{82}BrBr$. By contrast, the billiard-ball model predicts the ratio of 1.0 : 8.8 : 10.3 for $\alpha_{He} : \alpha_{Xe} : \alpha_{CH\,Br}$. This suggests a high inelasticity in the actual collisions of recoil bromine, even with monatomic molecules.

Examination of the data in Figs. 1 and 2 shows that the ratio of the two products is almost constant at any mole fraction of the moderators within the range of experimental uncertainty.

It is thus, likely that the chemical reaction range does not change significantly in the substitution reaction of H or Br in methyl bromide by the hot Br atom. This is accord with the similar dependencies of the yields upon the pressure.

The authors are grateful to Mr. T. Ohkubo for his assistance throughout this work. They also wish to express their gratitude to Dr. K. Motojima and the members of the Reactor Chemistry Laboratory in JAERI.

(Received October 23, 1968)

A new copper(II) chelate of the Schiff base derived from pyruvic acid and ethanolamine has been prepared. The crystal structure of this complex, $[Cu(pyv=etham)_2]\cdot 4H_2O$, has been determined from three dimensional X-ray diffraction data. The dimensions of monoclinic cell are $a=6.50$Å, $b=19.75$Å, $c=7.26$Å, $\beta=113.0°$ and $Z=2$. The space group is $P2_1/n$. The structure has been refined by three dimensional difference syntheses to $R=0.126$. It has been disclosed that copper(II) links to the 2-hydroxyethyliminopyruvate anion through the terminal carboxylate group, and the nitrogen of the Schiff base linkage. Having a center of symmetry, the complex molecule is in the *trans*-configuration and has normal bond distances and angles. The coordination around copper(II) is square planar; the Cu-O and Cu-N distances are 1.92 and 2.00Å, respectively. Two additional oxygen atoms of the water molecules at 2.57Å complete a distorted octahedron around copper(II). The complex molecules are held together in the crystal by the O-H···O hydrogen bonds, forming a three dimensional network.

The reaction of copper(II) with the Schiff base derived from salicylaldehyde and ethanolamine results in the formation of the copper(II) Schiff base complex of either one-to-one type or one-to-two type, depending upon the condition employed there.[1] On the other hand, a similar reaction of copper(II) with the Schiff base derived from pyruvic acid and ethanolamine exclusively gives the copper(II) Schiff base complex of one-to-two type, regardless of the method of preparation. The molecular structure of these one-to-two type copper(II) Schiff base complexes is not always easy to predict, in view of the fact that there are three donating groups in those Schiff base ligands, though the donating tendency of alcoholic oxygen is estimated to be comparatively weak. It is also important to know the geometrical configuration of the two 2-hydroxyethyliminopyruvate ions around the copper(II). The main purpose of the present work was to elucidate these points and determine the detailed structure of the complex.

Experimental

The preparation of bis(2-hydroxyethyliminopyruvato)-copper(II).

A mixture of copper(II), pyruvic acid and ethanolamine in 1 : 2 : 2 molar ratio was treated at about 60°C for two hours in aqueous ethanol (one-to-one by volume mixture).

A dark blue solution was gradually obtained, being accompanied by precipitation of pale blue microscopic crystals.

The precipitate was filtered by suction and recrystallized from an aqueous ethanol solution. The final pure product appears as thin pale blue needles elongated along the *c*-axis. The result of the elementary analysis nearly coincides with the calculated values for bis(2-hydroxyethyliminopyruvato)copper(II) tetrahydrate.

Found: C, 30.42; H, 5.98; N, 6.92%. Calcd: C, 30.34; H, 6.07; N, 7.08%.

Cell dimensions were calculated from measurements on rotation and Weissenberg photographs, calibrated with Cu wire ($a_0=3.6147$), using Cu$K\alpha$ radiation ($\lambda=1.5418$Å).

*1 Deceased on Aug. 1, 1968.

1) A. Nakahara, H. Matsumoto and H. Yamamoto, *Sci. Rep.*, College of General Education, Osaka Univ., **12**, 11 (1963).

The results are:

$a=6.50\pm0.01$Å, $b=19.75\pm0.02$Å, $c=7.26\pm0.01$Å

$\beta=113.0\pm0.2°$.

The cell contains two formula units of ($[Cu(HOCH_2CH_2NCCH_3COO)_2]\cdot4H_2O$); density calculated: 1.53 g·cm^{-3}; density measured: 1.52 g·cm^{-3}. Systematic absence indicates the space group to be $P2_1/n$. Relative intensities were obtained from equi-inclination Weissenberg photographs taken with Cu$K\alpha$ radiation using multiple films. The crystal was a rod of dimensions $0.1\times0.05\times2.0$ mm. Data were collected for all levels from $hk0$ through $hk6$ and $h0l$.

The intensities were estimated visually by comparison with a calibrated scale and corrected for the usual Lorentz and polarization factors. No absorption correction was made.

The range of relative intensities was 1 to 30000.

1292 reflections fell within this range, whereas 385 others were too weak to be observed.

Determination of Structure

The presence of two formula units in a unit cell of the space group $P\,2_1/n$ requires the copper atoms to occupy one of the sets of twofold positions. Without loss of generality they can be placed at 000 and ½ ½ ½.

Attempts were made to deduce the positions of the lighter atoms from a three dimensional Patterson function and Fourier synthesis of electron density, $\rho(x,y)$, of which all the phases were assumed to be positive. It was possible to locate all the atoms except one water oxygen atom.

The first three dimensional structure factor calculation on the basis of the deduced atomic positions led to an R index of 0.24. All the atomic positions were fixed by three dimensional F_o synthesis. In this calculation all those F_os were excluded for which $F_c<\frac{1}{2}F_o$. The structure was then refined by a three dimensional difference synthesis. Finally R index was reduced to 0.126. All calculations were carried out on a FACOM231 computer.

The final atomic positions, and isotropic temperature factors and their estimated standard deviations are given in Table 1.

Table 2 gives the comparison of observed and calculated structure factors. The superimposed sections of the final electron density distribution are shown in Fig. 1.

Description and Discussion of the Structure

The structure projected upon a plane normal to the b-axis is shown in Fig. 2, and the environment of each copper atom is illustrated in Fig. 3. The interatomic distances and the bond angles calculated on the basis of the atomic parameters in Table 1 are given in Table 3.

The new complex, bis(2-hydroxyethyliminopyruvato)copper(II) is in trans-configuration. The 2-hydroxyethyliminopyruvate group is coordinated to copper(II), as a bidentate chelate, through the terminal carboxylate oxygen and the nitrogen of the Schiff base linkage, while the alcohol group is free from coordination. This is quite reasonable since the donating tendency of the alcohol oxygen has been estimated to be comparatively weak. The coordination around copper is approximately square planar. The distances from the copper(II) to the four donor atoms are 2.00 Å for Cu–N and 1.92 Å for Cu–O. The fifth and the sixth coordination positions are occupied by oxygen atoms of water molecules, being 2.57 Å distant from the copper(II) atom; hence the copper(II) has a tetragonally distorted octahedral environment, as has very often been observed in copper(II) com-

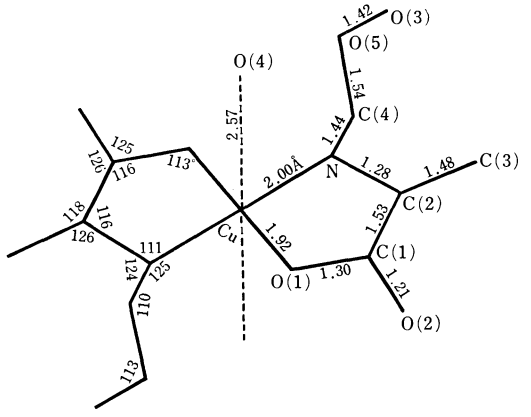

Fig. 3. The environment of the copper atom, showing bond distances and bond angles.

plexes. The N–Cu–O angle in the chelate ring is 84.6°; and the weaker Cu–OH_2 bond is inclined at an angle of 85° with respect to the plane of the copper and four ligand atoms.

These values may be compared with the corresponding values for other copper(II) complexes: Cu–O=1.95 Å, Cu-N(amino)=2.00 Å and N–Cu–O =85.2° in bis(glycinato)copper(II) monohydrate;[2] Cu–O=1.97—1.99 Å, Cu–N(amino)=2.00 Å and N–Cu–O=83.6° in copper(II) glutamate dihydrate;[3] Cu–O=1.88 Å and Cu–N(imino)= 1.99 Å in bis(*N*-phenylsalicylaldiminato)copper-(II).[4]

The bond distances in the chelate ring are: 1.30 Å for O(1)–C(1), 1.53 Å for C(1)–C(2) and 1.28 Å for O(2)–N, and are in good agreement with

Table 3. Interatomic distances and angles

I Distance			
Cu–N	2.00Å	C(1)–C(2)	1.53Å
Cu–O(1)	1.92	C(2)–C(3)	1.48
Cu–O(4)	2.57	C(4)–C(5)	1.54
O(1)–C(1)	1.30	C(3)···O(5)	2.72
O(2)–C(1)	1.21	O(3')···O(5)	2.65
O(3)–C(5)	1.42	O(4')···O(5)	2.75
N–C(2)	1.28	O(2'')···O(4)	2.81
N–C(4)	1.44		
II Angle			
N–Cu–O(1)	84.6°	N–C(4)–C(5)	110°
Cu–O(1)–C(1)	113	C(4)–C(5)–O(3)	113
O(1)–C(1)–C(2)	116	C(3)–C(2)–N	126
O(1)–C(1)–O(2)	125	C(2)–N–Cu	111

3) C. M. Gramaccioli and R. E. Marsh, *Acta Cryst.* **21**, 594 (1966).

4) L. Wei, R. M. Stogsdill and E. C. Lingafelter, *Acta Cryst.* **17**, 1058 (1964).

those found in various complexes: C–O=1.28 Å and C–C=1.52 Å in bis(glcinato)copper(II) monohydrate and copper(II) glutamate dihydrate; C–O=1.31 Å and C–N(imino)=1.30 Å in bis(*N*-phenylsalicylaldiminato)copper(II) and disodium glycylglycylglycinatocuprate(II).[5]

In the carboxyl group, C(1)–O(1) bond has lengthened and C(1)–O(2) bond has shortened compared with the values found in glycine(both 1.25 Å). This fact indicates that these bonds have 20% and 80% double bond character, respectively.[6] O(2) atom of the carboxyl group, C(3) atom of the methyl group and C(4) atom of the ethanolamine group lie almost in the plane of the chelate ring, the deviation ranging from 0.04 Å to 0.09 Å. C(5) atom of the ethanolamine moiety is displaced from that plane and the angle between C(4)–C(5) bond and the plane is 62°.

The only contacts less than 3.5 Å between adjacent molecules are made by the free water oxygen O(5), the water oxygen O(4) weakly coordinated to the copper atom, the ethanolamine oxygen O(3) and the carboxyl oxygen O(2).

The distances are 2.67 Å—2.81 Å as shown in Fig. 2.

These short distances and the angles suggest hydrogen bonding between them. By these hydrogen bonds, the complexes are packed in layers parallel to the plane (101).

Stabilization within the layer is provided by hydrogenbonded bridges O(5)···O(3), O(5)···O(3′) and O(5)···O(4′).

Between adjacent layers there exists a hydrogen bond O(4)···O(2″) in the direction normal to the plane (100).

Part of the cost of this investigation has been defrayed by a Scientific Research Grant of the Ministry of Education, to which the authors' thanks are due.

Note added in proof: The crystal and molecular structures of the related complexes, pyruvidene-*β*-alaninatoaquocopper(II) dihydrate and *N*-salicylideneglycinatoaquocopper(II) hemihydrate, prepared by one of the authors (A. N.) have also been determined.[7,8]

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 1515—1518 (1969)

Measurement of Negative Ions Formed by Electron Impact. III. The Ionization Efficiency Curves of Negative Ions of *m/e* 26 and 42 from Nitroalkanes

Satoru TSUDA, Akira YOKOHATA and Michihiro KAWAI

Department of Chemistry, Faculty of Engineering, University of Hiroshima, Senda-machi, Hiroshima

(Received November 8, 1968)

The studies of this series were extended to the negative ions of *m/e* 26 and 42 obtained from nitroalkanes; nitromethane, nitroethane, 1-nitropropane, and 2-nitropropane. For *m/e* 26 (probably, CN^-) ions, the contribution of three or two processes in the range from zero to ~20 eV of electron energy was observed for nitromethane or other samples. On the basis of ΔH_f values of the reactants and products, and of the value of $EA(CN)$, the plausible reactions to be assigned to each process were presented. For the first process, $CH_3NO_2+e^-\rightarrow CN^-+H_2O+OH$, $RNO_2+e^-\rightarrow CN^-+R_1OH+OH$. For the second process, $CH_3NO_2+e^-\rightarrow CN^-+H_2O+O+H$, $CH_3NO_2+e^-\rightarrow CN^-+H_2+O_2+H$, $RNO_2+e^-\rightarrow CN^-+R_1+HO_2+H$, and $C_3H_7NO_2+e^-\rightarrow CN^-+C_2H_4+H_2+O+OH$ irrespective of kind of nitropropane. For the third process, $CH_3NO_2+e^-\rightarrow CN^-+3H+O_2$. For *m/e* 42 (probably, CNO^-) ions, the contribution of two processes was observed. By taking $\Delta H_f(CNO)=x$ (eV), $EA(CNO)=y$ (eV), and also combining the observed onset values with the calculated values of appearance potential of reactions to be assigned for each process — for the first process, $CH_3NO_2+e^-\rightarrow CNO^-+H_2+OH$, $RNO_2+e^-\rightarrow CNO^-+R_1OH+H$; for the second process, $CH_3NO_2+e^-\rightarrow CNO^-+HO+2H$, $CH_3NO_2+e^-\rightarrow CNO^-+H_2+O+H$, $RNO_2+e^-\rightarrow CNO^-+R_1O+2H$ — a relation of $x-y\simeq 2$(eV) was derived.

Recently, several studies have been reported on the measurement of negative ion mass spectra by the electron impact method.[1-4] However, they were only made for limited kinds of compounds. Furthermore, data on the ionization efficiency (*IE*) curves of negative ions are very limited.[5-7] We published previously the results of measurement of *IE* curves of NO_2^-, O^- and $CH_2NO_2^-$ ions from nitroalkanes; nitromethane, nitroethane, 1-nitropropane and 2-nitropropane.[8] This work has been extended to the measurements of negative ions of *m/e* 26 and 42 and affords information on *IE* curves of these negative ions for which as far as the authors know few reports have been found.

Experimental

This investigation was carried out using a Hitachi RMU-6D mass spectrometer equipped with a T-2M ion source having a rhenium filament. The ion detection circuit consisted of a ten stage electron multiplier and of a Faraday collector. The experimental condition and the correction method of electron energy scale were identical to those previously described.[8]

The materials used were of research grade and no further purifications have been done.

Results and Discussion

Formation of *m/e* 26 Ions. In nitromethane, *m/e* 26 ions can be assigned to CN^-. Although the possibility of $C_2H_2^-$ ions in other samples might be considered, little formation[1] of $C_2H_2^-$ ions from alcohols appears to rule out this possibility. Figure 1 shows that, except for nitromethane, two processes contribute to the formation of CN^- ions. The first process appears at a considerably lower energy than 3 eV irrespective of the compounds and the second one seems to appear at ~5.2 eV in nitroethane, ~4.4 eV in 1-nitropropane

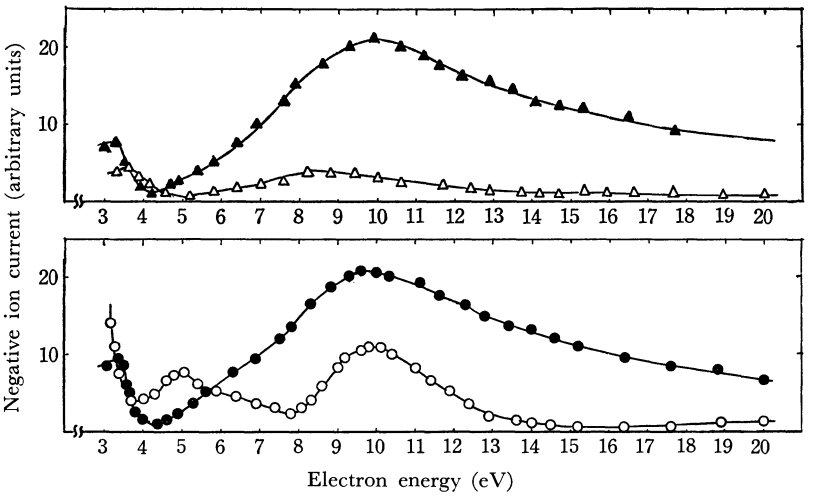

Fig. 1. Ionization efficiency curves of negative ions of *m/e* 26 from nitroalkanes.
○ CH_3NO_2 ● 1-$C_3H_7NO_2$ △ $C_2H_5NO_2$ ▲ 2-$C_3H_7NO_2$

and 2-nitropropane.*1 In nitromethane three processes can be found; the second one seems to appear at ~3.7 eV and the third at ~7.8 eV.

For the first process in nitromethane, reactions (1), (2) and (3) are expected. Their appearance potentials can be estimated to be −0.85 eV, 1.47 eV and 2.12 eV, respectively,*2 by using $\Delta H_f(CH_3NO_2) = -0.8$ eV,[9] $\Delta H_f(CN) = 3.87$ eV,[10] $\Delta H_f(H_2O) = -2.50$ eV, $\Delta H_f(OH) = 0.38$ eV, $\Delta H_f(HO)_2 = 0.2$ eV, $\Delta H_f(H_2) = 0.00$ eV, $\Delta H_f(H_2O_2) = -1.41$ eV, $\Delta H_f(H) = 2.26$ eV*3 and $EA(CN) = 3.4$ eV*4

$$CH_3NO_2 + e^- \rightarrow CN^- + H_2O + OH \quad (1)$$
$$(AP_{calc} = -0.85 \text{ eV})$$

$$CH_3NO_2 + e^- \rightarrow CN^- + HO_2 + H_2 \quad (2)$$
$$(AP_{calc} = 1.47 \text{ eV})$$

$$CH_3NO_2 + e^- \rightarrow CN^- + H_2O_2 + H \quad (3)$$
$$(AP_{calc} = 2.12 \text{ eV})$$

Among these reactions, the possibility of reaction (1) is very great, because the appearance potential of the first process has been qualitatively found to be very low. Thus, the process which appears at a considerably lower energy than 3 eV may be concluded to be due to reaction (1). A negative value of the appearance potential of this reaction means that the occurrence of this reaction is possible even with the electrons of thermal energy. The situation is quite similar to that of NO_2^- from nitromethane in which the appearance potential of dissociative electron capture shows a negative value because of $EA(NO_2) > D(CH_3\text{-}NO_2)$.

For the other samples, the occurrence of reactions (4) or (5) resulting in the formation of alcohols can be strongly expected under the analogy with reaction (1). The appearance potentials of reactions (4) and (5) can be estimated to be −0.53 eV and −0.96 eV, by using $\Delta H_f(CH_3OH) = -2.08$ eV, $\Delta H_f(C_2H_5OH) = -2.44$ eV, $\Delta H_f(C_2H_5NO_2) = -0.70$ eV and $\Delta H_f(1\text{-}C_3H_7NO_2) = -0.63$ eV.*5

*1 Since the tailing due to the first process might be overlapped with the appearance of the second process, the exact determination of appearance potential of the second process is difficult. In this work, the minimum values in *IE* curves have been taken up as the object of discussion.

*2 These values mean the lowest value of the energy needed for the appearance of the reaction.

9) R. J. Kandel, *J. Chem. Phys.*, **23**, 84 (1955).

10) V. H. Dilbeler, R. M. Reese and J. L. Franklin, *J. Am. Chem. Soc.*, **83**, 1813 (1961).

*3 For the values of ΔH_f, see the report of Bernecker. (R. R. Bernecker and F. A. Long, *J. Phys. Chem.*, **65**, 1565 (1961)).

*4 For the electron affinity (*EA*) of CN, the values of 3.2 eV and 3.6 eV have been published. In this work, 3.4 eV (the mean value) was used. (J. T. Herron and V. H. Dibeler, *J. Am. Chem. Soc.*, **82**, 1555 (1960); E. Lederle, *Z. Physik. Chem.*, **B17**, 362 (1932).

*5 The value of $\Delta H_f(C_2H_5NO_2)$ can be estimated in the following way.

$$NH \rightarrow N + H, \qquad \Delta H = 3.61 \text{ eV}$$
$$NO \rightarrow N + O, \qquad \Delta H = 6.52 \text{ eV}$$
$$NO_2 \rightarrow NO + O, \qquad \Delta H = 3.16 \text{ eV}$$

Therefore, $\Delta H_f(NO_2) = 0.32$ eV can be obtained by using the known values of $\Delta H_f(NH)$, $\Delta H_f(H)$ and $\Delta H_f(O)$. Combining the appearance potential (10.9 eV) of the reaction ($C_2H_5NO_2 + e^- \rightarrow C_2H_5^+ + NO_2 + 2e^-$) with $\Delta H_f(NO_2) = 0.32$eV, we obtain a value of −0.70 eV for $\Delta H_f(C_2H_5NO_2)$; S. Tsuda and W. H. Hamill, *Advan. Mass Spectry.*, **3**, 249 (1965).

In the same way, $\Delta H_f(1\text{-}C_3H_7NO_2) = -0.63$ eV can be also estimated; V. I. Vedeneyev, L. V. Gurvich, V. N. Kondrat'yev, V. A. Medvedev and Ye. L. Frankevich, "Bond Energies, Ionization Potentials and Electron Affinities," Edward Ltd., London (1966), p. 80.

$$C_2H_5NO_2 + e^- \rightarrow CN^- + CH_3OH + OH \quad (4)$$
$$(AP_{calc} = -0.53\ eV)$$
$$1\text{-}C_3H_7NO_2 + e^- \rightarrow CN^- + C_2H_5OH + OH \quad (5)$$
$$(AP_{calc} = -0.96\ eV)$$

For 2-nitropropane, the same interpretation would be also applied.

For the second process of nitromethane, reactions (6) and (7) might be considered. The values of their appearance potential can be estimated to be 3.53 eV and 3.59 eV which are almost consistent with the observed onset value of 3.7 eV.

$$CH_3NO_2 + e^- \rightarrow CN^- + H_2 + O_2 + H \quad (6)$$
$$(AP_{calc} = 3.53\ eV)$$
$$CH_3NO_2 + e^- \rightarrow CN^- + H_2O + O + H \quad (7)$$
$$(AP_{calc} = 3.59\ eV)$$

In other words, the second process can be interpreted with other complicated electron capture processes different from reaction (1) or resulting in a further dissociation of product of reaction (1).

For the second process of nitroethane and 1-nitropropane, the possibility of reactions (8), (9) or (10) would be pointed out. Their appearance potentials give the values of 5.02 eV, and 4.56 eV or 4.59 eV which are almost consistent with the observed onset values; 5.2 eV (for nitroethane) and ~4.4 eV (for 1-nitropropane)

$$C_2H_5NO_2 + e^- \rightarrow CN^- + CH_3 + HO_2 + H \quad (8)$$
$$(AP_{calc} = 5.02\ eV)$$
$$1\text{-}C_3H_7NO_2 + e^- \rightarrow CN^- + C_2H_5 + HO_2 + H \quad (9)$$
$$(AP_{calc} = 4.56\ eV)$$
$$1\text{-}C_3H_7NO_2 + e^- \rightarrow CN^- + C_2H_4 + H_2 + OH + O$$
$$(AP_{calc} = 4.59\ eV) \quad (10)$$

For the third process in nitromethane, reaction (11) resulting in a further dissociation of product accompanied with the rearrangement might be assigned. This reaction gives a value of 8.05 eV for the appearance potential which is almost consistent with the observed onset value, ~7.8 eV.

$$CH_3NO_2 + e^- \rightarrow CN^- + 3H + O_2 \quad (11)$$
$$(AP_{calc} = 8.05\ eV)$$

Formation of *m/e* 42 Ions. In nitromethane, the ions of *m/e* 42 can be assigned to CNO^-. In other samples, however, the possibility of $C_2H_4N^-$ ions exists. Figure 2 shows*6 that two processes contribute to the formation of these ions. The first process appears at ~3 eV in nitromethane, nitroethane and 2-nitropropane and at ~2.6 eV*7 in 1-nitropropane, and the second ones seem to appear at ~7.5 eV in nitromethane, ~7.2 eV in nitroethane and ~6.8 eV in 1-nitropropane and 2-nitropropane.

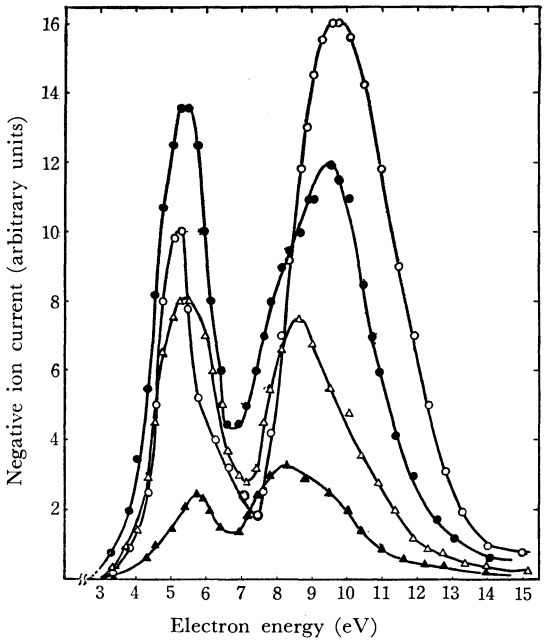

Fig. 2. Ionization efficiency curves of negative ions of *m/e* 42 from nitroalkanes.

○ CH_3NO_2 ● $1\text{-}C_3H_7NO_2$
△ $C_2H_5NO_2$ ▲ $2\text{-}C_3H_7NO_2$

In the case of CNO^- ions, the lack of knowledge of the values of $\Delta H_f(CNO)$ and $EA(CNO)$ makes difficult the assignment of reactions which correspond to each process. It is possible, however, to have some interesting discussions. Now, taking $\Delta H_f(CNO)=x(eV)$ and $EA(CNO)=y(eV)$, the appearance potentials of reactions to be expected would be estimated as follows.

For the first process;

$$CH_3NO_2 + e^- \rightarrow CNO^- + H_2O + H \quad (12)$$
$$CH_3NO_2 + e^- \rightarrow CNO^- + H_2 + OH \quad (13)$$
$$C_2H_5NO_2 + e^- \rightarrow CNO^- + CH_3OH + H \quad (14)$$
$$1\text{-}C_3H_7NO_2 + e^- \rightarrow CNO^- + C_2H_5OH + H \quad (15)$$

Then, the appearance potentials of each reaction can be estimated as follows, by using the known values of ΔH_f.

$$AP_{12} = x - y + 0.56, \quad AP_{13} = x - y + 1.18$$
$$AP_{14} = x - y + 0.88, \quad AP_{15} = x - y + 0.45$$

Combining these values with the observed onset values leads to the following results.
For nitromethane; $x-y=2.44$ or $x-y=1.82$.
For nitroethane; $x-y=2.12$, for 1-nitropropane; $x-y=2.15$.

For the second process;

*6 In general the *IE* curve of resonance type appears to correspond to the electron capture process. If so, the possibility of ion pair formation ($R^+ + NO_2^-$) discussed in the second report[8] might be required to be replaced with another mechanism (for example, $CH_3NO_2 + e^- \rightarrow NO_2^- + CH + 2H$; $AP_{calc}=7.9$ eV.

*7 estimated by extrapolation.

$$CH_3NO_2 + e^- \rightarrow CNO^- + OH + 2H \quad (16)$$

$$CH_3NO_2 + e^- \rightarrow CNO^- + H_2 + O + H \quad (17)$$

$$C_2H_5NO_2 + e^- \rightarrow CNO^- + CH_3O + 2H \quad (18)$$

$$1\text{-}C_3H_7NO_2 + e^- \rightarrow CNO^- + C_2H_5O + 2H \quad (19)$$

By the same treatment, the following results can be obtained.

For nitromethane; $x-y=1.79$ or $x-y=1.88$, for nitroethane and 1-nitropropane; $x-y=2.02$, $x-y=2.02$.

If the value of 2.44 eV is excluded,*8 a value of 1.97 ± 0.13 eV can be estimated for the mean value of $(x-y)$. Here, it should be noticed that a relatively good constancy of $(x-y)$ has been found. In other words, this suggests that the assignments above mentioned are plausible ones.

On the other hand, the appearance potential of the reactions resulting in the formation of C_2H_4N species from nitroethane (for specific example) can be approximately estimated to be 9.6 or 8.9 eV*9 by taking $D(NO\text{-}O)=3.2$ eV, $D(N\text{-}O)=6.6$ eV, $D(H\text{-}C_2H_5)=4.2$eV, $D(O\text{-}H)=4.4$eV and $D(O\text{-}O)=5.1$ eV.*10 Of course, this estimation is the approximate one in the meaning that there are assumed to be $D(H\text{-}C_2H_4NO_2)=D(H\text{-}C_2H_5)$, $D(C_2H_4NO\text{-}O)=D(NO\text{-}O)$ and $D(C_2H_4N\text{-}O)=D(N\text{-}O)$. Although the nitro group has a tendency to weaken the carbon-hydrogen bond,[9] its effect cannot be considered to be great. Now, combining the value of 9.6 or 8.9 eV with the observed value ($\sim$3 eV) of appearance potential, we can obtain the value of 6.6 or 5.9 eV for the electron affinity of C_2H_4N species. Judging from the values of electron affinity of various species published hitherto, however, this is too high. At any rate, few reports on the formation of $C_2H_4N^-$ ions and the lack of knowledges of $\Delta H_f(C_2H_4N)$ and EA (C_2H_4N) make difficult a further discussion. Thus, in this work the possibility of $C_2H_4N^-$ ions was not taken into consideration.

In the range of electron energy higher than 16—20 eV, ion pair formations might be expected. The determination of onset values, however, was difficult because of little change of ion current in addition to the weak intensity.

*8 This means that reaction (12) is to be rejected.

*9 Products to be assigned; $OH+O$ or $H+O_2$.

*10 For each D value, see the article of Vedeneyev *et al.*, in *5.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 1519—1524 (1969)

Preparation of Star-Type Graft Copolymer through the Polymerization of Methyl Methacrylate with Use of the Potassium Complexes of Polystyrene having a Benzophenone Unit

Koji NOBUTOKI and Hiroshi SUMITOMO

Faculty of Agriculture, Nagoya University, Chikusa, Nagoya

(Received November, 12, 1968)

Polystyrene ketone possessing a benzophenone structural unit in the middle part of the chain was synthesized by the coupling reaction of one-ended living polystyrene with 2,4'-dichlorobenzophenone. Polystyrene ketone potassium ketyl was prepared by the reaction of polystyrene ketone with an equivalent amount of potassium naphthalene complex in tetrahydrofuran. Polystyrene ketone potassium dianion was also formed with excess potassium in the solvent. These polystyrene ketone potassium adducts induced a quantitative polymerization of metyl methacrylate. Gross polymer from each of the reaction systems was elution-fractionated into four fractions in which a new class of star-type graft copolymer was included together with polystyrene and polymethyl methacrylate. Each fraction was characterized by means of the measurements of the yield, molecular weight and styrene content. Consideration was also made on a possible mechanism of the polymerization.

Syntheses of well defined block, graft and star-type branched copolymers by means of anionic living polymerization have been recently developed.[1-11] Polymerization and graft copolymerization initiated by the alkali metal complexes of aromatic ketone and of polyvinyl benzophenone have also been studied.[12-17] An attempt was made in a previous paper[18] to prepare a new class of star-type graft copolymers with different kinds of branches, starting from the potassium adducts of polystyrene ketone possessing one or two carbonyl groups in the middle part of the chain. Few investigations, however, have been made as to the mechanism of initiation by ketyl or dialkali metal complexes. The present paper is concerned with an attempt to obtain star-type graft copolymers with polymethyl methacrylate branches, starting from the potassium adducts of polystyrene ketone possessing a benzophenone structural unit in the middle part of the chain and with the consideration on a possible initiation mechanism of the polymerization.

Experimental

Materials. Styrene (St) and methyl methacrylate (MMA) were purified by the usual methods. Tetrahydrofuran (THF) was distilled after refluxing with sodium. Each monomer and the solvent were directly introduced into a polymerization vessel by distillation from calcium hydride and from sodium-benzophenone, respectively, after evacuation by repeating freezing and thawing in a vacuum line (10^{-6} mmHg).

2,4'-Dichlorobenzophenone (DCBP) was recrystallized from petroleum ether. Methyl phenyl isopropenyl ether was synthesized according to the method of

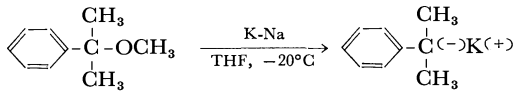
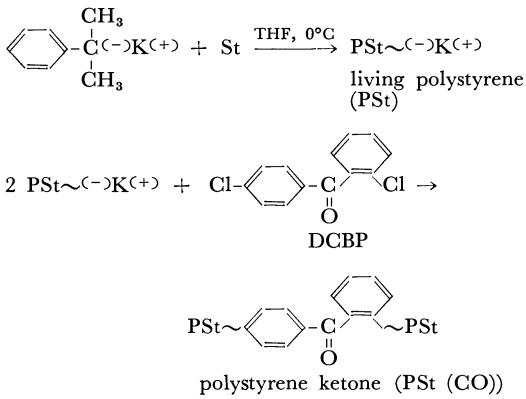
Ziegler and Dislich.[19]

Polymerization Procedures. General experimental techniques for a homogeneous anionic polymerization developed by Szwarc *et al.*[20] and by Morton *et al.*[21] were employed in the present investigation. Phenyl isopropyl potassium was prepared by the reaction of methyl phenyl isopropenyl ether with potassium-sodium alloy in THF *in vacuo*. This solution was filtered through a sintered glass filter to remove a small amount of potassium methoxide formed in the reaction.



One-ended living polystyrene (PSt) prepared from the reaction of St with phenyl isopropyl potassium in THF was coupled with DCBP resulting in the formation of polystyrene ketone (PSt(CO)) having one carbonyl group in the middle part of the chain. In the coupling reaction two procedures were adopted, *i. e.* i) the solution of the coupling agent was added slowly to the solution of living polystyrene until its red color disappeared and ii) reversely, the solution of living PSt was added to the solution of the coupling agent.



Fractional precipitation of the coupling reaction product was made using benzene as a solvent and methanol as a precipitant at room temperature.

Potassium ketyl of PSt ketone was obtained by the treatment of PSt ketone with an equivalent amount of potassium naphthalene in THF. Potassium dianion of PSt ketone was also prepared by the reaction of PSt ketone with an excess of potassium in THF and the solution was filtered through a sintered glass filter to remove excess potassium.

The polymerization of MMA initiated by these adducts was performed in a vacuum system at room temperature. The resulting gross polymer was separated into four fractions using an extraction technique. Number average molecular weights of polymers were measured in benzene at 25°C using Hewlett-Packard 302 Vapour Pressure Osmometer (VPO).

Results and Discussion

Preparation of Polystyrene Ketone. Phenyl isopropyl potassium was prepared by the reaction of methyl phenyl isopropenyl ether with potassium-sodium alloy in THF. One-ended living PSt was prepared by the polymerization of St in THF with the use of phenyl isopropyl potassium. The results are shown in Tables 1 and 2.

PSt ketone having a benzophenone structural unit in the middle part of the chain was obtained by the stoichiometric coupling reaction of the living PSt with DCBP. The results of the coupling reactions are shown in Table 3.

The number average molecular weights Mn of the products are considerably smaller than the value, 1800, for PSt ketone calculated from Mn of starting living PSt. It is likely that unreacted PSt or mono-substituted PSt may also be contained in the product because of the low rate of coupling reaction of living PSt with DCBP.

Comparing A with B there is a difference in Mn of the products. It seems probable in the coupling reaction that the substitution reaction of living PSt with two chlorine atoms is in competition with the addition reaction of living PSt to a carbonyl group in DCBP. When an excess amount of living PSt is added to DCBP, tri-chain PSt would be formed.

Fractional precipitation for the coupling reaction

product was carried out using benzene as a solvent and methanol as a precipitant at room temperature. These results are shown in Table 4.

The molecular weight of PSt ketone is calculated to be 1800 from the number average molecular weight of starting living PSt. Therefore, the values of molecular weights of Fr. 1 and Fr. 2 in both A- and B series may suggest that they contain tri-chain PSt. On the other hand, low molecular weight fractions Fr. 6 of A, Fr. 4 and 5 of B are considered to consist mainly of "mono"PSt.

Infrared-, UV- and visible absorption spectra of PSt ketone are shown in Figs. 1 and 2.

The stretching vibration of the carbonyl group in PSt ketone appears at 1660 cm^{-1} in the IR spectrum. It is known that the absorption based on the n–π^* transition of the carbonyl group of benzophenone exists at 330 mμ. PSt gives no absorption in UV- and visible absorption spectra. Therefore

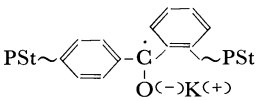
a broad absorption band in the region of 330 to 450 mμ may be considered to be characteristic of PSt ketone. It is clear from these facts that a benzophenone structural unit enters in the PSt chain.

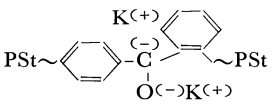
Preparations of Polystyrene Ketone Potassium Adducts. Table 5 represents the conditions of the reactions of PSt ketone with an equivalent amount of potassium-naphthalene or excess potassium in THF.

Figure 3 illustrates visible absorption spectra of PSt ketone potassium adducts.

The maximum absorptions appear at 384 mμ for dark yellow solution of the potassium ketyl and at 545 mμ for purple solution of the potassium dianion of PSt ketone. The change of the color from dark yellow to purple is observed by the addition of the THF solution of potassium naphthalene into the THF solution of PSt ketone potassium ketyl. These maximum absorptions are respectively in accord with those of benzophenone potassium ketyl at 382 mμ and benzophenone potassium dianion at 536 mμ.



polystyrene ketone potassium ketyl



polystyrene ketone potassium dianion

Polymerization of Methyl Methacrylate with Polystyrene Ketone Potassium Adducts. The results of the polymerization of MMA with PSt ketone potassium adducts are shown in Table 6.

A gross polymer obtained in the PSt-MMA system was elution-fractionated using acetonitrile, cyclohexane and carbon tetrachloride - cyclohexane (4 : 1) as solvents into four fractions as shown in Fig. 4.

In Table 7 are presented the compositions and the molecular weights of the fractions determined by infrared analysis, elementary analysis and vapor pressure osmometry. The composition of Fr. I, as seen in the table, consists almost all of PSt. The molecular weight of Fr. I was higher than that of the parent PSt ketone. Therefore the formation of tetrachain PSt of benzpinacol type structure, to which extremely short MMA chain may attach, and its inclusion in this fraction may be considered (*cf.* reaction (5)). Fr. IV was confirmed to be polymethyl methacrylate (PMMA) from the results of infrared- and elementary analyses. The PSt-PMMA graft copolymer must be contained in

	St content[b] (wt%)	>90	40.4	41.9	0

a) Calcd. from elementary analysis data.
b) Calcd. using calibration curve of optical density ratio (D_{700}/D_{1720}).

Fr. II and III. The fact that the molecular weight of Fr. III is much smaller than that calculated from its St content might be attributed to the intermixing of low molecular weight PMMA.

From the experimental results described above possible mechanisms of the polymerization are presumed as follows.

In the polymerizations of MMA initiated with PSt(CO)-K dianion and - ketyl, PSt and PMMA together with PSt-PMMA star-type graft copolymer were formed. PSt(CO)-K dianion would react with MMA to result in the formation of PMMA dianion through the bond-formation mechanism (1) and PSt(CO)-K ketyl and the monomer anion through the electron-transfer mechanism (2). The formation of PSt and PMMA suggests the occurrence of the electron transfer from PSt(CO)-K ketyl as shown in reaction (3).

PSt-PMMA graft copolymer may be produced by the bonding of MMA with alcoholate anion of PSt(CO)-K ketyl as represented in reaction (4).

Contrary to the case of an equilibrium between benzophenone-alkali metal ketyl and benzpinacolate, the presence of PSt substituted benzpinacolate was denied by means of the measurement of the molecular weight of killed PSt(CO)-K ketyl. The formation of PSt substituted benzpinacolate shown in reaction (6) is improbable. The molecular weight of Fr. I in Table 7 was higher than that of the parent PSt(CO). It is probable that PSt-PMMA graft copolymer formed in the reaction (5) may be partly included in Fr. I together with PSt(CO) formed in the reaction (3).

In view of so small a content, if any, of the graft copolymer with short MMA-grafts in Fr. I, it seems that the radical anion carrying extremely low molecular weight PMMA may be preferentially contributed to the further addition of MMA (reaction (4)) compared with reaction (5). The coupling reaction (5), however, may also be possible because of the decrease in the coulombic repulsion between the chain end anions. In conclusion both the electron transfer and the bond formation were ascertained to coexist in the intitations of MMA with use of PSt(CO)-K ketyl and dianion.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 1525—1530 (1969)

Thermodynamic Properties of Galvinoxyl Radical and Its Phenol Derivative; Mechanism of the Phase Transition*[1]

Akio KOSAKI, Hiroshi SUGA and Syûzô SEKI

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka

and Kazuo MUKAI and Yasuo DEGUCHI

Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto

(Received November 13, 1968)

Measurements of heat capacity of Galvinoxyl radical and its phenol derivative were carried out in the temperature region from 12 to 300°K. Galvinoxyl radical exhibits a phase transition of first-order nature at 81.5°K which corresponds to the susceptibility anomaly already measured. The enthalpy and entropy of transition amount to 1504.6 J/mol and 18.67 J/(°K·mol), respectively. The entropy change, which corresponds formally to R ln 9.45, cannot be explained by taking only the magnetic contribution. On the other hand, its phenol derivative, the corresponding diamagnetic substance, has not thermal anomaly in the above temperature region. X-Ray diffraction patterns at room temperature for both substances agree well with each other in their diffraction angles. From these experimental findings, it seems to be plausible that a kind of transformation of the crystal structure of Galvinoxyl radical takes place at the transition point which may be induced by a pairing of magnetic spins between neighboring molecules.

Recently, magnetic properties of stable organic free radical crystals have attracted interest of many chemists and physicists. Among these crystals, tetracyano-quinondimethane (TCNQ salts) as anion radicals, Würster Blue (WB salts) as cation radicals and 1,3-bisdiphenylene-2-phenyl allyl (BDPA) as a neutral one would be the typical substances. As the molecular structures of these radicals are considered to be planar, the magnetic properties of crystals composed of these molecules would be similar to each other.

The present substance, Galvinoxyl radical, 2,6-di-*t*-butyl-4(3,5-di-*t*-butyl-4-oxocyclohexa-2,5-dienylidene methyl) phenoxyl (hereafter, designated as G. R., see Fig. 1) is considered to be composed of non-planar molecules due to the mutual intramolecular steric hindrance of the attached tertial butyl groups. Accordingly, it is expected that the physico-chemical properties of G. R. may be different more or less from those of the radical crystals mentioned above. The magnetic susceptibility of G. R.[1] has already been measured by two of the present authors (K. M. & Y. D.) and H. Nishiguchi. According to their results, G. R. is paramagnetic above the magnetic transition point, 82.5°K, where the susceptibility drops down very sharply on cooling. We have undertaken the measurement of heat capacity from 13 to 300°K through the transition point in order to study the mechanism of this magnetic anomaly. Furthermore, we have measured the heat capacity of its phenol derivative, 2,6-di-*t*-butyl-4 (3,5-di-*t*-butyl-4-oxocyclohexa-2,5-dienylidene methyl) phenol (see Fig. 1) for comparison, in order to elucidate the effect of the radical nature on the properties of G. R.

Samples. G. R.[2] was synthesized from 2,6-di-*t*-butyl phenol. After condensation with formaldehyde

*1 This paper was presented before the 21st Annual Meeting of the Chemical Society of Japan.

1) K. Mukai, H. Nishiguchi and Y. Deguchi, *J. Phys. Soc. Japan*, **23**, 125 (1967).

2) M. S. Kharasch and B. S. Joshi, *J. Am. Chem. Soc.*, **79**, 1439 (1957).

the product was oxidized by lead dioxide. Needle crystals of blue-black color were obtained.

Yellow needle crystal of its phenol derivative were prepared by the reaction between G. R. and di(3,5-di-*t*-butyl-4 hydroxy phenyl) methane in ether solution.

The both substances were ground, in a dry box to the fine powders for packing it into a calorimeter cell. The weight of G. R. used for measurement was 13.6159 g. The radical concentration was determined to be 106± 5% from the value of the Curie constant derived from the data of susceptibility above 82.5°K. The weight of the phenol derivative used for measurement was 18.6619 g.

Calorimeter and Cryostat. Adiabatic type calorimeter and cryostat[3] described previously were used for measurement of the heat capacity. Gold cell, provided with a platinum resistance thermometer, heater and inner platinum fins for thermal conduction, was used in order to avoid the chemical reaction with the radical. Measurements of heat capacities were performed from 11 to 300°K.

X-Ray Analysis. Taking the Debye-photographs of the samples, the identification was made at room temperature.

Results

Experimental data are listed for G. R. in Table 1 and for its phenol derivative in Table 2. These data are based on a molecular weight of 421.649 g for G. R. and 422.657 g for its phenol derivative and also on the relation 0°C=273.15°K. The heat capacities in these tables are the ratio of the increase in enthalpy to the rise in temperature and are equal to the differential heat capacity only when the correction for curvature is negligible. The temperature T listed in these tables is the arithmetic mean of the initial and the final temperature.

As are shown the experimental data of G. R.

with the open circles in Fig. 2, an exceedingly sharp anomaly is found at 81.5°K. Around the transition temperature, it takes a long time (1—2 hr) for thermal equilibration, so that the heat capacity values in these regions are inferior in accuracy to those in the normal region where the thermal relaxation time is of the order of 2—4 min. The heat capacity peak is so sharp that 90% of the whole enthalpy change occurs in the narrow range of 3°K. Although the latent heat effect could not be observed exactly on account of the experimental difficulty, it is highly probable that the transition is of the first order. Three independent runs were performed for the determination of the enthalpy change of the transition. The average value is found to be 1504.56±5.34 J/mol. The entropy of the transition is 18.674 J/(°K·mol). This value corresponds formally to $R \ln 9.45$. The anomalous heat capacity has a tail extending down to about 60°K and sharply decreases to the normal value at the higher temperature side.

Experimental data of its phenol derivative are plotted with the filled circles in Fig. 2 with those of G. R. The result stands in contrast with that of G. R. in the point that no thermal anomaly is observed at the temperature region of G. R. Smoothed values of the heat capacity, enthalpy, entropy and Gibbs-energy functions are listed for G. R. in Table 3 and of its phenol derivative in Table 4. Values of their thermodynamic functions at 298.15 K are listed in Table 5. The detailed values of the anomalous heat capacity are listed in Table 6.

Discussions

In the present time we know only three free radical crystal whose heat capacity had been measured. Among them, for BDPA[4] and tetramethyl-2,2,6,6-piperidol-4-oxyl-1,[5] their heat capacity data show that there is no phase transition and their behaviors of the magnetic heat capacity are explained with a linear Ising and Heisenberg models with a coupling between neighboring chains. On the other hand, the heat capcacity data of Wüster Blue Perchlorate (WBP)[6] shows that there is a phase transition at 189.9 K which is corresponding to the magnetic transition temperature.[7,8] The mechanism of this magnetic transition has been discussed by Chesnut[9] and McConnell[10,11] and others. Chesnut explained the mechanism by the model of exciton-exciton interactions. McConnell *et al.* on the other hand, investigated the pressure dependence of the magnetic transition of WBP and $(C_6H_5)_3PCH_3(TCNQ)_2$ and found that this magnetic transition took place even under the low exciton density. Based on these observation, it seems to be improbable that the exciton-exciton interactions make the transition to be cooperative. Moreover the change of crystal structure of WBP[12] was observed by the X-ray analysis. According to these facts, it may be plausible to consider that the magnetic anomaly is induced by the change of the crystal structure.[13]

Now, turning to the present substances investigated, the measurement of the magnetic susceptibility of G. R.[1] shows the magnetic transition at 82.5°K and G. R. was found to be paramagnetic above the transition temperature and to be diamagnetic (weak paramgnetic[14]) below it. The sharp rise of the magnetic susceptibility from the low temperature side of the transition is considerablly

different from those of BDPA and WBP. This behavior cannot be explained only by use of a model of magnetic chains linearly interacted, but may be interpreted in such a way that a kind of pairing process of spins is assumed with, large J-value below the transition temperature and small J-value above it. If this kind of pairing state be of singlet (dimerization of spins), entropy change for this process amounts to R ln 2. The present results of the heat capacity, however, revealed that the entropy change associated with the phase transition is found to be R ln 9.45. There is a large difference, R ln 4.73 between them. In order to explain this large discrepancy, we may expect that the magnetic pairing process may be accompanied with a cooperative change of crystal structure. In this respect, it is very much desirable to study the crystal structure of the low temperature phase of this material.

We may proceed to the case of the diamagnetic phenol derivative. As is shown in Fig. 2 in the temperature above the transition points of G. R., the heat capacities of the phenol derivative are at the most 2% larger than those of G. R. While below the transition region the heat capacities of the phenol are about 5% larger than those of G. R. These facts probably mean that the crystal structure of G. R. changes at the transition temperature, whereas that of the phenol derivative does not. The results of measurements of the heat capacity and of X-ray analysis show that the crystal structure of G. R. is almost the same to that of the phenol derivative at room temperature. Therefore, we should like to consider that the phase transition of G. R. is induced by a cooperative process of pairing of magnetic spins in contrast to the case of WBP. In conection with this point of view, it may be recalled that some authors[13] attributed the phase transition of WBP to the order-disorder transition of perchlorate ion accompanied with the charge-transfer of TMPD cores. In this case perchlorate ions are in an ordered state with respect to their orientation below its transition temperature. This process results in the difference of the electrostatic potential at TMPD cores and therefore is accompanied by the charge-transfer. Here, the unpaired electrons are localized in one of the two molecules in this model. However it may be, this charge-transfer state may be called rather ionic-bonded one. On the analogy of this process, one may propose that the magnetic transition of G. R. is induced by the creation of "covalent-like" bond between two molecules. For, in contrast to the existence of perchlorate ion between WB ions, molecules of G. R. are directly in contact with each other. From this points of view, the symbol J given above means the coulomb integral rather than the exchange one.

Apart from the discussion of the phase transition of the stable free radical crystal, we may illustrate the following facts for reference.

There are known some substances which change their crystal structures accompanied with magnetic anomaly. Vanadium dioxide is one of the case. The crystal structure of the low temperature phase of this compound constitutes a deformed lattice of the rutile-type structure and that of the high temperature phase constitutes the normal rutile-type one.[15] This substance has a magnetic anomaly[16] at the corresponding transition temperature. Some authors[17] assume the appearance of metal-metal bond in its crystal, since the metal-metal distance is found to be shortened at the lower temperature phase. Our model adopted to explain the mechanism of the phase transition of G. R. may be looked upon as a similar kind one.

Summary

The heat capacities of G. R. and its phenol derivative were measured in order to study the nature of the magnetic anomaly. It was found that the heat capacity of G. R. shows an anomaly at 81.5°K which just corresponds to the magnetic transition temperature. The enthalpy and entropy of transition are 1504.6 J/mol and 18.67 J/(°K·mol) (*i. e.* R ln 9.45). The heat capacity of its phenol derivative, on the other hand, has no anomaly at the temperature region measured. The thermodynamic functions for both substances were evaluated by integrating respective heat capacity data. The values at 298.15°K are, in units of J/(°K·mol); $C_p°=654.28$, $S°=670.10$, $(H°-H_0°)/T=341.31$, $-(G°-H_0°)/T=328.74$ for Galvinoxyl radical, $C_p°=654.28$, $S°=662.24$, $(H°-H_0°)/T=340.04$, $-(G°-H_0°)/T=322.18$ for its phenol derivative.

The authors should like to express their sincere thanks to the Toyo Rayon Co., Ltd. who defrayed a part of the financial support for the present investigation.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 1531—1533 (1969)

The Reactions of a Mixture of Benzene and *cis*-2-Butene Photosensitized by Cadmium

Shigeru TSUNASHIMA, Shin SATOH and Shin SATO

Department of Applied Physics, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received November 15, 1968)

Using the cadmium-photosensitized *cis-trans* isomerization of *cis*-2-butene, the lifetime of triplet benzene has been estimated to be of the order of 10^{-5} sec for both benzene-d_0 and -d_6. This technique provides a new method for measuring the lifetime of the triplet state of some molecules.

Recently, the efficiencies of hydrocarbons in quenching the triplet cadmium have been measured using the cadmium-photosensitized *cis-trans* isomerization of *cis*-2-butene.[1] In the cases examined previously, the activated quencher molecule formed in quenching triplet cadmium atoms did not cause the isomerization of 2-butene.[1] In the case of benzene, however, the molecule thus activated is thought to cause the isomerization, because the isomerization of 2-butene occurs effectively by means of triplet benzene.[2,3] Namely, a two-step energy-transfer-process such as cadmium→benzene →2-butene may be involved in the reactions of a mixture of benzene and 2-butene photosensitized by triplet cadmium. If this energy-transfer-process is indeed involved, it may be possible to estimate the lifetime of triplet benzene.

The lifetime of triplet benzene has already been estimated in the benzene-photosensitized *cis-trans* isomerization of 2-butene[3] and in the benzene-photosensitized phosphorescence of biacetyl.[4] In these cases, however, such complications arise as the estimation of the rate of the intersystem crossing.

With this prospect in mind, a study of the reactions of a mixture of benzene and *cis*-2-butene photosensitized by triplet cadmium was undertaken.

Experimental

Research-grade *cis*-2-butene supplied by the Takachiho Trading Co. was used after bulb-to-bulb distillation. The gas-chromatographic analysis showed that the impurities were less than 0.5%. Spectorgrade benzene supplied by the Wako Chemical Co. was used after recrystallization and bulb-to-bulb distillation. The mass-spectrometric analysis of benzene-d_6 supplied by the Merck Co. showed that the isotopic impurities were less than 2%.

The light source and the apparatus were similar to those reported on in a previous paper.[5]

A mixture of benzene and *cis*-2-butene was irradiated at 270±1°C in the presence of cadmium vapor with a cadmium lamp through a Toshiba UV-29 filter which cut off all wavelengths below 2700Å. After being separated from benzene with a cold trap at −80°C, the 2-butenes were analysed by gas chromatography using a column packed with dimethylsulforane on celite (30 m long) supplied by the Shimadzu Co.

Immediately after each run, the light intensity of the resonance line at 3261 Å was measured using the cadmium-photosensitized *cis-trans* isomerization of *cis*-2-butene assuming the quantum yield to be 0.5.[5] The initial rate of the isomerization (R) was calculated using Eq. (I):

$$R = (([C]+[T])/2t) \ln (([C]+[T])/([C]-[T])) \quad (I)$$

Here, t represents the reaction time. [C] and [T] are the amounts of *cis* and *trans*-2-butenes respectively obtained after the irradiation.[1]

Results

The rate of the *cis-trans* isomerization of 2-butene was measured at 270±1°C as a function of the benzene pressure (at constant butene pressures) and also of the butene pressure (at a constant benzene pressure and a constant pressure ratio of benzene to 2-butene).

Figure 1 shows the plots of R/R_0 as a function of the benzene pressure at 5.1 mmHg, 14.7 mmHg, and 22.2 mmHg of *cis*-2-butene. Here, R and R_0 are the rates of the isomerization of *cis*-2-butene in the presence and in the absence of benzene respectively. The rate of the isomerization decreased

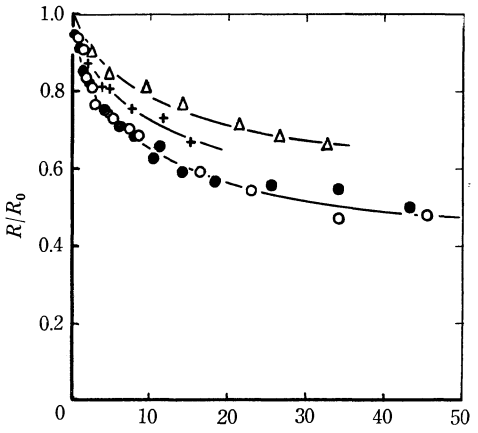

Fig. 1. The ratio of R/R_0 as a function of the benzene pressure at constant 2-butene pressures; 5.1 mmHg (○), 14.7 mmHg (+), and 22.2 mmHg (△) for for benzene-d_0; 5.1 mmHg (●) for benzene-d_6.

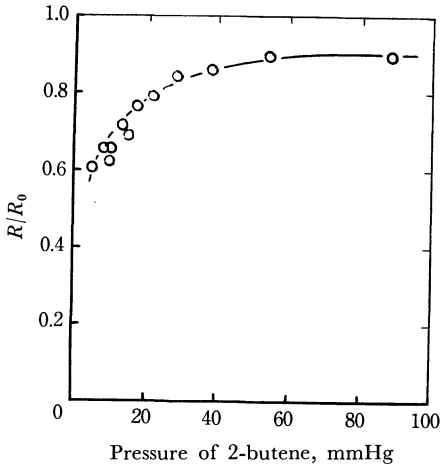

Fig. 2. The ratio of R/R_0 as a function of the 2-butene pressure at 10.9 mmHg of benzene-d_0.

with an increase in the benzene pressure. The effect of benzene-d_6 on the rate of the isomerization was almost the same as that of benzene-d_0; *i. e.*, there was no hydrogen-deuterium isotope effect on the rate of isomerization.

Figure 2 shows the plots of R/R_0 as a function of the 2-butene pressure at 10.9 mmHg of benzene. The rate of the isomerization increased with an increase in the butene pressure.

As is shown in Fig. 3, the R/R_0 values obtained with equal pressures of benzene and 2-butene increased with an increase in the total pressure. This clearly indicates that an energy transfer process such as cadmium→benzene→2-butene is involved in the mechanism.

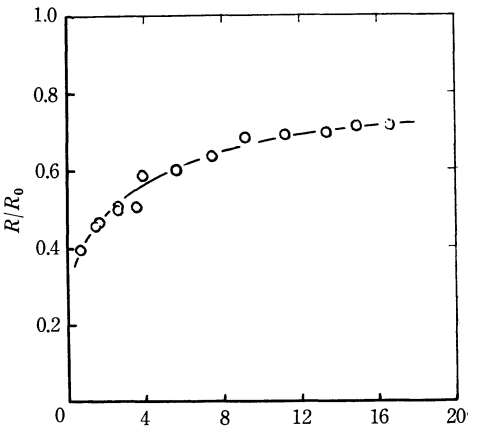

Fig. 3. The ratio of R/R_0 as a function of the total pressure at equal pressures of benzene-d_0 and 2-butene.

Discussion

If a benzene molecule quenches only the triplet cadmium atom and does not cause the *cis-trans* isomerization of 2-butene, a linear relationship should be obtained between R/R_0 and the pressure ratio, [benzene]/[2-butene].[1] As is shown in Fig. 4, this is not the case with benzene-2-butene mixtures. If an activated benzene molecule formed in quenching triplet cadmium can always cause the *cis-trans* isomerization without following the other reaction paths, the rate of the isomerization should not be affected by the pressure of benzene or 2-butene. However, the ratio R/R_0 is affected by the pressure change in both benzene and 2-butene. These facts indicate that only a part of the activated benzene formed in quenching triplet cadmium

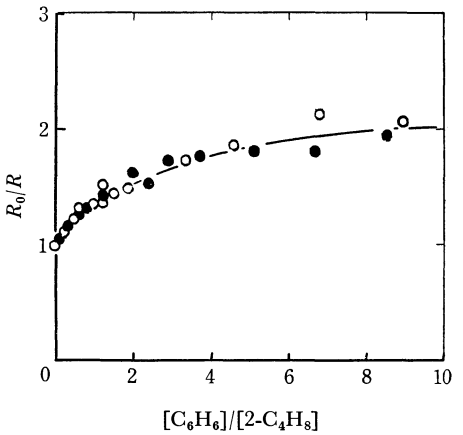

Fig. 4. The ratio of R_0/R as a function of the ratio of the pressure of benzene to that of 2-butene. ○: benzene-d_0; ●: benzene-d_6.

5) S. Tsunashima and S. Sato, This Bulletin, **41**, 284 (1968).

gives rise to the isomerization of 2-butene.

To explain these results, the following mechanism may be suggested:

$$Cd + h\nu \rightarrow Cd^*$$

$$Cd^* + 2\text{-}C_4H_8 \rightarrow Cd + 2\text{-}C_4H_8^* \quad (1)$$

$$2\text{-}C_4H_8^* + M \rightarrow \tfrac{1}{2}cis + \tfrac{1}{2}trans + M \quad (2)$$

$$Cd^* + C_6H_6 \rightarrow Cd + \alpha C_6H_6^* + (1-\alpha)C_6H_6' \quad (3)$$

$$C_6H_6^* \rightarrow C_6H_6 \quad (4)$$

$$C_6H_6^* + C_6H_6 \rightarrow 2C_6H_6 \quad (5)$$

$$C_6H_6^* + 2\text{-}C_4H_8 \rightarrow C_6H_6 + 2\text{-}C_4H_8^* \quad (6)$$

$$C_6H_6' + M \rightarrow C_6H_6 + M \quad (7)$$

where Cd* and 2-C_4H_8* are, respectively, a triplet cadmium atom and a triplet 2-butene molecule which isomerizes to *cis*- or *trans*-2-butene with an equal probability by collisional deactivation.[5] C_6H_6* may be a triplet benzene molecule in the state of $^3B_{1u}$, because its excitation energy is close to that of triplet cadmium. C_6H_6' denotes an activated quencher molecule which can not cause the isomerization of 2-butene and which is probably the vibrationally-excited ground state of benzene. α is the fraction of C_6H_6* formed by the reaction (3).

The steady-state treatment of the above mechanism gives the following equation:

$$(1-\beta)/(R/R_0-\beta) = 1/\alpha(1+k_4/k_6[C_4H_8] + (k_5/k_6)([C_6H_6]/[C_4H_8])) \quad (II)$$

where

$$1/\beta = 1 + (k_3/k_1)([C_6H_6]/[C_4H_8])$$

The left-hand side of Eq. (II) involves k_3/k_1, which is the relative efficiency of benzene against 2-butene in quenching triplet cadmium.

Using the data obtained with a constant pressure ratio, the left-hand side of Eq. (II) is in Fig. 5 plotted against the reciprocal of the 2-butene pressure, assuming various values for k_3/k_1. As the figure shows, the relation in Eq. (II) holds when the value of k_3/k_1 is assumed to be in the range of 2.5—1.5. This value is slightly larger than that calculated from the quenching cross-section of benzene obtained by Steacie and LeRoy by a physical method.[6] The value also is a little larger than those of olefins.[1] This is not unreasonable because benzene has six π-electrons and the excitation energy of triplet benzene is close to that of triplet cadmium.

Using the data obtained at a constant benzene pressure (Fig. 2), the α ratios are estimated to be 0.77±0.18 (2.5), 0.71±0.20 (2.0), and 0.66±0.23 (1.67), where the values in parentheses indicate the assumed values of k_3/k_1. That is, triplet benzene is about 70% formed through the reaction (3), although the ratio depends slightly on the estimation of k_3/k_1.

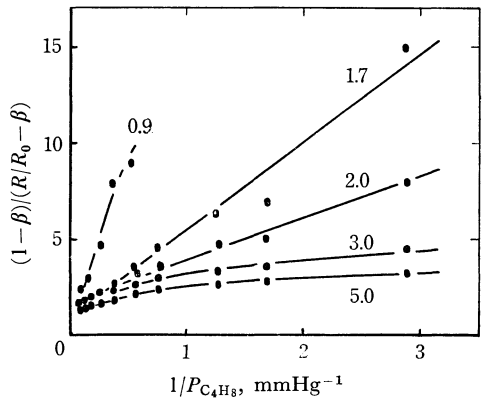

Fig. 5. The plots of Eq. (II) at various values of k_3/k_1 as a function of the reciprocal of the 2-butene pressure.

The rate constant ratios of k_5/k_6 and k_4/k_6 are estimated to be 0.05 and in the order of 10^{-4} mol/l using Eq. (II), k_5/k_6, which is the ratio of the rate constant of the self-quenching of triplet benzene against that of the energy-transfer process to 2-butene, is very small. This is consistent with the results obtained in the benzene-photosensitization of 2-butene.[2]

The lifetime of triplet benzene ($1/k_4$) is estimated to be in the order of 10^{-5} sec assuming the value of k_6 to be 10^9 l/mol sec (*cf.* 0.96×10^9 l/mol sec[4] and 2.0×10^9 l/mol sec[3,7]). The value of the lifetime is correct, however, in terms of the order because of a large experimental error and because of the uncertainty of the values used for the calculations, such as k_3/k_1, α, and k_6. In the benzene-photosensitization, the lifetime of triplet benzene has been estimated to be 12 μsec[3] and 26 μsec[4] at room temperature. In spite of a higher temperature and a different source of triplet benzene, the lifetime estimated here agrees well with the literature values.[3,4]

In conclusion, it may be said that the lifetime of the triplet state of some molecules can be estimated using the cadmium-photosensitized *cis-trans* isomerization of 2-butene, although this method contains a few parameters.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 1534—1538 (1969)

Electrodeposition of Water-soluble Resin by a Constant Voltage or by Pulses*1

Yoshio NAKAMURA, Fumio OKI and Hiroshi NOZAKI

Institute of Industrial Science, The University of Tokyo, Roppongi, Minato-ku, Tokyo

(Received November 20, 1968)

The mechanism of deposition was investigated using maleic-linseed oil as a sample. The deposition was made by a constant voltage or by continuous pulses with high voltages, and the initial current-time relations were observed by means of a synchroscope. When we applied pulses with α/β values which were smaller than a value, the current decreased gradually after some time and a deposited film was found on the anode, but the decreases in the current was not found for a long time when the value of β was much larger than the value of α. The induction time was found from the current-time curve observed during a constant voltage deposition. These results were discussed from the standpoint that the deposited film is formed by coagulation resulted from ionic combination with hydrogen ions.

Detailed knowledge of the mechanism of the electrodeposition of water-soluble resin would be useful in enabling the coating method to be satisfactorily applied in varying circumstances.

Finn and Mell[1] pointed out that local ionic precipitation or coagulation may be important factor in the film formation. From the results of the analyses of the deposited film, it has been made clear that the role of metal ions in deposition is minor,[2-4] this is clear from the fact that we can obtain the deposited film on platinum plates. Tawn and Berry[5] suggested a mechanism in which the coagulation of organic anions results from an increase in the concentration of hydrogen ions generated at the anode, but they could not support the mechanism with specific experimental results. Maeda *et al.*[3] found that $I \cdot \tau^{1/2}$ is nearly constant and explained $I \cdot \tau^{1/2}$ as a parameter which gives a critical concentration of hydrogen ions at the anode, where I=current density and τ is the induction time on the anode potential *vs.* the time curve which is observed during a constant current deposition. Moreover, they found that the period of the induction time increases with an increase in the acid value of the sample.

From the results of many analyses of the gases given off at the anode,[6-9] it has been clarified that the Kolbe reaction of organic anions in deposition is minor and that the principal electrode reaction during deposition is the oxygen evolution reaction.

Up to the present, many fundamental investigation related to the mechanism of the deposition have been performed at a constant current. In the case of the deposition of water-soluble resin, the current density is low, so that the anode potential for the period of induction time is of the order 1 to 2 V (*vs.* SCE). On the other hand, the practical application of the deposition of water-soluble resin to painting has been performed at a constant voltage, the values of the applied voltages ranging 50 to 200 V. It is questionable whether or not there is any essential difference in the electrode reaction between the cases of a constant current deposition and those of a constant voltage deposition.

In this report, we will describe the results observed by the use of a synchroscope in observing the electrode phenomena at a constant voltage deposition or at a continuous pulse deposition.

Experimental

Samples. The maleic-linseed oil used as the water-soluble resin was obtained by the additive reaction of maleic anhydride to linseed-oil. The reaction was performed for three hours at 200°C and for an hour at

230°C. During the reaction, the mixed solution was stirred mildly and kept in a nitrogen atmosphere. The mole ratio of maleic anhydride to linseed oil was 2.4 : 1. The crude maleic-linseed oil was neutralized by a potassium hydroxide solution in order to make it soluble in water after which the solution was kept in a separating funnel for a few days. After removing the unsoluble substances, we added sulfuric acid to the solution in order to coagulate the maleic-linseed oil. Then the coagulated maleic-linseed oil was dissolved in an ethylcellosolve-water solution and stirred for about ten hours.

A small quantity of carbon tetrachloride was then added to the solution. The solution was shaken for about an hour and then kept in a separating funnel for a day. The maleic-linseed oil was recovered in the carbon tetrachloride layer and the carbon tetrachloride was removed by vaporization. Finnally, maleic-linseed oil was kept for several hours at 50°C and 5 mmHg. The purification procedure after the coagulation by sulfuric acid was performed two times. The purified maleic-linseed oil was then dissolved into a potassium hydroxide solution and the solution used as a sample. The pH of the solution was adjusted only by a potassium hydroxide solution and by the maleic-linseed oil.

Apparatus. The cell was of a beaker type with two platinum plates as the cathodes. The distance between the cathodes was 5 cm, and the surface area of each cathode was 6 cm^2. The platinum anode was placed at the center of the cathodes. A bright platinum plate and wire were used as the anodes; the apparent surface areas of the platinum plate and wire were 2 and 0.31 cm^2 respectively. The platinum plate and wire were rinsed with a concentrated potassium hydroxide solution and dipped in a nitric acid solution for several minutes before each run.

A Takasago Regulated DC Power Supply GPO-50-2 was used as the potentiostat. The pulse generator used in this experiment was an Iwasaki Power Supply PS-201. The potential-time or current-time curves were observed by means of a National Synchroscope SS-5302 B.

The deposition (electrolysis) circuit is shown in Fig. 1. The bath solution was kept at 25±0.5°C.

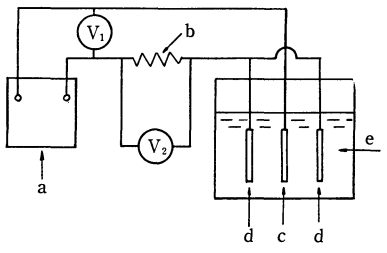

Fig. 1. Deposition circuit.

Results

Deposition by Continuous Pulses. When we applied continuous pulses to the deposition cirucit, the figure shown in Fig. 2 was obtaind.

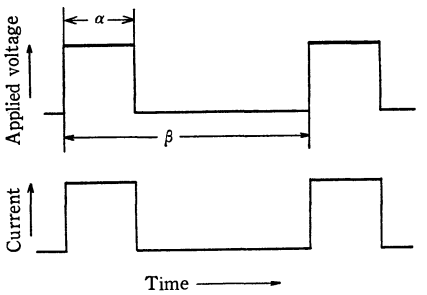

Fig. 2. Applied voltage and current curves against to time before deposited film is formed.

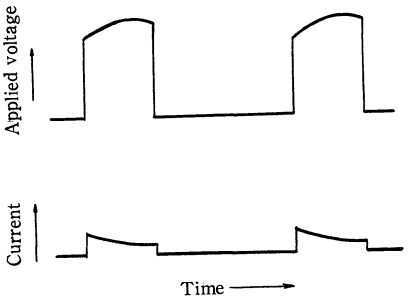

Fig. 3. Applied voltage and current curves against to time after deposited film was formed.

On the other hand, when we decreased only the value of β (see Fig. 2) while keeping the pulse width, α (see Fig. 2), constant, the figure gradually changed to the figure shown in Fig. 3.

The current decreased and the applied voltage increased. These phenomena were caused by the resistance of the deposited film on the anode. Actually, the film was found to have been deposited on the anode after the current decreased.

On the other hand, when the value of β was much larger than the value of α, the current has never been observed to decrease over a long period. These phenomena show that the film formation is not made by the direct discharge of organic anions. If the film formation is made by the direct discharge of organic anions, the current will decrease in spite of the value of β.

In order to make these phenomena clear, we investigated the effects of the current density, the pH of the bath solution, and the rate of the rotation of the electrode on the value of α/β_0, where β_0 is a value of β such that the current begins to decrease one minute after the value of β has been set at a constant value of α. The relation α and α/β_0 are shown in Table 1 at several applied potentials. The values of the applied potential and the current in Table 1. were measured before the deposited film was formed, that is, before the current decreased. The resin concentration was 5% in weight and the pH of the bath solution was 7.6. As may be seen in Table 1, the value of

α/β_0 is nearly constant in spite of the value of α at a constant applied voltage.

Using a platinum wire as the anode, we measured the relation between I and α/β_0 at various applied voltages at pH 7.5 and 8.6, where I is the current density. The results at pH 7.5 are shown in Table 2.

Table 1. Relation between α and α/β_0

Applied voltage (V)	Current density (mA/cm²)	α (μsec)	β_0 (μsec)	α/β_0
		5	19	0.26

pH, 1: 7.5, 2: 8.6
Resin concentration 5% in weight

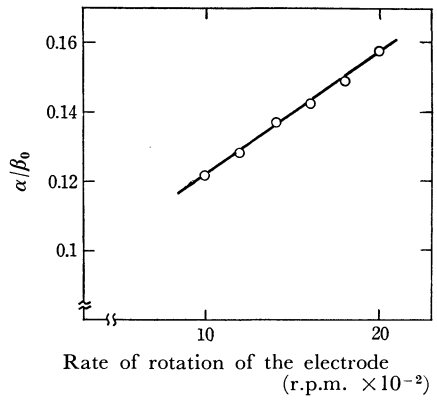

Fig. 5. Relation between α/β_0 and rate of rotation of the electrode. Resin concentration 5% in weight, pH 8.8.

Figure 4 shows the relation between I and α/β_0. α/β_0 decreases with an increase in the current densities.

Using a rotative electrode, we established the effects of the rate of the rotation of the electrode on the α/β_0 value at a constant applied voltage. The results are shown in Fig. 5. The resin concentration was 5% in weight, and the pH of the bath solution was 8.8. The observed current density was not affected by the rate of the rotation.

Constant Voltage Deposition. An induction time has been observed on the potential-time curve when the deposition was performed by a constant current density. It has been found that the values of $I \cdot \tau^{1/2}$ are nearly constant.[3,10] On the other hand, when the deposition was performed by a constant voltage with a high applied voltage, we found no induction time on the current-time curve recorded by means of an XY recorder. These findings show that the direct discharge of organic anions may occur at a constant voltage deposition. However, when the deposition is performed by a constant voltage, the initial current density is much higher than a current density at a constant current deposition. Therefore, the induction time may be considered to be very short at the constant-voltage deposition according to the relation that $I \cdot \tau^{1/2} =$ constant.

Then we observed an initial current-time relation by means of a synchroscope during a constant voltage deposition.

When the bath solution was a buffer solution composed of a 1/15 M Na_2HPO_4 solution (160 cc) and a 1/15 M KH_2PO_4 solution (10 cc), we obtained the current-time curve shown in Fig. 6. When the bath solution was a buffer solution including 5% (by weight) of maleic-linseed oil, the results shown in Fig. 6 were obtained. Curve 2 decreases with time more rapidly than Curve 1 and has some

Applied voltage 8 (V)

induction time. The period of time from P to Q is the induction time; we named that time τ_v. τ_v corresponds to the induction time τ (see Fig. 10) in the constant-current deposition.

Current-time curves observed at various applied voltages are shown in Fig. 7, where the resin concentration was 5% (by weight) and where the pH of the solution was kept at 7.7. The current densities for the induction time increase weight an increase in the applied voltages, but the length of the induction time decreases with an increase in the applied voltages.

The current-time curves observed at various pHs of the solution are shown in Fig. 8. The applied voltage was kept at 8 V, and the resin concentration was kept at 5% (by weight). The current densities for the induction time increase with an increase in the pHs of the solution.

Discussion

Deposition by Continuous Pulses. We consider that the decrease in the current, *i. e.*, the deposition of organic anions, was affected by only the value of β when α was constant. The anode reaction during the current flow must be the electrolysis of water as follows:

$$4H_2O = 4H^+ + 2O_2 + 4e \quad (1)$$

$$4OH^- = 2H_2O + O_2 + 4e \quad (2)$$

Hydroxide ions are in equilibrium as follows:

$$H^+ + OH^- = H_2O \quad (3)$$

Thus, the concentration of hydrogen ions will increase near the anode surface. However, hydrogen ions will decrease upon diffusion and the chemical reaction shown in Eq (4):

$$R(COO^-)_n + H^+ = R(COO^-)_{n-1}COOH \quad (4)$$

This reaction leads to the coagulation of organic anions, *i.e.*, deposition.

The schematic representation of the change in the concentration of hydrogen ions against the time at the anode is given in Fig. 9 (a) and (b). Figure 9(a) shows current *vs.* time curves, while Fig. 9(b) shows a speculative representation of the concentration of hydrogen ions *vs.* time curves at the anode surface. If the current is like Curve 1, that is to say, if β is sufficiently long in comparison

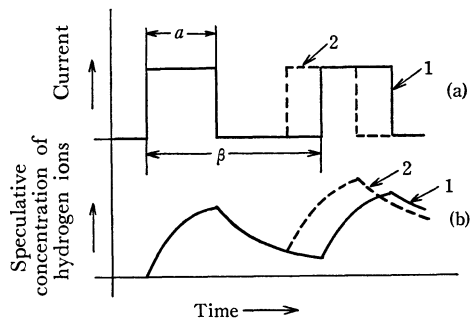

Fig. 9. Current and speculative concentration of hydrogen ions curves against to time.

with α, the diffusion time of the hydrogen ions is so long compared with the generation time of hydrogen ions that the increase in hydrogen ions at the anode surface remains very small.

However, if the β value is decreased while the value of α is kept constant, the decrease in the number of hydrogen ions by diffusion is restrained compared with the generation of the ions, so that the hydrogen ion concentration will increase rapidly at the anode. Thus, when the β value is decreased while the value of α is kept constant, the current may decrease as a result of the coagulation of organic anions.

When the applied voltages are increased, the current densities increase. If the value of α is kept constant, the rate of the generation of hydrogen ions at the anode increases with an increase in the current densities, in accordance with Faraday's law. Therefore, the period of time until hydrogen ion concentration increases to a certain critical concentration will decrease with an increase in the current densities. Thus, the value of α/β_0 decreases with an increase in the applied voltages, *i. e.*, the current densities.

As the sample became soluble in water at about pH 7 and as the pH of the neutralization point was about 9 to 10, carboxyls of this sample are not neutralized completely below pH 9. Therefore, as the number of dissociated organic anions per molecule increases with an increase in the pHs, the number of hydrogen ions required to neutralize dissociated anions will increase with an increase in the pHs of the bath solution. Consequently, if the value of α and the current density are kept constant, the value of β_0 must decrease with an increase in the pHs of the solution.

If the solution is stirred, the diffusion layer of the hydrogen ions will decrease. As a result, the diffusion rate of hydrogen ions from the anode to the bulk solution increases upon an increase in the rate of the rotation of the electrode. Therefore, the increase rate of the hydrogen ion concentration at the anode during electrolysis will decrease with an increase in the rate of the rotation of the electrode when the other conditions are kept constant. Thus, if the value of α and the current density are kept constant, the value of β_0 must decrease, *i. e.*, α/β_0 increases with an increase in the rate of the rotation of the electrode.

Constant Current Deposition. In order to compare these findings with the results on constant-current deposition, we measured the relation between I and $I\cdot\tau^{1/2}$ in the constant-current deposition using the same sample as we used in studying the constant-voltage deposition: the results are shown in Fig. 10. $I\cdot\tau^{1/2}$ increases with an increase in the current densities. We calculated the values of $I_v\cdot\tau_v{}^{1/2}$ from the results of the constant-voltage deposition (see Fig. 7): they are shown in Fig. 10, where I_v is the arithmetic mean value of the current density at induction time τ_v (see Fig. 6). As is shown in Fig. 10, the values of $I_v\cdot\tau_v{}^{1/2}$ are comparable to the values of $I\cdot\tau^{1/2}$. The values of $I_v\cdot\tau_v{}^{1/2}$, calculated from Fig. 8, are shown against the pHs of the bath solution in Fig. 11. $I_v\cdot\tau_v{}^{1/2}$ increases with an increase in the pHs of the bath solution. These results can be explained by the same consideration as we used to describe the effects of the pHs of the solution on the α/β_0 in continuous-pulse deposition. Thus, the film formation in constant-voltage deposition can also be explained in terms of the coagulation of organic anions.

Infrared Spectra of Biuret-hydrate and Its Deuterated Compound

Toyozo UNO, Katsunosuke MACHIDA and Yutaka SAITO

Faculty of Pharmaceutical Sciences, Kyoto University, Sakyo-ku, Kyoto

(Received December 2, 1968)

The infrared spectra between 4000 and 33 cm^{-1} of biuret-hydrate and between 4000 and 250 cm^{-1} of its deuterated compound have been recorded. The vibrational assignments have been made by referring to the infrared spectra of the related compounds and the isotopic frequency shift. Normal coordinate analysis of the in-plane vibrations of biuret and biuret-d_5 as twelve-body problem has been carried out by using the molecular model of the planar *trans-cis* conformation. A simple Urey-Bradley force field has been employed and the force constants have been refined by the least squares method. The calculation of potential energy distributions has shown that the NH in-plane deformation and the CN stretching vibrations couple appreciably with each other and give the imide II and III bands at 1515 and 1365 cm^{-1}, respectively, just as in the case of diacetamide.

In the infrared spectra for the condensed phase, aliphatic imides[1] and monosubstituted amides[2] show the imide II band and the amide II band, respectively, in the region between 1550 and 1500 cm^{-1}. These bands are fairly strong and quite characteristic of the –CONH– group in which the C=O and the NH bonds take the *trans* conformation with each other.[3] It has been proved by the normal coordinate analysis of *N*-methylacetamide[4] and diacetamide[5] that both the amide II and the imide II bands arise from the coupling between the NH in-plane deformation and the CN stretching vibrations of the *trans* –CONH– group. According to the X-ray analysis, a molecule of biuret ($NH_2CONHCONH_2$) has the *trans-cis* –CONHCO– group[6] in the biuret-hydrate crystal. It is interesting to examine the infrared spectra of this crystal and to see if there exists the coupling analogous to the case of amides and imides.

Besides the hydrate crystal, biuret has also the anhydrate crystal. The infrared spectra of both crystals have been recorded in the region between 4000 and 650 cm^{-1} and several bands have already been assigned.[7-9] In the present paper, we report the infrared spectra of biuret-hydrate between 4000 and 33 cm^{-1} and the assignment of the fundamental frequencies of biuret given on the basis of the spectral change on deuteration and a comparison with related compounds such as urea,[10] diacetamide[5] and acylureas.[11] This paper includes also the normal coordinate analysis of the in-plane vibrations of biuret and biuret-d_5 in the *trans-cis* conformation.

Experimental

Commercially available biuret was purified several times by recrystallization from water and ethanol. The hydrate was prepared by crystallization from water.[12] Deuterated biuret-hydrate was prepared by the usual exchange reaction with heavy water, and was left in the atmosphere saturated with heavy water for three weeks in order to avoid the contamination of the anhydrate crystal in the sample.

The infrared spectra were recorded on a Koken DS 301 infrared spectrophotometer equipped with sodium chloride and potassium bromide prisms (4000—450 cm^{-1}), on a Perkin Elmer model 521 grating spectrophotometer (900—250 cm^{-1}) and on a Hitachi FIS-3 grating spectrophotometer (400—33 cm^{-1}). The samples were subjected to the measurement in the form of a solid dispersed in Nujol and hexachlorobutadiene (H.C.B.). The absorption frequencies are listed in Tables 1 and 2 together with the assignment.

Results and Discussion

The Region above 1800 cm^{-1}. Biuret-hydrate shows four bands at 3487, 3438, 3214 and 3010 cm^{-1}. These bands are obviously due to the stretching vibrations of the NH and the NH_2 group as well as of the crystal water, but it is rather difficult to assign them to the specific vibrations of individual groups. These bands are replaced by the bands at 2585, 2412, 2321 and 2272 cm^{-1} on deuteration.

The Region between 1800 and 900 cm^{-1}. Figure 1 shows the infrared spectra between 1800 and 800 cm^{-1} of biuret-hydrate and its deuterated compound. The undeuterated compound shows only three bands between 1750 and 1550 cm^{-1}, although two C=O stretching and two NH_2 bending bands are expected in this region. On deuteration, the two bands at 1749 and 1718 cm^{-1} shift slightly to lower frequencies and the band at 1608 cm^{-1} disappears completely as seen in Fig. 1. It is obvious therefore that the former bands are due to the C=O stretching vibrations and the latter to the NH_2 bending vibrations. By referring to biuret-anhydrate which shows two peaks at 1620 and 1588 cm^{-1},[8,6] it is conceivable that the two NH_2 bending absorptions of hydrate crystal overlap to give one band at 1608 cm^{-1}. The corresponding ND_2 bending absorptions of deuterated biuret-hydrate were identified as the weak bands at 1168 and 1130 cm^{-1} from analogy with urea-d_4.[10] The band at 1130 cm^{-1} of biuret-hydrate may be assigned to the NH_2 rocking vibrations and the band at 915 cm^{-1} of deuterated biuret-hydrate to the ND_2 rocking vibrations. These frequencies are comparable to the corresponding frequencies of urea and urea-d_4.[10]

Takimoto assigned the bands of biuret-anhydrate at 1420, 1326 and 950 cm^{-1} to the CN stretching vibrations.[9] The bands of biuret-hydrate corresponding to these bands are observed at 1420, 1365 and 958 cm^{-1}. Among these bands, the bands at 1420 and 958 cm^{-1} hardly shift on deuteration as seen in Fig. 1, and are assigned undoubtedly to the CN stretching vibrations. The 1365 cm^{-1} band cannot be assigned to a simple CN stretching vibration since this band disappears on deuteration as seen in Fig. 1. Uno and Machida concluded in consequence of the normal coordinate analysis of diacetamide that the imide II and III bands arise from the coupling between the NH in-plane deformation and the CN stretching vibrations of the –CONHCO– group. Analogously the deuteration sensitive band at 1365 cm^{-1} of biuret-hydrate may be assigned to the imide III band arising from the coupling between the NH in-plane deformation and the CN stretching vibrations of the –CONHCO– group. To the imide II absorption of biuret-hydrate expected from this coupling, we assigned the weak band at 1515 cm^{-1} which disappears on deuteration. Such a weak imide II band has also been found around 1480 cm^{-1} for acylureas.[11] The 1096 cm^{-1} band is assigned to the remaining CN stretching vibration. For deuterated biuret-hydrate, the bands at 1462, 1435, 1273 and 935 cm^{-1} can be assigned to the four CN stretching vibrations. According to the normal coordinate analysis, however, the band at 1273 cm^{-1} is due to a complicated vibration concerned with the CN stretching, the ND in-plane deformation (imide III') and the ND_2 rocking vibrations.

The Region between 900 and 33 cm^{-1}. Figure 2 shows the infrared spectra between 900 and 33 cm^{-1} of biuret-hydrate and between 900 and 250 cm^{-1} of deuterated biuret-hydrate. Referring to the C=O out-of-plane deformation frequency of urea (785 cm^{-1}) and urea-d_4 (776 cm^{-1}),[10] we assigned the bands at 801 and 765 cm^{-1}

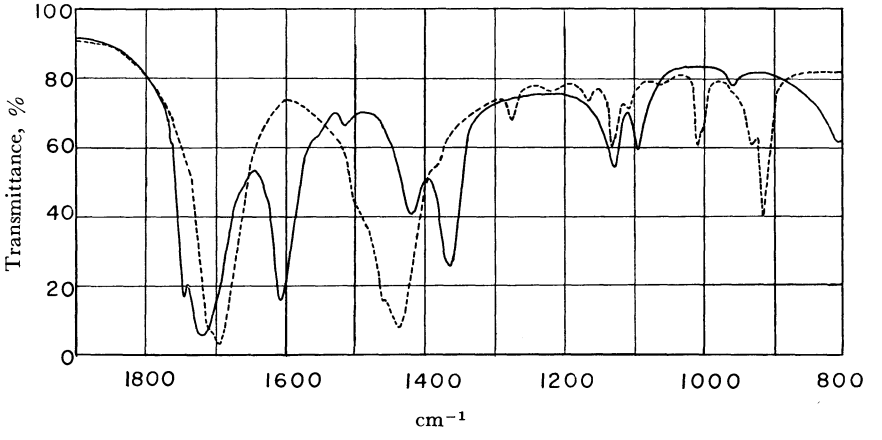

Fig. 1. Infrared spectra of biuret-hydrate (——) and its deuterated compound (----) in the region between 1900 and 800 cm^{-1}.

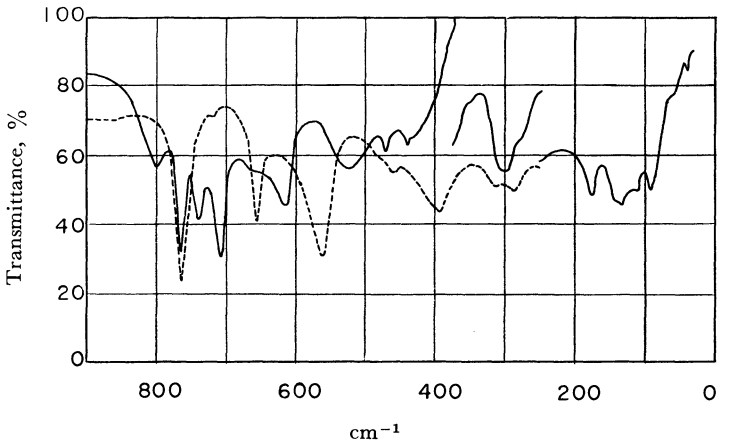

Fig. 2. Infrared spectra biuret-hydrate (——) and its deuterated compound (----) in the region between 900 and 33 cm^{-1}.

of biuret-hydrate and the band at 764 cm^{-1} of deuterated biuret-hydrate to the corresponding vibrations. The band at 712 cm^{-1} is assigned to the NH_2 wagging or the NH out-of-plane deformation (imide V) vibrations and the band at 520 cm^{-1} to the NH_2 torsional vibration from analogy with urea[10] and diacetamide.[5] The counterparts of these bands for deuterated biuret-hydrate are found at 558 and 392 cm^{-1}. Throughout this region the spectral change on deuteration is so complicated that the assignment of the bands due to the in-plane deformation vibrations is quite difficult. From the large separation between the in-plane NH and ND deformation and the in-plane skeletal deformation frequencies, it is expected at first sight that the shift of the latter frequencies on deuteration may not be appreciable. Normal coordinate analysis revealed, however, fairly big effects of the deuteration on the in-plane skeletal deformation frequencies. We assigned the bands at 741, 618, 471, 439 and 178 cm^{-1} for biuret-hydrate and the bands at 653, 558, 450 and 392 cm^{-1} for deuterated biuret-hydrate to the skeletal in-plane deformation vibrations by referring to the calculated frequencies.

Normal Coordinate Analysis

Since it is almost impossible to give a complete assignment of all fundamental frequencies of such a big molecule as biuret on the purely empirical basis, we have carried out the normal coordinate analysis according to Wilson's method.[13] The **G** matrices were set up by using the *trans-cis* conformation and the structural parameters based on Hughes *et al.*'s X-ray study[6] as shown in Fig. 3. The

NH_2 and the NH stretching vibrations were separated from the other vibrations.[13,14] A description of the internal coordinates is shown in Fig. 4 and the internal symmetry coordinates were constructed as shown in Table 3. A simple Urey-Bradley force field was employed, and the fifteen force constants shown as the set A of Table 4 were used first. In a trial calculation we transferred the bending constant H(CNC) and the repulsion constant F(CNC) from diacetamide[5] and the other force constants from urea,[15] but the calculated frequencies were

so deviated from the observed ones that we could not enter the refinement process. Then we took the values of the $K(CN)_I$, $H(CNH)_I$, H(CNC), $F(CNH)_I$ and F(CNC) from diacetamide[5] (the subscript I specifies the force constant concerned with the –CONHCO– group) and the other force constants from urea.[15] In the first step of the force constant refinement, only the frequencies higher than 900 cm^{-1} of biuret and deuterated biuret were taken into account, and the values of the stretching constants and the bending constants concerned with hydrogen atoms were adjusted several times by referring to the Jacobian matrix elements and were further refined by the least squares method. After this refinement the absorption frequencies below 900 cm^{-1} were assigned to the vibrational modes by referring to the calculated frequencies. This assignment was checked by the product rule[16] by assuming that the two unobserved frequencies of deuterated biuret were the same as the calculated frequencies. The observed product ratio (7.21) agrees well with the theoretical ratio (7.06) obtained from calculated frequencies. In the next step, we fixed the values of the repulsion constant F(HNH) and the bending constant H(CNC) to zero and 0.50, respectively, since they showed large dispersions, and refined all the other force constants to obtain a converged set (see the set A in Table 4). The value of the stretching constant $K(CN)_I$ obtained in this step is smaller than that of the CN stretching constant for the $-CONH_2$ groups, $K(CN)_U$. This result is comparable with the case of bis(biuret) copper(II) chloride[17] and is consistent with the expectation from the difference in the CN bond lengths between the –CONHCO– and the $-CONH_2$ groups. Since the two $-CONH_2$ groups are not equivalent to each other in the *trans-cis* conformation of biuret, it seems too crude to fix the two constants appearing pairwise for the two $-CONH_2$ groups to the same value. On the other hand, the increase in the number of independent force constants is not favorable to obtain any converged set of force constants uniquely. Accordingly, in the final step of the force constant refinement, we tried to refine only the stretching constants for the C=O and the CN bonds of each $-CONH_2$ group independently. Their values were initially taken from the set A, and the sixteen force constants except the repulsion constant F(NHH) were refined by the least squares method to obtain a converged set. The force constants used in the final calculation are shown as the set B of Table 4

together with their dispersions. The bonds and angles specified by the subscripted notation for the force constants are indicated in Fig. 5. Tables 5 and 6 show the frequencies calculated from these force constants, the corresponding observed frequencies and the potential energy distributions. The agreement between the calculated and the observed frequencies is excellent throughout both isotopic species.

It is seen from Table 5 that the coupling of the NH in-plane deformation vibration with the CN stretching vibrations does occur for the imide II and III frequencies empirically assigned, although it is not so appreciable as in the case of diacetamide.[5] As seen in Tables 5 and 6, the skeletal in-plane deformation vibrations couple appreciably with one another for the frequencies below 700 cm^{-1}, and it is difficult to assign each fundamental frequency to the vibration of a particular group. The vibrational mode of 1011 cm^{-1} band of deuterated biuret is quite complicated by the mixing of the C=O stretching, the CN stretching, the ND in-plane deformation, the ND_2 bending and the CNC deformation vibrations as seen in Table 6. This situation may be comparable with the cases for the 1035 cm^{-1} band of diacetamide-d_1 contributed by the skeletal stretching and deformation vibrations[5] and for the 1005 cm^{-1} band of urea-d_4 contributed by the C=O stretching and the ND_2 bending vibrations.[15] As seen in Table 4, the values of the stretching constant $K(CO)_T$ and $K(CO)_C$ obtained in the final calculation are not

$\Delta=(|\nu_{obsd}-\nu_{calcd}|/\nu_{obsd})\times 100$

much different from each other, reflecting rather small difference between the two C=O bond lengths. These values correspond nearly to the average of the K(CO)'s for urea (6.49) and diacetamide (9.80). The values of the stretching constants for the CN bonds increase in the order $CN_I < CN_{UC} < CN_{UT}$ as expected from the difference in the bond lengths. The $K(CN)_I$ is similar to the $K(CN)_I$ of diacetamide,[5] and the $K(CN)_{UC}$ to the K(CN) of urea(5.24) and close to the K(CN) of acetamide(5.53).[18,19] The $K(CN)_{UT}$ is close to that of *N*-methylformamide(6.15).[20] The values of H(NCN), F(NCN) and F(NCO) are comparable with those of urea. These results may be taken as indicating an excellent transferability of the Urey-Bradley force constants throughout a variety of urea and amide derivatives.

The authors would like to express their thanks to Professor Toru Takenaka and Miss Kazuko Nogami of Kyoto University for the measurement of the infrared spectra between 900 and 250 cm^{-1} and the staff of Central Research Laboratory, Hitachi, Ltd. for the measurement between 400 and 33 cm^{-1}. Thanks are due to the staff of the Kyoto University Computer Center for the use of the KDC II computer.

The Crystal Structure of Riboflavin Hydrobromide Monohydrate

Nobuo TANAKA,*1 Tamaichi ASHIDA, Yoshio SASADA*2 and Masao KAKUDO

Institute for Protein Research, Osaka University Joan-cho, Kita-ku, Osaka

(Received December 5, 1968)

The crystal structure of riboflavin hydrobromide monohydrate has been determined by a three-dimensional X-ray analysis. The space group is $P2_12_12_1$ with four formula units in the unit cell of dimensions $a=18.28$, $b=6.99$ and $c=14.77$ Å. The structural parameters were refined by means of a block-diagonal least-squares method, the final R factor being 0.07. The ribitol does not form a furanose ring but a chain. The protonation of the isoalloxazine ring occurs at the N(1) atom, and the C(4a)-N(10) bond is found to be a double bond. The bromide ion is situated midway between two isoalloxazine rings separated by a period along the b axis.

Riboflavin, in the form of the mono- and dinucleotide, is a prosthetic group of several enzymes concerning biochemical oxidation-reduction. These enzymes act as hydrogen carriers from a substrate to an acceptor molecule, when riboflavin alternatively accepts and releases two hydrogen atoms.

The electronic structure of riboflavin has been investigated in order to elucidate the mechanism of the transfer of the hydrogen atom. Guzzo and Tollin[1] have suggested from the study of EPR spectra that it is reduced into semiquinone by strong acid. On the other hand, Pullman and Pullman have proposed the keto form to the reduced riboflavin from the theoretical calculation.[2]

The present study has been undertaken to establish the relationship between the structural characteristics of mono-protonated riboflavin and its biological function.

Experimental

The crystals were obtained from 6 N HBr solution of riboflavin. They are yellow rods elongated along the b axis. Unit cell dimensions were determined from the equatorial Weissenberg photographs about the b and c axes, on which the powder pattern of aluminum were superposed for calibration. The crystal data are shown in Table 1.

The equi-inclination Weissenberg photographs were taken for layer lines 0 to 5 about the b axis and 0 to 10 about c with Cu$K\alpha$ radiation. The number of independent reflections recorded was 2261, but the intensities of 225 of these were too weak to be measured. The relative intensities were measured visually and the range was 1 to 4000. They were corrected for Lorentz and polarization factors and spot-size factors for the equi-inclination Weissenberg photographs, but the corrections for absorption and secondary extinction were neglected. A rod-shaped crystal having a cross section of 0.5 mm × 0.3 mm was used for the b axis photographs. A crystal for the c axis photographs, cut perpendicularly to the b axis, has a dimension of 0.2 mm × 0.2 mm × 0.3 mm.

Structure Determination and Refinement

From a three-dimensional Patterson function the bromide ion was easily located at $x=0.205$, $y=0.250$ and $z=0.119$. Fourier synthesis with the phases based on the bromide ion has an additional mirror plane because the y parameter of the heavy atom was a special value. The atoms in the isoalloxazine ring and C(1') in the ribityl group were located near the planes of $y=0.25$, while the as-

signment of the peaks to the other light atoms was somewhat puzzling because of the presence of the additional mirror plane. Successive Fourier summations were able to give well resolved peaks for all twenty-nine non-hydrogen atoms.

Atomic positions and anisotropic temperature factors were refined by a block-diagonal least-squares method. A difference Fourier map, calculated after several cycles of least-squares refinement, gave a fair indication of the positions of the hydrogen atoms. Further refinement, including hydrogen atoms, was proceeded with anisotropic temperature factors for all the non-hydrogen atoms and with isotropic ones for hydrogen atoms. Atomic scattering factors were taken from the "International Tables for X-Ray Crystallography." Anomalous scattering effect was corrected for the bromide ion ($\Delta f' = -0.9$, $\Delta f'' = 1.4$). Weighting scheme was as follows;

$$w = 1.0 \quad \text{if } |F_o| > 0$$
$$w = 0.5 \quad \text{if } |F_o| = 0$$

the R factor was reduced to 0.07 after the refinement. Final atomic parameters are listed in Table 2, and $|F_o|$ and $|F_c|$ are tabulated in Table 3.

Discussion

The bond lengths and angles are shown in Fig. 3. The mean value of the estimated standard deviations for the bond lengths between non-hydrogen atoms except the bromide ion is 0.02 Å and that for the bond angles is 1.0°.

The difference Fourier synthesis (Fig. 2) shows that the addition of proton does not occur at the O(2) atom but at N(1) by hydrogen bromide. This is also supported by the fact that both exocyclic C–O lengths correspond to that of the double bond. The present result agrees with the location of the proton suggested by theoretical calculation,[2,3] and suggests that the pathway 1 in the reduction of riboflavin shown in Fig. 4 is reasonable, contrary to Guzzo and Tollin's expectation.[1]

The C(4)–C(4a) bond in the isoalloxazine ring is 1.49 Å, which corresponds to the single bond length, and the C(4a)–N(10) bond is shorter than the mean value of the other C–N lengths. Therefore, it is presumed that π-electrons are localized at the C(4a)-N(10) bond.

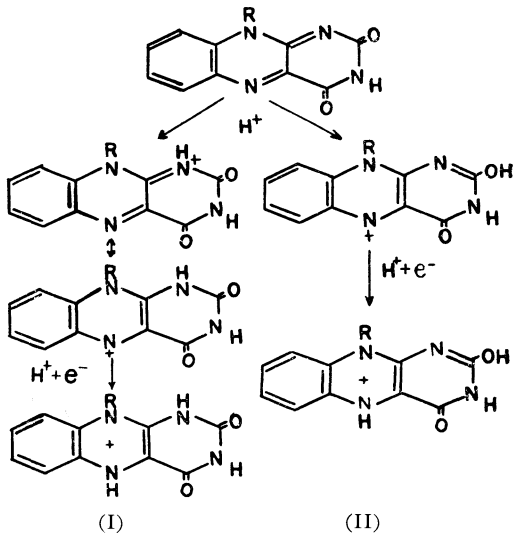

Fig. 4. Alternative pathways for the reduction of isoalloxazine.

On the theoretical calculation of the bond orders in the ring, the Hückel approximation was applied to a system of 16 conjugated π-electrons and 4 mobile electrons due to the hyperconjugation of the two methyl groups, where the Coulomb and exchange integrals were taken from the Ladik's[4]. There are several relations proposed

C(8)—C(8a)	1.56	1.41	1.39

for converting the bond order into length.[5-10] For C–C bonds, approximately the same values were obtained by all the relations, and the converted bond lengths by, say, Coulson's[5] are in good agreement with those observed, as shown in Table 4. On the other hand, the converted C–N lengths show somewhat wider variations with the relations, and agreement between the theoretical and observed lengths is not so good. But if experimental errors are taken into account, significant disagreement is only for N(9)–C(8a). This may suggest that this approximation is not necessarily satisfactory in the present molecule.

The valence angles at the N(1) and N(3) atoms with an extra-annular hydrogen atom are 125° and 122°, respectively, and that at N(10) without hydrogen is 119°. They are consistent with the nitrogen valence angle in heterocyclic compounds discussed by Singh.[11] There are some small valence angles at the C(8a) and C(4) atoms which are bonded to the nitrogen atoms with an extra-annular hydrogen atom, whereas slightly large ones are found at the C(4a) and C(10a) atoms bonded to the N(10) atom. These facts have been reported in alloxane,[12] anhydrous alloxane,[13] anhydrous barbituric acid,[14] barbituric acid dihydrate,[15] pyridimine,[16] and 2-amino-4,6-dichloropyridine.[17]

The best planes of the isoalloxazine ring and the six-membered rings are listed in Table 5 together with the deviations of the atoms from them, where the nomenclatures of the rings are as follows:

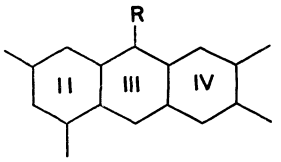

Table 5. The best plane of the rings

and the I represents the isoalloxazine ring. The dihedral angles between the planes are also given in this table. Though the ring IV is strictly planar, the other two rings are puckered; the deviations of the atoms from their best planes are significant. The dihedral angles between the planes indicate that the isoalloxazine ring takes, though slightly, a boat form. However, the isoalloxazine ring in

* May be a bifurcated hydrogen bond
** The intramolecular hydrogen bond

1,3,10-trimethyl isoalloxazine iodide[18] has been reported to be nearly coplanar.

In the ribityl group, the C(1')–C(2'), C(2')–C(3') and C(3')–C(4') bonds are a little shorter than the normal C–C length of sp^3 hybridization, whereas the C(4')–C(5') does not differ significantly from the normal one. The C–O lengths in this group are between 1.41 Å and 1.44 Å, and their mean value, 1.428 Å, corresponds to the usual single C–O length. The valence angles C–C–C and C–C–O in this group do not differ significantly from their mean value, 107° and 110°, respectively.

The ribitol does not form a furanose ring but a chain, which has not been found in cases of nucleoside, nucleotide and nucleic acid. The conformation angles defined by Sundarlingam[19] are; $\phi_{C_2'-C_3'}=62°$ and $\phi_{C_3'-C_4'}=167°$, whereas they are 34° and −37° in the furanose ring of 5'-AMP.[20]

The molecular packing viewed along the *b* axis is shown in Fig. 5. The hydrogen bonds are shown by the dotted lines, where each figure represents a distance between the non-hydrogen atoms. Table 6 tabulates the X-H distances and X–H–Y angles related to the hydrogen bond. The H(2,i)-OW(i), 1.92 Å, is the normal hydrogen bond. The H(23,i) is located near both O(2',i) and O(3',i) atoms; the distances are 2.36 Å and 2.06 Å, respectively. Thus, the two contacts, OW-H(23)-O(2') and OW-H(23)-O(3'), seem to consist a bifurcated hydrogen bond. Another hydrogen atom of water molecule makes *a* weak hydrogen bond with the N(10) atom related by the screw axis along the *a*. This hydrogen bond may suggest the subsequent transfer of the hydrogen atom from the substrate.

The bromide ion contributes to the three hydrogen bonds with the N(3), O(2') and O(4') atoms. Though the Br(i)-N(3,i) distance, 3.51 Å, seems a little longer, the Br(i)-H(1,i) is 2.40 Å, which shows that it is a normal hydrogen bond. The bromide ion is situated midway between two isoalloxazine rings separated by a period along the *b* axis, and nearly above the center of the ring III which is indicated to have positive charge from the theoretical calculation of the bond orders.

Influence of Impurities on Phosphate Coating Formation*1

Takao UMEGAKI, Hiroshi ITO*2 and Taijiro OKABE

Department of Applied Chemistry, Faculty of Engineering, Tohoku University, Sendai

(Received October 5, 1968)

The applicability of wet-process phosphoric acid containing such impurities as Al^{3+}, Ca^{2+}, Fe^{3+} and SO_4^{2-} was examined. From the viewpoint of the corrosion resistivity of the phosphate coating, Al^{3+} ion was found to be the most undesirable contaminator. NaF was recognized as the most effective masking reagent for an elimination of Al^{3+} hindrance. SO_4^{2-} also affected the phosphate coating formation, but the presence of less than 1% SO_4^{2-} did not disturb the coating formation when an appropriate amount of accelerator was added to the phosphatizing solution.

This investigation was initiated for the purpose of examining whether phosphoric acid manufactured by wet-process was applicable to a process of phosphate coating or not. Recently, a wet-process phosphoric acid has come to be available at cheap cost in Japan. In ordinary methods, however, it is impossible to use phosphoric acid as raw material for the phosphatizing solution because of the presence of such impurities as Al^{3+}, Ca^{2+}, SO_4^{2-} and so on. Khain[1-4] has already investigated the formation of the phosphate coating, using the phosphatizing solution containing nitrates of metals with mono-, bi- and trivalency as reaction accelerators. As the pH lowering occured in their solutions, characteristic effect of nitrates could not be examined individually. The qualitative study of undesirable influences of SO_4^{2-}, AsO_4^{3-}, Cr^{3+} and Al^{3+} in the ordinary acidic bath of zinc phosphate was also reported by Nagai.[5] In the present paper influences of Al^{3+}, Fe^{3+}, Ca^{2+} and SO_4^{2-} on $Zn_3(PO_4)_2$ phosphatizing solutions were described, and an effective chemical procedure was proposed to eliminate the hindrance of Al^{3+}.

Experimental

A) Stock Solution for Phosphatization. A solution was prepared by dissolving 17 g of zinc oxide in 34 g of boiling 85% phosphoric acid, cooled to room temperature, and then adding 6 g of 60% nitric acid, diluted finally to 100 m*l* with distilled water. All chemicals used were reagent-grade materials. Table 1 shows the composition of the solution thus prepared.

Table 1. Composition of stock solution for phosphating (wt%)

Zn^{2+}	PO_4^{3-}	NO_3^-
10.3	24.8	4.34

B) Phosphatizing Solution. Various kinds of phosphatizing solutions were prepared by adding 1.7 g of Na_2CO_3 and a certain amount of 18% $NaNO_2$ solution as an accelerator to 95 g of the above-mentioned stock solution, and diluting to 1 *l* with distilled water. At this stage, free acidity and total acidity of the solution were 1.98 and 30.56 in point,*3 respectively. Furthermore, SO_4^{2-}, NO_3^-, Al^{3+}, Ca^{2+} and Fe^{3+} were added to the above solutions for experiments on the effects of these materials.

C) Procedure. Specimens of commercial mild steel, 3 mm × 5 mm × 20 mm, were used for the phosphate coating. The elemental composition of the mild steel is given in Table 2. The specimens were polished with emery paper (No. 400), degreased with benzene, dried, and dipped into the phosphatizing solution. After phosphatization at 25°C, the amount of iron dissolved from the specimen in the solution was determined by colorimetric analysis with Nitroso R salt. The corrosion resistance of phosphate coating was tested by dipping the specimen in a 100 m*l* of air-bubbled 3% NaCl solution for 10 hr at 25°C and then determining the amount of iron dissolved in the solution. A relative resistivity of phosphate coating may be indicated by this test, although it has not been officially approved yet.

Table 2. Composition of mild steel used (wt%)

Results and Discussion

The experimental results at various concentrations of accelerators are shown in Figs. 1 and 2. The amount of dissolved iron increased linearly with phosphatizing time, in the case of the solution containing 1 g/*l* of the accelerator concentration as shown in Fig. 1, whereas, at 2g/*l* and 3 g/*l* of the accelerator concentration, the amount of dissolved iron reached saturation after 20 min. Figure 2 shows that, with respect to the corrosion resistance of phosphate coating, the most favorable concentration of accelerator was 4 g/*l*. The influences of sulfate addition to the phosphatizing solution are shown in Figs. 3 and 4. Sulfate ion caused an increase in amounts of dissolved iron and a decrease of resistivity. The presence of more than 1% sulfate was undesirable in the process of the phosphate coating. Figures 5 and 6 show that the amount of dissolved iron and the corrosion resistance were dependent on the concentration of accelerator when the phosphatizing solution contained 1% of sulfate ion. From the results shown in Fig. 6, it was concluded that the presence of 1% sulfate ion did not disturb the film formation

if more than 4 g/*l* of the accelerator was added to the phosphatizing solution. As shown in Fig. 7, the lessening of corrosion resistivity was caused by addition of $Al(NO_3)_3$ and $Fe(NO_3)_3$, whereas the phosphatizing solution containing 3—5 g/*l* of

$Ca(NO_3)_2$ gave more sturdy film. Fe^{3+} ion does not exist in the phosphatizing solution with high pH, and therefore the influence of Fe^{3+} ion could be easily eliminated by adding alkaline to enhance the pH of the phosphatizing solution. On the other hand, Al^{3+} was recognized as one of the most undesirable contaminators on the phosphatizing solution, because a milky-white amorphous coating lacking in adhesive ability to iron surface appeared by the addition of only 0.585 g/*l* of Al^{3+} and the solution containing 1.76 g/*l* of Al^{3+} gave neither amorphous coating nor oxide film. The maximum allowable concentration of Al^{3+} in the phosphatizing solution was estimated to be less than 0.01 g/*l*. Therefore, various kinds of Al^{3+} masking reagents were examined in order to avoid the Al^{3+} hindrance. Table 3 and Table 4. shown that the corrosion resistivity of the phosphate coating was improved by an addition of NaF, and that the masking effect of NaF was most remarkable. A sturdy coating was obtained by the addition of more than 2 g/*l* of NaF, even though the phosphatizing solution contained 2.93 g/*l* of Al^{3+}. In the case of the presence of 0.23 g/*l* of Al^{3+}, the addition of more than 1.3 g/*l* of NaF to the phosphatizing solution was necessitated. The sturdiness of phosphate coating thus obtained was comparable with that obtained from an ordinary phosphatizing solution without Al^{3+}.

3.83	0.23	0.010
4.68	0.23	0.023

Conclusion

The reaction mechanism of phosphate coating formation is commonly accepted as follows:

(1) $Fe + 2H_3PO_4 = Fe(H_2PO_4)_2 + H_2$

(2) $Zn(H_2PO_4)_2 = ZnHPO_4 + H_3PO_4$

(3) $ZnHPO_4 = Zn_3(PO_4)_2 + H_3PO_4$

Corrosion reaction represented by Eq. (1) begins when the iron specimen is dipped in the phosphatizing solution. As a result, both equilibriums of Eq. (2) and (3) are shifted to the right hand by the decrease of H_3PO_4 concentration and then an insoluble $Zn_3(PO_4)_2$ crystallized on the iron surface. Recently, composition and crystal structure of the phosphate coating have been classified by many investigators. Therefore, in addition to the above-mentioned qualitative explanation, the rate-determining factors of the coating formation can be

discussed, taking the precise crystal structure into consideration. Later, the hindrance of Al^{3+} and the reaction mechanism will be reported, from a viewpoint of electrochemistry. Although a theoretical explanation of the influence of each impurity has not been established yet, the following conclusions have been made: (a) Al^{3+} is the most undesirable contaminator for the phosphatizing solution, and the addition of NaF is effective in eliminating the hindrance of Al^{3+}. (b) The interference of Fe^{3+} can be avoided by the addition of alkali to the phosphatizing solution. (c) The addition of an appropriate amount of the accelerator makes it possible to use the wet-process phosphoric acid containing Ca^{2+} and SO_4^{2-} as raw material for the phosphatizing solution.

This investigation was supported by a grant from Nippon Kokan (Japan Steel and Tube) Corp., for which the authors wish to express their sincere appreciation.

Determination of Traces of Constituents with Schiff Bases. III.[1] Extraction-Spectrophotometric Determination of Nickel with Salicylidene-*o*-aminophenol

Hajime Ishii and Hisahiko Einaga

National Institute for Researches in Inorganic Materials, Science and Technology Agency, Hon-komagome, Bunkyo-ku, Tokyo

(Received October 7, 1968)

A method was established for the spectrophotometric determination of microgram amounts of nickel after the extraction of nickel(II) as a salicylidene-*o*-aminophenol (SAP) complex from an alkaline aqueous solution into chloroform. Nickel(II) reacts with SAP to form a complex which can be extracted into organic solvents such as benzene, chloroform, methyl isobutyl ketone, *etc.*, in the presence of ammonium ions. The extraction of nickel was almost quantitative, and a maximum and constant absorbance was obtained in the pH range from 8.5 to 9.8. The complex extracted was very stable and had an absorption maximum at 418 mμ. The composition of the complex was confirmed to be 1 to 1 (metal to ligand). A linear relationship was maintained between the concentration of nickel and the absorbance. The molar extinction coefficient and the sensitivity for $\log(I_0/I)=0.001$ at 418 mμ were 17000 and 3.5×10^{-3} μg Ni/cm^2, respectively. Several ions such as cobalt(II), copper(I and II), chromium(III), lead(II), manganese(II) and citrate interfered with the determination.

Recently, salicylidene-*o*-aminophenol (SAP), a Schiff base obtained by the condensation of salicylaldehyde with *o*-aminophenol, has been used for the spectrofluorimetric determination of aluminum[2-7] and gallium[7] and for the separation and indirect spectrophotometric determination of copper.[8] The authors have previously reported the direct spectrophotometric determination of copper using the complex formation of SAP with copper(II).[1] This reagent was found to react also with nickel(II) in an alkaline aqueous medium to form a complex which could be extracted in the presence of ammonium ions into organic solvents such as benzene, chloroform, carbon tetrachloride, methyl isobutylketone (MIBK), *etc.* This paper will describe a direct spectrophotometric method for the determination of traces of nickel after extraction of it as a SAP complex into chloroform.

Experimental

Apparatus. The recording of absorption spectra and all the other spectrophotometric measurements were made with a Hitachi Model EPS-3T automatic recording spectrophotometer and a Hitachi Model 139 spectrophotometer, respectively, using 10 mm matched cells. The pH measurements were made with a Toa Dempa glass-electrode Model HM-5A pH meter. The shaking was done with an Iwaki Model KM shaker.

Reagents. *Standard Nickel(II) Solution.* A stock solution containing about 1000 μg of nickel per m*l* was prepared by dissolving nickel chloride in water, followed by adding a small amount of hydrochloric acid enough to give approximately 0.1 N hydrochloric acid solution. Standardization was made by titration with a 0.01 M EDTA solution. The stock solution was appropriately diluted to make working solutions of nickel(II).

SAP Solution. A 0.01% solution was prepared by dissolving 25 mg of SAP in 250 m*l* of chloroform. SAP used in this work was synthesized and purified by the method proposed by Dagnall *et al.*[2]

Buffer Solutions. Buffer solutions were prepared by mixing a 1 M ammonium chloride solution and a 1 M aqueous ammonia solution in the ratios required.

Extracting Solvent. Commercial chloroform of analytical reagent grade was used without further purification.

Recommended Procedure. In a 50 m*l* separatory funnel, an aliquot of the sample solution containing less than 30 μg of nickel(II) is taken. Add 1 m*l* of the buffer solution (pH 9), and dilute to 30 m*l* with distilled water. Add 10.0 m*l* of a 0.01% SAP solution in chloroform, and shake vigorously for 10 min. After the phase separation, transfer the organic phase into a 50 m*l* flask containing about 1 g of anhydrous sodium sulfate. Then transfer the organic solution into a cell and measure the absorbance at 418 mμ using a reagent blank as a reference. The amount of nickel can be obtained from the calibration curve.

Results and Discussion

Selection of Extracting Solvent. Nickel(II) is extracted as its SAP complex from an alkaline aqueous solution into organic solvents such as benzene, chloroform, carbon tetrachloride, MIBK, *etc.* in the presence of ammonium ions. Among them, chloroform seemed to be the best for the present purpose, because of the relatively high extractability of the complex and the good separability of two phases; an aqueous and an organic phases. For this reason, chloroform was used as the extracting solvent in this work.

Absorption Spectra. Figure 1 shows the absorption spectra of SAP and its nickel(II) complex extracted in chloroform at pH 9. The absorption maximum of the complex appears at 418 mμ, while that of SAP, at 354 mμ. This maximum absorption wavelength of 418 mμ, which was used for the determination of nickel, did not shift in either case, when pH value of the aqueous phase was varied from 7 to 10.5 or when the molar ratio

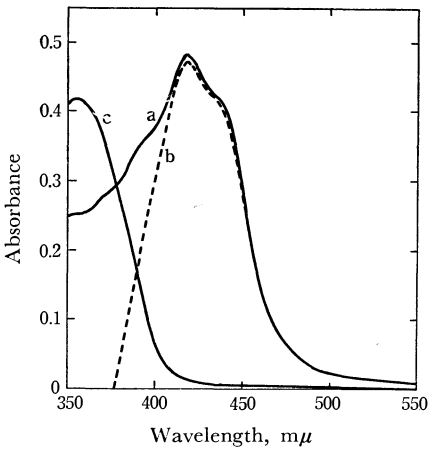

Fig. 1. Absorption spectra of SAP and its nickel-(II) complex.
Ni: 16.5 μg, SAP: 4.3×10^{-7} mol/10 m*l* of chloroform, pH : 9, $V_{aq}/V_{org}=1$, Shaking time: 30 min.
a : Ni(II)-SAP complex measured against chloroform
b : Ni(II)-SAP complex measured against a reagent blank
c : SAP alone (reagent blank) measured against chloroform

of nickel to SAP was varied 1 : 5 to 5 : 1. Taking this fact and those described in the subsequent paragraph into account, it was considered that only one species of the complex was extracted into chloroform under the conditions studied. The absorption spectra of the complex in benzene and in MIBK were essentially similar to that in chloroform, except that the absorbancepeak occurred at 424 mμ in benzene and 420 mμ in MIBK, respectively.

The Effect of pH Value. The effect of pH value on the absorbance at 418 mμ was examined over a pH range from 6.8 to 10.3. As shown in Fig. 2, it can be seen that a maximum and constant absorbance is obtained in the pH range from 8.5

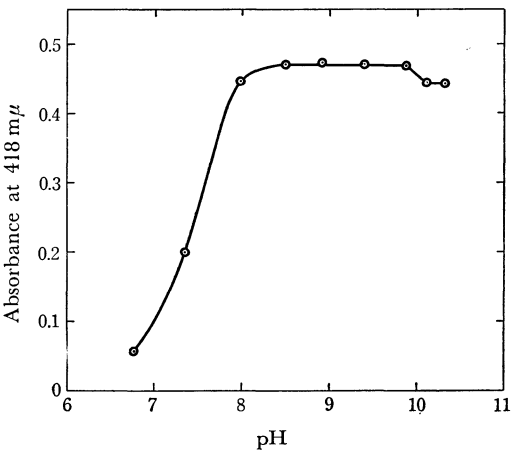

Fig. 2. Effect of pH.
Ni: 16.5 μg, $V_{aq}/V_{org}=1$

to 9.8. In subsequent experiments, therefore, the extraction of nickel was carried out at about pH 9.

The Effect of the Amount of SAP. Figure 3 shows the effect of the amount of SAP on the absorbance. About an 8-fold molar excess of the reagent over the amount of nickel is necessary to obtain a maximum and constant absorbance. Therefore, 10 m*l* of a 0.01% solution of the reagent in chloroform was used. This corresponds to 4.7×10^{-6} mol, and it is about an 8-fold molar excess over the highest point on the calibration curve in Fig. 4, *i. e.*, 33 μg of nickel.

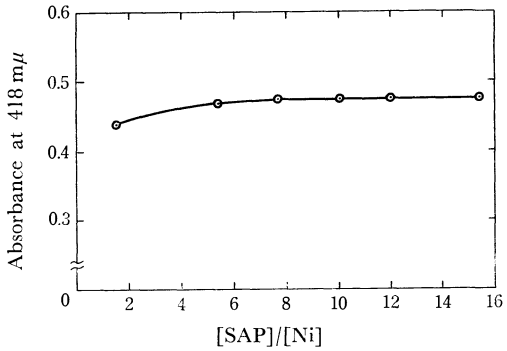

Fig. 3. Effect of amount of SAP.
Ni: 16.5 μg, $V_{aq}/V_{org}=1$

The Effect of the Shaking Time. The variation of shaking time from 1 to 30 min revealed that a 5-min shaking was enough to attain a good extraction under the recommended conditions, although the shaking time must be increased with the decrease of the ratio of SAP to nickel. The extraction of nickel was reproducible and 93.1% of it present in an aqueous phase were extracted by a single extraction. Therefore, one extraction seems to be sufficient for the determination of nickel.

The Effect of Volume of the Aqueous Phase. The absorbance of the extract was decreased with increasing the volume of the aqueous phase to that of organic phase. Considering this fact and the application of the method to the analysis of practical sample, the volume ratio of the aqueous to the organic phase was kept 3 in the recommended procedure.

The Stability of the Color. The absorbance of the extract did not change at all for at least 12 hr. The complex, therefore, seems to be very stable in chloroform.

Adherence to Beer's Law. As is seen in Fig. 4, a linear relationship was maintained between the concentration of nickel and the absorbance up to at least 33 μg of nickel per 10 m*l* of the extract. The molar extinction coefficient was about 17000, and the sensitivity was 3.5×10^{-3} μg Ni/cm^2, which corresponds to $\log(I_0/I)=0.001$.

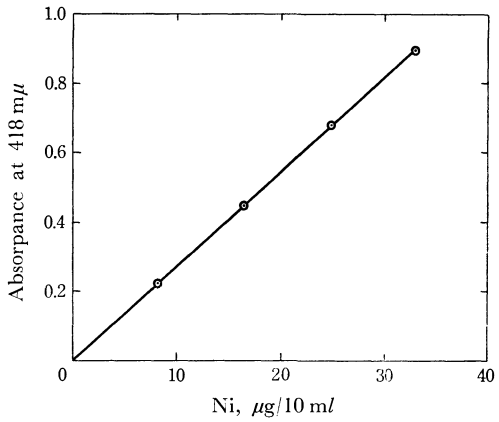

Fig. 4. Calibration curve for nickel.
pH: 9, $V_{aq}/V_{org}=3$

The Effect of Diverse Ions. The effect of diverse ions on the determination of nickel was examined at pH 9 and the results are summarised in Table 1. Cobalt(II), copper(I and II), chromium(III), lead(II), manganese(II) and citrate interfered with the determination. The interferences by these cations and citrate may be due to the complex formation with SAP and with nickel, respectively.

The Composition of the Complex. Although the composition of the complex has been already reported to be 1 to 1 (metal to ligand) from the analytical results of the isolated complex,[7] the authors also examined the composition in chloroform by means of the continuous variation and the molar ratio methods. Extraction was performed at pH 9, and the absorbance was measured at three wavelengths between 400 and 440 mμ. Both methods revealed that nickel(II) forms a 1-to-1 complex with SAP. As an example, the result of the continuous variation method is shown in Fig. 5.

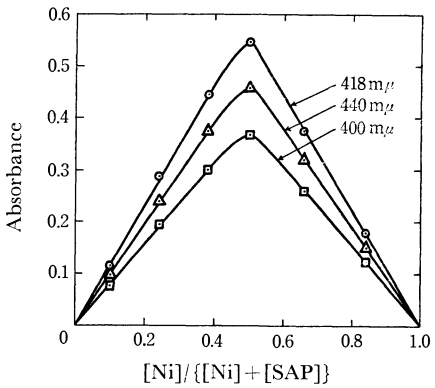

Fig. 5. Continuous variation method.
$[Ni]+[SAP]=7.0\times10^{-5}$ M, pH: 9,
$V_{aq}/V_{org}=1$, Shaking time: 30 min

Comparison with Other Methods. The proposed method has the following advantages: A relatively broad pH range is tolerable, the color of the extract is very stable, and the sensitivity is superior to that of other methods, *e. g.*, the dimethylglyoxime-oxidizing agent method (sensitivity: 4.2×10^{-3} μg Ni/cm^2).[9]

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 1561—1569 (1969)

Scandium Content of Igneous Rocks and Some Oceanic Sediments

Tsuneo SHIMIZU

Department of Chemistry, Faculty of Education, Gunma University, Maebashi, Gunma

(Received October 23, 1968)

Based on the analyses of 105 individual samples and 5 composites, totaling 158 rock samples, the following averages of scandium for various types of Japanese igneous rocks have been obtained (in ppm): granites 5.6, granodiorites 7.4, liparites 6.1, quartz diorites and diorites 11.4, dacites 14.1, andesites 21.8, gabbros 26.9, basalts 27.2 and ultramafic rocks 9.5. Scandium is determined by a combined ion-exchange-spectrophotometric method. Using Poldervaart's suggested ratio of rock types, an abundance figure of 17 ppm Sc for the crust is suggested. The results on the abundance values for scandium in various types of igneous rocks confirm generally the figures given by Norman and Haskin in 1968. Analyses are also performed on Pacific oceanic sediments, giving as averages 18.7 ppm Sc for 4 red clays, 12.1 ppm Sc for 2 volcanic muds and 13.1 ppm Sc for 2 globigerina oozes. Brief discussion on the geochemistry of scandium is given.

A considerable amount of data has been reported for the abundance of scandium in igneous rocks, mostly based on spectrochemical methods. However, data on the abundance of scandium in granitic rocks is rather unreliable because of lack of sensitivity in usual spectrochemical methods. Fryklund and Fleischer[1] have reviewed the previous works involving the geochemistry of scandium prior to 1962, and presented the abundance figures for various igneous rock clans and for the earth's crust as a whole. Currently, averages and concentration ranges for scandium as well as many other elements have been reported

1) V. C. Fryklund, Jr. and M. Fleisher, *Geochim. Cosmochim. Acta*, **27**, 643 (1963).

by Kolbe and Taylor[2] for granites and granodiorites from Australia and South Africa using an improved spectrographic technique. Detailed geochemistry of scandium was not discussed.

Recent development in neutron activation analysis has facilitated the accurate determination of scandium in rocks and minerals, yielding and accumulating reliable data for scandium in materials of geochemical interest. Thus, Stueber and Goles[3] have analyzed 113 ultramafic rocks for sodium, manganese, chromium, scandium, and cobalt by a neutron activation method. Discussing the effect of serpentinization on the abundances of the elements, these authors revealed that scandium abundance is highly dependent on mineral composition and also that the pre-serpentinization mineral composition determines the scandium abundance in the serpentine. Norman and Haskin[4] have reported the results of neutron activation analyses for scandium and iron in 76 samples of igneous and sedimentary rocks, including 9 composites. The highest scandium contents (average, 30 to 40 ppm) were found in basalts and gabbros and the lowest in nepheline syenites and limestones (−1 ppm). Despite increasing amount of data for scandium in igneous rocks, there is still much controversy among the authors as to a possible geochemical relationship between Sc^{3+} and Fe^{2+}, Mg^{2+}, or other major elements or ions in igneous rocks. Taylor[5] gives a general review of the geochemistry of elements including scandium as well as a survey of the analytical data published previously.

In order to develop a routine analytical method for scandium, which is comparable in accuracy to neutron activation analysis, a combined ion-exchange-spectrophotometric method has been worked out for scandium in rocks.[6] Furthermore, 158 igneous rock samples including 5 composites and 8 pelagic sediments from the Pacific Ocean have been analyzed for scandium in order to define the occurrence and abundance of scandium in the igneous rocks and sediments of Japan. It is also intended to summarize the geochemical behavior of scandium. Average abundance figures are suggested for various types of igneous rocks and for the earth's crust as a whole. The results on the abundance values for scandium in various types of igneous rocks confirm generally the figures given by Norman and Haskin.[4]

Analytical Method

The procedure has been described in detail elsewhere.[6] In brief, after 0.5 to 1.5 g of a powdered rock sample is decomposed by means of perchloric-hydrofluoric acid digestion, the resulting residue is dissolved in dilute hydrochloric acid. When any undissolved residue is found, it is put into solution by fusion with sodium carbonate. Traces of scandium in the solution are separated from all interferences by successive cation- and anion-exchange chromatographic techniques in acid ammonium sulfate media. Scandium in the effluent then is coprecipitated together with ferric hydroxide and separated from the ferric ion by an anion-exchange in hydrochloric acid medium. Finally, scandium is determined spectrophoto-

TABLE 1. SCANDIUM IN THE ROCK STANDARDS (in ppm)

metrically with bromopyrogallol red as a color reagent.

In order to obtain information about the accuracy and precision of the procedure, 8 standard rock samples, G-1 (granite), G-2 (granite), GSP-1 (granodiorite), AGV-1 (andesite), W-1 (diabase), BCR-1 (basalt), PCC-1 (peridotite) and DTS-1 (dunite), were analyzed for scandium. The results are quoted in Table 1. For comparison, earlier literature values for scandium in the rock standards are also listed in Table 1. Generally agreement with previous values is excellent. The following standard deviations (in ppm) indicated by ± sign for three types of igneous rocks also give a general idea of precision of the present method: av. 34.7± 1.2 for basalt (8 detens.), av. 20.7±1.3 for andesite (13 detens.), av. 11.9±1.2 for quartz diorite (8 detens.).

Analytical Results

Analytical results are presented in Tables 2 to 6 along with necessary descriptions. Marine sediments of the Pacific Ocean were collected in 1925—1928 through the deep sea expedition carried out by the Hydrographical Department of the former Japanese Navy.

Discussion

Abundance of Scandium. From the values listed in Table 2 the following averages for ultramafic rocks are obtained:

	Sc, ppm	Range
7 Peridotites	10.0	5.5—13.5
Dunite	8.5	
Cortlandite	6.9	
All ultramafic rocks (9 samples)	9.5	5.5—13.5

For an average abundance figure of scandium in ultramafic rocks, Turekian and Wedepohl[7] give 15 ppm on the basis of the data of Pinson, Ahrens and Frank.[8] Vinogradov[9] gives 10 ppm Sc. Vinogradov[10] also gives a value of 5 ppm Sc, deriving this figure from Borisenko,[11] who estimated the average scandium contents of ultramafic rocks of the Soviet Union to be 5 ppm for peridotites, 3 ppm for dunites, and 52 ppm for pyroxenites. Compiling the determinations of Pinson, Ahrens and Frank,[8] Liebenberg,[12] and Borisenko and Rodionov,[13] Fryklund and Fleischer[1] give an average scandium abundance of 9 ppm for peridotites, of 30 ppm for perknites and of less than 5 ppm for olivine dunites. Stueber and Goles[3] give an average of 5.4 ppm Sc for 14 dunites, of 42 ppm Sc for 9 pyroxenites, and of 15.7 ppm Sc for all ultramafic rocks studied. Norman and Haskin[4] have reported measurement for scandium in 3 peridotites (all about 12 ppm Sc), 2 pyroxenites (8 and 56 ppm Sc), 2 dunites (9.1 and 3.6 ppm Sc) and 3 perknites (3.4, 3.7 and 17.1 ppm Sc) from various locations. The values found in this work all fall within the range for individual samples analyzed by the above authors. Because of the large number of determinations involved, the overall average given by Stueber and Goles[3] may at the present time provide a sound representation of ultramafic rocks of variable mineralogical composition. However, the striking preference of scandium for pyroxene is now well established so that the compiled averages given by Fryklund and Fleischer[1] for dunites, peridotites and perknites may provide a better basis for comparison between averages for the individual rock classes. An average for scandium obtained in this work (9.5 ppm) is in good agreement with their average (9 ppm) for peridotites.

Table 2. Scandium in ultramafic rocks

Rock mark	Sample	Sc (ppm)
HOK	Orthopyroxene peridotite Horoman, Hokkaido	13.5
HK56081904	Peridotite, Besshi, Ehime	13.3
YN64010907	Peridotite, Toba, Mie	12.5
HK56081902	Enstatite bearing peridotite, Besshi, Ehime	11.7
HK51031101	Peridotite, Kamogawa, Chiba	7.3
10127	Peridotite, Ogawa, Saitama	6.2
Tamura 95	Peridotite, Miharu, Fukushima	5.5
49IIO-189	Dunite, Oshika, Nagano	8.5
TA-4	Cortlandite, Miharu, Fukushima	6.9

Averages for mafic rocks are computed from Table 3 as follows:

	Sc, ppm	Range
15 Basalts	27.2	15.5—42.5
10 Gabbros	26.9	16.6—32.3
9 Diabases	18.1	17.7—18.5
All mafic rocks (34 samples)	25.4	15.5—42.5

For average abundance figures of scandium for "basaltic rocks" Vinogradov[9,10] gives 24 ppm,

OB-2	Basalt, Hata, Shizuoka	31.9
NB-1	Basalt, Ajiro, Shizuoka	28.0
OB-1	Basalt, Fudo, Shizuoka	21.3
OB-3	Basalt, Karatsu, Saga	16.3
OB-4	Basalt, Karatsu, Saga	15.5
HG-1	Gabbro, Shisaka Island, Ehime	32.3
3302	Olivine gabbro, Kamioka, Gifu	29.7
KG-1	Gabbro, Miharu, Fukushima	26.7
SH135	Picrite gabbro, Hidaka Hokkaido	16.6
65081902	Diabase, Katashina Gunma	18.5
	Basalt, composite of 7, Japan	21.5
	Gabbro, composite of 6, Japan	19.4
	Diabase, composite of 8, Japan	17.7
OB-5	Basalt, Hawaii, U.S.A.	17.0
666-SC-11	Gabbro, South California U.S.A.	17.0

and Turekian and Wedepohl[7] give 30 ppm. Borisenko[11] gives 20 ppm Sc for gabbros, and Hamaguchi and his collaborators[14] give a neutron activation value of 32 ppm Sc for a composite of 7 Japanese basaltic rocks. Fryklund and Fleischer[1] give a figure of 38 ppm Sc for 99 basalts. Norman and Haskin[4] have recently reported that 8 oceanic sub-alkaline basalts have more than 35 ppm Sc, ranging 35 to 50 ppm; five of 8 continental and island alkali basalts contain less than 30 ppm Sc, ranging from 10 to 55 ppm; a composite of 282 continental (alkali and tholeiitic) basalts contains 30 ppm Sc.

With 36 mafic rocks scandium contents obtained here range from 16 to 42 ppm, the difference involved being a factor of approximately three. The average 24 ppm for 36 mafic rocks is somewhat lower than those given by Fryklund and Fleischer,[1] and Norman and Haskin.[4] This average is also considerably lower than the activation value for the composite of 7 basaltic rocks given by Hamaguchi and his collaborators.[14] The scandium contents of two American mafic rocks are somewhat lower than the average reported here.

14) H. Hamaguchi, R. Kuroda, K. Tomura, M. Osawa, K. Watanabe, N. Onuma, T. Yasunaga, K. Hosohara and T. Endo, *Geochim. Cosmochim. Acta*, **23**, 296 (1961).

It is of interest to see how the scandium distribute among rock-forming minerals in a basaltic rock. Based on radioactivation analysis, Onuma[15] revealed that an alkali olivine basalt from Takashima, Kyushu, shows a scandium content of 18.1 ppm, while values for scandium in its constituent minerals are:

51.2 ppm	for augite (clinopyroxene)
21.4 ppm	for bronzite (orthopyroxene)
not detected	for plagioclase

The striking preference of scandium for pyroxene, particularly clinopyroxene, is well illustrated. With Skaergaard rocks Wager and Mitchell[16] found scandium in the clinopyroxenes of all basic rocks and in apatites of the later basic differentiates, but not in plagioclase or in olivine or opaque iron minerals.

The following averages are obtained from the data listed in Table 4 for intermediate rocks.

	Sc, ppm	Range
32 Andesites	21.8	12.4—28.6
5 Dacites	14.1	10.0—19.1
7 Quartz diorites and diorites	11.4	5.7—21.6
5 Obsidians	29.9	26.5—34.9
2 Pitchstones	7.6	6.0— 9.2
All intermediate rocks (51 samples)	19.1	5.7—34.9

For average abundance figures of scandium in intermediate rocks, Vinogradov gives values of 15 ppm in 1956[9] and of 2.5 ppm in 1962[10] for "neutral rocks" (diorites+andesites). Borisenko[11] gives 3 ppm Sc for diorites. There is no basis for comparison with Turekian and Wedepohl,[7] as they listed no figure for andesites. Fryklund and Fleischer[1] report averages of 34 ppm Sc for 72 andesites, 21 ppm Sc for 68 dacites, and 14 ppm Sc for 32 rhyodacites. Norman and Haskin[4] give 15 ppm Sc for a composite of 85 intermediate rocks of many localities, consistent with the average obtained in this work for intermediate rocks.

Scandium does not distribute uniformly even in the same province as can be seen from its abundance in the rocks of Mt. Asama, Nagano (Table 4). In andesites of Mt. Asama, scandium content ranges 10 to 35 ppm, the difference involved being a factor of more than three.

There is comparatively little reliable information about the abundance figure of scandium in silicic rocks. As can be seen in Table 5 scandium content in 61 silicic rocks ranges from 2.9 to 13 ppm, and average scandium values are:

15) N. Onuma, private communication.

27 granites	5.6 ppm
13 granodiorites	7.4 ppm
composite of 7 granites and 11 granodiorites	6.4 ppm
3 liparites	6.1 ppm

An average for all silicic rocks is 6.3 ppm. Acidic igneous rocks have much less scandium than intermediate and mafic rocks. Hamaguchi and his collaborators[14] give a neutron activation value of 2.3 ppm for scandium in a composite of 20 Japanese granitic rocks, so there is a difference of a factor of almost three in an average scandium between the composite and 61 silicic rocks reported here.

Borisenko[11] gives 1 ppm Sc for granites. Turekian and Wedepohl[7] give 14 ppm Sc for high-calcium granites and 7 ppm Sc for low-calcium granites. Vinogradov gives 7 ppm Sc[9] and 3 ppm Sc[10] as the average for scandium in silicic rocks. Fryklund and Fleischer[1] obtain average scandium values of 11 ppm for 14 quartz latites and 5 ppm for 24 rhyolites. Kolbe and Taylor[2] have recently given averages and ranges for 32 elements including scandium for granitic rocks of the Snowy Mountains, Australia and South-Western Cape Province, South Africa. Their scandium averages are 13 ppm for 4 gneissic rocks, 13 ppm for 20 granodiorites, and 5 ppm for 8 leucogranites, all from the Snowy Mountains. For Cape granites, they give 6.6 ppm Sc for 17 coarsely porphyritic granites, 4.1 ppm Sc for 6 medium-grained granites, and 2.3 ppm Sc for 8 fine-grained granites. Norman and Haskin[4] suggest an average value of 5 ppm Sc for granites, based principally on the analyses of the composites. Scandium averages obtained in the present work are well in line with such recent estimates as given by Kolbe and Taylor,[2] and Norman and Haskin.[4]

Scandium values for sedimentary rocks and oceanic sediments are listed in Table 6. Scandium content of oceanic clays ranges from 11 to 20 ppm, averaging 19 ppm. Red clays tend to have a little higher value of scandium than volcanic muds. Judging from scandium contents of both igneous rocks and oceanic sediments there seems to be no prominent tendency for scandium to become enriched, relative to average igneous rocks, at the oceanic bottom by some mechanism. Plotting the scandium contents *vs.* iron or manganese for the oceanic clays listed in Table 6 has revealed no positive correlations. As far as the scandium is concerned, coprecipitation along with hydrated oxide of iron or manganese or adsorption (ion-exchange) mechanisms caused by submarine ferro-manganese minerals are unlikely to play an important role in accumulating scandium into oceanic sediments.

Turekian and Wedepohl[7] summarize scandium figures of 13 ppm for shales, 1 ppm for sandstones, and 1 ppm for carbonates, estimating also 2 and 19 ppm for deep sea carbonates and clays, respectively. Horn and Adams[17] have currently made a new approach to geochemical balancing and to estimation of element abundances using a high speed digital computer. Their computer-derived abundance figures for scandium are 10.1 ppm for shale, 0.733 ppm for sandstone, 0.683 ppm for carbonate, 22.8 ppm for oceanic clay, and 2.09 ppm for oceanic carbonate. Norman and Haskin[4] took a value of 12 ppm Sc found in the composite of 40 North American shales as a representative value for that rock type. They also found 20 ppm Sc for a composite of 55 North American metamorphosed shales. Their values for scandium in 4 carbonate sediments and 2 carbonate metasediments were quite low, ranging 0.40 to 1.57 ppm. Scandium estimates (14.4 and 11.5 ppm) in the present work for 2 globigerina oozes are markedly higher than the averages just mentioned for oceanic carbonates. High contents of scandium in globigerina ooze can partly be accounted for as due to the con-

TABLE 6. SCANDIUM IN MARINE SEDIMENTS AND SEDIMENTARY ROCKS

Sample record number	Sample	Location	Depth (m)	Sc (ppm)
1666	Red clay	11°19'N, 151°57'E	5893	20.3

17) M. K. Horn and J. A. S. Adams, *ibid.*, **30**, 279 (1966).

tribution of red clays included in globigerina ooze.

Computations are carried out to obtain an approximate figure for the crustal bundance of scandium. Assuming the average crust to be composed of equal portions of the continental crust consisting of one part of basaltic and five parts of granitic rocks and the oceanic crust consisting of basaltic rocks only (Hamaguchi and Kuroda[18]), a value has been estimated to be 17.3 ppm for the crustal abundance of scandium. Using Poldervaart's suggested ratio of rock types in the crust (basalt+tholeiite 48.9%; diorite-andesite 10.3%; granodiorite 40.8%),[19] a value of 17.1 ppm for the crustal abundance of scandium has been estimated. The two estimates are in excellent agreement.

The classic abundance values usually given for the crust are 5 to 6 ppm Sc (*e. g.*, Fleischer[20]). Vinogradov[10] gives 10 ppm Sc. These figures refer to the abundance of scandium in the continental crust, based on a 2 : 1 weight ratio of felsic to basic rock abundances. Fryklund and Fleischer[1] suggest a figure of 30 ppm Sc for the crust, using Poldervaart's estimate.[19] Abundances in the continental crust, based on a mixture of equal portions of basaltic and granitic rocks, have been given by Taylor,[21] who gives a value of 22 ppm for scandium. Horn and Adams[17] give 15.1 ppm as the abundance for scandium in igneous rocks. Matsuo and Onuma[22] suggest 22 ppm Sc using Poldervaart's ratio.[19]

Geochemical Behavior of Scandium. Judging from the distribution of scandium in magmatic rocks, it may be reasonably stated that scandium concentrates preferentially into early crystallization products. This behavior of scandium is consistent with the previous knowledge about the geochemical behavior of scandium during magmatic differentiation. However, there is still considerable controversy about the geochemical coherence between scandium and other major elements or ions in igneous rock. Rankama and Sahama[23] state that during magmatic crystallization scandium preferentially enters the early ferro-magnesian minerals, occupyring the Mg-Fe positions, thereby becoming impoverished in residual magma. Because the radius of Sc^{3+} (0.81 Å) is considerably larger than that of Mg^{2+} (0.66 Å) and its electronegativity is also greater ($E_{Sc}=1.3$, $E_{Mg}=1.2$), scandium would be retarded from entering crystals compared to Mg^{2+}. On the other hand, the radius of Fe^{2+} (0.74 Å) is much closer to that of Sc^{3+}, and the electronegativity of Sc^{3+} is much smaller than that of Fe^{2+} ($E_{Fe}=1.65$). Based on these observations Ringwood[24] postulated that scandium should exhibit a far greater tendency to enter a suitable lattice site than iron, and this tendency dominates its behavior.

Reviewing the previous knowledge about the diadochy of scandium with other metal ions, Fryklund and Fleischer[1] indicated that plots of scandium content against total iron actually show a better correlation than those against FeO alone, although they believe the geochemical correlation can be best expressed by saying that Sc^{3+} is in diadochy with Fe^{2+}.

Norman and Haskin[4] stated that the presently available evidence does not support predictions for a close geochemical relationship between Sc^{3+} and Fe^{2+}, Mg^{2+}, or any other major element or ion in igneous rocks. According to these authors there should be obvious correlation between scandium and iron within a single class of rocks, say all basic rocks, or all basalts, as well as over the broader range of rock acidities, if a coherence of scandium with iron is really being observed. In view of the possibility of scandium provinces and the absolute lack of observed correlation between iron and scandium for individual rock types, they concluded that the correlation diagrams such as Fe^{2+} *vs.* Sc, $Fe^{2+}+Fe^{3+}$ vs. Sc are not adequate to establish or to refute the existence of any close geochemical relationship between scandium and iron.

It is true that an ordinary coefficient of correlation, which is computed to obtain a quantitative measure of the strength of a relationship such as Fe^{2+} *vs.* Sc, can lead to extremely misleading conclusions unless it is interpreted carefully. Essentially, we have to deal primarily with many geochemical relations as problems of partial correlation. Therefore, observed geochemical correlations (measured by the coefficient of correlation) should be corrected by converting the ordinary coefficient to the coefficient of partial correlation, which does a fair job of eliminating the disturbing effects of other variables. However, this is not always an easy task in geochemical works. It may be thought that the close geochemical correlation of scandium against Fe^{2+} or total iron revealed by many workers does not exclude the possibility that Fe^{2+} or Fe^{2+} plus Fe^{3+} ions are the cause of enrichment of scandium in mafic rocks by diadochy, although it can imply that high contents of both iron and scandium in mafic rocks are

merely the effects of some other common cause. This cause is not established at the present time. and if present it is not thought so decisive as to change the sign of the coefficient of correlation usually found in diagrams of Fe^{2+} *vs.* Sc^{3+}.

The anthor does not expect that the whole behavior of scandium is governed strictly by the geochemical behavior of iron. There may be some contribution of other major or minor elements like Mn^{2+} (Taylor,[5] Liebenberg[12]), which may in part affect the behavior of scandium during magmatic crystallization. Also, even though not appreciable, a certain amount of scandium becomes concentrated in residual magmas, because it acts as network former in magmas rich in volatiles, thus forming big tetrahedral complexes (ScO_4^{5-}), which is not accepted into silicate minerals and is therefore concentrated in residual magmas (Ringwood[25]).

Although the behavior of scandium is complex, we have no positive reason at the present time to reject the close geochemical coherence between Fe^{2+} (or Fe^{2+} plus Fe^{3+}) and Sc^{3+} ions. Substitution of scandium for iron may dominate its behavior during magmatic crystallization. Norman and Haskin[4] noted that Goldschmidt's rules, even with corrections, should not be applied to group III transition elements, and a successful theory can not be based solely or mostly on comparison of the general properties of the Sc^{3+} cation with those for major elements in melts. Curtis[26] has already drawn attention to the fact that the behavior of certain cations of the transition elements, involving d electrons, is dependent largely on their stabilization energy in six-fold and in four-fold co-ordination. However, with no deposition of its d orbitals in four- or six-fold co-ordination, scandium ion (Sc^{3+}) should not acquire any additional stabilization energy, so that the effects of such stabilization may be negligible.

Recently, Nockolds[27] has attempted to estimate bonding energies for metal-oxygen bonds, in which charge, radius, and electronegativity would be involved in a single function, and to use the results to account for behavior of elements during magmatic crystallization. As far as scandium is concerned, a coupled substitution like $X^{3+}Al \rightleftharpoons X^{2+}Si$ or $2X^{3+} \rightleftharpoons 3X^{2+}$ + vacant octahedral site must be considered. According to Nockolds,[27] when two cations of different valency involving the coupled substitution are capable of substitution in a crystal lattice, that substitution will take place preferentially whose sum of relative total bonding energies is the greater. Accepting Goldschmidt's fifteen per cent tolerance in ionic radius for easy substitution, we may expect that major elements Mg^{2+} and Fe^{2+} in six-fold co-ordination should be replaced by Sc^{3+}. For coupled substitutions of the type $X^{3+}Al \rightleftharpoons X^{2+}Si$, the sums of the relative bonding energies are:

$$ScAl = 600$$
$$MgSi = 580$$
$$Fe^{2+}Si = 560$$
$$Fe^{3+}Al = 545$$

Therefore, scandium should exhibit a markedly preferential entry and would be incorporated preferentially with respect to Mg^{2+} as well as with respect to Fe^{2+}. This kind of substitution must depend on the presence of available aluminum, thus perhaps playing a major role in controlling the behavior of scandium during magmatic differentiation.

It is well established that scandium becomes concentrated in early pyroxenes. Although scandium is substituting for Fe^{2+} in this mineral, it is of interest to see that scandium does not favor the coexisting olivines at levels above the analytical detection limit. This is usually accounted for as due to the difficulty of balancing charges (Taylor[5]). However, if we assume the substitution of the type $2X^{3+} \rightleftharpoons 3X^{2+}$ + vacant octahedral site, we might have substitutions involving $3Mg^{2+}$, 606; $2Sc^{3+}$, 600; $3Fe^{2+}$, 534, where numerical values stand for the relative bonding energies. If this substitution could occur in olivine-rich ultramafic rocks, scandium should not show any preferential incorporation with respect to Mg^{2+}. This may account for low abundance of scandium in olivine-rich ultramafic rocks.

Favorable evidence supporting the idea that scandium is replacing Ca^{2+} rather than Mg^{2+} or Fe^{2+} have also been offered by Snyder.[28] Based on many available determinations of scandium and calcium in rocks and related minerals, Norman and Haskin[4] pointed out that scandium contents closely paralleled calcium contents. If scandium substitutes for calcium, the coupled substitution of the type Sc Al=Ca Si must be assumed, the sums of the relative total bonding energies being:

Sc Al, 600 and Ca Si, 580

Therefore, scandium may enter into early fractions in excess of calcium, thus becoming impoverished in the magma. However, this substitution suffers from the embarrassment that scandium is not observed in feldspars, not even in the most calcic plagioclases. This is presumably due to the fact that the effective ionic radius range for substitution of calcium is 0.96 to 1.30 Å, far removed from the radius of scandium (0.81 Å). The substitution Sc Al=Ca Si is not thought to proceed as readily as does the coupled substitution Sc Al=Fe^{2+} Si

under normal conditions. The apparent correlation between scandium and calcium is thought to be due to some other common cause.

C., for providing the rock standards, and to Dr. N. Onuma, The University of Tokyo, for permission to use his unpublished data.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 1569—1572 (1969)

Chromium(III) Complexes with *N,N'*-Ethylenediaminediacetic Acid*[1]

Yuki FUJII,*[2] Eishin KYUNO and Ryokichi TSUCHIYA

Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa

(Received October 23, 1968)

The following chromium(III) complexes containing *N,N'*-ethylenediaminediacetic acid (EDDA) were newly prepared: $[Cr(Hedda)_2]Cl\cdot 3H_2O$ (red) (I), $[Cr_2(OH)_2(edda)_2]\cdot 6H_2O$ (purple) (II), $H[Cr(edda)(ox)]\cdot 2H_2O$ (purple) (III), $[Cr(edda)(dip)]I\cdot 5H_2O$ (orange) (IV), $K[Cr(NCS)_2(edda)]\cdot H_2O$ (reddish purple) (V) and $[Cr(Cl)(edda)(H_2O)]\cdot 3H_2O$ (bluish purple) (VI), where edda, ox and dip are the abbreviations of the *N,N'*-ethylenediaminediacetate and oxalate anions, and α,α'-dipyridyl respectively. On the basis of the experimental results, it was concluded that EDDA is coordinated as a terdentate ligand in complex I and as a quadridentate in the other complexes prepared in the present work. Furthermore, it was also suggested that complex II has a dimer structure and complex V has *trans* configuration (with respect to the coordinated carboxylate oxygen).

The preparation and properties of the cobalt(III) complexes with *N,N'*-ethylenediaminediacetic acid (EDDA) have already been reported;[1-3] here EDDA behaves only as a quadridentate ligand, not as a terdentate toward a cobalt(III) ion. In the case of the platinum(II) and platinum(IV) complexes with EDDA, however, it has been pointed out that the ligand behaves as a bidentate or quadridentate toward a platinum(II) ion, whereas it behaves as a terdentate or a quadridentate toward platinum(IV) ion.[4]

The purpose of this study was to find how EDDA could behave toward a chromium(III) ion by attempting to prepare various complexes containing EDDA as a quadridentate or a terdentate ligand and to investigate the structure of these complexes.

Experimental

Preparation of the Complexes. *1) Bis-(hydrogen-N,N'-ethylenediaminediacetato)chromium(III) Chloride Trihydrate,* $[Cr(Hedda)_2]Cl\cdot 3H_2O$ (I). To the aqueous solution of chromium(III) chloride hexahydrate (5g, 0.019 mol), about 10g (0.056 mol) of EDDA were added and the mixture was heated on a water bath. After adjusting the pH of the solution to 2—3, it was cooled to 0°C. Pink crystals were separated out and recrystallized from aqueous solution. Yield, 2.5g (27.1%). Found: Cr, 10.27; C, 29.46; H, 5.41; N, 11.31; Cl, 7.35%. Calcd for $[Cr(Hedda)_2]Cl\cdot 3H_2O$: Cr, 10.57; C, 29.30; H, 5.75; N, 11.39; Cl, 7.24%.

Bromide of the complex I, $[Cr(Hedda)_2]Br\cdot 3H_2O$, was obtained by treating the mixed acetylacetone complex, $[Cr(acac)(edda)]\cdot 2H_2O$,[5] with *N*-bromosuccinimide in glacial acetic acid. Found: C, 27.14; H, 5.33; N, 10.57%. Calcd for $[Cr(Hedda)_2]Br\cdot 3H_2O$: C, 26.97; H, 4.91; N, 10.49%.

2) Bis-(ethylenediaminediacetato)-μ-dihydroxodichromium(III) Hexahydrate, $[Cr_2(OH)_2(edda)_2]\cdot 6H_2O$ (II). Five

grams (0.01 mol) of complex I were suspended in 50ml of water and the mixture was heated on a water bath. The complex I was gradually dissolved as a small amount of ammonium carbonate was added and then the color of the solution turned from red to purple. After adjusting the pH of the solution to about 7, it was cooled to 0°C. Reddish purple crystals were separated out and recrystallized from aqueous solution. Yield, 2.5g (84.2 %). Found: Cr. 17.73; H_2O, 17.20%. Calcd for $[Cr_2(OH)_2(edda)_2]\cdot 6H_2O$: Cr, 17.50; H_2O, 18.19%.

The thermal decomposition for this complex was carried out and the complexes which contain various amount of water of crystallization were obtained by successive dehydration. The dehydrated products at several desined temperatures were as follows: $[Cr_2(OH)_2(edda)_2]$ $4H_2O$ (at 46°C) (Found: C, 26.42; H, 5.32; N, 10.27%. Calcd: C, 25.81; H, 5.09; N, 10.03%), $[Cr_2(OH)_2(edda)_2]\cdot 2H_2O$ (at 80°C) (Found: C, 27.52; H, 5.09; N, 10.44%. Calcd: C, 27.59; H, 5.04; N, 10.73%), and $[Cr_2(OH)_2(edda)_2]$ (at 110°C) (Found: Cr, 20.80; C, 29.84; H, 4.65; N, 11.12%. Calcd: Cr, 21.38; C, 29.63; H, 4.57; N, 11.52%.).

3) Hydrogen Ethylenediaminediacetatooxalatochromate(III) Dihydrate, H[Cr(edda)(ox)]·$2H_2O$(III). To the aqueous solution of the complex II (2.8g, 0.005 mol), 1.3g (0.01 mol) of oxalic acid dihydrate was added and the solution was heated on a water bath. After adjusting the pH the solution to 1—2 with a small amount of oxalic acid dihydrate, it was cooled to 0°C. Purple crystals were separated out. Yield, about 2.7g (83.6%). Found: Cr, 13.74; C, 27.01; H, 4.45; N, 7.89%. Calcd for H[Cr(edda)(ox)]·$2H_2O$: Cr, 14.81; C, 27.35; H, 4.02; N, 7.98%.

4) Ethylenediaminediacetato- α,α'-dipyridylchromium(III) Iodide Pentahydrate, [Cr(edda)(dipy)]I·$5H_2O$ (IV). To the aqueous solution of the complex II (2.8)g, 1.6g (0.01 mol) of α, α'-dipyridyl was added and the mixture was heated on a water bath. After adjusting the pH of the solution to 3—4, about 5 g of sodium iodide, ethanol and ether were added. When it was cooled to 0°C, orange crystals were separated out and recrystallized from the mixed solution of water, ethanol and ether. Yield, about 2.6g (43.3%). Found: C, 32.32; H, 4.35; N, 8.50%. Calcd for [Cr(edda)(dipy)]I·$5H_2O$: C, 32.06; H, 4.72; N, 9.31%.

5) Potassium Diisothiocyanatoethylenediaminediacetatochromate(III) Monohydrate, K[Cr(NCS)$_2$(edda)]·H_2O (V). To the aqueous solution of the complex II (2.8g), 4g (0.04 mol) of potassium thiocyanate was added and the solution was heated on a water bath. After adjusting the pH of the solution to 4—5, it was cooled to 0°C. Reddish purple crystals were separated out and recrystallized from aqueous solution. Yield, about 2.4g (60.0%). Found: Cr, 13.19; C, 23.68; H, 3.12; N, 13.71%. Calcd for K[Cr(NCS)$_2$(edda)]·H_2O: Cr, 13.02; C, 24.06; H, 3.03; N, 14.03%.

6) Chloroethylenediaminediacetatoaquochromium(III) Trihydrate, [Cr(Cl)(edda)(H_2O)]·$3H_2O$ (VI). To the aqueous solution of the complex II (2.8g,) 4g (0.03 mol) of ethylenediamine dihydrochloride was added and the solution was heated on a water bath. When it was cooled to 0°C, blusidh purple crystals were separated out. Yield, about 0.5g (15.0%). Found: Cr, 15.09; C, 22.15; H, 4.95; N, 8.48%. Calcd for [Cr(Ci)(edda)(H_2O)]·$3H_2O$: Cr, 15.58; C, 21.59; H, 4.84; N, 8.39%.

Apparatus. The absorption spectra, reflecting absorption spectra and infrared absorption spectra were measured with a Hitachi EPS Spectrophotometer, a Hitachi EPU-2A Spectrophotometer equipped with the standard Hitachi Reflection Attachment, and a Nippon Bunko DS-301 Infrared Spectrometer. The quantity of the water of crystallization contained in the complex II was estimated from TGA curves measured with Derivatograph. The magnetic susceptibility was measured with a Gouy balance at room temperature.

Results and Discussion

Electronic Absorption Spectra. The visible absorption spectra for the complexes I, II, IV, V and VI and those by the diffusc-reflectance method for the complexes II and III are shown in Fig. 1, Fig. 2 and Fig. 3, respectively, and the numerical values of the absorption maxima are summarized in Table 1 together with those of the related compounds.

The first absorption peak of the complex I is in good agreement with that of *trans*-K[Cr(ida)$_2$]·$3H_2O$,*3 differing from that of the complexes II, III, and that of NH_4[Cr(edta)]·$2H_2O$[6] and [Cr(acac)(edda)]·$2H_2O$. From these results, it may be presumed that the complex I belongs to N_2O_4-type complex which has a *trans* structure

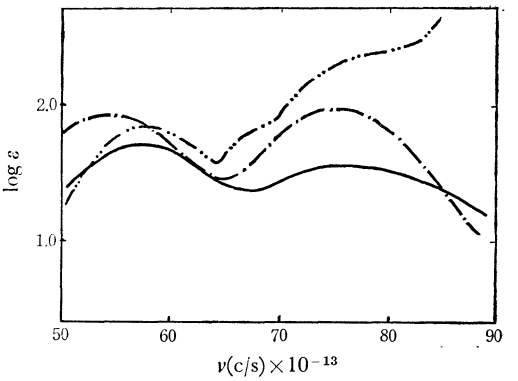

Fig. 1. Electronic spectra: I (——), II (—·—), IV (—··—).

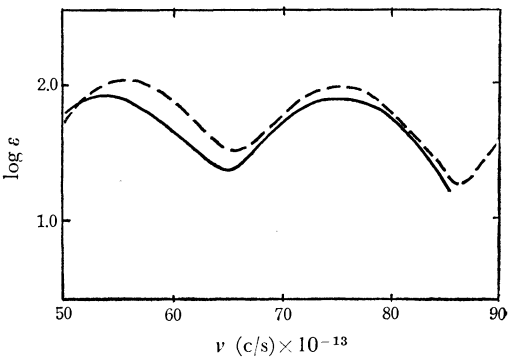

Fig. 2. Electronic spectra: V (----), VI (——).

*3 It will be published elsewhere.

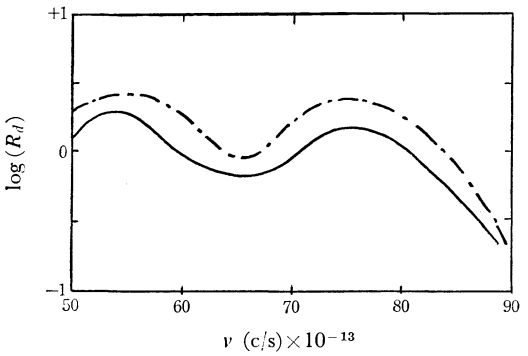

Fig. 3. Absorption spectra by the diffuse-reflectance method: II (—·—), III (——).

with respect to coordinated nitrogen atoms.

Since the spectrum of the complex II in an aqueous solution nearly agrees with the reflecting absorption spectrum of II, it may be suggested that the structure of the complex II in the solid state is also hold in the aqueous solution.

The spectra of the complexes II and III are very close to that of the edta complex, $NH_4[Cr(edta)]\cdot 2H_2O$, and they are also similar to the spectrum of the complex, $[Cr(acac)(edda)]\cdot 2H_2O$. Therefore, it may be suggested that the complexes II and III belong to N_2O_4-type.

The spectrum for the complex IV gives a complicated curve, showing two shoulders at 67.5×10^{13}/sec and at 79.0×10^{13}/sec, probably due to the α,α'-dipyridyl.

The complex V shows a specific absorption band at 100×10^{13} sec ($\log\varepsilon=2.99$) and the presence of this band indicates that the NCS^- coordinates with the chromium(III) ion.[7]

Since the spectrum of the complex VI in an aqueous solution was slowly turned to the spectrum of the complex II, it may suggest that the complex VI gradually undergoes dechlorination to form the dimer structure with respect to chromium(III) ion in an aqueous solution.

Derivatogram and Magnetic Moment. The derivatogram of the complex II is shown in Fig. 4. From the TGA curve, the formula of II may be $[Cr_2(OH)_2(edda)_2]\cdot 6H_2O$ and the composition of the thermal decomposition product between 100 and 180°C must be $[Cr_2(OH)_2(edda)_2]$.

The values of the effective magnetic moment of complex II and of the thermal decomposition products are remarkably lower than that of complex I which corresponds to the spin only value for tervalent chromium, as seen in Table 2. These facts may suggest that complex II and the thermal

decomposition products have a dimer structure bridged by OH^- groups.[8]

IR Spectra. Infrared absorption spectra of the six new complexes were measured to confirm whether carboxylate groups were coordinated or not and to obtain the configurational informations on the coordinated edda. It is well known that the carboxylate group, in general, exhibits the absorption band in the region between 1700 and 1750 cm^{-1} for the free acids.[9]

All the spectra of the complexes studied show bands at 1620 and 1675 cm^{-1}, as seen in Table 3. Therefore, it will be obvious that these bands are due to coordinated carboxylate groups.

The complex V shows the strong $\nu_{C\equiv N}$ band at 2095 cm^{-1}, and *cis*-$K[Cr(NCS)_2(ox)(en)]$[10] shows three strong $\nu_{C\equiv N}$ bands at 2120, 2080 and 2062 cm^{-1}. These suggest that the complex V has a higher symmetry than *cis*-$K[Cr(NCS)_2(ox)(en)]$, and then, α-form may be considered as the configuration of edda in the complex V.

Table 3. IR data (cm^{-1})

Complex	-COO-Cr(III)
$eddaH_2$	1736 (-COOH)
$[Cr(edda\ H)_2]Cl\cdot 3H_2O$	1670, 1635
$[Cr_2(edda)_2(OH)_2]\cdot 6H_2O$	1635
$[Cr(edda)(dipy)]I\cdot 5H_2O$	1656
$H[Cr(edda)(ox)]\cdot 2H_2O$	1655
$K[Cr(NCS)_2(edda)]\cdot H_2O$	1670, 1622
$[Cr(Cl)(edda)(H_2O)]\cdot 3H_2O$	1675(sh), 1640, 1620
$[Cr(edda)(acac))]\cdot 2H_2O$	1675(sh), 1630

On the other hand, the complex $[Cr(acac)(edda)]\cdot 2H_2O$ shows the splitted bands of ν_{N-H} at 3260 and 3140 cm^{-1} and this suggests that the configuration of the edda in the complex may be β-form (*cis* with respect to coordinated carboxylate oxygens).

Properties of the Complexes. Complex II was prepared from complex I with the appropriate pH adjustment in an aqueous solution, but the conversed attempt to prepare complex I from complex II was successful only in the case when both the pH adjustment and the addition of $eddaH_2$ were achieved. This fact supports that the complex I is 1 : 2 complex, as mentioned in the term of the absorption spectra.

The structure of complex I is very interesting because it has two eight membered-rings in the complex and the edda coordinates to the metal ion as a terdentate ligand, with one nitrogen and two oxygen atoms.

Since it is very easy to expel the water of crystallization from complex II, it is dehydrated to $[Cr_2(OH)_2(edda)_2]\cdot 4H_2O$ not only from hot aqueous solution but also often even at room temperature.

Though complex VI is easily decomposed to complex II in an aqueous solution, it is certain that Cl^- coordinates to Cr(III) ion in the fresh solution of VI, because it is adsorbed by neither Na nor Cl form ion exchangers.

Ionic Equilibria in Mixed Solvents. IV.*[1] Solvent Effect on Dissociation Constants of Acids

Hitoshi OHTAKI

The Laboratory of Analytical Chemistry, Faculty of Science, Nagoya University, Chikusa, Nagoya

(Received October 25, 1968)

Equilibrium of hydronium ions with alkoxonium ions in water-alcohol mixtures being taken into account, solvent effects on dissociation constants of acids were quantitatively interpreted by the following: free energy changes on transferring ions from an aqueous solution to a mixed solvent and difference in standard states in different solvent compositions. Choosing suitable values for "effective ionic radii" for ions involved, satisfactory agreements were found between experimental and calculated values of ΔpK, the difference of pK in water and in an aqueous mixture, for positively charged acids (*e. g.*, ammonium, anilinium, *etc.*) as well as neutral acids yielding a negatively charged conjugate base (*e. g.*, acetic acid, benzoic acid, *p*-nitrophenol, *etc.*).

Numerous investigations have been made on dissociation equilibria in aqueous mixed solvents. Variation of a dissociation constant of an acid, HA (*e. g.*, acetic acid), was qualitatively interpreted in terms of the variation of activity coefficients of component ions in different media applying the Born solvation energy equation. Taking into consideration the variation of the concentration of water in the solution, the behavior of the dissociation constant was better expressed as a function of dielectric constant of bulk solutions.[1] However, the above treatment was not successful for positively charged acids, which dissociate as follows:

$$BH^+ \rightleftarrows H^+ + B$$

A dissociation constant of the acid, BH^+, usually *increases* and then sharply *decreases* passing through a maximum with decreasing water concentration in the solvent. Paabo, Bates and Robinson[2] introduced a quantity not clearly defined which they called the "basicity effect" in their study of dissociation equilibria of ammonium ion in aqueous methanol solutions. Glover's assumptions[3] of formation of polymerized methanol molecules or somewhat unusual complexes of organic solvent molecules with water have not been confirmed.

Previous authors have paid little attention to the equilibrium between hydronium ion and an organic solvent molecule in their studies on the solvent effects on dissociation constants of acids. Equilibrium constants of a hydronium ion with a series of alcohol molecules have been determined by Conway, Bockris and Linton.[4] Equilibrium constants of the reaction

$$H_3O^+ + ROH \rightleftarrows H_2O + ROH_2^+ \qquad (1)$$

were found to be 0.23, 0.059 and 0.037 for R= $-CH_3$, $-CH_2CH_3$ and $-CH_2CH_2CH_3$, respectively.[4]

The present paper attempts a quantitative interpretation for the variation of dissociation constants of acids in aqueous methanol and ethanol solutions on the basis of the knowldege of hydronium-alkoxonium ion equilibria and of a suitable model for solvated ions in solution.

Standard Chemical Potential of Hydrogen Ion in an Aqueous Mixture. A chemical potential of hydrogen ion in a solution is formally described as:

$$\mu_H = \mu^\circ_H + \boldsymbol{R}T \ln(H^+) \qquad (2)$$

where μ_H and μ°_H denote the chemical potential and the standard chemical potential of hydrogen ion, respectively. ( ) represents activity. The standard state is defined so that the activity coefficient of hydrogen ion, as well as those of any other ions present in the solution, tends to unity as the composition of the solution approaches the given solvent composition.

In an aqueous solution all protons exist as hydrated ones so that Eq. (2) may be described as:

$$\mu_H(w) = \mu^\circ_H(w) + \boldsymbol{R}T \ln(H_3O^+(w)) \qquad (3)$$

the hydronium ion, H_3O^+, being assumed to be a unique entity of hydrated proton. Symbol (w) stands for water.

As seen in Eq. (1), however, in aqueous mixtures both hydronium and alkoxonium ions are considered to be thermodynamic entities which determine the chemical potential of hydrogen ion. Therefore, μ_H in aqueous alcohol mixtures must be

* Part III, *Inorg. Chem.*, **7**, 1205 (1968).

3) D. Glover, *J. Am. Chem. Soc.*, **87**, 5275, 5279 (1965).

4) B. E. Conway, J. O'M. Bockris and H. Linton, *J. Chem. Phys.*, **24**, 834 (1956).

described as:

$$\mu_{H}(s) \equiv (1-x)\mu_{H_3O}(s) + x\mu_{ROH_2}(s)$$
$$= (1-x)\mu^{\circ}_{H_3O}(s) + x\mu^{\circ}_{ROH_2}(s) + \boldsymbol{R}T\ln(H_3O^{+}(s))^{1-x}(ROH_2^{+}(s))^{x} \quad (4)$$

when one mole of hydrogen ion produces fractions of $1-x$ of hydronium ion and of x of alkoxonium ion. The symbol (s) denotes the solvent of an aqueous alcohol mixture. Thus, the standard chemical potential of hydrogen ion in the aqueous alcoholic solution is defined as:

$$\mu^{\circ}_{H}(s) \equiv (1-x)\mu^{\circ}_{H_3O}(s) + x\mu^{\circ}_{ROH_2}(s) \quad (5)$$

and hence, the activity of hydrogen ion, (H^{+}), is denfied as:

$$(H^{+}(s)) \equiv (H_3O^{+}(s))^{1-x}(ROH_2^{+}(s))^{x} \quad (6)$$

Dissociation Constants of Ammonium Ion in Water-Methanol Solutions. One mole of proton liberated from a mole of ammonium ion is shared to both H_2O and ROH according to the equilibrium given in Eq. (1). Thus, the dissociation equilibrium of ammonium ion in a water-methanol mixture is described as:

$$NH_4^{+}(s) + (1-x)H_2O(s) + x\mathrm{ROH}(s) \rightleftarrows NH_3(s) + (1-x)H_3O^{+}(s) + x\mathrm{ROH}_2^{+}(s) \quad (7)$$

Here x denotes a fraction of alkoxonium ion formed and is given by the following equation through the equilibrium constant, κ, of Eq. (1):

$$x = \frac{\kappa y}{1 - y + \kappa y} \quad (8)$$

activities of water and methanol being approximated to be equal to their mole fractions. y represents the mole fraction of methanol in the solvent.

The free energy change given as $(pK(s) - pK(w))\boldsymbol{R}T\ln 10$ corresponds to the free energy change of the transfer reaction:

$$NH_4^{+}(s) + (1-x)H_2O(s) + x\mathrm{ROH}(s) + H_3O^{+}(w) + NH_3(w) \rightarrow NH_4^{+}(w) + (1-x)H_3O^{+}(s) + x\mathrm{ROH}_2^{+}(s) + H_2O(w) + NH_3(s) \quad (9)$$

Thus, the difference of dissociation constants in an aqueous solution and in an aqueous methanol solution, $\Delta pK = pK(s) - pK(w)$, is given as:

$$\Delta pK = [(\mu^{\circ}_{NH_4}(w) - \mu^{\circ}_{NH_4}(s)) + (\mu^{\circ}_{H_2O}(w) - (1-x)\mu^{\circ}_{H_2O}(s) - x\mu^{\circ}_{ROH}(s)) + (\mu^{\circ}_{NH_3}(s) - \mu^{\circ}_{NH_3}(w)) + ((1-x)\mu^{\circ}_{H_3O}(s) + x\mu^{\circ}_{ROH_2}(s) - \mu^{\circ}_{H_3O}(w))]/\boldsymbol{R}T\ln 10 \quad (10)$$

Estimation of the Variation of the Standard Chemical Potentials. The variation of the standard chemical potential corresponds to the variation of the free energy on transferring one mole of the relevant species from one medium to another. We estimate the variation of the standard chemical potentials of ions from an aqueous solution to an aqueous methanol solution on the basis of a model which is essentially similar to that proposed by Stokes[5] with a slight modification for hydronium ion: The hydronium ion, H_3O^{+}, is a sphere with a "crystal radius" of $r = 1.4$ Å and is surrounded by a layer of 2.8 Å (the diameter of a water molecule) thickness of the first hydration shell. This layer has a minimum dielectric constant of about 5[5-7] (ε_1). The first hydration shell is covered with the second hydration shell whose thickness is 2.8 Å. The dielectric constant in the second hydration shell (ε_2) is given as:[5]

$$\frac{1}{\varepsilon_2} = \frac{1}{2}\left(\frac{1}{\varepsilon_1} - \frac{1}{\varepsilon_0}\right) \quad (11)$$

For values of dielectric constant of bulk solution, ε_0, a monograph by Harned and Owen[8] is referred to.

According to this model, the variation of the standard chemical potentials, or the free energy change of the transfer, of a hydronium ion, $\Delta\mu^{\circ}_{H_3O}$ is evaluated from an aqueous solution to an aqueous methanol solution.

$$\Delta\mu^{\circ}_{H_3O} = \mu^{\circ}_{H_3O}(s) - \mu^{\circ}_{H_3O}(s)(w) = \frac{Ne^2}{2}\left[\frac{2.8}{r(r+2.8)\varepsilon_1(s)} + \frac{2.8}{(r+2.8)(r+5.6)\varepsilon_2(s)} + \frac{1}{(r+5.6)\varepsilon_0(s)}\right] - \left[\frac{2.8}{r(r+2.8)\varepsilon_1(w)} + \frac{2.8}{(r+2.8)(r+5.6)\varepsilon_2(w)} + \frac{1}{(r+5.6)\varepsilon_0(w)}\right] = \frac{Ne^2}{2}\left[\left(\frac{0.0952}{\varepsilon_2(s)} + \frac{0.143}{\varepsilon_0(s)}\right) - 0.0112\right] \quad (12)$$

where N denotes the Avogadro number and e the charge unit.

For an alkoxonium ion, ROH_2^{+}, the corresponding radius of the ion is assumed to be the same as that of the hydronium ion, while it is assumed that the alkoxonium ion is not solvated. In the course of the transfer of ROH_2^{+} ion from pure water to an aqueous methanol solution, the values of $\Delta\mu^{\circ}_{ROH_2}$ are given as:

$$\Delta\mu^{\circ}_{ROH_2} = \mu^{\circ}_{ROH_2}(s) - \mu^{\circ}_{ROH_2}(w) = \frac{Ne^2}{2}\left(\frac{1}{1.4\varepsilon_0(s)} - 0.00910\right) \quad (13)$$

The crystal radius of ammonium ion is reported to be 1.48 Å.[2,9] An assumption of unsolvated ammonium ion leads to the value of $\Delta\mu^{\circ}_{NH_4}$ calculated by the following equation:

5) R. H. Stokes, *J. Am. Chem. Soc.*, **86**, 979 (1964).
6) J. B. Hasted, D. M. Riston and C. H. Collie, *J. Chem. Phys.*, **16**, 1 (1948).
7) G. H. Haggis, J. B. Hasted and T. J. Buchanan, *ibid.*, **20**, 1452 (1952).
8) H. S. Harned and B. B. Owen, "The Physical Chemistry of the Electrolytic Solutions," 3rd ed., Reinhold Publ. Corp., New York (1964), p. 161.
9) R. A. Robinson and R. H. Stokes, "Electrolyte Solutions," 2nd ed., Butterworths, London (1959), p. 461.

$$\Delta\mu^\circ_{NH_4} = \mu^\circ_{NH_4}(s) - \mu^\circ_{NH_4}(w) = \frac{Ne^2}{2}\left(\frac{1}{1.48\varepsilon_0(s)} - 0.00861\right) \quad (14)$$

A neutral ammonia molecule is expected to be subjected to the smallest change in free energy in the course of the transfer of the molecule from an aqueous solution to an aqueous methanol solution.

The free energy change caused by the variation of the standard state in each solution, which is given in terms of $\mu^\circ_{H_2O}(w) - (1-x)\mu^\circ_{H_2O}(s) - x\mu^\circ_{ROH}(s)$ in Eq. (10), is given as:

$$\mu^\circ_{H_2O}(w) - (1-x)\mu^\circ_{H_2O}(s) - x\mu^\circ_{ROH}(s) = RT\ln(H_2O(s))^{1-x}(ROH(s))^x/(H_2O(w)) = RT\ln(1-y)^{1-x}\cdot y^x \quad (15)$$

since the activity of water in aqueous solution is defined to be unity.

Table 1. Variation of dissociation constant of ammonium ion in water-methanol solutions at 25°C

Methanol, wt%	ΔpK(calcd)	ΔpK(obsd)[2]
0	—	—
10	−0.10	−0.099

80	−0.84	—
90	−0.71	—
100	+0.10	—

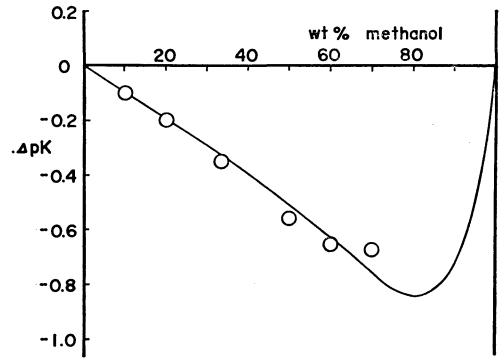

Fig. 1. Variation of ΔpK of ammonium ion as a function of the concentration of methanol. —— calculated; ○ experimental values by Paabo *et al.*[2]

In Table 1 are listed values of ΔpK of ammonium ion thus calculated by Eq. (10) and are compared with values of ΔpK reported by Paabo *et al.*[2] and the results are visualized in Fig. 1.

Dissociation Constants of Other Acids in Water-Methanol Solutions. Similar treatments were applied to systems of some acids in water-methanol solutions.

For an acid of BH^+ type, ΔpK is described in a form similar to Eq. (10); thus,

$$\Delta pK = [(\mu^\circ_{BH}(w) - \mu^\circ_{BH}(s)) + (\mu^\circ_{H_2O}(w) - (1-x)\mu^\circ_{H_2O}(s) - x\mu^\circ_{ROH}(s)) + (\mu^\circ_B(s) + \mu^\circ_B(w)) + ((1-x)\mu^\circ_{H_3O}(s) + x\mu^\circ_{ROH_2}(s) - \mu^\circ_{H_3O}(w))]/RT\ln 10 \quad (16)$$

and $\Delta\mu^\circ_{BH}$ is given as:

$$\Delta\mu^\circ_{BH} = \mu^\circ_{BH}(s) - \mu^\circ_{BH}(w) = \frac{Ne^2}{2r}\left(\frac{1}{\varepsilon_0(s)} - \frac{1}{\varepsilon_0(w)}\right) \quad (17)$$

the acid, BH^+, being assumed to be unsolvated. For terms of $\Delta\mu^\circ_{H_3O}$, $\Delta\mu^\circ_{ROH_2}$, $\Delta\mu^\circ_{H_2O}$, $\Delta\mu^\circ_{ROH}$ and $\Delta\mu^\circ_B$, the same values as calculated in the preceding section were used.

For an acid of HA type, ΔpK is given as:

$$\Delta pK = [(\mu^\circ_{HA}(w) - \mu^\circ_{HA}(s)) + (\mu^\circ_{H_2O}(w) - (1-x)\mu^\circ_{H_2O}(s) - x\mu^\circ_{ROH}(s)) + ((1-x)\mu^\circ_{H_3O}(s) + x\mu^\circ_{ROH_2}(s) - \mu^\circ_{H_3O}(w)) + (\mu^\circ_A(s) - \mu^\circ_A(w))]/RT\ln 10 \quad (18)$$

In Eq. (18) we put $\mu^\circ_{HA}(s) - \mu^\circ_{HA}(w) \simeq 0$, because HA is neutral. For the ion A^-

$$\Delta\mu^\circ_A = \mu^\circ_A(s) - \mu^\circ_A(w) = \frac{Ne^2}{2r}\left(\frac{1}{\varepsilon_0(s)} - \frac{1}{\varepsilon_0(w)}\right) \quad (19)$$

Since "crystal radius" of any ion of these acids has not been evaluated, r of the ion was used as a parameter of calculation so that calculated results would best fit the experimental data. In this sense we shall call r the "effective ionic radius".

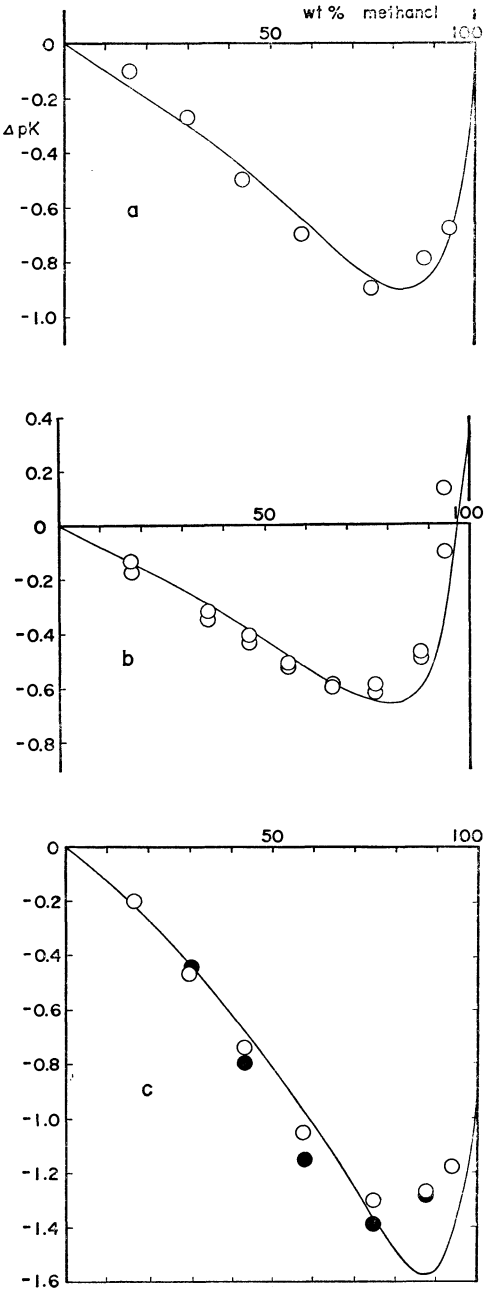
Table 2. Effective ionic radii of ions in water-methanol solutions

Ion	r (Å)	Ref.
Ammonium	1.48	2
Diethylethanolammonium	1.4	10
Anilinium	1.8	11, 12
Diethanolammonium	2.3	10
Piperidinium	1.1	10
Trimethylpyridinium	0.9	10
Pyridinium	0.9	10
Acetate	0.8	10, 11, 15
Mandelate	0.8 (0.7—0.9)*	10
p-Nitrophenolate	1.3	10
o-Nitrophenolate	1.1 (1.0—1.2)*	10
m-Nitrophenolate	1.1 (1.0—1.2)*	10
3,4-Dinitrophenolate	1.4	10
2,5-Dinitrophenolate	1.4	10
2,4-Dinitrophenolate	1.3	10

* Values in brackets show the range of r spread.

Comparison of ΔpK values thus calculated with those observed are demonstrated for some aliphatic and aromatic amines, heterocyclic nitrogen compounds, aliphatic and aromatic carboxylic acids and phenols, and some examples are graphically represented in Fig. 2. The values of the "effective ionic radii" adopted are summarized in Table 2.

Dissociation Constants of Acids in Water-Ethanol Solutions. The validity of the present treatment was tested for dissociation equilibria of some acids in water-ethanol solutions. Resulting values of ΔpK in some examples are shown in Fig. 3 and values of r examined are tabulated in Table 3.



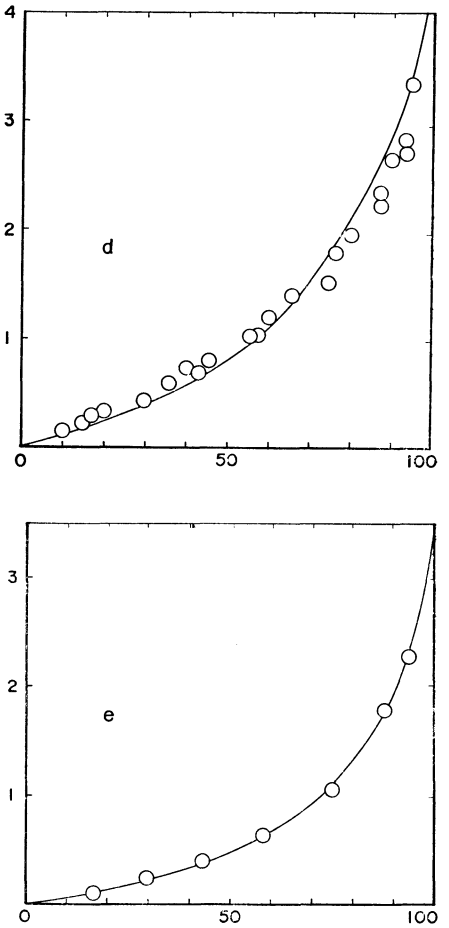


Fig. 2. Variation of ΔpK of various acids as a function of the concentration of methanol. Lines drawn show calculated values of ΔpK's using corresponding values of r in Table 2.
a, diethylethanolammonium
b, anilinium
c, pyridinium (○) and trimethylpyridinium (●)
d, acetic acid
e, *p*-nitrophenol

Discussion

From Tables 2 and 3 it is seen that ammonium, diethylethanolammonium and anilinium ions have similar values of the effective ionic radius despite the fact that their pK values are widely spread (pK(ammonium)=9.245,[2] pK(diethylethanolammonium)=9.90[10] and pK(anilinium)=4.60[11]

c, acetic acid; d, formic acid.

Table 3. Effective ionic radii of ions in water-ethanol solutions

Ion	r (Å)	Ref.
Ammonium	1.4—1.5	13
Anilinium	1.4—1.8	11, 13
Acetate	0.8 (0.7—0.9)*	11, 13, 14
Formate	1.3	13, 14
Propionate	0.9 (0.8—1.0)*	13, 14
Benzoate	0.8 (0.7—0.9)*	13, 14

* Values in brackets show the range of r spread.

or 4.62[12]) in aqueous solution at 25°). Similar phenomena may be found in systems of acetic acid ($pK=4.76$[10-12]) in aqueous solution at 25°), propionic acid ($pK=4.87$,[13,14]) benzoic acid ($pK=4.20$[13,14]) and mandelic acid ($pK=3.45$[10]). Thus the variation of pK may mainly be caused by the energy change of electrostatic interactions of charged atom with solvent moleculeus.

The effective ionic radius is found to remain unchanged when the solvent is changed from water-methanol to water-ethanol mixtures.

The fact that the effective ionic radius scarcely changes for various ions with the same functional group but with different molecular volumes may indicate that the effective ionic radius may not give the size of the whole molecule but that of a charged site such as oxygen in a carboxylate group and a phenolate or nitrogen in an ammonium group and a heterocyclic compound. A charge in

12) A. Bacarella, E. Grunwald, H. P. Marshall and E. L. Purlee, *J. Org. Chem.*, **20**, 747 (1955).
13) R. G. Bates, "Determination of pH," John Wiley and Sons, Inc., New York (1964), p. 195.

an ion may be located on a specific site such as oxygen or nitrogen atom, and the electrostatic interaction of the ion with the surrounding medium may be described as a function of the distance from the charged atom in question. A hydrophobic group which occupies the major part of the volume of an ion may contribute to a lesser extent to the electrostatic interaction between the charged site in the molecule and the surrounding medium. Solvation of ions having hydrophobic groups may be smallest so that the relationships of Eqs. (17) and (19) may hold with a good approximation.

Similarly the assumption that the alkoxonium ion, $R\text{-}OH^{2+}$, has the same effective ionic radius as that of hydronium ion may be supported in spite of their different molecular volumes.

From results in Tables 2 and 3, the effective ionic radii are estimated as follows: 1.4—1.5 Å for $-NH_3^+$ in ammonium and aliphatic ammonium ions, 0.9—1.1 Å for $>NH^+$ in hererocyclic compounds, 0.7—0.9 Å for $-O^-$ in carboxylic acids, 1.1—1.4 Å for $-O^-$ in phenols. Values of the effective ionic radii of diethanolammonium and formate ions are large as compared with the related compounds. This may be attributed to easier hydration of these ions: relatively hydrophilic ethanol groups in the former may allow water molecules to approach a charged nitrogen atom with electrostatic interactions, and the latter, formate ion, has no aliphatic radicals.

Some discrepancies observed in water-ethanol systems seem to be due to a more or less crude approximation that activities of water and ethanol are put equel to their mole fractions. Vapor pressure data show that water-methanol mixtures[16] are better approximated to the ideal mixtures than water-ethanol mixtures.[17]

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 1578—1583 (1969)

The Kinetics of Substitution Reactions Involving Metal Complexes. XIII. Reactions of Zinc(II) with *meso*-Butylenediaminetetraacetatocobaltate(II) and with Propylenediaminetetraacetatocobaltate(II)

Hiroshi OGINO, Toshiyuki BABA*1 and Nobuyuki TANAKA

Department of Chemistry, Faculty of Science, Tohoku University, Katahira-cho, Sendai

(Received October 31, 1968)

Kinetics of the substitution reactions of zinc(II) with *meso*-butylenediaminetetraacetatocobaltate(II) (cobalt(II)-*meso*-BDTA) and propylenediaminetetraacetatocobaltate(II) (cobalt(II)-PDTA) have been studied. The reaction of zinc(II) with cobalt(II)-*meso*-BDTA complex proceeds through two simultaneous reaction paths involving the acid dissociation reactions of the cobalt(II) complex. On the other hand, the reaction of zinc(II) with cobalt(II)-PDTA proceeds through four simultaneous reaction paths, of which two involve electrophilic substitution reactions and the others, the acid dissociation reactions of the cobalt(II) complex. This kinetic behavior is discussed on the basis of the natures of the ligands.

Kinetic studies of the reactions of zinc(II) with ethylenediaminetetraacetatocobaltate(II) (cobalt(II)-EDTA) and trimethylenediaminetetraacetatocobaltate(II) (cobalt(II)-TRDTA) have been reported.[1] According to the results, the variation of ligands affects the rates of both the electrophilic substitution (S_E) reactions and the acid dissociation reactions of the cobalt(II) complexes. As it seems important to know of the effects of other ligands on both the mechanisms and the rates of the reactions, substitution reactions of zinc(II) with cobalt(II) complexes containing *meso*-butylene-

diaminetetraacetate (*meso*-BDTA)*2 and propylenediaminetetraacetate (PDTA)*3 are investigated at ionic strength 0.2 and 25°C in this study.

Experimental

The preparations and standardizations of the solutions of zinc(II) nitrate, cobalt(II) nitrate and disodium dihydrogen propylenediaminetetraacetate (Na_2H_2pdta) were made by the same method as reported previously.[2,3]

meso-Butylenediaminetetraacetic acid was prepared by the following procedures: *meso*-Butylenediamine was prepared by the method of Dickey *et al.*,[4] and this diamine was converted to the *meso*-BDTA by the method of Dwyer and Garvan.[5] Crude *meso*-BDTA was recrystallized from hot water. Found: C, 40.19; H, 7.00; N, 8.03%. Calcd for $C_{12}H_{20}N_{20}O_8 \cdot 2H_2O$; C, 40.38; H, 6.78; N, 7.83%.

By measuring NMR spectra of *meso*-butylenediamine,[6] *meso*-BDTA[6] and cobalt(III)-*meso*-BDTA complex[7] in aqueous solutions, it was confirmed that *meso*-BDTA thus obtained did not contain *dl*-BDTA as impurity.

The stock solution of disodium dihydrogen *meso*-butylenediaminetetraacetate (Na_2H_2*meso*-bdta) was prepared from equimolar sodium carbonate and H_4*meso*-bdta. The concentration of *meso*-BDTA was determined by amperometric titration with the above-mentioned solutions of metal nitrates. All other chemicals used were analytical reagent grade.

It was reported that cobalt(II)-EDTA, cobalt(II)-TRDTA and cobalt(II)-PDTA give polarographic one-electron oxidation waves in acetate buffer-potassium nitrate media.[8] In this study, it was found that cobalt(II)-*meso*-BDTA gives a similar polarographic one-electron anodic wave with the half-wave potential at +0.099 V *vs.* SCE. The rates of the reactions of zinc(II) with cobalt(II)-*meso*-BDTA and cobalt(II)-PDTA were followed by the measurements of the decrease of the polarographic anodic diffusion current with time.

The measurements of both current-voltage and current-time curves were made with a Yanagimoto GR-103 Galvarecorder and a Yanagimoto AP-1 applying potentiometer. The dropping mercury electrode had an m value of 1.84 mg/sec and a drop time t_d of 4.26 sec at 55 cm of the mercury height in an air-free solution containing 0.1 M acetate buffer and 0.1 M potassium nitrate at 25°C and −0.50 V *vs.* SCE.

The ionic strength was adjusted to be 0.2 with potassium nitrate. Gelatin was added as a maximum suppressor by 0.005% in concentration. The pH of the solution was measured with a Hitachi-Horiba F-5 pH meter.

Results

It is known that zinc(II) and cobalt(II) ions form monoacetato complexes in acetate buffer solutions at ionic strength of 0.2.[9,10] Therefore, the overall reactions of zinc(II) with cobalt(II)-*meso*-BDTA or cobalt(II)-PDTA are expressed by

$$\left\{\begin{matrix}Zn^{2+}\\ \rightleftarrows\\ ZnOAc^{+}\end{matrix}\right\} + \left\{\begin{matrix}CoY^{2-}\\ \rightleftarrows\\ CoHY^{-}\\ \rightleftarrows\\ \vdots\end{matrix}\right\} \underset{k^-}{\overset{k^+}{\rightleftharpoons}} \left\{\begin{matrix}ZnY^{2-}\\ \rightleftarrows\\ ZnHY^{-}\\ \rightleftarrows\\ \vdots\end{matrix}\right\} + \left\{\begin{matrix}Co^{2+}\\ \rightleftarrows\\ CoOAc^{+}\end{matrix}\right\} \quad (1)$$

where Y^{4-} means a quadrivalent *meso*-BDTA or PDTA anion. The reactions were initiated by adding a known amount of cobalt(II)-*meso*-BDTA or cobalt(II)-PDTA solution into an acetate buffer-potassium nitrate solution containing zinc(II) ions in a large excess. Considering the anodic current, $\bar{i}$, given by cobalt(II)-*meso*-BDTA or cobalt(II)-PDTA complex, the forward rate constant of Eq. (1), k^+, is written as follows:[10]

$$2.303 \log \frac{\bar{i}_0^2 - \bar{i}_e\bar{i}}{\bar{i}_0(\bar{i} - \bar{i}_e)} = \frac{\bar{i}_0 + \bar{i}_e}{\bar{i}_0 - \bar{i}_e} k^+ t \quad (2)$$

where subscripts e and 0 denote equilibrium and initial conditions, respectively.

It was found that the changes in the initial concentration of cobalt(II) complex did not affect the values of k^+.

Figure 1 shows the values of k^+ which were obtained from the reactions between zinc(II) and cobalt(II)-*meso*-BDTA as a function of the hydrogen ion concentration. The change in concentrations of zinc(II) ions does not affect the values of k^+ as shown in Fig. 1. The plots fit the equation in which the rate is dependent on the

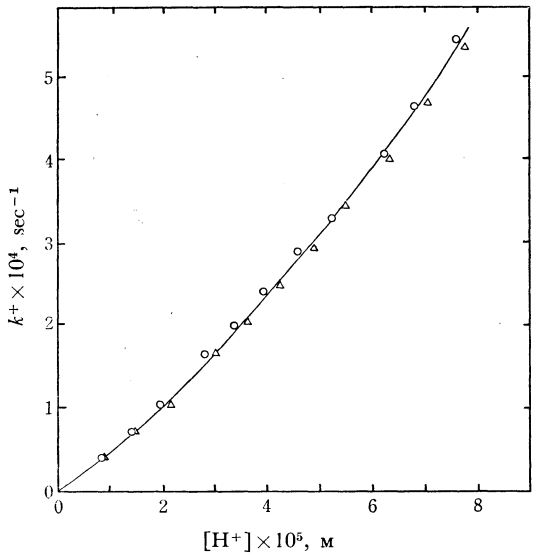

Fig. 1. k^+ for the reaction between zinc(II) and cobalt(II)-*meso*-BDTA as a function of hydrogen ion concentration. $[Zn^{2+}]_{0,app}$'s are 10.3 mM for ○ and 20.6 mM for △. Acetate ion concentrations are 0.096_8 M for ○ and 0.093_8 M for △.

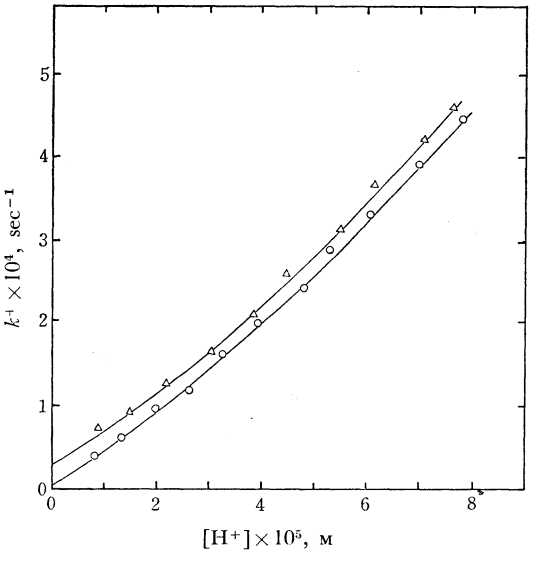

Fig. 2. k^+ for the reaction between zinc(II) and cobalt(II)-PDTA as a function of hydrogen ion concentration. $[Zn^{2+}]_{0,app}$'s are 5.15 mM for ○ and 25.8 mM for △. Acetate ion concentrations are 0.098_4 M for ○ and 0.092_4 M for △.

second power of the hydrogen ion concentration. From Fig. 1, the equation,

$$k^+ = 0.51_0 \times 10[H^+] + 0.02_7 \times 10^6[H^+]^2 \quad (3)$$

was obtained at $[Zn^{2+}]_{0,app}$ equal to both 10.3 mM and 20.6 mM.

In Fig. 2, the values of k^+ which were obtained from the reactions between zinc(II) and cobalt(II)-PDTA are plotted against the hydrogen ion concentration. In this case, the values of k^+ increase with the concentration of zinc(II) ions. From Fig. 2, the following equations were obtained:

$$\text{At } [Zn^{2+}]_{0,app} = 5.15 \text{ mM},$$
$$k^+ = 0.05 \times 10^{-4} + 0.40_8 \times 10[H^+] + 0.02_0 \times 10^6[H^+]^2 \quad (4)$$
$$\text{At } [Zn^{2+}]_{0,app} = 25.8 \text{ mM},$$
$$k^+ = 0.33 \times 10^{-4} + 0.43_3 \times 10[H^+] + 0.01_7 \times 10^6[H^+]^2 \quad (5)$$

From the results mentioned above and those reported in the previous paper,[1] the reaction of zinc(II) with cobalt(II)-*meso*-BDTA and that of zinc(II) with cobalt(II)-PDTA are considered to proceed through the following reaction paths:

$$\text{(i)} \quad Zn^{2+} + CoY^{2-} \overset{k_{Zn}^{CoY}}{\rightleftharpoons} ZnY^{2-} + Co^{2+} \quad (6)$$

$$\text{(ii)} \quad CoY^{2-} + H^+ \rightleftharpoons CoHY^- \quad (7a)$$
$$Zn^{2+} + CoHY^- \overset{k_{Zn}^{CoHY}}{\rightleftharpoons} ZnHY^- + Co^{2+} \quad (7b)$$

$$\text{(iii)} \quad CoY^{2-} + H^+ \overset{k_{H}^{CoY}}{\rightleftharpoons} Co^{2+} + HY^{3-} \quad (8a)$$
$$Zn^{2+} + HY^{3-} \rightleftharpoons ZnY^{2-} + H^+ \quad (8b)$$

$$\text{(iv)} \quad CoY^{2-} + 2H^+ \overset{k_{2H}^{CoY}}{\rightleftharpoons} Co^{2+} + H_2Y^{2-} \quad (9a)$$
$$Zn^{2+} + H_2Y^{2-} \rightleftharpoons ZnY^{2-} + 2H^+ \quad (9b)$$

Equation (10) was obtained on the basis of these reaction mechanisms.

$$k^+\alpha_{CoY(H)} = k_{Zn}^{CoY}\frac{[Zn^{2+}]_{0,app}}{\alpha_{Zn(OAc)}} + (k_{Zn}^{CoHY}K_{CoHY}^{H}\frac{[Zn^{2+}]_{0,app}}{\alpha_{Zn(OAc)}} + k_{H}^{CoY})[H^+] + k_{2H}^{CoY}[H^+]^2 \quad (10)$$

where

$$\alpha_{CoY(H)} = 1 + K_{CoHY}^{H}[H^+]$$
$$\alpha_{Zn(OAc)} = 1 + \beta_{ZnOAc}[OAc^-]$$
$$[Zn^{2+}]_{0,app} = [Zn^{2+}]_0 + [ZnOAc^+]_0$$
$$K_{CoHY}^{H} = [CoHY^-]/[CoY^{2-}][H^+]$$

β_{ZnOAc} represents the formation constant of acetatozinc(II) complex reported in the previous paper.[9] It has been shown that the values of K_{CoHY}^{H} are $10^{3.0}$ and $10^{2.4}$ for cobalt(II)-EDTA and cobalt(II)-TRDTA complexes, respectively.[11] Since it is unlikely that the values of K_{CoHY}^{H} for cobalt(II)-*meso*-BDTA and cobalt(II)-PDTA complexes are very different in magnitude from those for Co(II)-EDTA and cobalt(II)-TRDTA complexes and all measurements were carried out

11) G. Anderegg, *Helv. Chim. Acta*, **47**, 1801 (1964).

at pH range from 4.2 to 5.0, it is reasonable to assume that the values of $\alpha_{CoY(H)}$ do not differ significantly from unity.

The rate constants for the reaction between zinc(II) and cobalt(II)-*meso*-BDTA were obtained from the analysis of Eq. (3) with the aid of Eq. (10), and are given in Table 1. It should be noted that reaction paths (i) and (ii) were not observed in this reaction.

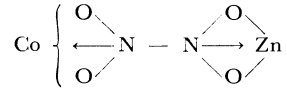
The rate constants for the reaction between zinc(II) and cobalt(II)-PDTA were obtained from the analysis of Eqs. (4), (5) and (10), and are also given in Table 1.

Table 1. Rate constants at ionic strength 0.2 and 25°C

Rate constant	*meso*-BDTA	PDTA
k_{Zn}^{CoY} ($l\,mol^{-1}\,sec^{-1}$)	$<7\times10^{-4}$	2×10^{-3}
k_{Zn}^{CoHY} ($l\,mol^{-1}\,sec^{-1}$)	—	$\sim2\times10^{-2}$
k_{H}^{CoY} ($l\,mol^{-1}\,sec^{-1}$)	5.1	4.3
k_{2H}^{CoY} ($l^2\,mol^{-2}\,sec^{-1}$)	3×10^{4}	2×10^{4}

Discussion

By the application of the treatment of Bydalek *et al.*,[12-14] it was proposed previously[1] that the binuclear intermediate,



(A)

was formed for the acid-independent electrophilic substitution (S_E) reaction,

$$Zn^{2+} + CoY^{2-} \xrightarrow{k_{Zn}^{CoY}} ZnY^{2-} + Co^{2+} \qquad (11)$$

where Y^{4-} denotes a quadrivalent EDTA or TRDTA anion. Furthermore, it was shown that the change of the rate constants of reaction (11) can be related to the equation,[1]

$$\frac{k_{Zn}^{Cotrdta}}{k_{Zn}^{Coedta}} = \frac{K_{Coedta}}{K_{Cotrdta}} \qquad (12)$$

It is shown in Table 2 that the order of the observed rates of S_E reactions is given as

$$TRDTA > EDTA > PDTA > meso\text{-}BDTA \approx 0$$

Table 2 gives also the comparisons of the observed rate constant ratios of various S_E reactions, $k_{Zn}^{CoY'}/k_{Zn}^{CoY}$, and the stability constant ratios, $K_{CoY}/K_{CoY'}$. The observed values of PDTA system and especially *meso*-BDTA system are not in agreement with the calculated values. These disagreements are considered to be due to the following reasons: The formation of binuclear intermediate (A) is accompanied necessarily by the rotation about the ethylenic carbon-carbon bond. PDTA and *meso*-BDTA complexes contain one and two methyl groups on the ethylenic carbon-carbon bond, respectively. Hence, the rotational barrier about the ethylenic bond increases with the order,

$$EDTA < PDTA < meso\text{-}BDTA$$

This steric hindrance of methyl groups leads to the decrease in the rate of reaction (11), so that the acid-independent S_E reaction of zinc(II) with cobalt(II)-*meso*-BDTA could not be observed. In addition, the inductive effect of the methyl groups increases the basicity of nitrogen in ligands and strengthens the cobalt-nitrogen bonds. This effect may assist also the decrease of reaction rate because the S_E reaction is accompanied by breaking of a cobalt-nitrogen bond.

In the previous paper,[1] the value of k_H^{CoY}/k_{Zn}^{CoY} for both EDTA and TRDTA matched best with the calculated intermediate stability constant ratio of $K_{Himda}\times K_{el}/K_{Znimda}$, where imda denotes iminodiacetate segment and K_{el} implies a correction for an electrostatic attraction. This fact suggests that the intermediate formed in the reac-

Table 2. Comparisons of ratios of observed rate constants with those of stability constants

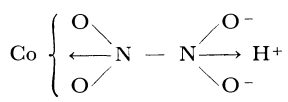
tion between CoY^{2-} ion and hydrogen ion corresponds to the structure,



(B)

If the basicities and steric environments of ligands are similar, it is expected that the rate constant of the reaction of CoY^{2-} with a hydrogen ion, k_H^{CoY}, can be related to Eq. (13), which is analogous to Eq. (12):

$$\frac{k_H^{CoY'}}{k_H^{CoY}} \fallingdotseq \frac{K_{CoY}}{K_{CoY'}} \tag{13}$$

In Table 2, are also given the comparison of the ratios of observed rate constants, $k_H^{CoY}/k_H^{CoY'}$, and those of the stability constants, $K_{CoY}/K_{CoY'}$. Although the value of $k_H^{Cotrdta}/k_H^{Coedta}$ is in good agreement with the value of $K_{Coedta}/K_{Cotrdta}$, the observed values of $k_H^{Copdta}/k_H^{Coedta}$ and $k_H^{Co\,meso\text{-}bdta}/k_H^{Coedta}$ do not agree with the ratios of the stability constant. However, these disagreements are not so marked as those in the values of $k_{Zn}^{CoY'}/k_{Zn}^{Coedta}$. This seems to be attributable to the fact that the complete rotation about the ethylenic carbon-carbon bond is not required for the reaction between CoY^{2-} and a hydrogen ion taking place. In fact, molecular models show that both hydrogen and cobalt ions can coordinate simultaneously to each nitrogen atom in a ligand without complete rotation about the ethylenic bond. An extreme case is the reaction between cyclohexanediaminetetraacetato complex (CyDTA complex) ions and hydrogen ions. Although cyclohexane ring in CyDTA forbids the rotation of the two iminodiacetate groups, the reaction of CyDTA complex ions with hydrogen ions proceeds.[16,17]

Table 3. Values of k_H^{CoY} and k_{Co}^{HY} at ionic strength 0.2 and 25°C

Ligand	k_H^{CoY} $l\,mol^{-1}\,sec^{-1}$	k_{Co}^{HY} $l\,mol^{-1}\,sec^{-1}$	Ref.
TRDTA	5×10^2	8×10^6	1
EDTA	3×10	8×10^6	1
meso-BDTA	5.1	4×10^6	This work
PDTA	4.3	7×10^6	This work

In Table 3, are shown the values of k_H^{CoY} for various ligands. The values of k_H^{CoY} can be related to the rate constants, k_{Co}^{HY} of the complex-forming reactions,

$$Co^{2+} + HY^{3-} \underset{k_H^{CoY}}{\overset{k_{Co}^{HY}}{\rightleftharpoons}} CoY^{2-} + H^+ \tag{14}$$

with the equation,

$$k_H^{CoY} = \frac{k_{Co}^{HY}}{K_{CoY}K_{HY}} \tag{15}$$

where K_{HY} denotes the fourth dissociation constant of H_4Y. The values of k_{Co}^{HY} calculated by Eq. (15) are also given in Table 3. In accord with the previous conclusion that the second-order rate constants of the complex-forming reactions of a metal ion with related ligands (with the same charge and a similar size) are almost the same,[1,18] the values of k_{Co}^{HY} given in Table 3 are essentially identical for various ligands. Hence, the nature of ligands may reflect predominantly to the values of k_H^{CoY}.

It may be seen in Table 3 that the order of the values of k_H^{CoY} is as follows:

$$TRDTA > EDTA > meso\text{-}BDTA > PDTA$$

The increase in basicities of PDTA and *meso*-BDTA by the presence of methyl groups may cause the decrease in the value of k_H^{CoY} with the following order:

$$k_H^{Coedta} > k_H^{Copdta} > k_H^{Co\,meso\text{-}bdta}$$

However, as is seen in Table 3, the value of $k_H^{Co\,meso\text{-}bdta}$ is larger than the value of k_H^{Copdta} in spite of the increase of the number of methyl groups in the ligand. This can be understood by considering the conformation of methyl groups in the coordinated ligands. There are two possibilities of the orientation of a methyl group on the N–C–C–N chelate ring of the coordinated PDTA; that is, an equatorial and an axial orientations. The complex with a methyl group of equatorial orientation is strainless as in the EDTA complex, while the complex with a methyl group of axial orientation is more crowded on the chelate and is strained. In fact, it is known that the orientation of a methyl group of the coordinated PDTA is equatorial.[19-22] In the *meso*-BDTA complex, there are two methyl groups on the N–C–C–N chelate ring. Molecular models reveal that the orientation of one methyl group in the coordinated *meso*-

BDTA is equatorial and the orientation of another methyl group is necessarily axial. Therefore, it is considered that the *meso*-BDTA complex is not more stable than the PDTA complex due to the presence of axial methyl group.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 1583—1588 (1969)

Preparation and Circular Dichroism of *trans(N)*- and *cis(N)*-Isomers of (Ammoniatriacetato)(amino-acidato)cobalt(III) Complexes

Norio KOINE and Naokazu SAKOTA

Department of Industrial Chemistry, Faculty of Engineering, Ehime University, Bunkyo-cho, Matsuyama

and Jinsai HIDAKA and Yoichi SHIMURA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka

(Received November 1, 1968)

Eleven new complexes, *trans(N)*- or *cis(N)*-isomers of (ammoniatriacetato)(amino-acidato)-cobalt(III) ions, have been synthesized as their potassium salts, where the amino acids are glycine, β-alanine, γ-aminobutyric acid, sarcosine, L-alanine, L-serine, L-valine and L-proline. The geometrical isomers have been separated by ion-exchange column chromatography and their structures determined on the basis of their absorption spectra and proton magnetic resonance spectra. Stereoselectivity about the formation of the *trans* and *cis* isomers was found. The circular dichroism of the complexes containing optically active amino acidato ligands has been measured and discussed in relation to so-called vicinal contribution by the optically active ligands.

It has been recognized that the transition metal complexes, in which the configuration around the central metal ion is not chiral but the ligand coordinated has a kind of chiral configuration, show markedly the cotton effect in the d→d absorption bands of the central metal ion by so-called vicinal effect.[1] It has been pointed out that the CD curve due to the vicinal effect shows the split components of the d→d absorption bands more clearly than that of the configurational effect which arises from a chiral configuration near around the central metal ion.[2] These investigations have been achieved on the basis of the fact that the vicinal and the configurational contributions to the CD are separable and additive.[3,4] In these circumstances, it is thought to be desirable to study more in detail the vicinal contribution for various kinds of metal complexes. Two geometrical isomers, *trans(N)* and *cis(N)*, are possible for the (ammoniatriacetato)(L-amino-acidato)cobalt(III) ion, $[Co(ata)(L\text{-}am)]^-$, where the ata and the L-am are coordinated as a tetradentate and a bidentate ligand respectively.*1 Both the isomers of this complex have no chiral configuration near around the central cobalt(III) ion in a first approximation but have the vicinal CD contribution mainly due to an asymmetric carbon atom of the ligand amino acid ion.

The present study is concerned with the preparation, the d→d absorption spectra and CD spectra of the *trans(N)*- and *cis(N)*-K[Co(ata)(am)] complexes including both optically active and non-active amino acid ions as the bidentate ligand am. Only one complex, *cis(N)*-K[Co(ata)(gly)]·$2H_2O$,

*1 The abbreviation "ata" represents a tervalent ammoniatriacetate ion, $N(CH_2COO)_3^{3-}$ and "am" a univalent amino acid ion in general, and "gly" glycinate, "β-ala" β-alaninate, "γ-ambut" γ-aminobutyrate, "sar" sarcosinate, "L-ala" L-alaninate, "L-ser" L-serinate, "L-val" L-valinate, and "L-pro" L-prolinate ion.

has been known[5] in this group.

Experimental

Preparation of Potassium (Ammoniatriacetato)-(amino-acidato)cobaltate(III): K[Co(ata)(am)]·n-H_2O. A solution of 10.2 g of cobalt(II) acetate tetrahydrate in 20 m*l* of water was added to a solution containing 8.0 g of ataH_3 in 15 m*l* of 2 N potassium hydroxide. To this 6.0 g of lead dioxide was added and the resulting mixture was mechanically stirred at 60°C for about 30 min. The color of the solution changed from dark red to blue violet. After the mixture had been cooled to room temperature, an excess of lead dioxide was filtered off. To the filtrate a calculated amount of the amino acid concerned was added and the solution was mechanically stirred at 60°C until its color changed to reddish violet. The solution was cooled in an ice bath for one hour and a small quantity of insoluble material precipitated was filtered off. The reddish violet filtrate was treated as follows; as in (1) for the glycinato, sarcosinato and L-serinato complexes and as in (2) for the other amino acidato complexes. (1): A large amount of ethanol was added to the filtrate. The reddish violet deposit was filtered and washed with methanol and ether, and then dried in a vacuum desiccator. The yield was approximately 14 g. (2): In order to remove the lead(II) ion, 3.7 g of potassium sulfate was added to the filtrate and the mixed solution was thoroughly stirred at 60°C. After the resulting solution had been cooled to room temperature, the lead sulfate precipitated was filtered off. The filtrate was concentrated to the syrup on a vacuum evaporator. This syrup was diluted by adding an appropriate amount of methanol and then the insoluble by-products were filtered off. It was confirmed, by the column chromatographic method, that the by-products were not the complex desired. A large amount of ethanol-ether mixture (1 : 1) was added to the filtrate. The reddish violet product deposited was filtered and washed with methanol-ether mixture and ether, and then dried in a vacuum desiccator. The yield was approximately 7 g.

Separation of *trans*(*N*)- and *cis*(*N*)-K[Co(ata)·(am)]·$n$$H_2O$. Each of the products obtained in (1) or (2) was separated into the *trans*(*N*) and *cis*(*N*) isomers by the column chromatographic method. Namely, about 7 g of the crude product was dissolved in water and passed through a column (30 mm×500 mm) containing strong anion exchange resin(Dowex 1X-8, 100—200 mesh, chloride form). After the column had been swept with water, the adsorbed band was eluted with 0.07 N aqueous solution of potassium chloride at a rate of about 2.5 m*l* per min. By elution with 0.07 N potassium chloride, two colored bands, a reddish purple one and a violet one, were eluted in this order and completely separated from each other. The earlier fraction was confirmed to be the *trans*(*N*) isomer and the one eluted later to be the *cis*(*N*) isomer by the measurement of their absorption spectra.[5,6]

Each of the eluates was concentrated to dryness on a vacuum evaporator. The resulting crude complexes, which were contaminated with a small amount of potassium chloride, were treated as follows. In the case of the *trans*(*N*) isomers of the glycinato, sarcosinato and L-serinato complexes and of all the *cis* isomers, the crude complex was dissolved in a least amount of water as possible and less soluble potassium chloride was filtered off. The complex desired was obtained by adding methanol, little by little, to the filtrate. It was then recrystallized from water by adding methanol, washed with a water-methanol, methanol and then ether, and dried in air.

On the other hand, each of the *trans*(*N*) complexes other than the glycinato, sarcosinato and L-serinato ones was dissolved in methanol at 50°C. After the potassium chloride remaining in solid had been filtered off, the filtrate was kept in a refrigerator overnight. The complex deposited was gathered by filtration and washed with a small amount of methanol and ether, and then dried in air. The complex was recrystallized from hot methanol containing a small amount of water.

The *cis* isomers of the β-alaninato, γ-aminobutyrato and sarcosinato complexes could not be isolated because of their negligible yields. In the elution of L-prolinato

6) N. Matsuoka, J. Hidaka and Y. Shimura, This Bulletin, **40**, 1868 (1967).

complex, the violet band (*cis* isomer) was not observed; only the *trans*(*N*) isomer (reddish purple band) was isolated.

All of the complexes reported here are soluble in water. Of these complexes the *trans* isomers are soluble in methanol except those of the glycinato, sarcosinato and L-serinato complexes, which are sparingly soluble, while all the *cis* isomers are insoluble in methanol.

The results of the chemical analyses for all the complexes prepared are shown in Table 1.

Measurements. The electronic absorption spectra of the complexes were measured by a Beckman DU spectrophotometer. The CD spectra were recorded with a Roussel-Jouan dichrograph and the RD curves with a Yanagimoto recording spectropolarimeter model-185. All the measurements were made in aqueous solutions at room temperature.

The proton magnetic resonance (PMR) spectra of the complexes were obtained on a Japan Electron Optics JNM-4H-100 spectrometer operating at 100 Mc/sec, in deuterium oxide with NaTMS (sodium trimethylsilylpropanesulfonate) as an internal standard. The acidic solution (pH: about 0.6) was prepared by adding concentrated hydrochloric acid to the deuterium oxide solution.

Results and Discussion

Stereoselectivity. As described in Experimental section, the column chromatographic investigation shows that the *trans*(*N*) isomer of L-prolinato complex is stereospecifically formed. This coincides with the consideration derived from the construction of molecular models. Namely, the stereospecificity of L-prolinato complex is attributed to the fact that the steric hindrance is remarkable between a pyrrolidine ring of the coordinated L-prolinate and one of the three acetate groups of ata in the *cis*(*N*) isomer. This consideration is also available in the case of *cis*(*N*) sarcosinato complex. A similar unbalanced formation is also observed in the case of β-alaninato or γ-aminobutyrato complex. Considering the formation of a trace amount of the *cis* isomer, it seems likely that the unbalance depends on the crowding of $-NH_2$ protons of the amino acid ion with the protons of the two acetate groups of ata in the *cis* isomers. This kind of crowding is expected to exist also in the *cis* isomers of glycinato or other L-aminoacidato complexes: so the pronounced unbalance in the case of the β-alaninato and γ-aminobutyrato complexes is mainly due to the instability of the six or seven membered chelate ring as compared with the five membered chelate ring.

Absorption Spectra. The absorption data of $[Co(ata)(am)]^-$ complex ions are summarized in Table 2 and their representative curves are shown in Fig. 1. It has been well known that *trans*-$[Co(O)_4(N)_2]$-type complexes show more remarkable splitting than *cis* isomers in their first absorption bands.[6-8] The first absorption bands of the reddish purple complexes obtained in the present study show quite similar splitting patterns, and this absorption behavior points out that the reddish purple complexes have the *trans*(*N*) structure (Fig. 1). In the first band of *trans*-$[Co(O)_4(N)_2]$-type complexes, it may be of interest that the ratio, $\{\log \varepsilon_{max}(\text{sub.})/\log \varepsilon_{max}(\text{major})\}$, of a sub- and a major-band for the complexes with tridentate ligand is smaller than those for the complexes with bidentate ligand.[5,9,10] This situation also stands for the present *trans*(*N*) complexes.

In the absorption curves of the violet complexes, a vague shoulder is observed at the shorter wavelength side of the major peak of the first absorption band (at *ca.* 570 mμ). This pattern shows that the violet complex is the *cis*(*N*) isomer.[6]

Proton Magnetic Resonance Spectra. In order to confirm the structure of the complexes, the PMR spectra of *cis*(*N*)-$[Co(ata)(gly)]^-$ and *trans*(*N*)-$[Co(ata)(L\text{-}ala)]^-$ ions were measured in deuterium oxide (Fig. 2) and in acidic deuterium oxide solution. Recently, Smith and Sawyer[10] discussed the PMR spectra of the ata complexes, $[Co(ata)(OH)(OH_2)]^-$ and *trans*(*N*)-$[Co(ataH)_2]^-$ and it has been shown that the methylene protons of the acetate groups of the complexes exhibit one symmetrical AB pattern and one singlet in the region of 4.6—3.7 ppm from NaTMS and that the chemical shift on the singlet, which was assigned to

the protons of the uncoordinated acetate group of the latter complex, is much affected by the pH variation of the solution.

In the corresponding field, the spectra for the acetate protons of ata of the present complexes are quite similar to those reported by Smith and Sawyer, and all the peaks can be assigned as follows. For the glycinato complex (Fig. 2A), the AB pattern with centers at 4.41 and 3.99 ppm (J_{AB}= 17 cps) is assigned to the nonequivalent coupled acetate protons of two chelate rings of the ata, which are not co-planar with the glycinate ring, and the singlet at 4.12 ppm to the acetate protons of the third chelate ring of the ata, which is co-planar with the glycinate ring. The spectra of glycinato and L-alaninato complexes resemble each other, though a more complicated spectrum may be expected for the L-alaninato complex because all the acetate protons of ata have different environments. The AB pattern at 4.68 and 4.30 ppm (J_{AB}=17 cps) and the singlet at 4.30 ppm are assigned to the coordinated ata (Fig. 2B).

In acidic deuterium oxide solution (pH: about 0.6), no variation is observed in chemical shifts for all the peaks except the lowest field peak of AB pattern of the L-alaninato complex, which is overlapped by the HDO peak and shifts to down-field in acidic solution. These observations confirm that the ata functions as a tetradentate ligand.

The singlet at 3.35 ppm for the glycinato complex is assigned to the methylene protons of the glycinate chelate ring. For the L-alaninato complex, the AX_3 quartet at 3.90 ppm and the AX_3 doublet at 1.59 ppm, each with a coupling constant of 7 cps, are assigned to the methine proton and methyl protons of the L-alaninate chelate ring respectively.

These results agree with those reported by Buckingham and co-workers for several glycinato and L-alaninato complexes.[4,11]

Circular Dichroism. The CD or RD curves of the *trans*(*N*) ata complexes are quite similar to each other (Fig. 3), and the same relationship is also true for the CD or RD curves of the *cis*(*N*) ata complexes (Fig. 4).

As mentioned above, Liu and Douglas[2] pointed out that the existence of absorption components of the visible d→d transition band is shown more clearly through the CD due to the vicinal contribution than that due to the configurational one. Considering the symmetry of the *trans*(*N*) ata

complex ion, the CD curves of the *trans*(N) complexes may be expected to split into three components.[2,7] In fact, the CD curves show the three components, a negative, a positive and a negative ones, listing from the longer wavelength side; on the contrary the absorption band splits into only two components in appearance (Figs. 1 and 3). This behavior resembles that of $[Co(ox)(\beta\text{-ala})_2]^-$ ion rather than that of $[Co(ox)(gly)_2]^-$ ion.[7]

The first absorption bands of *cis*(N) ata complexes split into two components as mentioned before. In the corresponding region, their CD curves show two components (a negative one and a positive one), as may be seen in Fig. 4.

From these facts, it may be concluded that the CD curve due to only the vicinal effect points out more clearly the absorption components than that due to the configurational chirality.

As shown in Table 3, the CD peaks are more intense for the ata complexes than those of the other optically active complexes which have only the so-called vicinal effect due to the optically active ligand.[1] Similar behavior was observed between the CD curves of triethylenetetramine and ethylenediamine complexes, and it was assumed that the fixed conformation of triethylenetetramine causes a greater effect than the rather mobile conformation of ethylenediamine.[12] Similar consideration may also be available for the present case.

Spectroscopic Studies of the Structures of the Dimer of Diethylaluminum 2-Aminoethoxide $(AlEt_2OCH_2CH_2NH_2)_2$ and Related Compounds*[1]

Hideo SATO, Ryokichi TARAO and Hiromi HIGASHI

The Central Research Laboratories, Chisso Co., Ltd., Kamariya, Kanazawa-ku, Yokohama

(Received December 14, 1968)

The infrared and proton nuclear magnetic resonance spectra of the solutions of diethylaluminum 2-aminoethoxide $(AlEt_2OCH_2CH_2NH_2)_2$ and related compounds were measured. The infrared frequencies and intensities of the NH_2 stretching, scissors, and rocking vibration bands, and the NMR internal chemical shifts of the ethyl groups attached to the aluminum atom were compared with the corresponding data of suitable model compounds. It was concluded by taking the results of these experiments into consideration that $(AlEt_2OCH_2CH_2NH_2)_2$ was represented by the structural formula I with two Al←NH_2 coordination bonds. Similarly, most of the related compounds studied were reasonably represented by the formulas with two Al←NRR′ coordination bonds, while $(AlEt_2OCH_2CH_2N(C_6H_{11})_2)_2$ was assumed to be represented by formula III with two Al←O coordination bonds, exceptionally.

It has been reported by one of the authors and by Hurley and his coworkers that the reactions of triethylaluminum $(AlEt_3)_2$ with several aminoethanols ($HOCH_2CH_2NRR'$; R,R′=H, alkyl, cycloalkyl, and/or aryl groups) in the 1 : 1 molar ratio give the crystals of the dimers of diethylaluminum 2-aminoethoxides formulated as $(AlEt_2OCH_2CH_2NRR')_2$ quantitatively.[1-3] There are three possible structural formulas, I, II, and III, for these dimeric substances, $(AlEt_2OCH_2CH_2NRR')_2$:

[III]

Formula I with a 10-membered ring has two Al←NRR' coordination bonds, formula II with a 7-membered ring has one Al←NRR' and one Al←O bond, and formula III with a 4-membered ring has two Al←O bonds. Several attempts were made by Higashi and by Hurley to assign the most probable formula on the basis of several experimental facts but no decisive evidence was obtained.[2,3] In this paper this problem will be investigated by the infrared (IR) and proton nuclear magnetic resonance (NMR) spectra of the solution of diethylaluminum 2-aminoethoxide $(AlEt_2OCH_2CH_2NH_2)_2$. At first, the IR and NMR spectra of ethylaluminum chloride-*n*-propyl amine coordination compounds—$AlEt_{3-m}Cl_m \cdot n\text{-}PrNH_2$ (m=0, 1, 2, 3)—will be studied and the results will be used to discuss the problem mentioned above.

Experimental

Preparation of the Samples. $(AlEt_2OCH_2CH_2NH_2)_2$, $(AlEt_2OCH_2CH_2NMeH)_2$, $(AlEt_2OCH_2CH_2NMe_2)_2$, $(AlEt_2OCH_2CH_2NEtH)_2$, $(AlEt_2OCH_2CH_2NEt_2)_2$, $(AlEt_2OCH_2CH_2NPhH)_2$, $(AlEt_2OCH_2CH_2NPh_2)_2$, $(AlEt_2OCH_2CH_2N_2(C_6H_{11})_2)_2$, $(AlEt_2OCH_2CH_2CH_2CH_2NH_2)_2$, and $(AlEt_2OCH(CH_3)CH_2NH_2)_2$ were prepared by the reactions of $(AlEt_3)_2$ with the corresponding alkanolamine, following the synthetic methods described in Refs. 1 and 2. $(Ali\text{-}Bu_2OCH_2CH_2NH_2)_2$ was prepared by the reaction of $Ali\text{-}Bu_3$ with monoethanolamine, following the method given in Ref. 3. $(AlEt_2OCH_2C(CH_3)_2NH_2)_2$, $(AlEt_2OCH_2CH(CH_3)NH_2)_2$, and $(AlEt_2OCH_2CH(C_2H_5)NH_2)_2$ were obtained by the reaction of $(AlEt_3)_2$ with the corresponding alkanolamine as transparent prismatic crystals. Since the last three substances are new compounds, their yields in syntheses, aluminum contents, measured molecular weights and melting points are summarized in Table 1.

Measurements of IR and NMR Spectra. The IR spectra of the dilute solutions of the samples (in general, the concentrations of the solutions were fixed to either 5.26 g/100 m*l* soln for the measurements using the cell of thickness of 0.1 mm or 1.10 g/100 m*l* soln for the measurements using the cell of thickness of 0.5 mm) were measured in the 4000—420 cm^{-1} region by using KRS-5 liquid fixed cell (thickness: 0.1 mm and/or 0.5 mm). Another cell of the same thickness filled with the solvent was put in the reference optical path to compensate the absorption of the solvent. A Japan Spectroscopic Co. Model DS-402G infrared spectrophotometer was used. In general, benzene was used as solvent except for the measurement in the 720—620 cm^{-1} region, in which the absorption of benzene was very intense. In the 720—620 cm^{-1} region, *p*-xylene was used because it was transparent in this region.

The NMR spectra were measured by Varian A-60 A high resolution NMR spectrometer at 60 Mc, 14092 gauss, and at room temperature. About 0.5 m*l* of the benzene solution of the sample (5% weight/volume solution) was injected into the sample tube by a hypodermic syringe under nitroegen atmosphere and sealed. The values of chemical shifts were represented by ppm units (standard: benzene, the field higher than benzene signal was taken as positive).

Results and Discussion

The Spectra of $AlEt_{3-m}Cl_m \cdot n\text{-}PrNH_2$ (m= 0, 1, 2, 3). The NMR spectra of the equimolar mixtures of $(AlEt_{3-m}Cl_m)_2$ (m=0, 1, 2) and $n\text{-}PrNH_2$ in benzene were measured. The internal

chemical shifts (δ) of the ethyl group attached to the Al atom (hereafter abbreviated as the al-Et group) are shown in Table 2. The NMR spectrum of $AlEt_3 \cdot n\text{-}PrNH_2$ is shown in Fig. 1. Although in benzene solution the solvent effect on the chemical shift values of the NMR signals of the solute is very large, such an effect can be neglected so far as the internal chemical shift value ($\delta = \delta_{CH_3} - \delta_{CH_2}$) of the compounds of CH_3CH_2X type is concerned.[4] It has been known that in ethylaluminum compounds the magnetic anisotropy of the atom in the β-position relative to the methylene group affects the δ value of the al-Et group.[5] The δ value of the al-Et group of $AlEt_3 \cdot n\text{-}PrNH_2$ is -1.30 ppm, which is almost equal to the δ value of the al-Et group in $AlEt_3 \cdot NEt_3$ (-1.29 ppm).

The IR spectra of the equimolar mixtures of $(AlEt_{3-m}Cl_m)_2$ ($m=0$, 1, 2, 3) and $n\text{-}PrNH_2$ in benzene and in *p*-xylene were measured. The spectra in the 4000—2700 cm^{-1} region are shown in Fig. 2. The frequencies and the intensities (qualitative) are shown in Table 3, and these data for the NH_2 stretchings and NH_2 scissors are summarized in Table 4. The bands at 3390 and 3330 cm^{-1} of $n\text{-}PrNH_2$ correspond to the bands at 3389 and 3323 cm^{-1} found by Wolff and Schmidt in carbon tetrachloride solution and assigned to the NH_2 antisymmetric and symmetric stretching vibrations, respectively, by them.[6] The band at 1626 cm^{-1} is assigned to the NH_2 scissors. All of these three bands—the NH_2 antisymmetric and symmetric stretchings and the NH_2 scissors—shift to lower frequencies and their intensities increase when $n\text{-}PrNH_2$ forms coordination compounds with $AlEt_{3-m}Cl_m$. As regards the magnitudes of the shifts and the intensities of these three bands caused by the coordination bond formation with

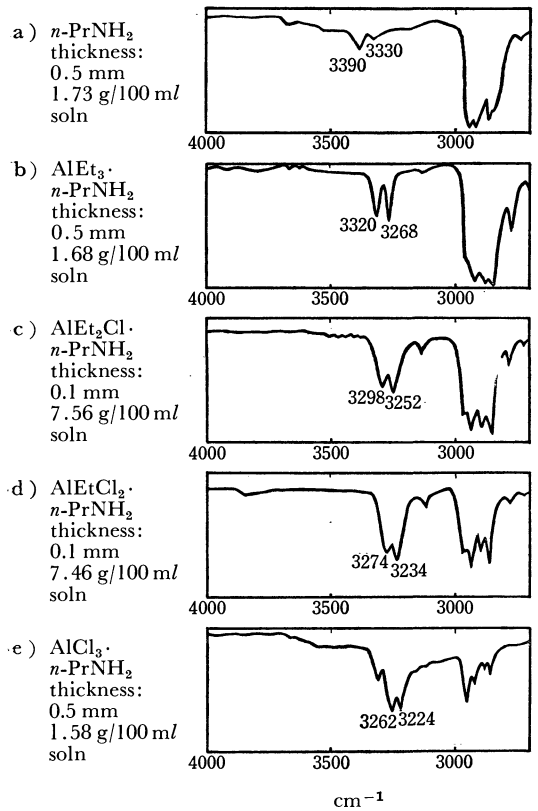

Fig. 2. The IR spectra of $AlEt_{3-m}Cl_m \cdot n\text{-}PrNH_2$ ($m=0$, 1, 2, 3).

Table 4. The frequencies and intensities (molar extinction coefficients: l/cm·mol—shown in parentheses) of the NH_2 vibration bands of $AlEt_{3-m}Cl_m \cdot n\text{-}PrNH_2$ ($m=0$, 1, 2, 3)

	$\gamma_{as}(NH_2)$ cm^{-1}	$\gamma_s(NH_2)$ cm^{-1}	$\delta(NH_2)$ cm^{-1}
$n\text{-}PrNH_2$	3390 (8.7)	3330 (4.9)	1626 (10)
$AlEt_3 \cdot n\text{-}PrNH_2$	3320 (44)	3268 (50)	1578 (68)
$AlEt_2Cl \cdot n\text{-}PrNH_2$	3298 (70)	3252 (80)	1576 (100)
$AlEtCl_2 \cdot n\text{-}PrNH_2$	3274 (94)	3234 (113)	1571 (93)
$AlCl_3 \cdot n\text{-}PrNH_2$	3262 (121)	3224 (113)	1571 (98)

$(AlEt_3)_2$, $(AlEt_2Cl)_2$, $(AlEtCl_2)_2$, and $(AlCl_3)_2$, the shifts and the intensities (molar extinction coefficients) increase in this order. This observation can be explained by the well-known fact that the electron-accepting tendency of $AlEt_{3-m}Cl_m$ becomes larger in the order of $m=0$, 1, 2, 3, and corresponds with the fact that the lower frequency shifts of the COC stretching absorption bands of diethyl ether (Et_2O) in the coordination compound $AlEt_{3-m}Cl_m \cdot Et_2O$ become larger in the order of $m=0$, 1, 2, 3.[7]

The IR Spectrum of $(AlEt_2OCH_2CH_2NH_2)_2$. The IR spectrum of the solution of $(AlEt_2OCH_2CH_2NH_2)_2$ is shown in Figs. 3a and 3b, together with the spectrum of the solution of $(AlEt_2OCH_2CH_2NMe_2)_2$ in Fig. 3c. The tentative assignments of the principal absorption bands given in Table 5 are made by taking the assignments of $(AlEt_2OEt)_2$,[8] ethanol,[9] ethylamine,[10] and $n\text{-}PrNH_2$,[6] into consideration.

Two sharp bands at 3375 and 3309 cm^{-1} are assigned to the NH_2 antisymmetric and symmetric

stretching vibrations respectively. These assignments are consistent with the fact that these two bands disappear in the spectrum of $(AlEt_2OCH_2CH_2NMe_2)_2$.

A sharp band at 1590 cm^{-1} is assigned to the NH_2 scissors. $(HgNH_2)^+$ has a sharp band due to the NH_2 scissors at 1543 cm^{-1}.[11] This band disappears in the spectra of $(AlEt_2OCH_2CH_2NMeH)_2$ and $(AlEt_2OCH_2CH_2NMe_2)_2$.

The broad and strong band at 664 cm^{-1} is assigned to the NH_2 rocking band overlapped by the AlC_2 antisymmetric stretching band. As shown in Fig. 4, this band (AlC_2 antisymmetric stretching) is much narrower in $(AlEt_2OEt)_2$, $(AlEt_2OCH_2CH_2NMeH)_2$, and $(AlEt_2OCH_2CH_2NMe_2)_2$, in which no NH_2 group exists. In each spectrum of $AlEt_{3-m}Cl_m \cdot n\text{-}PrNH_2$ ($m=0$, 1, 2, 3), there is a band of considerable intensity at about 670—660 cm^{-1}, which can be assigned to the NH_2 rocking, as shown in Table 3. In $(HgNH_2)^+$, the NH_2 rocking band appears at 668 cm^{-1}. These facts support this assignment.

Next, the problem to assign the most probable formula from among I, II, and III as the structural formula of the dimer $(AlEt_2OCH_2CH_2NH_2)_2$ will be discussed by taking the IR spectroscopic observations described above into consideration. The frequencies and intensities of the NH_2 stretchings, scissors, and rocking of $(AlEt_2OCH_2CH_2NH_2)_2$ will be compared with the frequencies and intensities of these bands of $AlEt_3 \cdot n\text{-}PrNH_2$, in which the NH_2 group coordinates with Al atom, and of $n\text{-}PrNH_2$ in dilute solution, in which the NH_2 group does not coordinate with any atom. The detailed discussion will be given below.

As described previously the NH_2 antisymmetric and symmetric stretching bands of $(AlEt_2OCH_2CH_2NH_2)_2$ exist at 3375 cm^{-1} (molar extinction coefficient, $\kappa=58$ *l*/cm·mol) and 3309 cm^{-1} ($\kappa=42$), respectively. In $n\text{-}PrNH_2$, these appear at 3390 cm^{-1} ($\kappa=8.7$) and 3330 cm^{-1} ($\kappa=4.9$) respectively. On the other hand, in $AlEt_3 \cdot n\text{-}PrNH_2$, these appear at 3320 cm^{-1} ($\kappa=44$) and 3268 cm^{-1} ($\kappa=50$) respectively. The data of frequencies do not make clear the problem whether the NH_2 group coordinates to the Al atom or not. The values of molar extinction coefficients of $(AlEt_2OCH_2CH_2NH_2)_2$, however, are almost equal to the values of $AlEt_3 \cdot n\text{-}PrNH_2$, and too large for the NH_2 group not to be coordinated with the Al atom. The lower frequency shift and the increase of

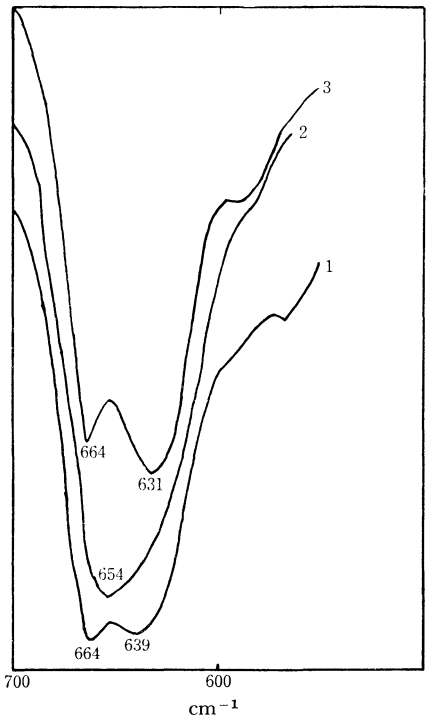

Fig. 4. The IR bands containing the NH_2 rocking band (superposed by the AlC_2 antisymmetric stretching and the CH_2 rocking band of al-Et group). Cell thickness: 0.1 mm, *p*-xylene solution.
1. $(AlEt_2OCH_2CH_2NH_2)_2$ 5.26 g/100 m*l* soln.
2. $(AlEt_2OEt)_2$ 5.26 g/100 m*l* soln.
3. $(AlEt_2OCH_2CH_2NMeH)_2$ 5.75 g/100 m*l* soln.

the intensity of the NH_2 antisymmetric and symmetric stretching vibration bands caused by the coordination of the NH_2 group are generally interpreted by the increase of the polar character of the N–H bond owing to the coordination bond formation.[12]

The NH_2 scissors band of $(AlEt_2OCH_2CH_2NH_2)_2$ exists at 1590 cm^{-1} (κ=69). The frequency and the intensity of this band are almost equal to the values of the corresponding bands of $AlEt_3$·*n*-$PrNH_2$ (1578 cm^{-1}, κ=68), and different from the values of the corresponding bands of *n*-$PrNH_2$ (1626 cm^{-1}, κ=10).

The NH_2 rocking band of $(AlEt_2OCH_2CH_2NH_2)_2$ exists at 664 cm^{-1}; this frequency coincides with the frequencies of the NH_2 rocking bands of $AlEt_{3-m}Cl_m$·*n*-$PrNH_2$ (m=0, 1, 2, 3), though the intensity is uncertain owing to the superposition of the band with the AlC_2 antisymmetric stretching band.

These observations apparently support formula I; they cannot be interpreted reasonably by assuming either formula II or III.

The relative intensities and frequencies of all bands (including the NH_2 stretching and the NH_2 scissors) remained unchanged when the concentration of $(AlEt_2OCH_2CH_2NH_2)_2$ in the solution was changed from 1.10 g/100 m*l* to 10.0 g/100 m*l*; this implies that intermolecular hydrogen bondings are not present. The relation between the concentrations and the molar extinction coefficients are shown in Table 6.

In Table 7, the frequencies and the molar extinction coefficients of the NH_2 stretching and scissors bands are shown for $(AlEt_2OCH_2CH_2NH_2)_2$ and six related compounds. It is apparent from these data that the dimers of these six related compounds also take the structures with two Al←NH_2 coordination bonds, in other words the structures corresponding to formula I.

The NMR Spectrum of $(AlEt_2OCH_2CH_2NH_2)_2$. The NMR spectrum of the solution of $(AlEt_2OCH_2CH_2NH_2)_2$ is shown in Fig. 5. For the sake of comparison, the spectrum of $(AlEt_2OCH_2CH_2NMe_2)_2$ is shown in Fig. 6. The broad signal at 6.3 ppm present in Fig. 5 is assigned to the NH_2 protons because it disappears in Fig. 6. The quintet at 5.17 ppm present in Fig. 5 turns to a triplet in Fig. 6. This quintet can be assigned to the NCH_2 protons because this change (quintet→triplet) is interpreted as due to the presence or the absence of the spin-spin coupling with the NH_2 protons. The assignments of the rest of the signals can also be easily made as shown in these figures by considering the signal intensities and the spin-spin couplings. In Fig. 7, the chemical shifts of methyl and methylene protons of the al-Et groups of $(AlEt_2OCH_2CH_2NH_2)_2$ and twelve related compounds are shown. For the sake of comparison, the corresponding chemical shifts of $(AlEt_3)_2$ and $(AlEt_2OEt)_2$ are also shown in this figure.

As mentioned previously, in ethylaluminum compounds the magnetic anisotropy of the atom in the β-position relative to the methylene group affects the δ value of the al-Et group. For this reason, it seems quite possible to choose the most probable formula among I, II, and III as the formula of $(AlEt_2OCH_2CH_2NH_2)_2$ by considering the δ value of the al-Et group, independent of the assumption based on the IR spectroscopic observations.

The δ value of the al-Et group of $(AlEt_2OEt)_2$, which can be regarded as a model compound of the formula III, is -1.14 ppm, as shown in Fig. 7. The corresponding δ values of $(AlEt_2OCH_2CH_2NH_2)_2$ and related compounds are, except for the following three compounds, $(AlEt_2OCH_2CH_2NPhH)_2$, $(AlEt_2OCH_2CH_2NPh_2)_2$, and $(AlEt_2OCH_2CH_2N(C_6H_{11})_2)_2$, always -1.31——-1.38 ppm; these values differ from the δ value of $(AlEt_2OEt)_2$ by about 0.2 ppm.

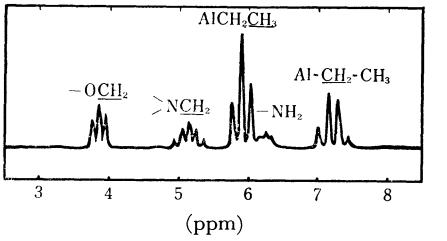

Fig. 5. The NMR Spectrum of $(AlEt_2OCH_2CH_2NH_2)_2$.

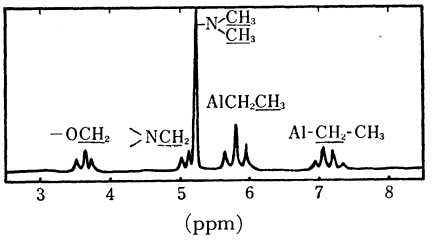

Fig. 6. The NMR spectrum of $(AlEt_2OCH_2CH_2NMe_2)_2$.

If formula III is assumed, this difference of the δ value should be interpreted as the effect of the N atom exerted through two methylene groups. The fact that the δ value of $(AlEt_2OCH_2CH_2CH_2NH_2)_2$ is -1.37 ppm is, however, the strong evidence against this interpretation. The δ value of the ethyl group of $HOCH_2CH_2NEt_2$ is 1.47

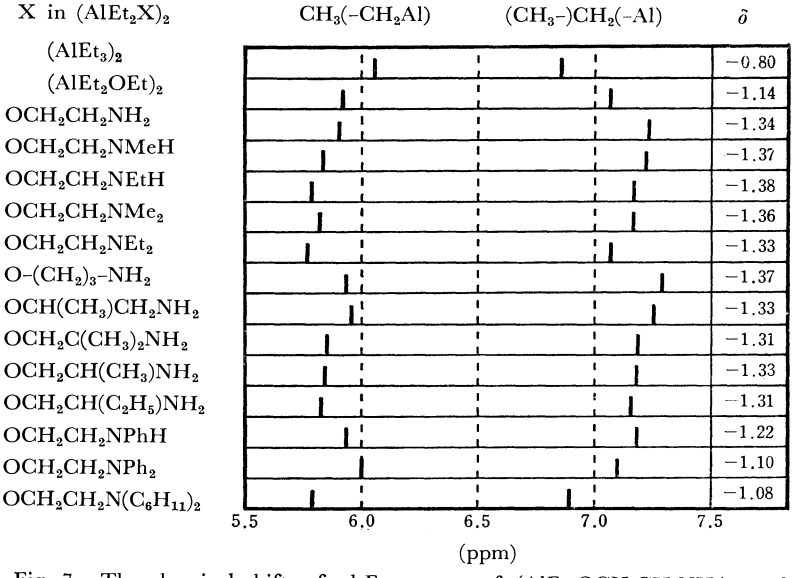

Fig. 7. The chemical shifts of al-Et groups of $(AlEt_2OCH_2CH_2NH_2)_2$ and related compounds.

ppm in benzene, and the δ value of the ethyl group of $(AlEt_2OCH_2CH_2NEt_2)_2$ attached to the N atom is 1.80 ppm. This difference of the δ value is reasonably interpreted by the decrease of the electron density of the N atom caused by the coordination of unshared electron pair of the N atom with the Al atom.

Next, if formula II is assumed, there should be two aminoethoxyl groups, one coordinating with Al atom and the other possessing an unshared electron pair. The facts that the NH_2 signal appears as a broad signal and that the NCH_2 and the OCH_2 signals do not suggest the presence of two kinds of the $-CH_2CH_2NH_2$ groups, do not support formula II.

These considerations lead to the conclusion that the dimers of $(AlEt_2OCH_2CH_2NH_2)_2$ and related compounds, whose δ values of the al-Et groups are about -1.34 ppm, are represented by the structural formula I with two Al←NRR′ coordination bonds. This conclusion is consistent with the result of considerations based on IR spectroscopic data described previously. $(AlEt_2OCH_2CH_2N(C_6H_{11})_2)_2$ has the δ value of -1.08 ppm, which is nearly equal to the δ value of the al-Et group of $(AlEt_2OEt)_2$. This anomalous value may be interpreted by the assumption that this compound exceptionally takes the structural formula III, since the unshared electron pair of the N atom could not coordinate with the Al atom owing to the steric hindrance of two cyclohexyl groups The δ values of the al-Et groups of $(AlEt_2OCH_2CH_2NPhH)_2$ and $(AlEt_2OCH_2CH_2NPh_2)_2$, -1.22 and -1.10 ppm respectively, may be due to the magnetic anisotropy of the phenyl rings, although the possibility of formula III could not be excluded.

Still another support of the formula I is obtained from the NMR spectra of the system $(AlMe_2OCH_2CH_2NMe_2)_2+(AlEt_3)_2$. In this system, the redistribution of the al-Me groups and al-Et groups take place, and the species $(AlRR'OCH_2CH_2NMe_2)_2$—R, R′=methyl or ethyl—is produced. There are fine structures corresponding to $NMe_2\rightarrow AlEt_2O-$, $NMe_2\rightarrow AlEtMeO-$, and $NMe_2\rightarrow AlMe_2O-$ in the signal of the methyl group of $(AlRR'OCH_2CH_2NMe_2)_2$ attached to the N atom. Although this observation no doubt supports formula I for $(AlRR'OCH_2CH_2NMe_2)_2$, the details will be described in the forthcoming publication.

The authors are indebted to Professors Takehiko Shimanouchi and Ichiro Nakagawa of the University of Tokyo and to Dr. Osamu Yamamoto of the Government Chemical Industrial Research Institute, Tokyo, for valuable discussions. They are also grateful to Dr. Go Hata of Toyo Rayon Co. for his advice on the measurement of IR spectra, and to Dr. Akiko Hirakawa of the University of Tokyo for her advice on the IR spectrum of n-$PrNH_2$ in solution.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 1596—1600 (1969)

Spectrophotometric Study of Solution Equilibria between Ammonia and Copper(II) and Nickel(II) Chelates of Aminopolycarboxylic Acids

Mutsuo KODAMA and Katsumi MIYAMOTO

Department of Chemistry, Ibaraki University, Mito, Ibaraki

(Received November 20, 1968)

The addition of ammonia produces a remarkable change in the visible absorption spectra of copper(II)- and nickel(II)-aminopolycarboxylate chelates. This can be ascribed to the formation of a mixed ligand chelate involving ammonia and the aminopolycarboxylate anion. On the basis of the change in the absorbance of copper(II)- and nickel(II)-aminopolycarboxylate chelates, the solution equilibria between ammonia and these aminopolycarboxylate chelates were investigated. Copper(II) and nickel(II) chelates of ethylenediaminetetraacetic acid (EDTA), *N*-(2-hydroxyethyl)-ethylenediamine-*N*,*N'*,*N'*-triacetic acid (EDTA-OH), ethylenediaminetetrapropionic acid (EDTP), cyclohexanediaminetetraacetic acid (CyDTA), and diethylenetriaminepentaacetic acid (DTPA) were found to form mixed ligand chelates with a composition of $M(NH_3)Z^{2-n}$. From the intercept of the linear relation between $\log (A_Y-A)/(A-A_M)$ and $\log [NH_3]_f$, the equilibrium constant, K^{NH_3}, defined as $K^{NH_3}=[M(NH_3)Z^{2-n}]/[MZ^{2-n}]\cdot[NH_3]_f$, was determined.

In a previous paper,[1] we studied the effects of ammonia and the thiocyanate ion on the substitution reaction of the nickel(II)-EDTA chelate with Eriochrom Black T (BT). The addition of ammonia or the thiocyanate ion brought about a considerable change in the absorption spectrum of the nickel(II)-EDTA chelate in the visible-light region, and made the substitution reaction of nickel(II)-EDTA chelate more sluggish. This was ascribed to the formation of a mixed ligand chelate involving ammonia or the thiocyanate ion, which is non-reactive in the substitution reaction between the nickel(II)-EDTA chelate and BT.

Ammonia was also found to exert a strong effect on the visible absorption spectra of copper(II) and nickel(II) chelates of EDTA and its related compounds. This also can be attributed to the formation of a mixed ligand chelate involving ammonia. In this paper, a spectrophotometric study of the solution equilibria between ammonia and copper(II) and nickel(II) chelates of aminopolycarboxylic acids will be presented.

Experimental

Reagents. The purification of ethylenediaminetetraacetic acid (EDTA), *N*-(2-hydroxyethyl)-ethylenediamine-*N*,*N'*,*N'*-triacetic acid (EDTA-OH), ethylenediaminetetrapropionic acid (EDTP), cyclohexanediaminetetraacetic acid (CyDTA), and diethylenetriaminepentaacetic acid (DTPA) and the preparation of their solutions have been described previously.[2-5] The methods of preparing and standardizing metal(II) perchlorate solutions have also been given in previous papers.[2,4] The concentration of the ammonia solution was standardized against a standard hydrochloric acid solution, using Methyl Organge as an indicator. All the other chemicals were of an analytical reagent grade and were used without further purification. The ionic strength of the sample solution was adjusted to 0.30 by adding an appropriate volume of a 1.0 M sodium perchlorate solution.

Apparatus and Experimental Procedures. All the absorption measurements were conducted at 25°C using a Hitachi EPS-3 pen-recording spectrophotometer. The experimental procedures employed were the same as before.[2]

Results and Discussion

The visible spectra of copper(II) and nickel(II) chelates of EDTA, EDTA-OH, EDTP, CyDTA, and DTPA in solutions ($\mu=0.30$) containing an excess amount of un-complexed aminopolycarboxylate are reproduced in Figs. 1 and 2. Copper(II)- and nickel(II)-aminopolycarboxylate chelates showed absorption maxima at about 700 and 370 mμ respectively. When ammonia was added to the metal(II)-aminopolycarboxylate chelate solution, as has previously been observed in the absorption curve of the nickel(II)-EDTA chelate,[1] a remarkable change in the absorbance of these metal(II)-aminopolycarboxylate chelates was also observed. However, the shape of the absorption

spectra was little affected by the addition of ammonia. Typical results obtained in an EDTA-OH system are shown in Figs. 3 and 4. Although the results are not shown here, similar results were also obtained in other systems. In the copper(II)-EDTA-OH system, as is illustrated by the absorption curves in Fig. 3, the absorbance decreased with an increase in the concentration of ammonia until

it reached its minimum value. On the other hand, in the nickel(II) system, the absorbance in the region from 300 to 450 mμ was found to increase with an increase in the concentration of ammonia until it reached its maximum value (Fig. 4). The above change in the absorbance of metal(II)-aminopolycarboxylate chelates upon the addition of ammonia may be attributed to the formation of a mixed ligand chelate involving ammonia.

As has been discussed previously,[1,2] if the mixed ligand chelate $M(NH_3)Z^{2-n}$ is formed, the following relation can be expected thermodynamically:

$$\log \frac{A_Y - A}{A - A_M} = \log K^{NH_3} + \log [NH_3]_f \qquad (1)$$

where A_Y, A, A_M, K^{NH_3}, and $[NH_3]_f$ have the same meanings as before.[1] Here, $(A_Y - A)/(A - A_M)$ can be equated with $[M(NH_3)Z^{2-n}]/[MZ^{2-n}]$.

When $M(NH_3)_2Z^{2-n}$ and $M(NH_3)Z^{2-n}$ are both formed, the following relation can be derived in place of Eq. (1), provided that the molar extinction coefficients of $M(NH_3)Z^{2-n}$ and $M(NH_3)_2Z^{2-n}$ are the same:

$$K^{NH_3}(1 + K^{2NH_3}[NH_3]_f) = \frac{A_Y - A}{A - A_M} \times \frac{1}{[NH_3]_f} \qquad (2)$$

where $K^{2NH_3} = [M(NH_3)_2Z^{2-n}]/[M(NH_3)Z^{2-n}] \cdot [NH_3]_f$ and $(A_Y - A)/(A - A_M)$ can be equated with $[M(NH_3)_iZ^{2-n}]_t/[MZ^{2-n}]$. Here, $[M(NH_3)_iZ^{2-n}]_t$ means the total concentration of mixed ligand chelates.

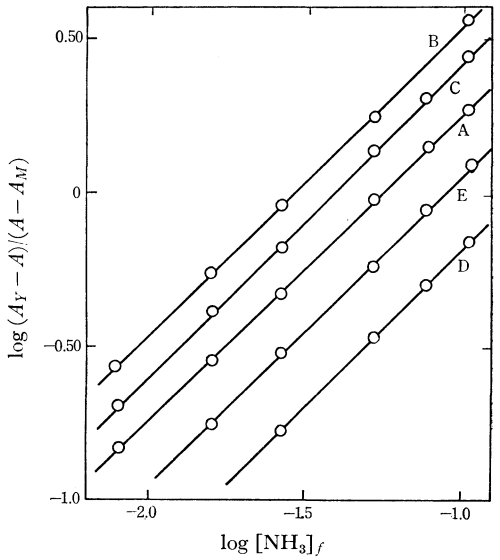

Fig. 6. The plot of $\log (A_Y - A)/(A - A_M)$ against $\log [NH_3]_f$.
$\mu = 0.30$, pH = 9.30
Concentration of nickel(II)-aminopolycarboxylate chelate = 10.0 mM
Concentration of un-complexed aminopolycarboxylate = 10.0 mM
A: EDTA, B: EDTA-OH, C: EDTP,
D: CyDTA, E: DTPA

The effect of ammonia on the absorption curves of copper(II)- and nickel(II)-aminopolycarboxylate chelates was studied in the ammonia concentration range from 15 to 200 mM. The experimental data were then analyzed with the aid of Eqs. (1) and (2). In both cases, only the plot of $\log (A_Y - A)/(A - A_M)$ against $\log [NH_3]_f$ gave a straight line with a slope of unity. The results are shown in Figs. 5 and 6. This clearly indicates that, under the present experimental conditions, only the mixed ligand chelate $M(NH_3)Z^{2-n}$ is formed.

$\log K^{NH_3}$ values were evaluated from the $\log (A_Y - A)/(A - A_M)$ values at $\log [NH_3]_f = 0$; they are listed in Table 1. At lower ammonia concentrations, the decrease in the concentration of un-complexed ammonia due to the formation of the mixed ligand chelate should be taken into consideration. Hence, the correct concentration of un-complexed ammonia at lower ammonia concentrations was calculated by using successive approximations with the aid of the following relations:

$$\frac{[NH_3]_i - X}{(\alpha)_{HNH_3}} = [NH_3]_f \qquad (3a)$$

$$\frac{K^{NH_3}}{(\alpha_H)_{NH_3}} \cdot X^2 - \left[\frac{K^{NH_3}}{(\alpha_H)_{NH_3}}([NH_3]_i + MZ^{2-n}]) - 1\right] \cdot X + \frac{K^{NH_3}}{(\alpha_H)_{NH_3}}([NH_3]_i \times [MZ^{2-n}]) = 0 \qquad (3b)$$

where $(\alpha_H)_{NH_3}$ is the (α_H) value of ammonia; $[NH_3]_i$, the initial concentration of ammonia, and $[MZ^{2-n}]$, the concentration of the metal(II)-aminopolycarboxylate chelate.

In EDTA, EDTP, and CyDTA system, if these aminopolycarboxylates act as hexadentate ligands and if metal(II)-aminopolycarboxylate chelates have octahedral configurations, the formation of the mixed ligand chelate with ammonia will always involve the breakage of one metal(II)-oxygen (carboxylate) bond and the subsequent formation of one metal(II)-nitrogen (ammonia) bond. Therefore, the mixed ligand chelate would have one of the two structures shown in Fig. 7.

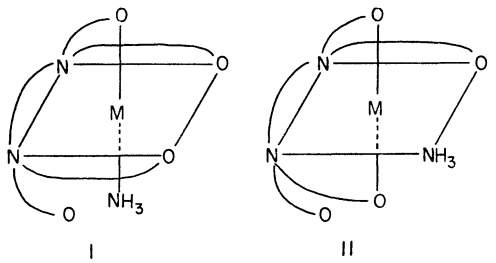

Fig. 7. The structure of a mixed ligand chelate.

As is illustrated by the successive formation constants of copper(II)-ammine complexes,[6] if the structure I is assumed for the copper(II) chelate, the equilibrium constant, K^{NH}, must be very small because of the expected Jahn-Teller distortion of the copper(II) chelate. On the other hand, if the structure II fits, the equilibrium constant is expected to have a value nearly identical with $(k_1)_{NH_3}/(k_1)_{Ac}$. Here, $(k_1)_{NH_3}=[Cu(NH_3)^{2+}]/[Cu^{2+}]\cdot[NH_3]_f$, $(k_1)_{Ac}=[Cu(Ac)^+]/[Cu^{2+}]\cdot[Ac^-]_f$ and $[Ac^-]_f$ denotes the concentration of un-complexed acetate ions. From the thermodynamic point of view, $(k_1)_{NH_3}/(k_1)_{Ac}$ corresponds to the following chemical equilibrium, where an acetate ion replaced by ammonia gains its complete translational, rotational, and conformational freedom:

$$CuZ(Ac)^{1-n} + NH_3 = Cu(NH_3)Z^{2-n} + Ac^- \qquad (4)$$

In the formation of the mixed ligand chelate between metal(II)-aminopolycarboxylate chelate and ammonia, however, the $-CH_2-COO^-$ group of the aminopolycarboxylate anion replaced by ammonia obtains in part its freedom of translation, rotation, and conformation. Therefore, in the above discussion, the instability due to the fact that the $-CH_2-COO^-$ group gains less translational, rotational and conformational freedom should be taken into consideration. Because of the lack of knowledge on the entropy effect described above, we can not estimate the instability due to the entropy loss quantiatively or even semi-quantitatively. At least, however, from the thermodynamic point of view, K^{NH_3} can safely be expected to be smaller than the $(k_1)_{NH_3}/(k_1)_{Ac}$ value. In spite of the rather rough approximation, however, the agree-

ment between the observed K^{NH_3} value and the calculated $(k_1)_{NH_3}/(k_1)_{Ac}$ value was satisfactory (Table 1). This agreement may confirm the latter structure, II, for the copper(II) chelate. In the EDTP system, $(k_1)_{prop}$, defined as $[Cu(prop)^+]/[Cu^{2+}]\cdot[prop^-]_f$, was used in place of $(k_1)_{Ac}$. Here, the smaller K^{NH} values for the CyDTA and DTPA systems can be ascribed to the steric effect due to the cyclohexane ring of CyDTA and the $-CH_2-CH_2-N(CH_2-COO^-)-CH_2-CH_2-N(CH_2-COO^-)_2$ group of DTPA. It is also interesting to note that the K^{NH_3} value of the EDTA-OH chelate is approximately twice that of the EDTA chelate. This may be attributed to the fact that, statistically, ammonia is expected to form a mixed ligand chelate more easily with the EDTA-OH chelate than the EDTA chelate.

In the nickel(II) system, as nickel(II)-aminopolycarboxylate and ammine complexes are essentially octahedral, no definite conclusion about the location of coordinated ammonia in the mixed ligand chelate can be drawn on the basis of a comparison of the observed K^{NH_3} value with the $(k_1)_{NH_3}/(k_1)_{Ac}$ value.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 1600—1603 (1969)

Determination of Kinetic Parameters of the Electrode Reaction of Ethylenediaminetetraacetatoaquochromate(III) Ions by the Potentiostatic Method

Akifumi YAMADA and Nobuyuki TANAKA

Department of Chemistry, Faculty of Science, Tohoku University, Katahira-cho Sendai

(Received November 22, 1968)

Kinetic parameters of the electrode reaction of ethylenediaminetetraacetatoaquochromate-(III)/ethylenediaminetetraacetatoaquochromate(II) at the dropping mercury electrode have been determined by the potentiostatic method in sodium chloride solutions of ionic strength 0.5 containing 0.1 M acetate buffer. The measured standard rate constant $(k_s)_{ms}$ is 2.1×10^{-1} cm sec^{-1} and the measured transfer coefficients $(\alpha_c)_{ms}$ and $(\alpha_a)_{ms}$ are 0.58 for the cathodic and 0.39 for the anodic process. The correction for the effect of the electrical double layer has been made on these parameters. The values obtained are: $(k_s)^{\xi}_{corr}=1._7\times10$ cm sec^{-1}, $(\alpha_c)_{corr}=0.54$ and $(\alpha_a)_{corr}=0.43$. The standard potential -1.220 V *vs.* SCE determined by the potentiostatic method is compared with -1.218 V *vs.* SCE obtained by the measurement of the equilibrium potential. These values are in good agreement within the experimental error.

The reduction of ethylenediaminetetraacetatoaquochromate(III) (Cr(III)-EDTA) ions at the dropping mercury electrode was studied by Pecsok and co-workers[1] over a wide range of pH. These authors showed that the electrode reaction of Cr(III)-EDTA proceeds reversibly at the dropping mercury electrode and they reported the values of the polarographic half-wave potential at various pH's. Kinetic parameters of the electrode reaction, however, have not been reported yet for either Cr(III)-EDTA or Cr(II)-EDTA complexes.

In this study, the theoretical treatment of the potentiostatic method for the study of fast electrode reactions, which was reported previously,[2] has been applied to the electrode reaction of Cr(III)-EDTA ions on the dropping mercury electrode and the kinetic parameters have been determined.

Experimental

Hydrogen ethylenediaminetetraacetatoaquochromate-(III) was prepared according to the method of Hamm.[3] Cr(II)-EDTA was prepared with Cr(III)-EDTA by electrolytic reduction. Redistilled water was used to prepare the solution of a desired concentration. The potentiostat was constructed in this laboratory[4] with an operational amplifier. The rise time and the input impedance are 3 μsec and 100 MΩ, respectively. A dropping mercury electrode of a long drop time (about 60 sec) was used for a cathode. The resistance of this capillary was 2.00 Ω at room temperature. The potential of the working electrode was measured against a saturated calomel electrode (SCE) with a Luggin

capillary. A platinum wire electrode served as an auxiliary electrode. Electrolytic solutions were deaerated by bubbling purified nitrogen gas through the solution. Measurements were made at 25°C in solutions of ionic strength 0.5 (NaCl) containing 0.1 M acetate buffer. The pH of the solution was kept at 5.0 in order to avoid the formation of acid complexes.[1,5] Correction was made for the charging current, although the charging current decreased to zero within 30 to 40 μsec in most cases.

Results

Some preliminary measurements of current-potential behavior following the application of potential step were made with Cr(III)-EDTA ions at the slowly dropping mercury electrode. Figure 1 shows a typical example of a cathodic current-potential curve of Cr(III)-EDTA ions which was obtained in an acetate buffer solution of pH 5.0. The current was measured at 0.5 msec after the beginning of the electrolysis. Figure 2 shows plots of the logarithmic function of the current against the electrode potential. Plots of $\log\{I/(I_d-I)\}$ *vs.* E, where I is the current density, I_d, the limiting diffusion current density, and E, the electrode potential, yielded a straight line with a reciprocal slope of 60 mV and a half-wave potential of -1.222 V *vs.* SCE.

From the relation given by the equation,

$$E_e = (E_0)_{eq} + 0.0591 \times \log\{[\text{Cr(III)-EDTA}]/[\text{Cr(II)-EDTA}]\} \quad \text{at } 25°\text{C} \qquad (1)$$

the standard oxidation-reduction potential $(E_0)_{eq}$ of the reaction

$$\text{Cr(III)-EDTA} + e \rightleftharpoons \text{Cr(II)-EDTA}$$

is obtained by plotting $\log\{[\text{Cr(III)-EDTA}]/[\text{Cr(II)-EDTA}]\}$ against equilibrium potential E_e. The results are shown in Fig. 3. The value of $(E_0)_{eq}$ and the reciprocal slope of the plots were calculated to be -1.218 V *vs.* SCE and 57.8 mV, respectively. The concentration of each complex was determined by the potentiostatic or the polarographic method.

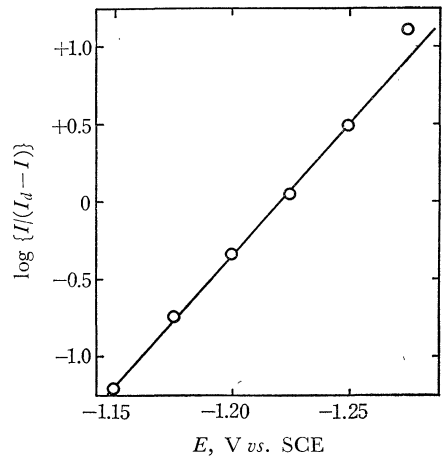

Fig. 2. Log-plots for the reduction of 2 mM Cr(III)-EDTA which were obtained by the potentiostatic method in the solutions containing 0.1 M acetate buffer and 0.4 M NaCl (pH 5.0) at 25°C. The currents were measured at 0.5 msec after the beginning of electrolysis.

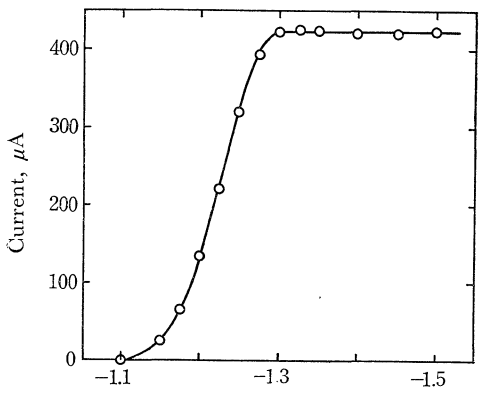

Fig. 1. Current-potential relations for the reduction of 2 mM Cr(III)-EDTA which were obtained by the potentiostatic method in the solutions containing 0.1 M acetate buffer and 0.4 M NaCl (pH 5.0) at 25°C. Surface area of the electrode is 0.0346 cm². The currents were measured at 0.5 msec after the beginning of electrolysis.

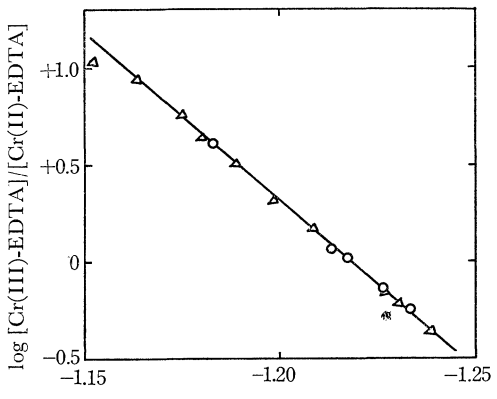

Fig. 3. Reaction of $\log[\text{Cr(III)-EDTA}]/[\text{Cr(II)-EDTA}]$ in Eq. (1) *vs.* equilibrium potential E_e which was obtained in the solutions containing 0.1 M acetate buffer and 0.4 M NaCl (pH 5.0) at 25°C. The concentration of each complex was determined by the potentiostatic method (indicated with ○) or by the polarographic method (indicated with △). In the case of polarographic measurement, the solution contains 2×10^{-6} M LEO as a maximum suppressor.

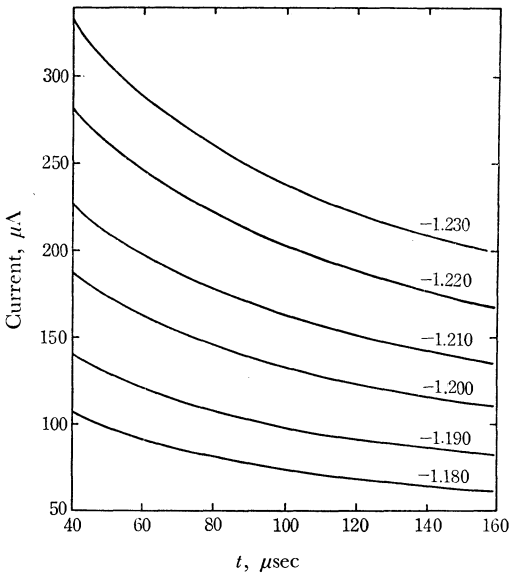

Fig. 4. Current-time relations for the reduction of 1 mM Cr(III)-EDTA which were obtained by the potentiostatic method in the solutions containing 0.1 M acetate buffer and 0.4 M NaCl (pH 5.0) at 25°C. Surface area of the electrode is 0.0346 cm². The figure on each curve indicates the controlled electrode potential (V *vs.* SCE).

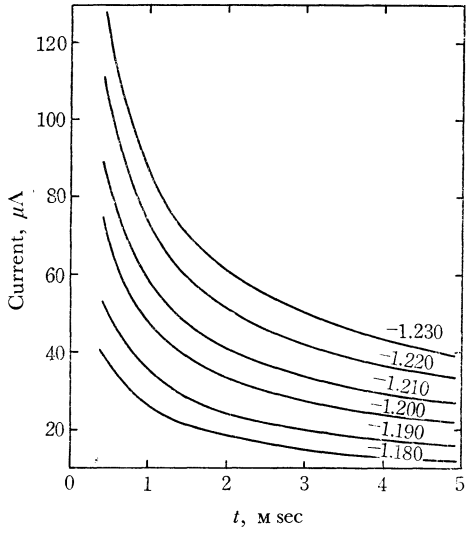

Fig. 5. Current-time relations for the reduction of 1 mM Cr(III)-EDTA which were obtained by the potentiostatic method in the solutions containing 0.1 M acetate buffer and 0.4 M NaCl (pH 5.0) at 25°C. Surface area of the electrode is 0.0346 cm². The figure on each curve indicates the controlled electrode potential (V *vs.* SCE).

Examples of current-time curves obtained at various electrode potentials are given in Figs. 4 and 5. Charging currents were immediately decreased to zero within 30 to 40 μsec.

If only the oxidant O is present initially in the solution and the reductant R is generated *in situ*, the relation between current and time on the potentiostatic method can be represented by the equations,[2]

$$I\sqrt{t}/I_\tau\sqrt{\tau} = \sqrt{\pi}\lambda_{ms}\sqrt{t}\exp(\lambda^2_{ms}\sqrt{t})\mathrm{erfc}(\lambda_{ms}\sqrt{t}) \quad (\tau \gg t) \tag{2}$$

$$(k_c)_{ms} = I_\tau\sqrt{\pi}\lambda_{ms}\sqrt{\tau}/n\boldsymbol{F}C_0^\circ \tag{3}$$

$$(k_a)_{ms} = \lambda_{ms}\sqrt{D_\mathrm{R}} - \sqrt{D_\mathrm{R}/D_\mathrm{O}}\,(k_c)_{ms} \tag{4}$$

In Eqs. (2) to (4), I means the current density at time t, τ the sufficiently long time (*e.g.*, $\lambda_{ms}\sqrt{\tau} > 5$), I_τ the current density at time τ, D the diffusion coefficient, and $(k_a)_{ms}$ and $(k_c)_{ms}$ are the measured anodic and the measured cathodic rate constant at a given potential.

Since the left-hand side of Eq. (2) and t are measurable, the values of λ_{ms} at various potentials can be determined. With these λ_{ms} values the rate constant $(k_c)_{ms}$ and $(k_a)_{ms}$ are determined provided the diffusion coefficients are known. The current-time relations shown in Figs. 4 and 5 were analyzed by means of these equations for the potentiostatic method with the results given in Table 1. The diffusion coefficients were calculated from the measurements of limiting current density following the application of potential step. They are 6.3×10^{-6} cm² sec^{-1} for Cr(III)-EDTA and 5.6×10^{-6} cm² sec^{-1} for Cr(II)-EDTA.

Table 1. Kinetic parameters of the electrode reaction of Cr(III)-EDTA/Cr(II)-EDTA in 0.1 M acetate buffer + 0.4 M NaCl (pH 5.0) 25°C

E V *vs.* SCE	$(k_c)_{ms}$ cm sec^{-1}	$(k_a)_{ms}$ cm sec^{-1}	$(k_c)_{corr}$* cm sec^{-1}	$(k_a)_{corr}$* cm sec^{-1}
−1.180	0.085_2	0.37_8	0.098_8	0.43_8
−1.190	0.10_5	0.32_1	0.11_9	0.36_4
−1.200	0.13_7	0.27_4	0.15_3	0.30_5
−1.210	0.16_6	0.24_2	0.18_3	0.26_7
−1.220	0.20_8	0.20_5	0.22_6	0.22_3
−1.230	0.23_5	0.16_0	0.25_2	0.17_1

* Calculated with the assumption that no specific adsorption takes place and ϕ_0 is constant over the potential region under investigation.

Kinetic parameters of the electrode reaction are calculated from the relations,*1,2

$$(k_c)_{ms} = (k_s)_{ms}\exp\left[-\frac{(\alpha_c)_{ms}n\boldsymbol{F}}{\boldsymbol{RT}}(E-(E_0)_{ms})\right] \tag{5}$$

$$(k_a)_{ms} = (k_s)_{ms}\exp\left[+\frac{(\alpha_a)_{ms}n\boldsymbol{F}}{\boldsymbol{RT}}(E-(E_0)_{ms})\right] \tag{6}$$

where $(k_s)_{ms}$ is the measured standard rate constant, $(E_0)_{ms}$ the measured standard potential, $(\alpha_c)_{ms}$

*1 $(\alpha_c)_{ms}$ and $(\alpha_a)_{ms}$ are denoted as α_{ms} and β_{ms}, respectively, in Ref. 2.

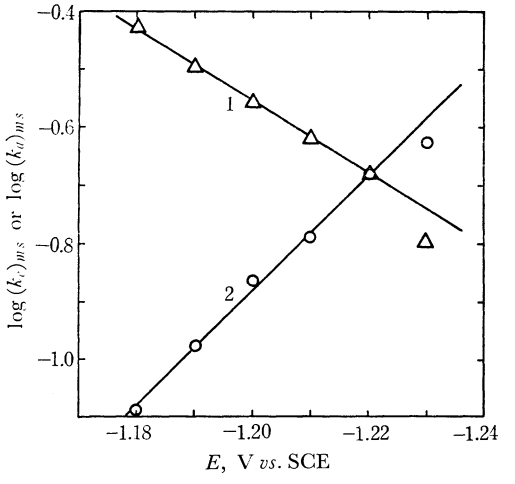

Fig. 6. Relations of (1) $\log(k_a)_{ms}$ *vs.* E and (2) $\log(k_c)_{ms}$ *vs.* E obtained with 1 mM Cr(III)-EDTA in the solutions containing 0.1 M acetate buffer and 0.4 M NaCl (pH 5.0) at 25°C

and $(\alpha_a)_{ms}$ are the measured cathodic and the measured anodic transfer coefficient, respectively, and $\boldsymbol{F}$, $\boldsymbol{R}$ and T have their usual meanings. The relation of $\log(k_a)_{ms}$ *vs.* E and that of $\log(k_c)_{ms}$ *vs.* E are shown in Fig. 6. Using the values given in Table 1 the following kinetic parameters were obtained:

$$(E_0)_{ms} = -1.220 \text{ V } vs. \text{ SCE}$$
$$(k_s)_{ms} = 2.1\times10^{-1} \text{ cm sec}^{-1}$$
$$(\alpha_c)_{ms} = 0.58,\ (\alpha_a)_{ms} = 0.39$$

Discussion

Since the measured rate constants $(k_c)_{ms}$ and $(k_a)_{ms}$, which were determined by the above-mentioned method, involve the influence of the electrical double layer, the correction for the effect of the double layer is necessary. The Levich and the Frumkin correction[2] were made on the assumption that no specific adsorption took place and that the value of ϕ_0 was constant in the potential region under investigation:*2

$$(k_c)_{corr} = (k_c)_{ms}\left[1-\frac{\zeta_O}{\kappa D_O}(k_c)_{ms}-\frac{\zeta_R}{\kappa D_R}(k_a)_{ms}\right]^{-1} \quad (7)$$

$$(k_a)_{corr} = (k_a)_{ms}\left[1-\frac{\zeta_O}{\kappa D_O}(k_c)_{ms}-\frac{\zeta_R}{\kappa D_R}(k_a)_{ms}\right]^{-1} \quad (8)$$

with

$$\zeta_j = \frac{\exp[(|z_j|-|z|/2)\boldsymbol{F}\phi_0/\boldsymbol{RT}]-1}{+|z_j/z|-1/2} \quad (9)$$

$$1/\kappa = \sqrt{\boldsymbol{RT}\varepsilon/8\pi z^2\boldsymbol{F}^2C_t} \quad (10)$$

where z_j is the ionic charge of the jth species, z the charge of the symmetrical indifferent electrolyte, ϕ_0 the difference of potential across the diffuse double layer from the plane of closest approach to the bulk of solution, ε the dielectric constant, C_t the total concentration of a z-z indifferent electrolyte.

Corrected kinetic parameters are determined by the relation,*3,2)

$$(k_c)_{corr} = (k_s)_{corr}\exp\left[-\frac{(\alpha_c)_{corr}n\boldsymbol{F}}{\boldsymbol{RT}}(E-(E_0)_{corr})\right] \quad (11)$$

$$(k_a)_{corr} = (k_s)_{corr}\exp\left[+\frac{(\alpha_a)_{corr}n\boldsymbol{F}}{\boldsymbol{RT}}(E-(E_0)_{corr})\right] \quad (12)$$

$$(k_s)_{corr} \fallingdotseq (k_s)^c_{corr}\exp[((\alpha_c)_{corr}n-z_O)\boldsymbol{F}\phi_0)/\boldsymbol{RT}] \quad (13)$$

where $(k_s)_{corr}$ is the corrected rate constant at $E=(E_0)_{corr}$ and $(k_s)^c_{corr}$ is the corrected standard rate constant expressed in terms of concentration for the cathodic process.

In order to estimate the potential ϕ_0, the differential capacity and the electrocapillary curve of the supporting electrolyte were measured by the conventional method. The equipment for these measurements was previously described.[6] The value of ϕ_0 was calculated to be −0.073 V at −1.220 V *vs.* SCE by the Gouy-Chapman theory.[7]

The rate constants at various potentials which were determined by this procedure are also given in Table 1. The corrected kinetic parameters were as follows:

$$(E_0)_{corr} = -1.220 \text{ V } vs. \text{ SCE}$$
$$(k_s)_{corr} = 2.2\times10^{-1} \text{ cm sec}^{-1}$$
$$(\alpha_c)_{corr} = 0.54$$
$$(\alpha_a)_{corr} = 0.43$$
$$(k_s)^c_{corr} = 1._7\times10 \text{ cm sec}^{-1}$$

The standard potential $(E_0)_{corr}$ was found to be the same, within the experimental error, with $(E_0)_{eq}$ which was obtained by the measurement of the equilibrium potential.

The authors are grateful to Dr. Reita Tamamushi, the Institute of Physical and Chemical Research, for his valuable suggestion on this study. They also thank the Ministry of Education for the financial support granted for this research.

*2 $(k_c)_{corr}$ and $(k_a)_{corr}$ are denoted as $(k_c)_{app}$ and $(k_a)_{app}$, respectively, in Ref. 2.

*3 $(k_s)_{corr}$, $(k_s)^c_{corr}$, $(E_0)_{corr}$, $(\alpha_c)_{corr}$ and $(\alpha_a)_{corr}$ are denoted as $(k_s)_{app}$, $(k_s)^c_{app}$, $(E_0)_{app}$, α_{app} and β_{app}, respectively, in Ref. 2.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 1604—1608 (1969)

Epoxidation of Eight- and Twelve-Membered Cyclic Olefins with Hydrogen Peroxide in the Presence of Metal Oxide Catalysts*[1]

Jo ITAKURA, Hisao TANAKA and Hiroo ITO

Research Laboratory, Toa Gosei Chemical Industry Co., Funami-cho, Minato-ku, Nagoya

(Received April 25, 1968)

The oxidation of eight- and twelve-membered cyclic olefins by H_2O_2 was carried out in various alcohols using some metal oxides as catalysts. In contrast to the case of cyclohexene and norbornene, which can be hydroxylated, the oxidation of 1,5,9-cyclododecatriene, cyclododecene, 1,3- and 1,5-cyclooctadiene and cyclooctene with H_2O_2 in the presence of selenium dioxide resulted in selective formation of the corresponding monoepoxides. The following rate equation was obtained with cyclooctene (COE) in isopropanol:

$$-d[H_2O_2]/dt = k_3'[SeO_2][H_2O_2] + k_3''[SeO_2][H_2O_2][COE].$$

It is well known that the oxygen compounds of some heavy metals, such as tungsten, selenium, vanadium, osmium, molybdenum and chromium, catalyze the H_2O_2 oxidation in characteristic fashion. The oxidation of olefins yields α-diols as the main product.[1-4] Epoxide formation as intermediate was suggested for WO_3 and SeO_2 catalyzed reactions.[3,4] The present paper describes some results obtained on the H_2O_2 oxidation of eight- and twelve- membered cyclic olefins in the presence of metal oxides, especially selenium dioxide.

Experimental

Materials. Commercial cycloolefins were distilled to remove antioxidants before use. *trans, cis*-1,5-Cyclodecadiene was prepared by the cooligomerization of butadiene with ethylene using a catalyst composed of nickel acetylacetonate, triphenyl phosphite and triethylaluminum. Hydrogen peroxide and selenium dioxide (G. R. grade) were used without further purification. Alcohols of G. R. grade were distilled and used as solvents in the preparation, but for the kinetic purposes, they were dried by refluxing over magnesium or calcium metal.

Preparative Experiments. SeO_2 was dissolved in alcohol, olefin was then added, and the alcoholic solution of H_2O_2 was added dropwise with agitation and cooling within 2 hr. After agitation for further several hours, the reaction mixture was washed with aqueous solutions of sodium bisulfite and sodium carbonate. The ether extract of aqueous washings and other organic layers were brought together and dried over sodium sulfate. The product was distilled under reduced pressure. The determination of the amount of epoxide formed was carried out with the hydrogen chloride-dioxane-method,[5] in which the optimal reaction time of epoxide with H_2O_2 was pre-determined for each epoxide.

Kinetic Procedure. The reaction was carried out in alcoholic media at 25—50°C with the following initial concentration ranges of reagents: $[SeO_2]_0$=3.33—26.67 mmol/*l*, $[Olefin]_0$=0.300—1.333 mol/*l*, $[H_2O_2]_0$=0.147—0.294 mol/*l*, $[H_2O]_0$=29.8 mmol/*l*. Aliquots were taken out at intervals, the reaction was stopped by addition of an alcoholic potassium hydroxide solution, and the peroxide content was determined iodometrically.

Results and Discussion

Oxidation of Several Cylcoolefins. The results of oxidation of *trans,trans,cis*-1,5,9-cyclododecatriene (*t,t,c*-CDT) under various reaction conditions are shown in Table 1.

In contrast to the oxidation of cyclohexene,[4] epoxide was produced selectively regardless of solvents. The content of water exhibited little effect on the selectivity of epoxide. 9,10-Epoxy-1,5-cyclododecadiene was obtained by distillation of the product: bp 102°C/2.5 mmHg, n_D^{20} 1.5017. Found: C, 80.72; H, 10.03%. Calcd for $C_{12}H_{18}O$: C, 80.85; H, 10.18%. The infrared spectrum, which was identical with that reported,[6] showed strong absorption bands of *trans* and *cis* double bonds at 972cm^{-1} and 700 cm^{-1}, respectively. Meanwhile, gas chromatography indicated the presence of two isomers in a molar ratio of 97 to 3,

suggesting that *trans* double bond of *t,t,c*-CDT is oxidized more easily than *cis*. This could be attributed to the larger internal strain of the former. Similar results have also been reported recently for the organic peracid oxidation of the same olefin.[7]

Table 2 shows the oxidation results of cyclododecene (CDE).

A mixture of *trans* and *cis* CDE in a molar ratio of 68 to 32 was oxidized to give two isomeric epoxides in an approximately constant ratio. Epoxycyclododecane (a *trans-cis*-mixture with 72 : 28) was isolated by distillation: bp 116—117°C/4.7mmHg, n_D^{20} 1.4763. Found: C, 79.05; H, 12.08%. Calcd for $C_{12}H_{24}O$: C, 79.06; H, 12.17%.

The epoxidation of eight-membered cyclic olefins is summarized in Table 3. An excellent yield was attained with cyclooctene (COE), while lower yields were observed with 1,3- and 1,5-cyclooctadiene (COD).

Physical properties of the isolated epoxides were as follows: epoxycyclooctane, mp 56—57°C; 3,4-epoxy-1-cyclooctene, bp 74—75°C/13 mmHg, n_D^{20} 1.4832; 5,6-epoxy-1-cyclooctene, bp 80—81°C/18 mmHg, n_D^{20} 1.4890.

The SeO_2 catalyzed H_2O_2 oxidation of *trans, cis*-1,5-cyclodecadiene, however, resulted in the formation of several products including small amounts of epoxides which could not be identified. No examination was made on the possibility of double bond isomerization, though the olefin is known to be a relatively unstable compound, which can easily be isomerized either to *cis,cis*-1,6-cyclodecadiene,[8] or to 1,2-divinylcyclohexane.[9]

The oxidation results with several metal oxides

8) P. Heimbach, *Angew. Chem.*, **78**, 604 (1966).
9) G. Wilke and P. Heimbach, *ibid.*, **75**, 10 (1963).

other than SeO_2 are summarized in Table 4. Epoxides were also obtained in good selectivities with the oxides of tungsten, molybdenum and vanadium as catalysts. All the systems given in Table 4 were heterogeneous because of the poor solubilities of catalysts. With $H_2WO_4 \cdot H_2O$, the amount of distillation residue increased, as did the water content in the reaction medium.

Kinetics on Oxidation of Cyclooctene. The only example of kinetic investigation on H_2O_2 oxidation in the presence of SeO_2 so far seems to be that reported by Ogata and Tabushi,[10] who employed dimethylaniline as substrate. No information has been available on the kinetic behavior of the oxidizing system on olefinic double bond. The fact that the oxidation of cycloolefin was essentially an epoxidation prompted us to the kinetic study. Cyclooctene was chosen as the substrate.

No reaction occurred on treatment of cyclooctene with 90% H_2O_2 alone or SeO_2 alone. The system SeO_2-H_2O_2 in isopropanol shows a very slight decrease in the H_2O_2 concentration only after a long period with agitation.

Effects of the Concentration of Reaction Components. The results of oxidation of COE are summarized in Table 5. In every run, plots of H_2O_2 consumption against reaction time indicated that the rate $-d[H_2O_2]/dt$ was directly proportional to H_2O_2. Water, which was formed by the reaction, did not seem to influence the rate at all, while the apparent value of pH varied slightly (in the range of 0.1 to 0.2) during the course of reaction. Hence the following equation is obtained:

$$-\frac{d[H_2O_2]}{dt} = k_1[H_2O_2] \quad (1)$$

To determine the effect of SeO_2, rates of H_2O_2 consumption were measured at various initial concentrations of SeO_2, while keeping initial concentration of H_2O_2 and COE constant. The results are given in Fig. 1, which suggests a first order relationship between the rate and $[SeO_2]$. A slight deviation from the direct proportionality as observed for low concentrations of SeO_2 might be ascribed to the decrease in acidity. Combining the result with Eq. (1), we have the following equation:

$$-\frac{d[H_2O_2]}{dt} = k_2[H_2O_2][SeO_2] \quad (2)$$

In order to determine the effect of cyclooctene concentration, rates were measured varying its initial concentration, and the extrapolated values of $(-d[H_2O_2]/dt)/[H_2O_2]$ at $t=0$, or $(k_1)_0$, were calculated (see Table 5). Although a linear relationship exists between $(k_1)_0/[SeO_2]$ and $[COE]_0$, as shown in Fig. 2, they are not directly proportional to each other. This was proved to be valid for different temperatures applied. Figure 2 gives the

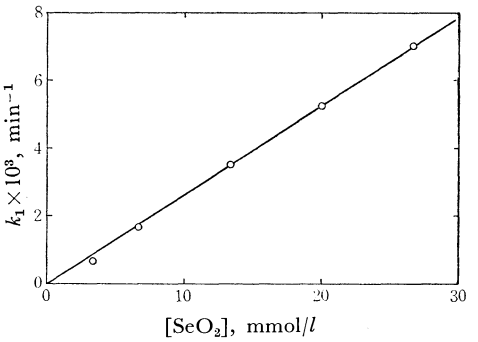

Fig. 1. Effect of concentration of SeO_2 on the rate.
($[COE]_0=1.333$ mol/l, $[H_2O_2]_0=0.147$ mol/l, $[H_2O]_0=29.8$ mmol/l, 30°C, in isopropanol)

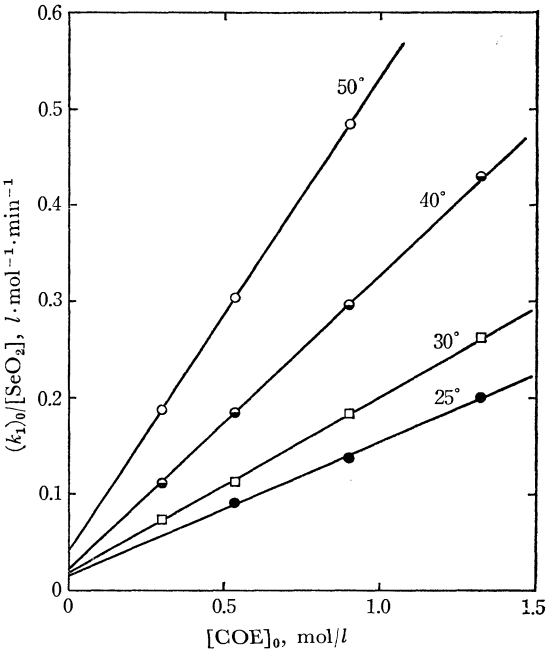

Fig. 2. Effect of initial concentration of COE on the rate.
($[H_2O_2]_0=0.147$ mol/l, $[H_2O]_0=29.8$ mmol/l, in isopropanol)

equation:

$$-\frac{d[H_2O_2]}{dt} = k_3'[SeO_2][H_2O_2] + k_3''[SeO_2][H_2O_2][COE] \quad (3)$$

Table 6 summarizes the values of k_3' and k_3''. For k_3'', the Arrhenius plot gives a straight line, from which apparent activation energy and activation entropy are calculated:

$$\Delta H^{\ddagger} = 9.67 \text{ kcal} \cdot \text{mol}^{-1},$$
$$\Delta S^{\ddagger} = -38.2 \text{ cal} \cdot \text{mol}^{-1} \cdot {}^{\circ}\text{C}^{-1} \ (40^{\circ}\text{C}).$$

The first term of the right side in Eq. (3) expresses the rate of H_2O_2 consumption, which is of

10) Y. Ogata and I. Tabushi, This Bulletin, **32**, 215 (1959).

Table 6. Values of k_3' and k_3''

Temp. °C	k_3' $l\cdot mol^{-1}\cdot min^{-1}$	k_3'' $l^2\cdot mol^{-2}\cdot min^{-1}$
25	0.0155	0.138
30	0.017	0.184
40	0.021	0.306
50	0.038	0.495

zeroth order with respect to COE concentration. On the other hand, the rate of H_2O_2 consumption in the system SeO_2–H_2O_2–*i*PrOH (in the absence of COE) was shown to be much smaller than the corresponding value of the term $k_3'[SeO_2][H_2O_2]$. This fact means that the term expresses mainly reactions of H_2O_2 in which both SeO_2 and COE actually participate. The k_3' values do not satisfy the Arrhenius equation, so that the activation energy is not obtainable. The term may therefore include several reactions, in which COE does and does not participate. Ogata and Tabushi[10] have previously obtained comparable results on the oxidation of dimethylaniline with SeO_2-H_2O_2, and proposed two independent routes for amine oxide formation. Considering our results, this concept is now extended for oxidation of olefinic double bonds as follows:

$$H_2O_2 + SeO_2 \rightleftarrows \text{Peracid } A_1 \xrightarrow{+\text{Olefin}} H_2SeO_3 + \text{Epoxide} \quad (4)$$

$$H_2O_2 + SeO_2 \rightleftarrows \text{Peracid } A_2 \xrightarrow{+\text{Olefin}} H_2SeO_3 + \text{Epoxide} \quad (5)$$

A highly active peracid A_1 in Eq. (4) would be formed by a slow reaction of H_2O_2 with SeO_2, which then reacts with COE rapidly, whereas a more stable peracid A_2, formed through a fast reaction, would oxidize the olefin slowly. No attempts, however, were made by us to obtain information on the structures of these active peracids.

Effect of Solvents. As Table 5 indicates, less-polar alcohols favor the oxidation.

The effect of water content in the reaction medium is also given in Table 5. It is apparent that an increase in water concentration causes a marked reduction of the rate. As already discussed in the previous report on oxidation of dimethylaniline in methanol-water medium,[10] this effect could be attributed mainly to a hindering action of water in regenerating SeO_2 dehydration of H_2SeO_3, that is formed through the oxidation reaction (see Eqs. 4 and 5). If SeO_2 is not smoothly regenerated, the effective concentration of the oxide is lowered, and then, according to Eqs. (4) and (5), the formation of active peracids may also be hindered.

Hydroxylation and Epoxidation. On studying the hydroxylation of cyclohexene with H_2WO_4-H_2O_2, Payne and Smith[3] proposed a reaction scheme including formation of epoxide as the intermediate. A similar conclusion was also obtained by Sonoda and Tsutsumi for SeO_2-catalyzed hydroxylation of the cycloolefin on the basis of the product analysis.[4] Our results have now provided examples, in which the epoxides can actually be isolated by treating cycloolefins with SeO_2- of H_2WO_4-H_2O_2. It is evident, that the reaction of H_2O_2 with the olefinic double bond in the presence of oxides of W, Se, Mo and V is essentially an epoxidation, and it is also hardly doubtable that the hydroxylation occurs with many olefins as the successive hydrolysis of the epoxide formed. In fact, there seem to exist certain differences between epoxides of cyclohexene and higher-membered cyclic olefins in the ease of ring opening in acidic media.[11] Such differences can not simply be explained through the electronic effect, as is known for epoxides of substituted aliphatic olefins, since we have here no branched chains. Some steric effects such as steric hindrance or internal strain should be considered to play a part.

The authors wish to thank Toa Gosei Chemical Industry Co. for permission to publish these results.

(Received July 27, 1968)

A normal compound, 2',7'-dibromotribiphenylenepropane (IV), and an abnormal compound, 2',7',2'',7''-tetrabromotribiphenylenepropane (VI), were obtained by the Michael addition of 9,9'-bifluorenylidene (I) and 2,7-dibromofluorene (III). In addition, another normal compound, 2,7,2',7'-tetrabromotribiphenylenepropane (VIII) and three abnormal compounds, IV, VI, and tribiphenylenepropane (VII), were isolated by the Michael addition of 2,7,2',7'-tetrabromo-9,9'-bifluorenylidene (IX) and fluorene (II). In both cases, the normal compounds were obtained in the presence of sodium ethoxide in ethanol. The abnormal compounds might be formed by the further condensation of 2,7-dibromo-9,9'-bifluorenylidene (V) and III or II in the presence of alkali. The related compounds, 2,7-dibromotribiphenylenepropane (X), IV, VI, VIII, and 2,7,2',7',2'',7''-hexabromotribiphenylenepropane, were synthesized by the reaction of substituted 9-fluorenyllithium and substituted 9-bromo-9,9'-bifluorenyl in an absolute xylene solution. The thermal decomposition of X and VIII afforded bromosubstituted or non-bromosubstituted-9,9'-bifluorenylidenes, 9,9'-bifluorenyls, fluorenones, and fluorenes. The ethanolysis of 2,7-dibromo-9'-hydroxy-9,9'-bifluorenyl gave fluorenone and III.

The formation of an abnormal addition product, 2',7',2'',7''-tetrabromotribiphenylenepropane(VI), together with a normal addition product, 2',7'-dibromotribiphenylenepropane (IV), by a Michael addition reaction between 2, 7-dibromofluorene (III) and 9,9'-bifluorenylidene (I) has been previously reported in this series.[2] The reactions of 2,7,2',7'-tertabromo-9,9'-bifluorenylidene (IX) and fluorene (II) have also been investigated by Pinck and Hilbert,[3] but they isolated no specific compound except tribiphenylenepropane (VII).

In view of the interest in the formation of abnormal addition products, we have sought to clarify the mechanism of this addition reaction.

The present study has been primarily concerned with a re-examination of the formation of several compounds, including IV, VI, and VII,[3,4] by reactions between I and III, IX and II under various base conditions.

A Michael addition between I[5] and III was carried out in ethanol using sodium ethoxide (15%) as the catalyst; it gave a good yield of IV. In the case of potassium hydroxide (1%) in a pyridine solution, VI was obtained as the major product, while II, IV, VII, fluorenone, and 2,7-dibromofluorenone were the minor products. These results are summarized in Table 1.

In other observations of the Michael addition between IX and II, the normal compound VIII was obtained exclusively with sodium carbonate (5%) in a pyridine solution, or VIII and 2,7-dibromo-α, δ-dibiphenylenebutadiene were obtained with sodium ethoxide (5.8%) in an alcoholic solution. A compound (mp 303—304°C (dec)), three abnormal products, IV, VI and VII, and two elimination products, III and 2,7-dibromofluorenone, were also isolated using potassium hydroxide (0.5—5%) in a pyridine solution. These results are summarized in Table 2.

A transitory carbanion (A) is formed in the initial step by an attack of the 2,7-dibromo-9-fluorenyl carbanion (III') on the highly-polarized acceptor

a) Py=Pyridine, EtOH=Ethanol, NaOEt=Sodium ethoxide.
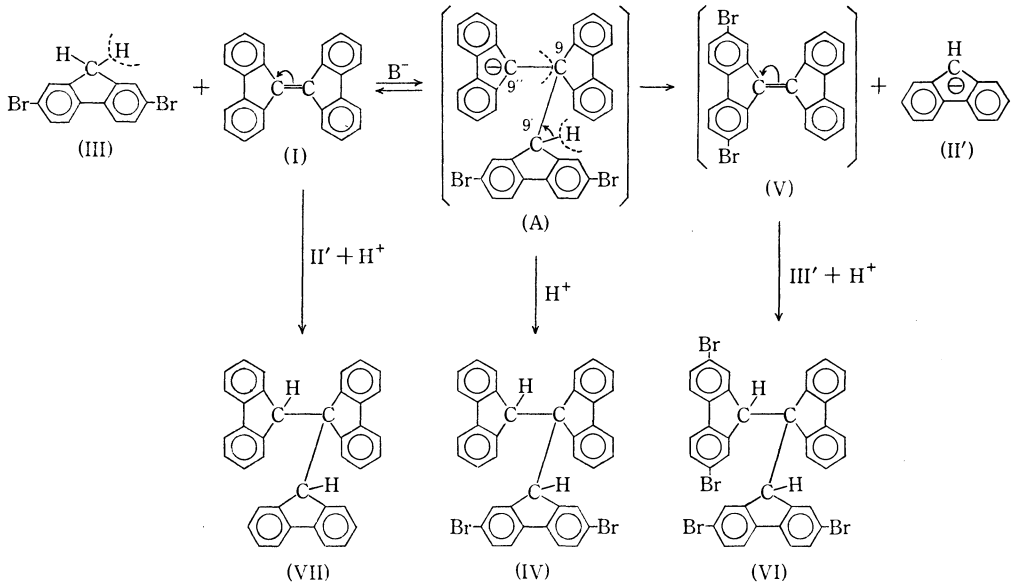
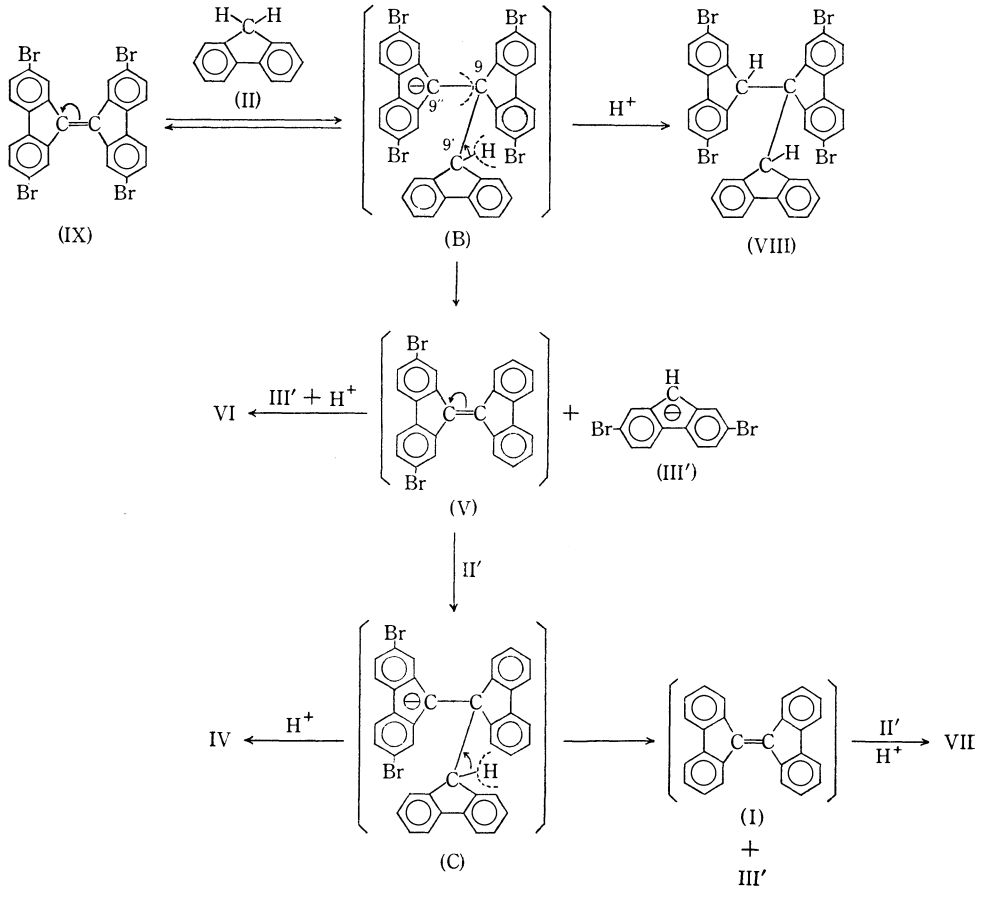
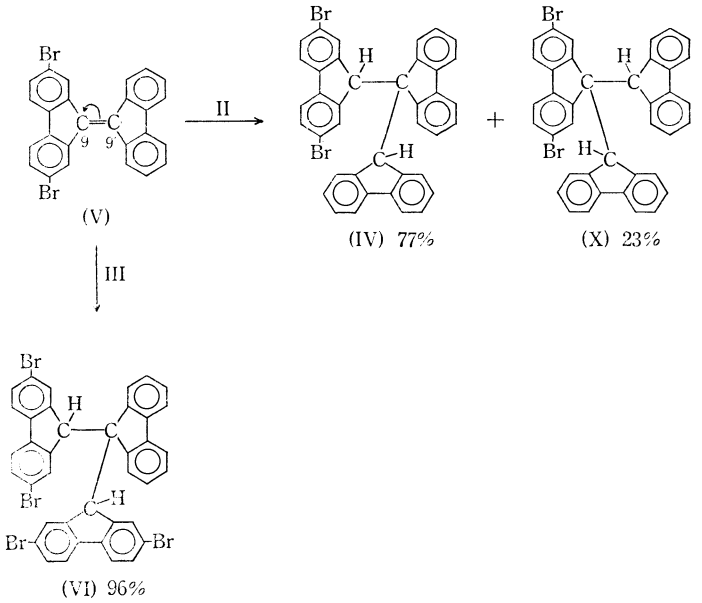
b) *=mp 303—304°C.
c) Reactions were carried out in sealed tube at 93—95°C (Runs 1—9) or 97—98°C (Runs 10, 11).
d) Run 2: The reaction was carried out in nitrogen medium at boiling point. 2,7-Dibromo-α,δ-dibiphenylenebutadiene was also obtained (0.56 g).
e) Run 3: 2,7-Dibromo-α,δ-dibiphenylenebutadiene (0.46 g) was also isolated.
f) Run 10: X (0.46 g) was also isolated.



Scheme I



Scheme II



Scheme III

I in the presence of the base. (A) may then be transformed to the normal compound IV by protonation. The 9'-methine proton in (A) is reactive, and the fission of the 9—9'' carbon-carbon bond is accelerated when 2,7-dibromo-9,9'-bifluorenylidene (V) and 9-fluorenyl carbanion (II') are formed upon an increase in the alkali concentration. The abnormal VI is formed by a second Michael addition of III' and V. In this case, the yield of the secondary product, VI, is also increased if the amount of the donor, III, is raised (see Table 1, Run 5). The isomeric VIII was not formed. The unexpected formation of VII can be explained in terms of the interaction of I with II' which was eliminated from (A). The sequence of steps is shown in Scheme I.

A second transitory carbanion (B) is also formed by the interaction of IX with II. The formation of normal, abnormal, and elimination products is also conceivable as in the case of Scheme I. This sequence of steps is shown in Scheme II.

(A) and (B) are very crowded ions, and so the formation of II', III', or the stable V by an elimination reaction is perhaps favored over the protonation of (A) or (B) because there is sufficient space to release steric compression upon an increase in the alkali concentration.

The reactions of V and II or III were also carried out separately (see Table 2, Scheme III). The former reaction gave the two isomers in the ratio of 77% (IV) to 23% (X). The latter afforded a 96% yield of VI.

The 9'-carbon is more electro-positive than the 9-carbon for such highly-polarized acceptors as V because of the inductive effect of the two bromines. Also, the active methylene in the 9-position of III is greatly activated by the same means. Thus, IV and VI were formed exclusively in both reactions through, respectively, addition and protonation.

Thus, the yield of VI was higher than that of IV, while X was not isolated from the reaction products *via* the intermediate V during the interaction between IX and II. The tertiary product VII might be formed by the reaction of II and the I is eliminated from the carbanion (C).

Five related bromosubstituted tribiphenylenepropanes, IV, VI, VIII, X, and 2,7,2',7',2'',7''-hexabromotribiphenylenepropane,[6] were synthesized in order to confirm the reaction products from the interaction between substituted-9-bromo-9,9'-bifluorenyl and 9-lithiofluorenes by the halogen-lithium interconversion reaction shown in Table 3.

The thermal decomposition products of bromosubstituted tribiphenylenepropanes are interesting from the standpoint of free radical reaction. The thermal decomposition of X at 320°C led to 2, 7-dibromo-9,9'-bifluorenyl,[7] IX, V, 9,9'-bifluorenyl,[8] II, fluorenone, and 2,7-dibromofluorenone. Also, the thermal decomposition of VIII at 320—330°C led to IX, 2,7,2',7'-tetrabromo-9,9'-bifluorenyl,[6] V, 2,7-dibromo-9,9'-bifluorenyl, I, 9,9'-bifluorenyl, 2,7-dibromofluorenone, fluorenone, III, and II. These compounds were probably obtained by means of the formation and interaction of substituted

a) All reactions were carried out in dry xylene medium.

b) Run 1: I (0.3 g), 9-hydroxy-9,9'-bifluorenyl (1.1 g) and III (1.55 g) were also isolated.

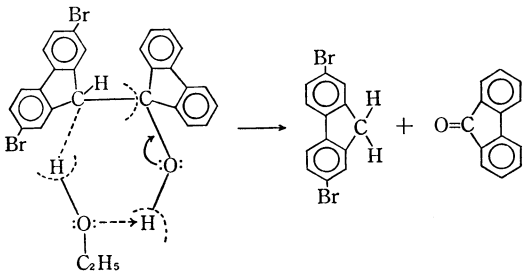
c) Run 6: 2,7,2',7',9-Pentabromo-9,9'-bifluorenyl (mp 420°C, 0.34 g), IX (0.04 g), 2,7,2',7'-tetrabromo-9-hydroxy-9,9'-bifluorenyl (0.5 g), 2,7,2',7'-tetrabromo-9,9'-bifluorenyl (0.26 g), III (0.6 g), and 2,7-dibromofluorenone (0.9 g) were also isolated.
2,7,2',7'-Tetrabromo-9-hydroxy-9,9'-bifluorenyl (mp 255—256°C, Found: C, 47.41; H, 2.39%. Calcd for $C_{26}H_{14}OBr_4$: C, 47.17; H, 2.13%). 2,7,2',7',9-Pentabromo-9,9'-bifluorenyl (mp>416°C, 79%) was obtained from the corresponding hydroxy compound by the action of hydrogen bromide in acetic acid.

d) cf). S. Kajigaeshi, *Nippon Kagaku Zasshi (J. Chem. Soc. Japan, Pure Chem. Sect.)*, **82**, 1712 (1961).

9-fluorenyl free radical species.

When 2,7-dibromo-9'-hydroxy-9,9'-bifluorenyl[9], one of the intermediates in the preparation of 2,7,9'-tribromo-9,9'-bifluorenyl,[9] was refluxed in ethyl alcohol for 25 min, fluorenone (89%) and III (78%) were formed. However, no reaction occured under the same conditions in a benzene solution. In two similar compounds, 9-hydroxy-9,9'-bifluorenyl[10] and 2,7-dibromo-9-hydroxy-9,9'-bifluorenyl[9], the same reaction did not occur in an ethyl alcohol solution.

In such a case, the reaction is presumably affected by an electron-attracting group, which makes the elimination of the two bromines easier. Ethanolysis can proceed through the hydrogen-bonded complex by means of the interaction of the substrate and a molecule of ethanol, as is indicated in Scheme IV.



Scheme IV

Experimental[11]

The Michael Reaction of 9,9'-Bifluorenylidene (I) with 2,7-Dibromofluorene (III). *General Procedure.* A mixture of 3.3g (0.01mol) of I, 3.2g (0.01 mol) of III, and 3m*l* of a 10% aqueous potassium hydroxide solution in 30m*l* of pyridine was heated in a sealed tube for 2hr. The mixture turned dark after 1.5hr, and precipitates were formed. Upon the filtration of the hot solution, a light yellow product was obtained.

The resulting product was extracted several times with ethyl acetate; the evaporation of the solvent from this extract afforded 0.1g of colorless fluffy crystals of IV; mp 285—287°C (dec). Found: C, 71.92; H, 3.68%. Calcd for $C_{39}H_{24}Br_2$: C, 71.78; H, 3.68%. The residue was recrystallized from benzene to yield 3.1g of colorless VI; mp 312—314°C (dec). Found: C, 57.86; H, 22.7%. Calcd for $C_{39}H_{22}Br_4$: C, 57.79; H, 2.74%.

After the orange yellow pyridine mother liquor had been allowed to cool, a light yellow deposit was collected and extracted with hot cyclohexane. Upon the cooling of the cyclohexane extract, 0.05g of 2, 7-dibromofluorenone, mp 198—200°C, was isolated. The residue was extracted by refluxing it with ethyl acetate to afford 0.4g of IV, mp 286°C (dec). The last residual part was recrystallized from benzene to yield 0.2g of VI, mp 313—314°C (dec).

The original pyridine mother liquor was poured into water; the yellowish-orange material thus precipitated was collected by filtration, dried, and purified by fractional vacuum sublimation at 100—160°C to afford 0.15g of fluorenone, mp 82—84°C, 0.2g of II, mp 112—114°C, and 0.1g of 2, 7-dibromofluorenone, mp 197—200°C. The work-up of the residual part by column chromatography (benzene) and fractional recrystallization from ethyl acetate gave 0.15g of 2,7-dibromofluorenone, mp 198—200°C, 0.05g of fluorenone, mp 83°C, 0.25g of VII, mp 291—293°C (dec), (no halogen), 0.7g of VI, mp 313—314°C (dec), 0.1g of IV, mp 286°C (dec), and 0.03 g of III, mp 163—164°C

The Michael Reaction of 2,7,2',7'-Tetrabromo-9,9'-bifluorenylidene (IX) with Fluorene (II). *Materials.* IX was prepared according to a method in the literature,[12] but the product remained impure. Found: C, 51.20; H, 1.79%. Calcd for $C_{26}H_{12}Br_4$: C, 48.49; H, 1.88%. IX was then oxidized by means of sodium bichromate in acetic acid; the oxidation products, 2,7-dibromofluorenone and a small amount of 2-bromo-7-chlorofluorenone[13] as an impurity, were confirmed by gas chromatography. Pure IX, mp 429°C (dec), (Found: C, 48.55; H, 1.79%) was prepared by the reaction of 2,7,9-tribromofluorene[9] with methanolic potassium hydroxide in acetone under conditions similar to those used in the preparation of I.[5]

General Procedure. A mixture of 2.00g (0.0031 mol) of IX, 1.55g (0.0093 mol) of II, 0.9g of potassium hydroxide in 5m*l* of water, and 25m*l* of pyridine was heated in a sealed tube at 93—95°C for 5.7hr. During this period, the mixture turned from red to dark, and colorless crystals were formed.

Upon cooling, the deposited crystals were filtered, to this filtrate was added 25m*l* of methanol with stirring and the precipitated material was filtered again. The pyridine-methanol mother liquor was poured into water, and the precipitate was filtered, washed with water, dried, and sublimed *in vacuo* at 80—200°C.

The crops of the first and second portions were combined, washed with water, and dried, and then the residue of the sublimation was added. There were subsequently isolated 0.55g of IV, mp 285—286°C (dec), 0.86g of Vl, mp 313—314°C (dec), 0.04g of VII, mp 292—293°C (dec), (no halogen), 0.20g of a material with a mp of 303—304°C (dec) (Found: C, 57.78; H, 2.53%. Calcd for $C_{39}H_{22}Br_4$: C, 57.79; H, 2.74%), and a trace of recovered IX, mp 429°C (dec) by means of fractional recrystallization from ethanol, ethyl acetate, and benzene. The material with a mp of 303—304°C (dec) (see Table 2) contained a small percentage VI in VIII. This contamination with VI could not be removed. It seems to be the reason for these solubilities lying close together; the IR and UV absorption spectra and the R_f-values obtained by thin layer chromatography are also similar. A phase diagram plotting the melting points *versus* the compositions of synthetic mixtures of authentic VIII and VI indicates that a material with a melting point o 303—304°C (dec) would correspond to about 4—5% VI in 96—95% VIII. The small amount of VI causes only a small elevation in the melting point of VIII.

10) V. Grignard and C. Courtot, *Compt. rend.*, **152**, 1493 (1911); C. Courtot, *Ann. Chem.*, **4**, 84 (1915).

11) All melting points are uncorrected.

12) J. Schmidt and H. Wagner, *Ann.*, **387**, 147 (1912).

13) K. Suzuki, *Nippon Kagaku Zasshi (J. Chem. Soc. Japan, Pure Chem. Sect.)*, **75**, 714 (1954).

The cyclohexane solution of the sublimed product was chromatographed on alumina. Further fractional recrystallization from ethanol gave 0.40g of III, mp 162—164°C, 0.15g of 2,7-dibromofluorenone, mp 200—202°C, and a trace of fluorenone, mp 82—84°C, while 0.59g of the II of the starting material, mp 112°C was also separated.

When sodium ethoxide was the catalyst, an unknown compound, mp 364°C (dec) was isolated as red needles (Table 2, Runs 2 and 3 or Table 1, Run 8). On oxidation with sodium bichromate in acetic acid, this material gave 73% of 2,7-dibromofluorenone and 41% of fluorenone, while the analytical results agreed with the value calculated for $C_{28}H_{16}Br_2$. The IR and UV absorption spectra of the compound with a mp of 364°C (dec) were very similar to those of α,δ-dibiphenylenebutadiene[14] and 2,7,2',7'-tetrabromo-α,δ-dibiphenylenebutadiene[15] respectively. Thus, the structure of the unknown compound is presumably 2,7-dibromo-α,δ-dibiphenylenebutadiene, which has not been described hitherto.

All the compounds in this reaction series were identified by mixed-melting-point determinations and by comparing their IR and UV absorption spectra with those of authentic samples.

The Michael Reactions of 2,7-Dibromo-9,-9-'bifluorenylidene (V) with Fluorene (II) or 2,7-Dibromofluorene (III). The reaction was performed in a similar manner, 1.5g (0.0031 mol) of V,[7] mp 242-243°C, 1.55g (0.0093 mol) of II, 0.9g of potassium hydroxide in 5m*l* of water, and 25m*l* of pyridine in a sealed tube were heated at 97—98°C for 10min.

The precipitate which formed upon cooling was fractionally recrystallized from ethyl acetate and benzene to afford 1.57g (77%) of IV, mp 285—286°C (dec) and 0.46g (23%) of X, mp 303°C (dec). Found (for X): C, 71.55; H, 3.59%. Calcd for $C_{39}H_{24}Br_2$: C, 71.78; H, 3.68%. In addition, 0.99g of II, mp 112—115°C, and a trace of 2,7-dibromofluorenone, mp 198°C, were isolated from the mother liquor and were purified by a combination of vacuum sublimation and column chromatography.

The product, 2.42 g of VI, mp 314°C (dec), was obtained in a good yield (96%) from 1.50 g of V and 3.03 g (0.0093 mol) of III under the reaction conditions described above.

The identities were confirmed by mixed-melting-point determinations and by a comparison of the IR and UV absorption spectra with those of authentic samples.

The Synthesis of 2',7'-Dibromotribiphenylenepropane (IV). *1) General Procedure.* The reaction of *n*-butyllithium and III in xylene led to 2,7-dibromo-9-fluorenyllithium, which then, upon treatment with carbon dioxide, gave 2,7-dibromofluorene-9-carboxylic acid, mp 208—209°C. Found: C, 45.49; H, 2.23%. Calcd for $C_{14}H_8O_2Br_2$: C, 45.69; H, 2.19%. IR: 1705 cm^{-1} (ν C–O) (KBr-disk).

2) *n*-Butyllithium was prepared from 2.8g (0.04 mol) of *n*-butyl bromide in 25 m*l* of anhydrous ether and 0.28g (0.04g atom) of lithium in 20m*l* of anhydrous ether. Then 9-fluorenyllithium was formed by adding 5g (0.03 mol) of fluorene in 50m*l* of anhydrous xylene to the *n*-butyllithium solution. To this mixture was added slowly 130m*l* of anhydrous xylene containing 5.7g (0.01 mol) of 2,7,9'-tribromo-9,9'-bifluorenyl with stirring.

After the reaction mixture had been allowed to stand overnight at room temperature, the precipitate was filtered, hydrolyzed with a dilute ammonium chloride solution, and recrystallized from ethyl acetate to give 3.8g (58.7%) of IV, mp 285—286°C (dec). mol wt: 658. Calcd for $C_{39}H_{24}Br_2$: 652.

Thermal Decomposition of 2,7-Dibromotribiphenylenepropane (X). Powdered X (5.0g; 0.0077 mol) was placed in a 100m*l* Erlenmeyer flask and then decomposed at 320°C in a preheated salt bath.

The red molten product was ground and extracted with boiling benzene, which had been filtered while hot. The orange colored residue was recrystallized form a large volume of benzene to yield 0.04g (2%) of IX, mp 430°C (dec).

The mother solution from this recrystallization was evaporated to dryness under reduced pressure. The fractional recrystallization of the residue from a mixture (1 : 1) of benzene and ethyl acetate gave 1.3g (35%) of 2,7-dibromo-9,9'-bifluorenyl, mp 268—270°C, 0.1g (4%) of 9,9'-bifluorenyl, mp 242—244°C, and 0.3g (6%) of of the starting material X, mp 303°C (dec).

When the product of the first benzene extraction was left to stand, red crystals (0.7g) of V, mp 240—242°C, separated out. This mother liquor was then evaporated to dryness under reduced pressure, and the residue was dissolved in benzene and chromatographed on alumina. A 0.7-g portion (27%) of 2,7-dibromofluorenone, mp 198—200°C, and 0.2g (7%) of fluorenone, mp 83°C, were isolated from the yellow band on the column. The colorless benzene eluate, upon evaporation and vacuum sublimation at 100°C, gave 0.05g (2%) of fluorene, mp 114°C. The residue from the sublimation was recrystallized from ethyl acetate to yield 0.15g of V, mp 240—242 °C (total; 0.85g, 23%).

Thermal Decomposition of 2,7,2',7'-Tetrabromotribiphenylenepropane (VIII). Finely powdered VIII (3.24g; 0.004 mol) was decomposed at 320—330°C in a preheated metal bath. The red molten product was then ground and extracted with boiling benzene. The insoluble red part was recrystallized from pyridine to yield 0.35g (14%) of IX (mp 429—430°C (dec)).

After the benzene mother liquor had been evaporated to a small volume, 0.59g (23%) of 2,7,2',7'-tetrabromo-9,9'-bifluorenyl,[3,5,7] mp 317—318°C, 0.68g (35%) of 2,7-dibromo-9,9'-bifluorenyl, mp 269—270°C, 0.25g (13%) of V, mp 241—242°C and the recovered VIII (0.02g; 1%) were separated by fractional recrystallization from ethyl acetate or benzene.

When the residual benzene solution was chromatographed on alumina, 0.03g (5%) of I, mp 182—184°C, 0.02g (3%) of 9.9'-bifluorenyl, mp 241—243°C, 0.01g (2%) of II (mp 114°C), and a trace of III were isolated. Moreover, 0.15g (6%) of 2,7-dibromofluorenone, mp 197—198°C, and 0.07g (10%) of fluorenone, mp 78—80°C, were separated from the two yellow bands.

The Reaction of 2,7-Dibromo-9'-hydroxy-9,9'-bifluorenyl in Ethanol. A mixture of 1.0g (0.002 mol) of 2,7-dibromo-9'-hydroxy-9,9'-bifluorenyl and 25m*l* of absolute ethanol was refluxed for 25min; the mixture turned yellow during this period. After half the volume

of the original alcohol had then been removed, pure crystals (0.5g;78%) of III, mp 165°C, were deposited.

The mother liquor was evaporated to dryness under reduced pressure, and the benzene solution of the residual part was chromatographed on alumina. Moreover, 0.32g (89%) of fluorenone, mp 81°C, was isolated from the yellow band and recrystallized from alcohol.

On the other hand, when 1.0g (0.002 mol) of 2,7-dibromo-9-hydroxy-9,9′-bifluorenyl was refluxed in absolute ethanol (45m*l*) for 3hr, 0.89g (89%) of the starting material was recovered.

The authors wish to express their gratitude to Drs. John and Elizabeth Weisburger of the National Institutes of Health, U.S.A., for supplying valuable information.

Synthesis of Adamantane Derivatives. III.[1] Synthesis of Adamantane Heterocycles

Tadashi SASAKI, Shoji EGUCHI and Takeshi TORU

Institute of Applied Organic Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya

(Received July 29, 1968)

Preparation of 1-adamantyl and adamantane-1-carbonyl derivatives having benzimidazole, 1,3,5-oxadiazole, oxazoline-2, quinoxaline, 2-aminothiazole, thiazolone, 2-methylthiazole, 1,2,3-thiadiazole, pyrazole or pyrazoline ring is described.

The unique structure of adamantane and the pharmaceutical effects of 1-adamantylamine hydrochloride on virus[2] have attracted many chemists and pharmacologists to do considerable work on the syntheses of adamantane derivatives,[3] although the biological activities of adamantane-containing agents are known in general to be quite reduced as the result of seemingly minor structural changes in the adamantane moiety.[4]

However, only a few 1-adamantyl heterocycles have been reported,[5] in which interesting interactions between adamantane and heterocyclic moiety could be anticipated from the pharmacological and also chemical viewpoints. Our present paper is concerned with the preparation of some 1-adamantane derivatives having a five- or six-membered heterocyclic ring.

Results and Discussion

Adamantane-1-carboxylic acid (I) was heated with *o*-phenylenediamine in the presence of hydrochloric acid or polyphosphoric acid, according to the general procedure for the preparation of benzimidazoles from aliphatic acids and *o*-phenylenediamine,[6] but these attempts were unsuccessful; in the former reaction, only the starting materials were recovered, and in the latter, adamantane was formed. The imidazole was obtained by the following stepwise method: *N*-(adamantane-1-carbonyl)-*o*-phenylenediamine (III) was prepared from adamantane-1-carbonyl chloride (II, Ad= adamantyl)[7,8] and *o*-phenylendiamine and III were refluxed with polyphosphoric acid ester (ppe) in chloroform to yield a benzimidazole derivative (IV).

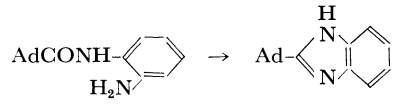
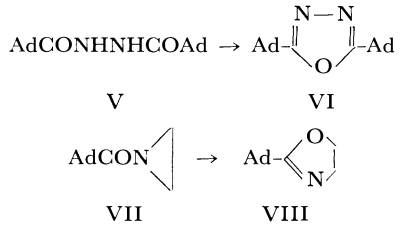
8) The crude acid, obtained from 1-adamantyl bromide and formic acid, should be purified by the alkaline extraction, followed by acidification with hydrochloric acid. The purified I was dissolved in a mixture of dry benzene and thionyl chloride and the reaction mixture was kept standing at around 50°C for 2 hr. If the crude acid was used for the preparation of the acid chloride II, a large amount of 1-adamantyl chloride was formed besides the desired acid chloride, as was pointed out by a recent report: L. F. Fieser, M. Z. Nazer, S. Archer, D. A. Berberian and R. G. Slighter, *J. Med. Chem.*, **10**, 517 (1967).



III IV

N,N'-Bis(adamantane-1-carbonyl)hydrazine (V), prepared from II, was treated with perchloric acid in acetic anhydride[9] to afford 2,5-di(1-adamantyl)-1,3,4-oxadiazole (VI) in 50% yield. VI was also prepared in a 40% yield from the reaction between V and ppe in chloroform, but treatment of V with concd. sulfuric acid was unsuccessful and gave only adamantane-1-carboxylic acid I. Acylaziridine is known to be rearranged by heating with sodium iodide to oxazoline derivative.[10] Thus, 2-(1-adamantyl)-2-oxazoline (VIII), isolated as its picrate, was prepared from adamantane-1-carbonylaziridine (VII) which was obtained from II and ethyleneimine.

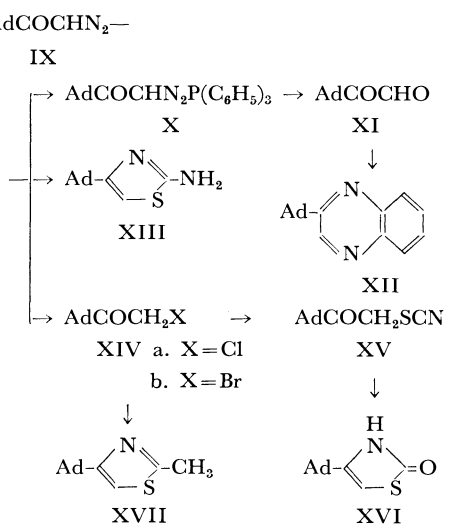


V VI

VII VIII

Adamantane-1-carbonyldizaomethane (IX)[11] could be an excellent precursor for the preparation of adamantane heterocycles. Treatment of II with excess diazomethane in ether gave the diazoketone IX in a good yield. Although reaction of IX with triphenylphosphine proceeded rather slowly (1 day) at room temperature, the triphenylphosphazine (X)[11] was obtained in a good yield of 88%. Phosphazine X was decomposed with nitrous acid to give 1-adamantylglyoxal (XI)[11-12] which, without isolation, was condensed with *o*-phenylenediamine to afford a quinoxaline derivative (XII) in 35% yield. Condensation of IX with thiourea in refluxing ethanol for 5 days afforded 4-(1-adamantyl)-2-aminothiazole (XIII) only in 8% yield after purification on a silica gel column, while heating a mixture of an ethanolic solution of IX and thiourea in a sealed tube at 100°C for 5 days afforded XIII in 20% yield, accompanied by a large amount of untractable decomposition products. The yield was improved up to 65% by using condensation reaction of thiourea with the haloketone (XIV)[11-12] which was easily prepared from IX and concd. hydrochloric or hydrobromic acid.

Reaction of the chloroketone (XIVa) with potassium thiocyanate gave oily adamantane-1-carbonylmethyl thiocyanate (XV) which was hydrolyzed to afford 4-(1-adamantyl)thiazol-2-one (XVI), whereas attempts to cyclize IX with potassium cyanide to the triazine in an aqueous medium were unsuccessful. A thiazole derivative (XVII) was also prepared by the cyclization of the haloketone (XIV) with thioacetamide.



IX X XI XIII XII XIV a. X=Cl b. X=Br XV XVII XVI

Though 1,3-dipolar cycloaddition reaction of diazoalkanes is well known to afford some heterocycles, the reactivity of most diazoketones in the cycloaddition reaction has been pointed out to be low.[13] Compound IX was also not expected to be very reactive, so drastic conditions were applied to the 1,3-dipolar cycloaddition of IX. Treatment of IX with cyanoacetylene in dioxane at 100°C gave 3(5)-(adamantane-1-carbonyl)-5(3)-cyanopyrazole (XVIII) in 92% yield, while IX did not react with it at room temperature. The structure of XVIII was confirmed from analytical and spectral data; the NMR spectrum of XVIII showed a singlet at 2.72 τ due to a ring proton and a broad singlet at -4.2 τ due to an NH proton which disappeared on deuteration. Cycloaddition of IX with acrylamide gave 3-(adamantane-1-carbonyl)-5-carbamoyl-2-pyrazoline (XIX), the structure of which was confirmed from analytical and spectral data.[14] The cycloaddition of diazoalkane with isocyanate has been reported by

several workers.[15] The reaction of IX with benzoylisothiocyanate in dioxane at 100°C gave a thiadiazole derivative (XX) in 47% yield. This structure was confirmed from infrared and ultraviolet spectrum[16] which had the maxima at 238 mμ (ε 18200) and 299 mμ (ε 15700) in ethanol.

The infrared, NMR and ultraviolet spectral data of the reaction products are summarized in Table 1.

Table 1. Spectroscopic data of the reaction products

Experimental

The microanalyses were performed on a Yanagimoto C. H. N. Corder, Model MT-1, while the IR spectra and the UV spectra were obtained on a JASCO Model IR-S infrared spectrophotometer and a JASCO Model ORD/UV-5 ultraviolet spectrophotometer, respectively. All the melting points were measured on a Yanagimoto micromeltingpoint apparatus and are uncorrected.

***N*-(Adamantane-1-carbonyl)-*o*-phenylenediamine (III).** To a solution of *o*-phenylenediamine (0.3 g) and triethylamine (0.3 g) in dry ether was added a solution of II, obtained from 0.5 g of I, in the same solvent. The reaction mixture was stirred overnight at room temperature and filtered. The precipitates were washed with water and recrystallized from aqueous methanol to give 470 mg (63%) of III as colorless plates, mp 229—231°C.

Found: C, 74.99; H, 8.53; N, 10.42%. Calcd for $C_{17}H_{22}ON_2$: C, 75.52; H, 8.20; N, 10.36%.

2-(1-Adamantyl)benzimidazole (IV). The compound III (200 mg) was refluxed in chloroform added with 5 drops of ppe. The mixture was poured into water and the organic layer was washed with aqueous sodium bicarbonate, dried over sodium sulfate and evaporated to dryness. Recrystallization of the residue from chloroform afforded 180 mg (96%) of IV as colorless needles, mp>300°C.

Found: C, 80.82; H, 8.06; N, 11.20%. Calcd for $C_{17}H_{20}N_2$: C, 80.91; H, 7.99; N, 11.10%.

2,5-Di(1-adamantyl)-1,3,4-oxadiazole (VI). *N,N'*-Bis(adamantane-1-carbonyl)hydrazine (V)[6] (400 mg) was dissolved in hot acetic anhydride (15 m*l*), added with 4 drops of 60% perchloric acid. After 10 min, the mixture was cooled and filtered. Water was added to the filtrate and the separated crystals were collected. The combined crystals were washed with water and recrystallized from aqueous acetone affording the oxadiazole (VI) (190 mg, 50%) as colorless plates, mp >300°C in a sealed tube.

Found: C, 78.26; H, 9.21; N, 8.38%. Calcd for $C_{22}H_{30}ON_2$: C, 78.06; H, 8.93; N, 8.28%.

2-(1-Adamantyl)-2-oxazoline (VIII). A mixture of ethyleneimine (0.13 g) and triethylamine (0.3 g) in dry ether was added dropwise to a solution of II, obtained from 0.5 g of I, in dry ether. The reaction mixture was stirred for 30 min under ice-cooling and then for 10 min at room temperature. The solution was filtered and the precipitates were washed with dry ether. The filtrate was dried over sodium sulfate and evaporated *in vacuo* affording a brownish oil (VII); the infrared spectrum showed absorptions at 3050 (ν_{CH}) and 1680 (ν_{CO}) cm^{-1}. The oil VII was refluxed in acetone (15 m*l*) with sodium iodide (0.2 g) for 26 hr. The solution was concentrated *in vacuo* and the residual oil was extracted with ether. The ether extracts were washed with water, dried and condensed *in vacuo*. The residue gave the picrate on treatment with picric acid, which was recrystallized from ethanol to afford yellow needles (0.52 g, 43% based on I), mp 216—218°C.

Found: C, 52.75; H, 5.20; N, 13.24%. Calcd for $C_{19}H_{22}O_8N_4$: C, 52.53; H, 5.10; N, 12.90%.

Adamantane-1-carbonyldiazomethane (IX). A solution of II, obtained from 1.0 g of I, in ether was added to a solution of diazomethane in ether under cooling. After standing for 2 days at room temperature, the solvent and excess diazomethane were removed *in vacuo* and residual yellow solid was recrystallized from methanol to give 0.82 g (72% based on I) of IX as yellow plates, mp 69—71°C.

Found: C, 70.85; H, 8.00; N, 13.34%. Calcd for $C_{12}H_{16}ON_2$: C, 70.56; H, 7.90; N, 13.72%.

α-(Adamantane-1-carbonyl)triphenylphosphazine (X). A mixture of the diazoketone IX (200 mg) and triphenylphosphine (330 mg) in dry ether was stirred for 1 day, cooled and the resulting precipitates were filtered. The precipitates were washed with dry ether and recrystallized from benzene affording 410 mg (88%) of the triphenylphosphazine X as yellow crystals, mp 125—127°C.

Found: C, 76.81; H, 6.20; N, 5.56%. Calcd for $C_{30}H_{31}ON_2P$: C, 77.23; H, 6.70; N, 6.00%.

2-(1-Adamantyl)quinoxaline (XII). An aqueous solution of sodium nitrite (60 mg) was added to a suspension of X (410 mg) in acetone (2 m*l*) and then 20% hydrochloric acid was added to the mixture under ice-cooling. The reaction mixture was stirred for 30 min under ice-cooling and then for 30 min at room temperature. The mixture was extracted with ether and the ether extracts were washed, dried and evaporated *in vacuo* leaving an oil of XI whose infrared spectrum showed absorptions at 2730 (ν_{CHO}), 1700 (ν_{CO}) and 1660 (ν_{CO}) cm^{-1}. A mixture of XI, *o*-phenylenediamine (100 mg) and anhydrous acetic acid (1 drop) was refluxed in ethanol for 4 days. The solvent was evaporated leaving a brownish oil which was dissolved in a small amount of methanol and solidified on cooling. Recrystallization from methanol gave 80 mg (35% from X) of a quinoxaline XII as dark brown plates, mp 119—120°C.

Found: C, 82.04; H, 7.58; N, 10.57%. Calcd for $C_{18}H_{19}N_2$: C, 81.78; H, 7.68; N, 10.60%.

1-Adamantyl chloromethyl ketone (XIVa). Concentrated hydrochloric acid was added to a solution of IX (0.8 g) in dioxane (4 m*l*) under ice-cooling. The reaction mixture was heated at 70°C for 5 min until evolution of nitrogen had ceased completely. The reaction mixture was allowed to cool to room temperature and then water was added to it. The resulting precipitates were collected by filtration, and recrystallized from a mixture of acetone and petroleum ether (bp 40—60°C) to give 0.7 g (84%) of XIVa as colorless plates, mp 106—107°C, which showed a positive Beilstein test.

Found: C, 67.47; H, 8.05%. Calcd for $C_{12}H_{17}OCl$: C, 67.76; H, 8.06%.

1-Adamantyl bromomethyl ketone (XIVb). The work-up as above except using hydrobromic acid instead of hydrochloric acid afforded the precipitates which were recrystallized from methanol giving 220 mg (87.5%) of XIVb as colorless powder, mp 78—79°C, from 200 mg of IX. XIVb showed a positive Beilstein test.

Found: C, 56.17; H, 6.93%. Calcd for $C_{12}H_{17}OBr$: C, 56.04; H, 6.67%.

4-(1-Adamantyl)-2-aminothiazole (XIII). *a) from IX.* A mixture of IX (300 mg) and thiourea (400 mg) was heated at 100°C in ethanol (10 m*l*) in a sealed tube for 5 days. Ethanol was removed and the residue was dissolved in chloroform. The solution was washed with water, dried and chromatographed on a silica gel column, using chloroform as an eluent. Recrystalliza-

tion from acetone gave 70 mg (20%) of XIII as colorless needles.

b) from XIVa. XIVa (80 mg) and thiourea (150 mg) were refluxed in ethanol for 12 hr. The solvent was removed *in vacuo* and the residue was recrystallized from acetone to give 70 mg (65%) of XIII, mp 224—226°C.

Found: C, 66.91; H, 7.82; N, 11.73%. Calcd for $C_{13}H_{18}N_2S$: C, 66.60; H, 7.74; N, 11.95%.

4-(1-Adamantyl)thiazolone (XVI). An acetone solution (15 m*l*) of XIVa (170 mg) and potassium thiocyanate (78 mg) was refluxed for 5 hr. After cooling, the solution was filtered and the filtrate was evaporated *in vacuo*. The residue was dissolved in a mixture of methanol (1 m*l*), water (3 m*l*) and concd. hydrochloric acid (0.5 m*l*) and the mixture was maintained at 70°C for 15 hr. After cooling, the precipitates were collected and recrystallized from a mixture of chloroform and *n*-hexane to give 80 mg (42.5%) of XVI as colorless plates, mp 293.5—295.5°C.

Found: C, 65.95; H, 7.24; N, 5.80%. Calcd for $C_{13}H_{17}ONS$: C, 66.36; H, 7.28; N, 5.95%.

4-(1-Adamantyl)-2-methylthiazole (XVII). A solution of thioacetamide (120 mg) in dry benzene (2 m*l*) was added in small portions to a solution of XIVa (200 mg) in the same solvent (2 m*l*). After refluxing for 24 hr, benzene was removed *in vacuo* and the residue was recrystallized from methanol affording 100 mg (45.5%) of XVII as colorless plates, mp 97—98°C.

Found: C, 72.17; H, 8.19; N, 6.00%. Calcd for $C_{14}H_{19}NS$: C, 72.16; H, 8.22; N, 6.01%.

4-(Adamantane-1-carbonyl)-5-benzoylamino-1,2,-3-thiadiazole (XX). A mixture of IX (100 mg) and benzoyl isothiocyanate (0.5 m*l*) was kept at 100°C for 1 day. On addition of *n*-hexane to the cooled reaction mixture, yellowish white crystals were separated and further crops were obtained from the mother liquor giving an overall yield of 85 mg (47%) of XX. Recrystallization from a mixture of acetone and *n*-hexane gave yellowish white needles, mp 225—226°C.

Found: C, 65.46; H, 5.68; N, 11.48%. Calcd for $C_{20}H_{21}O_2N_3S$: C, 65.36; H, 5.76; N, 11.44%.

3(5)-(Adamantane-1-carbonyl)-5(3)-cyanopyrazole (XVIII). IX (200 mg) and cyanoacetylene (100 mg) was heated at 100°C in anhydrous dioxane for 1 day. Water was added to the cooled solution to give colorless crystals. Recrystallization from a mixture of methanol and *n*-hexane afforded 230 mg (92%) of XVII as colorless needles, mp 224.5—225.5°C.

Found: C, 70.53; H, 6.43; N, 16.45%. Calcd for $C_{15}H_{17}ON_3$: C, 70.56; H, 6.71; N, 16.46%.

3-(Adamantane-1-carbonyl)-5-carbamoyl-2-pyrazoline (XIX). IX (270 mg) and acrylamide (120 mg) were heated at 100°C in dioxane in the presence of triethylamine (1 drop) for 1.5 days. Addition of water to the cooled reaction mixture afforded solids which were recrystallized from methanol giving 50 mg (14%) of XIX as yellow needles, mp 275—277.5.5°C.

Found: C, 65.63; H, 7.37; N, 15.25%. Calcd for $C_{15}H_{21}O_2N_2$: C, 65.43; H, 7.69; N, 15.26%.

The authors wish to express their thanks to Takeda Chemical Industries, Ltd., for running the NMR spectra, and especially to Mr. Akiho Ishihara of their laboratories who carried out the microanalyses.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 1622—1627 (1969)

The Alkaline Ethanolyses of Chlorophenyldiphenylsulfonium Halides, Chlorophenyl Phenyl Sulfones and Chloronitrobenzene in Aqueous Ethanol[1)]

Shigeru OAE and Yong He KHIM

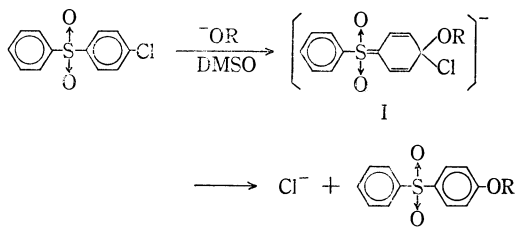
Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sugimoto-cho, Sumiyoshi-ku, Osaka

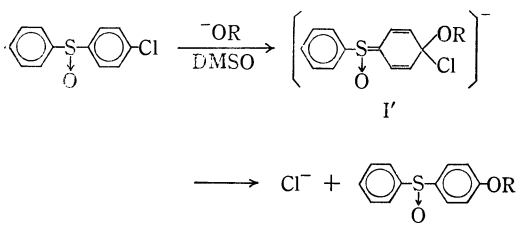
(Received September 5, 1968)

o-, *m*-, and *p*-Chlorophenyldiphenylsulfonium halides were prepared and subjected to the alkaline ethanolysis in order to compare the activating effects of *o*-, *m*-, and *p*-diphenylsulfonio groups with those of *o*-, *m*-, and *p*-phenylsulfonyl and nitro-groups. The diarylsulfonio group at either ortho or para position was found to facilitate the nucleophilic substitution of aryl chloride powerfully. While the effect of diarylsulfonio group was not only substantially larger than that of phenylsulfonyl group, but also exceeding even that of nitro group. Meanwhile, with ethoxide ion in ethanol the alkaline decomposition reaction, presumed to be initiated by the attack of ethoxide on the sulfur atom of chlorophenyldiphenylsulfonium halide, occurred competitively along with the S_N reaction, but the rate of the S_N reaction of *p*-chlorophenyldiphenylsulfonium perchlorate was found to be about 9 times larger than that of the decomposition reaction. Substitution of a methyl group at ortho to diphenylsulfonio, phenylsulfonyl and -sulfinyl groups did change very little the rates of the ethanolyses of the corresponding *p*-substituted chlorobenzenes, suggesting that essentially there is no or little steric inhibition for the 3d-orbital resonance with either sulfonio, sulfinyl, or sulfonyl group in the S_N reaction of these compounds.

In the previous paper,[1)] dealing with the alkaline hydrolyses of chlorophenyl phenyl sulfones and sulfoxides in aqueous dimethyl sulfoxide, we have shown that both phenylsulfonyl and -sulfinyl groups at either *o*- or *p*-positions markedly accelerate the aromatic S_N reaction of hydrolysis.

This reaction is presumed to involve the initial formation of an addition intermediate (I or I') which is undoubtedly stabilized by the 3d-orbital conjugative effect of phenylsulfonyl or phenylsulfinyl group.





In the nucleophilic substitution of aromatic halides, an electron-accepting group such as sulfonyl or nitro group, is known to accelerate the rate especially when the group is located at either ortho or para to the halogen group.[2)] Meanwhile the acidity constants[3)] of *m*- and *p*-methylsulfinyl, sulfonyl and dimethylsulfonio-phenols reveal that the sulfonio group at *p*-position can display a relatively strong electron-accepting 3d-orbital resonance effect, and its effect is even larger than that of the corresponding sulfonyl group. Therefore, the sulfonio group when substituted at either ortho or para-position is expected to facilitate the alkaline hydrolysis substantially more than when substituted at meta-position, while the ethanolysis of the sulfonio-substituted chlorobenzene will be much faster than the corresponding sulfonyl compound. In fact, *p*-dimethylsulfonic group is known to increase the reactivity of 2-nitrochlorobenzene more than *p*-trimethylammonio

group in the alkaline methanolysis.[4] However there is no quantitative data to compare the activating effects of sulfonio group with other corresponding sulfur groups. In order to examine the effect of sulfonio group in the aromatic S_N reaction we have synthesized comparatively more stable sulfonium salts, *i. e.*, *o*-, *m*- and *p*-chlorophenyldiphenylsulfonium perchlorate from diphenylethoxysulfonium tetrafluoroborate and chlorophenyl Grignard reagents and subjected to the alkaline S_N reactions in aqueous ethanol in order to compare the relative activating effect of diphenylsulfonio group with those of phenylsulfonyl and nitro groups.

Meanwhile, in view of the formation of the various products in the treatment of triarylsulfonium salt with bases, the alkaline decomposition is expected to give different products dependent on the nature of the bases. In fact, we have found that the reaction of triphenylsulfonium bromide with dimsyl anion in dimethyl sulfoxide gives diphenyl sulfide, benzene, thioanisole and *o*-methylmercaptophenol, while the treatment with piperidide anion gives diphenyl sulfide and phenylpiperidine; meanwhile the reaction with *p*-methylthiophenoxide ion also gave diphenyl sulfide and phenyl tolyl sulfide. In the case with ethoxide anion, diphenyl sulfide, benzene and aldol resins were obtained as main products together with a small amount of phenetole. The detailed mechanisms of these alkaline decompositions of triarylsulfonium halides will be reported in another paper.[5]

For the kinetic experiments of S_N and alkaline decomposition reactions, the ethoxide anion in aqueous ethanol was selected as the base. In this case the attack could occur at both the carbon atom bearing chlorine atom and the sulfur atom of the sulfonium salt. However, when *o*- and *p*-chlorophenyldiphenylsulfonium perchlorate were treated with potassium hydroxide in 70% (vol%) aqueous ethanol, both *o*- and *p*-ethoxyphenyldiphenylsulfonium perchlorate were the major isolable products, indicating that the reaction appears to proceed through a typical aromatic S_N path like in the cases of the sulfones and the sulfoxides[1] as reported in our previous paper.

The products obtained after the treatment with ethoxide in aqueous ethanol were carefully recrystallized and subjected to the IR, NMR, UV and elemental analyses. Since both hydroxide and ethoxide ion can exist in an equilibrium, one would expect to obtain both *p*-ethoxyphenyl- and *p*-hydroxyphenyl-diphenylsulfonium compounds, however, the *p*-hydroxyphenyl compound could not be detected among the products. This means that ethoxide ion being more nucleophilic than hydroxide ion, attacks preferentially the aromatic carbon undergoing the S_N reaction. While the alkaline decomposition reaction was expected to take place competitively with the aromatic S_N reaction, only under a prolonged heating diphenyl sulfide and benzene were obtained as the main products from the reaction of triphenylsulfonium bromide with ethoxide ion. Undoubtedly, this decomposition is initiated by the attack of ethoxide ion on the sulfur atom of the sulfonium salt.

Recently, Bunnett and Happer[6] demonstrated that *o*-chlorophenyl-triphenylphosphonium iodide reacts with sodium methoxide in methanol to afford triphenylphosphin oxide and chlorobenzene suggesting the reaction to proceed through a nucleophilic attack of methoxide ion on the phosphorus atom with the elimination of chlorobenzene.

The mode of the alkaline decomposition (or the nucleophilic attack on the sulfur atom) of triphenylsulfonium and *p*-chloro- or *p*-ethoxyphenyldiphenylsulfonium halides would be identical, and the ease of their alkaline decompositions would not be much different each other, since the effect of only one chloro group from para-position would be very small. Therefore, the rates of the aromatic S_N reaction of chlorophenyldiphenylsulfonium halides by ethoxide ion can be estimated by measuring the amounts of both the aromatic S_N reaction and the alkaline decomposition and correcting the amount of the alkaline decomposition into the aromatic S_N reaction of chlorophenyldiphenylsulfonium halides. Thus we have compared the relative magnitudes of the activating effect of diphenylsulfonio group with those of phenylsulfonyl, -sulfinyl and nitro groups in the aromatic S_N reaction of alkaline ethanolysis.

Results and Discussion

The alkaline decomposition of triarylsulfonium bromide was found to obey the second order kinetic rate law; first order with respect to both the sulfonium concentration and potassium hydroxide concentration as shown in Figs. 1 and 2. The results of the alkaline decompositions of triarylsulfonium halides are shown in Table 1.

The rates of the aromatic S_N ethanolyses of *o*- and *p*-chlorophenyldiphenylsulfonium perchlorate which are corrected with that of the alkaline decomposition of triphenylsulfonium perchlorate are shown in Table 2 along with those of similar aromatic S_N reactions of chloronitrobenzenes and chlorophenyl phenyl sulfones. The rates of the sulfones at 105°C are calculated by extrapolating the values at 155°C using their activation

parameters.

All the values of $\Delta H^{\neq}$ and $\Delta S^{\neq}$ are also shown in Table 2. When the relative rates of the sulfonium perchlorates are compared with those of the sulfones and the nitrobenzenes, one finds that the activating effects of diphenylsulfonio group are markedly larger than those of the corresponding phenylsulfonyl and even exceed those of nitro groups.

Unfortunately, the rate of the aromatic S_N reaction of the *m*-isomer of the sulfonium perchlorate cannot be obtained directly because the aromatic S_N reaction is apparently so slow that the alkaline decomposition takes place faster than the S_N reaction, leading to the preferential decomposition. This means, however, that the S_N reaction of both the *o*- and *p*-sulfonium perchlorates are markedly faster than that of the *m*-isomer, since the S_N reaction of the *p*-isomer is nearly ten times faster than the decomposition of triphenylsulfonium perchlorate.

Our previous assumption that the reactivity of the alkaline decomposition of chlorophenyldiphenylsulfonium perchlorate is nearly the same as that of triphenylsulfonium perchlorate, would be quite valid because there is little or negligible difference in the rates of the decomposition of triphenyl- and tritolyl-sulfonium bromides. Thus, the markedly increased reactivities of the ortho- and para-isomers over that of the *m*-isomer is undoubtedly associated with the 3d-orbital conjugative effect of the diphenylsulfonio groups to stabilize the intermediate complex (III and IV) rather than their

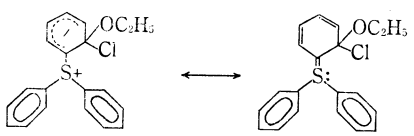
(III)



(IV)

inductive effect, like in the similar cases of the sulfoxide and the sulfones reported previously.[1]

In the previous cases of the aromatic S_N reactions of chlorophenyl phenyl sulfones and chloronitrobenzenes, the *p*-isomers are the most reactive in both cases and the relative rate of the *p*-sulfone is 24 times as that of the *m*-isomer.

Earlier, the theoretical considerations[7] and the studies of dissociation constants[8] of various sulfoxides, sulfones and sulfonium halides have revealed that the 3d-orbital resonance effect is quite stereo-insensitive. In seeking further supporting evidence for the stereo-insensitivity of the 3d-orbital resonance, we have synthesized sterically crowded sulfoxide, sulfone and sulfonium perchlorate which have one methyl group at ortho position and subjected them to the kinetic experiments of the alkaline ethanolysis in aqueous ethanol for both the sulfone and the sulfonium compound and the hydrolysis in aqueous dimethyl sulfoxide for the sulfoxide. The kinetic results are shown in Table 3.

Inspection of the data reveals clearly that the electron-accepting conjugative effects of diphenylsulfonio, phenylsulfonyl and sulfinyl groups are not much inhibited by the bulky ortho methyl group at the *o*-position. The small reductions of the rates by the substitution of *o*-methyl group are undoubtedly due to the electron-releasing inductive effect of methyl group.

This may serve another evidence to support that there is little or almost no steric hindrance in the electron-accepting type conjugation involving 3d-orbital resonance of the sulfur atom.

Experimental

***o*-, *m*- and *p*-Chlorophenyldiphenylsulfonium Perchlorate.** The titled compounds were prepared by the method of Andersen.[9] Diphenyl sulfoxide (8 g) was dissolved in 15 m*l* of anhydrous methylene chloride containing triethyloxonium tetrafluoroborate[10] (8.6 g). After the solution was stirred for about 30 min at room temperature, 50 m*l* of anhydrous ethyl ether was added to this solution and then the methylene chloride - ethyl ether mixture was replaced by tetrahydrofuran by decantation. This solution of ethoxydiphenylsulfonium tetrafluoroborate[11] was slowly added to the Grignard reagent prepared from *p*-chlorobromobenzene (20.4 g) and magnesium (2.7 g) in anhydrous

tetrahydrofuran (60 ml) below −5°C with vigorous stirring. After the addition was over, the solution was stirred further for 30 min and then allowed to stand at room temperature overnight. The mixture was hydrolyzed with 0.5 N hydrobromic acid solution, extracted with chloroform four times, and then dried over calcium chloride. Evaporation of chloroform followed by recrystallization of the residue from acetone-chloroform mixture gave 8.7 g (59%) of colorless *p*-chlorophenyldiphenylsulfonium bromide. Mp 221—222°C. Found: C, 57.63; H, 4.10%. Calcd for $C_{18}H_{14}ClBrS$: C, 57.4: H, 3.72%. When a sodium perchlorate solution was added to a hot solution of *p*-chlorophenyldiphenylsulfonium bromide, colorless crystals of the corresponding sulfonium perchlorate salt appeared immediately, which was collected and recrystallized from ethylene chloride-ether, Mp 160—161°C. Found: C, 54.71; H, 3.65%. Calcd for $C_{18}H_{14}Cl_2O_4S$: C, 54.5; H, 3.52%.

The *o*- and *m*-isomers were similarly prepared from the corresponding *o*- and *m*-chlorophenylphenylethoxysulfonium tetrafluoroborate which were obtained from the corresponding sulfoxides, the Meerwein salt and phenylmagnesium bromide. Both *o*- and *m*-isomers were recrystallized from chloroform-acetone-ether.

o-Isomer: Mp 147—148°C. Found: C, 54.8; H, 3.70%. Calcd for $C_{18}H_{14}Cl_2O_4S$: C, 54.5; H, 3.52%.

m-Isomer: Mp 118—120°C. Found: C, 55.01; H, 3.80%. Calcd for $C_{18}H_{14}Cl_2O_4S$: C, 54.5; H, 3.52%.

Triphenylsulfonium and Tritolylsulfonium Halide. Diphenylethoxysulfonium tetrafluoroborate prepared from diphenyl sulfoxide (9.4 g) and triethyloxonium tetrafluoroborate (10 g) was added to phenylmagnesium bromide in tetrahydrofuran below −5°C, then the reaction mixture was treated similarly to that described above, and 8 g (50%) of colorless triphenylsulfonium bromide was obtained. Mp 292—293°C (Ref.[12]) Mp 291—292°C); perchlorate; Mp 212—213°C.

Tritolylsulfonium bromide was similarly prepared from ditolylethoxysulfonium tetrafluoroborate and tolyl magnesium bromide. Mp 244—245°C.

2-Methyl-4-Chlorophenyldiphenylsulfonium Perchlorate. The titled bromide compound was prepared from 2-methyl-4-chloro-phenylphenylethoxysulfonium tetrafluoroborate obtained by reacting the corresponding sulfoxide (6 g, 0.024 mol) with triethyloxonium tetrafluoroborate (5.25 g, 0.028 mol), with the phenylmagnesium bromide (0.072 mol) as described above. The bromide salt was purified by recrystallization from acetone-ethylene chloride mixture, mp 222—223°C, yield 4.0 g (33%): 2-methyl-4-chlorophenyl-diphenylsulfonium perchlorate was quantitatively obtained by treating the corresponding sulfonium bromide with a sodium perchlorate solution. mp 193—194°C. Found: C, 55.07; H, 4.09%. Calcd for $C_{19}H_{16}O_4Cl_2S$: C, 55.5; H, 3.94%.

2-Methyl-4-Chlorophenylphenylsulfoxide and Sulfone. 2-Methyl-4-chlorophenyl phenyl sulfide, prepared by the reaction of 2-methyl-4-chlorobenzenediazonium salt with thiophenolate, was oxidized as usual with hydrogen peroxide in glacial acetic acid containing a few drops of concentrated sulfuric acid to the corresponding sulfoxide and sulfone in nearly quantitative yields and both sulfoxide and sulfone were recrystallized from benzene-petroleum ether mixture: sulfoxide, mp 39—40°C, sulfone, mp 82—83°C. Found: C, 58.70; H, 4.18%. Calcd for $C_{13}H_{11}O_2ClS$: C, 58.50; H, 4.33%.

2-Methyl-4-Chloroaniline. *o*-Methylacetoanilide

12) a) W. A. Bammer, *J. Am. Chem. Soc.*, **74**, 5078 (1952). b) B. S. Wildi, S. W. Taylar and H. A. Potratz, *ibid.*, **73**, 1965 (1951).

(47 g) obtained from the reaction of *o*-toluidine with acetic acid was dissolved in 70 m*l* of glacial acetic acid in a three necked flask and then liquid chlorine (14.5 g) was introduced into the flask in a sealed system which is connected with rubber tubes with vigorous stirring. After the reaction was over, the mixture was poured into a large amount of cold water, filtered, washed with cold water, recrystallized from ethanol, and 55 g of colorless crystals of 2-methyl-4-chloroacetoanilide was obtained. The amide (55 g) was hydrolyzed with hydrochloric acid in aqueous ethanol and then the salt (20 g) was treated with sodium hydroxide solution to give 2-methyl-4-chloroaniline (11 g). Bp 103—104°C/2 mmHg.

Chlorodiphenyl Sulfones and Chloronitrobenzenes. *o*-, *m*- and *p*-Chlorophenylphenyl sulfones were obtained by the oxidation of corresponding sulfide with hydrogen peroxide in glacial actic acid; the *o*-isomer, mp 108—109°C, the *m*-isomer, mp 113—114°C, the *p*-isomer, mp 90—91°C. Freshly distilled *o*-, *m*- and *p*-chloronitrobenzenes were used in the kinetic experiments.

Alkaline Ethanolyses of Chlorophenyldiphenylsulfonium Perchlorate. *p*-Chlorophenyldiphenylsulfonium perchlorate (1.7 g) was reacted with potassium hydroxide (0.75 g) in 6.3 m*l* of aqueous ethanol (3.6 m*l* ethanol +2.7 m*l* H_2O) at 90°C for 8 hr in an ampoule and then the mixture was poured into cold water, acidified with hydrochloric acid, extracted with chloroform 5 times and the chloroform extract was dried over calcium chloride. After chloroform was evaporated, the crystalline residue (1.2 g) was found to be the mixture of the starting sulfonium and *p*-ethoxyphenylsulfonium salt. The *p*-ethoxysubstituted sulfonium perchlorate (0.8 g) was separated by careful recrystallization with alcohol-acetone-methylene chloride mixture and finally with methylene chloride-acetone-ether. Mp 109—110°C. Found: C, 59.00; H, 4.71%. Calcd for $C_{20}H_{19}ClO_5S$: C, 58.98; H, 4.78%. The NMR charts of both *p*-chlorophenyldiphenylsulfonium perchlorate and *p*-ethoxyphenyldiphenylsulfonium perchlorate were shown in Fig. 3.

The kinetic Experiment. Ethanol was purified first by distillation after refluxing with sodium hydroxide for 10 hr, then with magnesium ethoxide for 3 hr and again distilled. Kinetic measurements and the rate

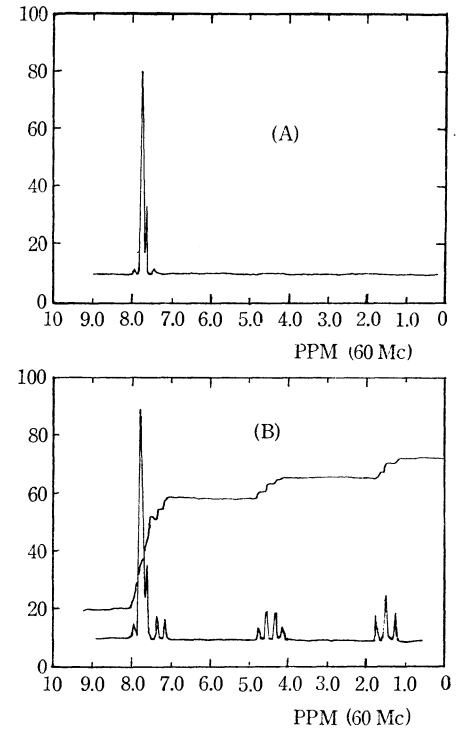

Fig. 3. NMR spectra of *p*-chlorophenyldiphenylsulfonium perchlorate (A) and *p*-ethoxyphenylsulfonium perchlorate (B).

calculations of alkaline ethanolyses were carried out using the same method described in our previous work[1] by the usual Volhard method. Each run was carried out in ampoules. The concentrations of both an aryl chloride and potassium hydroxide were at around 1.3×10^{-1} N and 2.8×10^{-1} N, respectively. Kinetic measurement and the rate calculations of alkaline decomposition of the triarylsulfonium salt were performed under the same condition as in the ethanolyses, but by the use of the ultraviolet spectra of the diaryl sulfides (at $\lambda=285$ mμ).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 1628—1633 (1969)

A Study of the Solvent Effect in the Copolymerization of *N*-Phenylethylenimine with β-Propiolactone

Tsutomu KAGIYA, Tomizo KONDO and Kenichi FUKUI

Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received September 9, 1968)

The effect of the solvent on the copolymerization of *N*-phenylethylenimine with β-propiolactone has been studied quantitatively. The copolymerization rates for the various solvents used increase in the order: diethyl ether < toluene < carbon tetrachloride < methyl acetate < *N,N*-dimethylacetamide < anisole < dioxane < acetone < ethylene dichloride < acetonitrile < acetophenone < nitrobenzene < dimethyl sulfoxide < nitroethane. The rates in solvents with high dielectric constants are much larger than those in solvents with low dielectric constants. However, in the case of solvents with similar dielectric constants, the rates decrease with an increase in the nucleophilicity of the solvent; moreover, the dependency of the copolymerization rate on the nucleophilicity of the solvents is much larger in the solvents with high dielectric constants than in those with low dielectric constants. The rate of the consumption of *N*-phenylethylenimine is markedly affected by the nucleophilicity of the solvents in solvents with high dielectric constants, but it is little affected in solvents with low dielectric constants. Although there is no effect of the nucleophilicity of the solvents on the consumption rate of β-propiolactone, the rate of the consumption of β-propiolactone varies with the electrophilicity of the solvent in solvents with high dielectric constants. On the other hand, the β-propiolactone content in the copolymer increases in proportion to the nucleophilicity of the solvents with high dielectric constants, whereas the β-propiolactone content in solvents with low dielectric constants is almost constant regardless of the electric nature of the solvents.

We have studied the copolymerization of *N*-phenylethylenimine with β-propiolactone. As has been mentioned in a previous paper, *N*-phenylethylenimine and β-propiolactone copolymerized with the acid present in the β-propiolactone without the addition of any catalyst,[1] while in the copolymerization with various Brönsted acids, the composition of the copolymer varied with the kind of acid.[2] On the other hand, it has been reported that, in the polymerization of *N*-phenylethylenimine with formic acid, the polymerization rates were markedly affected by the nucleophilicity and the dielectric constant of the solvents.[3]

In the ionic copolymerization, a number of instances have been reported in which the rate and the composition of the copolymer were markedly influenced by the solvents. No quantitative study of the solvent effect on the polymerization has, however, yet been reported.

The purpose of this paper is to investigate quantitatively the solvent effect on the rate and the composition of the copolymer in the copolymerization of *N*-phenylethylenimine with β-propiolactone.

Experimental

Materials. The method of the preparation and purification of *N*-phenylethylenimine and purification of β-propiolactone were described in a previous paper.[1] The acetonitrile, anisole, diethyl ether, methyl acetate, *N,N*-dimethylacetamide, carbon tetrachloride, toluene, ethylene dichloride, acetone, nitrobenzene, nitroethane, and acetophenone were purified by the usual methods.[4] Dimethyl sulfoxide of a guaranteed reagent grade was used without further purification.

Copolymerization Procedure. Measured amounts of β-propiolactone (0.005 mol) and a solvent (5 *ml*) were placed into a glass ampule under nitrogen atmosphere, and then *N*-phenylethylenimine (0.005 mol) was added to this system at −78°C. After the ampule had been sealed and maintained at 0—1°C for a definite period of time, the products were washed with chloroform and diethyl ether, separated by a centrifuge, and dried *in vacuo*. The method of the determination of the copolymer composition has already been described.[1]

Results and Discussion

The copolymerization was carried out without the addition of any catalyst in various kinds of

solvents. The plots of the copolymerization rate against the dielectric constant of the solvent (ε) are shown in Fig. 1. Although the rates tend to increase with an increase in the dielectric constant of the solvent, there are great differences in the rate, even in the solvents with similar dielectric constants, *i. e.*, nitrobenzene, acetonitrile, and *N,N*-dimethylacetamide.

In order to investigate the effect of the electric nature of the solvent, the rate was plotted against K_D, where K_D is the nucleophilic equilibrium constant of a solvent in the nucleophilic solvation to a deuterium atom of a methanol-d molecule[5] (Fig. 2). It was found that the effects of the solvents on the copolymerization rate may be classified into two large groups, that is, solvents with high dielectric constants ($\varepsilon>10$) and those with low dielectric constants ($\varepsilon<10$).

In solvents with high dielectric constants, the rates decrease markedly with an increase in the nucleophilicity of the solvent, while in solvents with low dielectric constants the rates are almost constant, regardless of the nucleophilicity of the solvent. Ethylene dichloride ($\varepsilon\fallingdotseq10$) shows the intermediate behavior in these groups. The cause of the great deviation of dimethyl sulfoxide from the other solvents with high dielectric constants may be due to its much larger electrophilicity.

The relation between the consumption rates of the monomers and the K_D values is shown in Fig. 3. The consumption rate of *N*-phenylethylenimine in

the solvents with high dielectric constants decreased markedly with an increase in the nucleophilicity of the solvents, while in the solvents with low dielectric constants the consumption rate was almost

5) T. Kagiya, Y. Sumida and T. Inoue, This Bulletin, **41**, 767 (1968).

constant, regardless of the nucleophilicity of the solvents. On the other hand, the consumption rate of β-propiolactone is much smaller than that of *N*-phenylethylenimine, and the effect of the nucleophilicity of the solvent on the rate of the consumption of β-propiolactone was small. These facts show that, in the solvents with high dielectric constants, the consumption rate of *N*-phenylethylenimine is more affected by the nucleophilicity of the solvents than is the consumption rate of β-propiolactone.

Moreover, in order to investigate the effect of the electrophilicity of the solvent on the consumption rates of each monomer, the rates were plotted against the $\Delta\nu_{C=O}$ values of the solvents (Fig. 4), where $\Delta\nu_{C=O}$ was defined as the relative difference between the C=O absorption band of acetophenone observed in solution and the C=O absorption band of acetophenone in benzene.[5] As is shown in Fig. 4, although the effect of the electrophilicity of the solvent on the consumption rate of *N*-phenylethylenimine is small, the consumption rate of β-propiolactone decreased markedly with an increase in the $\Delta\nu_{C=O}$ value of the solvents in the case of the solvents with high dielectric constants. On the other hand, in the solvents with low dielectric constants, the rate consumption of β-propiolactone is not affected by the $\Delta\nu_{C=O}$ value of the solvents.

The notes are the same as Fig. 3.
The number of a solvent is same as Fig. 1.

In view of these facts, it may be assumed that, although the solvents with low dielectric constants have no effect on the propagation reaction, in the solvent with high dielectric constants, the propagation reaction of *N*-phenylethylenimine is much affected by the nucleophilicity of the solvent, and that of β-propiolactone, by the electrophilicity. These results may lead to the explanation that *N*-phenylethylenimine (large nucleophilicity) directly attacks the cationic end group of the polymer, whereas β-propiolactone (large electrophilicity) coordinates electrophilically with the counter-anion and then reacts with the cationic end group. Therefore, in the solvents with high dielectric constants the competitive coordination of the solvents with the cationic end group (or the counter-anion) may depress the reaction of *N*-phenylethylenimine (or β-propiolactone).

The relation between the β-propiolactone content in the copolymer and the K_D values of the solvents is shown in Fig. 5. In the solvent with high dielectric constants the β-propiolactone content is much smaller than in the solvents with low dielectric constants, and it increases in proportion to the K_D value of the solvent. On the other hand, in the solvents with low dielectric constants, the β-propiolactone content is almost constant (32%). The variation in the copolymer composition with the kind of solvent also indicates that the effect of the solvent on the reaction of *N*-phenylethylenimine differs from that of β-propiolactone.

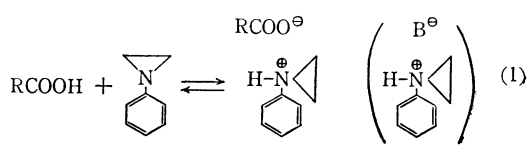
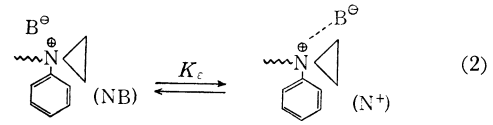
Mechanism of the Copolymerization. From these experimental facts, the mechanism of the copolymerization may be postulated as follows:

Initiation

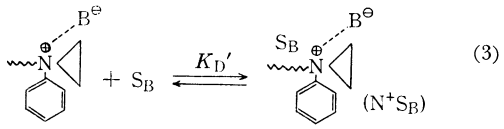


Propagation

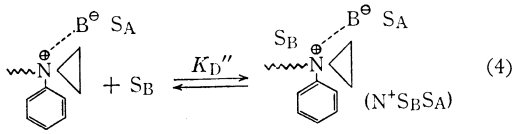


(2)

Nucleophilic solvation

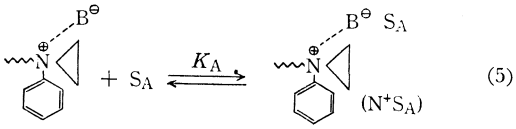


(3)

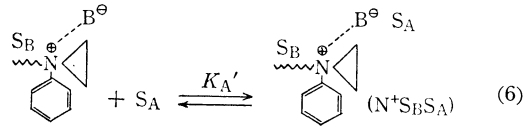


(4)

Electrophilic solvation



(5)

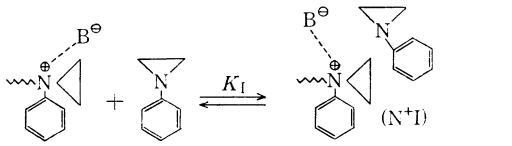


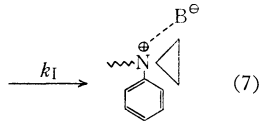
(6)

S_B; nucleophilic solvent, S_A: electrophilic solvent.

Reaction of N-phenylenimine in propagation

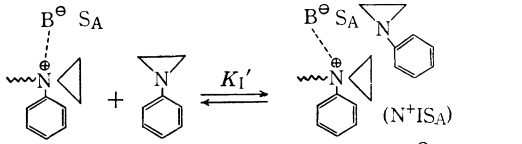
Reaction with dissociated immonium ion:
Nonsolvated

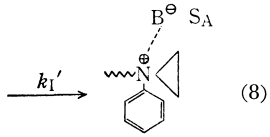




(7)

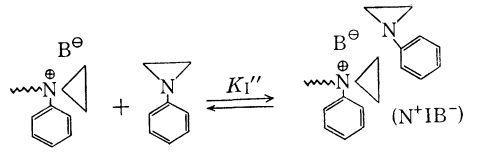
Solvated

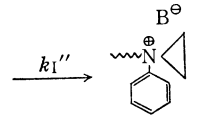




(8)

Reaction with undissociated immonium ion:

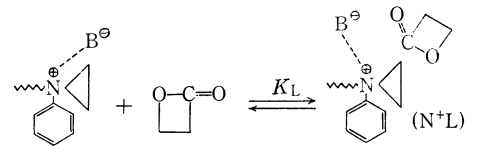


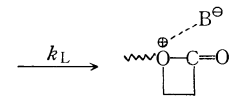


(9)

Reaction of β-propiolactone in propagation

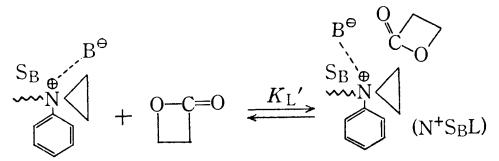
Reaction with dissociated immonium ion:
Nonsolvated

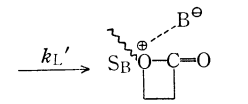




(10)

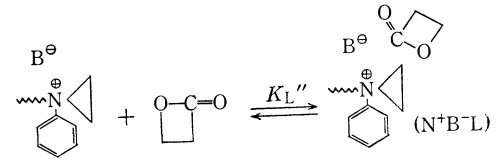
Solvated

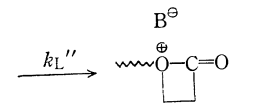




(11)

Reaction with undissociated immonium ion:





(12)

The initiation reaction is considered to be the reaction of the acid present in β-propiolactone with *N*-phenylethylenimine to produce compound I as has been described in a previous paper.[2] This compound dissociates partially from the immonium ion, and the reaction is in equilibrium. The equilibrium constant (K_ε) is considered to increase with an increase in the dielectric constant of the solvent. Equations (3) and (4) show the nucleophilic solvation of the solvent to the immonium ion. Since the coordinations of the solvents with both propagating species and methanol-d are nucleophilic reac-

tions, the equilibrium constants (K_D' and K_D'') are considered to increase with an increase in K_D. Equations (5) and (6) show the electrophilic solvation of the solvent to the counter-anion of the polymer end. The coordination of the solvent with both the counter-anion and acetophenone are considered to be electrophilic reactions. Therefore it seems reasonable to assume that K_A and K_A' are larger in the solvents with larger $\Delta\nu_{C=O}$ values. On the other hand, on the basis of the fact that there is no effect on the propagation reaction in the solvents with low dielectric constants, it is considered that the coordination of the solvent with the undissociated immonium ion is small.

In the propagation reaction, immonium and oxonium ions are considered to react with the monomers by the same mechanism. Therefore, the propagation reactions of immonium ions with monomers are shown as an example. The reaction rate of *N*-phenylethylenimine decreases with an increase in the nucleophilicity of the solvent; *i. e.*, in a low-nucleophilic solvent such as the nitro compound, the reaction rate of *N*-phenylethylenimine is much larger than in a nucleophilic solvent such as dimethylacetamide. Since these facts may indicate that the competitive coordination of the nucleophilic solvent with the cationic end group depresses the coordination of *N*-phenylethylenimine, the reaction of *N*-phenylethylenimine is considered to occur by means of a nonsolvated immonium ion, as is shown by Eqs. (7) and (8). From the fact that the reaction rate of *β*-propiolactone decreases with an increase in the electrophilicity of the solvent in the solvents with high dielectric constants, the reaction of *β*-propiolactone may proceed by means of a dissociated immonium ion whose counter ion is not solvated by the solvent, as is shown by Eqs. (10) and (11). On the other hand, the propagation in the solvents with low dielectric constants is assumed to occur by means of the reaction of the undissociated immonium ion with monomers (Eqs. (9) and (12)).

Kinetics. On the basis of the mechanism postulated, the effect of the solvent on the copolymerization rate and the copolymer composition was kinetically investigated. From the fact that the amount of *β*-propiolactone consumed is much less than that of *N*-phenylethylenimine, the quantity of immonium ions is considered to be much larger than that of oxonium ions. Therefore, the concentration of the compound I, $\alpha[C]_0$, may be approximately expressed by Eq. (13), where $[C]_0$ is the initial concentration of the catalyst and where α is a constant ($0<\alpha<1$):

$$\alpha[C]_0 = [N^+] + [N^+B^-] + [N^+S_B] + [N^+S_A] + [N^+I] + [N^+L] + [N^+S_BL] + [N^+IS_A] + [N^+B^-I] + [N^+B^-L] + [N^+S_AS_B] \quad (13)$$

On the other hand, according to Eqs. (2), (3), ⋯, (11) and (12), the equilibrium equations will be:

$$[N^+]/[N^+B^-] = K_\varepsilon \quad (14)$$

$$[N^+S_B]/([N^+][S]) = K_D' \quad (15)$$

$$[N^+S_A]/([N^+][S]) = K_A \quad (16)$$

$$[N^+S_AS_B]/([N^+S_A][S]) = K_D'' \quad (17)$$

$$[N^+S_AS_B]/([N^+S_B][S]) = K_A' \quad (18)$$

$$[N^+I]/([N^+][I]) = K_I \quad (19)$$

$$[N^+IS_A]/([N^+S_A][I]) = K_I' \quad (20)$$

$$[N^+B^-I]/([N^+B^-][I]) = K_I'' \quad (21)$$

$$[N^+L]/([N^+][L]) = K_L \quad (22)$$

$$[N^+S_BL]/([N^+S_B][L]) = K_L' \quad (23)$$

$$[N^+B^-L]/([N^+B^-][L]) = K_L'' \quad (24)$$

where [I] and [L] are the concentrations of *N*-phenylethylenimine and *β*-propiolactone respectively. By combining Eqs. (13), (14), ⋯, (23) and (24), the concentrations of N^+I, N^+L, N^+S_BL, N^+IS_A, N^+B^-I, and N^+B^-L are represented by Eqs. (25), (26), (27), (28), (29) and (30) respectively:

$$[N^+I] = K_\varepsilon K_I\alpha[C]_0[I]/f(K,M,S) \quad (25)$$

$$[N^+L] = K_\varepsilon K_L\alpha[C]_0[L]/f(K,M,S) \quad (26)$$

$$[N^+S_BL] = K_\varepsilon K_L'K_D'\alpha[C]_0[L][S]/f(K,M,S) \quad (27)$$

$$[N^+IS_A] = K_\varepsilon K_I'K_A\alpha[C]_0[I][S]/f(K,M,S) \quad (28)$$

$$[N^+B^-I] = K_I''\alpha[C]_0[I]/f(K,M,S) \quad (29)$$

$$[N^+B^-L] = K_L''\alpha[C]_0[L]/f(K,M,S) \quad (30)$$

where $f(K,M,S) = 1+K_I''[I]+K_L''[L]+K_\varepsilon(1+K_I[I]+K_L[L]+K_D'[S]+K_A[S]+K_L'K_D'[S][L]+K_AK_I'[S][I]+K_A'K_D'[S]^2)$.

The reaction rates of *N*-phenylethylenimine and *β*-propiolactone are represented by Eqs. (31) and (32) respectively:

$$-d[I]/dt = k_I[N^+I] + k_I'[N^+IS_A] + k_I''[N^+B^-I] \quad (31)$$

$$-d[L]/dt = k_L[N^+L] + k_L'[N^+S_BL] + k_L''[N^+B^-L] \quad (32)$$

By substituting Eqs. (25), ⋯, (29) and (30) into Eqs. (31) and (32), Eqs. (33) and (34) are derived:

$$-\frac{d[I]}{dt} = \frac{(K_\varepsilon K_Ik_I+K_\varepsilon K_I'K_Ak_I'[S]+K_I''k_I'')\alpha[C]_0}{f(K,M,S)}[I] \quad (33)$$

$$-\frac{d[L]}{dt} = \frac{(K_\varepsilon K_Ik_L+K_\varepsilon K_L'K_D'k_L'[S]+K_L''k_L'')\alpha[C]_0}{f(K,M,S)}[L] \quad (34)$$

Since the propagations in the solvents with high dielectric constants occur mainly by the reaction of the dissociated immonium ion and the monomers, Eqs. (33) and (34) may be expressed approximately by Eqs. (35) and (36):

$$-\frac{d[I]}{dt} = \frac{K_\varepsilon(K_I k_I + K_A K_I k_I'[S])\alpha[C]_0}{f(K,M,S)}[I] \quad (35)$$

$$-\frac{d[L]}{dt} = \frac{K_\varepsilon(K_L k_L + K_D K_L' k_L'[S])\alpha[C]_0}{f(K,M,S)}[L] \quad (36)$$

Because $[S] \gg 1$, $K_A K_I' k_I'[S]$ and $K_D' K_L' k_L'[S]$ are considered to be much larger than $K_I k_I$ and $K_L k_L$ respectively. Therefore, Eqs. (35) and (36) may be approximately expressed by Eqs. (37) and (38) respectively:

$$-d[I]/dt = (K_\varepsilon K_A K_I' k_I'[S]\alpha[C]_0[I])/f(K,M,S) \quad (37)$$

$$-d[L]/dt = (K_\varepsilon K_D' K_L' k_L'[S]\alpha[C]_0[L])/f(K,M,S) \quad (38)$$

Taking the reciprocal of Eqs. (37) and (38), and considering that the concentration of the solvent is much larger than unity, two approximate equations, Eqs. (39) and (40), may be obtained:

$$1/(-d[I]/dt) \fallingdotseq \frac{K_D'(1+K_L'[L])}{K_A K_I' k_I'\alpha[C]_0[I]} + \frac{(1+K_I'[I]+K_D''[S])}{K_I' k_I'\alpha[C]_0[I]} \quad (39)$$

$$1/(-d[L]/dt) \fallingdotseq \frac{K_A(1+K_I'[I])}{K_D' K_L' k_L'\alpha[C]_0[L]} + \frac{(1+K_L'[L]+K_A'[S])}{K_L' k_L'\alpha[C]_0[L]} \quad (40)$$

Equations (39) and (40) explain the experimental results that, in the polar solvents with similar dielectric constants, the reaction rate of *N*-phenylethylenimine (or *β*-propiolactone) decreases with an increase in the K_D' (or K_A). On the other hand, considering that the terms containing K_ε in Eqs. (33) and (34) are negligible in the solvents with low dielectric constants, the rate equations of the monomers may be approximately expressed by Eqs. (41) and (42) respectively:

$$-d[I]/dt = K_I'' k_I''\alpha[C]_0[I] \quad (41)$$

$$-d[L]/dt = K_L'' k_L''\alpha[C]_0[L] \quad (42)$$

According to Eqs. (41) and (42), we can explain the experimental finding that, in the solvents with low dielectric constants, there was no effect of the electric nature of the solvent on the reaction rates of the monomers.

Since the scale of the reaction of *N*-phenylethylenimine is much larger than that of *β*-propiolactone in the solvents with high dielectric constants, the copolymerization rate may be almost equal to the reaction rate of *N*-phenylethylenimine. Therefore the copolymerization rate (R_p) in the solvents with high dielectric constants is:

$$R_p \fallingdotseq K_\varepsilon(K_I k_I + K_A K_I' k_I'[S])\alpha[C]_0[I]/\{1+K_I''[I]+K_L''[L]+K_\varepsilon(1+K_I[I]+K_L[L]+K_D'[S]+K_A[S]+K_L' K_D'[S][L]+K_A K_I'[S][I]+K_A' K_D'[S]^2)\} \quad (43)$$

By assuming $0 < K_\varepsilon < 1$, Eq. (43) explains the experimental facts that, in solvents with high dielectric constants, the copolymerization rate increased with an increase of the K_ε value, while in solvents with similar dielectric constant the rate decreased with an increase in the K_D'. The copolymerization rate in solvents with low dielectric constants is represented by the sum of Eqs. (41) and (42);

$$R_p \fallingdotseq -d[I]/dt + -d[L]/dt = (K_I'' k_I''[I]+K_L'' k_L''[L])\alpha[C]_0 \quad (44)$$

This equation shows that there is no effect of the solvents with low dielectric constants on the copolymerization rate.

The *β*-propiolactone content in the copolymer (C_L) is given by Eq. (45):

$$C_L = [Y]_L/([Y]_I + [Y]_L) \quad (45)$$

where $[Y]_I$ and $[Y]_L$ are the amounts of *N*-phenylethylenimine and *β*-propiolactone respectively present in the copolymer. In the solvents with high dielectric constants, by considering that $[Y]_I \gg [Y]_L$ because the *β*-propiolactone content in the copolymer is smaller than 26%, as is shown in Fig. 5, the *β*-propiolactone content may be approximately expressed by Eq. (46):

$$C_L \fallingdotseq [Y]_L/[Y]_I \quad (46)$$

By combining Eqs. (35), (36) and (46), and by assuming that $[I] \fallingdotseq [L]$ in the early stage of the copolymerization, Eq. (47) is derived:

$$C_L \fallingdotseq (K_L k_L + K_D' K_L' k_L'[S])/(K_I k_I + K_A K_I' k_I'[S]) \quad (47)$$

This approximate equation can explain the experimental fact that the *β*-propiolactone content increases in proportion to the K_D' value of the solvent. On the other hand, in the solvents with low dielectric constants, *β*-propiolactone content is approximately expressed by Eq. (48), which is derived from Eqs. (41), (42) and (45):

$$C_L \fallingdotseq K_L'' k_L''/(K_L'' k_L'' + K_I'' k_I'') \quad (48)$$

Equation (48) explains the fact that, in the solvents with low dielectric constants, the *β*-propiolactone content is almost constant, independent of the characteristic nature of the solvents.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 1634—1640 (1969)

Effect of the Binary Solvent System on the Copolymerization of *N*-Phenylethylenimine with β-Propiolactone

Tsutomu KAGIYA, Tomizo KONDO and Kenichi FUKUI

Fuculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received October 17, 1968)

The effect of the binary solvent system on the copolymerization of *N*-phenylethylenimine with β-propiolactone has been studied quantitatively. The copolymerization was carried out in three kinds of binary solvent systems, each consisting of components with similar dielectric constants (ε) and with very different nucleophilicities: (1) the nitrobenzene - *N,N*-dimethylacetamide system, $\varepsilon \fallingdotseq 36$, (2) the ethylene dichloric'e - tetrahydrofuran system, $\varepsilon \fallingdotseq 10$, (3) the toluene-anisole system, $\varepsilon \fallingdotseq 3$. In the binary solvent system with the highest dielectric constant, the copolymerization rate decreased with an increase in the content of the nucleophilic solvent. In the nitrobenzene - *N,N*-dimethylacetamide system, the copolymerization rate markedly decreased upon the addition of a small amount of *N,N*-dimethylacetamide in nitrobenzene. On the other hand, in the ethylene dichloride - tetrahydrofuran binary solvent system, with a lower dielectric constant than the nitrobenzene and *N,N*-dimethylacetamide system, the rates decreased in proportion to the tetrahydrofuran content. The β-propiolactone content in the copolymer increased with the amount of the larger nucleophilic solvents, and the dependency of the copolymer composition on the nucleophilicity of the solvents was much larger in the binary solvents with high dielectric constants than in the binary solvents with low dielectric constants. In the toluene - anisole system, which has a very low dielectric constant, the copolymerization rate and the composition of the copolymer were almost constant, independent of the composition of the solvents.

We have studied the solvent effect in the copolymerization of *N*-phenylethylenimine with β-propiolactone. It has been reported[1] that, in the copolymerization of *N*-phenylethylenimine with β-propiolactone in various solvents, the copolymerization rate and the composition of the copolymer were much affected by the nucleophilicity, the electrophilicity, and the dielectric constant of the solvents. The dependency of the rate and the composition of the copolymer on the nucleophilicity and electrophilicity of the solvent increased with an increase in the dielectric constant of the solvent. On the basis of the kinetic study, the roles of the solvent in the copolymerization could be quantitatively explained.

In this paper, the effect of the binary solvent system on the copolymerization of the *N*-phenylethylenimine with β-propiolactone will be quantitatively investigated.

Experimental

Material. The methods of the purification of the materials were described in a previous paper.[1]

Copolymerization Procedure. Measured amounts of β-propiolactone (0.005 mol) and the binary solvents (total volume: 2 ml) were placed in a glass ampule under a nitrogen atmosphere, and then *N*-phenylethylenimine (0.005 mol) was added to this system at −78°C. After the ampule had been sealed and maintained at 0—1°C for a definite period of time, the solid products were washed with chloroform and diethyl ether, separated by a centrifuge, and dried *in vacuo*.

The method of the determination of the copolymer composition was described in a previous paper.[2]

Results and Discussion

The copolymerization of *N*-phenylethylenimine with β-propiolactone was carried out in the binary solvent system without the addition of any catalyst. Three binary solvent systems, each consisting of components with similar dielectric constants and very different nucleophilicities, were used, as is shown in Table 1.

The Effect of the Solvent on the Copolymerization Rate. The relations between the copolymerization rate and the mole fraction of the solvents are show in Fig. 1 (A, B, C). In the binary solvent system A, with the highest dielectric constant, the copolymerization rate in nitrobenzene was much larger than that in *N,N*-dimethylacetamide, and the rate was markedly depressed by the addition of small amounts of *N,N*-dimethylacetamide. According to

the mechanism postulated in the previous paper, that the competitive coordination of the nucleophilic solvent to the cationic growing end of the polymer depresses the reaction of the monomers, this fact indicates that *N, N*-dimethylacetamide, with a larger nucleophilicity, coordinates selectively to the cationic growing end of the polymer.

On the other hand, in the ethylene dichloride-tetrahydrofuran binary solvent system B, with a lower dielectric constant than A, the copolymerization rate decreased in proportion to the amount of tetrahydrofuran. In view of this fact, the coordination of the solvent to the cationic polymer end may be considered to increase proportionally with the amount of tetrahydrofuran. The effect of the nucleophilicity of the solvent on the copolymerization rate in A is larger than that in B. This finding is in accord with the finding that the dependency of the rate on the nucleophilicity of the solvent increased with the dielectric constant of the solvent.

In the binary solvent system C, consisting of components with low dielectric constants, the effect of the solvents on the copolymerization rate is small compared with that of the solvent with a high dielectric constant. This fact may lead to a consideration that the propagation mechanism in the solvent with a low dielectric constant differs from that in the solvents with high dielectric constants. It is considered that, in the solvent with a low dielectric constant, the propagation proceeds mainly by means of undissociated ions, whereas that in the solvents with high dielectric constants proceeds by means of dissociated ions, and that coordination of the solvent to the undissociated ions is small.

The Effect of the Solvent on the Copolymer Composition. The plots of the β-propiolactone content (mol%) in the copolymer (conversion 6.5—17.8%) against the mole fraction of the solvent are shown in Fig. 2. It may be seen that, in the solvents with high dielectric constants, A and B, the β-propiolactone content increased with an incerase in the amounts of nucleophilic solvents. Moreover, Fig. 2

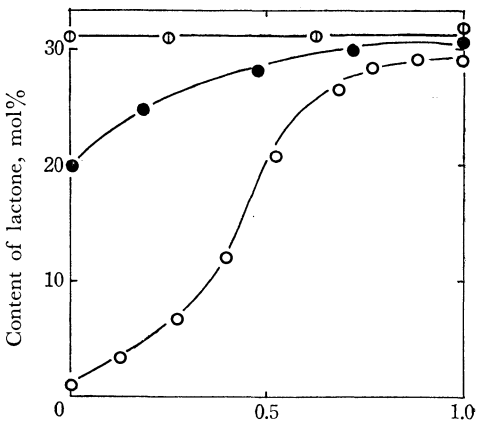

Fig. 2. Relations between contents of β-propiolactone and mole fraction of the solvent in the binary solvent systems.
○: (A) Nitrobenzene ↔ *N,N*-Dimethylacetamide

shows that the dependency of the copolymer composition on the nucleophilicity of the solvent in A is larger than that in B. In view of this fact and the results obtained previously, it may be considered that the degree of the effect of the nucleophilic solvent on the copolymer composition increases with the dielectric constant of the solvent. On the other hand, in the solvent with a low dielectric constant (the toluene - anisole system), the solvent has no effect on the copolymer composition.

The Effect of the Solvent on the Reaction Rates of Monomers. The reaction rates of the monomers were obtained from the copolymerization rate and the composition of the copolymer as shown in Fig. 1 and Fig. 2. The relations between the reaction rate of *N*-phenylethylenimine and the mole fraction of the solvent are shown in Fig. 3. In A, with the highest dielectric constant, the effect of the nucleophilic solvent on the reaction rate of *N*-phenylethylenimine is larger than that in the ethylene dichloride - tetrahydrofuran system.

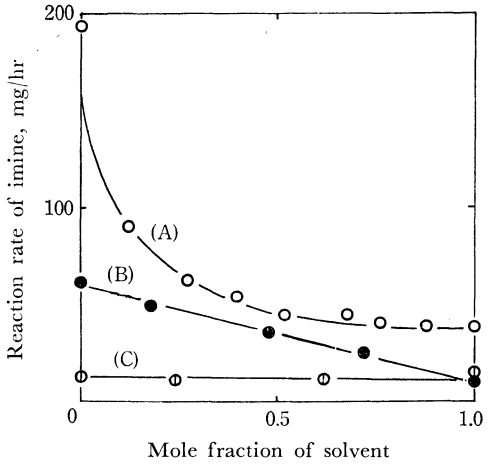

Fig. 3. Relations between reaction rate of *N*-phenylethylenimine and mole fraction of solvent in the binary solvent systems.
○: (A) Nitrobenzene ↔ *N*,*N*-Dimethylacetamide
●: (B) Ethylene dichloride ↔ Tetrahydrofuran
⦶: (C) Toluene ↔ Anisole
Abscissa is mole fraction of *N*,*N*-dimethylacetamide, tetrahydrofuran and anisole.

In C, with its low dielectric constant, the reaction rate of *N*-phenylethylenimine remains almost constant, independent of the mole fraction of the solvent. In comparison with Fig. 1, it is found that the relations of the apparent copolymerization rate and the reaction rate of *N*-phenylethylenimine to the mole fraction of the solvent resemble each other, whereas the plots of the reaction rate of *β*-propiolactone against the mole fraction (Fig. 4) differ, in Fig. 1 and Fig. 3. These facts may indicate that the copolymerization rate is much more affected by the reaction rate of *N*-phenylethylenimine with the propagating species than by that of *β*-propiolactone, considering that the reaction rate of *β*-propiolactone is very small. Therefore, it may be suggested that the propagating species consist mainly of immonium ions and a few oxonium ions.

The relations between the reaction rate of *β*-propiolactone and the mole fraction of the solvent are shown in Fig. 4. In A and B, the reaction rate of *β*-

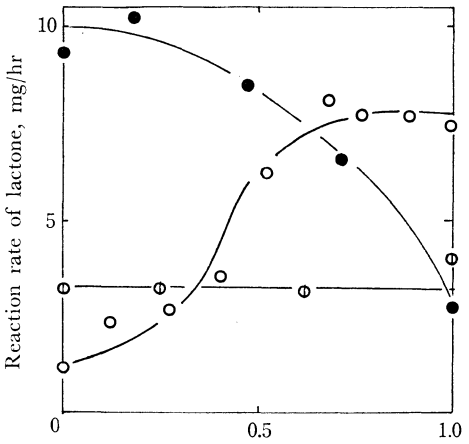

Fig. 4. Relations between reaction rate of *β*-propiolactone and mole fraction of solvents in the binary solvent systems.

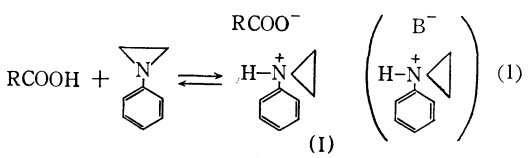
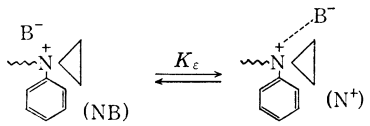
propiolactone decreases with an increases in the amounts of nitrobenzene and tetrahydrofuran respectively. Considering that, in a solvent with a high dielectric constant, the reaction of *β*-propiolactone is much depressed by the electrophilic solvent, as has been described in a previous paper, this fact may be due to the larger electrophilicities, of nitrobenzene and tetrahydrofuran than of *N*,*N*-dimethylacetamide and ethylene dichloride respectively. In the nonpolar solvent, C, there is no effect of the solvent on the reaction rate of *β*-propiolactone.

Mechanism of the Copolymerization. From these experimental facts, the following mechanism of the copolymerization was postulated:
Initiation

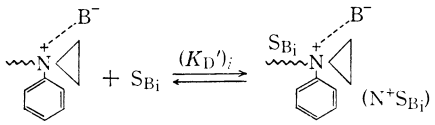


Propagation

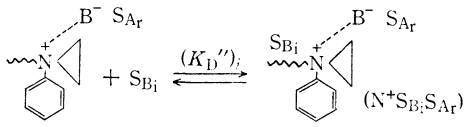


(2)

Nucleophilic solvation

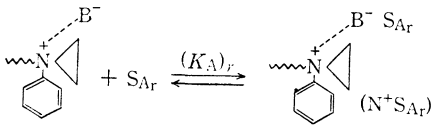


(3)

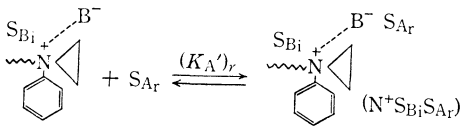


(4)

Electrophilic solvation



(5)



(6)

S_B; nucleophilic solvent, S_A; electrophilic solvent, i; 1, 2. r; 1, 2.

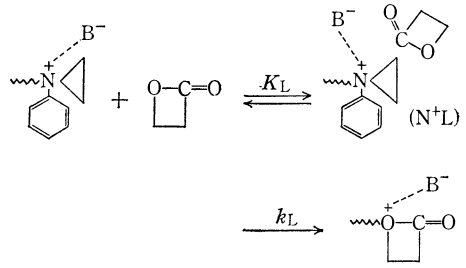
(9)

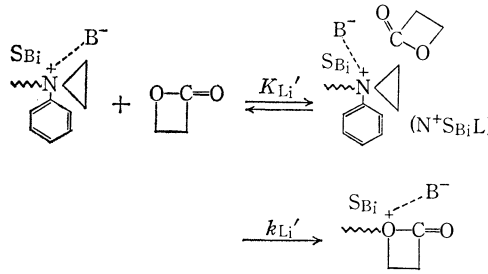
Reaction of β-propiolactone in propagation

Reaction with dissociated immonium ion;
Nonsolvated



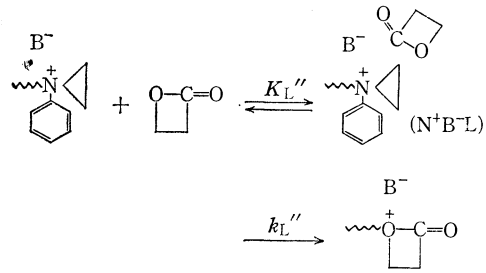
(10)

Solvated



(11)

Reaction with undissociated immonium ions;



(12)

The initiation reaction is considered to be the reaction of the acid present in β-propiolactone with *N*-phenylethylenimine to produce compound (I), as has been described in a previous paper. This compound dissociates partially to the immonium ion, and the reaction is in equilibrium. The equilibrium constant (K_ε) is considered to increase with an increase in the dielectric constant of the

solvent. Equations (3) and (4) show the nucleophilic solvation of the solvents to the immonium ion. Since the coordinations of the solvent to both the propagating species and methanol-d are nucleophilic reactions, the equilibrium constants (K_D' and K_D'') are considered to increase with an increase in the $\Delta\nu_{O-D}$ (or K_D) value.[3] Equations (5) and (6) show the electrophilic solvation of the solvent to the polymer end. Since the coordination of the solvent to both the counter-anion and acetophenone are electrophilic reactions, it seems reasonable to assume that K_A and K_A' are larger in the solvents with larger $\Delta\nu_{C=O}$ values.[3] On the other hand, on the basis of the fact that there is no effect on the propagation reaction in the solvents with low dielectric constants, it may be considered that the coordination of the solvent to the undissociated immonium ion is small.

In the propagation reaction, both immonium ions and oxonium ions are considered to react with the monomers by the same mechanism. Therefore, the propagation reactions of immonium ions with monomers are shown as an example. From the fact that, in the solvent with high dielectric constants, the reaction rate of *N*-phenylethylenimine was depressed with an increase in the nucleophilicity of the solvent, the reaction of *N*-phenylethylenimine is considered to occur by means of nonsolvated immonium ions, as is shown in Eqs. (7) and (8). Since, in the solvents with high dielectric constants, the reaction rate of β-propiolactone decreased with an increase in the electrophilicity of the solvent, the reaction of β-propiolactone may proceed by means of dissociated immonium ions whose counter ions are not solvated by the solvent, as is shown by Eqs. (10) and (11). On the other hand, the propagation can proceed in a solvents with a low dielectric constant; therefore, it is assumed to occur by means of the reaction of the undissociated immonium ions with monomers (Eqs. (9) and (12)).

Kinetics. On the basis of the mechanism postulated, the effects of the solvent on the copolymerization rate and the copolymer composition were quantitatively investigated. From the fact that the amount of β-propiolactone consumed is less than that of *N*-phenylethylenimine, the quantity of immonium ions is considered to be much larger than that of oxonium ions. Therefore, the concentration of compound I, $\alpha[C]_0$, may be approximately expressed by Eq. (13), where $[C]_0$ is the initial concentration of the catalyst and where α is the constant $(0<\alpha<1)$:

$$\alpha[C]_0 = [N^+] + [N^+B^-] + \sum_{i=1}^{2}[N^+S_{Bi}] + \sum_{r=1}^{2}[N^+S_{Ar}] + \sum_{i=1}^{2}\sum_{r=1}^{2}[N^+S_{Bi}S_{Ar}] + [N^+I] + [N^+L] + \sum_{r=1}^{2}[N^+IS_{Ar}] + \sum_{i=1}^{2}[N^+S_{Bi}L] + [N^+B^-I] + [N^+B^-L] \quad (13)$$

On the other hand, according to Eqs. (2), (3),⋯, (11) and (12), the equilibrium equations will be:

$$[N^+]/[N^+B^-] = K_\varepsilon \quad (14)$$

$$[N^+S_{Bi}]/([N^+][S_i]) = (K_D')_i \quad (15)$$

$$[N^+S_{Ar}]/([N^+][S_r]) = (K_A)_r \quad (16)$$

$$[N^+S_{Ar}S_{Bi}]/([N^+S_{Ar}][S_i]) = (K_D'')_i \quad (17)$$

$$[N^+S_{Ar}S_{Bi}]/([N^+S_{Bi}][S_r]) = (K_A')_r \quad (18)$$

$$[N^+I]/([N^+][I]) = K_I \quad (19)$$

$$[N^+L]/([N^+][L]) = K_L \quad (20)$$

$$[N^+IS_{Ar}]/([N^+S_{Ar}][I]) = (K_I')_r \quad (21)$$

$$[N^+S_{Bi}L]/([N^+S_{Bi}][L]) = (K_D')_i \quad (22)$$

$$[N^+B^-I]/([N^+B^-][I]) = K_I'' \quad (23)$$

$$[N^+B^-L]/([N^+B^-][L]) = K_L'' \quad (24)$$

where [I] and [L] are the concentrations of *N*-phenylethylenimine and β-propiolactone respectively. By combining Eqs. (13), (14),⋯, (23) and (24), the concentrations of N^+I, N^+L, N^+IS_{Ar}, N^+S_{Bi}, N^+B^-I, and N^+B^-L may be represented as in Eqs. (25), (26), (27), (28), (29), and (30) respectively:

$$[N^+I] = K_\varepsilon K_I\alpha[C]_0[I]/f(K,M,S) \quad (25)$$

$$[N^+L] = K_\varepsilon K_L\alpha[C]_0[L]/f(K,M,S) \quad (26)$$

$$[N^+IS_{Ar}] = K_\varepsilon(K_I')_r(K_A)_r\alpha[C]_0[I][S_r]/f(K,M,S) \quad (27)$$

$$[N^+S_{Bi}L] = K_\varepsilon(K_L')_i(K_D')_i\alpha[C]_0[L][S_i]/f(K,M,S) \quad (28)$$

$$[N^+B^-I] = K_I''\alpha[C]_0[I]/f(K,M,S) \quad (29)$$

$$[N^+B^-L] = K_L''\alpha[C]_0[L]/f(K,M,S) \quad (30)$$

where $f(K,M,S) = 1 + K_I''[I] + K_L''[L] + K_\varepsilon(1 + K_I[I] + K_L[L] + \sum_{i=1}^{2}(K_D')_i[S_i] + \sum_{r=1}^{2}(K_A)_r[S_r] + \sum_{r=1}^{2}\sum_{i=1}^{2}(K_D')_i(K_A')[S_i][S_r])$.

The reaction rates of *N*-phenylethylenimine and β-propiolactone are represented by Eqs. (31) and (32) respectively:

$$-d[I]/dt = k_I[N^+I] + \sum_{r=1}^{2}k_{Ir}'[N^+IS_{Ar}] + k_I''[N^+B^-I] \quad (31)$$

$$-d[L]/dt = k_L[N^+L] + \sum_{i=1}^{2}k_{Li}'[N^+S_{Bi}L] + k_L''[N^+B^-L] \quad (32)$$

By substituting Eqs. (25),⋯, (29) and (30) into Eqs. (31) and (32), Eqs. (33) and (34) are derived:

3) T. Kagiya, Y. Sumida and T. Inoue, This Bulletin, **41**, 767 (1968).

$$-\mathrm{d[I]}/\mathrm{d}t = (K_\varepsilon K_\mathrm{I} k_\mathrm{I} + K_\varepsilon \sum_{r=1}^{2} (K_\mathrm{I}')_r (K_\mathrm{A})_r k_{\mathrm{I}r}' [\mathrm{S}_r] + K_\mathrm{I}'' k_\mathrm{I}'') \alpha [\mathrm{C}]_0 [\mathrm{I}] / f(\mathrm{K,M,S}) \tag{33}$$

$$-\mathrm{d[L]}/\mathrm{d}t = (K_\varepsilon K_\mathrm{L} k_\mathrm{L} + K_\varepsilon \sum_{i=1}^{2} (K_\mathrm{L}')_i (K_\mathrm{D}')_i k_{\mathrm{L}i}' [\mathrm{S}_i] + K_\mathrm{L}'' k_\mathrm{L}) \alpha [\mathrm{C}]_0 [\mathrm{L}] / f(\mathrm{K,M,S}) \tag{34}$$

Since the propagation in the solvents with high dielectric constants is considered to occur mainly with the dissociated immonium ions, Eqs. (33) and (34) may be approximately expressed by Eqs. (35) and (36):

$$-\frac{\mathrm{d[I]}}{\mathrm{d}t} = \frac{K_\varepsilon (K_\mathrm{I} k_\mathrm{I} + \sum_{r=1}^{2} (K_\mathrm{I}')_r (K_\mathrm{A})_r k_{\mathrm{I}r}' [\mathrm{S}_r]) \alpha [\mathrm{C}]_0 [\mathrm{I}]}{\mathrm{C}_1 + K_\varepsilon (\mathrm{C}_2 + \sum_{i=1}^{2} (K_\mathrm{D}')_i [\mathrm{S}_i] + \sum_{r=1}^{2} (K_\mathrm{A})_r [\mathrm{S}_r] + \sum_{i=1}^{2} \sum_{r=1}^{2} (K_\mathrm{D}'')_i (K_\mathrm{A}')_r [\mathrm{S}_i][\mathrm{S}_r])} \tag{35}$$

$$-\frac{\mathrm{d[L]}}{\mathrm{d}t} = \frac{K_\varepsilon (K_\mathrm{L} k_\mathrm{L} + \sum_{i=1}^{2} (K_\mathrm{L}')_i (K_\mathrm{D}')_i k_{\mathrm{L}i}' [\mathrm{S}_i]) \alpha [\mathrm{C}]_0 [\mathrm{L}]}{C_1 + K_\varepsilon (C_2 + \sum_{i=1}^{2} (K_\mathrm{D}')_i [\mathrm{S}_i] + \sum_{r=1}^{2} (K_\mathrm{A})_r [\mathrm{S}_r] + \sum_{i=1}^{2} \sum_{r=1}^{2} (K_\mathrm{D}'')_i (K_\mathrm{A}')_r [\mathrm{S}_i][\mathrm{S}_r])} \tag{36}$$

where $C_1 = 1 + K_\mathrm{I}''[\mathrm{I}] + K_\mathrm{L}''[\mathrm{L}]$, $C_2 = 1 + K_\mathrm{I}[\mathrm{I}] + K_\mathrm{L}[\mathrm{L}]$.

Considering that the nucleophilic equilibrium constants of *N,N*-dimethylacetamide ($(K_\mathrm{D}')_\mathrm{DMA}$ and $(K_\mathrm{D}'')_\mathrm{DMA}$) are much larger than those of nitrobenzene ($(K_\mathrm{D}')_\mathrm{NB}$ and $(K_\mathrm{D}'')_\mathrm{NB}$), the following relationships may be obtained, even in the case of $[\mathrm{S}]_\mathrm{DMA} \gg [\mathrm{S}]_\mathrm{NB}$: $(K_\mathrm{D}')_\mathrm{DMA}[\mathrm{S}]_\mathrm{DMA} \gg (K_\mathrm{D}')_\mathrm{NB}[\mathrm{S}]_\mathrm{NB}$, $(K_\mathrm{D}'')_\mathrm{DMA}[\mathrm{S}]_\mathrm{DMA} \gg (K_\mathrm{D}'')_\mathrm{NB}[\mathrm{S}]_\mathrm{NB}$. Therefore, since the selective solvation of *N,N*-dimethylacetamide to the cationic end of the polymer brings on an increase in the terms containing K_D' and K_D'' in a denominator of Eq. (35), the reaction rate of *N*-phenylethylenimine may markedly decrease upon the addition of *N,N*-dimethylacetamide. On the other hand, in the ethylene dichloride - tetrahydrofuran system, considering that the equilibrium constants of tetrahydrofuran ($(K_\mathrm{D}')_\mathrm{THF}$ and $(K_\mathrm{D}'')_\mathrm{THF}$) are much larger than those of ethylene dichloride ($(K_\mathrm{D}')_\mathrm{EDC}$ and $(K_\mathrm{D}'')_\mathrm{EDC}$), the terms containing K_D' and K_D'' in a denominator of Eq. (35) may be approximately expressed by Eqs. (37) and (38):

$$\sum_{i=1}^{2} (K_\mathrm{D}')_i [\mathrm{S}_i] = (K_\mathrm{D}')_\mathrm{THF} [\mathrm{S}]_\mathrm{THF} \tag{37}$$

$$\sum_{i=1}^{2} \sum_{r=1}^{2} (K_\mathrm{D}'')_i (K_\mathrm{A})_r [\mathrm{S}_i][\mathrm{S}_r] = \sum_{r=1}^{2} (K_\mathrm{D}'')_\mathrm{THF} [\mathrm{S}]_\mathrm{THF} (K_\mathrm{A})_r [\mathrm{S}_r] \tag{38}$$

Equations (37) and (38) indicate that the terms containing $(K_\mathrm{D}')_\mathrm{THF}$ and $(K_\mathrm{D}'')_\mathrm{THF}$ increase in proportion to the amounts of tetrahydrofuran. Therefore, considering that these terms are larger than the other terms in the denominator of Eq. (35), the experimental finding that the reaction rate of *N*-phenylethylenimine decreased in proportion to the amount of tetrahydrofuran can be explained.

Equation (36) explains the fact that, in the solvents with high dielectric constants, the reaction rate of *β*-propiolactone decreased with an increase in the amounts of the electrophilic solvents, such as nitrobenzene and tetrahydrofuran.

On the other hand, in the solvents with low dielectric constants, the terms containing K_ε in Eqs. (33) and (34) are considered to be negligible. Therefore, the rate equations of monomers may be approximately expressed by Eqs. (39) and (40):

$$-\mathrm{d[I]}\mathrm{d}t = K_\mathrm{I}'' k_\mathrm{I}'' \alpha [\mathrm{C}]_0 [\mathrm{I}] \tag{39}$$

$$-\mathrm{d[L]}/\mathrm{d}t = K_\mathrm{L}'' k_\mathrm{L}'' \alpha [\mathrm{C}]_0 [\mathrm{L}] \tag{40}$$

According to Eqs. (39) and (40), we can explain the experimental finding that, in the solvent with low dielectric constants, the nucleophilicity and electrophilcity of the solvent has no effect on the reaction rates of the monomers.

Since the *N*-phenylethylenimine content is much larger than that of *β*-propiolactone in the solvents with high dielectric constants, the copolymerization rate may be almost equal to the reaction rate of *N*-phenylethylenimine. Therefore, the copolymerization rate (R_p) in the solvents with high dielectric constants will be:

$$R_p = \frac{K_\varepsilon (K_\mathrm{I} k_\mathrm{I} + \sum_{r=1}^{2} (K_\mathrm{I}')_r (K_\mathrm{A})_r k_{\mathrm{I}r}' [\mathrm{S}_r]) \alpha [\mathrm{C}]_0 [\mathrm{I}]}{C_1 + K_\varepsilon (C_2 + \sum_{i=1}^{2} (K_\mathrm{D}')_i [\mathrm{S}_i] + \sum_{r=1}^{2} (K_\mathrm{A})_r [\mathrm{S}_r] + \sum_{i=1}^{2} \sum_{r=1}^{2} (K_\mathrm{D}'')_i (K_\mathrm{A}')_r [\mathrm{S}_i][\mathrm{S}_r])} \tag{41}$$

Considering that $C_1 > C_2 + \sum_{i=1}^{2} (K_\mathrm{D}')_i [\mathrm{S}_i] + \sum_{r=1}^{2} (K_\mathrm{A})_r [\mathrm{S}_r] + \sum_{i=1}^{2} \sum_{r=1}^{2} (K_\mathrm{D}'')_i (K_\mathrm{A}')_r [\mathrm{S}_i][\mathrm{S}_r]$, Eq. (41) explains the following experimental facts: in the solvents with high dielectric constants, the copolymerization rate increased with the K_ε value, while in the solvents with similar dielectric constants, the rate decreased with an increase in the amounts of the nucleophilic solvents.

In the solvents with low dielectric constants, the β-propiolactone content in the copolymer is larger than in the solvents with high dielectric constants. Therefore, the copolymerization rate in a solvent with a low dielectric constant should be represented by the sum of Eqs. (39) and (40):

$$R_p = -\mathrm{d[I]}/\mathrm{d}t + -\mathrm{d[L]}/\mathrm{d}t$$
$$= (K_I''k_I''[\mathrm{I}] + K_L''k_L''[\mathrm{L}])\alpha[\mathrm{C}]_0 \quad (42)$$

This equation shows no effect of the solvents with low dielectric constants on the copolymerization rate.

The β-propiolactone content in the copolymer (C_L) is given by Eq. (43):

$$C_L = [\mathrm{Y}]_L/([\mathrm{Y}]_I + [\mathrm{Y}]_L) \quad (43)$$

where $[\mathrm{Y}]_I$ and $[\mathrm{Y}]_L$ are the amounts of *N*-phenylethylenimine and β-propiolactone respectively present in the copolymer. In the solvents with high dielectric constants, by considering the fact $[\mathrm{Y}]_I \gg [\mathrm{Y}]_L$, the β-propiolactone content may be approximately expressed by Eq. (44):

$$C_L \fallingdotseq [\mathrm{Y}]_L/[\mathrm{Y}]_I \quad (44)$$

By combining Eqs. (35), (36) and (44), and by assuming $[\mathrm{I}] \fallingdotseq [\mathrm{L}]$ in the early stages of the copolymerization, Eq. (45) is derived:

$$C_L \fallingdotseq \frac{K_L k_L + \sum_{i=1}^{2} (K_L')_i (K_D')_i k_{Li}'[\mathrm{S}_i]}{K_I k_I + \sum_{r=1}^{2} (K_I')_r (K_A)_r k_{Ir}'[\mathrm{S}_r]} \quad (45)$$

This approximate equation can explain the experimental fact that the β-propiolactone content increased with an increase in the amounts of the nucleophilic solvents. On the other hand, in the solvents with low dielectric constants, the β-propiolactone content can be approximately expressed by Eq. (46), which is derived from Eqs. (39), (40), and (43):

$$C_L = K_L''k_L''/(K_L''k_L'' + K_I''k_I'') \quad (46)$$

This equation (46) explains the fact that, in the solvents with low dielectric constants, the β-propiolactone content is almost constant, regardless of both the electric natures and the dielectric constants of the solvents.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 1640—1643 (1969)

Studies on Stable Free Radicals. II.*[1] Reactivity of Stable Nitroxide Radicals and NMR Spectra of Reaction Products

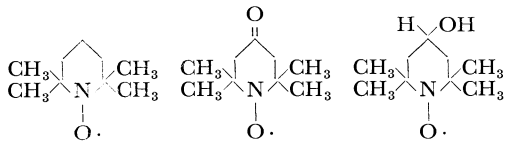
Keisuke MURAYAMA, Syoji MORIMURA and Takao YOSHIOKA

Central Research Laboratoies Sankyo Co., Ltd., Shinagawa-ku, Tokyo

(Received September 9, 1968)

We have isolated coupled products of such stable free radicals as 2,2,6,6-tetramethyl-4-oxopiperidine-1-oxyl (II), cyclohexane-1-spiro-2'-(4'-oxoimidazolidine-1'-oxyl)-5'-spiro-1''-cyclohexane (IV) and 2,2,6,6-tetramethyl-4-oxopiperidine-1-thiyl derived from bis-[2,2,6,6-tetramethyl-4-oxopiperidyl-(1)]disulfide (VII) with a *C*-radical derived from α,α'-azo-bis(isobutyronitrile). The reactive site in these stable free radicals was studied from the structure of the coupled products. The homolysis of the disulfide (VII) appeared to be accelerated by an attack of the *C*-radical, 1-methyl-1-cyanoethyl. The NMR spectra of the products suggested a slow inversion of the nitrogen atom in piperidine derivatives.

Extremely stable free radicals, such as 2,2,6,6-tetramethylpiperidine-1-oxyl (I), 2,2,6,6-tetramethyl-4-oxopiperidine-1-oxyl (II) and 2,2,6,6-tetramethyl-4-hydroxypiperidine-1-oxyl (III), have



(I) (II) (III)

recently been prepared[1] by the oxidation of corresponding hindered amines. These radicals, which are considered to exist in an *O*-radical form (A)

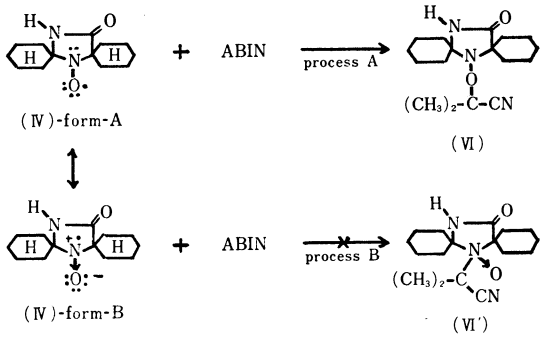
and/or another *N*-radical form (B),[2-4] can be preserved for long periods in air under normal conditions without undergoing any significant changes. It has further been found that these radicals were stable even under ionic reaction conditions.[2]

Reactions of the stable free radicals with *C*-radicals[5,6] have also been found; Neiman *et al.* deduced that the stable free radicals, I, II, and III, reacted only with an active *C*-radical (R·) derived from ethylbenzene,[5] while they did not react with a peroxy radical (ROO·). However, they did not isolate coupled products of the *C*-radical with the stable radicals. Therefore, the reactive site in the stable radicals has not been firmly established as being either an *O*-radical (A) or an *N*-radical (B). Depending upon the radical present either an N-O-R compound (C) (process A) or an *N*-oxide (D) (process B) would be expected when the radicals having Form A and Form B respectively are treated with a reactive radical, R·.

The present authors sought to confirm the reactive site of stable *N*-oxide radicals with another radical by isolating coupled products of the radicals with a typical *C*-radical derived from α,α'-azobisisobutyronitrile (ABIN). From the structure of these coupled products, we have then determined the reactive site in these radicals.

Results and Discussion

The reaction of II or a new stable free radical, cyclohexane-1-spiro-2'-(4'-oxoimidazolidine-1'-oxyl)-5'-spiro-1''-cyclohexane (IV) with ABIN, was carried out in a 2:1 molar ratio in a solution



of anhydrous methanol at 63°C for 30 hr. Subsequently the coupled reaction product, prepared from the 1-methyl-1-cyanoethyl radical (derived from ABIN) and a stable radical, II or IV, was obtained, accompanied by 2,3-dimethyl-2,3-dicyanobutane. As is shown below, the structures of these products were deduced to be 1-(1-methyl-1-cyanoethoxy)-2,2,6,6-tetramethyl-4-oxopiperidine (V) or 1-(1-methyl-1-cyanoethyl)-2,2,6,6-tetramethyl-4-oxopiperidine-1-oxide (V') and cyclohexane-1-spiro-2'-[1'-(1-methyl-1-cyanoethoxy)-4'-oxoimidazolidine]-5'-spiro-1''-cyclohexane (VI) or cyclohexane-1-spiro-2'-[1'-(1-methyl-1-cyanoethyl)-4'-imidazolidine-1'-oxide]-5'-spiro-1''-cyclohexane (VI') respectively, on the basis of the results of elemental analyses, the molecular weight measurements, and the molecular peaks in the mass spectra. The structures V' and VI' were, however, doubtful, since no deoxy products were obtained in the reactions of the above coupled products with triphenylphosphine (or triethylphosphite) in an acetic acid solution at 110°C for 5 hr.[7] Strong support

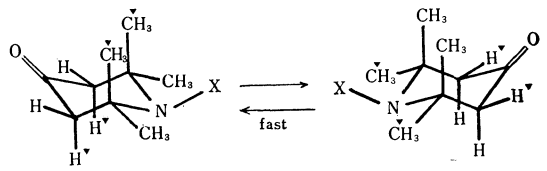
for the two molecular structures V and VI was given by the high-resolution double-focusing mass spectra. The expected molecular ion peaks at *m/e* 238.169 and 305.211, corresponding to $C_{13}H_{22}N_2O_2$ and $C_{17}H_{27}N_3O_2$ respectively, were found by the measurement of the millimass units. Since no fragment ion peak $(M-16)^+$ [8] or $(M-17)^+$ [9] was found, the V′ and VI′ structures were eliminated.

In order to investigate the behavior of stable free radicals other than *N*-oxyl radicals, a reaction of ABIN was carried out with a stable *N*-thiyl radical such as 2,2,6,6-tetramethyl-4-oxopiperidine-1- thiyl, which had been established by Bennett *et al.* using an ESR technique.[10] The precursor, bis-[2,2,6,6-tetramethyl-4-oxopiperidyl-(1)] disulfide (VII),[10] reacted with ABIN in a 1 : 2 molar ratio to give 1-(1-methyl-1-cyanoethylthio)-2,2,6,6-tetramethyl-4-oxopiperidine (VIII) in a benzene solution under gentle reflux for 7 hr. The product VIII could be characterized as the corresponding 2,4-dinitrophenylhydrazone and semicarbazone. The structure of VIII was deduced from the results of elemental analyses and the IR and NMR spectra, especially from the absence of the fragment ion peaks, $(M-32)^+$ and $(M-33)^+$.

This finding that the disulfide VII reacted with ABIN at 80°C to give VIII as the product in a good yield is instructive; over the limited range of 140—200°C, the homolytic fission of the S–S bond into the *N*-thiyl radical has been confirmed by ESR techniques,[10] while we observed no homolytic fission of the S–S bond at 80°C (ESR). Therefore, the homolytic cleavage of the disulfide bond appeared to be accelerated by the action of the 1-methyl-1-cyanoethyl radical at 80°C. Similar cleavages of various disulfides by the 1-methyl-1-cyanoethyl radical have been observed by Schmidt *et al.* when they examined the effect of substituents on the homolysis of the S–S bond.[11]

The NMR spectra of *N*-substituted 2,2,6,6-tetramethyl-4-oxopiperidines (V) and VIII showed interesting features. In the NMR spectra of 2,2,6,6-tetramethyl-4-oxopiperidine (IX),[12] 1,2,2,6,6-pentamethyl-4-oxopiperidine (X)[12] and 1-benzenesulfonyl-2,2,6,6-tetramethyl-4-oxopiperidine (XI),[13] the C-3 and C-5 methylene protons, and the



[X=-H,(IX), -CH_3 (X), -SO_2-⟨○⟩ (XI)][14]

C-2 and C-6 methyl protons have been found to give single sharp lines in a carbon tetrachloride and in a benzene solution. These facts suggest that the nitrogen inversion and/or the ring inversion is rapid at room temperature, as is shown above. It was, however, found that four methyl groups of *N*-substituted piperidines (V) and (VIII) (Fig. 1) gave rise to two sharp lines, indicative of two kinds of methyl protons. A_2B_2 quartets ($J_{gem}=13.5$ cps), indicative of two methylene protons, were further observed as well as in the case of 1-benzenesulfenyl-2,2,6,6-tetramethyl-4-oxopiperidines (XII).[13] Hence, the inversion rates of the nitrogen atom and of the piperi-

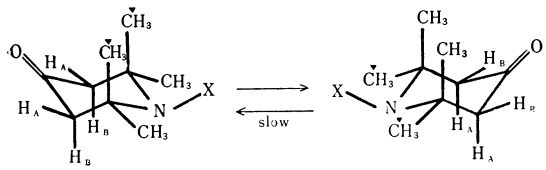
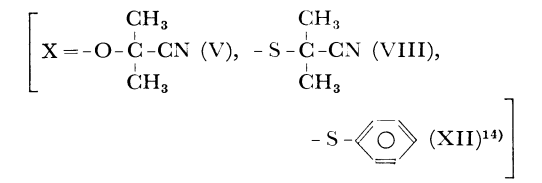
dine ring may be considered to be slower in V and VIII than in IX, X, and XI.





Thus, we confirmed that the *N*-oxyl and *N*-thiyl radicals could react with the *C*-radical derived from ABIN, and that the reaction apparently proceeded through process A, since no *N*-oxides V′ and VI′ were obtained even by careful separation techniques.

Experimental

All melting points are uncorrected.

The IR spectra were determined by means of Nujol mull and liquid films.

The NMR spectra were obtained using a Varian A-60 NMR spectrometer, using tetramethylsilane as the internal standard at 32°C.

The mass spectra were obtained using a JEOL-JMS-OIS mass spectrometer with an ionizing voltage of 70eV.

2,2,6,6-Tetramethyl-4-oxo-1-(1-methyl-1-cyanoethoxy)-piperidine (V). A mixture of 2,2,6,6-tetramethyl-4-oxopiperidine-1-oxyl (II) (11.7 g, 0.069 mol) and α,α'-azo-bis(isobutyronitrile)(ABIN) (5.0g, 0.0305 mol) was gently refluxed in a methanol solution for 30hr. After the solvent had then been evaporated under diminished pressure at 30°C, 2,3-dimethyl-2,3-dicyanobutane was excluded by sublimation under diminished pressure (0.060 mmHg) at 90°C. Then the oily residue was chromatographed on 100 g of Brockmann aluminum oxide and eluted with anhydrous petroleum ether to give 7.3 g (50.4 %)[14] of crude V. The crude crystals, V, were recrystallized from petroleum ether to give an analytically pure sample; mp 72.5—73.5°C.

Mass spectrum: M^+, *m/e* 238.169.

Cyclohexane-1-spiro-2′-(4′-oxoimidazolidine-1′-oxyl)-5′-spiro-1″-cyclohexane (IV). To a suspension of cyclohexane-1-spiro-2′-(4′-oxoimidazolidine)-5′-spiro-1″-cyclohexane[15] (corresponding amine) (22.2 g, 0.10 mol) in acetic acid (200 m*l*) were slowly added a solution of EDTA (0.5 g) and sodium tungstate (0.45 g) in water (3 m*l*) and then a 30 % aqueous solution of hydrogen peroxide (25 m*l*) with stirring at room temperature. Stirring was continued for an additional 50 hr at room temperature. After the solvent had been evaporated *in vacuo*, a 50 m*l* portion of water was added to the residue. The suspension of the crude product the (residue) was treated with potassium carbonate, and additional stirring was continued for 3 hr. The separated crystalline substance was filtered and washed with water. By recrystallization from benzene, IV was obtained as faintly reddish crystals, mp 227—228°C, in a good yield of 20.6 g (86.8%).

Found: C, 65.84; H, 8.93; N, 11.87%. Calcd for $C_{13}H_{21}N_2O_2$: C, 65.79; H, 8.92; N, 11.87%.

IR cm^{-1}: $\nu_{C=O}$ 1708; ν_{N-H} 3180 and 3070.

Cyclohexane-1-spiro-2′-[1′-(1-methyl-1-cyanoethoxy)-4′-oxoimidazolidine]-5′-spiro-1″-cyclohexane (VI). A mixture of cyclohexane-1-spiro-2′-(4′-oxoimidazolidine-1′-oxyl)-5′-spiro-1″-cyclohexane (IV) (10.0 g, 0.0422 mol) and ABIN (3.5 g, 0.0214 mol) was refluxed in a methanol solution. After 30hr, 10.3 g (79.8 %) of crude VI were separated out as crystals. These crystals were filtered and washed with ether. The crude material was recrystallized from glacial acetic acid to give an analytically pure sample; 7.8g, mp 190—191°C.

Found: C, 66.64; H, 8.99; N, 13.61%. Calcd for $C_{17}H_{27}N_3O_2$: C, 66.84; H, 8.91; N, 13.76%.

Anionic Copolymerization of Isoprene and 1,1-Diphenylethylene

Heimei YUKI and Yoshio OKAMOTO

Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka

(Received September 19, 1968)

Anionic copolymerization of isoprene (M_1) and 1,1-diphenylethylene (M_2) was carried out in tetrahydrofuran (THF), dioxane, benzene, and *n*-heptane by using *n*-butyllithium (*n*-BuLi), Na-naphthalene, Na- and K-dispersions as initiators. An alternating copolymer was obtained in the copolymerization in THF, which proceeded without a chain transfer and a termination. Monomer reactivity ratios, r_1, obtained by assuming the rate constant $k_{22}=0$, were 0.12 (Li^+), 0.11 (Na^+), and 0.11 (K^+) in THF at 0°C. The r_1 value in benzene at 40°C, however, was affected by the counter ion as follows: 37 (Li^+), 0.38 (Na^+), and 0.05 (K^+). With Li^+ counter ion the values were 0.50 in dioxane at 30°C and 29 in *n*-heptane at 40°C. The order of rate constants in the copolymerization in THF with *n*-BuLi at 0°C, was $k_{12}>k_{11}>k_{21}$, the last of which was 2.64×10^{-3} *l*/mol sec.

Among the anionic copolymerizations of the monomer pairs which copolymerize alternatingly,[1] the results of detailed studies were reported previously on the copolymerizations of 1,1-diphenylethylene and styrene,[2] of 1,1-diphenylethylene and 2,3-dimethylbutadiene,[3] and of *trans*-stilbene and styrene.[4]

In the present study, the copolymerization of isoprene (M_1) and 1,1-diphenylethylene (M_2) will be investigated under various reaction conditions. The results will be correlated with those of the copolymerization reported previously.

Experimental

Materials. *Isoprene.* The purified monomer (Phillips polymerization grade) was redistilled *in vacuo* from lithium aluminum hydride before use.

1,1-Diphenylethylene. This was first stirred with Na-K alloy under dry nitrogen, and then *n*-butyllithium (*n*-BuLi) in heptane was added to the mixture until a red color due to 1,1-diphenylhexyllithium appeared. The colored solution was carefully distilled *in vacuo* to obtain the pure monomer.

Tetrahydrofuran (THF) and Dioxane. Each of these solvents was refluxed over metallic sodium and then over lithium aluminum hydride, from where it was distilled onto Na-K alloy and naphthalene. From the green solution the solvent was transferred to a reaction vessel on a vacuum system before use.

Benzene and n-Heptane. Each of these solvents purified in the usual manner was distilled under high vacuum in the presence of *n*-BuLi.

n-BuLi. *n*-BuLi was prepared in *n*-heptane and the concentration was determined by double titration.[5]

Na-Naphthalene (Na-Naph.). The concentration of the solution was determined by the titration of a sample solution after hydrolysis by water.[6]

n-Butyl Alcohol. A small amount of metallic sodium was added to the alcohol (spectro grade). The alcohol containing sodium butoxide was then distilled under high vacuum to prepare a standard *n*-butyl alcohol solution in *n*-heptane. The solution was used for the colorimetric titration of a carbanion solution.

Polymerization. The polymerization was carried out in a glass ampoule under dry argon. To the ampoule, isoprene and a solvent were distilled by means of a vacuum line, and then 1,1-diphenylethylene and an initiator were added with hypodermic syringes. The polymerization was terminated after the manner of titration with the *n*-butyl alcohol solution in *n*-heptane to estimate the concentration of living ends.

Electronic Spectrum. The electronic spectrum of a reaction mixture was measured with a Hitachi 124 Spectrophotometer. The sample solution was prepared in a high vacuum system.

NMR Spectrum. The spectrum of the polymer was taken in a carbon tetrachloride solution with a JNM-4H-100 Spectrometer (Japan Electron Optics Laboratory Co., Ltd.) at 60°C.

Molecular Weight. The molecular weight of the polymer was measured on a Mechrolab Vapor Pressure Osmometer, Model 301A, using benzene as a solvent.

Viscosity. The solution viscosity of the polymer in toluene was measured at 30.0°C.

Results

The copolymerization of isoprene (M_1) and 1,1-diphenylethylene (M_2) in THF at 0°C was carried out with *n*-BuLi as an initiator, the initial molar ratio of monomers, $[M_1]_0/[M_2]_0$, being 0.650. The results are shown in Fig. 1. The reaction

proceeded so slowly that it took 80 hr to be completed, when unchanged 1,1-diphenylethylene remained in the system, but isoprene was completely consumed. Since 1,1-diphenylethylene can not be homopolymerized, the yield of the copolymer is maximum when the two monomers copolymerize alternatingly, if $[M_1]_0/[M_2]_0<1$. In Fig. 1, the yield against the theoretical amount of the alternating copolymer is also shown. It reaches 100%, indicating the formation of the alternating copolymer in the system. It was observed that the concentration of the living ends titrated by *n*-butyl alcohol was constant regardless of the reaction time and was nearly equal to the concentration of the initiator used.

The relationship between the polymer yield (curve B in Fig. 1) and the polymer molecular weight is shown in Fig. 2. A linear relationship was found between the two and the line almost agreed with the theoretical line for the living polymer produced by alternating copolymerization. There was also a linearity between log Yield and log [η].

The material balance after the prolonged copolymerization reaction was examined. A part of the results is listed in Table 1. As isoprene was com-

pletely incorporated into the copolymer, the copolymer composition, $[m_1]/[m_2]$, was calculated from the polymer yield and the initial monomer concentrations.[3,4] The $[m_1]/[m_2]$ ratio in the copolymer obtained in THF slightly exceeded unity with increasing the $[M_1]_0/[M_2]_0$ ratio from 0.6 to 0.9. The alternating copolymer was powder. On the other hand, the copolymer obtained in benzene was viscous and contained a great deal of isoprene, even at $[M_1]_0/[M_2]_0=0.6$.

The copolymer composition was also examined by other methods as shown in Table 2. The elementary analyses of the copolymer are well consistent with the calculations based on the copolymer compositions derived from the polymer yields. The copolymer compositions obtained from the ratios of aromatic to aliphatic protons in their NMR spectra are also in accord with the above compositions within analytical errors.

The monomer reactivity ratio, r_1, was obtained from the integrated Mayo-Lewis copolymer composition equation, assuming $k_{22}=0$.[2] The r_1 values thus obtained are listed in Tables 3—5. In the copolymerizations in THF at 0°C using *n*-BuLi, Na-naphthalene, and K-dispersion as initiators, the r_1 values were almost constant (0.11—0.12). In benzene at 40°C, however, the values were 37, 0.38, and 0.05 with *n*-BuLi, Na-dispersion, and K-dispersion respectively. With *n*-BuLi in dioxane at 30°C and in *n*-heptane at 40°C, the values were 0.50 and 29 respectively. The r_1 value at 25°C in THF seemed to be smaller than that at 0°C. The copolymerization carried out in benzene without an initiator gave no polymer even after 216 hr at 40°C

(Table 5), suggesting that no polymerization occurred by free radical mechanism under the reaction conditions employed.

The NMR spectrum of the alternating copolymer obtained with *n*-BuLi in THF is shown in Fig. 3. The homopolymerization of isoprene by *n*-BuLi in the same solvent yielded a polymer with 29% 1,2-, 71% 3,4- and ~0% 1,4-structures. The analysis was done with NMR spectrum according to the method of Chen.[7] The alternating copolymer showed no peak in its NMR spectrum at the same position as that of the polyisoprene. On the other hand, in the IR spectrum of the copolymer, an absorption due to the vinyl group was found at 910 cm^{-1}, but very weak suggesting that there was little 1,2-structure in the copolymer. Therefore, assuming that the isoprene was incorporated in the copolymer through 3,4- and 1,4-additions, the ratio of 3,4- to 1,4-addition was 17:83, on the basis of the NMR spectrum.

At $[M_1]_0/[M_2]_0=0.650$, the copolymerization by *n*-BuLi carried out in THF at 0°C was followed spectrophotometrically. As soon as *n*-BuLi was added, the reaction mixture showed an absorption maximum at 496 mμ due to the diphenylethylene anion; its optical density had been constant during 150 hr at least. The molar extinction coefficient*1 was 1.7×10^4, which agrees closely with 1.8×10^4 of 1,1-diphenylhexyllithium anion.[8] These results apparently indicate that the most of the living ends present in the system were 1,1-diphenylethylene anion.

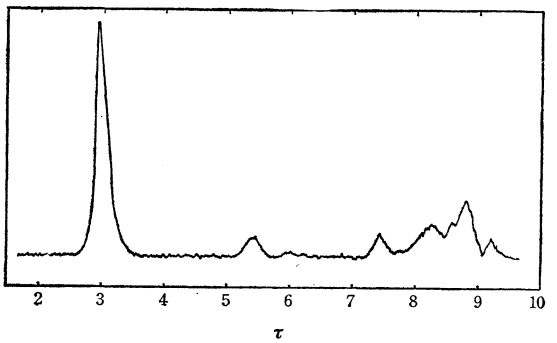

Fig. 3. NMR spectrum of the alternating copolymer of isoprene and 1,1-diphenylethylene in carbon tetrachloride at 60°C.

Discussion

The copolymerization of isoprene (M_1) and 1,1-diphenylethylene (M_2) initiated by *n*-BuLi in THF under a condition of $[M_1]_0/[M_2]_0<1$ proceeded without a termination and a chain transfer to give an alternating copolymer. Among the rate constants of the propagation reactions, k_{22} must be zero and k_{12} must be greater than k_{11} in such a copolymerization reaction.

$$\sim\sim M_1^- + M_1 \xrightarrow{k_{11}} \sim\sim M_1^- \quad (1)$$

$$\sim\sim M_1^- + M_2 \xrightarrow{k_{12}} \sim\sim M_2^- \quad (2)$$

$$\sim\sim M_2^- + M_1 \xrightarrow{k_{21}} \sim\sim M_1^- \quad (3)$$

*1 Calculated for the initiator concentration assuming the living polymer system.

7) H. Y. Chen, *Anal. Chem.*, **34**, 1793 (1962).

8) R. Waack and M. A. Doran, *J. Am. Chem. Soc.*, **85**, 1651 (1963).

$$\sim\sim M_2^- + M_2 \xrightarrow{k_{22}} \sim\sim M_2^- \quad (4)$$

The sum of the concentrations of the living ends, $[M_1^-]+[M_2^-]$, should be equal to that of the initiator, $[C]_0$.

$$[M_1^-] + [M_2^-] = [C]_0 \quad (5)$$

In Eq. (5), $[M_1^-]$ is negligible because the anion existing in the system was mostly M_2^-, which must be far more stable than the M_1 anion owing to the conjugation with its two benzene rings. So we can assume $k_{12} \gg k_{21}$ and get[3]

$$-\frac{d[M_1]}{dt} = k_{21}[C]_0[M_1] \quad (6)$$

The equation shows that process (3) is the rate determining step in the copolymerization.

Recently, Ureta *et al.*[9] have reported the anionic copolymerization of styrene (M_1) and 1,1-diphenylethylene (M_2), in which they found that process (3) was a reversible reaction as follows:

$$\sim\sim M_2^- + M_1 \underset{k_{-21}}{\overset{k_{21}}{\rightleftarrows}} \sim\sim M_2M_1^- \quad (7)$$

If so in the present copolymerization, Eq. (6) must be rewritten as

$$-\frac{d[M_1]}{dt} = k_{21}[M_2^-][M_1] \times \frac{k_{12}[M_2]}{k_{-21}+k_{12}[M_2]} \quad (8)$$

The analysis of the results in Fig. 1 gave a linear relationship between log $[M_1]$ and t as is shown in Fig. 4, indicating that the rate of the consumption of isoprene is first order with respect to its own concentration as represented by Eq. (6). Consequently, there must be $k_{12}[M_2] \gg k_{-21}$ in Eq. (8) and the reversible reaction (7) may be neglected. From Fig. 4, we can get $k_{21}=2.64\times10^{-3}$ *l*/mol sec in THF at 0°C. Taking into account the difference of the reaction temperature, the above value seems to be greater than $k_{21}=1.3$—1.8×10^{-3} *l*/mol sec found in the copolymerization of 2,3-dimethylbutadiene (M_1) and 1,1-diphenylethylene (M_2) by means of *n*-BuLi at 22°C. The values indicate that isoprene is sterically and electronically more reactive than 2,3-dimethylbutadiene because the latter has one more methyl group.

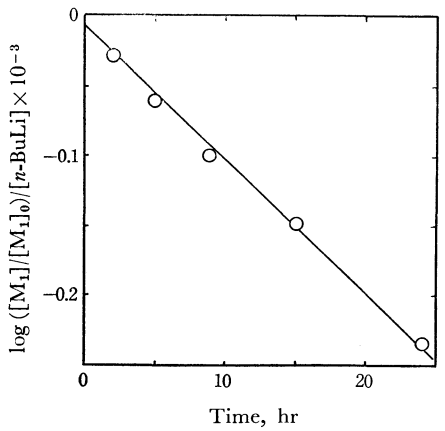

Fig. 4. Anionic copolymerization of isoprene (M_1) and 1,1-diphenylethylene (M_2).—First order plot
$[M_1]_0$: 6.48 mmol, $[M_2]_0$: 9.97 mmol,
[*n*-BuLi]: 0.107 mmol, THF: 15.0 m*l*,
temp.: 0°C.

The monomer reactivity ratios, r_1, obtained in the copolymerizations of 1,1-diphenylethylene (M_2) with three comonomers (M_1) by *n*-BuLi are summarized in Table 6. 1,1-Diphenylethylene was always more reactive to the M_1 anion than the corresponding M_1 monomer in THF. In benzene, 1,1-diphenylethylene was more reactive when the comonomer was styrene or 2,3-dimethylbutadiene, while less reactive when isoprene was the comonomer. In the copolymerization of isoprene and 1,1-diphenylethylene with *n*-BuLi, the monomer reactivity ratio was strongly influenced by the solvent (Table 5). The r_1 value in hydrocarbon solvent was larger than unity, while in dioxane and THF, the value approached zero with the increasing polarity of the solvent. No effect of the initiator on the r_1 value was observed in the copolymerization in THF, but in benzene the value varied in the order of $Li^+ \gg Na^+ > K^+$. When the counter ion was either Na^+ or K^+, a small influence of the solvent was observed on the r_1 value. These tendencies suggest that the r_1 value may decrease with an increase in the ionic character of the carbon - metal bond. Similar results have been reported in the anionic copolymerizations of butadiene and styrene,[10] and of isoprene and styrene.[11] The high reactivity of the dienes observed in these copolymerizations was explained by preferential absorption of the dienes at the active center.*2 Such an absorption may be excluded for 2,3-dimethylbutadiene because of its steric hindrance.

*2 Worsfold denied the above explanation from the result of the kinetic study of the copolymerization of styrene and isoprene. D. J. Worsfold, *J. Polymer Sci. A-1*, **5**, 2783 (1967).

It is well known that $NaB(Ph)_4$ depresses the dissociation of an ion pair to free ions in the anionic polymerization of styrene.[12] The presence of $NaB(Ph)_4$ of the present copolymerization with Na^+ counter ion in THF had no influence on the r_1 value as is shown in Table 3. The fact demonstrates that, if the copolymerization may involve two kinds of propagating species, a free ion and an ion pair, the r_1 values for these two species will be very similar.

The alternating copolymer consisted of isoprene unit having 83% of 1,4-structure, in comparison with ~0% in the polyisoprene polymerized under the same conditions. In the copolymerization isoprene adds to the bulky 1,1-diphenylethylene anion at the sterically less hindered 4-position, and then the resulting isoprenyl anion adds to 1,1-diphenylethylene at the less hindered 1-position than the 3-position. A similar result was observed in the alternating copolymer of 2,3-dimethylbutadiene and 1,1-diphenylethylene,[3] in which the microstructure of 2,3-dimethylbutadiene was only 1,4 addition. A small portion of the 3,4-addition appeared in the copolymer of isoprene and 1,1-diphenylethylene may be attributed to the less steric hindrance than that of 2,3-dimethylbutadiene.

(Received September 26, 1968)

By using the method of Allan-Robinson's flavone synthesis, the condensation of 3,ω-dimethoxy-2,4,6-trihydroxyacetophenone with 3,4-dibenzyloxybenzoic anhydride gave a mixture of 3,6- and 3,8-dimethoxy-3',4'-dibenzyloxy-5,7-dihydroxyflavone (X and XI). The catalytic debenzylation of the above flavones then gave axillarin (I) and 3,8-dimethoxy-5,7,3',4'-tetrahydroxyflavone (IV) respectively. Axillarin 7-*O*-methyl ether(III) was prepared by the partial methylation of X, followed by catalytic debenzylation.

Axillarin (quercetagetin 3,6-dimethyl ether) was first isolated from the leaves of cocklebur (*Xanthium pensylvanicum*)[1] and later from the flowers and leaves of *Iva axillaris* Pursh. ssp. *robustor*.[2] Its structure was identified as 3,6-dimethoxy-5,7,3',4'-tetrahydroxyflavone (I) (quercetagetin type) on the basis of spectral data[1] and by a comparison of the tetraethyl ether (II) of I with a synthetic sample.[2] 5,3',4'-Trihydroxy-3,6,7-trimethoxyflavone (III) (7-*O*-methyl ether of I) was also isolated from the leaves of *Cyanostegia microphylla*.[3] On the other hand, 3,8-dimethoxy-5,7,3',4'-tetrahydroxyflavone (IV) (gossypetin type), an isomer of I, was isolated from *Ricinocarpus muricatus* Muell. Arg.[4] Recently, a synthesis of IV starting from 4-benzyloxy-2-hydroxy-3,6,ω-trimethoxyacetophenone (V) has been reported.[5]

In previous papers,[6,7] the authors reported the

By using the method of Allan-Robinson's flavone synthesis, the reaction of the ketone VIII with 3,4-dibenzyloxybenzoic anhydride and potassium 3,4-dibenzyloxybenzoate, followed by treatment with alcoholic potassium hydroxide, yielded a mixture of flavones. The mixture was then acetylated without further purification. After repeated recrystallizations of the acetylated product from methanol, 5,7-diacetoxy-3',4'-dibenzyloxy-3,6-dimethoxyflavone (IX), $C_{35}H_{30}O_{10}$, mp 135—136.5°C, was obtained as colorless needles. The NMR spectrum*3 of IX showed a singlet at δ 7.19 (1H) which could be attributed to the C-8 proton (not the C-6 proton) on the basis of a comparison with the spectra data of some of the flavones reported on in the literature (Table 1).[4,8] The treatment of IX with dilute alkali gave 3',4'-dibenzyloxy-5,7-dihydroxy-3,6-dimethoxyflavone (X), mp 147.5—148.5°C. From the mother-liquor of the recrystallization of IX, 3',4'-dibenzyloxy-5,7-dihydroxy-3,8-dimethoxyflavone (XI), mp 180—181.5°C (from ethyl acetate), was obtained after treatment with aqueous potassium hydroxide.

The catalytic debenzylation of X gave the desired flavone I, which was shown to be identical with natural axillarin*4 by a mixed-melting-point determination and by a comparison of their ultraviolet spectra. Moreover, the IR-spectra of natural quercetagetin 3,6-dimethyl ether,*5 natural axillarin,*4 and the synthetic axillarin were superimposable upon one another. I was also obtained from IX by debenzylation and subsequent hydrolysis.

The synthetic axillarin (I) was converted to tetraacetate XII and tetraethyl ether II by the usual methods. The tetraethyl ether II was also synthesized by the Allan-Robinson reaction of

*4 The natural axillarin and its tetraethyl ether were kindly supplied by Professor W. Herz, Florida State University.

*5 The IR-spectrum of natural quercetagetin 3,6-dimethyl ether was kindly supplied by Dr. E. Wong, Plant Chemistry Division, Department of Science and Industrial Research, New Zealand.

4,6-diethoxy-5,ω-dimethoxy-2-hydroxyacetophenone (XIII)[6] with 3,4-diethoxybenzoic anhydride.

The partial methylation of X gave 3',4'-dibenzyloxy-5-hydroxy-3,6,7-trimethoxyflavone (XIV). The debenzylation of XIV yielded axillarin 7-*O*-methyl ether (III). Its triacetate (XV) was prepared by acetylation. The properties of these compounds were identical with those described by Ghisalberti *et al.*[3]

On the other hand, the debenzylation of XI afforded a tetrahydroxyflavone (IV) whose identity with the natural substance*[6] was confirmed by a mixed-melting-point determination and by a comparison of their ultraviolet spectra. Its tetraacetate (XVI) and tetraethyl ether (XVII) were prepared by the usual methods. The NMR spectra of these compounds (XVI and XVII) show one proton signal corresponding to the C-6 proton at δ 6.81 and 6.47 respectively; these values are in accordance with those observed for the triacetate (XVIII) and triethyl ether (XIX) of VII.[3,7]

Experimental*[7]

3,6-Dimethoxy- (X) and 3,8-dimethoxy-3',4'-dibenzyloxy-5,7-dihydroxyflavone (XI). A mixture of the ketone (VIII)[6] (3.1 g), 3,4-dibenzyloxybenzoic anhydride (29 g), and potassium 3,4-dibenzyloxybenzoate (13 g) was heated at 170°C for 5 hr and then at 180°C for 8 hr under reduced pressure. The reaction mixture was then cooled and refluxed for 20 min with a solution of potassium hydroxide (15 g) in aqueous ethanol (80%; 350 m*l*). After the evaporation of the solvent under a vacuum, the residue was dissolved in water and saturated with carbon dioxide. The resulting precipitate was extracted with ethyl acetate. The extract was washed with water, dried, and evaporated to 25 m*l*. The separating crystals (3,4-dibenzyloxybenzoic acid) were then filtered off and washed with ethyl acetate. The combined filtrate was evaporated, and the residue was recrystallized from methanol to give a crude flavone mixture (about 4.7 g).

A mixture of the crude flavones, acetic anhydride (12 g), and pyridine (1.0 m*l*) was heated at 120°C for 2 hr and then poured into water. The resulting mixture was extracted with ether, and the extract was washed with dilute hydrochloric acid and a dilute sodium carbonate solution and then allowed to stand in a refrigerator for one day. The separating crystals were collected and recrystallized from methanol and then ethanol to give 5,7-diacetoxy-3',4'-dibenzyloxy-3,6-dimethoxyflavone (IX) in the form of colorless needles, mp 135—136.5°C; yield, 2.13 g (26% from VIII). IR: 1764, 1641, 1609, 1601 cm^{-1}. UV: λ_{max}^{EtOH} mμ (log ε); 252 (4.32), 350 (4.21).

Found: C, 69.08; H, 4.80%. Calcd for $C_{35}H_{30}O_{10}$: C, 68.84; H, 4.95%.

A solution of IX (1.47 g) in ethanol (200 m*l*) was gently refluxed with aqueous potassium hydroxide (10%; 10 m*l*) for 3 min. The resulting solution was acidified with dilute hydrochloric acid, and the solvent was evaporated under a vacuum. The resulting precipitate was collected and recrystallized from methanol to give X in the form of pale yellow needles, mp 147.5—148.5°C; yield, 1.2 g (95%). It gave a green color with an alcoholic ferric chloride solution. IR: 3430, 1653, 1613, 1593 cm^{-1}. UV: λ_{max} mμ (log ε); (EtOH) 255 (4.27), 273 (4.23), 347 (4.35); (EtOH-AcONa) 276 (4.36), 322 (4.38), 364 (4.23); (EtOH-EtONa) 277 (4.47), 298 (4.18), 312 (4.18), 384 (4.27); (EtOH-$AlCl_3$) 262, 285, 368.

Found: C, 70.66; H, 4.76%. Calcd for $C_{31}H_{26}O_8$: C, 70.71; H, 4.98%.

The concentration of the methanolic filtrate which was obtained in the case of recrystallization of IX, followed by hydrolysis with aqueous potassium hydroxide (a 2% potassium hydroxide solution (25 m*l*) and methanol (75 m*l*)), yielded yellow crystals. On repeated crystallizations from ethyl acetate, XI was obtained in the form of yellow needles, mp 180—181.5°C; yield, 1.32 g (18% from VIII). It gave a green color with an alcoholic ferric chloride solution. IR: 3155 (broad), 1653, 1604, 1592, 1577 cm^{-1}. UV: λ_{max} mμ (log ε); (EtOH) 258 (4.28), 277 (4.32), 339 (4.21), 355 (4.20); (EtOH-AcONa) 257.5 (4.04), 284 (4.38), 320 (4.18), 366 (4.08); (EtOH-NaOEt) 233 (4.21), 286.5 (4.40), 316 (4.11), 390 (3.98); (EtOH-$AlCl_3$) 263, 287, 306i,*[8] 360, 420.

Found: C, 70.99; H, 4.97%. Calcd for $C_{31}H_{26}O_8$: C, 70.71; H, 4.98%.

Axillarin (3,6-Dimethoxy-5,7,3',4'-tetrahydroxyflavone) (I). *a) From the dihydroxyflavone X.* A mixture of X (560 mg) and Pd-C (5%; 1.0 g) in methanol-ethyl acetate (2:1; 150 m*l*) was shaken in an atmosphere of hydrogen until 2.1 mol of hydrogen had been absorbed. After the catalyst had been filtered, the filtrate was evaporated under a vacuum; the residue was recrystallized from acetonitrile to give I in the form of yellow needles, mp 207—208°C (192—193°C sinter); yield 292 mg (80%). It gave a green color with an alcoholic ferric chloride solution.

Found: C, 56.11; H, 4.26%. Calcd for $C_{17}H_{14}O_8 \cdot H_2O$: C, 56.04; H, 4.43%.

After drying at 120—130°C/0.2 mmHg for 3 hr, this substance had a mp of 207—208°C or 217—218°C (207—209°C sinter). It was identified with natural axillarin by a mixed-melting-point determination and by a comparison of their infrared and ultraviolet sepctra. IR: 3380, 3130, 1652, 1602 cm^{-1}. UV: λ_{max} mμ (log ε); (EtOH) 259 (4.25), 295 (3.91), 358 (4.32); (EtOH-AcONa) 272 (4.27), 300 (3.95), 367 (4.24); (EtOH-EtONa) 273 (4.32), 410 (4.35); (EtOH-$AlCl_3$) 278, 410. Natural axillarin:*[4] mp 207.5—209°C. IR: 3390, 3130, 1653, 1604 cm^{-1}. UV: λ_{max} mμ (log ε); (EtOH) 259 (4.26), 296 (3.92), 355 (4.33); (EtOH-AcONa) 273 (4.27), 299 (3.94), 369 (4.25). b) From the diacetoxyflavone IX. A mixture of IX (450 mg), Pd-C (5%: 1.0 g), and methanol - ethyl acetate (2 : 1 : 150 m*l*) was treated by a method similar to that used for a). Then, the crude product was hydrolyzed with 20% sulfuric acid (5 m*l*) in methanol (25 m*l*) for 2 hr. After the addition of water (10 m*l*), the solvent was evaporated under a vacuum. The resulting precipitate was recrystallized from acetonitrile, mp 207—208°C (192—193°C sinter); yield, 180 mg (71%). It was identical with the sample described in a).

Axillarin Tetraethyl Ether (3,6-Dimethoxy-5,7,3',4'-tetraethoxyflavone) (II). *a) From Axillarin (I).* A mixture of synthetic axillarin (I) (80 mg), anhydrous potassium carbonate (2.0 g), and diethyl sulfate (1.0 m*l*) in dry acetone (20 m*l*) was refluxed for 24 hr, and then the reaction mixture was treated in the usual manner. Recrystallization from *n*-hexane give II in the form of colorless needles, mp 99.5—100.5°C; yield, 100 mg (89%). After drying at 80°C/0.1 mmHg for 1 hr, it had a mp of 110—111.5°C. It was identified with natural axillarin tetraethyl ether by a mixed-melting-point determination and by a comparison of their ultraviolet spectra. IR: 1641, 1623, 1607 cm^{-1}. UV: λ_{max}^{EtOH} mμ (log ε); 240 (4.31), 335 (4.36). Natural one:*4 mp 109.5—111°C. UV: λ_{max}^{EtOH} mμ (log ε); 240 (4.29), 335 (4.33). (lit mp 109°C,[2] mp 108—110 °C[2]).

Found: C, 65.25; H, 6.56%. Calcd for $C_{25}H_{30}O_8$: C, 65.49; H, 6.60%.

b) From the ketone XIII. A mixture of XIII[6] (1.0 g), 3,4-diethoxybenzoic anhydride (3.0 g), and potassium 3,4-diethoxybenzoate (1.0 g) was treated by a method similar to that used for X and XI. The crude product was recrystallized from *n*-hexane to give II, mp 99.5—100.5°C (after drying; mp 110—111.5°C; yield, 200 mg (13%). It was identical with the sample described in a).

Found: C, 65.30; H, 6.61%. Calcd for $C_{25}H_{30}O_8$: C, 65.49; H, 6.60%.

3',4'-Dibenzyloxy -5- hydroxy - 3,6,7 - trimethoxyflavone (XIV). To a solution of X (400 mg) in ethyl acetate (30 m*l*), an ethereal diazomethane solution was added; then the solution was allowed to stand in a refrigerator for 24 hr. After the evaporation of the solvent, the residue was recrystallized from ethanol to give XIV in the form of pale yellow needles, mp 151.5—153°C; yield, 380 mg (93%). It gave a green color with an alcoholic ferric chloride solution. IR: 1652, 1640, 1615, 1599 cm^{-1}. UV: λ_{max} mμ (log ε); (EtOH) 239 (4.28), 256 (4.31), 274 (4.26), 345 (4.39); (EtOH-$AlCl_3$) 265, 286, 366.

Found: C, 70.78; H, 5.25%. Calcd for $C_{32}H_{28}O_8$: C, 71.10; H, 5.22%.

Axillarin 7-*O*-Methyl Ether (3',4',5-Trihydroxy-3,6,7-trimethoxyflavone) (III). A mixture of XIV (300 mg), Pd-C (5%; 450 mg), and methanol - ethyl acetate (1:1; 150 m*l*) was treated by a method similar to that used for I. The crude product was recrystallized from methanol to give III in the form of pale yellow prisms, mp 237—238°C; yield, 160 mg (80%). It gave a green color with an alcoholic ferric chloride solution. IR: 3380, 1651, 1603, 1593 cm^{-1}. UV: λ_{max} mμ (log ε); (EtOH) 260 (4.32), 356 (4.37); (EtOH-$AlCl_3$) 279, 415. (lit[3] mp 235—236°C. UV: λ_{max}^{EtOH} mμ (log ε); 271 (4.29), 360 (4.31)).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 1653—1659 (1969)

Reactions of α-Cyano-β-methoxy-β-alkylacrylic Esters with Hydrazine and Hydroxylamine

Hideo BABA, Isaburo HORI, Toshio HAYASHI and Hiroshi MIDORIKAWA

The Institute of the Physical and Chemical Research, Yamato-machi, Saitama

(Received September 27, 1968)

α-Cyano-β-methoxy-β-alkyl (Me, Et, *n*-Pr, *n*-Bu, *n*-Am, and *i*-Bu)-acrylic esters (I) react with hydrazine to give β-hydrazino intermediates. The hydrazino group of these intermediates is cyclized preferentially between its terminal NH_2 and the cyano group in a neutral or acidic medium to give 5-aminopyrazole derivatives, and preferentially between the terminal NH_2 and the ester group in the presence of a base to give 5-pyrazolone derivatives. When the β-alkyl of I is isopropyl, *t*-butyl, *etc.*, I affords only the 5-pyrazolone derivatives in the reaction with hydrazine. The reactions of I with hydroxylamine gave 5-aminoisoxazole derivatives, but in the case of the β-*t*-butyl derivative of I they gave 5-aminoisoxazole accompanied by the 5-isoxazolone derivative.

It has recently been found that the alkoxyl group of α-cyano-β-methoxycrotonic esters is easily displaced with such simple amines as ammonia, alkylamine, and benzylamine to give α-cyano-β-aminocrotonic esters, which exist in the enamine form, with an intramolecular hydrogen-bond between the amino and the ester carbonyl group.[1)]

The reaction has now been extended to use with hydrazine and hydroxylamine as the amine in view of the formation of two possible cyclized compounds, as is illustrated in Charts 1 and 2.

Both geometric isomers of methyl α-cyano-β-methoxycrotonate (Ia) reacted rapidly with one mole of hydrazine hydrate in water at room temperature to form the same methyl α-cyano-β-hydrazinocrotonate (IIa) in a 90% yield. Similarly, from Ib—g the corresponding intermediates (IIb—g) were obtained.

The cyclization of II took place preferentially

between the hydrazino and the cyano group to afford only the corresponding 3-alkyl-4-alkoxycarbonyl-5-aminopyrazole (III) in a neutral or acidic medium. That is, II cyclized to III slowly when left standing at room temperature for prolonged periods, when heated over the melting point, when refluxed in ethanol - water (4:1), or immediately after being dissolved in 15% hydrochloric acid. However, in the presence of a base such as hydrazine, ammonia or potassium carbonate, II cyclized preferentially between the hydrazino and the ester group to give only the corresponding 3-alkyl-4-cyano-5-pyrazolone (Va—f), while II was recovered in abundance.

V was also isolated along with a large amount of II when I was reacted with an excess of hydrazine. That this reaction perhaps proceeds through II can be seen by the experimental results shown in Table 1. Namely, the variations in the amounts of IIb and Va with the variety of the reaction time in Reactions (1) and (2) were approximately equal. Furthermore, this result indicetes that the cyclization of II to V is significantly slower than the formation of II from I.

Table 1. The results of the reactions of Ib or IIb with hydrazine by varing the reaction time

(1) Ib + 2 NH_2NH_2 —
(2) IIb + NH_2NH_2 — → IIb + Va

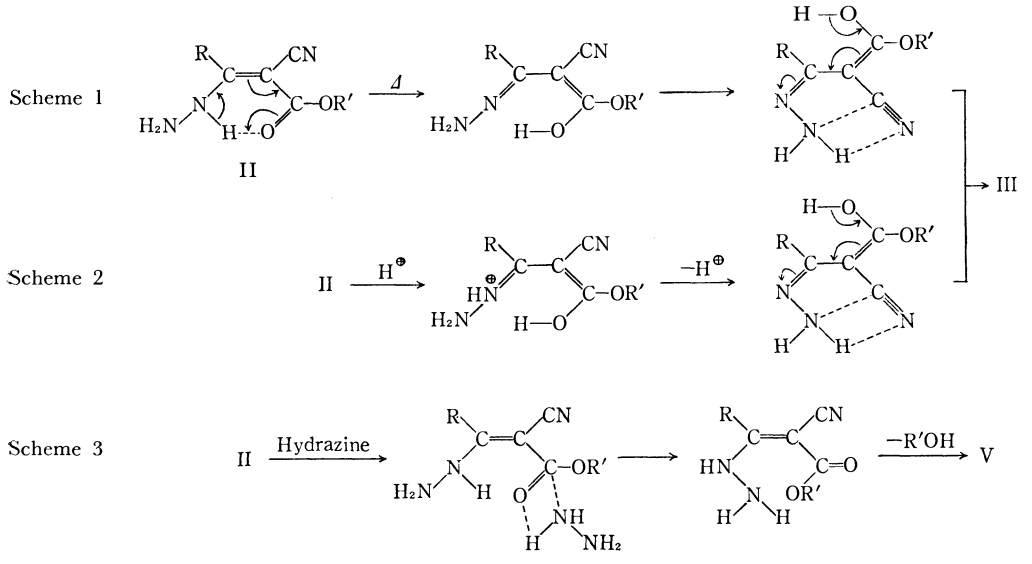
1	79	9.7	78	8.3
2	72	13.9	73	12.5
5	50	26.4	56	26.4

The infrared spectra of II exhibited an intense cyano band due to conjugation with an unsaturated bond in the 2198—2210 cm^{-1} region similar to that of β-aminoacrylonitriles.[2] The NMR spectra of II and ethyl α-cyano-β-(2,2-dimethylhydrazino)-crotonate (VI) prepared from Ib and 1,1-dimethylhydrazine indicated broad signals in the highly deshielded region (10.63—10.79 ppm). These signals were assigned to the NH proton hydrogen-bonded with the ester carbonyl group, much as with the simple β-amino derivatives described in a previous report.[1] Therefore, these spectral observations reveal that II has a hydrazino-ethylene structure rather than a tautomeric hydrazone structure; moreover, there is a *cis*-relation between the hydrazino and the ester group. Consequently, the following courses (Schema 1—3) for the cyclizations of II to III and V are possible.

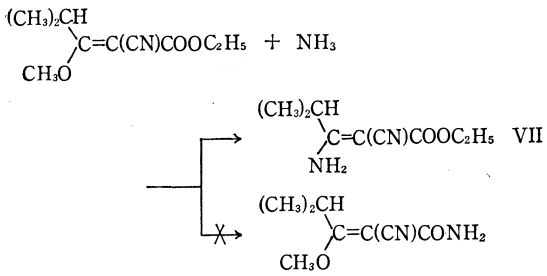
On the other hand, I with a bulky β-alkyl group such as isopropyl or *t*-butyl, or with a β-aryl group instead of β-alkyl, on a similar reaction with one mole of hydrazine hydrate, gave merely the corresponding 3-alkyl(aryl)-4-cyano-5-pyrazolone (Vg—i) as the cyclized product, plus a fairly large amount of the unchanged material (I); no open-chain intermediate was isolated. In order to obtain a high yield of V, an excessive use of hydrazine was necessary because hydrazine was consumed to form its salt of the acidic V. For example, one hour's treatment of I (R = *i*-Pr, R' = Me) with one mole of hydrazine gave 41.4% of the pyrazolone (Vg), whereas a similar treatment with two moles of hydrazine gave almost a two-fold yield. In these reactions, the formation of Vg—i was distinctly faster than that of Va from Ib or IIb, as is shown in Table



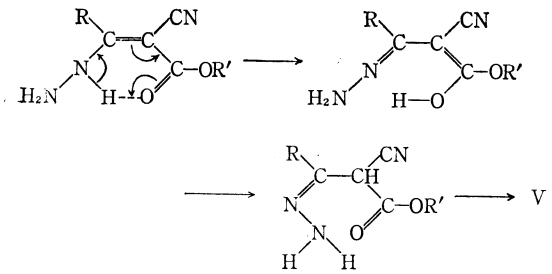
2) F. Scotti and E. J. Frazza, *J. Org. Chem.*, **29**, 1800 (1964).

1, although this primary nucleophilic attack by hydrazine on the β-carbon atom was expected to be probably more restricted by the steric hindrance than that in the case of I (R=*n*-alkyl and *i*-Bu).

It is evident that no hydrazine attaches to the ester group of I to form the acid hydrazide, for the reaction of I (R=*i*-Pr, R'=Et) with ammonia gave only the normal enamine (VII) instead of the acid amide expected.



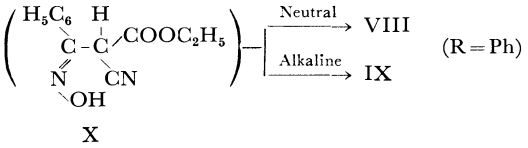
For the intermediate (II) in the formation of Vg—i, a strong steric compression is expected between the bulky β-alkyl (or aryl) and the hydrazino group on the β-carbon atom. Presumably the bulky alkyl groups push against the ester guoup to strengthen the hydrogen-bonding between the hydrazino and the ester group and follow the cyclization between them, as is illustrated below:



(R=*i*-Pr, *t*-Bu, Ph)

On the other hand, under conditions similar to those in the reaction with hydrazine, the starting materials (I, except for R=*t*-Bu) and hydroxylamine reacted readily to give only the 3-alkyl(aryl)-4-alkoxycarbonyl-5-aminoisoxazoles (VIII) in better yields. I (R=*t*-Bu) afforded approximately equivalent amounts of 5-aminoisoxazole (VIIIi) and 3-*t*-butyl-4-cyano-5-isoxazolone (IX) in poor total yields. However, in all cases, no open-chain intermediate was isolated.

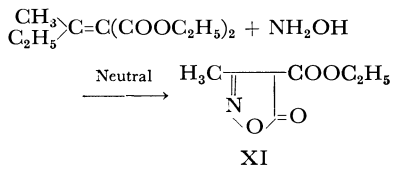
Dornow and Teckenburg[3] have reported that I (R=Ph, R'=Et) reacted with hydroxylamine to form the 5-aminoisoxazole (VIIIj) in a neutral medium and the 5-isoxazolone (IX, R=Ph) in an alkaline medium, presumably by means of the cyclization of the intermediate α-cyano-β-oximino ester (X).



(R=Ph)

X

However, the similar reaction of diethyl 1-ethoxyethylidenemalonate with hydroxylamine in a neutral medium easily gave the cyclized product, 3-methyl-4-ethoxycarbonyl-5-isoxazolone (XI), no intermediate being isolated. Therefore, if the reaction



XI

reported proceeds *via* the β-oximino ester (X), the VIII yielded in the neutral medium will be contaminated by the IX cyclized on the ester group. Furthermore, ethyl α-cyano-β-methoxy-aminocrotonate (XII), which can not be cyclized, was prepared from the reaction of Ib with *O*-methylhydroxylamine. The broad NH signal in the highly deshielded region (11.64 ppm) observed

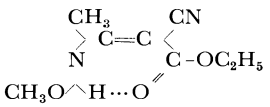
in its NMR spectrum showed that it has the structure of the enamine with hydrogen-bonding:



XII

From these observations, it seems likely that the formations of VIII and IX proceed *via* the β-hydroxyamino analog (II′) of II and follow the mode of the cyclization represented in Schema 1 and 3 respectively.

Experimental[4)]

Materials. Methyl α-cyano-β-methoxy-β-alkylacrylates (Id—g, Table 3) were synthesized, by the use of a method described in a previous paper[5)], from the corresponding acylcyanoacetic esters (Table 2), which had themselves been prepared from a modification of the Hori and Midorikawa method[6)] using acid chloride instead of acid anhydride.

The Reaction of Ia—g with Hydrazine (The Formation of II). To a solution of 80% hydrazine hydrate (5 mmol) in water (4 ml), there was added I (5 mmol) all at once; the mixture was then stirred at room temperature for 15—30 min. The resulting precipitate was collected by filtration, washed with a small quantity of ice water, and recrystallized from methanol (IIa and IIb), ethanol (IIe and IIg, or benzene (IIc, IId, and IIf).

In the reaction of both Ia and Ic, two geometric isomers[5)] were used as the starting material, but both the isomers gave the same product (IIa and IIc, respectively) in approximately equal yields. Therefore, only a stable isomer or an equilibrium mixture was used as the starting material (I) in all the reactions to be described below.

Methyl α-cyano-β-hydrazinocrotonate (IIa): colorless needles, mp 133—134°C, yield 90% from either of the geometric isomers. IR (νcm^{-1}): 2198 (νC≡N), 1667 (νC=O). NMR: 10.68 (NH).

Found: C, 46.75; H, 5.57; N, 26.84%. Calcd for $C_6H_9O_2N_3$: C, 46.44; H, 5.58; N, 27.08%.

Ethyl α-cyano-β-hydrazinocrotonate (IIb): colorless plates, mp 116—117°C, yield 90.5%. IR (cm^{-1}): 2201 (νC≡N), 1664 (νC=O). NMR: 10.73 (NH).

Found: C, 50.09; H, 6.44; N, 24.54%. Calcd for $C_7H_{11}O_2N_3$: C, 49.69; H, 6.55; N, 24.84%.

Methyl α-cyano-β-hydrazino-β-ethylacrylate (IIc): colorless needles, mp 100—101°C, yields 86% from a stable isomer, and 85% from a labile isomer. IR(cm^{-1}): 2208 (νC≡N), 1664 (νC=O). NMR: 10.63(NH).

Found: C, 49.49; H, 6.68; N, 24.49%. Calcd for $C_7H_{11}O_2N_3$: C, 49.69; H, 6.55; N, 24.84%.

Methyl α-cyano-β-hydrazino-β-*n*-propylacrylate (IId)-colorless needles, mp 114.5—115.5°C, yield 83%. IR (cm^{-1}): 2198 (νC≡N), 1667 (νC=O). NMR: 10.70(NH).

Found: C, 52.74; H, 7.15; N, 22.85%. Calcd for $C_8H_{13}O_2N_3$: C, 52.44; H, 7.15; N, 22.94%.

Methyl α-cyano-β-hydrazino-β-*n*-butylacrylate (IIe): colorless prisms, mp 109—110°C, yield 90%. IR (cm^{-1}): 2208(νC≡N), 1664 (νC=O). NMR: 10.68 (NH).

Found: C, 54.97; H, 7.43; N, 21.49%. Calcd for $C_9H_{15}O_2N_3$: C, 54.80; H, 7.67; N, 21.31%.

4) All melting points and boiling points were uncorrected. The infrared absorption spectra were measured with a Shimadzu Model IR-27A infrared spectrophotometer in Nujol solid state. The NMR spectra were recorded with a JNM-C-60 high-resolution NMR spectrometer operating at 60 Mc. The chemical shift values for imino group of IIa—g, VI and XII were reported in ppm downfield from tetramethylsilane as an internal standard, in deuteriochloroform (carbon tetrachloride for VI) as solvent.

Methyl α-cyano-β-hydrazino-β-*n*-amylacrylate (IIf): colorless plates, mp 117—118°C, yield 85.3%. IR (cm^{-1}): 2208 (νC≡N), 1664 (νC=O). NMR: 10.74 (NH).

Found: C, 57.15; H, 7.19; N, 19.85%. Calcd for $C_{10}H_{17}O_2N_3$: C, 56.85; H, 8.11; N, 19.89%.

Methyl α-cyano-β-hydrazino-β-isobutylacrylate (IIg): colorless needles, mp 97—98°C, yield 86.8%. IR (cm^{-1}): 2210 (νC≡N), 1667 (νC=O). NMR: 10.79 (NH).

Found: C, 55.13; H, 7.59; N, 21.63%. Calcd for $C_9H_{15}O_2N_3$: C, 54.80; H, 7.67; N, 21.31%.

The Formation of 3-Alkyl-4-alkoxycarbonyl-5-aminopyrazoles (III) from II. (i) The foregoing β-hydrazino compound (IIa, IIb, or IIc) was heated to 130—140°C for 3 hr. After cooling, the resinous product was triturated in ether to give a precipitate. Recrystallization from benzene afforded IIIa and IIIb in yields of over 80%.

(ii) A mixture of II (6 mmol) and ethanol (4 m*l*) containing water (1 m*l*) was refluxed for 4—8 hr on a steam bath. The resulting clear solution was evaporated under reduced pressure. The resinous residue was cooled in an ice-box for 2—3 days; the crystallization was induced by scratching the inside wall of the vessel with a glass rod. It was purified by recrystallization from benzene to obtain III in yields of 75—90%.

(iii) To a suspended mixture of 2 mmol of the β-hydrazino compound (IIa, IIb, or IIc) in water (4 m*l*) there was added 15% hydrochloric acid (2 m*l*); the mixture was then warmed on a steam bath until it became a clear solution. After cooling to room temperature, the mixture was neutralized with an aqueous potassium carbonate solution. The crystalline substance thus formed was recrystallized from benzene, affording III in yields over 75.5%.

The same product (IIIa, IIIb, or IIIc) was obtained from all three reactions. For the formation of IIId—g only the method (ii) was used; IIId was obtained as a hydrate. Also, IIIg afforded a benzene-addition product (determined by a study of the IR and the NMR spectra). The benzene-free product of IIIg was obtained by triturating it with ether instead of by recrystallization from benzene. IIIb and IIIc easily took the water of crystallization when they were allowed to stand in moist air or were recrystallized from water. These crystal waters (IIIb, IIIc, and the forgoing IIId) were driven off by heating the substances under reduced pressure or by leaving them standing in a desiccator ($CaCl_2$).

3-Methyl-4-methoxycarbonyl-5-aminopyrazole (IIIa): colorless microcrystals, mp 145—146.5°C.

Found: C, 46.83; H, 5.43; N, 27.36%. Calcd for $C_6H_9O_2N_3$: C, 46.44; H, 5.85; N, 27.08%.

3-Methyl-4-ethoxycarbonyl-5-aminopyrazole (IIIb): colorless prisms, mp 109—110°C (lit[7] 113°C).

Found: C, 49.83; H, 6.48; N, 25.07%. Calcd for $C_7H_{11}O_2N_3$: C, 49.69; H, 6.55; N, 24.84%.

Hydrate: colorless needles (from water), mp 66—67°C (lit[7] 69°C).

Found: C, 44.77; H, 7.01; N, 22.63%. Calcd for $C_7H_{11}O_2N_3 \cdot H_2O$: C, 44.91; H, 7.00; N, 22.45%.

3-Ethyl-4-methoxycarbonyl-5-aminopyrazole (IIIc): colorless needles, mp 102—103°C.

Found: C, 49.94; H, 6.37; N, 24.34%. Calcd for $C_7H_{11}O_2N_3$: C, 49.69; H, 6.55; N, 24.84%.

Hydrate: colorless needles (from water), mp 81—82°C.

Found: C, 47.24; H, 6.64; N, 23.38%. Calcd for $C_7H_{11}O_2N_3 \cdot \frac{1}{2}H_2O$: C, 47.18; H, 6.79; N, 23.58%.

3-*n*-Propyl-4-methoxycarbonyl-5-aminopyrazole(IIId): colorless prisms, mp 80—81°C

Found: C, 52.70; H, 6.80; N, 23.61%. Calcd for $C_8H_{13}O_2N_3$: C, 52.44; H, 7.15; N, 22.94%.

Hydrate: colorless needles (from water) or colorless prisms (from benzene), mp 70—71°C.

Found: C, 50.22; H, 7.12; N, 22. 20%. Calcd for $C_8H_{13}O_2N_3 \cdot \frac{1}{2}H_2O$: C, 49.99; H, 7.34; N, 21.86%.

3-*n*-Butyl-4-methoxycarbonyl-5-aminopyrazole(IIIe): colorless capillaries, mp 72—73°C.

Found: C, 54.88; H, 7.59; N, 21. 71%. Calcd for $C_9H_{15}O_2N_3$: C, 54.80; H, 7.67; N, 21.31%.

3-*n*-Amyl-4-methoxycarbonyl-5-amipopyrazole(IIIf): colorless capillaries, mp 73—74°C.

Found: C, 56.58; H, 7.84; N, 19.88%. Calcd for $C_{10}H_{17}O_2N_3$: C, 56.85; H, 8.11; N, 19.89%.

3-Isobutyl-4-methoxycarbonyl-5-aminopyrazole(IIIg): colorless microcrystals, mp 104—106°C.

Found: C, 55.27; H, 7.57; N, 21.25%. Calcd for $C_9H_{15}O_2N_3$: C, 54.80; H, 7.67; N, 21.31%.

Benzene-addition compound: colorless microcrystals, mp 109—110°C. IR (cm^{-1}): 684 (benzene, -CH, out of plane). NMR: 7.36 (benzene).

Found: C, 59.17; H, 7.32; N, 19.07%. Calcd for $C_9H_{15}O_2N_3 \cdot \frac{1}{3}C_6H_6$: C, 59.17; H, 7.68; N, 18.82%.

The formation of III was proved by the absence of the cyano group in the infrared spectra and by the reaction to be described below.

The Hydrolysis of IIIa or IIIb. A mixture of IIIa or IIIb (3 mmol) and 4N sodium hydroxide (6 m*l*) was gently refluxed for 2 hr. After this mixture had been cooled, the resulting clear solution was adjusted to pH 5 with hydrochloric acid under cooling in ice water. The crystals which separated were collected and washed with water and ethanol.

3-Methyl-5-aminopyrazole-4-carboxylic acid (IV): colorless needles, mp 124—125°C, yields 87—95%.

Found: C, 42.76; H, 4.90; N, 29.71%. Calcd for $C_5H_7O_2N_3$: C, 42.55; H, 5.00; N, 29.78%.

Both IIIa and IIIb gave the same product.

The Decarboxylation of IV. A mixture of 2.5 g of the foregoing carboxylic acid (IV) in water (20 m*l*) was boiled for 2 hr, and then the solvent was evaporated under reduced pressure. In order to remove a trace of water, benzene (3 m*l*) was added to it and again evaporated. The distillation of the residue gave 1.5 g (87.5%) of a fraction distilling at 146.5—147°C/4 mmHg; it became a crystalline mass on cooling.

3-Methyl-5-aminopyrazole: hygroscopic colorless needles, mp 47—48°C (lit 47°C,[8] 94°C[9]).

Found: C,48.61; H, 7.15; N, 40.71%. Calcd for $C_4H_7N_3$: C, 49.46; H, 7.27; N, 43.27%.

Picrate: yellow needles, mp 206—207°C (lit 213—214°C,[7] 205—209°C[9]).

Found: C, 36.79; H, 2.81; N, 25.79%. Calcd for $C_{10}H_{10}O_7N_6$: C, 36.81; H, 3.09; N, 25.76%.

The Formation of 3-Alkyl-4-cyano-5-pyrazolones (V). A. By the Base Treatment of II. (i) A suspension of powdered IIa—g (6 mmol) and 80% hydrazine hydrate (6 mmol) in water (8 m*l*) was stirred at room temperature for 1 hr. The reaction mixture was filtered to give a large amount of unchanged material (the melting point was not depressed on admixture with II). After the filtrate had been acidified with hydrochloric acid, the resulting precipitate was collected by filtration, washed with a small amount of ice water, and recrystallized from water to give Va—f.

Both IIa and IIb gave the same product (Va); the yields were 6.3% and 8.3% respectively. Vb was obtained in a yield of 12.8%. The results of this reaction (for IIb) obtained by varying the reaction period are shown in Table 1 (Reaction 2). In the case of IId—g, the reaction period was extended to 5 hr, giving the corresponding yields of 50% (Vc), 6.06% (Vd), 20% (Ve), and 78.2% (Vf).

(ii) To a solution of 28% ammonia water (3 m*l*) and water (3 m*l*), 3.3 mmol of powdered IIa or IIb were added; the mixture was then stirred at room temperature for 4 hr. Filtration gave the unchanged material. The filtrate was worked up as before to afford Va in a yield of 76%.

(iii) A mixture of IIa or IIb (0.2 g) and a 10% aqueous potassium carbonate solution (4 m*l*) was stirred at room temperature for 1 hr. After the resulting clear solution had been acidified with hydrochloric acid, the separated crystals were purified as before to obtain 43.6—50% of Va.

In the reaction of IIa and IIb, the same product (as shown by the melting point and the infrared spectrum) was obtained from all three reactions (A(i)—(iii)).

3-Methyl-4-cyano-5-pyrazolone (Va): colorless prisms, mp 275—277°C (dec). IR (cm^{-1}): 2242 ($\nu C{\equiv}N$).

Found: C, 48.68; H, 4.30; N, 34.08%. Calcd for $C_5H_5ON_3$: C, 48.78; H, 4.09; N, 34.14%.

3-Ethyl-4-cyano-5-pyrazolone (Vb): colorless prisms, mp 232—234°C. IR (cm^{-1}): 2242 ($\nu C{\equiv}N$).

Found: C, 52.63; H, 4.93; N, 30.70%. Calcd for $C_6H_7ON_3$: C, 52.54; H, 5.15; N, 30.64%.

3-*n*-Propyl-4-cyano-5-pyrazolone (Vc): colorless plates, mp 215—216°C. IR (cm^{-1}): 2232 ($\nu C{\equiv}N$).

Found: C, 55.87; H, 6.30; N, 28.05%. Calcd for $C_7H_9ON_3$: C, 55.61; H, 6.00; N, 27.80%.

3-*n*-Butyl-4-cyano-5-pyrazolone (Vd): colorless plates, mp 174—175°C. IR (cm^{-1}): 2237 ($\nu C{\equiv}N$).

Found: C, 58.28; H, 6.54; N, 25.64%. Calcd for $C_8H_{11}ON_3$: C, 58.16; H, 6.71; N, 25.44%.

3-*n*-Amyl-4-cyano-5-pyrazolone (Ve): colorless plates, mp 168—169°C. IR (cm^{-1}): 2237 ($\nu C{\equiv}N$).

Found: C, 60.45; H, 7.40; N, 23.23%. Calcd for $C_9H_{13}ON_3$: C, 60.31; H, 7.31; N, 23.45%.

3-Isobutyl-4-cyano-5-pyrazolone (Vf): colorless plates, mp 220—221°C. IR (cm^{-1}): 2232 ($\nu C{\equiv}N$).

Found: C, 58.09; H, 6.31; N, 25.92%. Calcd for $C_8H_{11}ON_3$: C, 58.16; H, 6.71; N, 25.44%.

B. By the Reaction of Ia and Ib with an Excess of Hydrazine. Into a solution of 80% hydrazine hydrate (12 mmol) in water (8 m*l*), I (6 mmol) was stirred at room temperature, and then the mixture was stirred for an additional hour. Filtration gave a large amount of II (mp and mixed mp 131°C (IIa) or 115°C (IIb)). The treatment of the filtrate as A(i) gave Va in yields of 6.3—9.7%; mp 275—276°C. The product was identified with the Va obtained by Procedure A by a mixed-melting-point determination and by a study of the infrared spectra. The results of this reaction (for Ib) are shown in Table 1 (Reaction 1).

C. By the Reaction of I (R=*i*-Pr, *t*-Bu and Ph, R'=Me) with Hydrazine. I (3.3 mmol) was stirred into a solution of 80% hydrazine hydrate (3.3 mmol) and water (4 m*l*) at room temperature, and then the mixture was stirred for 1 hr. After the same work-up as in A(i), the separated V was recrystallized from water, benzene-methanol (Vg), or methanol-water (Vh and Vi). The use of more hydrazine resulted in an increase in the yield. Thus, the use of two equivalent moles of hydrazine nearly doubled the yield. In the case of I (R=Ph), a large amount of the starting material was recovered.

3-Isopropyl-4-cyano-5-pyrazolone (Vg): colorless microcrystals, mp 222—223°C, yield 41.4% and 80% (with two equivalent moles of hydrazine). IR (cm^{-1}): 2227 ($\nu C{\equiv}N$).

Found: C, 55.80; H, 5.72; N, 27.90%. Calcd for $C_7H_9ON_3$: C, 55.61; H, 6.00; N, 27.80%.

3-*t*-Butyl-4-cyano-5-pyrazolone (Vh): colorless prisms, mp 254—255°C, yields 30% and 73% (with two equivalent moles of hydrazine). IR (cm^{-1}): 2232 ($\nu C{\equiv}N$).

Found: C, 57.94; H, 6.44; N, 25.91%. Calcd for $C_8H_{11}ON_3$: C, 58.16; H, 6.71; N, 25.44%.

3-Phenyl-4-cyano-5-pyrazolone (Vi): colorless microcrystals, mp 254—255°C, yields 3.5% and 7.5% (with two equivalent moles of hydrazine). IR (cm^{-1}): 2237 ($\nu C{\equiv}N$).

Found: C, 64.79; H, 3.63; N, 22.60%. Calcd for $C_{10}H_7ON_3$: C, 64.86; H, 3.81; N, 22.69%.

All the compounds of V obtained by all the procedures (A, B, and C) gave a positive color reaction with ferric chloride, and their infrared spectra all indicated the presence of the cyano group and the disappearance of the ester-carbonyl group.

The Preparation of Ethyl α-Cyano-(2,2-dimethylhydrazino)crotonate (VI). A mixture of 1,1-dimethylhydrazine (0.36 g) in water (8 m*l*) and 1 g of powdered Ib was stirred at room temperature for 1 hr. The resulting precipitate was collected by filtration, washed thoroughly with water, and recrystallized from acetone-water to give 0.75 g (63.5%) of VI. Colorless needles, mp 83—85°C. IR (cm^{-1}): 2203($\nu C{\equiv}N$), 1668 ($\nu C{=}O$). NMR: 10.26 (NH).

Found: C, 54.75; H, 7.63; N, 21.38%. Calcd for $C_9H_{15}O_2N_3$: C, 54.80; H, 7.67; N, 21.31%.

The Reaction of I (R=*i*-Pr, R'=Et) with Ammonia. A mixture of 28% ammonia water (1 m*l*) in water (2 m*l*) and I (3.3 mmol) was stirred at room temperature for 1 hr. The resulting precipitate was collected by filtration, washed with water, and recrystallized from benzene to give 0.4 g (74.2%) of ethyl α-cyano-β-amino-β-isopropylacrylate (VII). Colorless columns, mp 119—120°C. IR(cm^{-1}): 2203($\nu C{\equiv}N$), 1686($\nu C{=}O$).

Found: C, 59.65; H, 7.47; N, 15.37%. Calcd for $C_9H_{14}O_2N_2$: C, 59.32; H, 7.74; N, 15.37%.

The Reaction of Ia—g and I (R=*i*-Pr and Ph) with Hydroxylamine. A solution of hydroxylamine hydrochloride (5 mmol) in water (3 m*l*) was neutralized with a solution of potassium carbonate (2.5 mmol) in water (3 m*l*). Into this I (5 mmol) was stirred at

room temperature. (In the reactions of Id—g, methanol was added to the mixture until it became a clear solution.) After it had been stirred for 1 hr, the precipitate which separated was recrystallized from ethanol (VIIIa, b, c, f, and VIIIj), ethanol - water (VIIIe,d, and VIIIg), or benzene (VIIIh). All the infrared spectra showed the disappearance of the cyano group.

3 - Methyl - 4 - methoxycarbonyl - 5 - aminoisoxazole (VIIIa): colorless prisms, mp 140—141°C, yield 78%.

Found: C, 46.20; H, 4.93; N, 17.81%. Calcd for $C_6H_8ON_2$: C, 46.15; H, 5.16; N, 17.94%.

3-Methyl-4-ethoxycarbonyl-5-aminoisoxazole (VIIIb): colorless needles, mp 133—134°C (lit[10] 133—134°C), yield 88.2%.

Found: C, 49.80; H, 5.91; N, 16.59%. Calcd for $C_7H_{10}O_3N_2$: C, 49.40; H, 5.92; N, 16.46%.

3-Ethyl-4-methoxycarbonyl-5-aminoisoxazole (VIIIc): colorless prisms, mp 151—152°C, yield 97%.

Found: C, 49.40; H, 5.71; N, 16.70%. Calcd for $C_7H_{10}O_3N_2$: C, 49.40; H, 5.92; N, 16.46%.

3 - *n* - Propyl - 4 - methoxycarbonyl -5- aminoisoxazole (VIIId): colorless prisms, mp 116—117°C, yield 56.5%.

Found: C, 52.06; H, 6.40; N, 15.36%. Calcd for $C_8H_{12}O_3N_2$: C, 52.16; H, 6.57; N, 15.21%.

3 - *n* - Butyl - 4 - methoxycarbonyl - 5 - aminoisoxazole (VIIIe): colorless needles, mp 97—98°C, yield 75.8%.

Found: C, 54.48; H, 6.86; N, 14.24%. Calcd for $C_9H_{14}O_3N_2$: C, 54.53; H, 7.12; N, 14.13%.

3 - *n* - Amyl - 4 - methoxycarbonyl - 5 - aminoisoxazole (VIIIf): colorless needles, mp 129—130°C, yield 84.5%.

Found: C, 56.75; H, 7.25; N, 13.20%. Calcd for $C_{10}H_{16}O_3N_2$: C, 56.59; H, 7.60; N, 13.20%.

3 - Isobutyl - 4 - methoxycarbonyl - 5 - aminoisoxazole (VIIIg): colorless prisms, mp 99—100°C, yield 50%.

Found: C, 54.54; H, 6.99; N, 14.08%. Calcd for $C_9H_{14}O_3N_2$: C, 54.53; H, 7.12; N, 14.13%.

3 - Isopropyl - 4 - methoxycarbonyl - 5 - aminoisoxazole (VIIIh): colorless prisms, mp 121—122°C, yield 54.5%.

Found: C, 52.50; H, 6.61; N, 14.92%. Calcd for $C_8H_{12}O_3N_2$: C, 52.16; H, 6.57; N, 15.21%.

3-Phenyl-4-ethoxycarbonyl-5-aminoisoxazole (VIIIj): colorless needles, mp 123°C (lit[3] 123°C), yield 85%.

Found: C, 62.23; H, 5.14; N, 12.11%. Calcd for $C_{12}H_{12}O_3N_2$: C, 62.06; H, 5.21; N, 12.06%.

In the case of the reaction of I (R = *t*-Bu) with hydroxylamine, an excess of hydroxylamine (10 mmol) was used, and to the mixture ethanol was added until it became a clear solution. The mixture was then stirred for 30 hr at room temperature and subsequently concentrated to about 2 m*l*. Upon the cooling of the mixture in an ice-chest, the product was obtained. Recrystallization from ethanol - water gave VIIIi, whose infrared spectrum indicated the absence of the cyano group.

3 - *t* - Butyl - 4 - methoxycarbonyl - 5 - aminoisoxazole (VIIIi): colorless needles, mp 112—113°C, yield 16.7%.

Found: C, 54.59; H, 7.22; N, 14.50%. Calcd for $C_9H_{14}O_3N_2$: C, 54.53; H, 7.12; N, 14.13%.

Furthermore, the filtrate was acidified with hydrochloric acid to give a precipitate whose recrystallization from ethanol yielded IX. Its ferric chloride test was positive.

3 - *t* - Butyl - 4 - cyano -5- isoxazolone (IX): colorless prisms, mp 217—218°C, yield 12.7%. IR (cm^{-1}): 2237($\nu C{\equiv}N$).

Found: C, 57.82; H, 5.89; N, 17.11%. Calcd for $C_8H_{10}O_2N_2$: C, 57.82; H, 6.07; N, 16.86%.

The Reaction of Diethyl 1-Ethoxyethylidenemalonate with Hydroxylamine. To a neutralized solution of hydroxylamine hydrochloride (0.18 g) with potassium carbonate, diethyl 1-ethoxyethylidenemalonate (0.6 g) was added at room temperature, and then the mixture was stirred for 1 hr. After the reaction mixture had been acidified with hydrochloric acid, the crystallization of the resulting product from methanol afforded 0.31 g (69.5%) of 3-methyl-4-ethoxycarbonyl-5-isoxazolone (XI), whose ferric chloride test was positive. Colorless needles, mp 167—168°C (lit 170—171°C,[11] 166°C[12]).

Found: C, 49.37; H, 5.20; N, 8.09%. Calcd for $C_7H_9O_4N$: C, 49.12; H, 5.30; N, 8.18%.

The Preparation of Ethyl α-Cyano-β-methoxyaminocrotonate (XII). *O*-Methylhydroxylamine hydrochloride (0.85 g) was neutralized with a solution of potassium carbonate (0.7 g) in water (10 m*l*). To the solution there was added Ib (1.6 g), and then the mixture was stirred at room temperature for 3 hr. After the usual work-up, the recrystallization of the resulting precipitate from methanol - water gave 1.6 g (87%) of XII. Colorless needles, mp 60—62°C. IR (cm^{-1}): 2198 ($\nu C{\equiv}N$), 1667 ($\nu C{=}O$). NMR: 11.64 (NH).

Found: C, 52.27; H, 6.72; N, 14.98%. Calcd for $C_{18}H_{12}O_3N_2$: C, 52.16; H, 6.57; N, 15.21%.

The authors wish to express their hearty thanks to Professors Taro Hayashi and Tatsuo Takeshima for their kind advice and encouragement and to Professor Toshiro Miwa of Osaka City University for his suggestions about the reaction mechanism. Thanks are also due to Dr. Haruo Homma and his staff for their microanalyses.

Solvent Effect under High Pressure. III.[1] The Application of the Electrostriction Model to the Activation Entropy

Yasuhiko KONDO and Niichiro TOKURA

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Suita, Osaka

(Received September 30, 1968)

The expression which relates the activation entropies of the reactions measured in various solvents with the products of the coefficients of thermal expansion and the molar volumes of the respective solvents has been derived based on the concepts of the electrostriction theory. For three Menschutkin reactions and one acylation reaction linear correlations to be expected from the above expression have been found between the activation entropies and the products of the coefficients of thermal expansion and the molar volumes of the solvents. Moreover, the interrelation between the activation volumes and the activation entropies has been discussed based on this model.

Various attempts have been made to clarify the mechanism of how the solvent influences the rate of the reaction in solution. These attempts have used two alternative methods. One of which seeks out the quantitative relation between the experimental results and the various characteristics of the solvents.[2-6] The other is the method of applying empirically-determined solvent parameters.[7]

In a previous paper[1] the present authors have used an analytical expression which combined the activation volumes measured in various solvents with compressibilities of those solvents based on an electrostriction model.

As that relation has been proved to hold for two Menschutkin reactions,[1] the present authors have now tried to extend this model to an analysis of the dependence of an activation entropy of a reaction in a solution on the nature of the solvent.

In this paper the analytical expression proposed by the present authors will be compared with the experimental results of the various workers.

Discussion

In the previous paper[1] the following expression has been derived to describe the dependence of an activation volume on the compressibility of the solvent;

$$\Delta V_0^{\neq} = \{V_{\neq} - (\overline{V}_A^\circ + \overline{V}_B^\circ)\} - Z\Delta PKV^\circ \qquad (1)$$

where $V_{\neq}$, $\overline{V}_A^\circ$, $\overline{V}_B^\circ$ and V° denote the molar volumes of an activated complex, the reactant A, the reactant B, and a solvent in its pure state and where Z, ΔP, and K denote the solvation number of an activated complex, an average pressure within a solvation shell of an activated complex, and the compressibility of the solvent, respectively.

As one example of the above relationship, the experimental results of $\Delta V_0^{\neq}$ measured by Hartmann *et al.*[8] are plotted against the value of KV° in Fig. 1.

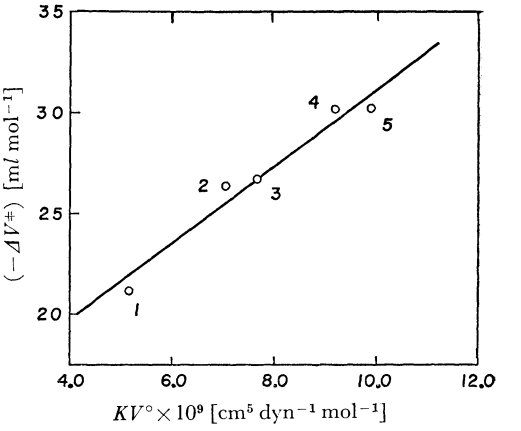

Fig. 1. Plot of $(-\Delta V^{\neq})$ measured in various solvents by Hartmann *et al.*[8] *vs.* KV°.
Reaction: ω-Bromoacetophenone+α-Picoline
Solvent 1: $PhNO_2$, 2: PhBr, 3: PhCl,
4: Acetone, 5: $PhCH_3$

In order to derive the expression for the activation entropy, it would be suitable to adopt a procedure similar to that used in the preceding paper for deriving the activation volume.

We assume that in the vicinity of an ionic species in the solution the entropy of a solvent, S_{solv}°, is changed to S_{solv}' by the electrostatic influence caused by the ionic charge of the solute.

Then the total entropy, S_t, of the solution composed of N moles of a solvent and n moles of a solute may approximately be expressed, as follows;

$$S_t = (N-nZ)S_{solv}^{\circ} + nS_s^{\circ} + nZS_{solv}' + \Delta S_{cratic} \quad (2)$$

where S_{solv}°, S_s°, S_{solv}', ΔS_{cratic} and Z are the molar entropies of a free solvent, a pure solute and a solvated solvent, and a cratic entropy change on dilution and a solvation number, respectively.

Therefore, the partial molar entropy of a solute, $\bar{s}_s$, is given by;

$$\bar{s}_s = \left(\frac{\partial S_t}{\partial n}\right) = s_s^{\circ} + Z(S_{solv}' - S_{solv}^{\circ}) + \Delta s_{cratic} \quad (3)$$

In Eq. (3) the term $(S_{solv}' - S_{solv}^{\circ})$ indicates the entropy change which accompanies the transfer of a solvent molecule from the pure state under an atmospheric perssure into the ionic cosphere of a solute.

Practically, the change is produced by the electrostriction of a solvent molecule resulting from the electrostatic interaction of a solvent molecule with the ionic charge of a solute. However, at present we will estimate the value assuming that the entropy change is produced by exerting an external pressure on a solvent molecule.

Making use of the thermodynamical relation,[9] Eq. (4);

$$\left(\frac{\partial S}{\partial P}\right)_T = -\left(\frac{\partial V}{\partial T}\right)_P \quad (4)$$

and the coefficient of a thermal expansion, α, as defined by:

$$\frac{1}{V}\left(\frac{\partial V}{\partial T}\right) = \alpha \quad (5)$$

the entropy change caused by applying external pressure on a solvent molecule may be approximately given by;

$$\Delta S = -\alpha V^{\circ}(P-1) = -\alpha V^{\circ}\Delta P \quad (6)$$

where V° and P denote the molar volume of a pure solvent and the average pressure within the cosphere of an ionic solute.

The partial molar entropy of a solute can be obtained approximately by substituting Eq. (6) into Eq. (3):

$$\bar{s}_s = s_s^{\circ} - Z\Delta P\alpha V^{\circ} + \Delta s_{cratic} \quad (7)$$

In the discussion of an activation entropy we have only to treat the entropy at an appropriately chosen standard state. Since the cratic entropy term is dependent only on the composition of the solution, not on the characteristics of the solvent, it makes an equal contribution to all the activation entropies based on the same standard state.

If we assume that the activated complex is of an ionic nature while the reactants are nonpolar, we would be able to use Eq. (7) as the entropy of the activated complex. Then the activation entropy for the bimolecular reaction is given by:

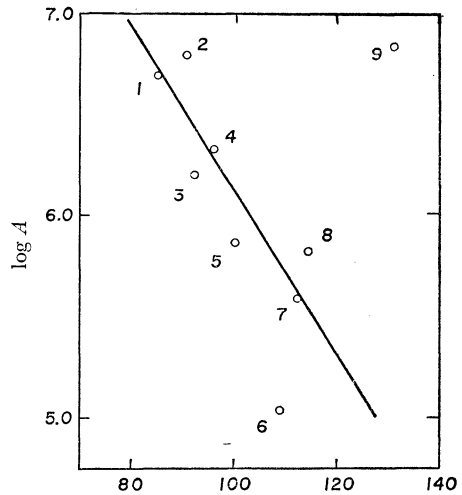
$$A + B \longrightarrow M^{\ddagger} \longrightarrow \text{Product}$$

$$\Delta S^{\ddagger} = \{\overline{S_{\ddagger}}^{\circ} - (\overline{S_A}^{\circ} - (\overline{S_A}^{\circ} + \overline{S_B}^{\circ})\}$$

$$= S_{\ddagger}^{\circ} - (\overline{S_A}^{\circ} + \overline{S_B}^{\circ}) + C - Z\Delta P\alpha V^{\circ} \quad (8)$$

where C denotes the constant characteristic of the chosen standard state.

As the activation entropies measured in various solvents should be affected by the second term on the right hand side of Eq. (8), the linear relation may be expected to hold in the plotting of the activation entropies against the αV° values of the solvents. These plots are given in Figs. 2, 3, 4 and 5.*1,*2



$\alpha V^{\circ} \times 10^3$ [ml mol^{-1} deg^{-1}]

Fig. 2. Plot of log$A$ measured in various solvents by Grim *et al.*[4] *vs.* αV°.
Reaction: EtI + Et_3N
Solvent 1: $PhNO_2$, 2: PhCN, 3: PhI, 4: PhBr, 5: PhCl, 6: Bz, 7: PhF, 8: $PhCH_3$, 9: Cyclohexane

9) G. N. Lewis and M. Randall, "Thermodynamics and the Free Energy of Chemical Substances," McGraw-Hill, New York (1923); 2nd Ed., Revised by K. S. Pitzer and L. Brewer (1961).

*1 The values of the density and the coefficient of the thermal expansion were calculated at 25°C by means of the polynominal equation in "The International Critical Tables" and by means of the differentiation of these with respect to the temperature.

*2 In Figs. 2, 3, and 5, log A is used in place of an activation entropy where A was calculated by this equation:

$$k = A\exp(\Delta E^{\ddagger}/\boldsymbol{R}T)$$

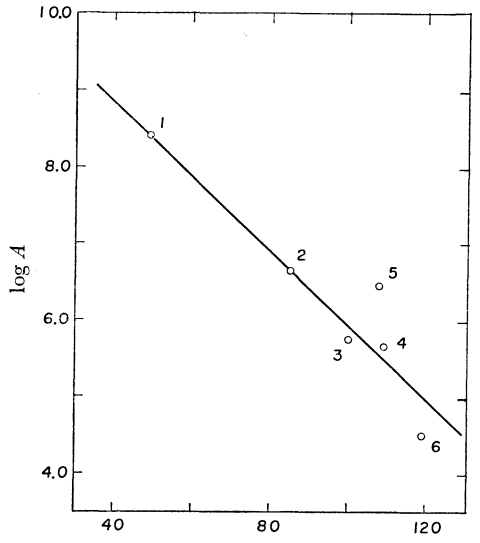


Fig. 3. Plot of log A measured in various solvents by Hartmann *et al.*[10] *vs.* $\alpha V°$.
Reaction: MeI + Pyridine
Solvent 1: MeOH, 2: $PhNO_2$, 3: PhCl, 4: Bz, 5: Acetone, 6: CCl_4

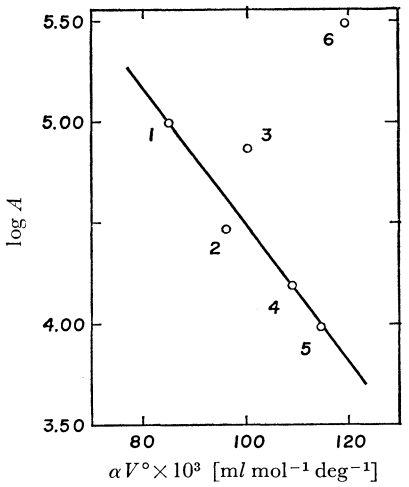

Fig. 5. Plot of log A measured in various solvent by Hinshelwood *et al.*[11] *vs.* $\alpha V°$.
Reaction: *m*-Nitroaniline + Benzoyl chloride
Solvent 1: $PhNO_2$, 2: PhBr, 3: PhCl, 4: Bz, 5: $PhCH_3$, 7: CCl_4

As is shown in these figures, approximately linear correlations have been found in all these examples in spite of the varieties of the solvent used. Moreover, the signs of the solpes of these plots are those to be expected from Eq. (8).

When we compare Eq. (8) with Eq. (1), we can see that the solpes of both these plots represent the values of $Z\Delta P$.

If the assumed model describes the reaction in a solution precisely, the values of $Z\Delta P$ obtained by the two methods should be equal to each other (Table 1).

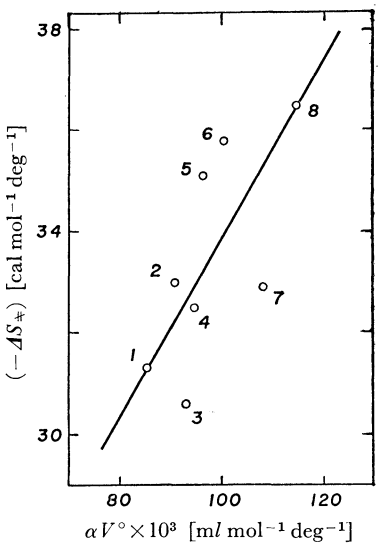

Fig. 4. Plot of $(-\Delta S^{\neq})$ measured in various solvents by Hartmann *et al.*[8] *vs.* $\alpha V°$.
Reaction: ω-Bromoacetophenone + α-Picoline
Solvent 1: $PhNO_2$, 2: PhCN, 3: Propionitrile 4: Cyclohexanone, 5: PhBr, 6: PhCl, 7: Acetone, 8: $PhCH_3$

TABLE 1. THE VALUES OF $Z\Delta P$ DERIVED BY THE TWO METHODS

	Reaction		
	EtI + Et_3N	MeI + Pyridine	MeI + α-Picoline
$Z\Delta P$ from $\Delta V_0^{\neq}$ (kg·cm^{-2})	2.6×10^3	2.6×10^3	1.9×10^3
$Z\Delta P$ from $\Delta S^{\neq}$ (kg·cm^{-2})	7.9×10^3	9.4×10^3	7.6×10^3

Though this equality does not hold accurately in these cases as is shown in Table 1, these values are of the same order for each example.

Previously Laidler and Chen[12] reported a linear correlation between the activation volumes and the activation entropies for the alkaline hydrolysis of esters in an aqueous solution. Recently Hepler[13] found a similar relation between the volume changes

10) H. Hartmann, H. Kelm and G. Rinck, *Z. Physik. Chem. N. F.*, **44**, 335 (1965).
11) N. J. T. Pickles and C. N. Hinshelwood, *J. Chem. Soc.*, **1936**, 1353.
12) K. J. Laidler and D. Chen, *Trans. Faraday Soc.*, **54**, 1026 (1958).
13) L. G. Hepler, *J. Phys. Chem.*, **69**, 965 (1965). In the original formula Hepler considered the above relation to be based on the Maxwell equation: $(\partial S/\partial V)_T = (\partial P/\partial T)_v$. Thermodynamically, the following equation can be proved easily: $(\partial P/\partial T)_v = (\alpha/K)$ where K indicates the coefficient of an isothermal compressibility. Therefore Eq. (11) agrees with his opinion.

and the entropy changes for the acid dissociation reaction in a water solvent.

For the reaction in the single solvent the effect of changing reactants reveals itself in the activation entropy change upon the variation in $Z\Delta P$, for in our model the values of $Z\Delta P$ function as the measure of the development and the redistribution of the charge accompanying the formation of an activated complex.

Then, from Eq. (7) the following equation may be obtained:

$$\Delta\Delta S^{\ddagger} = -\alpha V^{\circ} \cdot \Delta(Z\Delta P) \tag{9}$$

Similarly, for the activation volume:

$$\Delta\Delta V_0^{\ddagger} = -KV^{\circ} \cdot \Delta(Z\Delta P) \tag{10}$$

By combining Eqs. (9) and (10), we obtain:

$$\Delta\Delta S^{\ddagger} = (\alpha/K)\Delta\Delta V^{\circ\ddagger} \tag{11}$$

This relation is similar not only that derived thermodynamically be Hepler,[13] but also to the alternative form of the observation by Laidler and Chen.[12] Thus, it may be concluded that this model, based on the electrostriction theory, is applicable to the analysis of the activation volume and entropy for a reaction in a solution.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 1663—1667 (1969)

The Hydrogenation Catalysts Prepared from Transition Metal Chloride and Triethylaluminum*1

Yoshinobu TAKEGAMI, Toru UENO and Takao FUJII

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received October 4, 1968)

Catalysts composed of anhydrous iron(III) chloride, cobalt(II) chloride, or nickel(II) chloride plus triethylaluminum have been used for the hydrogenation of olefin. The catalytic activity has changed with the $Al(C_2H_5)_3/MCl_n$ ratio. The optimum ratios for the hydrogenation of styrene have been found to be 1—7 for the iron catalyst, 0.2—1 for the cobalt catalyst, and 0.3—2 for the nickel catalyst. Cyclohexane has been used satisfactorily as a solvent. Tetrahydrofuran could be used for the nickel catalyst, but its presence was unfavorable for the iron and cobalt catalysts. The gas evolved in the reaction of the transition metal chlorides with triethylaluminum has been found to be essentially ethane, and sluggish gas absorption was observed when the atmosphere was switched to hydrogen. Ethylbenzene was formed in the treatment of the catalyst with styrene under nitrogen; the amount increased considerably if the catalyst was pre-treated with hydrogen. Ethane was formed in the hydrogen-treatment of the reaction mixture of nickel chloride and triethylaluminum. On the basis of these results, it has been assumed that metal hydride has been formed by the hydrogenolysis of metal - ethyl bonds.

Breslow and his co-workers[1] have reported Ziegler-type soluble catalysts composed of acetylacetonates or alkoxides of transition metals plus triethyl- or tri-isobutylaluminum. They hydrogenated various olefins at 30—50°C and at 3.7 atm. They postulated that the active sites for the hydrogenation are transition metal - hydrogen bonds. Lapporte and Schuett[2] have reported the hydrogenation of aromatic hydrocarbons with catalysts composed of nickel(II) 2-ethylhexanoate plus triethylaluminum at 150—210°C and at 1000 psi, and they assumed that finely-divided transition metal is responsible for the hydrogenation. Analogous catalyst systems have also been patented.[3,4]

As part of their investigation of the synthesis and the catalysis of transition metal hydrides prepared by the use of Grignard reagents[5-8] or lithium aluminum hydride,[9-12] the present authors have

studied the activity of the catalysis prepared by the reaction of iron(III) chloride, cobalt(II) chloride, or nickel(II) chloride with triethylaluminum. In this paper, some novel aspects of the natures of these catalysts and of the mechanism of catalyst formation will be reported.

Experimental

Materials. Triethylaluminum was obtained from the Ethyl Co. Anhydrous iron(III) chloride was prepared by the dehydration of a hexa-hydrate (from Merck) with thionyl chloride.[13] The solvent, tetrahydrofuran and cyclohexane, were dried over sodium and distilled just before use. The other reagents used were the purest among the available commercial materials.

The Preparation of the Catalysts and the Hydrogenation. The apparatus consisted of a four-necked flask (100 m*l*) equipped with a stirrer, a dropping funnel, and a thermometer; it was jointed to a gas buret through a silica gel tube. To a solution of 40 m*l* of cyclohexane containing 0.003 — 0.005 mol of transition metal chloride, a desired amount of triethylaluminum solution in cyclohexane was added through the dropping funnel. The solution immediately turned black or brown-black, and there was an accompanying gas evolution. The mixture was then stirred for an additional hour until the gas evolution ceased.

The hydrogenation of olefin was carried out by introducing 2 m*l* of olefin into the catalyst solution prepared above. The speed of stirring was kept constant (900 rpm) during the hydrogenation. After the hydrogenation, the reaction mixture was poured into cold aqueous hydrochloric acid in order to destroy the catalyst. The hydrogenation product was extracted with ethyl ether, washed with water, concentrated by the evaporation of ether, and gas-chromatographed.

Determination of Ethane. Anhydrous nickel(II) chloride (0.005 mol) was placed in a 300 m*l* two-necked flask equipped with a magnetic stirrer, and the flask was flushed with nitrogen. The triethylaluminum solution was added slowly. When the gas evolution ceased, the reaction mixture was degassed completely by evacuating the flask until a half of the solvent had been distilled. Then, the atmosphere was switched to hydrogen. Gas samples (2—5 m*l*) were removed periodically by the use of a syringe and subjected to gas chromatography. The amount of ethane was determined by the use of the absolute calibration curve prepared for a hydrogen - ethane mixture.

Results and Discussion

The Reaction of Transition Metal Chlorides with Triethylaluminum. The reaction of anhydrous transition metal chlorides with triethylaluminum was carried out under a nitrogen atmosphere and at 0°C. A black-colored substance (suspended in the solvent)was formed immediately, and there was an accompanying gas evolution. The amount and composition of the gas are represented in Table 1. A great portion of the evolved gas was ethane, but its amount was relatively small. When the atmosphere was switched from nitrogen to hydrogen after the reaction, a diminution in the gas volume was observed. However, the rate was quite sluggish; the gas-volume diminutions represented in the last columm of Table 1 are those observed during reaction periods of 5—15 hr.

Hydrogenation of Olefin. Using a black-colored suspension as a catalyst, the hydrogenation of styrene was carried out at 0 or 35°C. For most of the experiments, about 0.003 mol of transition metal chlorides and 3 m*l* of styrene were used. Cyclohexane was used as the solvent. Figures 1—3 show the hydrogen absorption curves for the hydrogenation with iron, cobalt, and nickel catalysts respectively. The numerals attached to

each curve represent the $Al(C_2H_5)/MCl_n$ ratios (abbreviated as "molar ratio" below further description). As may be seen in Figs. 1—3, the catalytic activity of these catalysts is dependent on the molar ratio; the optimum molar ratios for iron, cobalt, and nickel catalysts are 1—7, 0.2—1, and 0.3—2 respectively.

Several other olefins were tentatively hydrogenated using the iron catalyst (the molar ratio was 3); the ease of hydrogenation was found to vary in the order; styrene > indene > cyclohexene > safrole > *d*-limonene > isosafrole. Actually, the rate of the hydrogenation of isosafrole was nearly zero. Acetophenone and ethyl vinyl ether could not be hydrogenated with this catalyst; furthermore, in the presence of the ketone or ether, the hydrogenation of styrene was considerably depressed.

In the runs shown in Figs. 1—3, cyclohexane was used as the solvent. When a cyclohexane-tetrahydrofuran (1 : 3—10) mixture was used as the solvent, the catalysts was quite different in nature from those observed in the cyclohexane solvent. In the cases of the iron and cobalt catalysts, no active catalyst for the hydrogenation of styrene could be obtained at any molar ratio of 1—12. Furthermore, when a small amount of tetrahydrofuran was added the halfway through the rapid hydrogenation carried out in the cyaclohexane solvent, the rate of hydrogenation was considerably lowered, showing the presence of tetrahydrofuran to be unfavorable for the iron and cobalt catalysts. In the case of the nickel catalyst, on the other hand, an active catalyst was prepared in the cyclohexane-tetrahydrofuran solvent. As may be seen in Fig. 4, the optimum molar ratio for the hydrogenation of styrene was 1—12; this was a very much wider range than the optimum ratio of 0.3—2 observed in the cyclohexane solvent (Fig. 3).

Centrifugation of the Catalyst. Breslow and his co-workers[1b] have pointed out that the use of halogen derivatives of transition metals leads,

in general, to insoluble catalyst systems. In our experiments, the black-colored substance suspended well in a solvent and the black-colored substance did not separate from the solvent even when the mixture stood for several days. When the catalyst system was centrifuged (2800 rpm), a black-colored precipitate was isolated, while the solvent was still black-colored. The precipitate and the solution were assumed to constitute the soluble and insoluble parts of the catalyst system respectively. The precipitate and the solution were then tested for the hydrogenation of styrene. The rates were taken as the reaction periods for 50% hydrogen uptake and are listed in Table 2. In general, both the solution and the precipitate were active in the hydrogenation, while there was a trend for the activity of the former or the latter to be predominant in the case of the nickel or the cobalt catalyst respectively. In the case of the nickel catalyst prepared in the cyclohexane - tetrahydrofuran solvent, only the solution was active, as may be seen in run 7. Since, in these experiments, the amount of the precipitate decreased with an increase in the molar ratio, and since only a small amount of the precipitate was isolated in runs 2, 4, and 6, the rate of the hydrogenation catalyzed by precipitates may depend on both the catalytic activity and the amount of the precipitate. However, the rate of the hydrogenation seems to be affected by the catalytic activity, rather than the amount, of the precipitate, since it was found in a preliminary experiment that the rate of the hydrogenation was very slightly affected by changing the amount of catalyst (1—0.1 times), and since a rapid hydrogenation occurred with a very small amount of the precipitate in runs 2 and 4.

e) Only 1% of hydrogen was absorbed during the reaction period of 300 min.

Styrene-treatment of the Nickel Catalyst. In the previous publications,[8,10)] it has been reported that, when the catalyst prepared by the use of a Grignard reagent or lithium aluminum hydride was treated with styrene under a nitrogen atmosphere, ethyl benzene was formed by the hydrogen migration from the catalyst to styrene. We applied this styrene-treatment to the nickel catalysts prepared in the cyclohexane - tetrahydrofuran solvent at the molar ratio of 6.0. 1) One of the catalysts was treated with styrene under nitrogen (at 35°C, for 8 hr) immediately after the preparation of the catalyst; 0.08 mol of ethylbenzene was formed per mol of nickel chloride. 2) The other catalyst was stirred under hydrogen for 20 min*[2] after the preparation of the catalyst. Thereafter, the atmosphere was switched to nitrogen and the catalyst was treated with styrene; 0.35 mol of ethylbenzene was thus formed per mole of nickel chloride.

Formation of the Catalyst. It is felt that the strict dependence of the catalytic activity on the molar ratio is strong evidence that metallic component does not furnish an active sites. If the catalysts are finely-divided metal, as Lapporte reported,[2)] the fact that a higher molar ratio lowers the catalytic activity can not be explained. In fact, however, Lapporte operated under conditions which were not as mild as ours. The agreement in the molar ratio dependence between the present catalysts and the transition metal hydride catalysts prepared by the use of a Grignard reagent or lithium aluminum hydride suggests that the active sites of the present catalysts are, at least in part, transition-metal-hydride in character.

*[2] No gas absorption was observed during the treatment.

Three processes for the transition metal hydride formation are possible: (a) the elimination of ethylene from the transition metal - ethyl bonds; (b) the absorption of hydrogen on the transition metal, and (c) the hydrogenolysis of the transition metal - ethyl bonds. However, the elimination of ethylene to give transition metal hydride is improbable, since the greater part of the gas evolved during the preparation of the catalyst was ethane, as may be seen in Table 1. Ethylene might not be observed if it polymerized immediately, but the catalyst was found to be inactive in the polymerization of ethylene under the conditions employed. When the reaction of transition metal chloride with triethylaluminum was carried out under nitrogen and the atmosphere was switched to hydrogen, a sluggish gas absorption was observed if cyclohexane was used as the solvent, while no gas absorption occurred if a cyclohexane - tetrahydrofuran mixture was used as the solvent. The gas absorption might result from the reaction of the transition metal with hydrogen to form transition-metal-hydride sites, but in view of the sluggishness of the gas absorption, it appears improbable that the hydride sites thus formed can be intermeditaes in the relatively rapid hydrogenation of olefin which we observed.

The hydrogenolysis of metal - ethyl bonds to give transition-metal hydride and ethane seems to offer the most probable explanation for the formation of transition-metal-hydride sites without any apparent gas absorption, and for the fact that the amount of ethylbenzene formed in the styrene-treatment of the nickel catalyst increased considerably if the catalyst was pre-treated with hydrogen.

$$M\text{-}Cl \xrightarrow{Al(C_2H_5)_3} M\text{-}C_2H_5 \xrightarrow{H_2} M\text{-}H + C_2H_6 \uparrow$$

In order to establish the hydrogenolysis process, the ethane which was formed in the hydrogen-treatment of the catalyst component was determined. As may be seen in Fig. 5, ethane was formed rapidly.

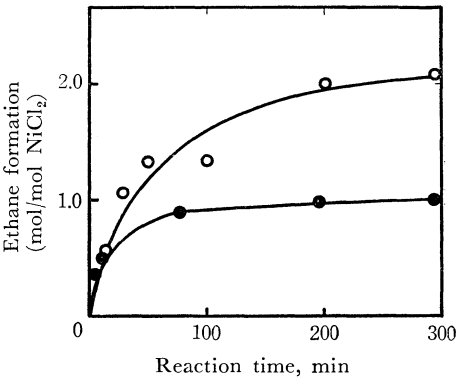

Fig. 5. Ethane formation in the hydrogen-treatment of the $NiCl_2$-$AlEt_3$.
○: molar ratio=2.2, at 35°C, in cyclohexane solvent.
●: molar ratio=2.2, at 35°C, in cyclohexane-tetrahydrofuran solvent.

Although no gas absorption was observed during the hydrogen-treatment of the nickel catalyst in the cyclohexane - tetrahydrofuran solvent (Expt. 1 in Table 1), about 2 mol of ethane was formed per mole of nickel chloride, confirming the hydrogenolysis process described above.

Benzylidenation of L-Sorbose[1—3]

Takashi MAEDA, Mitsuru KIMOTO (née KATSUHARA), Shigeru WAKAHARA and Kanji TOKUYAMA

Shionogi Research Laboratory, Shionogi & Co., Ltd., Fukushima-ku, Osaka

(Received September 15, 1968)

The acid-catalyzed benzylidenation of L-sorbose (I) was studied. The reaction by Reichstein's procedure gave a mixture of two diastereomeric 2,3:4,6-di-*O*-benzylidene-α-L-sorbofuranoses (III and IV), which were then successfully separated by preparative thin-layer chromatography. The use of slightly acidic conditions yielded 1,3:4,6-di-*O*-benzylidene-β-L-sorbofuranose (XI), 1,2:4,6-di-*O*-benzylidene-α- (XVII and XVIII) and -β-L-sorbofuranoses (XIX and XX), 1,2-*O*-benzylidene-α-L-sorbopyranoses (XXI and XXII), and 1,3-*O*-benzylidene-L-sorbose (XXIII). The absolute configurations at the acetal center of the five-membered benzylidene rings were assigned. A reaction sequence (I→(XXI, XXII⇄XXIII)→XI→IV→III) comparable with that of the ethylidenation of I was established.

1,2-*O*-Isopropylidene-α-L-sorbopyranose has been proposed as a key intermediate in the acetonation of L-sorbose(I)yielding 2,3:4,6-di-*O*-isopro-pylidene-α-L-sorbofuranose.[4] However, in the course of recent studies of the acetonation of I using weakly acidic conditions, we have isolated for the first time several types of isomers such as 1,3:4,6-di-*O*-isopropylidene-β-L-sorbofuranose,[5] and 1,3:4,6-di-*O*-isopropylidene-α-[6] and -β-L-sorbofuranoses.[5] The presence of these isomers suggests the complicated nature of the acetalation of I. More recently, ethylidenated L-sorboses corresponding to the acetonated ones have also been isolated from the ethylidenation of I under weakly acidic conditions, and a reaction sequence of the ethylidenation has been established as follows: I→[1,2-*O*-ethylidene-α-L-sorbopyranose ⇄ 1,3-*O*-ethylidene-α-L-sorbopyranose (1,3-*O*-acetal)] → 1,3:4,6-di-*O*-ethylidene-β-L-sorbofuranose(1,3:4,6-di-acetal) → 2,3:4,6-di-*O*-ethylidene-α-L-sorbofuranose.[2]

An important difference between the acetonation and the ethylidenation is that, with the former, a compound corresponding to the 1,3-*O*-acetal was not isolated, a fact probably explainable in terms of the Brown-Brewster-Schechter rule.[7] A pathway from the 1,3-*O*-acetal to the 1,3:4,6-di-*O*-acetal seemed to be required in the acetalations of I. The idea of the existence of this important pathway from a pyranose to a furanose would receive strong support if compounds of the 1,3-*O*-acetal type could be found in other acetalation reactions. From this point of view, we have described the benzylidenation of I with benzaldehyde. The structures of the products were determined by proton magnetic resonance (PMR) spectroscopic and chemical evidence. The PMR data are reported in Tables 1 and 2, and some of the spectra are shown in Figs. 1—4, which also indicate a clue to the elucidation of the diastereomeric configurations at the acetal centers of the products.

Reichstein and Grüssner[8] reported that the reaction of I with benzaldehyde in the presence of an acid gave a brown syrup. We could separate this syrup into two dibenzylidene-L-sorboses, III and IV, by preparative thin-layer chromatography. As the oxidation of the syrup mixture of III and IV afforded L-xylo-hexulosonic acid in good yield,[8] III and IV can be said to be diastereomeric 2,3:4,6-di-*O*-benzylidene-α-L-sorbofuranoses. The facts that III and IV reacted with trityl chloride-pyridine to yield tritylates (V and VI respectively) and with acetic anhydride-pyridine to give acetates (IIIa and IVa respectively) (see Figs. 1 and 2) supported their structures. The general characteristics of the PMR data of III and IV, especially the small coupling constants of $J_{3,4}$ (0.5 Hz),[5,9,10] leave no doubt that they have a furanose ring. As the phenyl group is equatorial in the chair con-

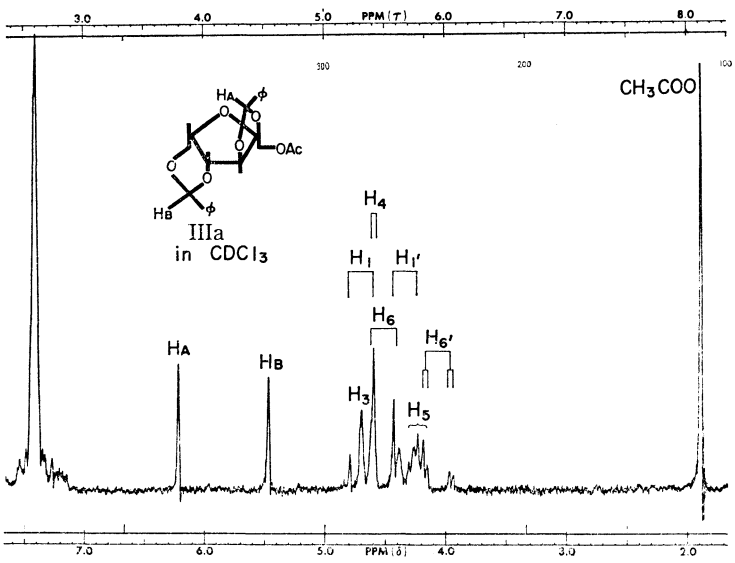

Fig. 1. PMR spectrum of IIIa in $CDCl_3$ at 60 MHz.

formation of the six-membered 4,6-*O*-benzylidene group, the diastereomerism between III and IV must be caused by the five-membered 2,3-*O*-benzylidene ring. The benzylic proton signals of III and IV in $CDCl_3$ appear at τ 3.80 and 4.55 and at τ 4.07 and 4.58 respectively. It is well known that a benzylic proton of 1,3-dioxolane resonates at a lower field than that of 1,3-dioxane.[11] The signals observed at τ 3.80 and 4.07 can be assigned to the benzylic protons of 2,3-*O*-benzylidenacetals. This assignment was supported by the benzylic proton signal (τ 4.56) of 4,6-*O*-benzylidene - 2,3 - *O* - isopropylidene - α - L - sorbofuranose (VIII), which was derived from 2,3-*O*-isopropylidene-α-L-sorbofuranose (VII)[12] and which was hydrolyzed to the starting material quantitatively.

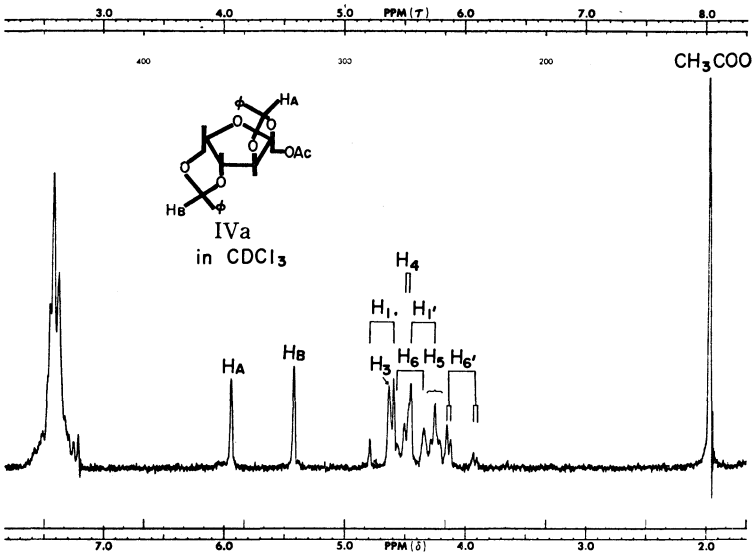

Fig. 2. PMR spectrum of IVa in $CDCl_3$ at 60 MHz.

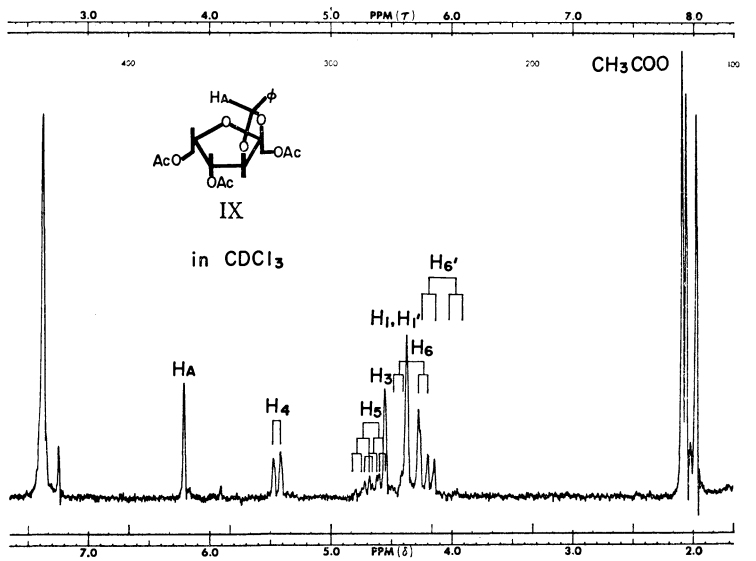

Fig. 3. PMR spectrum of IX in $CDCl_3$.

The selective removal of the 4,6-*O*-benzylidene rings of III and IV, followed by acetylation, yielded two 1,4,6-tri-*O*-acetyl-2,3-*O*-benzylidene-α-L-sorbofuranoses, IX and X respectively; in them the spectra of the lower-field benzylic protons of the parent compounds, III and IV, remained unchanged (see Figs. 3 and 4). Thus, it was unequivocally established that III and IV are, respectively, H-*endo* and H-*exo*[11,13] diastereomers at the acetal center of the 2,3-*O*-benzylidene ring. Since benzylic protons on dioxolane rings fused directly to five-membered cyclic systems are deshielded when in the *endo* position,[2,11,14] III and IV are assigned the H-*endo* and H-*exo* configurations respectively. Recently, Ferrier and Hatton[13] reported the assignment of diastereomeric 1,2 : 3,5-di-*O*-benzylidene-α-D-xylofuranoses on the basis of the difference in benzylic protons in the chemical shifts at τ 3.83 (H-*endo*) and 4.10 (H-*exo*); these values are in good agreement with our findings for sorbose derivatives (see Chart I).

Chart I

The use of a trace of *p*-toluenesulfonic acid as a catalyst afforded mainly another dibenzylidene derivative (XI), which reduces a Fehling solution. The methylation of XI with methyl iodide in the presence of silver oxide yielded methyl glycoside (XII), which was also obtainable by the acetal interchange reaction of methyl 1,3:4,6-di-*O*-isopropylidene-*β*-L-sorbofuranoside (XIII)[5] with a large excess of benzaldehyde. The debenzylidenation of XII with 60% acetic acid, followed by acetylation, afforded methyl 1,3,4,6-tetra-*O*-acetyl-*β*-L-sorbofuranoside (XIV)[9] and partially debenzylidenated sorbofuranoside (XV). The PMR spectra of XV, showing a pattern closely related to that of the methyl 4,6-di-*O*-acetyl-1,3-*O*-isopropylidene-*β*-L-sorbofuranoside (XVI)[9] obtained from XIII by a similar procedure, suggest that the structure of XV is methyl 4,6-di-*O*-acetyl-1,3-*O*-benzylidene-*β*-L-sorbofuranoside. Therefore, the structure of XI was determined to be 1,3:4,6-*O*-benzylidene-*β*-L-sorbofuranose. The benzylic proton singlets at τ 4.47 and 4.53 in $CDCl_3$, showing the presence of two 1,3-dioxanes, also supported the proposed structure. The absence of diastereomers in XI is quite natural, since it has only 1,3-dioxanes (see Chart II).

TABLE 3. THE ASSIGNMENT OF THE ANOMERIC AND DIASTEREOMERIC CONFIGURATIONS OF 1,2:4,6-DI-*O*-BENZYLIDENE-L-SORBOFURANOSES

Compound	$[\alpha]_D$	IR spectra OH (in CCl_4)	PMR spectra Benzylic H of 1,2-*O*-ring (in $CDCl_3$)	Configuration	
				Anomeric	Diastereomeric
XVII	−31.0	3558 cm^{-1}	τ 4.04	α	H-*endo*
XVIII	+34.7	3556	4.21	α	H-*exo*
XIX	+22.7	3629	3.80	β	H-*endo*
XX	+166.6	3630	3.97	β	H-*exo*

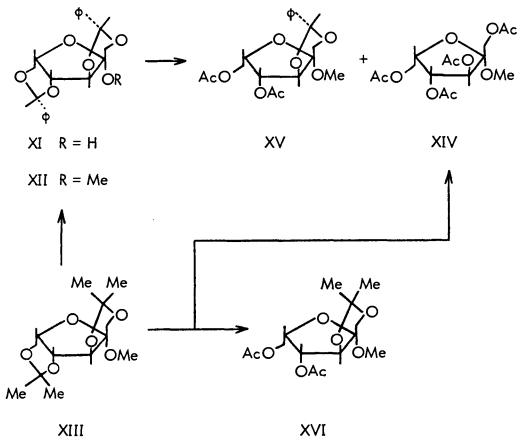

Chart II

When the benzylidenation reaction was carried out in dimethyl sulfoxide (DMSO), four non-reducing dibenzylidenated sorboses (XVII, XVIII, XIX, and XX) (see Table 3) and three mono-benzylidenated sorboses (the reducing XXIII and the non-reducing XXI and XXII) were isolated. The PMR spectra of their respective actates of XVII, XVIII, XIX, and XX, XVIIa, XVIIIa, XIXa, and XXa in C_6D_6[15] gave H_3 signals appearing at τ 4.40—4.73 in the AcO–CH region as somewhat broad singlets. The coupling constants of $J_{3,4}$ (0.5 Hz) furnished obvious evidence for their furanose structures.[9,10,13] Furthermore, two benzylic protons were observed at τ 3.80—4.21 (1,3-dioxolane) and τ 4.54—4.60 (1,3-dioxane) in each case. These results firmly established that XVII, XVIII, XIX, and XX are the anomeric and diastereomeric 1,2:4,6-di-*O*-benzylidene-L-sorbofuranoses.

Their anomeric configurations were substantiated by the use of the infrared spectra, where characteristic bands due to intramolecular hydrogen bonding between C_3–OH and C_2–O are sometimes present in α-anomers, but are always, absent in β-ones. Strong bands due to hydrogen bonding were observed in infinite dilute carbon tetrachloride solutions of XVII (3558 cm^{-1}) and XVIII (3556 cm^{-1}), but not in the cases of XIX (3629 cm^{-1}) and XX (3630 cm^{-1}). Therefore, XVII and XVIII were identified as α-anomers, and XIX and XX, as β-anomers. These identifications were in accord with the results of the optical rotation of the respective acetates XVIIa—XXa; the α-anomers (XVIIa and XVIIIa) showed negative signs of rotations, while the β-anomers (XIXa and XXa) showed positive signs, as was to be expected from the signs of the corresponding acetonated derivatives. The two α-anomers and β-anomers should differ only in stereochemistry at the acetal center of the 1,2-*O*-benzylidene ring. Model experiments indicated, for the H-*endo* configuration, the nearness of the benzylic proton of the 1,2-*O*-benzylidene ring to the ring oxygen of furanose and that of the acetoxy group of the α-anomer or H_3 of the β-anomer to the phenyl group of 1,2-*O*-benzylidene ring. Therefore, in the PMR spectra, benzylic proton signals should be deshielded,[11] and the acetoxy signal of the α-anomer,

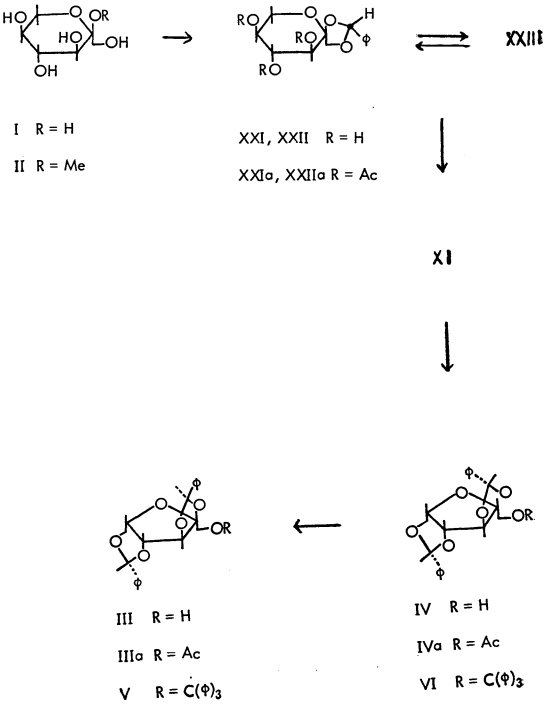

Chart III

15) The signals in C_6D_6 are more resolved than in $CDCl_3$.

and the H_3 signal of the β-anomer should be shielded,[16] when the position is H-*endo*. Table 1 obviously shows that, in each case, benzylic protons of the 1, 2-*O*-benzylidene rings of XVIIa and XIXa resonate at a field lower by 0.17 ppm than those of the corresponding anomers, XVIIIa and XXa respectively, while the acetoxyl of XVIIa and the H_3 of XIXa appear at a higher field than those of XVIIIa of XIXa appear at a higher field than those of XVIIIa and of XXa. Accordingly, XVIIa and XIXa were assigned the H-*endo* configuration, and XVIIIa and XXa, the H-*exo* (see Chart III).

The triacetates, XXIa and XXIIa, were very similar in IR and PMR spectra. The benzylic proton signals at τ 3.95 (XXIa) and 4.00 (XXIIa) (in $CDCl_3$)[16] fall into the range of 1,3-dioxolanes.[11,13,14] The coupling constants obtained, $J_{3,4}$, $J_{4,5}$, and $J_{5,6}$ are evidently the values of $J_{a,a}$, of pyranose in the 1C conformation.[17] Signals due to H_3, H_4, and H_5 appeared in the range of AcO–$\underset{|}{\overset{|}{C}}$H. The structures of XXI and XXII are, then, consistent with diastereomeric 1, 2-*O*-benzylidene-α-L-sorbopyranoses. They correspond to that of 1,2-*O*-isopyropylidene-α-L-sorbopyranose, which has been concluded to be the initial intermediate in the acetonation reaction of I.[4]

The acetylation of reducing monobenzylidene sorbose (XXIII) at an ordinary temperature gave three acetylated compounds, two reducing diacetates (XXIV and XXV) and one non-reducing triacetate (XXVI). These diacetates were methylated with methyl iodide in the presence of silver oxide to yield glycosides. The glycoside derived from XXIV was identified with XV, and the glycoside from XXV was identified with methyl 4,5-di-*O*-acetyl-1,3-*O*-benzylidene-α-L-sorbopyranoside (XXVII), which had been prepared by the benzylidenation[18] of methyl α-L-sorbopyranoside (II),[19] followed by acetylation. Therefore, the structure of XXIV and XXV were determined to be 4,6-di-*O*-acetyl-1,3-*O*-benzylidene-β-L-sorbofuranose and 4,5-di-*O*-acetyl-1,3-*O*-benzylidene-α-L-sorbopyranose respectively. These products showed that XXIII is 1,3-*O*-benzylidene-L-sorbose, an equilibrium mixture of 1,3-*O*-benzylidene-β-L-sorbofuranose (XXIIIf) and α-L-sorbopyranose (XXIIIp). The results of the optical rotationary dispersion (ORD) showing the absence of any carbonyl group (see Fig. 5), a value of optical rotation similar to those of XV and XXIV, and a small coupling constant of $J_{3,4}$ suggest that the structure of XXVI is 2,4,6-tri-*O*-acetyl-1,3-*O*-benzylidene-β-L-sorbofuranose.

The behavior of XXIII is very interesting. It may be considered to exist as the furanose (XXIIIf) in a crystalline state from its sharp melting point and its positive optical rotation in chloroform; however, it may be considered to be in an eqilibrium with the furanose (XXIIIf), a keto-form (XXIIIk) and the pyranose (XXIIIp) in solutions since the optical rotation, in pyridine, for instance, changes slowly with the time (see Chart IV).

During the course of these structure studies, an

interesting transformation between III, IV and XI was observed. Under usual benzylidenation conditions, III and IV were the major products and the amounts of the others were negligibly small. The relative yields were checked by means of the PMR spectra using the benzylic proton singlets at τ 3.80 (III), 4.07 (IV), and 4.47 (XI) as the key signals; the results are reported in Table 4. Table 4 shows clearly that the reaction proceeds in the sequence of XI→IV→III. It has been suggested that the H-*exo* isomer is produced in a kinetic phase and that the H-*endo* isomer is preponderant at an equilibrium,[11,13] in the benzylidention of I, the H-*exo* isomer (IV) was also found as a kinetic product, indicating that the reaction occurred with the retention of the diastereomeric configuration at the acetal center in the step XI→IV.

As the monobenzylidenated compounds (XXI, XXII, and XXIII) were obtained under slightly acidic conditions, the benzylidenation of I can be said to proceed *via* a pathway, I→(XXI, XXII⇄XXIII)→XI→IV(H-*exo*)→III(H-*endo*), similar to that in the ethylidenation of I.[2] Since these types of ethylidenated and benzylidenated compounds correspond to the acetonated ones, the reaction pathway of the acetonation should be concluded to be the same as that above. A detailed discussion of this mechanism of the acetalation of I will be presented in following papers.

Experimental

All the melting points were recorded on a Kofler micro-stage apparatus and have been corrected.

The solvents used were removed under reduced pressure.

Thin-layer chromatography was carried out on a silica gel plate with benzene - ether (3:1 v/v, solvent A), ether - petroleum ether (5:1 v/v, solvent B; 2:1 v/v, solvent C; 1:1 v/v, solvent D; 1:2, solvent E), and chloroform - acetone (9:1 v/v, solvent F; 1:1, solvent G). Seliwanoff reagent[20] spray was used for detection; the R_f values are listed in Table 5. Preparative thin-layer chromatography was performed on silica gel with the same solvent systems as were used for detection, while the spots located with iodine vapor were extracted with either acetone or chloroform - methanol (9:1 v/v).

Table 4. Product-ratio (±5%) from the reaction of L-sorbose (I) (1.6 g) and benzaldehyde (40 ml) at 25°C for 6 hr in the presence of TsOH

Product	The acid concentration		
	0.1%	1.0%	10.0%
III	15.0	22.5	42.5
IV	35.0	55.0	52.5
XI	50.0	22.5	5.0

20) A. Anno and N. Seno, "Jikken Kagaku Kōza," Bd. 23, ed. by Chem. Soc. Japan, Maruzen, Tokyo (1957), p. 374.

The evaporation of the solvents gave the materials.

The optical rotations were determined in chloroform containing 1% ethanol unless otherwise stated, and the concentrations have been recorded in percentages. The ORD curve of XXVI was obtained for the methanol solution on a Nippon-Bunko ORD/UV 5 spectrometer.

The PMR spectra were measured on a Varian A-60A spectrometer using 5% solutions of the samples in either $CDCl_3$ or C_6D_6, with TMS used as the internal standard. The results obtained from the analysis of the spectra of the compounds examined are listed in Tables 1 and 2. Some of the spectra are shown in Figs. 1—4.

The IR spectra measurements of XVII, XVIII, XIX, and XX were made using a Nippon-Bunko DS402G infrared spectrometer and a 3.5±0.5 mg/8 m*l* solution in a carbon tetrachloride solution (in a 20 mm cell).

Benzylidenation of L-Sorbose (I). a) Dry hydrogen chloride (0.75 g) was introduced into a mixture of L-sorbose (I) (2.0 g) and benzaldehyde (48 m*l*). The mixture was stirred at room temperature for 6 hr and then stored in a refrigerator overnight. The clear solution was diluted with ether and the solution was washed with aqueous sodium bicarbonate, and then with water, dried, and the solvent removed. The syrup thus obtained was dissolved in chloroform, and the chloroform solution was washed with a sodium hydrogen sulfite solution, and then with water, and dried. The evaporation of the solvent gave a syrup (3.4 g) whose thin-layer chromatogram showed the presence of III and IV. From the syrup, III (0.28 g) and IV (0.11 g) were separated in pure states by repeated PTC (first with the solvent A and then two times with the solvent C).

III: plates (174 mg), mp 129—131°C (recrystallized from benzene - petroleum ether), $[\alpha]_D^{24}$ −8.7° (*c* 0.722). Found: C, 67.46; H, 5.59%; mol wt, 341. Calcd for $C_{20}H_{20}O_6$: C, 67.40; H, 5.66%; mol wt, 356.

IV: Amorphous powder, mp <51°C, $[\alpha]_D^{23}$ −10.6° (*c* 0.993). Found: C, 67.14; H, 5.52%; mol wt, 366. Calcd for $C_{20}H_{20}O_6$: C, 67.40; H, 5.66%; mol wt, 356.

b) A mixture of L-sorbose (I) (1.00 g), benzaldehyde (24m*l*), and TsOH (0.24 g) was stirred at room temperature. After 20 hr, the solution was worked up by the above-described procedure. A syrup (1.86 g) containing III, IV and XI was thus obtained. XI (9.5 mg) was isolated as plates by PTC with the solvent C followed by recrystallization from ethanol, mp 164.6—167°C, $[\alpha]_D^{22}$ +48.8° (*c* 0.934). Found: C, 67.48; H, 5.79%; mol wt, 363. Calcd for $C_{20}H_{20}O_6$: C, 67.40; H, 5.66%; mol wt, 356.

c) To a solution of L-sorbose (I) (10 g) in DMSO (60 m*l*), there were added benzaldehyde (100 m*l*) and conc. sulfulic acid (0.5 g). After stirring at room temperature for 3 days, the solution was neutralized with 2N sodium bicarbonate, dried, and evaporated. A crystalline syrup (8.47 g) was obtained by the same work-up as above. (i) The addition of ethanol to the syrupy crystals thus obtained gave XI (2.9g). The evaporation of the ethanol from the mother liquor yielded a syrup (4.91g). From the syrup, XVII, XVIII, XIX and XX were isolated by PTC (first with the solvent A and then with the solvent D). The isolated materials were further purified by recrystallization.

XVII: Cubics, mp 113.7—114.7°C (recrystallized from ether - petroleum ether; yield, 12 mg), $[\alpha]_D^{22}$ −31.0° (*c* 0.813). Found: C, 67.56; H, 5.72%; mol wt, 350.

XX: Needles, mp 148—154°C (recrystallized from ethanolpetroleum ether), $[\alpha]_D^{24}$ +166.6° (*c* 0.393). Found: C, 67.30; H, 5.66%; mol wt, 337. Calcd for $C_{20}H_{20}O_6$: C, 67.40; H, 5.66%; mol wt, 356.

(ii) The syrup (6.15 g was used) was separated into XXIII (1.38 g) and a mixture syrup of XXI and XXII (1.27 g) by PTC with the solvent G.

XXIII: Cubics, mp 183.5—184.6°C (recrystallized from methanol; yield, 342 mg), $[\alpha]_D^{23}$ +30.5° (*c* 0.387, methanol); $[\alpha]_D^{23}$ +36.0→+20.2° after 24 hr (*c* 0.962, pyridine); $[\alpha]_D^{23}$ +20.4° (*c* 0.984, DMSO). Found: C, 58.13; H, 6.03%; mol wt, 244. Calcd for $C_{13}H_{16}O_6$: C, 58.20; H, 6.01%; mol wt, 268.

The latter mixture, a syrup (1.27 g), was treated with acetic anhydride (13 m*l*) in pyridine (13 m*l*) in the usual way, and the reaction mixture was poured into ice water. From the resulting syrup, the triacetates XXIa and XXIIa were isolated by PTC with the solvent C. The isolated materials were then further purified by recrystallization.

XXIa: Needles, mp 126—131.5°C (recrystallized from ether; yield, 487 mg), $[\alpha]_D^{22}$ −125.2° (*c* 0.956). Found: C, 57.53; H, 5.62%; mol wt, 405. Calcd for $C_{19}H_{22}O_9$: C, 57.86; H, 5.62%; mol wt, 394.

XXIIa: Needles, mp 111—115°C (recrystallized from ether; yield, 118 mg), $[\alpha]_D^{23}$ −89.2° (*c* 0.937). Found: C, 57.94; H, 5.53%; mol wt, 396. Calcd for $C_{19}H_{22}O_9$: C, 57.86; H, 5.62%; mol wt, 394.

d) A mixture of L-sorbose (I) (1.6 g), and benzaldehyde (40m*l*) containing 0.1, 1.0 and 10.0% (w/v%) TsOH respectively was stirred at 25°C in a thermostat for 6 hr. The solution was then worked up much as in a). The PMR spectra of the resulting syrup was measured without further purification. The values are listed in the Table 4.

Tritylation of III and IV. a) A solution of III (139 mg) in pyridine (0.4 m*l*) was treated with trityl chloride (115 mg) at room temperature. After 2 days, the product was poured onto ice water, and the resulting syrup, separated from water by decantation, was taken up with chloroform. The chloroform solution was then washed with 1N HCl and water. The concentration of the dried solution and the purification of the residue by PTC with the solvent E and by recrystallization from ether gave V (122 mg) as cubics, mp 166—168°C, $[\alpha]_D^{23}$ −8.6° (*c* 0.985). Found: C, 78.20; H, 5.73%; mol wt, 601. Calcd for $C_{39}H_{34}O_9$: C, 78.24; H, 5.72%; mol wt, 599.

b) Needles of VI (40 mg) were obtained from IV

(118 mg) by the same procedure as that above. It had a mp of 195—197°C; $[\alpha]_D^{24}$ −20.4° (*c* 0.992). Found: C, 78.51; H, 5.83%; mol wt, 623. Calcd for $C_{39}H_{34}O_6$: C, 78.24; H, 5.72%; mol wt 599.

Acetylations of III and IV. a) A sample of III (122 mg) was acetylated in a mixture of acetic anhydride (3.0 m*l*) and pyridine (3.0 m*l*) in a refrigerator for 6 hr. The mixture was then poured onto crushed ice and neutralized with an excess of sodium hydrogen carbonate. The solution was extracted with chloroform; the chloroform solution was washed with water, 2N HCl, and water, dried with anhydrous magnesium sulfate and evaporated to a syrup. IIIa (93 mg) was then isolated by PTC with the solvent C; $[\alpha]_D^{24}$ −17.9° (*c* 1.617). Found: C, 66.23; H, 5.75%; mol wt, 411. Calcd for $C_{22}H_{22}O_7$: C, 66.32; H, 5.57%; mol wt, 398.

b) IV (218mg) gave IVa (217mg) as a syrup, $[\alpha]_D^{24}$ −12.1° (*c* 0.810). Found: C, 64.58; H, 5.43%; mol wt, 410.[21] Calcd for $C_{22}H_{22}O_7$: C, 66.32; H, 5.57%; mol wt, 398.

Hydrolysis of III and IV. a) A sample of III (150 mg) was hydrolyzed with 60% acetic acid (15m*l*) at 70°C. After 1.5 hr, the solvent was removed by the addition of an excess of ethanol and by subsequent evaporation. The residual syrup (112 mg) was acetylated with acetic anhydride (1.5 m*l*) and pyridine (1.5 m*l*) in a manner similar to that used for IIIa. The purification of the product by PTC with the solvent C gave IX (83mg) as a syrup; $[\alpha]_D^{23}$ −1.6° (*c* 0.973). Found: C, 57.96; H, 5.68%; mol wt, 401. Calcd for $C_{19}H_{22}O_9$: C, 57.86; H, 5.62%; mol wt, 394.

b) X (152 mg) was obtained from IV (600 mg) by the same work-up as that used for IX. It was a syrup, $[\alpha]_D^{22}$ −15.6° (*c* 0.286). Found: C, 56.17; H, 5.71%; mol wt, 434.[21] Calcd for $C_{19}H_{22}O_9$: C, 57.86; H, 5.62%; mol wt, 394.

Preparation of VIII from VII. A solution of VII (1.10 g) and benzaldehyde (0.55 g) in dioxane (10 m*l*) containing TsOH (0.50 g) was allowed to stand overnight at room temperature. The crystals thus deposited were then fitered. Recrystallization from acetone gave needles (1.2 g) of VIII; mp 207—208°C; $[\alpha]_D^{24}$ −8.0° (*c* 0.747, acetone). Found: C, 62.46; H, 6.74%. Calcd for $C_{16}H_{20}O_6$: C, 62.32; H, 6.64%.

Hydrolysis of VIII. VIII (0.5 g) was treated with 60% acetic acid (5 m*l*) at 70°C for 1.5 hr to yield VII quantitatively.

Acetylation of XI. XI (0.10 g) was not acetylated with acetic anhydride - pyridine or acetic anhydride-sodium acetate at 60°C; XI was thus recovered almost quantitatively.

Methylation of XI. XI (0.78 g) in methyl iodide (50 g) was refluxed for 24 hr in the presence of silver oxide (3.75 g). The cooled solution was filtered, and the filtrate evaporated. The recrystallization of the residue (1.02 g) from ethanol - petroleum ether gave XII (0.55 g) as needles mp 114—116°C, $[\alpha]_D^{23}$ +56.3° (*c* 0.959). Found: C, 68.13; H, 6.03; OCH_3, 8.40%; mol wt, 367. Calcd for $C_{21}H_{22}O_6$: C, 68.09; H, 5.99; OCH_3, 8.40%; mol wt, 370.

Preparation of XII from XIII. A mixture of XIII (98.5 mg),[5] benzaldehyde (10 g), and TsOH (10 mg) was stirred at room temperature. After 7.0 hr, a 2N sodium bicarbonate solution (1 m*l*) was added to the solution, which was then extracted with benzene. The benzene solution was evaporated to give a syrup, which was then purified by PTC using the solvent E. Recrystallization from ethanol gave XII as needles (20.6 mg), mp 114—115.5°C, this substance was found to be identical with XII by a study of the IR spectra, and by thin-layer chromatograms and admixture tests.

Hydrolysis of XII. XII (660 mg) was treated with 60% acetic acid at 50°C for 50 min. The mixture was then diluted with ethanol and evaporated. The resulting syrup (0.55 g) was acetylated in a way similar to that used for IIIa. The syrup (638mg) thus produced was separated into XIV (51 mg) and XV (245 mg) by PTC with the solvent C. The isolated materials were then further purified by recrystallization.

XIV: Needles (15 mg), recrystallized from ether-*n*-hexane; this substance was identified with an authentic sample.[9]

XV: Needles, mp 87.5°C (recrystallized from ethanol; yield, 42mg); $[\alpha]_D^{21}$ +23.5° (*c* 0.970). Found: C, 58.58; H, 5.97%; mol wt, 364. Calcd for $C_{18}H_{22}O_8$: C, 59.01; H, 6.05%; mol wt, 366.

Acetylations of XVII, XVIII, XIX and XX. The acetates, XVIIa, XVIIIa, XIXa and XXa were obtained from XVII, XVIII, XIX and XX, respectively in the same manner as has been described for the preparation of IIIa.

XVIIa: Syrup; $[\alpha]_D^{22}$ −38.6° (*c* 1.083). Found: C, 66.44; H, 5.56%; mol wt, 411. Calcd for $C_{22}H_{22}O_7$: C, 66.32; H, 5.57%; mol wt, 398.

XVIIIa: Needles, mp 144.5−146°C (recrystallized from ethanol); $[\alpha]_D^{22}$ −28.6° (*c* 0.979). Found: C, 66.29; H, 5.55%; mol wt, 412. Calcd for $C_{22}H_{22}O_7$: C, 66.32; H, 5.57%; mol wt, 398.

XIXa: Syrup; $[\alpha]_D^{22}$ +34.4° (*c* 0.987). Found: C, 66.79; H, 5.40%; mol wt, 392. Calcd for $C_{22}H_{22}O_7$: C, 66.32; H, 5.57%; mol wt, 398.

XXa: Needles, mp 136.5—139°C (recrystallized from ether-petroleum ether); $[\alpha]_D^{22}$ +147.1° (*c* 0.961). Found: C, 66.34; H, 5.67%; mol wt, 410. Calcd for $C_{22}H_{22}O_7$: C, 66.32; H, 5.57%; mol wt, 398.

Acetylation of XXIII. a) To a cooled solution (−5—−6°C) of XXIII (387 mg) in pyridine (4 m*l*), acetic anhydride (4 m*l*) was added. After storage in a refrigerator for 16 hr, the mixture was worked up much as IIIa had been to give a syrup (530 mg). From the syrup, XXIV (107 mg) was isolated in a pure state by PTC with the solvent B. Another syrup (160 mg) was obtained which contained mixture of XXVI major and XXV minor.

XXIV: Syrup, $[\alpha]_D^{23}$ −3.3° (*c* 0.859). Found: C, 57.96; H, 5.77%; mol wt, 363. Calcd for $C_{17}H_{20}O_8$: C, 57.95; H, 5.72%; mol wt, 352.

b) XXIII (351mg) was acetylated at room temperature for 16 hr. The resulting syrup (686 mg) was then separated into XXV (39 mg) and XXVI (349 mg) by repeated PTC (first with the solvent B and then with the solvent F.).

XXV: Needles, mp 181—183.5°C (recrystallized from chloroform - petroleum ether; yield, 19 mg), $[\alpha]_D^{23}$ −47.6° (*c* 0.550). Found: C, 57.77; H, 5.76%; mol wt, 373. Calcd for $C_{17}H_{20}O_8$: C, 57.95; H, 5.72%; mol wt, 352.

XXVI: Cubics, mp 75—77°C (recrystallized from

21) It was difficult to analyze correctly, because of its hygroscopic nature. However, the interpretation of the PMR spectrum supported the formula given.

aqueous ethanol; yield, 290 mg); $[\alpha]_D^{24}$ −10.5° (*c* 0.703). Found: C, 58.02; H, 5.64%; mol wt, 402. Calcd for $C_{19}H_{22}O_9$: C, 57.86; H, 5.62%; mol wt, 394. The ORD curve is shown in Fig. 5.

Methylation of XXIV. XXIV (44 mg) was methylated in a way similar to that used for XI. The recrystallization of a crude products (46 mg) gave cubics (9 mg) of XV; mp 87—88°C.

Methylation of XXV. XXV (92.5 mg) was methylated by the same procedure as was used for XI. The recrystallization of the residue (81 mg) gave XXVII (62 mg) as needles, mp 185—186°C; $[\alpha]_D^{23}$ −74.0° (*c* 0.995). Found: C, 59.09; H, 6.02%; mol wt, 364. Calcd for $C_{18}H_{22}O_8$: C, 59.01; H, 6.05%; mol wt, 366.

Preparation of XXVII from II. A mixture of II[19] (3.0 g), benzaldehyde (30 m*l*), and conc. sulfuric acid (0.15 g) was stirred at room temperature for 4 hr. The solution was then neutralized with a 2N K_2CO_3 solution and evaporated to a thick syrup. Methyl 1,3-*O*-benzylidene-α-L-sorbopyranoside[18] (202 mg) isolated as needles by PTC with the solvent *G* (R_f 0.47—0.58), followed by recrystallization from chloroform-ether. It had a mp of 187—188°C, and $[\alpha]_D^{23}$ −55.0° (*c* 0.936); Murphy[18] reported the values of mp 183—184°C and $[\alpha]_D$ −54.6° (*c* 1.06). The crystals (151 mg) were acetylated in the usual manner with acetic anhydride - pyridine. Needles (*c* 161 mg) of XXVII were obtained by recrystallization from ethanol; mp 186—186.5°C.

The authors express their deep gratitude to professor Toshihiko Okamoto, The University of Tokyo, and Dr. Ken'ichi Takeda, Director of this laboratory, for their encouragement. They are also indebted to Drs. Kazuo Tori, Shiroh Satoh and Kaoru Kuriyama for their useful discussions.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 1678—1683 (1969)

Mass Spectrometry of Tautomeric Compounds. I. Absence of Keto-Enol Tautomerism in Fragment Ions

Hisao NAKATA

Department of Chemistry, Aichi Kyoiku University, Daiko-cho, Higashi-ku, Nagoya

and Akira TATEMATSU

Faculty of Pharmacy, Meijo University, Showa-ku, Nagoya

(Received October 18, 1968)

In order to examine a possibility of keto-enol tautomerism in molecular and fragment ions, diethyl di-*n*-butylmalonate (Ia), methyl 2-*n*-butylhexanoate (IIa), and 2,2-di-*n*-propyl-5,5-dimethyl-1,3-cyclohexanedione (IIIa) were synthesized and their mass spectra were compared with those of respective mono-alkyl derivatives, Ib, IIb, and IIIb. The first step of the fragmentation of each dialkyl compounds is the cleavage of one of the alkyl side chains by McLafferty rearrangement to give an enol fragment ion (E). Comparisons of the behavior of this enol fragment ion with that of the corresponding molecular ion (K) of mono-alkyl derivatives indicate that the keto and enol forms of these compounds exhibited entirely different fragmentation patterns. Thus, the enol fragment ion of *m/e* 216 from Ia loses $C_3H_7\cdot$ through the allylic cleavage of an enol double bond to give an abundant *m/e* 173 peak, while the keto ion of *m/e* 216 from Ib loses C_4H_8 to afford a strong *m/e* 160 peak. In a similar manner, the enol fragment ion of *m/e* 130 from IIa gives an intense peak at *m/e* 87, and the keto ion of *m/e* 130 from IIb yields an ion at *m/e* 74. In the spectrum of IIIa, a peak at *m/e* 140 that is observed in the IIIb spectrum did not appear. These results clearly suggest that no keto-enol tautomerism takes place in these ions in a mass spectrometer.

During the course of an investigation of mass spectrometry of barbituric acid derivatives[1] we have found that the keto and enol forms of ethylbarbituric acid showed different fragmentation patterns, and therefore, a suggestion has been made[1] that no keto-enol tautomerism of this compound occurred in a mass spectrometer. We now extended the work to other tautomeric systems to clarify the correlation between mass spectrometry and prototropic rearrangement.

It is possible to produce unstable enol intermediates in a mass spectrometer by utilizing the well-

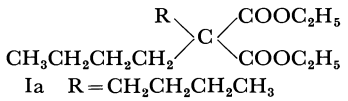
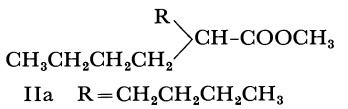
defined McLafferty rearrangement[2-4] of suitably chosen compounds. We have synthesized diethyl di-*n*-butylmalonate (Ia), methyl 2-*n*-butylhexanoate (methyl di-*n*-butylacetate) (IIa), and 2, 2-di-*n*-propyl-5,5-dimethyl-1,3-cyclohexanedione (IIIa), and their corresponding mono-alkyl derivatives (Ib, IIb, and IIIb). The mass spectra of these compounds are shown in Figs. 1—6.

The first step of the fragmentation of these dialkyl compounds is the cleavage of one of the alkyl side chains by the McLafferty rearrangement to give an enol fragment ion, *e.g.*, E. The corresponding ion of the keto form, *e.g.*, K, is identical with the molecular ion of mono-alkyl derivatives. Therefore, if we compare the mass spectral behavior of these enol fragment ions with that of respective mono-alkyl derivatives, it can be seen whether or not the keto-enol tautomerism, E⇌K, takes place in a mass spectrometer.

From spectra shown in Figs. 1 and 2, it is clear that the keto and enol forms of mono-*n*-butylmalo-



Ia R=$CH_2CH_2CH_2CH_3$
Ib R=H



IIa R=$CH_2CH_2CH_2CH_3$
IIb R=H

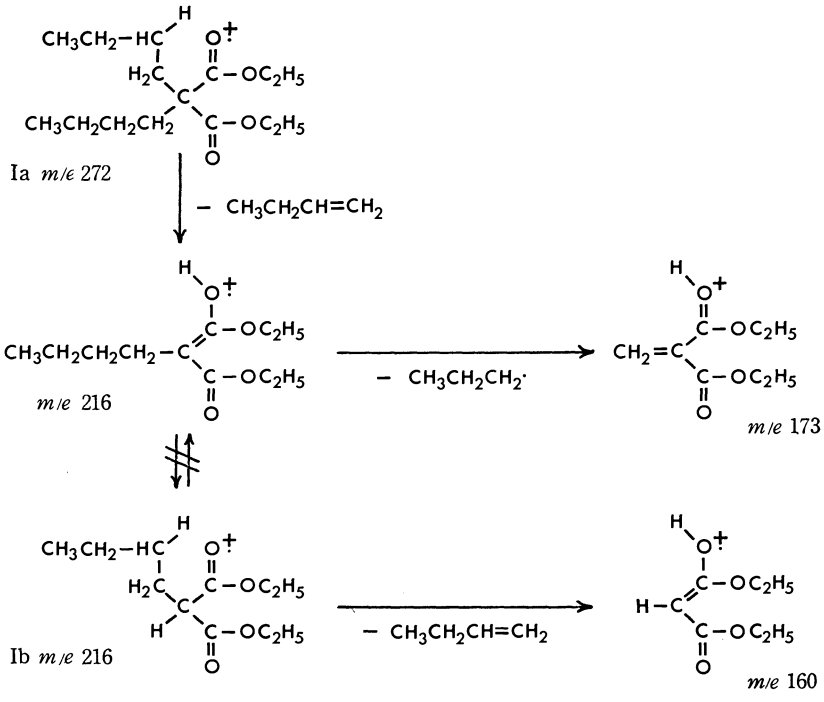

Scheme I

nate exhibited entirely different fragmentation patterns. Thus, the enol fragment ion of *m/e* 216 from di-*n*-butylmalonate (Ia) loses $C_3H_7\cdot$ through the allylic cleavage of an enol double bond to give an abundant *m/e* 173 peak (observed metastable ion peak at *m/e* 138.6), while the keto ion of *m/e* 216 from mono-*n*-butylmalonate (Ib) loses C_4H_8 by the McLafferty rearrangement to afford a strong *m/e* 160 peak. These fragmentations are summarized in Scheme I. Because no common peak of appreciable intensity was observed in these two spectra, it is concluded that the keto-enol tautomerism in these *m/e* 216 ions did not occur in a mass spectrometer.

Moreover, the *m/e* 160 ion from mono-*n*-butylmalonate (Ib) (Scheme I) corresponds to the enol form of diethyl malonate itself. It has already been known that the latter compound shows a very strong peak at *m/e* 115.[5] In Fig. 2, however, no intense peak at *m/e* 115 appeared, and this is consistent with the conclusion for the absence of the keto-enol tautomerism in this case also.

Essentially the same results were obtained with other two pairs of compounds. In the spectrum of methyl 2-*n*-butylhexanoate (IIa) (Fig. 3), the McLafferty rearrangement of the molecular ion gives an enol fragment ion at *m/e* 130, which then affords an intense peak at *m/e* 87 with elimination of $C_3H_7\cdot$ through the allylic cleavage. On the other hand, methyl hexanoate (IIb) (keto form) yields a strong *m/e* 74 peak (Scheme II). A moderately intense peak at *m/e* 87 in IIb probably arises from a fragmentation that is often encountered in long-chain methyl esters,[6] and not from the allylic cleavage of an enol double bond of the ester. From the bond energy considerations[7] the enol form of the ester is very unstable and should rearrange very rapidly to the ordinary ester (keto form), if other factors are not operative. The absence of the *m/e* 74 peak in the IIa spectrum (Fig. 3), therefore, showed that apparently very facile enol→keto tautomerism did not take place at all in fragment ions.

The general features of fragmentation of 2-*n*-propyl-5,5-dimethyl-1,3-cyclohexanedione (IIIb) are in good agreement with those observed for the corresponding 2-ethyl derivative, the fragmentation of which has been discussed in detail on the basis of double focusing technique[8] and deuterium labeling experiments.[9] The only difference in the IIIb spectrum is the appearance of an intense peak at *m/e* 140 (Fig. 6). This peak corresponds to M−42 and should originate from the McLafferty rearrangement of the molecular ion. The 2,2-di-*n*-propyl deriva-

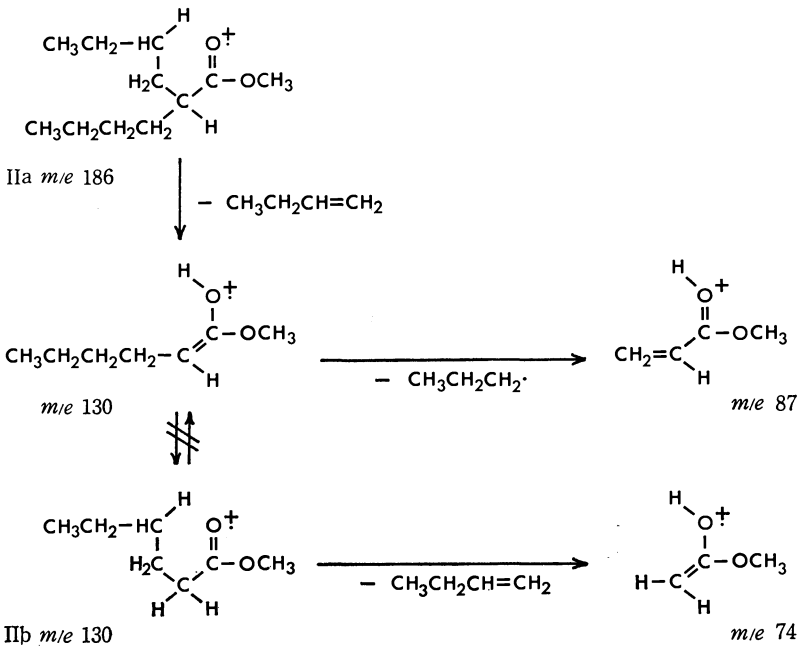
Fig. 4. Mass spectrum of methyl hexanoate (IIb).



Scheme II

tive (IIIa) also exhibited an M−42 peak at *m/e* 182. This ion must be represented as an enol structure because its formation is ascribable to the similar McLafferty rearrangement. If enol→keto tautomerism took place in this *m/e* 182 ion, the 2,2-di-*n*-propyl derivative (IIIa) would have afforded the intense *m/e* 140 peak. Although there are several common peaks in the spectra of IIIa and IIIb, the absence of this double McLafferty rearrangement peak at *m/e* 140 in the IIIa spectrum (Fig. 5) clearly excludes the possibility of keto-enol tautomerism in the *m/e* 182 ions.

In conclusion, we have no evidence for tautomeric changes in the molecular and fragment ions in a

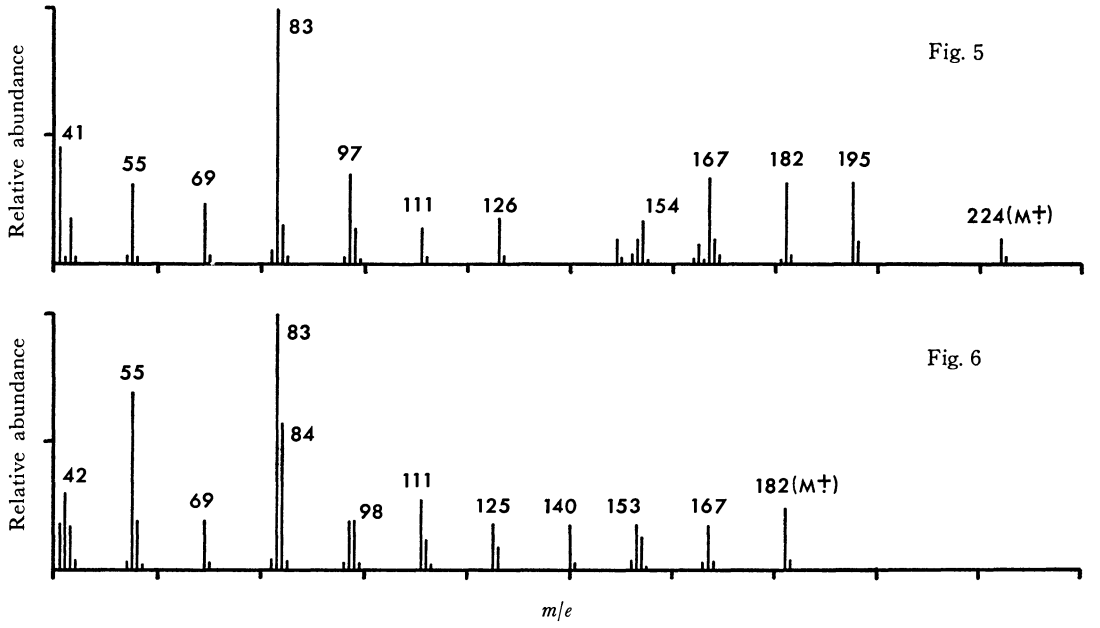


Fig. 5. Mass spectrum of 2,2-di-*n*-propyl-5,5-dimethyl-1,3-cyclohexanedione (IIIa).
Fig. 6. Mass spectrum of 2-*n*-propyl-5,5-dimethyl-1,3-cyclohexanedione (IIIb).

mass spectrometer.[10] From the viewpoint of the quasi-equilibrium theory of mass spectra[11] these results are not unexpected, for the production of ions in a mass spectrometer is usually considered to be a very rapid process and the average life time of ordinary ions is roughly in the range of 10^{-12}—10^{-5} sec.

One corollary from the present results is the argument against the arbitrary postulation for the structure of the molecular ion of tautomeric compounds. The fact that keto and enol forms of a given compound show different fragmentaion patterns should be noted in the formulation of the molecular ion. For the compounds we have examined, the molecular ion seems to have the structure of the most stable form that predominates in solution and in solid state. For other compounds, however, the molecular ion may not necessarily be the same as the most stable structure in solution, because several environmental factors such as hydrogen-bonding and solvation would affect the tautomeric equilibrium in solution. Conversely, the stability of each tautomeric form in gas phase may well be studied by applying the technique of mass spectrometry.

Experimental

The mass spectra were measured with a Hitachi RMU-7 mass spectrometer by using an all-glass inlet system heated at 200°C. The ionizing energy was maintained at 70 eV and the total ionizing current 80 μA. The infrared spectra were recorded with a JASCO model IR-G spectrophotometer. All melting points and boiling points are uncorrected.

Diethyl *n*-Butylmalonate (Ib). Diethyl *n*-butylmalonate (Ib) was prepared from diethyl malonate and *n*-butyl bromide.[12] Bp 128—129°C/20 mmHg. $\nu_{C=O}^{neat}$ 1755, 1736 cm^{-1}.

Found: C, 60.72; H, 9.66%. Calcd for $C_{11}H_{20}O_4$: C, 61.09; H, 9.32%.

Diethyl Di-*n*-butylmalonate (Ia). Diethyl di-*n*-butylmalonate (Ia) was synthesized from 38 g of Ib and 34 g of *n*-butyl bromide in the presence of sodium ethoxide (6 g of sodium in 130 m*l* of ethanol). The procedure was essentially the same as described for alkylation of diethyl methylmalonate with *n*-decyl bromide.[13] The material boiling at 155°C/23 mmHg[14] was collected. Yield 26 g. $\nu_{C=O}^{neat}$ 1730 cm^{-1} (broad).

Found: C, 65.96; H, 10.63%. Calcd for $C_{15}H_{28}O_4$: C, 66.14; H, 10.36%.

Methyl 2-*n*-Butylhexanoate (IIa). Alkaline hydrolysis and subsequent decarboxylation of Ia were carried out in a similar manner as described for the synthesis of 2-methyldodecanoic acid.[13] Re-esterification of the product with methanol afforded IIa. Thus, 38 g of diethyl di-*n*-butylmalonate (Ia) was treated with a solution of 40 g of potassium hydroxide in 200 m*l* of 95% ethanol and the mixture heated at reflux, with

10) A recent report by Djerassi and co-workers also indicated the absence of keto-enol tautomerism in fragment ions. See, J. K. MacLeod, J. B. Thomson and C. Djerassi, *Tetrahedron*, **23**, 2095 (1967).

stirring, for 3 hr. About 10 m*l* of water was added to the refluxed mixture when a white jelly solid appeared during the hydrolysis. About two-thirds of the solvent was removed by distillation, 100 m*l* of water was added, and the solution was acidified, under cooling, with 6 N sulfuric acid to bring the pH of the solution to 1—2. A white, precipitated solid was collected and dissolved in ether, and the aqueous layer was extracted with ether. Combined ether solutions were washed with water and with saturated sodium chloride solution, and dried over anhydrous sodium sulfate. Evaporation of the solvent afforded crystalline di-*n*-butylmalonic acid. This material was carefully heated over its melting point under reflux for 3 hr to perform decarboxylation.

The crude 2-*n*-butylhexanoic acid, after checked by its IR spectrum,[15] was dissolved in 150 m*l* of methanol containing 5 m*l* of concentrated sulfuric acid. The mixture was refluxed for 3 hr, and then 50 m*l* of benzene was added and about 50 m*l* of azeotropic mixture was distilled, and the residue was again refluxed for 1 hr. The esterification was effected by repeating the above procedure three times to remove water produced. Finally the mixture was cooled and poured onto ice-water. The organic phase was separated and aqueous phase was extracted with ether. The organic phase and the ether extracts were combined, washed with sodium bicarbonate solution, and dried over anhydrous sodium sulfate. The solvent was removed and the residue was distilled under reduced pressure. The material boiling at 112—116°C/32 mmHg was collected. Redistillation gave 13 g of pure methyl 2-*n*-butylhexanoate (IIa), bp 108—109°C/25 mmHg.[16] $\nu_{C=O}^{CHCl_3}$ 1739 cm^{-1}.

Found: C, 71.06; H, 11.84%. Calcd for $C_{11}H_{22}O_2$: C, 70.92; H, 11.90%.

Methyl Hexanoate (IIb). The commercially available methyl hexanoate (IIb) was purified by repeated distillation. Bp 148.5°C.

2,2-Di-*n*-propyl-5,5-dimethyl-1,3-cyclohexanedione (IIIa). About 9 g of 5,5-dimethyl-1,3-cyclohexanedione[17] was dissolved in a solution of 5 g of sodium bicarbonate in 200 m*l* of water and 10 m*l* of ethanol. To this solution was added 50 m*l* of allyl bromide and the mixture was refluxed for 5 hr. A sufficient amount of crystalline sodium bicarbonate was added to the reaction mixture for every 30 min during this period in order to maintain the water layer neutral or slightly basic. After cooling, the mixture was extracted with ether and the ether extracts were washed with sodium bicarbonate solution and dried over anhydrous sodium sulfate. Removal of the solvent gave a yellow oil. This material was chromatographed on 150 g of silica gel (40×400 mm column). Elution of the first band with chloroform afforded 12.6 g of 2,2-diallyl-5,5-dimethyl-1,3-cyclohexanedione as colorless needles, mp 65—75°C.[18] $\nu_{C=O}^{CHCl_3}$ 1724, 1693 cm^{-1}. Catalytic hydrogenation of 6.5 g of this 2,2-diallyl derivative in ethanol under atmospheric hydrogen over platinum oxide yielded 6.8 g of a colorless oil. After chromatographed on 150 g of silica gel (40×400 mm column), pure 2,2-di-*n*-propyl-5,5-dimethyl-1,3-cyclohexanedione (IIIa) was obtained. The pure material solidified on cooling, mp 42—43°C. $\nu_{C=O}^{CHCl_3}$ 1721, 1690 cm^{-1}.

Found: C, 74.95; H, 10.96%. Calcd for $C_{14}H_{24}O_2$: C, 74.95; H, 10.78%.

2-*n*-Propyl-5,5-dimethyl-1,3-cyclohexanedione (IIIb). Mono-allylation of 5,5-dimethyl-1,3-cyclohexanedione was conveniently carried out according to the directions of Lukeš and Hofman.[19] 2-Allyl-5,5-dimethyl-1,3-cyclohexanedione was obtained as colorless plates, mp 152—154°C.[18,19] $\nu_{C=O}^{CHCl_3}$ 1739, 1707 cm^{-1}. Catalytic hydrogenation of this 2-allyl derivative and recrystallization of the product from aqueous ethanol gave pure 2-*n*-propyl-5,5-dimethyl-1,3-cyclohexanedione (IIIb) as colorless, flattened needles, mp 167—168°C.[18,20] $\nu_{C=O}^{CHCl_3}$ 1741, 1709 cm^{-1}.

Found: C, 72.28; H, 10.06%. Calcd for $C_{11}H_{18}O_2$: C, 72.49; H, 9.96%.

The authors wish to express their gratitude to Mr. Hideo Yoshizumi of Meijo University for his measurements of mass spectra. This work was supported in part by a grant from the Ministry of Education.

The Addition Reactions of Dialkyl Phosphites to Polyfluorocyclobutenes

Teruo UEDA, Kan INUKAI and Hiroshige MURAMATSU

Government Industrial Research Institute, Nagoya, Kita-ku, Nagoya

(Received October 23, 1968)

The radiation-induced addition reactions of dialkyl phosphites to polyfluorocyclobutenes, such as perfluoro-, 1,2-dichlorotetrafluoro-, 1-chloro-2,3,3,4,4-pentafluoro-, 1,3,3,4,4-pentafluoro- and 1-chloro-3,3,4,4-tetrafluorocyclobutenes were carried out. In general, the corresponding dehydrohalogenated 1 : 1 adducts, polyfluorocyclobutenylphosphonates, were obtained as the main products instead of the expected 1 : 1 adducts. The direction of attack of the phosphonyl radical on the unsymmetrical double bond and reaction mechanism were discussed.

The syntheses of the polyfluorocycloalkenylphosphonates *via* ionic process have been investigated rather extensively. Knunyants and co-workers[1,2] prepared diethyl perfluorocyclobutenylphosphonate by the Arbuzov rearrangement of the phosphorane, which was obtained in the reaction between perfluorocyclobutene and triethyl phosphite. In the reactions between 1,2-dichloroperfluorocycloalkenes and trialkyl phosphites,[3] only the corresponding diphosphonates were obtained and no monophosphonates could be detected, regardless of the order of addition or the ratio of reactants.

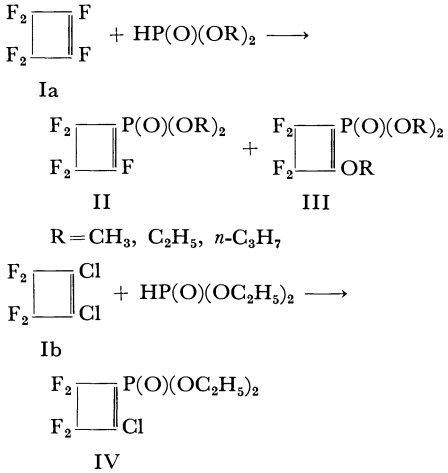
No paper has appeared so far on the syntheses of polyfluorocycloalkenylphosphonates by a free radical-induced addition reaction. As dialkyl chlorofluoroethylphosphonates were found to be produced in moderate yields by the radiation-induced addition reaction of dialkyl phosphites to chlorofluoroethylenes,[4] we extended the addition reaction under γ-ray irradiation to polyfluorocyclobutenes for syntheses of the polyfluorocyclobutyl- or polyfluorocyclobutenylphosphonates.

Results and Discussion

Perfluorocyclobutene (Ia), 1,2-dichlorotetrafluorocyclobutene (Ib), 1-chloro-2,3,3,4,4-pentafluorocyclobutene (Ic), 1,3,3,4,4-pentafluorocyclobutene (Id) and 1-chloro-3,3,4,4-tetrafluorocyclobutene (Ie) were prepared by conventional methods (see Experimental).

A mixture of polyfluorocyclobutene and dialkyl phosphite in a molar ratio of about 1 : 2 in a glass ampoule was irradiated at room temperature for a month. After unchanged reactants were recovered, products were separated by distillation and/or by preparative gas chromatography. The structure of the products was determined by elemental analysis, IR, NMR and mass spectroscopy. The reaction conditions and yields of products are shown in Table 1.

As a whole dehydrohalogenated 1:1 adducts were obtained as the main products instead of the expected simple 1:1 adducts. Addition of the dialkyl phosphites to Ia gave a mixture of dialkyl 2,3,3,4,4-pentafluoro - 1 - cyclobutenylphosphonate (II) and 2 - alkoxy-3, 3, 4, 4-tetrafluoro -1- cyclobutenylphosphonate (III) in total yields of 23—27%. Addition to Ib, however, resulted in only trace amounts of diethyl 2-chloro-3,3,4,4-tetrafluoro-1-cyclobutenylphosphonate (IV), probably due to a steric interaction between the attacking phosphonyl radical and chlorine atoms on the double bond.



In an addition to Ic, IV was also obtained along with III. The absence of II in the products in this case indicates that a phosphonyl radical attacked exclusively on the carbon bearing fluorine. Preferential attack of the phosphonyl radical on the

* Based on the amount of the polyfluorocyclobutenes added.

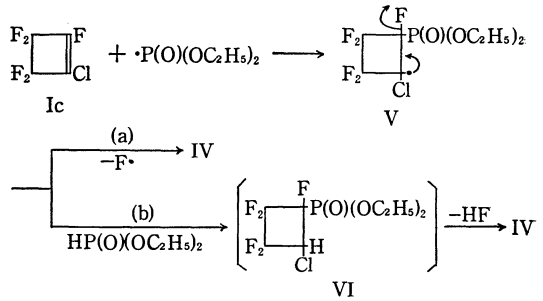
carbon bearing fluorine over on the carbon bearing chlorine of a double bond was observed in the addition to chlorofluoroethylenes.[4] The direction of the radical attack may be explained both by the steric effect and by the stability of an intermediate radical.

The structure of III was confirmed by comparing its IR spectrum with that of an authentic sample, prepared by a reaction of II or IV with alcohol in the presence of potassium hydroxide. Since the dialkyl phosphites produced the corresponding alcohols even at room temperature in the presence of hydrochloric acid or hydrofluoric acid, which was always formed in γ-irradiation of a mixture of the polyfluorocyclobutene and the dialkyl phosphite, III seems to be formed by the reaction of the 1 : 1 adducts, II or IV, with the alcohols. The carbon to carbon double bond of dialkyl polyfluorocyclobutenylphosphonates are known[3] to be reactive toward nucleophiles due to the electron-withdrawing effect of the P=O group.

The reasons why only the dehydrohalogenated 1 : 1 adducts were obtained in the addition to polyfluorocyclobutenes whereas the addition to chlorofluoroethylenes[4] produced the simple 1:1 adducts, may be the steric interaction between the substituted halogens and phosphorus atom, the conjugation of the P=O group with C=C group in the cyclobutenylphosphonates formed, and the instability of the 1 : 1 adducts.

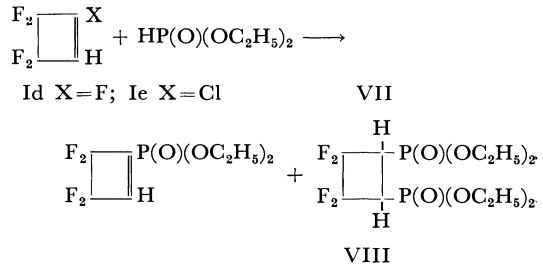
Since a mixture of polyfluorocyclobutene and dialkyl phosphite gave no products upon standing in the dark at room temperature for a month, the reactions under radiation seem to proceed through a free radical mechanism. For formation of II or IV from Ia—c, two routes are conceivable. One of them (a) involves a radical elimination of fluorine from an intermediate radical (V). The other (b) is through formation of an unstable 1:1 adduct (VI), which is supposed to be readily dehydrofluorinated.

There are seveal papers[5] on the chlorine elimination from an intermediate radical in addition reactions, but no example of fluorine elimination has been reported so far except one, in which removal of fluorine by a radical was assumed in a reaction of



perfluorobenzene with trimethylsilane under UV irradiation to explain the formation of pentafluorophenyltrimethylsilane.[6] Although it is difficult to obtain unambiguous evidence, the ionic elimination of hydrogen fluoride from VI seems to be the more probable route for the formation of IV.

Both Id and Ie gave diethyl 3,3,4,4-tetrafluoro-1-cyclobutenylphosphonate (VII) together with the diphosphonate (VIII) in the addition reaction with diethyl phosphite.



Though the directions of phosphonyl radical attack are not clear in these cases, in the addition reaction to 1,1-difluoroethylene the phosphonyl radical was found to attack exclusively on the $=CH_2$ side, yielding diethyl 2,2-difluoroethylphosphonate (IX) and

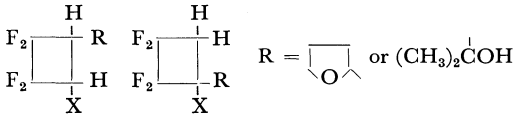
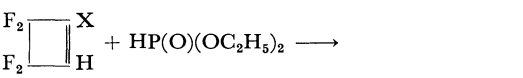
$$+ H(CF_2CH_2)_2P(O)(OC_2H_5)_2 \quad \text{X}$$

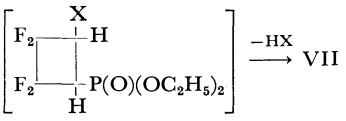
Furthermore, in the addition of tetrahydrofuran and 2-propanol to Id (X=F) and Ie (X=Cl) under similar conditions,[7] the 1 : 1 adduct formed was exclusively XI in the case of Ie and a mixture of two isomers, XI and XII, was obtained in a ratio of about 80 : 20 in the case of Id.



XI XII

From these observations, it may be reasonable to assume that the phosphonyl radical attacked preferentially on the double bond carbon bearing a hydrogen atom and the 1 : 1 adduct (XIII) formed by hydrogen abstraction from diethyl phosphite evolved readily hydrogen halide to give VII. Further addition of diethyl phosphite to VII would produce VIII. This was confirmed by the irradiation of a mixture of VII and diethyl phosphite, which yielded VIII. Dehydrofluorination of VIII with powdered potassium hydoxide gave tetraethyl 2,3,3-trifluoro-1-cyclobutenyl-1,4-diphosphonate (XIV).





XIII

The physical properties and results of analyses of new dialkyl polyfluorocyclobutenylphosphonates prepared are listed in Table 2.

Experimental[8]

Materials. 1,2-Dichlorotetrafluorocyclobutene (Ib) was obtained from the Peninsular ChemResearch, Inc., and used without further purification. Perfluorocyclobutene (Ia)[9] and 1-chloro-2,3,3,4,4-pentafluorocyclobutene (Ic)[10] were prepared by dechlorination with zinc dust from 1,2-dichlorohexafluoro- and 1,1,2-trichloropentafluorocyclobutenes, respectively. 1,3,3,4,4-Pentafluorocyclobutene (Id)[11] was synthesized from 1,2-dichlorohexafluorocyclobutane by reduction with lithium aluminum hydride in dibutyl ether, followed by dehydrofluorination with aqueous potassium hydroxide. 1-Chloro-3,3,4,4-tetrafluorocyclobutene (Ie)[12] was prepared from Ib by reduction with sodium borohydride in diglyme.

Addition Reactions of Dialkyl Phosphites to Perfluorocyclobutene (Ia). A mixture of 85 g (0.62 mol) of diethyl phosphite and 50 g (0.31 mol) of Ia was sealed in a glass tube and irradiated from ^{60}Co to a total dosage of 30.5 MR for a period of 480 hr. Distillation of the irradiation products under reduced pressure and nitrogen atmosphere, after removal of

the unchanged diethyl phosphite and cyclobutene, gave 12.8 g (0.045 mol, 14.8% yield) of diethyl perfluoro-1-cyclobutenylphosphonate (II), bp 73—74°C/1 mmHg, 13.2 g (0.043 mol, 14.0% yield) of diethyl 2-ethoxy-3,3,4,4-tetrafluoro-1-cyclobutenylphosphonate (III), bp 92—95°C/1 mmHg, and 5 g of a tarry material.

Using the same procedures, the addition reactions of other dialkyl phosphites to perfluorocyclobutene were carried out. The irradiation conditions and yields based on the amounts of the cyclobutene charged for each run are shown in Table 1.

Addition Reaction of Diethyl Phosphite to 1-Chloro-2,3,3,4,4-pentafluorocyclobutene (Ic). In a glass tube were sealed 135 g (0.98 mol) of diethyl phosphite and 88 g (0.49 mol) of Ic. After the content in the tube was irradiated to a total dosage 40 MR at room temperature, it was washed with aqueous sodium carbonate to remove the unchanged diethyl phosphite and extracted with ether. Distillation of the extract under reduced pressure and a nitrogen atmosphere gave 12.5 g of diethyl fluorophosphate, bp 75—77°C/45 mmHg,[13] 13.6 g (0.046 mol, 9.3% yield) of diethyl 2-chloro-3,3,4,4-tetrafluoro-1-cyclobutenylphosphonate (IV), bp 77—80°C/1 mmHg, and 15.9 g (0.052 mol, 10.5% yield) of III, bp 92—95°C/1 mmHg.

In a similar way, diethyl phosphite was added to the other polyfluorocyclobutenes, Ib, Id and Ie.

Dialkyl 2-Alkoxy-3,3,4,4-tetrafluoro-1-cyclobutenylphosphonate (III). To 0.7 g (0.013 mol) of potassium hydroxide in 1-propanol in a flask, 3.7 g (0.012 mol) of di-*n*-propyl perfluoro-1-cyclobutenylphosphonate was added. The reaction mixture was stirred at 40°C for 3 hr and, after addition of 50 m*l* of ether, poured into water. The organic layer was separated and distilled to give 2.0 g (0.005 mol, 48% yield) of di-*n*-propyl 2-propoxy-3,3,4,4-tetrafluoro-1-cyclobutenylphosphonate, bp 106—107°C/1 mmHg, whose IR spectrum and retention time of gas chromatogram were identical with those of III ($R=n\text{-}C_3H_7$) obtained in the addition of di-*n*-propyl phosphite to Ia.

Tetraethyl 3,3,4,4-Tetrafluorocyclobutenyl-1,2-diphosphonate (VIII). A mixture of 1.0 g (6 mmol) of diethyl phosphite and 0.5 g (1.9 mmol) of VII was irradiated to a total dosage of 40 MR. After treatment with aqueous sodium carbonate, the irradiation product was extracted with ether and dried. Upon evaporation of ether, there remained 0.65 g (1.5 mmol, 81% yield) of crude tetraethyl 3,3,4,4-tetrafluorocyclobutyl-1,2-diphosphonate, whose IR spectrum was identical with that of VIII produced in the addition of diethyl phosphite to Id or Ie.

Dehydrofluorination of VIII. To 0.5 g (12.5 mmol) of VIII, 0.7 g (12.5 mmol) of potassium hydroxide was added and stirred at room temperature for 2 hr. After addition of 50 m*l* of ether, the reaction mixture was poured into water and the organic layer was separated and dried. Distillation gave 2.7 g (7.1 mmol, 57% yield) of tetraethyl 2,3,3-trifluoro-1-cyclobutenyl-1,4-diphosphonate (XIV), bp 122—125°C/1 mmHg, n_D^{20} 1.4173, d_4^{20} 1.333, $\nu_{C=C}$ 1683 cm^{-1}, $\nu_{P=O}$ 1265 cm^{-1}.

Found: P, 16.4%; mol wt, 380. Calcd for $C_{12}H_{21}F_3O_6P_2$: P, 16.3%; mol wt, 380.

Addition Reaction of Diethyl Phosphite to 1,1-Difluoroethylene. To 138 g (0.1 mol) of diethyl phosphite in an autoclave cooled in a dry ice - acetone bath, 3.2 g (0.05 mol) of 1,1-difluoroethylene was condensed. The mixture was irradiated to a total dosage of 35 MR. Distillation of the irradiation products under reduced pressure and a nitrogen atmosphere gave 6.4 g (0.032 mol, 63.4% yield) of diethyl 2,2-difluoroethylphosphonate (IX), bp 73—76°C/5 mmHg, and 2.0 g (0.008 mol, 15% yield) of diethyl 2,2,4,4-tetrafluorobutylphosphonate (X), bp 100—103°C/1 mmHg. The orientation of the addition was established by means of the NMR spectra[14] of IX and X, which are presented below. The splitting pattern and coupling constants of the protons clearly indicated that the phosphonyl radical attacked the CH_2 group of 1,1-difluoroethylene.

IX: n_D^{20} 1.3990, d_4^{20} 1.194, τ_{CH_3} 8.69 ppm (triplet), J_{CH_3,CH_2} 7.2 cps, $\tau_{\underline{CH_2}CF_2H}$ 7.46 ppm (doublet of triplet), J_{CH_2,CF_2} 19.5 cps, $J_{CH_2,P}$ 4.9 cps, $\tau_{\underline{CH_2}CH_3}$ 5.86 ppm (doublet of quartet), $J_{CH_2,P}$ 8.2 cps, τ_{CHF_2} 3.78 ppm (triplet of quartet), $J_{H,F}^{gem}$ 56.1 cps.

Found: P, 14.9%. MR_D 41.0. Calcd for $C_6H_{13}F_2O_3P$: P, 15.3%; MR_D 40.9.

X: n_D^{20} 1.4002, d_4^{20} 1.287, τ_{CH_3} 8.65 ppm, $\tau_{\underline{CH_2}CF_2H}$ 7.20 ppm, $\tau_{\underline{CH_2}CH_3}$ 5.80 ppm, τ_{CHF_2} 3.72 ppm, $J_{H,F}^{gem}$ 54.3 cps.

Found: P, 11.0%; MR_D 50.2. Calcd for $C_8H_{15}F_4O_3P$: P, 11.6%; MR_D 50.3.

13) The structure was determined by comparing its IR spectrum with that of an authentic sample reported in the literature: L. W. Daasch and D. C. Smith, *Anal. Chem.*, **23**, 853 (1951).

14) The NMR spectra were obtained using a JNM-C-60 high resolution spectrometer (60 Mc for ^1H and 56.4 Mc for ^{19}F).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 1688—1693 (1969)

Polymerization of Formaldehyde in Liquid Carbon Dioxide. I. The Cause of the Polymerizability of the Monomer

Tsutomu KAGIYA, Masatsune KONDO,*1 Kōzō NARITA and Kenichi FUKUI

Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received November 4, 1968)

The cause of the polymerizability of formaldehyde in liquid carbon dioxide was studied in connection with the preparation conditions of the monomer. A liquid carbon dioxide solution of the monomer was prepared by two different methods, by means of the pyrolysis of α-polyoxymethylene and by means of that of the hemiformal of polyethylene glycol, under a carbon dioxide stream. By adding various sodium salts to the pyrolysis system of α-polyoxymethylene, the polymerization rate, without the addition of any catalyst, of the monomer thus obtained was found to decrease with an increase in the pK_a value of the conjugated acid of the salt. The polymerization rate also decreased with the amount of sodium carbonate added. The hemiformal of polyethylene glycol was prepared by bubbling the gas evolved by the pyrolysis of paraformaldehyde into polyethylene glycol. The amount of acid present in the hemiformal thus obtained increased linearly with the pyrolysis time. The polymerization rate of the monomer obtained by the pyrolysis of the hemiformal increased in proportion to the acid content in the hemiformal. On the basis of these results, the initiation mechanism in the polymerization of formaldehyde without any additional initiator in a liquid carbon dioxide solution was discussed.

In respect to the polymerization of formaldehyde, many papers have been reported. It is well known that formaldehyde is so reactive that it can be polymerized easily by the initiating action of an impurity in a monomer solution, even at the temperature of −78°C.[1] For this reason, little reproducibility of experimental results is observed in the polymerization. Little attention has, however, been paid to the cause of this phenomenon.

The present authors have already reported that the polymerization rate of formaldehyde is remarkably retarded by the addition of carbon dioxide,[2] and that reproducible results can be obtained in a formaldehyde polymerization in a liquid carbon dioxide solution.[3,4]

As has previously been reported, a liquid carbon dioxide solution containing 60 wt% of monomer is obtained when α-polyoxymethylene is pyrolyzed under a carbon dioxide stream and the mixed gas thus obtained is cooled at −78°C.[3]

In the present paper, the cause of the polymerizability of formaldehyde in this solution will be studied quantitatively in connection with the preparation conditions of the monomer solution; the initiation mechanism in the polymerization of formaldehyde without any additional initiator will also be discussed.

Experimental

Materials. Commercially available α-polyoxy methylene (α-POM; the degree of polymerization *ca.* 100) and paraformaldehyde (paraform; the degree of polymerization is from 10 to 100) are used without further treatment. The calcium carbonate, sodium carbonate, sodium hydroxide, sodium acetate, sodium sulfate, sodium cyanide, and sodium chloride were commercially obtained. Commercial polyethylene glycol (PEG; average molecular weight is 380 to 420) was used after removing a volatile fraction of PEG by heating it at 200°C for one hour under normal pressure. Commercial carbon dioxide was dried by passing it through two drying tubes packed with phosphorus pentoxide.

Preparation of Monomer. *Direct Method by the Pyrolysis of α-POM.* The monomer was prepared directly by the pyrolysis of α-POM. 100 g of α-POM or a mixture of 100 g of α-POM and a measured amount of various sodium salts was put into a 300 ml decomposer (A) and then decomposed by heating at 150 to 180°C under a carbon dioxide stream (flow rate: 160 ml/min) (Fig. 1.1). The resulting mixture of formaldehyde and carbon dioxide was condensed in the monomer reservoir (B) at −78°C. The solution thus obtained was homogeneous and contained 59 to 61 wt% of the monomer and 39 to 41 wt% of carbon dioxide.

Two-steps Method by Pyrolysis of the Hemiformal of PEG. The hemiformal was prepared by the reaction of PEG with the monomer produced by pyrolyzing paraform

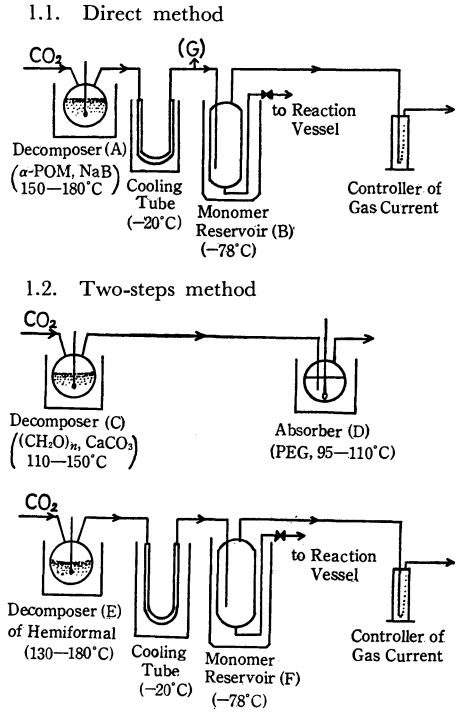

Fig. 1. Preparation apparatus of the carbon dioxide solution of formaldehyde.

(Fig. 1.2). 500 g of the paraform and a measured amount of the additive were placed in a 1000 m*l* decomposer (C) and decomposed by heating at 110 to 150°C under a carbon dioxide stream (flow rate: 160 m*l*/min). The mixed gas thus obtained was then introduced into a 1000 m*l* absorber (D) (95—110°C) containing 500 g of PEG to give the hemiformal. The formaldehyde content in the hemiformal was found to be *ca.* 25 wt%.

The monomer was prepared by the pyrolysis of the hemiformal (Fig. 1.2). 500 g of the hemiformal were put into a 1000 m*l* decomposer (E) and pyrolyzed at 130 to 180°C under a carbon dioxide stream (flow rate: 160 m*l*/min). The resulting mixture of formaldehyde and carbon dioxide was passed through a tube cooled at −20°C and then liquefied in the monomer reservoir (F) at −78°C.

Polymerization Procedure. A stainless-steel autoclave with a capacity of 30 m*l* (16 mmϕ × 150 mm) was used as the reaction vessel. Into the vessel, which has been degassed *in vacuo* and cooled with liquid nitrogen, 10 m*l* of a carbon dioxide solution of formaldehyde was charged; this solution was maintained at 20±1°C for one hour. After the polymerization, the unreacted monomer and carbon dioxide gas were purged out. The white powdery polymer thus obtained was washed sufficiently with cooled diethyl ether, dried *in vacuo* at room temperature, and weighed.

Analysis. *Measurement of the Acid Content in the Hemiformal of PEG.* 10 m*l* of a 0.1 N NaOH aqueous solution was added to 10 m*l* of the hemiformal, and the excess of sodium hydroxide was titrated with a 0.1 N HCl aqueous solution using phenolphthalein as the indicator.

Measurement of the Number-average Degree of polymerization of the Polymer. The inherent viscosity measurement of a solution containing 0.5 g of the polymer in 100 m*l* of *p*-chlorophenol containing 2% of α-pinene was carried out with the use of an Ostwald viscometer at 60°C. The number-average degree of polymerization of the polymer was calculated by the following equation.[3]

$$\eta_i = 2.14 \times 10^{-2} \bar{P}_n^{0.61} \quad (1)$$

Measurement of the Adsorption of Acid by Sodium Salts. A measured amount of sodium salt was added to a PEG solution containing a measured amount of formic acid. After the solution had been kept standing for one hour at room temperature, 10 m*l* of this PEG solution was titrated back with a 0.1 N HCl aqueous solution.

Gas Chromatographic Analysis of the Impurities Involved in the Monomer. The impurity content in the gas produced by the pyrolysis of α-POM was determined by gas chromatography (Yanagimoto, Type GCG-3D) using a diglycerol column. The gas sample was collected in a micro-syringe from a side arm (G) (*cf.* Fig. 1.1) through a rubber stopper.

Results and Discussion

Polymerizability of the Monomer Obtained by the Pyrolysis of α-POM with the Addition of Various Sodium Salts. The polymerizability of the monomer obtained by the pyrolysis of a mixture containing 0.1 mol of sodium salts of various Brönsted acids in 100 g of α-POM was studied without any additional initiator. As shown in Fig. 2, the

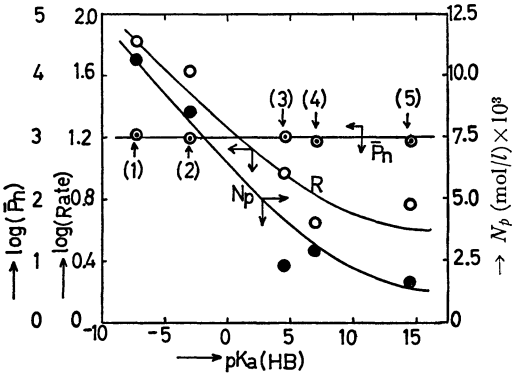

Fig. 2. Influence of pK_a of conjugated acid of sodium salts on the polymerization rate (R), the degree of polymerization ($\bar{P}_n$) and the number of moles of polymer chain (N_p). Pyrolysis condition: temperature, 150—180°C; time, 90 min; sodium salt/α-POM, 0.1 mol/100 g; Polymerization condition: temperature, 20°C; time, 60 min; monomer content, 60 wt-%; (1) NaCl, (2) Na_2SO_4, (3) $NaOCOCH_3$, (4) Na_2CO_3, (5) NaOH.

polymerization rate of the monomer thus obtained edcreased rapidly with an increase in the pK_a of the conjugated acid (HB) of sodium salt (NaB); the rate was almost constant above a pK_a of *ca.* 7. On the other hand, the degree of polymerization of the

polymer was not affected by the addition of sodium salts. The number of moles of the polymer chain of the resulting polymer, which was defined as the ratio of the polymer yield (polymerized monomer mol/unit volume of reaction vessel) to the number-average degree of polymerization, was plotted against the pK_a, as shown in the same figure. The number of moles of the polymer chain also decreased with an increase in the pK_a of acid, almost reaching a constant above a pK_a of *ca.* 7. These results suggest that the quantity of initiating species decreases with an increase in the pK_a. Therefore, the decrease in the polymerizability of the monomer may be ascribed to the decrease in the amount of the initiator. These results lead to the conclusion that the polymerization is initiated by an acidic substance present in the monomer. In order to confirm the role of sodium salt, the adsorption of acids, such as formic acid, by sodium salt was examined. The amount of the acid adsorbed by sodium salt increased with an increase in the pK_a of the conjugated acid of the salt, as is shown in Fig. 3.

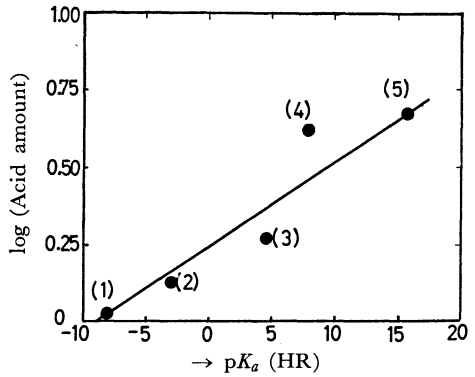

Fig. 3. Relationship between the amount of acid adsorbed by the salt and pK_a of conjugated acid of sodium salt. Formic acid content, 1.18 mol/*l* in PEG solution; reaction time, 1 hr; temperature, 20°C; (1) NaCl, (2) Na_2SO_4, (3) $NaOCOCH_3$, (4) Na_2CO_3, (5) NaOH.

From these results, it may be concluded that the sodium salt catches the Brönsted acid in the monomer, the polymerizability of the monomer was ascribed to the acid content of the monomer solution.

Effect of the Addition of Sodium Carbonate on the Pyrolysis of α-POM. As has been described above, the polymerizability of the monomer obtained by the pyrolysis of α-POM in the presence of sodium salts varied with the kind of sodium salts, and a remarkably depressing effect of the polymerizability was observed in the case of the addition of sodium carbonate. When the monomer was prepared by the pyrolysis of α-POM containing 0 to 10 wt% of sodium carbonate, the effect of the sodium carbonate content on the polymerizability of the monomer was examined.

As is shown in Fig. 4, both the polymerization rate and the number of moles of the polymer chain of the resulting polymer decrease with an increase in the amount of sodium carbonate, while the degree of polymerization is hardly affected by sodium carbonate. These findings indicate that the quantity of initiating species in the monomer decreases upon the addition of sodium salts.

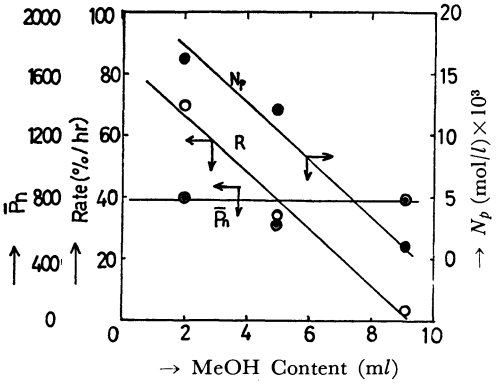

Fig. 4. Influence of the amount of sodium carbonate in decomposer (A) on the polymerization rate (R), the degree of polymerization ($\bar{P}_n$) and the number of moles of polymer chain (N_p). Pyrolysis and polymerization condition: the same condition as in case of Fig. 2.

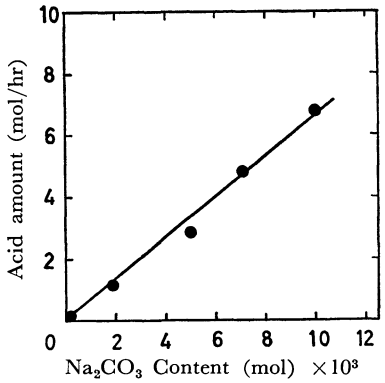

Fig. 5. Relationship between the amount of acid adsorbed by the salt and the amount of sodium carbonate. Formic acid content, 0.25 mol/*l*; reaction time, 1 hr; temperature, 20°C.

In order to make sure of the role of sodium salt, the ability of sodium carbonate to adsorb formic acid was also examined. As Fig. 5 shows, the amount of formic acid adsorbed by sodium carbonate increases proportionally with the amount of sodium carbonate.

These results are in accordance with the above finding that the polymerization caused by Brönsted acid is retarded by the adsorption of acid upon the addition of sodium salt.

Effect of the Impurities Present in the Monomer Gas on the Monomer Polymerizability. Gas chromatographic analysis of the pyrolyzed gas in the absence of sodium salts showed that the monomer contained methanol (0.45 mol%), water (0.35 mol%), and methyl formate (0.01 mol%) as impurities. In order to determine the influence of these impurities on the polymerization, the polymerizability of the monomer was examined in the presence of such additives as formic acid, methanol, water and methyl formate.

The results are shown in Table 1. Methyl formate had no influence on the polymerization, while water or methanol depressed the degree of polymerization but had no influence on the polymerization rate. On the other hand, both the polymerization rate and the degree of polymerization increased upon the addition of formic acid. These results show that formic acid acts as an initiator, while water and methanol act as chain transfer agents in the polymerization.

Table 1. Influence of substances contained in the gas obtained by the pyrolysis of α-POM on the monomer polymerizability

Substance	Rate (%/hr)	$R-R_0$ (%/hr)	$\bar{P}_n \times 10^2$	$N_p \times 10^3$ (mol/l)
Formic acid	21.9	18.4	20.0	3.8
Methanol	5.9	2.4	3.5	4.1
Methyl formate	5.2	1.7	5.9	1.8
Water	3.5	0	2.8	3.2
No additive	3.5	0	5.1	1.5

Polymerization condition: temperature 20°C, time 1 hr, substance/monomer (mole ratio) = 1/1000, R_0 is polymerization rate without any additive.

Formation of Acid. In order to clarify the acid formation quantitatively, the influence of the pyrolysis time and that of the addition of water on the acid formation in the pyrolysis of paraform were investigated.

As Fig. 6 shows, the amount of acid in the hemiformal thus prepared increased linearly with the pyrolysis time of the paraform. This indicates that the acid is not contained in paraform as an impurity, but is produced by a side reaction in the course of pyrolysis. In addition, the amount of acid also increased linearly with the amount of water added. From these results, it may be considered that formaldehyde reacts with water as in Eq. (2) and produces the equivalent mole of formic acid and methanol;

$$2CH_2O + H_2O \rightarrow HCOOH + CH_3OH \qquad (2)$$

According to these results, it may be concluded that the polymerization is initiated mainly by the formic acid produced by the reaction of formaldehyde with the water which is originally present in the paraform used.

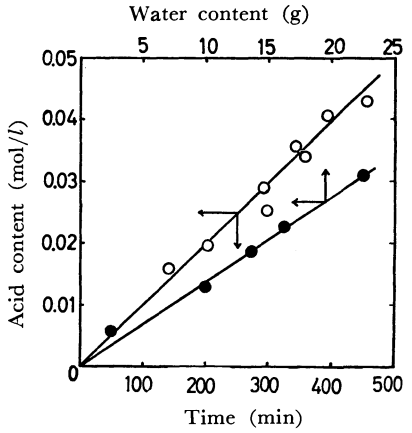

Fig. 6. Influence of the pyrolysis time and of the addition of water on the acid content of the hemiformal. Preparation condition: temperature, 95—115°C; PEG/paraform (weight ratio) = 1; $CaCO_3$/paraform (weight ratio) = 1; pyrolysis time, 110—150 min. (●).

Influence of the Acid Content in the Hemiformal on the Monomer Polymeizability. The monomer polymerizability was studied in connection with the acid content in the hemiformal. Hemiformals containing different amounts of acid were prepared by varying the pyrolysis time of the paraform or by adding different amounts of calcium carbonate to the paraform.

It was found that the polymerization rate increased linearly with the acid content in the hemiformal (Fig. 7). From this, it may be concluded that the polymerization is initiated by formic acid as in Eq. (3) and that the monomer polymerizability depends on the amount of acid in the monomer.

$$HCOOH + CH_2O \rightarrow HOCH_2{}^{\delta+}\cdots{}^{\delta-}OCH \qquad (3)$$
$$\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\quad \| \; O$$

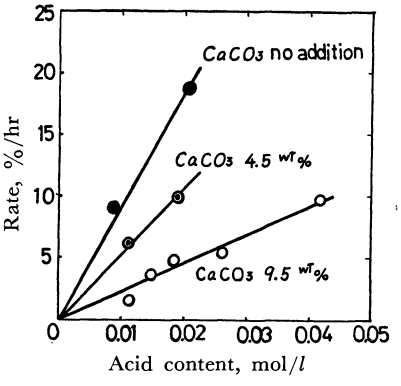

Fig. 7. Influence of the acid content of the hemiformal on the polymerization rate. Hemiformal preparation condition: the same condition as in case of Fig. 6; polymerization condition: the same condition as in case of Fig. 2.

On the other hand, straight lines with slopes differing with the amount of calcium carbonate were observed. That is, when a large amount of calcium carbonate was added to the paraform in the hemiformal preparation step, a great decrease in the polymerization rate was observed in spite of the higher acid content in the hemiformal.

In order to study the cause of this, hemiformals containing almost the same acid content (0.01 mol/*l*) were prepared by adding different amounts of calcium carbonate; the monomer polymerizability was then examined by the use of the monomer obtained by the pyrolysis of these hemiformals. As is shown in Fig. 8, both the polymerization rate and the

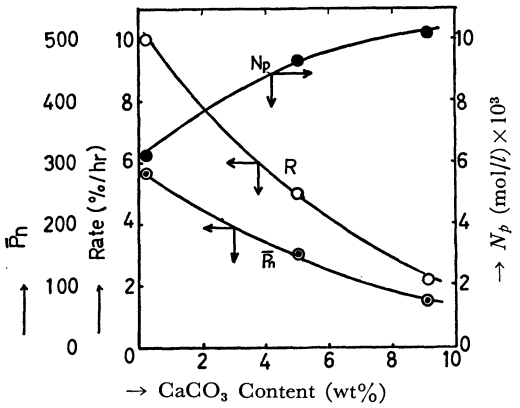

Fig. 8. Influence of the amount of calcium carbonate in the hemiformal preparation step on the polymerizability of monomer obtained by the pyrolysis of the hemiformals of the same acid content (0.01 mol/*l*).

degree of the polymerization of the resulting polymer decrease with an increase in the calcium carbonate content in the hemiformal preparation step, while the number of moles of the polymer chain increases.

This indicates that when hemiformals with the same acid content are prepared, the amount of a substance which acts as both a retarding and a chain transfer agent in the hemiformal may increase with the calcium carbonate content in the hemiformal preparation step. On the other hand, methanol content in the hemiformal may increase with the calcium carbonate content, because the pyrolysis time must be long when the calcium carbonate content is large.

Influence of the Addition of Methanol to the Hemiformal on the Monomer Polymerizability. Methanol may be considered to react with formic acid in the hemiformal pyrolysis step. From this, it may be supposed that methanol acts as both a retarding and a chain transfer agent.

In order to determine the influence of the methanol in the hemiformal pyrolysis step on the monomer polymerizability, methanol was added to a hemiformal containing 0.13 mol/*l* of the acid; the

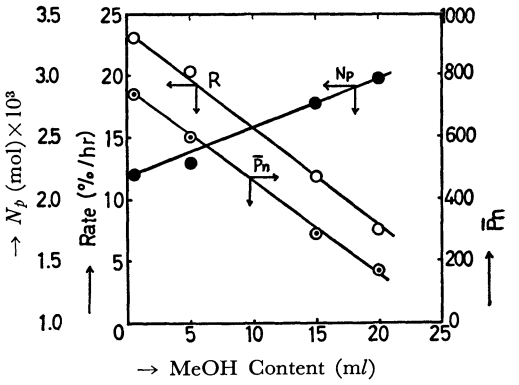

Fig. 9. Influence of the amount of methanol contained in the hemiformal on the rate of polymerization, the degree of polymerization and the number of moles of polymer chain. The hemiformal preparation condition: temperature, 100–115°C; time, 70 min; $CaCO_3$/paraform (weight ratio) = 0.1; acid content of the hemiformal, 0.3 mol/*l*.

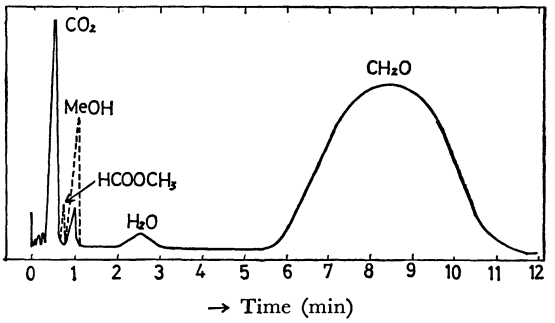

Fig. 10. Gas chromatography of the gas obtained by pyrolyzing the hemiformal. Pyrolysis condition: temperature, 135°C; measurement condition of gas chromatography: temperature, 120°C; carrier gas, He (74 ml/min); column, diglycerol.

polymerizability of the monomer obtained by the pyrolysis of these hemiformals was then examined. As Fig. 9 shows, both the polymerization rate and the degree of polymerization of the resulting polymer decreased proportionally with the amount of methanol added to the hemiformal, while the number of moles of the polymer chain increased.

On the other hand, from the results of the gas chromatographic analysis of the gas obtained by the pyrolysis of the hemiformal (Fig. 10), it was found that the amount of methyl formate formed increased with the amount of methanol in the hemiformal.

From these results, it may be concluded that methyl formate is produced by the reaction of methanol with formic acid present in the hemiformal during the course of the pyrolysis, and that the monomer polymerzability decreases in consequence of the decrease in the acid content of the monomer.

This is in accordance with the facts that both the polymerization rate and the degree of polymerization decrease, while the number of moles of the polymer chain of the polymer increases, with the amount of methanol in the hemiformal.

On the basis of these results, it may be concluded that, in the hemiformal preparation step, the addition of calcium salt to the paraform causes a decrease in the amount of an initiator (acid) in the hemiformal because of adsorption with the salt, and that then, in the hemiformal pyrolysis step, the addition of methanol to the hemiformal causes a decrease in the acid content of the monomer by means of a reaction with the alcohol.

Syntheses of Pterocarpans. III.*1 Synthetic Analogues of Neodulin*2

Kenji FUKUI, Mitsuru NAKAYAMA and Teruo HARANO

Department of Chemistry, Faculty of Science, Hiroshima University, Higashi Sendamachi, Hiroshima

(Received November 4, 1968)

4',5'-Dimethoxy-2'-hydroxyfurano[3'',2'':6,7]isoflavone was obtained from isoelliptol isoflavone by selective demethylation with boron tribromide. The treatment of the 2'-hydroxyisoflavone with sodium borohydride in absolute alcohol - tetrahydrofuran afforded 8,9-dimethoxyfurano[3',2':2,3]pterocarpan. 8,9-Dimethoxyfurano[2',3':3,4]pterocarpan was prepared from elliptol isoflavone by a similar procedure.

(−)-Neodulin was isolated from *Neorautanenia edulis* C. A. Sm. by Van Duuren.[1] Its structure was identified as 8,9-methylenedioxyfurano[3',2':2, 3]pterocarpan (I) on the basis of degradative studies and the results of spectral analyses. Recently, I was derived from dehydroneotenone (II), a naturally-occurring furano[3'',2'':6,7]isoflavone, by Brink *et al.*;[2] further the present authors achieved the total syntesis of II.[3] These facts confirmed the chemical structure of neodulin to be I. An analogue of I containing *ortho*-dimethoxyl groups instead of a methylenedioxy group, 8,9-dimethoxyfurano[3',2':2,3]pterocarpan (III), is a commonly-occurring type in coumestans and rotenoids. The present paper will describe the synthesis of III by a modification of the procedure reported earlier.[4,5]

The selective demethylation of dihydroisoelliptol isoflavone (2',4',5'-trimethoxy-4'',5''-dihydrofurano[3'',2'':6,7]isoflavone (IV)[6] with either boron tribromide or anhydrous aluminum chloride in acetonitrile[4,7] afforded 4',5'-dimethoxy-2'-hydroxy-4'',5'' - dihydrofurano[3'',2'':6,7] isoflavone (V), which then gave a mono-acetate by the usual method. The reduction of the 2'-hydroxydihydroisoflavone V with sodium borohydride in absolute alcohol - tetrahydrofuran, followed by cyclization with hydrochloric acid, gave 8,9-dimethoxy-4',5'-dihydrofurano[3',2':2,3]pterocarpan (VI). The dehydrogenation of the dihydrofuranoisoflavone IV with 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (D. D.Q.) or with 10% Pd-C gave isoelliptol isoflavone (2', 4', 5' - trimethoxyfurano[3'', 2'':6,7]isoflavone) (VII), which had been previously obtained from IV with *N*-bromosuccinimide.[6] By a procedure similar to that used for IV, VII gave the desired furanopterocarpan III *via* 4',5'-dimethoxy-2'-hydroxyfurano[3'',2'':6,7]isoflavone (VIII). The catalytic hydrogenation of III afforded dihydrofuranopterocarpan VI.

8, 9 - Dimethoxyfurano[2', 3', : 3, 4] pterocarpan (IX), an isomer of III, was also obtained from elliptol isoflavone (X)[8] *via* 2'-hydroxy-4',5'-di-

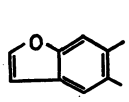
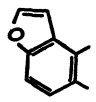
The NMR spectra of the two isomeric furanopterocarpans, III and IX, and the dihydrocompound VI are shown in Figs. 1—3 and Table 1.*3 In the spectra of these compounds the signals at δ 3.2—4.5 (3H, complex multiplets) and at δ 5.3—5.7 (1H, multiplet) can be assigned to the C-6 and C-6a, and the C-11a protons, respectively; the signals are fully consistent with the formulation of the pterocarpan system on the basis of the analyses previously reported.[4] Furthermore, a set of one-proton signals at δ 6.80 and 6.48 (each, 1H, singlet) in the spectrum of III (Fig. 1), which closely resemble those in the spectra of VI and IX, can be assigned to the aromatic protons at C-7 and C-10 respectively. The remaining two signals, those of aromatic protons at δ 7.70 (1H, singlet) and 7.07 (1H, doublet, J=1 Hz), can be attributed to the protons at C-1 and C-4 respectively in view of their small coupling constants.[10] However, in the spectrum of IX, the corresponding signals were found at δ 7.43 (1H, doublet) and 7.16 (1H, broad doublet) and formed an AB-type (J_{AB}=8.5 Hz), indicating that the two protons are oriented in *ortho* positions (C-1 and C-2) to one another. These facts show that the structures



(A)



(B)

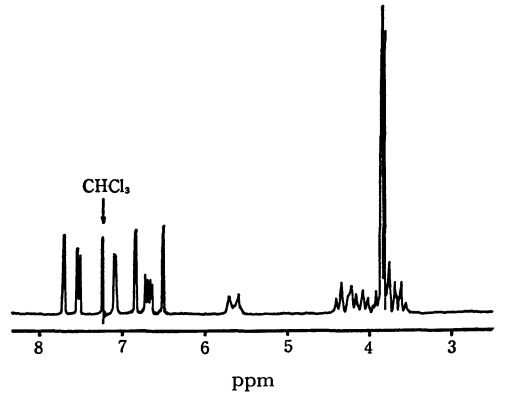


Fig. 1. NMR spectrum of III.

of III and IX belong to the linear ring system (A) and the angular ring system (B) respectively. From these results, it is apparent that the linear or angular pattern of furanopterocarpans can be determined easily by analyzing the NMR pattern of the aromatic protons of the A-ring. A long-range coupling is observed between the aromatic proton at C-4 or C-2 (broad singlet) and the β-furano-proton at C-4' (double doublet or broad singlet) in the

furanopterocarpans, III and IX. Similar observations have been reported in several earlier reports.[11] This phenomenon also appears as a double doublet at the C-4″ proton of acetyl derivatives of the furanoisoflavones, VIII and XI.

The ultraviolet spectra of the furanopterocarpan, III, and its dihydro compound, VI, are shown in Fig. 4. The former contains two absorption maxima, at *ca.* 25 mμ and at *ca.* 300 mμ, while the latter contains only one maximum, at *ca.* 300 mμ. The strong absorption in the region *ca.* 250 mμ is characteristic of the benzofuran grouping, as has previously been noted by the present authors and by others.[3,12]

Experimental*5

4′,5′-Dimethoxy-2′-hydroxy-4″,5″-dihydrofurano-[3″,2″:6,7]-isoflavone (V). *a) With Boron Tribromide.* A solution of boron tribromide in anhydrous methylene chloride (5 ml) was added, at room temperature, to a solution of the isoflavone IV[6] (1.0 g) in the same solvent (200 ml), and then allowed to stand overnight in the dark. After the solution had been poured into water, the separated solid was collected and washed with water. The product was recrystallized from ethanol to give V as light yellow needles; mp 204—205°C; yield, 0.8 g. It showed a negative ferric chloride reaction. IR: 1623 cm^{-1} (C=O). UV: λ_{max} mμ (log ε); 264 (3.92), 306 (4.10).

Found: C, 66.96; H, 4.81%. Calcd for $C_{19}H_{16}O_6$: C, 67.07; H, 4.75%.

b) With Aluminum Chloride. A mixture of IV (1.2 g) and anhydrous aluminum chloride (4.0 g) in anhydrous acetonitrile (30 ml) was refluxed for 12 hr. The solvent was removed as far as possible, and then the residue was treated with 10% hydrochloric acid. The separated solid was collected, washed with water, and recrystallized from ethanol to give V, mp 203—204°C, which was identical with the sample obtained in a); yield, 1.05 g.

The acetate: hot acetic anhydride - anhydrous sodium acetate method; mp 196—197°C (colorless needles from ethanol). IR: 1752, 1643 cm^{-1} (C=O). UV: λ_{max}

8,9-Dimethoxy-4',5'-dihydrofurano[3',2':2,3]-pterocarpan (VI). A solution of sodium borohydride (600 mg) in absolute ethanol (15 m*l*) was added, drop by drop, to a solution of the above isoflavone V (500 mg) in anhydrous tetrahydrofuran (80 m*l*). The reaction mixture was then kept for 60 hr at room temperature while being stirred. After acetone (20 m*l*) had been added to decompose the excess reducing agent, the solvent was removed under reduced pressure. The residue was treated with 10% hydrochloric acid, and then the separated solid was collected, washed with water and recrystallized from ethanol to give VI as colorless plates; mp 174—175°C; yield, 400 mg. IR: 1624, 1598, 1498 cm^{-1} (phenyl). UV: λ_{max} mμ (log ε); 294 (4.19), 298 (4.19); ($CHCl_3$) 299.5 (4.08).

Found: C, 69.92; H, 5.51%. Calcd for $C_{19}H_{18}O_5$: C, 69.92; H, 5.56%.

Isoelliptol Isoflavone (2',4',5'-Trimethoxyfurano-[3'',2'':6,7]isoflavone) (VII). *A) With* 10% *Pd-C.* A mixture of IV (1.7 g) 10% palladium-charcoal (300 mg), and diphenyl ether (30 m*l*) was refluxed for 12 hr. The catalyst was then filtered off, and the solvent removed by steam distillation. The resulting precipitate was collected and recrystallized from ethanol to give VII as colorless needles; mp 191—192°C (lit. mp 190—190.5°C[6]; mp 191°C[13]); yield, 1.0 g. This was identical with an authentic sample obtained from IV by the *N*-bromosuccinimide method.[6]

b) With D.D.Q. A mixture of IV (1.0 g), 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (700 mg), and absolute benzene (70 m*l*) was refluxed for 20 hr. After the solution had then been cooled, the precipitated hydroquinone derivative was filtered off and the solvent was removed as far as possible. The residual solid was recrystallized from ethanol to give a mixture of two compounds as colorless needles; mp 190—199°C; yield, 700 mg. The mixture (500 mg) was chromatographed on a silica gel column (12 g); subsequent elution with chloroform - *n*-hexane gave the desired isoflavone, VII (mp 190—191°C), which was identical with the sample derived by the above-described method; yield, 100 mg. Further elution with the same solvent gave the starting isoflavone, IV (mp 200—201°C; 400 mg).

3',4'-Dimethoxy-2'-hydroxyfurano[3'',2'':6,7]isoflavone (VIII). A mixture of VII (500 mg), boron tribromide (130 mg), and methylene chloride (20 m*l*) was treated by a method similar to that used for IV. The crude product was recrystallized from ethanol to give VIII as light yellow needles; mp 212—213°C (lit,[13] mp 200—201°C); yield, 400 mg. This was identical with an authentic sample obtained from VII by the aluminum chloride - acetonitrile method.[13] IR: 1620 cm^{-1} (C=O). UV: λ_{max} mμ (log ε); 239 (4.56), 260$_{sh}$*6 (4.36), 304 (4.15).

The acetate: hot acetic anhydride - anhydrous sodium acetate method; mp 216—217°C (colorless needles from ethanol). IR: 1745, 1643cm^{-1} (C=O). UV: λ_{max} mμ (log ε); 239 (4.53), 306 (4.02). NMR:*3,4 δ 8.55$_s$ (C-5); 7.94$_s$ (C-2); 7.59$_{bs}$ (C-8); 7.75$_d$ (J=2.5, C-5''); 6.90$_{dd}$ (J=2.5, 1.0, C-4''); 6.89$_s$ (C-6'); 6.73$_s$ (C-3'); 3.90$_s$ (6H, OC$\underline{H}_3$); 2.13$_s$ (3H, OCOC$\underline{H}_3$).

Found: C, 66.41; H, 4.33%. Calcd for $C_{21}H_{16}O_7$: C, 66.31; H, 4.24%.

8,9-Dimethoxyfurano[3',2':2,3]pterocarpan (III). A mixture of VIII (350mg), sodium borohydride (400mg), and absolute tetrahydrofuran - ethanol (4 : 1, 50m*l*) was treated by a method similar to that used for V. The crude product was recrystallized from ethanol to give III as colorless needles; mp 172—173°C; yield, 200mg. IR: 1617, 1586, 1535, 1510, 1500cm^{-1} (phenyl); ($CHCl_3$) 1620, 1590, 1520, 1493cm^{-1} (phenyl). UV: λ_{max} mμ (log ε); 247 (4.24), 255 (4.12), 299 (4.12); ($CHCl_3$) 250 (4.05), 256.5 (4.06), 302 (4.10).

Found: C, 70.28; H, 5.01%. Calcd for $C_{19}H_{16}O_5$: C, 70.36; H, 4.98%.

Hydrogenation of III. Furanopterocarpan III (300 mg) was hydrogenated in ethyl acetate (40 m*l*) over 10% Pd-C (600 mg) at atmospheric pressure and at room temperature. The catalyst was then filtered off, and the solvent was removed under reduced pressure. The residue was dissolved in benzene. The benzene solution was washed with a 5% aqueous sodium hydroxide solution and then with water. The evaporation of the dried solution and the chromatography of the resulting solid on silica gel with chloroform - *n*-hexane (1 : 1) gave colorless crystals, which were then recrystallized from ethanol to give VI; mp 174—175°C; yield, 150 mg. This was identical with the sample derived by the method described above.

4',5'-Dimethoxy-2'-hydroxyfurano[2'',3'':3,4]isoflavone (XI). 2'-Hydroxyisoflavone XI was prepared, according to the directions of Seshadri,[9] from elliptol isoflavone, X.[8] Recrystallization from ethanol gave XI; mp 207—208°C (lit.[9] mp 204—205°C).

Found: C, 67.57; H, 4.27%. Calcd for $C_{19}H_{14}O_6$: C, 67.45; H, 4.17%.

The acetate: hot acetic anhydride - anhydrous sodium acetate method; mp 205—206°C (colorless needles from ethanol). IR: 1770, 1744, 1637 cm^{-1} (C=O). UV: λ_{max} mμ (log ε); 230 (4.53), 247$_i$*7 (4.48), 312$_{sh}$*6 (3.81). NMR:*3,4 8.12$_d$ (J=9.0, C-5); 7.97$_s$ (C-2); 7.73$_d$ (J=2.0, C-5''); 7.55$_d$ (J=9.0, C-6); 7.13$_{bs}$ (C-4'') 6.87$_s$ (C-6'); 6.72$_s$ (C-3'); 3.90$_s$ (6H, OC$\underline{H}_3$); 2.13$_s$ (OCOC$\underline{H}_3$, 3H).

Found: C, 66.27; H, 4.40%. Calcd for $C_{21}H_{16}O_7$: C, 66.31; H, 4.24%.

8,9-Dimethoxyfurano[2',3':3,4]pterocarpan (IX). A mixture of XI (150 mg), sodium borohydride (200 mg), and absolute tetrahydrofuran - ethanol (6 : 1, 35 m*l*) was treated by a method similar to that used for V. The crude product was recrystallized from ethanol to give IX as colorless prisms; mp 180—181°C; yield, 70 mg. IR: 1613, 1596, 1492 cm^{-1} (phenyl). UV: λ_{max} mμ (log ε); 247.5 (4.17), 255.5 (4.13), 292.5 (3.90); ($CHCl_3$) 251 (4.12), 256 (4.12), 292.5 (3.89), 300$_i$*7 (3.86).

Thermal Decomposition of 1,1-Disubstituted-3-aryl-3-(aryloxythiocarbonyl)-2-thioureas*[1)]

Koshin MIYAZAKI

Research Department of the Takaoka Plant, Nippon Soda Co., Ltd., Mukaino-honmachi, Takaoka-shi, Toyama

(Received November 8, 1968)

1,1-Disubstituted-3-(4-chlorophenyl)-3-(phenoxythiocarbonyl)-2-thioureas of the formula R,R'N-C^1(=S)-N(*p*-Cl-C_6H_4-)-C'(=S)-OC_6H_5 (II), when kept at an elevated temperature without any solvent, decomposed into the corresponding thionocarbamates of the formula R,R'N-C(=S)-OC_6H_5 (III), while *p*-chlorophenyl isothiocyanate was eliminated. A carbon-14-labeling experiment showed that the decomposition proceeded only through the following path:

$$\text{II} \longrightarrow \text{R,R'N-C}^2\text{(=S)-OC}_6\text{H}_5 + p\text{-Cl-C}_6\text{H}_4\text{-N=C}^1\text{=S}$$

Kinetic studies of the various II showed that the decompositions were strictly first order. The rate constant at 175°C increased in the order: R,R'=$(CH_3)_2$>$(C_2H_5)_2$>CH_3,4-methylbenzyl≳(n-$C_3H_7)_2$>CH_3, benzyl>CH_3, 4-chlorobenzyl. Neither the products nor the rate of the decomposition reaction was influenced by the presence of a radical scavenger. Furthermore, a crossover decomposition reaction did not give any crossover products. On the basis of these results, a possible intramolecular mechanism of the decomposition involving a four-membered cyclic intermediate structure was proposed.

In an earlier paper,[1)] it was shown that *O*-aryl-*S*-(*N*,*N*-dimethylthiocarbamoyl)-*N*-(aryl)thiolimido carbonates with the formula I, when kept at a temperature higher than their melting points, rearranged within a few minutes into the corresponding 1, 1-dimethyl-3-aryl-3-(aryloxythiocarbonyl)-2-thioureas with the formula II (Eq. (1)).

$$(CH_3)_2N\text{-}\underset{\underset{S}{\|}}{C}\text{-}S\text{-}\underset{\underset{N\text{-}Ar'}{\|}}{C}\text{-}OAr \longrightarrow (CH_3)_2N\text{-}\underset{\underset{S}{\|}}{C}\text{-}\underset{\underset{Ar'}{|}}{N}\text{-}\underset{\underset{S}{\|}}{C}\text{-}OAr \qquad (1)$$

During the course of a continuous investigation of the rearrangement of I to II, it has been found that II gradually decomposed, when the reaction time was prolonged, into the aryl *N*,*N*-dimethylthionocarbamate (III), while aryl isothiocyanate (IV) was eliminated. It can easily be considered, however, that IV can be split off in the two ways shown in Eq. (2):

$$(CH_3)_2N\text{-}\underset{\underset{S}{\|}}{C^1}\text{-}\underset{\underset{Ar'}{|}}{N}\text{-}\underset{\underset{S}{\|}}{C^2}\text{-}OAr \xrightarrow{A} (CH_3)_2N\text{-}\underset{\underset{S}{\|}}{C^1}\text{-}OAr + Ar'\text{-}N{=}C^2{=}S$$
$$\text{(III)} \qquad \text{(IV)}$$
$$(CH_3)_2N\text{-}\underset{\underset{S}{\|}}{C^1}\text{-}\underset{\underset{Ar'}{|}}{N}\text{-}\underset{\underset{S}{\|}}{C^2}\text{-}OAr \xrightarrow{B} (CH_3)_2N\text{-}\underset{\underset{S}{\|}}{C^2}\text{-}OAr + Ar'\text{-}N{=}C^1{=}S \qquad (2)$$

In the present paper, a carbon-14-labeling experiment and the kinetics of the decomposition have been studied for a series of 1,1-disubstituted-3-(4-chlorophenyl)-3-(phenoxythiocarbonyl)-2-thioureas in order to clarify the decomposition mechanism.

Results and Discussion

The compounds II studied here were prepared by the reaction of an appropriate 1,1-disubstituted-3-(4-chlorophenyl)-2-thiourea with a proper aryl chlorothionoformate, as has been reported previously.[1)] The data are shown in Table 1. On being heated at 175°C without any solvent and under a slow stream of nitrogen, the compounds II underwent a gradual decomposition, with the elimination

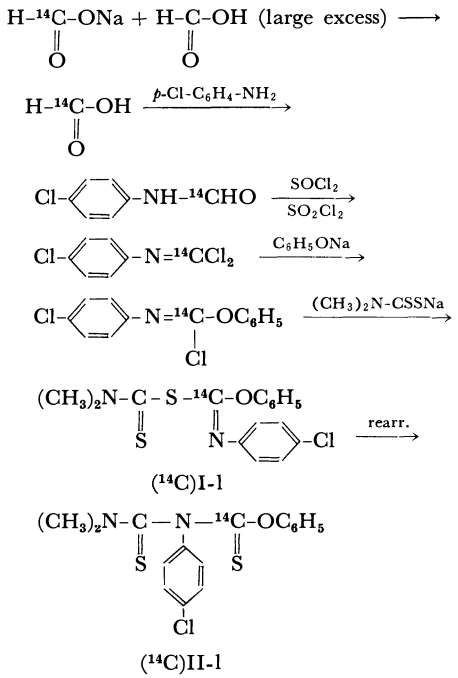
a) All melting points are uncorrected. b) Yields recorded are those of recrystallized products. c) From ethanol - acetone.
d) From methanol. e) Reported previously (lit. 1).

of *p*-chlorophenyl isothiocyanate (IVa); the corresponding aryl *N,N*-disubstituted-thionocarbamates could be detected as the other major decomposition products. The compounds IVa and the thionocarbamates isolated by a chromatograph were identified by a mixed-melting-point test and/or by the agreement of the IR spectra with those of the corresponding authentic samples. It will easily be seen that there are two possible ways to split off the compound IVa, as has been expressed in Eq. (2). In order to ascertain which way was preferable, the thermal decomposition of II-1, but with the C^2 atom (in Eq. (2)) labeled with a radioactive carbon, was studied; the radioactive II-1 was prepared by the method shown in the following scheme.



As a result of the experiment, it was found that the compound, IVa, formed by the decomposition of (14C)II-1 did not have any radioactivity, while phenyl *N,N*-dimethylthionocarbamate (IIIa) still retained its radioactivity, with almost the same specific activity as that of the starting material, (14C) II-1. These results show that the decomposition proceeds exclusively through the path B in Eq. (2).

In order to investigate the influence of the substituent (R, R') on the rate of decomposition, the kinetics of the decomposition were investigated on three compounds (II-1—II-3). The decomposition rates were determined by measuring the amount of the product IVa by spectrophotometry. As a result, it was found that the decomposition reactions followed good first-order kinetics (Fig. 1). The first-order rate constants, which were derived from the slopes of the straight lines in Fig. 1, are listed in Table 2.

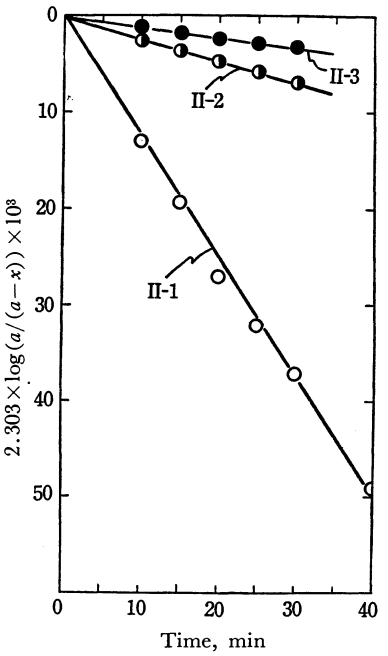


Fig. 1. First-order plots of kinetic data for II-1—II-3 at 175±0.5°C.

TABLE 2. FIRST-ORDER RATE CONSTANTS (k_1) OF THE DECOMPOSITION REACTIONS AT 175±0.5°C FOR II-1—II-3

Compd. No.	$k_1 \times 10^3$ (min^{-1})	Relative rate
II-1	12.80	(1)
II-2	2.32	0.18
II-3	1.04	0.08

In order to examine whether the decomposition, which followed the path B in Eq. (2), proceeded by an intermolecular route or by an intramolecular route, a crossover experiment was performed with two compounds of II. That is, an equimolecular mixture of II-1 and II-4 was heated without any solvent at 175°C for 1.5 hr under a slow stream of nitrogen. If the compounds II decomposed according to an ionic intermolecular mechanism involving the heterolytic cleavage of the (R, R')N–C^1 bond and the Ar'N–C^2 bond, crossover products, such as 4-tolyl *N,N*-dimethylthionocarbamate (IIId) and phenyl *N, N*-diethylthionocarbamate (IIIb), should be detected in the crossover reaction mixture. The thin-layer chromatograms of that reaction mixture, however, showed no detectable amounts of IIIb or IIIb. This result suggests that the decomposition involves an intramolecular mechanism rather than an intermolecular mechanism.

Another possible mechanism for the decomposition of II is homolytic cleavages of the above-mentioned two bonds. In order to investigate this possibility, the decomposition reaction of the compound

II-1, mixed with a small amount (*ca.* 2 wt%) of a radical scavenger such as *p*-quinone or 1,1-diphenyl-2-picrylhydrazyl (DPPH), was studied at 175°C. As a result, the decomposition products were found to be the same as in the absence of the scavenger, while the rate was scarcely affected by the presence of the scavenger. In view of the above facts, one may presume that the decomposition did not involve a radical route.

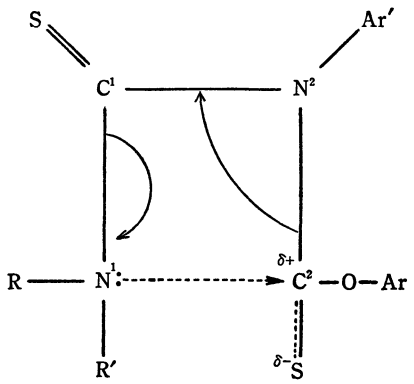

Fig. 2. Four-membered cyclic mechanism.

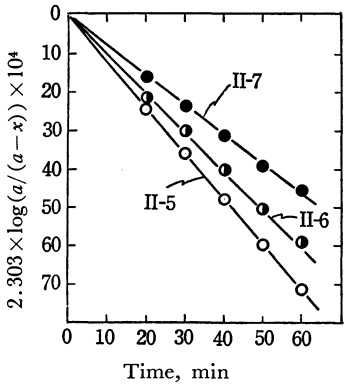

Fig. 3. First-order plots of kinetic data for II-5—II-7 at 175±0.5°C.

Taking the above results into consideration, it has been presumed that the decomposition of the compound II took place through an intramolecular mechanism involving a four-memberd cyclic intermediate structure, as in Fig. 2.

Since the decomposition reaction should be caused by a nucleophilic attack of the N^1 atom on the C^2 atom, it was expected that a stronger electron-donating inductive effect of the substituent (R, R'), which might promote the nucleophilic character of the N^1 atom, would result in a larger rate of decomposition. However, the results obtained concerning II-1—II-3 betrayed this expectation; the rate constants increased in the order of $R=CH_3>C_2H_5>n\text{-}C_3H_7$ (Table 2). This finding that the rate constants diminish regularly with an increase in the bulkiness of the alkyl groups indicates that the steric effect of R much outweighs the electronic effect. In an effort to determine the inductive effect of the substituent (R, R') upon the decomposition, further kinetic studies were carried out on a series of N^1-(4-substituted-benzyl)-N^1-methyl- analogues (II-5—II-7). Since the steric effects in three compounds should be virtually the same, the substituent effect caused by the inductive effect upon the rate of the decomposition can be demonstrated clearly. The kinetic results obtained are shown in Fig. 3, while the rate constants are listed in Table 3.

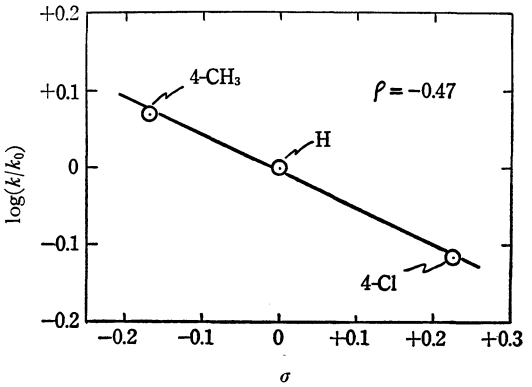

Fig. 4. Hammett plots for the thermal decompositions of II-5—II-7 at 175±0.5°C.

TABLE 3. FIRST-ORDER RATE CONSTANTS (k_1) OF THE DECOMPOSITION REACTION AT 175±0.5°C FOR II-5—II-7

Compd. No.	$k_1\times10^4$ (min^{-1})	Relative rate
II-5	12.0	1.18
II-6	10.2	(1)
II-7	7.8	0.77

Hammett plots of $\log(k/k_0)$ *vs.* σ gave a straight line, with $\rho=-0.47$ (Fig. 4). This fact indicates that the decomposition should be essentially accelerated by a stronger electron-donating inductive effect of the substituent on the N^1 atom.

The results of the carbon-14 labeling experiment, the crossover experiment, the scavenger experiment, and the Hammett correlation lend some support to the presumption of an internal four-membered cyclic mechanism such as that expressed in Fig. 2.

Experimental*2

Materials. *p*-Chlorophenyl Isothiocyanate (IVa). This was obtained by the usual method. Mp 44—45°C.[2]

1,1-Disubstituted-3-(4-chlorophenyl)-2-thioureas. These were prepared by the reaction of *p*-chlorophenyl

*2 All boiling and melting points are uncorrected.

Calcd for $C_{13}H_{17}NOS$: C, 64.57; H, 7.62; N, 6.28%. Phenyl *N*-benzyl-*N*-methyl- (IIIf) colorless oil*3 n_D^{23}: 1.6137. Found: C, 69.90; H, 5.88; N, 5.21%. Calcd for $C_{15}H_{15}NOS$: C, 70.04; H, 5.84; N, 5.45%. Phenyl *N*-(4-chlorobenzyl)-*N*-methyl- (IIIg) colorless oil*3 n_D^{23}: 1.6173. Found: C, 61.70; H, 4.88; N, 4.98%. Calcd for $C_{15}H_{14}ClNOS$: C, 61.75; H, 4.80; N, 4.80%. Phenyl *N*-(4-methylbenzyl)-*N*-methyl- (IIIh) colorless needles (from methanol) mp 57—58°C. Found: C. 70.70; H, 6.27; N, 5.15%. Calcd for $C_{16}H_{17}NOS$: C, 70.85; H, 6.28; N, 5.17%.

Carbon-14 Labeling Experiments. The sodium formate-^{14}C (specific activity: 10.8 mCi/mmol) was obtained from the Radiochemical Centre in England; it was dissolved into nonradioactive formic acid in order to obtain a moderate radioactive formic acid-^{14}C.

Labeled 4-Chloroformanilide. This was prepared in a 96% yield from 4-chloroaniline and the above formic acid-^{14}C.

Labeled (4-Chlorophenyl)imidocarbonyl Chloride. This was prepared in a 77% yield using the above labeled anilide and according to a procedure described in the literature.[7] Bp 132—135°C/29 mmHg.

Labeled Phenyl *N*-(4-Chlorophenyl)chloroformimidate. This was prepared in a 57% yield from the above labeled chloride and phenol, as has been described earlier.[1] Bp 157—159°C/4 mmHg.

Lableld *O*-Phenyl-*S*-(*N,N*-dimethylthiocarbamoyl) *N*-(4-Chlorophenyl)thiolimidocarbonate (^{14}C)I-1). This was prepared from sodium *N,N*-dimethyldithiocarbamate and the above labeled chloroformimidate by a method reported previously.[1] The crude reaction product was recrystallized several times from ethanol-acetone to give colorless prisms in a 58% yield. Specific activity: 1.40 μCi/mol.

Labeled 1,1-Dimethyl-3-(4-chlorophenyl)-3-(phenoxythiocarbonyl)-2-thiourea (^{14}C)II-1). This was prepared by the thermal rearrangement of (^{14}C)I-1, as has been reported previously.[1] In order to obtain the pure product, the crude product was chromatographed on silica gel twice and then recrystallized several times from ethanol-acetone to give colorless prisms in a 28% yield. A thin-layer chromatographic analysis of that refined product showed that it contained no impurities. Specific activity: 1.51 μCi/mol.

Thermal Decomposition of II. The apparatus used for the decomposition consisted of a 5-m*l*, pear-shaped flask fitted with an air condenser. Thin-layer chromatography was conducted by the use of silica gel (WAKO GEL B5-F); the prepared plate was activated at 110°C for 1hr and then stored in a deciccator. Silica-gel-column chromatography was carried out by the use of silica gel (WAKO GEL C-200) activated at 110°C for 1hr before use.

In a run, a weighed amount (*ca.* 100 mg) of II was placed in the reaction flask. The flask was flushed with nitrogen for 10 min at room temperature and then heated to 175±0.5°C in a constant-temperature bath for the desired length of time, nitrogen being passed into the flask at a slow rate throughout the decomposition. The reaction mixture, which showed two main spots besides the unchanged II upon thin-layer chromatography with a solvent mixture of *n*-hexane and chloroform (2/1), was chromatographed on a silica-gel column (15×250 mm) with the same solvent as was used above. After about 200 m*l* of the solution had been eluted, fractions (5 m*l* each) were tested by thin-layer chromatography in order to separate the newly-formed products. The two main products thus separated were identified by means of IR and melting-point comparisons with authentic samples.

Decomposition of (^{14}C)II-1. (^{14}C)II-1 (200 mg) was decomposed for 1.5hr in the same manner as above. IIIa and IVa, which had been carefully separated by cloumn chromatography, were each recrystallized several times from ligroin. Thus 15 mg of IIIa (specific activity: 1.44 μCi/mol) and 18 mg of IVa (specific activity: 0) were obtained.

Crossover Experiment. An equimolar mixture of II-1 and II-4 was heated at 175°C for 1.5 hr under a slow stream of nitrogen. The reaction mixture was then submitted to thin-layer chromatography on silica gel, using a solvent mixture of *n*-hexane - chloroform - acetic acid

Table 4. Decomposition rates of II-1 with a scavenger

	t(min)	10	20	30	40
$\ln(a/(a-x))$	(quinone)	0.128	0.267	0.368	0.490
	(DPPH)	0.125	0.261	0.372	0.480
	(neat)	0.130	0.270	0.370	0.493

(30 : 1 : 1) as the developer. After repeated attempts at chromatography, five major products: (R_f=0.31 (unchanged II-1), 0.45 (unchanged II-4), 0.47 (IIIa), 0.66 (IIIe) and 0.93 (IVa)) were obtained. However, neither IIIb (R_f: 0.61) nor IIId (R_f: 0.51) was detected.

Decomposition with a Scavenger. II-1, mixed with a small amount (*ca.* 2 wt% of II-1) of a scavenger, was heated at 175±0.5°C under a slow stream of nitrogen. The decomposition rates at each interval were as follows:

Decomposition Rate Measurement. In the above-described decomposition procedure, five or six runs for Compound II were started at the same time. Each one of these was taken out from a bath at every appropriate interval and cooled to room temterature by immersion in cold water. Each run thus obtained was then submitted to column chromatography in order to separate the IVa. The absorbance of the elute containing IVa was then measured at 275 mμ, which is the characteristic absorption for IVa. Since the change in the absorbance with the concentration of IVa in the solvent followed Beer's law well, the amount of IVa could be determined from the calibration line, which was decided in advance. Good first-order straight lines were obtained in this way (Figs. 1 and 3). From these data, the rate constants were calculated (Tables 2 and 3). The absorbance was measured on a Shimadzu MPS-50L spectrophotometer.

Radioactivity Counting. The radioactivity was measured by a liquid scintillation spectrometer (Nuclear Chicago Corp., Model 6801) using the following scintillator: naphthalene, 120 g; PPO, 7g; POPOP, 0.05 g; dioxane, 1000 m*l*.

The author wishes to express his deep gratitude to Professor Ryōzō Gotō of Kyoto Universiy for his kind direction, to Professor Aritsune Kaji of same University for his valuable suggestions and continuous encouragement, and to Dr. Jun-ichi Hayami of the same University for his helpful advice. Thanks are also due to Dr. Teruhisa Noguchi of the Biological Research Laboratory of Nippon Soda Co., Ltd., for his eager interest throughout the course of this investigation.

A New σ-Bonded Complex Formation between 2-Vinylpyridine and Palladium(II) or Platinum(II) Chloride

Akira KASAHARA, Keiko TANAKA[1] and Taeko IZUMI[2]

Department of Chemistry, College of General Education, Yamagata University, Yamagata

(Received November 11, 1968)

Sodium tetrachloropalladate(II) reacts with 2-vinylpyridine in methanol, ethanol, or isopropyl alcohol, to give, respectively, di-μ-chloro-bis[2-methoxy-2-(α-pyridyl)ethyl]dipalladium(II), di-μ-chloro-bis[2-ethoxy-2-(α-pyridyl)-ethyl]dipalladium(II), and di-μ-chloro-bis[2-isopropoxy-2-(α-pyridyl)ethyl]-dipalladium(II). The reaction of potassium tetrachloroplatinate(II) with 2-vinylpyridine in methanol or ethanol affords, respectively, di-μ-chloro-bis[2-methoxy-2-(α-pyridyl)ethyl]diplatinum(II) and di-μ-chloro-bis[2-ethoxy-2-(α-pyridyl)ethyl]diplatinum(II). The structures of these complexes containing the covalent metal - carbon bonding have been confirmed by a study of their absorptions and of the NMR spectra.

Recently, Cope and his co-workers reported that azobenzenes and *N*,*N*-dimethylbenzylamines react with palladium(II) halides or platinum(II) halides in an alcoholic solution to give complexes, **1**[3] and **2**[4], with carbon - methal σ-bonds.

4) A. C. Cope and E. C. Friedrich, *ibid.*, **90**, 909 (1968).

Furthermore, they found palladium(II) halides to react with allylic amines in an alcoholic solution to give complexes **3** containing an alkoxy group.[5] Yukawa and Tsutsumi[6] have also reported propagylamines which react with palladium(II) chloride in the presence of lithium chloride to give chlorovinylated products 4. Here we wish to report that, in alcoholic media, 2-vinylpyridine undergoes a similar electrophilic substitution by palladium(II) or platinum(II) chloride, producing a new σ-bonded complex.

Experimental

All melting points and boiling points are uncorrected. Molecular weights were determined with an osmometer (benzene: at 45°C). The NMR spectra were recorded on a Hitachi H-60 spectrometer in deuteriochloroform, using tetramethylsilane as the internal reference.

Di-μ-chloro-bis[2-methoxy-2-(α-pyridyl)ethyl]-dipalladium(II) (5-a). To a solution containing 6.96 g (0.02 mol) of sodium tetrachloropalladate(II) in 70 m*l* of methanol, a solution of 2-vinylpyridine (2.10 g, 0.02 mol) in 20 m*l* of methanol was added. After standing at room temperature for 10 hr, the reaction mixture was evaporated *in vacuo* to dryness and extracted with chloroform. The chloroform layer was washed with water and dried over anhydrous magnesium sulfate. After the removal of the solvent, the residue was chromatographed on alumina using dichloromethane. Recrystallization from benzene afforded yellow crystals (**5-a**); mp 157—159°C, (1.2 g, 11%). IR spectrum (KBr): 3018, 2950, 2830, 1608, 1580, 1495,1450, 1115, 842, and 765 cm^{-1}. NMR spectrum: 6.58 (singlet, $-OCH_3$), 5.82 (multiplet, $-CH_2-$), 4.55 (multiplet, –CH–), and 2.90—0.96 τ (multiplet, pyridyl protons).

Found: C, 34.68; H, 3.75; N, 5.11%; mol wt, 548. Calcd for $C_{16}H_{20}N_2O_2Pd_2Cl_2$: C, 34.56; H, 3.62; N, 5.03%; mol wt, 556.

Di-μ-chloro-bis[2-ethoxy-2-(α-pyridyl)ethyl]-dipalladium(II) (5-b). The ethoxy complex (**5-b**) was obtained similarly from sodium tetrachloropalladate(II) and 2-vinylpyridine in ethanol (100 m*l*). The yellow crystals were recrystallized from benzene-cyclohexane; mp 153—155°C. IR spectrum (KBr): 3020, 2970, 1602, 1580, 1490, 1450, 830, and 772 cm^{-1}. NMR spectrum: 8.77 and 6.38 (ethoxy protons), 5.80 (multiplet, $-CH_2-$), 4.50 (multiplet, –CH–), and 2.92—0.92 τ (multiplet, pyridyl protons).

Found: C, 37.22; H, 4.08; N, 4.89%; mol wt, 568. Calcd for $C_{18}H_{24}N_2O_2Pd_2Cl_2$: C, 37.04; H, 4.14; N, 4.79%; mol wt, 584.1.

Di-μ-chloro-bis[2-isopropoxy-2-(α-pyridyl)-ethyl]dipalladium(II) (5-c). The reaction between sodium tetrachloropalladate(II) and 2-vinylpyridine in isopropyl alcohol afforded the isopropoxy complex (**5-c**) (23% yield). The yellow crystals were recrystallized from benzene; mp 165—167°C. IR spectrum (KBr): 3020, 2980, 1608, 1580, 1490, 1450, 1385, 1377, 830, and 772 cm^{-1}. NMR spectrum: 8.87, 8.78, and 6.21 (isopropoxy protons), 5.86 (multiplet, $-CH_2-$), 4.38 (multiplet, –CH–), and 2.95—0.98 τ (multiplet, pyridyl (protons).

Found: C, 39.67; H, 4.63; N, 4.45%; mol wt, 601. Calcd for $C_{20}H_{28}N_2O_2Pd_2Cl_2$: C, 39.24; H, 4.61; N, 4.57%; mol wt, 612.1.

Di-μ-chloro-bis[2-methoxy-2-(α-pyridyl)ethyl]-diplatinum(II) (5-d). To a solution of 1.0 g (0.0024 mol) of potassium tetrachloroplatinate(II) in 20 m*l* of water and 5 m*l* of methanol, 0.25 g (0.0024 mol) of 2-vinylpyridine in 30 m*l* of methanol was added at room temperature. After the mixture had then stood for 2 days, a yellow-orange precipitate was filtered out and washed well with methanol (0.55 g, 62%); mp 240—243°C (dec). This yellow-orange solid was insoluble in all common solvents. IR spectrum (KBr): 3020, 2940, 2820, 1608, 1590, 1488, 1450, 1120, 790, and 758 cm^{-1}.

Found: C, 25.95; H, 2.62; N, 3.36%. Calcd for $C_{16}H_{20}N_2O_2Pt_2Cl_2$: C, 26.18; H, 2.74; N, 3.54%.

Di-μ-chloro-bis[2-ethoxy-2-(α-pyridyl)ethyl]diplatinum(II) (5-e). A yellow-orange product (**5-e**) was obtained similarly from potassium tetrachloroplatinate(II) and 2-vinylpyridine in ethanol-water (55% yield); mp 237—240°C (dec). IR spectrum (KBr): 3020, 2940, 1606, 1581, 1480, 1445, 1390, 830, 798, and 770 cm^{-1}.

Found: C, 28.04; H, 2.96; N, 3.43%. Calcd for $C_{18}H_{28}N_2O_2Pt_2Cl_2$: C, 28.27; H, 3.14; N, 3.67%.

The Preparation of 2-Alkoxy-2-(α-pyridyl)ethylpalladium(or platinum) Chloride *p*-Toluidine (6). A mixture of 0.10 g of Complex **5** and *p*-toluidine (5% excess) in benzene (30 m*l*) was heated to reflux for 30 min. After the solvent had then been removed under reduced pressure, the residue was recrystallized from a benzene-cyclohexane mixture to give the following complexes.

2-Methoxy-2-(α-pyridyl)-ethylpalladium(II) Chloride *p*-Toluidine (6, B:=*p*-Toluidine, R=CH_3, M=Pd). Yellow crystals, mp 215—218°C (dec).

Found: C, 48.45; H, 4.79; N, 7.16%. Calcd for $C_{16}H_{19}N_2OPdCl$: C, 48.38; H, 4.82; N, 7.02%.

5) A. C. Cope, J. M. Kliegman and E. C. Friedrich, *ibid.*, **89**, 287 (1967).

6) T. Yukawa and S. Tsutsumi, *Inorg. Chem.*, **7**, 1458 (1968).

2-Ethoxy-2-(α-pyridyl)ethylpalladium(II) Chloride *p*-Toluidine (6, B:=*p*-Toluidine, R=CH_2CH_3, M=Pd). Yellow crystals, mp 231—233°C (dec).

Found: C, 49.77; H, 5.26; N, 6.84%. Calcd for $C_{17}H_{21}N_2OPdCl$: C, 49.65; H, 5.14; N, 6.81%.

2-Isopropyoxy-2-(α-pyridyl)ethylpalladium(II) Chloride *p*-Toluidine (6, B:=*p*-Toluidine, R=$CH(CH_3)_2$, M=Pd). Yellow crystals, mp 175—178°C (dec).

Found: C, 51.04; H, 5.01; N, 6.63%. Calcd for $C_{18}H_{23}N_2OPdCl$: C, 50.86; H, 4.97; N, 6.58%.

2-Methoxy-2-(α-pyridyl)-ethylplatinum(II) Chloride *p*-Toludine (6, B:=*p*-Toluidine, R=CH_3, M=Pt). Yellow crystals, mp 198—200°C (dec).

Found: C, 39.71; H, 4.07; N, 5.66%. Calcd for $C_{16}H_{19}N_2OPtCl$: C, 39.54; H, 3.94; N, 5.74%.

2-Ethoxy-2-(α-pyridyl)ethylplatinum(II) Chloride *p*-Toluidine (6, B:=*p*-Toluidine, R=CH_2CH_3, M=Pt). Yellow crystals, mp 195—198°C (dec).

Found: C, 41.26; H, 4.25: N, 5.55%. Calcd for $C_{17}H_{21}N_2OPtCl$: C, 41.01; H, 4.23; N, 5.63%.

Reduction of Complex. General Procedure. To the complex (3.3 g) in absolute ether (200 m*l*), there was slowly added a mixture containing 1.0 g of lithium aluminum hydride or deuteride in 100 m*l* of absolute ether. The resulting black mixture was stirred at room temperature for 3 hr, then water or deuterium oxide (5 m*l*) was added with cooling. The ether layer was washed with water and dried over anhydrous magnesium sulfate. After the removal of the solvent, the product was isolated by distillation.

Reduction of Complex 5-a with Lithium Aluminum Hydride. This reduction gave a product, bp 205—208°C, which can be identified as 1-(α-pyridyl)-1-methoxyethane (**7**) on the basis of the following evidence. IR spectrum: 2820 cm^{-1} ($-OCH_3$). NMR spectrum: 8.71 (doublet, J=6.0 cps, $-CH_3$); 6.67 (singlet, $-OCH_3$); 6.37 (quartet, J=6.0 cps, –CH–), and 3.03—1.35 τ (multiplet, pyridyl protons).

Found: C, 69.85; H, 8.01; N, 10.09%, mol wt, 135. Calcd for $C_8H_{11}NO$: C, 70.03; H, 8.08; N, 10.21%, mol wt, 137.

Reduction of Complex 5-a with Lithium Aluminum Deuteride. This reduction gave 1-(α-pyridyl)-1-methoxyethane-2-d_1, bp 205—208°C. IR spectrum: 2820 cm^{-1} ($-OCH_3$). NMR spectrum: 8.70 (doublet, J=6.0 cps, $-CH_2D$), 6.67 (singlet, $-OCH_3$), 6.36 (triplet, J=6.0 cps, –CH–), and 3.02—1.32 τ (multiplet, pyridyl protons).

Found: C, 69.77; H, 8.69; N, 10.32%; mol wt, 136. Calcd for $C_8H_{10}DNO$: C, 69.54; H, 8.74; N, 10.13%, mol wt, 138.

Reduction of Complex 5-d with Lithium Aluminum Hydride. This reduction gave 1-(α-pyridyl)-1-methoxyethane (**7**), bp 205—208°C, which can be identified by means of its IR and NMR spectra.

Reduction of Complex 5-d with Lithium Aluminum Deuteride. This reduction gave 1-(α-pyridyl)-1-methoxyethane-2-d_1 (10), bp 205—208°C, which can be identified by means of its IR and NMR spectra.

Results and Discussion

The reaction of 2-vinylpyridine with sodium tetrachloropalladate(II) in alcohol produced di-μ-chloro-bis[2-alkoxy-2-(α-pyridyl) ethyl]dipalladium(II) (**5-a—c**). The dimeric structures for these complexes were supported by the molecular-weight determinations and by their reactions with *p*-toluidine, which give readily-soluble, monomeric derivatives. The structure of complex **5-a** was established by the following data.

The infrared spectrum of complex **5-a** shows new bands at 2830 and 1115 cm^{-1} which can be assigned to the CH_3O- stretching mode. In agreement with the proposed structure, the NMR spectrum of complex **5-a** shows four bands, at 6.58 (singlet), 5.82 (multiplet), 4.55 (multiplet), and 2.90—0.96 τ (multiplet), in the ratio 3 : 2 : 1 : 4. They are assigned to *O*-methyl protons, methylene protons, methine protons, and pyridyl protons respectively. The lithium-aluminum-hydride reduction of complex **5-a** gives 1-(α-pyridyl)-1-methoxy-ethane (**9**), whose structure can be established by means of its IR and NMR spectra. The lithium-aluminum-deuteride reduction of complex **5-a** gives deuterated amine (**10**), which was identified as 1-(α-pyridyl)-1-methoxy-ethane-2-d_1. The position of the deuterium and, therefore, the site of the carbon-to-palladium σ-bond, was established by a comparison of the NMR spectrum of **10** with that of the undeuterated **9**. The spectrum of **9** consists of a doublet at 8.71 τ (methyl protons, wt 3), a singlet at 6.67 τ (methoxy protons, wt 3), a quartet at 6.37 τ (methine proton, wt 1), and a multiplet at 3.03—1.35 τ (pyridyl protons, wt 4), whereas **10** shows the corresponding signals at 8.70 (doublet), 6.67 (singlet), 6.36 (triplet), and 3.02—1.32 τ (multiplet) in the ratio 2 : 3 : 1 : 4. The above evidence establishes that a σ-bond has been formed between the metal and the terminal methylene group of the vinyl moiety. The structures of complexes **5-b** and **5-c** are also proved by their NMR spectra.

The reactions of 2-vinylpyridine with potassium tetrachloroplatinate(II) in aqueous methanol or in aqueous ethanol give di-μ-chloro-bis[2-alkoxy-2-(α-pyridyl)ethyl]diplatinum(II) (**5-d,e**). The insolubility of these complexes in common solvents made impossible any NMR-spectra or molecular-weight measurements. However, the reactions with *p*-toluidine and with lithium aluminum hydride or deuteride indicate that they have a dimeric structure of the same type as that obtained from 2-vinylpyridine and sodium tetrachloropalladate(II). The reduction of complex **5-d** with lithium aluminum hydride gives 1-(α-pyridyl)-1-methoxyethane (**7**), while that with lithium aluminum deuteride gives 1-(α-pyridyl)-1-methoxy-ethane-2-d_1 (**10**).

The Solvent Effects in the Acylation of Alcohol. The Effects of Liquid Sulfur Dioxide on the Dissociation of Hydrogen-bonded Alcohol

Toshikazu NAGAI, Hironobu ABE and Niichiro TOKURA

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Suita, Osaka

(Received November, 21, 1968)

The reason for the rate-enhancing effect of liquid sulfur dioxide on the rate of the benzoylation of methanol has been studied. The observation of the NMR spectra revealed that the amount of the hydrogen-bonded methanol is decreased (but not completely eliminated) by sulfur dioxide in the liquid SO_2-CCl_4 system. The existence of a correlation between the rates of esterification and the dissociation of the associated alcohol accounts for the role of the sulfur dioxide as the agent for the dissociation of the methanol-hydrogen bonding during the esterification.

In continuation of our work on the solvent effect of the acylation of alcohol, the obvious effect of liquid sulfur dioxide has aroused the interest of the present authors since the reaction proceeds very rapidly in both first- and second-order-rate reactions.[1)]

Liquid sulfur dioxide is an electrophilic solvent, the reaction in which the ρ value in the Hammett's equation is negative, *viz.*, in which a cation plays a predominant role, being favored in this solvent.[2)]

The first-order acylation where the reaction rate is described as: Rate=k[RCOCl] can be well elucidated by the above interpretation because the rate-determining formation of the RCO^+ cation should be favored in liquid sulfur dioxide. However, the enhanced acylation by the second-order-rate law, first order both in alcohol and in acyl halide, is difficult to understand. An alternative explanation is that the association of alcohol by the hydrogen bonding may be disrupted in the presence of liquid sulfur dioxide, as was indicated by Hoyer,[3)] and the alcohol may be increased when the solvent is replaced by liquid sulfur dioxide.

In the present communication the effect of the sulfur dioxide concentration on the hydrogen bonding of methanol and the effect of that solvent on the reaction rate of the acylation have been compared with each other. The correlation between the two effects may be useful as evidence for the role of sulfur dioxide.

As for the effect of hydrogen-bonding on the rate of a reaction, the inhibition of phenol alkylation by ethers has been reported on by Hart *et al.*;[4)] they accounted for the quantitative decrease in the rate by assuming the formation of a 2 : 1 phenol-dioxane complex.

The dissociation of the hydrogen bonding which may be brought about by sulfur dioxide has been measured by means of the proton magnetic resonance spectra in liquid sulfur dioxide-carbon tetrachloride systems. The reaction rates of the esterification of benzoyl chloride with methanol, which follow the second-order rate law, have been followed by GLC analysis.

Experimental

Apparatus. The chemical shift data were determined from the proton magnetic resonance spectra obtained on a Nihondenshi spectrometer at 60 Mc. The reaction rates were measured by pressure vessels equipped with needle valves.

Materials. The methanol was dehydrated over magnesium and distilled. The liquid sulfur dioxide was purified by distillation over phosphorus pentoxide. The carbon tetrachloride was purified by washing it with alkali and sulfuric acid; it was distilled after dehydration over calcium chloride. The benzoyl chloride was purified by an ordinary method.

Procedure. *Proton Magnetic Resonance.* The solutions to be studied were prepared in NMR tubes as follows. After weighing the reagents in the tube and after adding methylsilane, the tube was connected with a pressure vessel containing liquid sulfur dioxide; then there was added a definite amount of sulfur dioxide by distillation under cooling in a liquid nitrogen bath. Finally, the tube was sealed and submitted to NMR analysis. The chemical shifts were all determined relative to the internal standard, tetramethylsilane. A dilution study of methanol in carbon tetrachloride was undertaken in order to determine the chemical shift associated with

monomeric methanol. This study covered the concentration range of 1.193—0.019 wt% methanol and was done at a constant temperature of 20°C. To establish complete hydrogen bonding, a measurement was carried out at around the melting point of methanol. For the purpose of detecting the dissociation of the hydrogen bonding, the molar ratios of the SO_2-CCl_4 mixtures were varied from 0 to 100%, while the methanol concentration was kept constant at about 6 mol/*l*.

Kinetic Procedure. The procedure used to follow the kinetics was as follows. Into a pressure vessel there were introduced 0.6164 mol/*l* of benzoyl chloride and 2.8829 mol/*l* of methanol in a liquid SO_2-CCl_4 mixture (SO_2: 0—92 mol%); then, after a definite period of time at 0°C, the reaction mixtures were added to a large amount of water. The solution was then introduced into a separatory funnel including a definite amount of nitrobenzene in CCl_4 and then washed seven times with pure water in order to remove any unreacted methanol and benzoyl chloride. The solvent of the CCl_4 solution thus obtained was distilled out under reduced pressure after drying over $MgSO_4$. The residual solution was submitted to GLC analysis. The concentration of methyl benzoate formed was determined by measuring the area of the gas chromatograms and by applying a previously-determined calibration factor, which was obtained from the area of methyl benzoate relative to that of a definite amount of nitrobenzene added as a standard. GLC was carried out under the following conditions: column; P.E.G. 6000, 4 m, 132°C; carrier; H_2 70 ml/min. The retention times were 9.5 min for methyl benzoate and 16.5 min for nitrobenzene.

Results and Discussion

The Hydrogen Bonding of the Methanol Molecules Themselves. The results of the dilution study of methanol in carbon tetrachloride are presented in Fig. 1. This study suggests that, below a concentration of 0.117 wt%, the methanol in carbon tetrachloride exists in only one state, probably the monomeric form. Assuming this to be the case, the value of δ_1, the chemical shift of monomeric methanol relative to tetramethylsilane, is 2.08 ppm.

The value of δ_A, the chemical shift of associated methanol, was determined to be δ 5.84 ppm by measuring the value for pure methanol around its melting point, −93°C.

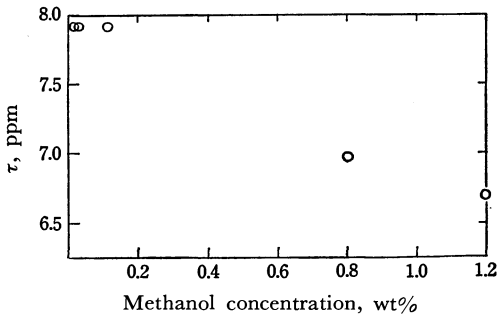

Fig. 1. Dilution study of methanol in carbon tetrachloride.

The chemical shift data, δ_{obs}, for the hydroxylic hydrogen atom of methanol measured at 20, 0, and −20°C at a definite concentration of about 6 mol/*l* in the SO_2-CCl_4 solvent mixture, together with those for the methyl, δ_{CH_3}, are listed in Table 1.

As may be seen in Table 1, upon an increase in the relative amount of SO_2, the hydroxylic hydrogen atom shifts to a higher magnetic field. This could be attributed to the change in the molecular complexation of alcohol, possibly owing to a weak interaction of the oxygen atoms of methanol with the sulfur atoms of sulfur dioxide, as is shown in Fig. 2, I, rather than that visualized in Fig. 2, II, which would result in a shift to a lower field, a shift contrary to the facts.

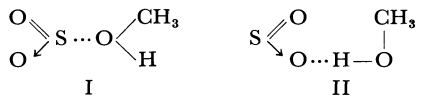

Fig. 2

The neighbor anisotropy effect of SO_2 on the shift will be omitted here since the shifts of the methyl protons remain constant throughout the various compositions of the solvent mixtures used.

Comprehensive studies[5-7] have been made of the nuclear magnetic resonance on the molecular complexation of alcohol or on hydrogen bonding between proton-donating acids and bases. In these studies, the shifts of the NMR signals have been considered from the standpoint of dilution or enthalpy change upon the formation of a hydrogen bond. Meanwhile, Hoyer[3] has observed in his IR studies that sulfur dioxide molecule can neither permit a hydrogen bond among alcohol molecules themselves nor make hydrogen bridges with the hydrogen atoms of the alcohols by using oxygen atoms of the sulfur dioxide molecule.

Saunders and Hyne[6] have interpreted their data by making the simplifying assumption that the methanol molecule exists in carbon tetrachloride in equilibrium with the monomer and the tetramer as follows:

$$4CH_3OH \overset{K_4}{\rightleftharpoons} (CH_3OH)_4 \qquad (1)$$

Assuming this to be the case in the present system, the following value, K_4, will be a parameter of the complexation in this system:

$$K_4 = \frac{M_4}{M_1^4} = \frac{C - M_1}{4M_1^4} \qquad (2)$$

$$C = M_1 + 4M_4 \qquad (3)$$

where M_1 and M_4 are the molar concentrations of the monomer and the tetramer respectively.

On the other hand, the observed chemical shift, δ_{obs}, follows Eq. (4):

$$\delta_{obs} = \frac{\delta_1 M_1 + \delta_A (C - M_1)}{C} \qquad (4)$$

where δ_1 and δ_A are the chemical shifts of the hydroxylic protons of the noncomplexed and complexed states respectively.

The K_4 values derived from Eqs. (2) and (4), together with the values of M_1/C, are listed in Table 2.

These results indicate that the association of methanol is possible in an appreciable amount in liquid SO_2 alone; this is somewhat different from the observation made by IR.[3]

When a smaller concentration of methanol (1.8 mol/l) was used, the hydroxylic hydrogen atom shifted to a higher field, δ 2.67 ppm relative to the TMS in liquid SO_2 at 20°C, thus affording larger M_1/C value; this is further evidence of the presence of the complexation of methanol in liquid SO_2.

Rate of S_N2-type Esterification. Benzoyl chloride was submitted to reaction with methanol in liquid sulfur dioxide-carbon tetrachloride mixtures. The reaction obeyed the second-order-rate law at the initial stage of the reaction, indicating that methanol acts in the rate-determining step of

** M_1: the unassociated monomer concentration derived from the equation: $4[M_1]^4K_4+[M_1]=C$.

the reaction. Another support for this was given by the fact that a small isotope effect was observed when CH_3OD was used in this esterification reaction. Consequently, the rate constant, k_2, should afford some information regarding the effect of the complexation of methanol on the S_N2-type reaction.

The k_2 values, together with the M_1/C and K_1 values, are visualized in Fig. 3.

The k_2 values increase as the amount of sulfur dioxide added is greater; however, the k_2' values, defined as is indicated in Eq. (5), were nearly constant, as is shown in Table 4.

$$\text{Rate} = k_2[\text{benzoyl chloride}][C] = k'_2[\text{benzoyl chloride}][M_1] \quad (5)$$

$$k'_2 = k_2\frac{[C]}{[M_1]} \quad (6)$$

The increase in the reaction rate of the esterification of benzoyl chloride by methanol, brought about by the addition of sulfur dioxide, may adequately be accounted for by assuming that the dissociated methanol monomer rather than the associated methanol participates in the esterification reaction and also by assuming that sulfur dioxide acts as the hydrogen bond-disrupting agent in the reaction.

The authors are grateful to Seitetsu Kagaku K. K. for its donation of liquid sulfur dioxide.

Reaction Rates in Binary Mixed Solvents. V[1)]

Yasuhiko KONDO, Toshiharu KUSAKA and Niichiro TOKURA

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Suita, Osaka

(Received November 22, 1968)

The rate constants of the Menschutkin reaction between methyl iodide and pyridine, *N,N*-dimethylaniline, 2,6-dimethylpyridine, and *N,N*-dimethyl-*o*-toluidine have been measured in a liq. SO_2-nitrobenzene mixture. These results have then been analyzed by the procedure described in a previous paper. The findings regarding the reactions of unsubstituted amines with methyl iodide have been explained theoretically by taking into account the specific solvation of amines by liq. SO_2 and that of an activated complex by a nitrobenzene solvent, whereas the behavior of the rate constants in the reactions of *o*-substituted amines in mixed solvents can be explained by assuming the specific solvation of an activated complex by liq. SO_2 only. In conformity with the above results and the difference in the effect of an *o*-methyl group on the reaction rates between liq. SO_2 and a nitrobenzene solvent, the mutual relation of the activation free energies of these reactions has been discussed.

In a previous paper of this series the present authors have discussed the theoretical procedure for analyzing the reaction rates measured in solvent mixtures. The additional possibility has been suggested that knowledge about the solvation phenomena of the solute could be drawn from an

1) Y. Kondo, Y. Honjo and N. Tokura, This Bulletin, **41**, 987 (1968).

analysis of the rate constants measured in mixed solvents which could not be drawn from an analysis of the reaction rates measured in pure solvents.

For a complete understanding of the reaction in solution it is necessary to summarize various informations originating from different sources.

One of the most useful methods of detecting the behavior of the solvent molecules near the reaction center is to examine the effect of the *o*-substitutent on the reaction rates in solution.[2-4] Accordingly, the effects of the *o*-methyl group on the rates of the Menschutkin reaction in liq. SO_2 have been compared with those in a methanol solvent,[3] and the difference in the behavior of the *o*-methyl group between these two solvents has been attributed to the specific solvation of the amines in liq. SO_2.[3]

In this paper the procedure for considering the mutual relation among activation free energies for the reactions in solution will be discussed by combining experimental results of different kinds obtained from different sources regarding the effects of an *o*-methyl group and the reaction rates in mixed solvents.

Experimental

Materials. The materials used in this experiment have been purified by methods described elsewhere.[3]

Kinetic Procedure. In most of all the kinetic runs given amounts of stock solutions of methyl iodide in liq. SO_2 were introduced into a reaction vessel containing given amounts of an amine solution in a nitrobenzene solvent, the mixture held at about −70°C by means of a pressure buret described elsewhere.[5a,5b] The reaction was started by placing the vessel into a thermostat bath held at the reaction temperature. The method of detecting the iodide ions produced during the reaction is almost the same as those described earlier.[3]

Typical results are shown in Table 1.

are obviously similar to that of curve 8 of model II in the previous paper.[1] The calculations were then made by taking the specific solvation of amines by liq. SO_2 and that of an activated complex by a nitrobenzene solvent into consideration. The interaction term, $\alpha_{14}x_1x_4$ and the molar volumes of the solvents which had been included in the original formula have been neglected in these calculations in order to make the computation easier.

$$\ln k_{mix} = x_1 \ln k_1 + x_4 \ln k_4 + \{x_4 \ln(K_R+1) - \ln(x_4K_R+1) - x_1 \ln(K_A+1) + \ln(x_1K_A+1) - x_1x_4\alpha_{14}\} \quad (1)$$

$$\Delta E_{mix}^{*} = x_1\Delta E_1^{*} + x_4\Delta E_4^{*} + x_1x_4\left\{\frac{\Delta H_A^{\circ}}{(1+1/K_A)(x_1+1/K_A)} - \frac{\Delta H_R^{\circ}}{(1+1/K_R)(x_4+1/K_R)}\right\} \quad (2)$$

The procedure of the calculation was as follows. (1) The calculated value of log k_{mix} have been best-fitted to the experimental values of log k_{mix} by searching for suitable values of both K_A and K_R. (2) The enthalpy changes, $\Delta H_A^{\circ} - \Delta H_R^{\circ}$, have been computed from the rates of the variation in K_A and in K_R thus obtained with respect to the temperature. (3) The theoretical values of ΔE_{mix}^{*} have been calculated from Eq. (2) by substituting into Eq.(2) the numerical values of ΔH_A° and ΔH_R° and of K_A and K_R obtained above.

These theoretical values are shown as smooth curves in Figs. 1, 2, 3 and 4.

As for the reactions of *o*-substituted amines, the results were analyzed by similar procedures except that only the specific solvation of an activated complex by liq. SO_2 has been taken into account. The parameters used in these calculations are summarized in Table 2.

Discussion

In these calculations the best values of K_A and K_R have been chosen without considering the boundary conditions, *i. e.*, Eqs. (3) and (4), which should

TABLE 2. THE PARAMETERS USED IN THESE CALCULATIONS

Reactions		Temperature 20°C	30°C	40°C	50°C	60°C	
Pyridine+MeI	K_A		1.5	3.0	6.0		$H_A^\circ=12.2$ (kcal mol^{-1})

	K_R		17	11	6.0		$H_R^\circ=-10.2$ (kcal mol^{-1})
2,6-Dimethylpyridine +MeI	K_A	6.0	8.0	7.0	8.5		$H_A^\circ=2.2$ (kcal mol^{-1})
	K_R	0	0	0	0		$H_R^\circ=0$ (kcal mol^{-1})
N,*N*-Dimethyl-*o*-toluidine+MeI	K_A		7.5	7.0	6.5	6.0	$H_A^\circ=-1.5$ (kcal mol^{-1})
	K_R		0	0	0	0	$H_R^\circ=0$ (kcal mol^{-1})

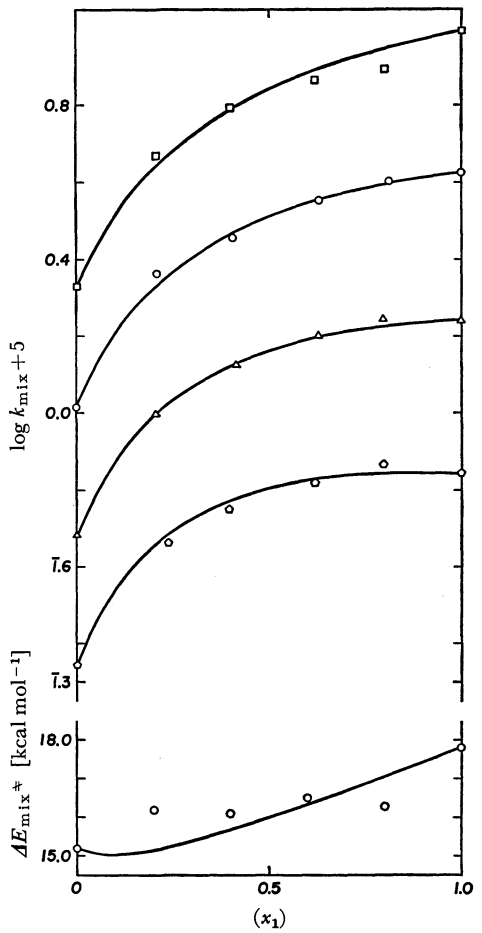

Fig. 4. Dependence of log k_{mix} and E_{mix}^* for the reaction of *N*,*N*-dimethyl-*o*-toluidine with methyl iodide in nitrobenzene - liq. SO_2 mixture upon mole fraction of liq. SO_2 (x_1).
□ (60°C), ○ (50°C), △ (40°C), ⬠ (30°C): experimental results, —: calculated results

be satisfied whenever the model is self-consistent.

$$(k_1/k_4) = \exp(\alpha_{A1}-\alpha_{A4}) \times \exp(\alpha_{B1}+\alpha_{M4}^*) \times (K_A+1)(K_R+1)(V_1/V_4) \quad (3)$$

$$(\Delta E_1^*-\Delta E_4^*) = \left\{\frac{\Delta H_A^\circ}{(1+1/K_A)} + \frac{\Delta H_R^\circ}{(1+1/K_R)}\right\} \quad (4)$$

However, if we try to describe an S-shaped curve like those in Figs. (1), and (2) by this model, values of both K_A and K_R must be chosen larger than those required by the boundary condition, Eq. (3).

One example of these situations is shown in Fig. 5, where the deviations from linearity, *i. e.*, $\Delta\log k_{mix}$, are calculated for various values of $(k_1/k_4)/(K_A+1)(K_R+1)$, which stand for the degree of consistancy.

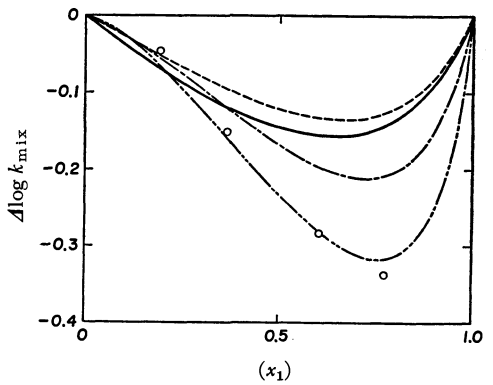

Fig. 5. Plots of the deviation from linearity, $\Delta\log k_{mix}$ *vs.* x_1 for the reaction of *N*,*N*-dimethylaniline with methyl iodide at 30°C, $(k_1/k_4)=5.69$.
experimental results: ○, calculated results: —— ($K_R=4.69$, $K_A=0$), ---- ($K_R=4.7$, $K_A=1$), —·— ($K_R=8.5$, $K_A=2$), —··— ($K_R=15$, $K_A=2.9$)

Judging from the above inconsistency, our model would be better applicable to the reaction rates of *o*-substituted amines than to those of unsubstituted amines; for unsubstituted amines the values of $(k_1/k_4)/(K_A+1)(K_R+1)$ are within the factor of three.

Though ΔE_{mix} could be fitted by this procedure to a considerable extent, the boundary condition, Eq. (4), could not be satisfied. The reason is the inconsistency described above. Therefore, the estimations of the theoretical values of ΔE_{mix}^* may be concluded to be richer in errors since, for these calculations, we have to rely only on the variation

TABLE 3. THE EFFECT OF *o*-METHYL GROUP IN LIQ. SO_2 AND IN A NITROBENZENE SOLVENT AT 40°C

Reaction	Solvent		
N,N-Dimethylaniline+MeI	$PhNO_2$	$k_H=21.0\times10^{-5}$, $k_{o-Me}=0.480\times10^{-5}$	$k_H/k_{o-Me}=43.7$
	Liq. SO_2	$k_H=4.69\times10^{-5}$, $k_{o-Me}=1.74\times10^{-5}$	$k_H/k_{o-Me}=2.69$
Pyridine+MeI	$PhNO_2$	$k_H=11.1\times10^{-4}$, $k_{o-Me}=5.31\times10^{-5}$	$k_H/k_{o-Me}=20.9$
	Liq. SO_2	$k_H=2.37\times10^{-4}$, $k_{o-Me}=1.60\times10^{-4}$	$k_H/k_{o-Me}=1.48$

k: $l\,mol^{-1}\,sec^{-1}$, k_H/k_{o-Me}; the ratio of the rate constants of the substituted and *o*-methyl substituted amines

in K_A and in K_R with a change in the temperature.

Although the above inconsistencies must be kept in mind, for the cases of unsubstituted amines the values of K_R are always larger than those of K_A, while for substituted amines only the values of K_A are needed for these calculations. In addition to these facts regarding the reactions of unsubstituted amines, the rate constants in a nitrobenzene solvent are larger than those in liq. SO_2. From these facts we can determine the positions of the activation free energies in liq. SO_2 relative to those in a nitrobenzene solvent.

As is shown in Table 3, the retarding effect by an *o*-substituted methyl group is more remarkable in a nitrobenzene solvent than in liq. SO_2. Consequently, the rate constants for the reactions of *o*-substituted amines become larger in liq. SO_2 than in a nitrobenzene solvent.

The difference in the effect of an *o*-methyl substituent between a methanol and a liq. SO_2 solvent has been attributed to the effect of the solvation of amines by liq. SO_2[3]. The addition compound formed from 2-methylpyridine and trimethyl boron has been reported to be less stable than that of 3- or 4-methylpyridine and trimethyl boron because of the *o*-methyl group.[6]

Therefore, if we assume that *o*-substituted amines are solvated to a lesser extent in liq. SO_2 than are unsubstituted amines, but that there is not much difference between the two in the solvation energy in a nitrobenzene solvent, we can determine the positions of the activation free energies of the former amines relative to those of the latter amines.

Summing up these conclusions, the following figure (Fig. 6) describes the mutual relations of the activation energies.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 1713—1718 (1969)

Phosphorus-proton Spin-spin Coupling in the P–O–C–H Group. A Comparison of Cyclic and Acyclic Systems

Masatsune KAINOSHO,* ASAO NAKAMURA* and Masamichi TSUBOI**

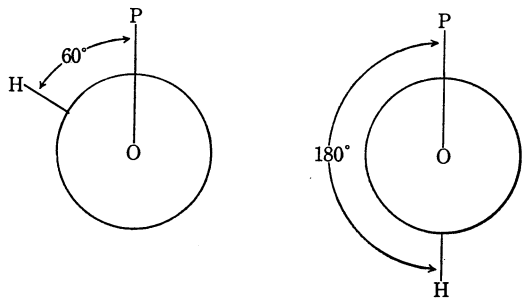
* *Central Research Laboratory, Ajinomoto Co., Inc., Kawasaki, Kanagawa*

** *Faculty of Pharmaceutical Sciences, The University of Tokyo, Bunkyo-ku, Tokyo*

(Received December 4, 1968)

Proton magnetic resonance spectra for eleven compounds with the POCH system have been examined. They are three 4-phenyl-2,2-disubstituted(X,Y)-1,3,2-dioxaphosphorinanes where X=Cl, Y=O (I); X=Cl, Y=S (II); and X=O$^-$K$^+$, Y=O (III); four 5,5-dimethyl-2,2-disubstituted (X,Y)-1,3,2-dioxaphosphorinanes where X=Cl, Y=O (IV); X=Br, Y=O (V); X=Cl, Y=S (VI); and X=OH, Y=O (VII); and four dimethyl phosphates, Y=P(-X)-(-OCH_3)$_2$, where X=Cl, Y=O (VIII); X=Br, Y=O (IX); X=Cl, Y=S(X); and X=O$^-$ ½Ba^{2+}, Y=O (XI). It has been found that the *1,3,2-dioxaphosphorinane* ring in each of I—VIII is virtually fixed in a chair form in the solution, and there is no appreciable ring inversion as confirmed by NMR spectra. The phosphorus-proton coupling constant of the POCH system with the *gauche* relation (J_g) and that with the *trans* relation (J_t) were determined in each of these compounds (I—VII). The $\frac{2}{3}J_g+\frac{1}{3}J_t$ values calculated from the determined J_g and J_t values are always smaller than the $\frac{2}{3}J_g+\frac{1}{3}J_t$ values observed for the corresponding acyclic compounds (VIII—XI). This difference was explained in terms of a slight flattening of *1,3,2-dioxaphosphorinane* ring from the ideal chair conformation.

In our previous papers,[1,2] it has been shown that the phosphorus-proton coupling constants in the POCH group show a marked stereospecificity; *i. e.*, 1.5—2.3 Hz for J_g and 22—28 Hz for J_t.

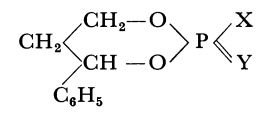


gauche *trans*

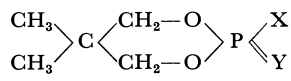
Fig. 1. The POCH system with *gauche* and *trans* conformations. Projected along the C–O axis.

The values of J_g and J_t, so far given, have rather large range of ambiguity. Nevertheless, they were very useful in determining the approximate conformation of a few phosphoric acid esters[1] and nucleotides.[2] A few other reports about the dihedral angular dependence of J_{POCH} have been made.[3,4] In this paper we present more precise knowledge of the J_g and J_t values on the basis of the NMR spectra of seven 1,3,2-dioxaphosphorinanes and four dimethyl phosphate derivatives.

Two series of the cyclic compounds were examined; they are 4-phenyl-2,2-disubstituted-1,3,2-dioxaphosphorinanes (I, II, III) and 5,5-dimethyl-2, 2-disubstituted-1,3,2-dioxaphosphorinanes (IV, V, VI, and VII):



I: X=Cl, Y=O
II: X=Cl, Y=S
III: X=O$^-$K$^+$, Y=O



IV: X=Cl, Y=O
V: X=Br, Y=O
VI: X=Cl, Y=S
VII: X=OH, Y=O

As will be detailed below, each of these cyclic compounds has been found to have a virtually frozen conformation, which is similar to the chair form of the cyclohexane ring as shown in Fig. 2. Therefore, J_g should be approximately equal to J_{AP} (or $J_{B'P}$) and J_t should be equal to J_{BP} (or $J_{A'P}$). The J_t and J_g values thus determined for various compounds will then be compared with

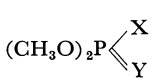
I—III $R_1,R_2=$; $R_3=C_6H_5$-
IV—VII $R_1,R_2=CH_3$-; $R_3=H$ (in this case a≡d, b≡c)

Fig. 2. Possible chair conformations of substituted 1,3,2-dioxaphosphorinanes.

one another. A question next arises: Are these values of J_t and J_g applicable to the acyclic system? For an answer to this question, we examined the NMR spectra of the following four acyclic dimethyl phosphate derivatives:



VIII: X=Br, Y=O
IX: X=Br, Y=O
X: X=Cl, Y=S
XI: X=O$^-$½Ba, Y=O

In each of these acyclic compounds, the observed POCH coupling constant should be considered as the mean of the values of equally populated three rotamers; *i. e.*, $J_{obs}=\frac{2}{3}J_g+\frac{1}{3}J_t$. A comparison will be made for the values of $\frac{2}{3}J_g+\frac{1}{3}J_t$ of cyclic (I—VII) and acyclic (VIII—XI) systems, and a discussion will be given to the differences found in these values.

Conformations of the 1,3,2-Dioxaphosphorinanes (I—VII). The NMR spectrum of I is shown in Fig. 3, a. As is seen here, the spectrum is too complicated to be analyzed on itself. The analysis was made by adopting two techniques. One of them is a triple resonance. On irradiating C and D protons simultaneously, the complex signals of E, A, and B protons become simpler (see Fig. 3, b), while on irradiating A and B signals simultaneously, the signals of C and D protons become simpler (see Fig. 3, c). The other method for the simplification of the spectra is to substitute C and D protons with deuterium. The NMR spectrum of the deuterated I is shown in Fig. 4. The signals of A, B, and E are now simpler patterns which can be readily analyzed. As an example, the parameters thus determined with II by a first order approximation are given in Table 1.

The observed values of the proton-proton coupling constants (Table 1) are in good agreement with what is expected when the *1,3,2-dioxaphosphorinane* ring is fixed to a chair form carrying the bulky phenyl group on the equatorial bond (Fig. 2, a, c). Thus, the coupling constants J_{AD} and J_{DE} are 11.3—11.9 Hz, and these values are expected when A, D and D, E are nearly in the *trans* relations[5] (see Table 1). On the other hand J_{AC}, J_{BC}, J_{BD} and J_{CE} are all small (2.4—5.0 Hz), and they are just what is expected for *gauche* coupling.[5]

The NMR spectrum of IV is given in Fig. 5, a. There are two methyl signals observed corresponding to the two methyl groups on C_5. When the lower-field methyl signal is irradiated strongly, the lower-field transitions of the ring methylene protons become sharper (see Fig. 5, b). This

observation indicates that there is a long range coupling existing between these protons.[6] Such an appreciable long range coupling through four bonds is known to take place only when the interacting nuclei are arranged so as to have the coplanar zigzag orientation ("W" letter orientation) with each other.[7,8] Therefore, the lower-field methyl signal must be assigned to the axial one. This implies that IV should have a nearly fixed conformation, either (a) or (b) in Fig. 2. If these two conformers were mixed with each other to a considerable amount, both two methyl groups would have a chance to experience the zigzag orientation with ring protons. Actually, however, no effect was observed in the methylene signals on irradiating at the upper-field methyl signal.

J_t and J_g Values in the Cyclic Systems (I —VII). Now that the conformation of *1,3,2-dioxaphosphorinane* systems is found to be fixed at one of the possible chair structures (Fig. 2), the J_g and J_t values are readily obtained. Those values, obtained by the ABX treatments of the simplified methylene spectra, are given in Table 2.

It has been shown that the J_t value (ranging, 22.3—32.2 Hz) is much greater than the J_g value (1.5—4.3 Hz). Thus the spin-spin coupling in the POCH system has a similar stereospecificity to that of the HCCH system.[5] It is interesting to point out that the substituent effect on the J_t value seems to be greater than that on the J_g value (see Table 2).

TABLE 2. PHOSPHORUS-PROTON COUPLING CONSTANTS (J_{POCH}) OF 1,3,2-DIOXAPHOSPHORINANES[a]

Compound	Solvent	J_g	J_t	J_g+J_t	X	Y
I[b]	$CDCl_3$	−(2.2)[c]	—	33.2	Cl	O
IV	$CDCl_3$	2.9	27.5	30.4		
V	$CDCl_3$	3.6	30.0	33.6	Br	O
II	$CDCl_3$	3.6(3.6)	32.2	35.8	Cl	S
VI	$CDCl_3$	4.3	28.6	32.9		
III	D_2O	1.9(1.5)	22.3	24.2	O^-K^+	O
VII	D_2O	12.2[d]			OH	O

a) Coupling constants are obtained by ABX treatment for the ring methylene protons.
b) Spectrum of I seems to be unsuitable for ABX treatment because of the line overlapping (see Fig. 3, 4).
c) Values in the parentheses show the coupling constant between phosphorus and E proton as defined in Table 1.
d) Estimated by the spacing of the doublet; equal to $\frac{1}{2}(J_g+J_t)$.

J_{POCH} Values in the Acyclic Systems (VIII —XI). In an acyclic system the J_t and J_g are not obtained separately. The observed J_{POCH} in a CH_3OP system, however, is considered to be exactly equal to $\frac{2}{3}J_g+\frac{1}{3}J_t$. The $\frac{2}{3}J_g+\frac{1}{3}J_t$ values, listed in Table 3, have been observed for VIII, IX, X and XI.

TABLE 3. PHOSPHORUS-PROTON COUPLING CONSTANTS IN VARIOUS DIMETHYL PHOSPHATES; $(CH_3O)_2P(=Y)X$[a]

Compound	Solvent	J_{obs}[b]	J_{calcd}[c]	ΔJ[d]	X	Y
VIII	$CDCl_3$	13.6	11.1	2.5	Cl	O
IX	$CDCl_3$	14.3	12.4	1.9	Br	O
X	$CDCl_3$	18.9	13.1 12.4	5.8 6.5	Cl	S
XI	D_2O	10.8	8.7	2.1	$O^-\frac{1}{2}Ba^{2+}$	O

a) Preparation of these compounds were carried out by conventional methods.
b) Obtained directly from the spacing of doublets.
c) Estimated using the corresponding J_g and J_t valuses in Table 2, by $J_{calcd}=\frac{1}{3}J_t+\frac{2}{3}J_g$.
d) $\Delta J=J_{obs}-J_{calcd}$

Discussion

As may be seen in Table 3, the $\frac{2}{3}J_g+\frac{1}{3}J_t$ value is always greater in an acyclic system than that in the corresponding cyclic system (the difference is 1.9—6.5 Hz). One might attribute this difference to an inversion of the *1,3,2-dioxaphosphorinane ring*. As was already shown, the six-membered ring is almost frozen to (a) or (c) given in Fig. 2. But the possibility that the ring experiences other conformations, such as (b) or (d), in a small fraction (α) of time has never been completely excluded. This would give slightly different coupling constants (J'_t and J'_g) from the strict J_t and J_g. The situation might make the $\frac{2}{3}J'_g+\frac{1}{3}J'_t$ value always greater than the $\frac{2}{3}J_g+\frac{1}{3}J_t$ value.
Thus,

$$\begin{aligned}\tfrac{1}{3}J'_t+\tfrac{2}{3}J'_g &= \tfrac{1}{3}[(1-\alpha)J_t+\alpha J_g]\\ &\quad+\tfrac{2}{3}[(1-\alpha)J_g+\alpha J_t]\\ &= (\tfrac{1}{3}J_t+\tfrac{2}{3}J_g)+\alpha/3(J_t-J_g)\\ &> \tfrac{1}{3}J_t+\tfrac{2}{3}J_g,\end{aligned}$$

as far as $J_t>J_g$. Therefore, the possible inversion of the ring, if any, does not explain the fact that the apparent $\frac{1}{3}J_t+\frac{2}{3}J_g$ value of the cyclic system is smaller than that of the acyclic system.

Instead, this fact can be explained by considering a slight deviation of the dihedral angle from 60° or 180°. X-ray studies of three 1,3,2-dioxaphosphorinanes, as are listed in Table 4, show that there is actually a ring flattening in each of the compounds examined. As may be seen in the table, the dihedral angle for the "*gauche*" and "*trans*" POCH group is 65° and 185°, respectively. It is

Table 4. Dihedral angles of P-O-C-H system in 1,3,2-dioxaphosphorinanes[a)]

Compound	∠P-O-C-H_A[b)]	∠P-O-C-H_B[b)]
2-Oxo-2-phenoxy[9)]	67°	187°
5-Methyl-5-bromomethyl-2-oxo-2-bromo-[10)]	64	184
VII[11)]	65	185

a) All angles are estimated by the assumption of tetrahedral carbon atom, using X-ray crystallographc data.
b) See Fig. 2.

probable that these dihedral angles are kept not only in the crystals but also in solutions. If the curve for J_{POCH} *versus* dihedral angle is similar to the curve for J_{HCCH} *versus* dihedral angle given by Karplus[5)], these greater dihedral angles should cause smaller values of apparent J_g and J_t than what would be observed when the dihedral angles were exactly 60° and 180°, respectively. Therefore, a correction should be made of each of the observed values of J_g and J_t, so as to bring it to the value corresponding to 60° or 180°.

As was already shown in a previous paper,[2)] ^{31}P spectra in D_2O solution of inosine-5'-monophosphate (IMP) and guanosine-5'-monophosphate (GMP) give a triplet whose spacings are considered to correspond to two approximately equal J_{POCH}'s where J_{POCH}=4.5 Hz. The fact that two equal J_{POCH}'s are observed means that the two dihedral angles $POC_5'H$ are both 60° in IMP or in GMP. Therefore, let us assume that J_g equals 4.5 Hz when the dihedral angle POCH equals exactly 60° (instead of 65°). The correction of the J_{POCH} value from that of the dihedral angle 185° to that of 180°C is considered to be about +5%, on the basis of the curve presented by Karplus[5)] for J_{HCCH}. This leads the J_t value to about 23.5 Hz for H-C-O-P(=O)O$^-$ system. With these values of J_g and J_t, the $\frac{2}{3}J_g+\frac{1}{3}J_t$ value (10.8 Hz) of the cyclic system is in an exact agreement with that of the acyclic system.

In summarizing, what has so far been observed can be explained by postulating the following items:

1) The *1,3,2-dioxaphosphorinane* ring of each of I—VII is fixed in a chair form in solution, and there is no appreciable inversion taking place.

2) In the fixed chair form, the dihedral angle of $POCH_A$ (see Fig. 2, a) is about 65° (instead of 60°) and that of $POCH_B$ (see Fig. 2, a) about 185° (instead of 180°).

3) The ^{31}POCH coupling constant depends upon the dihedral angle in a similar way to that of HCCH.

4) We do not need to assign different values of the coupling constant to cyclic and acyclic systems, as far as the same set of atoms (X and Y) are placed on P.

5) The nuclear spin coupling constant in the  group is 4.5 Hz if the dihedral angle is 60°, and 23.5 Hz if the dihedral angle is 180°.

Experimental

NMR Measurements. All spectra were recorded with a Varian A-60 and a HA-100 spectrometer. The 100 MHz frequency sweep decoupling experiments were achieved with two Hewlett-Puckard 200 ABR oscilators at the field-frequency controlled mode.

Lithium Aluminum Hydride Reduction of Ethyl Benzoylacetate. A solution of ethyl benzoylacetate (7.69 g, a mixture of 58% *keto* and 42% *enol* forms, determined by NMR analysis) in dry ether (50 m*l*) was added to an ice-cold solution of $LiAlH_4$ (24 g) in ether (100 m*l*), over a period of an hour. Stirring was continued for an additional 1 hr, then the mixture was treated with a small amount of water, dried ($MgSO_4$) and was fractionally distilled. The diol was distilled at 125°C/1.5 mmHg and the yield was 85% from *keto* form of ethyl benzoylacetate.

Found: C, 70.88; H, 7.66%. Calcd for $C_9H_{12}O_2$: C, 71.02; H, 7.95%.

Ethyl(*α,α*-dideuterio) benzoylacetate. The deuteration was achieved by the deuterium-hydrogen exchange reactions between ethyl benzoylacetate and *O*-deuterioethanol. The process of the reaction was followed by the NMR measurement.

2,2-Dideuterio-1-phenyl-1,3-propanediol. Lithium aluminum hydride reduction of ethyl (α,α-dideuterio)-benzoylacetate afforded the dideuterio diol. Its NMR spectrum showed that deuterium-hydrogen exchange was negligible during the course of preparation.

2-Oxo-2-chloro-4-phenyl - 1, 3,2 - dioxaphosphorinane (I). The cyclic phosphorochloridate was prepared by a similar method to that of Lanham.[12)] The yield was 29%.

Found: C, 46.55; H, 4.53; Cl, 15.32%. Calcd for $C_9H_{10}ClO_3P$: C, 46.47; H, 4.33; Cl, 15.24%.

2- Thiono -2- chloro - 4 - phenyl - 1,3,2 - dioxaphosphorinane (II). This compound was synthesized by following the procedure given in Lanham's patent,[12)] and was obtained as light yellow oil, which partly changed to colorless needles while it was kept in a refrigerator in a vacuum dessicator. Purification through vacuum distillation was not successful because a decomposition of the oil took place. Its purity was judged only by the NMR measurement.

Potassium 2-Oxo-2-hydroxy-4-phenyl-1,3,2-dioxaphosphorinane (III). To a solution of II (1.02 g) in a mixture of dioxane-water (17 : 3) was added 2 N KOH solution (5 m*l*). After stirring for a few minutes, the solvent was distilled off, and the residue was extracted.

with ethanol. After removal of ethanol the product was deposited as colorless solid, which was washed with acetone, and dried in air. The yield was 1.04 g (94%). The structure was characterized by NMR.

5,5-Dideuterated Compounds of I, II, and III. These compounds were prepared from 1-phenyl-1,3-(2,2-dideuterio)-propanediol by similar methods to those described for I, II, and III, above. The products were identified by their NMR spectra.

5,5-Dimethyl-2-thiono-2-chloro-1,3,2-dioxaphosphorinane (IV). To a solution of neopentylglycol (0.3 mol) in 150 m*l* of dichloroethane, was added gradually thiophosphoryl chloride (0.3 mol) in 50 m*l* of dichloroethane, with continuous stirring, while the reaction mixture was kept below 26°C by ice-water cooling. After the addition of thiophosphoryl chloride was completed, hydrogen chloride was removed by the vigorous bubbling of dry nitrogen. Removing the solvent under the reduced pressure, colorless crystals were obtained. Recrystallization from *n*-hexane gave colorless needles. Yield, 69%. Mp 92—93.5°C.

Found: C, 29.72; H, 5.11%. Calcd for $C_5H_{10}O_2$·SClP: C, 29.93; H, 5.02%.

5, 5-Dimethyl-2-oxo-2-bromo-1,3,2-dioxaphosphorinane (V). To a solution of neopentylglycol (5.2 g) in 30 m*l* dichloroethane was added slowly phosphoryl bromide in 20 m*l* dichloroethane. The orange colored product was obtained by a similar procedure to that for IV. The product was crystallized as colorless needles from *n*-hexane solution and they turned gradually to yellow with moisture. Mp 98—99°C.

Found: C, 27.06; H, 4.71%. Calcd for $C_5H_{10}O_3$-BrP: C, 26.22; H, 4.40%.

V was also prepared by the Michaelis-Arbuzov reaction between 5,5-dimethyl-2-methoxy-1,3,2-dioxaphosphorinane and bromine.

5,5-Dimethyl-2-oxo-2-chloro-1,3,2-dioxaphosphorinane (VI). VI was prepared by a known procedure[13] with 68% Yield. Mp 107—108°C.

Found: C, 32.83; H, 5.54%. Calcd for $C_5H_{10}O_3$-ClP: C, 32.54; H, 16.46%.

5, 5-Dimethyl-2-oxo-2-hydroxy-1,3,2-dioxaphosphorinane (VII). VII was prepared by the hydrolysis of VI in aqueous acetone. Recrystallization from hot aqueous solution gave colorless needles. A *thermogravimetric* analysis showed the product contained one water molecule.

Found: C, 33.16; H, 7.06%. Calcd for $C_5H_{11}O_4P \cdot H_2O$: C, 32.51; H, 7.12%.

The authors wish to express their gratitude to Miss Masako Kaneko for her help throughout this study, and to Dr. M. C. Woods and Mr. Iwao Miura of the Tohoku University for their help in the NMR measurements at an early stage of this work.

Note Added in Proof. After the completion of this work, the authors have extensively studied the conformation of 2,2-disubstituted-1,3,2-dioxaphosphorinanes by dipole moment measurements[14], infra-red[15] and NMR spectra.[16] The results thus far obtained strongly indicates a-conformation of Fig. 2 is the preferred one.

The Synthesis of Cyclic α-Amino Acids. III. The Synthesis of Methyl (+)- and (−)-3-Amino-3-*C*-carboxy-3-deoxypentopyranosides

Hiroaki YANAGISAWA, Mitsuhiro KINOSHITA and Sumio UMEZAWA

Department of Applied Chemistry, Faculty of Engineering, Keio University, Koganei-shi, Tokyo

(Received December 14, 1968)

Cyclization of D'-methoxy-diglycolaldehyde, prepared by periodate cleavage of methyl β-L-arabinopyranoside, with ethyl nitroacetate gave a mixture of stereoisomers of cyclic α-nitro ester, *i.e.* methyl (+)-3-deoxy-3-*C*-ethoxycarbonyl-3-nitropentopyranoside. Catalytic reduction of the cyclic α-nitro ester afforded an isomeric mixture of cyclic α-amino esters, from which, on column chromatography, there could be isolated four diastereoisomers of methyl (+)-3-amino-3-deoxy-3-*C*-ethoxycarbonylpentopyranoside. Hydrolysis of each diastereoisomer gave the corresponding cyclic (+)-α-amino acid having a skeleton of pentopyranoside. The stereochemistry of the isomeric amino acids was studied by NMR spectroscopy and chemical degradation. On the other hand, three enantiomeric cyclic (−)-α-amino acids were also obtained from methyl β-D-xylopyranoside by the analogous route as that from methyl β-L-arabinopyranoside.

In a previous paper[1] one of the authors and others reported the synthesis of a cyclic amino acid, *i. e.* 1-amino-2,6-dihydroxycyclohexane-1-carboxylic acid by condensation of glutardialdehyde with ethyl nitroacetate, followed by reduction and hydrolysis. The present paper is concerned with an extension of this work and presents the synthesis of methyl (+)- and (−)-3-amino-3-*C*-carboxy-3-deoxypentopyranosides (VI-d, VI-1) which are the first synthetic examples of cyclic α-amino acid having a pyranoside-skeleton.

Details of the synthesis are summarized in Scheme 1. The starting materials, D'- and L'-diglycolaldehyde (III-d. III-1) were prepared from methyl β-L-arabinopyranoside (I) and β-D-xylopyranoside (II) respectively, by periodate oxidation as was reported by Bear and Fischer[2].

The condensation reaction of III-d with ethyl nitroacetate was carried out in the presence of potassium acetate and potassium carbonate to give a dextrorotatory methyl (+)-3-deoxy-3-*C*-ethoxycarbonyl-3-nitropentopyranoside (IV-d) in 81% yield. The purification of IV-d was accomplished by silica gel chromatography, although the diastereoisomeric separation of IV-d was unsuccessful in this step. The acetylation of IV-d with acetic anhydride in pyridine gave a diacetyl derivative of IV-d, the NMR spectrum (in $CDCl_3$) of which showed the presence of two *O*-acetyl groups at about τ 7.84 and 7.92.

The condensation reaction of III-1 with ethyl nitroacetate gave a levorotatory nitro ester (IV-1).

The catalytic hydrogenation of the nitro esters IV-d and IV-1 with Raney Ni T-4 gave methyl (+)- and (−)-3-amino-3-deoxy-3-*C*-ethoxycarbonylpentopyranosides (V-d and V-1) as a syrup, respectively.

The amino ester V-d was shown by thin-layer chromatography to contain four ninhydrin positive components, VA-d (R_f 0.73), VB-d (R_f 0.55), VC-d (R_f 0.36) and VD-d (R_f 0.23). These components were separated from each other by silica gel column chromatography. The major component VB-d and minor one VD-d were obtained in crystalline states. The components, VA-d, VB-d, VC-d and VD-d were acetylated to give dextrorotatory crystalline triacetates, VIIA-d, VIIB-d, VIIC-d and VIID-d, respectively. These acetates were characterized as the fully acetylated diasteroisomeric amino esters on the basis of elemental and NMR analysis (Tables 1, 3 and 4).

By analogous chromatography four diastereoisomers of levorotatory amino esters, VA-1 (R_f 0.73), VB-1 (R_f 0.55), VC-1 (R_f 0.36) and VD-1 (R_f 0.23) were obtained from the mixed amino ester V-1. The crystalline major and minor isomers, VB-1 and VD-1 were characterized as the enantiomers of VB-d and VD-d, respectively (Table 1). Furthermore, the crystalline triacetates, VIIA-1, VIIB-1, and VIID-1 were also obtained from VA-1, VB-1 and VD-1, respectively (Table 1). The IR and NMR spectra of VIIA-1, VIIB-1 and VIID-1 were completely identical with those of VIIA-d, VIIB-d and VIID-d, respectively.

The hydrolysis of VA-d, VB-d, VC-d and VD-d afforded the isomeric methyl (+)-3-amino-3-*C*-carboxy-3-deoxypentopyranosides, VIA-d, VIB-d, VIC-d and VID-d, respectively, in good yields. Analogously, the enatiomeric (−)-amino acids,

VIA-1, VIB-1 and VID-1 were also obtained from the amino esters, VA-1,VB-1 and VD-1, respectively (Table 2).

Stereochemical Considerations. The anomeric carbon atom C-1 in each of the isomers of the (+)-amino acid (VI-d) apparently has the same configuration as that of the anomeric carbon atom in the methyl β-L-arabinopyranoside (I) used as a starting substance. The other asymmetric carbon atoms (C-2, C-3 and C-4), however, have unknown configurations, because they are new asymmetric centers which have been formed by the condensation reaction of the dialdehyde (II-d) with ethyl nitroacetate. The steric configurations

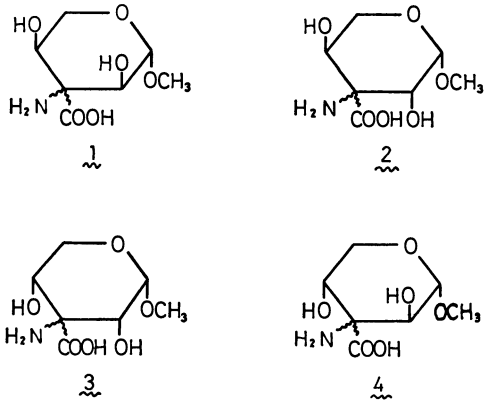

Fig. 1

of the isomeric (+)-amino acids, VIA-d, VIB-d, VIC-d and VID-d, therefore, must be assigned to any of the eight possible configurations. When the configuration at C-3 is let aside, the four formulas shown in Fig. 1 are possible for the isomeric (+)-amino acids.

Conformational and configurational studies based on the NMR (in $CDCl_3$) analysis[3] of the fully acetylated amino esters, VIIA-d, VIIB-d, VIIC-d and VIID-d, served to deduce the configurations at the two carbon atoms (C-2 and C-4) of the above-mentioned three unknown asymmetric carbon atoms in the amino acid isomers. The spectral features were assigned on the basis of chemical shifts, integrated area, magnitudes of splittings and decoupling splitting patterns (Fig. 2). The assigned chemical shifts and coupling constants are listed in the Tables 3 and 4. From the following results partial conformations for VIIA-d, VIIB-d, VIIC-d and VIID-d could be deduced on the assumption that most pyranoside sugars and their derivatives may exist in the chair conformations (*C1*, *1C*)[4].

The ring proton coupling constants ($J_{1,2}=1.8$, $J_{4,5e}=J_{4,5a}=2.0$ Hz) observed in the spectrum (Fig. 2, A) of VII-d indicate that the pair of H-1 and H-2 protons is in equatorial-axial or equatorial-equatorial orientation and H-4 proton is not antiparallel to H-5 axial proton. Decoupling reveals that the long range coupling of 1.5 Hz is found between H-2 proton and H-4 proton. Therefore, H-2 proton may be located on equatorial as well as

Table 3. Chemical shifts (τ) in $CDCl_3$ at 100 MHz

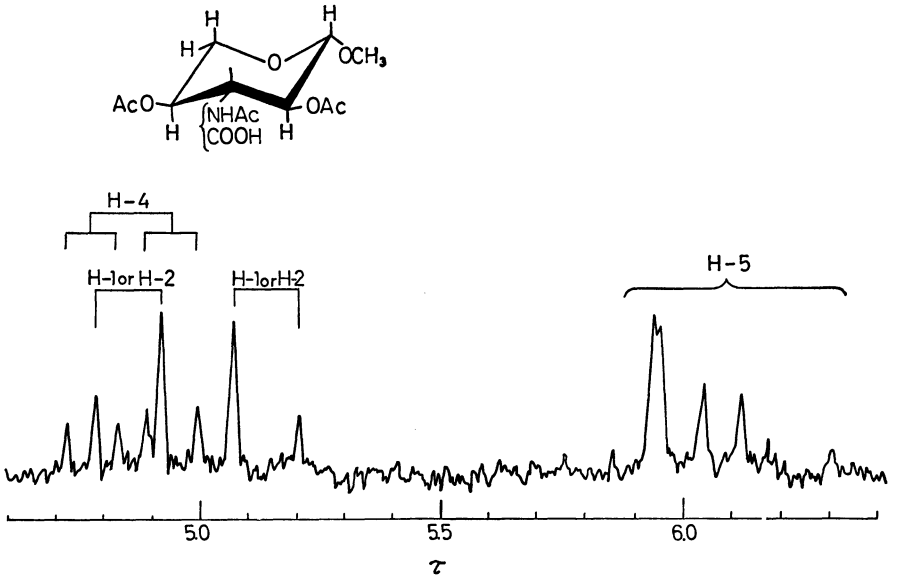

Fig. 3. NMR spectrum of VIIID-d in $CDCl_3$ at 60 MHz.

H-4 proton according to stereospecificity of the long-range coupling ("W"-conformation[5]). The chemical shifts (τ 7.79 and 7.88) for the ring-acetoxy protons at C-2 and C-4 also support this conformation, because they fall in the range of the chemical shifts (τ 7.80—7.90) reported for the axial orientation.[6] There must be then considered two possible partial conformations, **5** and **6** for VIIA-d (Fig. 2, A). The former is a *C1* conformation corresponding to the configuration **1** and the later is a *1C* conformation corresponding to the configuration **3**.

In the NMR spectrum (Fig. 2, B) of VIIB-d, the ring proton coupling constants ($J_{4,5a}=J_{4,5e}=1.4$—2.0 Hz) show that H-4 proton is not antiparallel to H-5 axial proton, therefore, H-4 proton is equatorial. The H-2 proton may be in axial orientation, because decoupling experiment shows no long-range coupling between H-2 and H-4 protons. The small coupling constant ($J_{1,2}=3.1$ Hz) shows that H-1 proron is gauche to the H-2 proton. Consequently, the H-1 proton thus may be located on equatorial orientation. The acetoxy signal at τ 7.78 indicates that one axial acetoxy group exists in VIIB-d. Conformation **7** is deduced as a possible partial conformation for VIIB-d and this is *C1* conformation corresponding to the configuration **2**.

The NMR spectrum (Fig. 2, C) of VIIC-d shows that the pair of H-1 and H-2 protons is in equatorial-axial or equatorial-equatorial orientation($J_{1,2}=4.7$ Hz), while H-4 proton is located on axial orientation ($J_{4,5e}=10.1$ Hz). The acetoxy signals at τ 7.93 and 8.00 indicate that VIIC-d has two equatorial ring-acetoxy groups.[6] Consequently, H-2 proton is located on axial orientation and H-1 proton is to be regarded as equatorial. A possible partial conformation for VIIC-d is deduced as **8** which is a *C1* conformation corresponding to the configuration **3**.

In the NMR spectrum (Fig. 2, D) of the last isomer VIID-d, the observed ring-proton coupling constants ($J_{1,2}=5.7$ and $J_{4,5a}=7.3$ Hz) reveal that H-1, H-2 and H-4 protons are all in axial orientation. The existence of two equatorial acetoxy groups is shown by the sharp singlet at τ 7.96, which is caused by overlapping of the two acetoxy signals. These results are confirmed by the NMR analysis for the triacetate (VIIID-d) of the free amino acid VID-d, which affords a spectrum of the AB and ABX type arising from the protons at the 1,2- and 4,5,5-positions, respectively (Fig. 3). Treating these protons as an isolated AB and ABX system, the following coupling constants are obtained; $J_{1,2}=8.3$, $J_{5a,5e}=12$, $J_{4,5e}=3.0$ and $J_{4,5a}=10.0$ Hz. From these results a possible partial conformation for VIID-d is to be considered as **9** which is a *1C* conformation corresponding to configuration **1**.

It is not possible to distinguish between the conformations **5** and **6** by the study of the ring proton resonances as described above. In other words, it remains unknown which of the configurations **1** and **3** is to be assigned for VIA-d. On the other hand, oxidation of the isomeric amino acids (VI-d) with chloramine-T yielded the corresponding methyl pentopyranosid-3-uloses (IX-d). They were isolated by preparative layer chromatography in the forms

5) L. D. Hall and L. Hough, *Proc. Chem. Soc.*, **1962**, 382; K. Heyns, J. Weyer and H. Paulsen, *Chem. Ber.*, **98**, 327 (1965); C. V. Holland, D. Horton and J. S. Jewell, *J. Org. Chem.*, **32**, 1818 (1967).

6) R. U. Lemieux, R. K. Kulling, H. J. Berstein and W. G. Schneider, *J. Am. Chem. Soc.*, **80**, 6098 (1958); F. W. Lichtenthaler and P. Emig, *Tetrahedron Letters*, **1967**, 577.

of their *p*-nitrophenylhydrazone derivatives which were characterized by IR spectra and mixed melting point determinations. The two same kinds of *p*-nitrophenylhydrazones, A_1 (mp 172°C dec., R_f 0.32) and A_2 (mp 174.5°C dec., R_f 0.43) were obtained from each of the oxidation products of VIA-d and VID-d. This indicates that the amino acids, VIA-d and VID-d are converted to a same methyl pentopyranosid-3-ulose by the chloramine-T oxidation and that VIA-d is the C-3 epimer of VID-d. The structures of the above-mentioned *p*-nitrophenylhydrazones can not be stated clearly at the present stage, because there must be considered the prototropy phenomenon which may be caused in the α-hydroxycarbonyl grouping[–(C=O)–CH(OH)–] of the oxidation products. However, the configuration **1** is to be assigned to VIA-d as well as to VID-d. The oxidation products of VIB-d and VIC-d afforded the *p*-nitrophenylhydrazones, B (mp 162—164°C dec., R_f 0.26) and C (mp 168°C dec., R_f 0.42), respectively, each of which was completely different from A_1 and A_2.

In conclusion, the above-mentioned experimental findings permit the assignment of the structural formulas **2** and **3** to VIB-d (major component)and VIC-d, respectively, and the formula **1** to VIA-d and VID-d, which are in epimeric relation with each other at C-3. The compound corresponding to the configuration **4** was not obtained.

Experimental

Paper chromatograms of amino acids were run with *n*-butanol - acetic acid - water (4 : 1 : 1) on Toyo Roshi No. 50 paper using an ascending technique, and spots were detected by means of a spray of a 0.5% pyridine solution of ninhydrin. Thin layer chromatography (TLC) and preparative layer chromatography (PLC) were conducted by the use of silica gel (Daiichi Pure Chemicals Co., Inc.). The prepared plates were activated at 110°C and the spray reagents used were 10% sulfuric acid and 0.5% pyridine solution of ninhydrin. Silica gel column chromatography was carried out by the use of silica gel (Kanto Chemical Co., Inc.) activated at 110°C before use. NMR spectra were taken with Japan Electron Optics JNM-4H-100 spectrometer and Varian A-60D spectometer at a frequency of 100 and 60 MHz by using about 10—20% solution of the sample in deuteriochloroform with tetramethylsilane as an internal standard.

Methyl (+)-3-Deoxy-3-*C*-ethoxycarbonyl-3-nitropentopyranoside (IV-d). Methyl β-L-arabinopyranoside[7] (I) (10.0 g, 0.061 mmol) was added in small portions to a stirred solution of periodic acid (27.8 g, 0.122 mmol based on H_5IO_6) in 500 m*l* of water at 20°C. The reaction mixture was allowed to stand for 20 hr at room temperature and was neutralized (pH 5) with hot 0.244 M strontium hydroxide solution (250 m*l*, 0.061 mol). The precipitate was removed by filtration and was washed with ethanol. The filtrate and washings were evaporated to afford the syrupy D'-methoxy-diglycolaldehyde (III-d), which was dissolved in ethanol (100 m*l*) and was filtered to remove a small amount of undissolved matter. The ethanolic solution of III-d was stirred under ice-cooling, while ethyl nitroacetate (8.1 g, 0.061 mol), 40% aqueous potassium acetate solution (14.2 m*l*) and 40% aqueous potassium carbonate solution (8.8 m*l*) were added successively. After the mixture was stirred in an ice bath for 3 hr, Amberlite IR-120 (100 m*l*) was added and was stirred for an additional one hour. The resin was removed by filtration and the filtrate (pH 4) was evaporated in a vacuum to afford a yellow syrup (14.6 g) of the title compound (IV-d). The product was purified through a silica gel (123 g) column. Elution with benzene-acetone (6 : 1) afforded 13.1 g (81%) of the pure nitro ester IV-d, $[\alpha]_D^{23}$ +157° (*c* 0.58, water), ν_{max}^{Film} 3455(OH), 1750 (ester C=O) and 1564 cm^{-1} (NO_2).

Found: C, 41.08; H, 5.91; N, 5.30%. Calcd for $C_9H_{15}NO_8$: C, 40.75; H, 5.70; N, 5.28%.

Di-*O*-acetyl Derivative of IV-d. A mixture of the nitro ester (IV-d) (136 mg), pyridine (6 m*l*) and acetic anhydride (2 m*l*) was allowed to stand overnight at room temperature. The reaction mixture was poured into ice-water and the liberated oil was extracted with four 10 m*l* portions of chloroform. The extracts were evaporated and the last trace of pyridine was removed by co-distillation with toluene. The residue was purified through a silica gel (20 g) column. Elution with benzene-acetone (10 : 1) afforded the title compound as a yellow syrup, yield 151 mg (84.5%), $[\alpha]_D^{32}$ +164° (*c* 0.9, ethyl acetate). The acetate was shown to be a mixture of diastereoisomers by its NMR spectrum. The NMR signals for the main isomer were observed at τ ($CDCl_3$): 7.84 and 7.92 (singlets, acetoxy protons); 6.62 (singlet, glycoside methyl protons); 5.60 (quartet, J=7.5 Hz, ester methylene protons); 8.67 (triplet, ester methyl protons); 6.06 and 5.62 (doublets, J=3.5 Hz, H-1 and H-2 proton); 6.19 (quartet, J=2.0 and 2.5 Hz, H-4 proton); 5.58 (quartet J=2.5 and 14.0 Hz, H-5 proton) and 6.12 (quartet J=2.0 and 14.0 Hz, H-5 proton).

Found: C, 44.95; H, 5.83; N, 4.13%. Calcd for $C_{13}H_{19}NO_{10}$: C, 44.69; H, 5.49; N, 4.01%.

Methyl (−)-3-Deoxy-3-*C*-ethoxycarbonyl-3-nitropentopyranoside (IV-1). Methyl β-D-xylopyranoside[8] (II) (9.0 g, 0.055 mol) was oxidized with a solution of periodic acid (25 g, 0.11 mol) in 300 m*l* of water by the same procedure as described for the preparation of III-d. A solution of the resulting L'-methoxy-diglycolaldehyde (III-l) in ethanol (120 m*l*) was stirred under ice-cooling, while ethyl nitroacetate (7.3 g, 0.055 mol), 40% aqueous potassium acetate solution (15 m*l*) and 40% aqueous potassium carbonate solution (10 m*l*) were added successively. The mixture was then worked up by the same procedure as described for the preparation of the nitro ester IV-d. The purified title compound IV-1 was obtained as a syrup, yield 13.7 g (94%), $[\alpha]_D^{20}$ −123° (*c* 1.14, water), ν_{max}^{Film} 3455 (OH), 1750 (ester C=O) and 1564 cm^{-1} (NO_2).

7) F. Smith and J. W. Cleve, *J. Am. Chem. Soc.*, **77**, 3159 (1955).

Methyl (+)-3-Amino-3-deoxy-3-*C*-ethoxycarbonylpentopyranoside (V-d). A solution of methyl (+)-3-deoxy-3-*C*-ethoxycarbonyl-3-nitropentopyranoside (IV-d) (9.79 g) was hydrogenated in ethanol (45 m*l*) with Raney Ni T-4 (30 m*l*) for 4.5 hr under 120 kg/cm² of an initial hydrogen pressure at 20—25°C. The contents were then filtered to remove the catalyst and the filtrate was evaporated in a vacuum to afford the crude V-d (6.93 g) as a brown syrup. The sample was shown by TLC using ethyl acetate to contain four diastereoisomeric amino esters, each of which was ninhydrin positive.

Separation of Diastereoisomers of V-d. The brown syrup (6.92 g) in a small amount of ethyl acetate was placed on a silica gel column (300 g, 5×43 cm) and eluted with ethyl acetate - ethanol (6 : 1). Fractions (*ca.* 10 m*l*) were collected and examined by TLC. Fractions, 113—123, 127—135, 138—157 and 163—185 gave the isomers, VA-d (syrup, 0.92 g, R_f 0.73), VB-d (crystalline solid, 2.76 g, R_f 0.55), VC-d (syrup, 0.64 g, R_f 0.36) and VD-d (crystalline solid, 0.56 g, R_f 0.23), respectively. Total yield was 47.5% based on the original nitro ester IV-d. The analytical sample of VB-d was obtained by two recrystallizations from ethyl acetate, followed by sublimation (90—110°C/1.5 mmHg), while the analytical sample of VD-d was given by only two recrystallizations from ethyl acetate (Table 1).

Methyl (−)-3-Amino-3-deoxy-3-*C*-ethoxycarbonylpentopyranoside (V-l) and Its Diastereoisomeric Separation. The nitro ester (IV-l) (9.95 g) was hydrogenated with Raney Ni T-4 (30 m*l*) as described on the preparation of the antipode V-d. The obtained brown syrup (7.75 g) of the crude V-1 was chromatographed on a silica gel column (250 g, 4.5×40 cm). Elution with ethyl acetate - ethanol (6 : 1) afforded four isomers, VA-1 (syrup, 1.39 g, R_f 0.73), VB-1 (crystalline solid, 2.45 g, R_f 0.55), VC-1 (syrup, 1.30 g, R_f 0.36) and VD-1 (crystalline solid, 1.19 g, R_f 0.23). The analytical sample of VB-1 was obtained by two recrystallizations from ethyl acetate, followed by sublimation (110—120°C/3 mmHg), while the pure sample of VD-1 was given by two recrystallizations from ethyl acetate (Table 1).

Methyl (+)-3-Acetamido-2,4-di-*O*-acetyl-3-deoxy-3-*C*-ethoxycarbonylpentopyranoside (VIIB-d). *(A Typical Example of the General Method for the Preparation of Isomeric Amino Ester Triacetate).* A mixture of the amino ester (VB-d) (297 mg), acetic anhydride (4 m*l*) and pyridine (12 m*l*) was allowed to stand for 2 days at room temperature. The mixture was evaporated in a vacuum. The semi-crystalline residue (498 mg) was purified through a silica gel (10 g) column. Elution with methyl ethyl ketone - *n*-hexane (1 : 1) afforded crystalline title compound (VIIB-d), yield 379 mg (83%), mp 115—117°C. Recrystallization from diisopropyl ether-acetone (20 : 1) yielded an analytically pure sample of VIIB-d, mp 118—120°C.

The other triacetates of the isomeric amino esters, VIIA-d, VIIC-d, VIID-d, VIIA-l, VIIB-l and VIID-l were prepared from the corresponding amino esters by the general procedure (Table 1).

Methyl (+)-3-Amino-3-*C*-carboxy-3-deoxypentopyranoside (VIB-d) *(A Typical Example of the General Procedure for the Preparation of the Isomeric Free Amino Acids).* The amino ester (VB-d) (230 mg, 0.98 mmol) was dissolved in a 0.457N barium hydroxide solution (2.32 m*l*, 0.53 mmol). After the solution had been allowed to stand for 20hr at 37°C in an incubator, the reaction mixture was treated with 1N sulfuric acid. The supernatant layer which was separated from barium sulfate by centrifuging was evaporated in a vacuum. The residual colorless powder was recrystallized from water-acetone to afford crystalline amino acid VIB-d (180 mg, 87.3%), from which an analytical sample was obtained by two recrystallizations from water-acetone, followed by drying over phosphorus pentoxide for 5 hr at 105—110°C/3 mmHg. (Table 2).

The other amino acid isomers, VIA-d, VIC-d and VID-d and their enantiomeric amino acids VIA-1, VIB-1 and VID-1 were prepared from the corresponding amino esters by the general procedure (Table 2).

Methyl (+)-3-Acetamido-2,4-di-*O*-acetyl-3-*C*-carboxy-3-deoxypentopyranoside (VIIID-d). The amino acid (VID-d) (40 mg) was acetylated with acetic anhydride (0.5 m*l*) and pyridine (1.5 m*l*) at room temperature overnight. After the mixture was evaporated in a vacuum, the crystalline residue was recrystallized from acetone - diisopropyl ether to afford a pure sample of VIIID-d, yield 25 mg (38.8%), mp 203—204°C, $[\alpha]_D^{26}$ +44° (*c* 0.7, Ethyl acetate).

Found: C, 46.85; H, 6.11; N, 4.11%, Calcd for $C_{13}H_{19}NO_9$: C, 46.83; H, 5.76; N, 4.20%.

Chloramine-T Oxidation *Oxidation of VIA-d.* To a solution of the amino acid (VIA-d) (80 mg 0.39 mmol) in water (1 m*l*) was added chloramine-T (109 mg, 0.39 mmol), and the mixture was shaken for 1 hr. The reaction mixture was filtered to remove an insoluble material. The filtrate was mixed with a solution of *p*-nitrophenylhydrazine hydrochloride (80 mg, 0.43 mmol) in methanol (1 m*l*) and was allowed to stand overnight. The orange-yellow precipitate was separated by centrifuging and was subjected to PLC [1 plate (20 cm×20 cm×0.8 mm), benzene - ethyl acetate (2 : 1)] and two kinds of *p*-nitrophenylhydrazones, A_1 (R_f 0.32) and A_2 (R_f 0.42) were obtained as crystals. They were recrystallized from ethyl acetate-ether: A_1, mp 172°C dec., ν_{max}^{KBr} 1593, 1538, 1501, 1470 and 1415 cm^{-2}; A_2 mp 174.5°C dec., ν_{max}^{KBr} 1595, 1504, and 1487 cm^{-1}.

Oxidation of VID-d was worked up by the same procedure as mentioned above. The oxidation product afforded the two kinds of crystalline *p*-nitrophenylhydrazone, which were identical with the above-mentioned *p*-nitrophenylhydrazones, A_1 and A_2 on the basis of melting points and IR spectra.

Oxidation of VIB-d and VIC-d were also carried out by the same procedure as described above to give crystalline *p*-nitrophenylhydrazones, B and C, respectively: B, mp 162—164°C dec. (from ethyl acetate), R_f 0.26, ν_{max}^{KBr} 1602, 1520, 1500, 1472, 1448 and 1407 cm^{-1}; Found: C, 49.26; 5.47; N, 13.71%. Calcd for $C_{12}H_{15}N_3O_6$: C, 48.48; H, 5.09; N, 14.14%; mp 168°C dec. (from ethyl acetate-ether), R_f 0.42, ν_{max}^{KBr} 1597, 1517, 1495 and 1468 cm^{-1}.

The authors thank Mr. Saburo Nakada for his elementary analysis, and Mr. Akihiro Takahashi and Mr. Tatsumi Kawakami for their technical assistance.

Photoreversible Photographic Systems. V. Reverse Photochromism of (Photospiran/Acid) System in Acetone

Isamu SHIMIZU, Hiroshi KOKADO and Eiichi INOUE

Imaging Science and Engineering Laboratory, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received June 17, 1968)

1,3,3-Trimethylindolino-6'-nitro-benzopyrylspiran (**1**) exhibits a photoreversible color change which is called "photochromism". However, it is transformed from a colorless form (A) into a colored form (C) which has a salt-like structure when acid such as malonic acid is added into acetone without irradiation with light. The color is bleached by irradiation with light. The color reappears thermally as the light source is removed. This photoreversible color change is termed "reverse photochromism". Another colored form (B) of compound (1) which has a merocyanine dye-like structure is converted into (C) as acid is added into the solution (B). The quantum yield of the photoconversion from C to A by irradiation with visible light depends on the solvent polarity. The quantum yield of the photoconversion from A to B also depends on the solvent polarity.

A photospiran 1,3,3-trimethylindolino-6'-nitro-benzopyrylspiran (**1**) is converted into a colored form (B) from the stable colorless one (A) by irradiation with ultraviolet light in organic solvents. The colored species (B) which is assumed to have a merocyanine dye-like structure is further transformed into another kind of colored species (C) as acid such as malonic acid (Brönsted acid) or $SnCl_4$ (Lewis acid) is added into the solution of B. The photospiran of the form (A) is directly transformed into the colored species (C) which is assumed to have a salt-like structure in the dark at room temperature, when acid is added in acetone. The colored species (C) is converted back into the colorless form (A) by irradiation with visible light. Therefore, the (photospiran(**1**)/acid) system in acetone exhibits a photoinduced reversible color change which is called reverse photochromism.

In this paper, the thermal or photochemical interconversion of the two isomers A and C is discussed. The molecular structures of A and C are given in Fig. 1.

light was obtained with a high pressure mercury lamp fitted with the Toshiba glass filters (V-V40×2)×V-Y43. The light intensity entering the cell was determined by the potassium ferrioxalate actinometry.

Results and Discussion

A colored species (B) was transformed into another colored form (C) by the addition of acid in the organic solvent. The colorless species, however, did not undergo any change by the addition of acid at room temperature in the organic solvents except for acetone and methyl ethyl ketone. In acetone the colorless form (A) was converted into the colored form (C) in the dark by addition of malonic acid. A thermal equilibrium was established between A and C. The absorption spectral change of the system (photospiran/acid) in acetone is shown in Fig. 2. In the system, the equilibrium constant of the reaction Eq. (1) can be formulated as

$$\mathrm{A} + \text{acid} \rightleftarrows \mathrm{C}, \tag{1}$$

$$K = \frac{[\mathrm{C}]}{[\mathrm{A}][\text{acid}]} \tag{2}$$

$$[\mathrm{C}] = [\mathrm{A}_0] - [\mathrm{A}], \tag{2}$$

where [A], [acid] and [C] are the concentrations of A, (acid), and C, and $[A_0]$ is the initial concentration of A.

Since the experiments are carried out with an excessive acid, we have

$$[\text{acid}] \gg [\mathrm{C}].$$

Thus we obtain from **2** and **3**

$$\frac{1}{[\text{acid}]} = \frac{K[\mathrm{A}_0]}{[\mathrm{C}]} - K. \tag{4}$$

Equation (4) can be converted into Eq. (5) in terms of the optical density (D_λ) and the molar extinction coefficient (ε_λ) at the absorption maximum ($\lambda m\mu$) of the colored species.

$$\frac{1}{[\text{acid}]} = \frac{K\varepsilon_\lambda[\mathrm{A}_0]}{D_\lambda} - K. \tag{5}$$

Figure 3 shows the plots of 1/[acid] against $1/D_\lambda$ for the systems photospiran/malonic acid and photospiran/maleic acid. The values of K and ε_λ were obtained from Fig. 3 and are shown in Table 1. The equilibrium constant increases as the dissociation constant of acid in water increases.

The colored species (C) was transformed into the colorless one (A) by irradiation with visible light, but color reappeared when irradiation was stopped. This *reversible* color change could be repeated as many times as desired. The absorption spectral change of the reverse photochromic system which is induced by irradiation with light

3), 4) After standing the irradiated sample in the dark

is given in Fig. 4. The thermal reaction from A to C followed first order reaction kinetics. The activation energy for the thermal reaction from A to C was calculated as 31.9 kcal/mol. The Arrhenius plot is shown in Fig. 5.

The colored species (B) of the photospiran (**1**) could be isolated in a stable form and was converted into C by dissolving into various solvents containing malonic acid in excess. The absorption spectra and their change by irradiation with visible light in methanol are shown in Fig. 6. The thermal reaction from A to C in each solvent was so slow that it could be neglected. The quantum yield of photoconversion from C to A in acetone and the other various solvents by irradiation with visible light (4358Å) are given in Table 2. The quantum yield of photoconversion from C to A in acetone by irradiation with ultraviolet light (3650Å) changed with irradiation time. The quantum yield of decoloration *versus* irradiation time (irradiation with either 4358Å or 3650Å light) is shown in Fig. 7. In the case of interconversion of two isomers (C) and (A) under the action of ultraviolet light, a photoequilibrium was established by light (3650Å). It changes with the molar extinction coefficients of the two isomers and also with the quantum yields $\phi_{C\to A}$ and $\phi_{A\to C}$ of photoconversion in both directions C to A and A to C *via* B. In other words, the colorless species (A) absorbed ultraviolet light and the transformation to B took place. The colored species (B) was transformed

1) Irradiated with 4358 Å
2) Irradiated with 3650 Å

instantly into C by the reaction with excess acid in the solution. These reactions are

$$C + h\nu\ (3650\,Å) \xrightarrow{\phi_{C\to A}} A \quad (6)$$

$$A + h\nu\ (3650\,Å) \xrightarrow{\phi_{A\to C}} B \quad (7)$$

$$B + \text{excess acid} \xrightarrow{\text{fast}} C \quad (8)$$

The quantum yield $\phi_{C\to A}$ was claculated as described below.

The rate of the photoconversion is represented by Eq. (8).

$$\frac{d[A]}{dt} = -\frac{d[C]}{dt}$$
$$= I_\lambda\{\varepsilon_C\phi_{C\to A}([C_0]-[A]) - \varepsilon_A\phi_{A\to C}[A]\} \quad (9)$$

I_λ: intensity of the irradiation light at λ mμ

$\phi_{C\to A}$, $\phi_{A\to C}$: quantum yield of the photoconversion from C to A, or from A to C

$[C_0]$: initial concentration of C

t: irradiation time.

Since the reaction rates for both directions are equal at the photoequilibrium

$$\varepsilon_C\phi_{C\to A}\{[C_0] - [A_\infty]\} - \varepsilon_A\phi_{A\to C}[A_\infty] = 0 \quad (10)$$

$$[A_\infty] + [C_\infty] = [C_0] \quad (11)$$

we have

$$\frac{\phi_{C\to A}}{\phi_{A\to C}} = \frac{\varepsilon_A}{\varepsilon_C}\left(\frac{[C_0]}{[C_\infty]} - 1\right) \quad (12)$$

The solution of Eq. (9) is given as

$$I_\lambda t = \frac{1}{\varepsilon_C\phi_{C\to A}+\varepsilon_A\phi_{A\to C}} \ln\left\{\frac{[C]-[C_\infty]}{[C_0]-[C_\infty]}\right\} \quad (13)$$

$[A_\infty]$, $[C_\infty]$; concentrations of A and C at photoequilibrium. Plots of $\log\{[C]-[C_\infty]\}/\{[C_0]-[C_\infty]\}$ *versus* irradiation time at 3650Å in various solutions are given in Fig. 8. The observed linearity of the curves in Fig. 8 provides a support for the proposed reaction scheme represented by Eqs. (6), (7) and (8). The quantum yield of photoconversion from A to C *via* B is calculated from Eq. (12) using values of $\phi_{C\to A}$ in Table 2 and is shown in Table 3.

n-C_3H_7OH	0.23
Acetone	0.27

Irradiation light : 3650 Å

The quantum yield of photoconversion from (C) to (A) decreases as the solvent polarity increases. On the other hand, the quantum yield of photoconversion from B to A increases as the solvent polarity increases. In a previous paper,[1] we presented evidence for the existence of the different colored species (B) and (C) from absorption spectra. The colored species (B) is assumed to have a mercyanine dye-like structure and C a salt-like structure. The difference in the solvent effect on the decoloration efficiencies $\phi_{C\to A}$ and $\phi_{B\to A}$ gives another evidence for the existence of B and C. The quantum yield of photoconversion from A to C *via* B as shown in Table 3 decreases as the solvent polarity increases. The absorption spectrum of A, especially its longest wavelength absorption band is shifted to the longer wavelength as the solvent polarity increases. In polar solvents, the excited state of the colorless species (A) interacts with the solvent, and also the efficiency of radiationless deactivation may increase, thus the quantum yield of the photoconversion from A to C through B decreases.

Conclusion

The photospiran (**1**) in acetone is converted into a colored form as acid is added, and the colored form C is bleached by irradiation with visible light. Thus, the (photospiran/acid) system in acetone exhibits a reverse photochromism. The photoconversion efficiency from colored to colorless form is controlled by external factors such as the solvent polarity. The reverse photochromism of the system is shown in a polymer film such as styrene - maleic acid copolymer. The color image can be printed out directly on the reverse photochromic film by irradiation with visible light through the transparent original picture, and the image can be erased by heating.

The reverse photochromic system described above is promising for use as reusable photobleaching type photosensitive material which has photosensitivity in visible regions.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 1730—1734 (1969)

Photoreversible Photographic Systems. VI. Reverse Photochromism of 1,3,3-Trimethylspiro[indoline-2,2′-benzopyran]-8′-carboxylic Acid

Isamu SHIMIZU, Hiroshi KOKADO and Eiichi INOUE

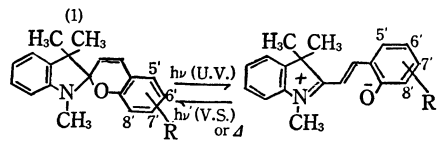
Imaging Science and Engineering Laboratory, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received June 17, 1968)

Many derivatives of 1,3,3-trimethylspiro[indoline-2,2′-benzopyran] (**1**) exhibit photoreversible color changes in organic solvents. One of the derivatives 1,3,3-trimethylspiro[indoline-2,2′-benzopyran]-8′-carboxylic acid (**2**) shows "reverse photochromism" in polar solvents. The compound **2** exhibits a deep color in the polar solvent and the color is bleached by irradiation with either visible or ultraviolet light. The color reappears thermally as the irradiation is ceased. The thermal conversion rate from the colorless form to the colored one depends on the solvents. On the other hand, the isomer 1,3,3-trimethylspiro[indoline-2,2′-benzopyran]-6′-carboxylic acid shows neither normal nor reverse photochromism under usual conditions, but exhibits reverse photochromism when acid such as malonic acid is added into the solution. The compound **2** is assumed to have a merocyanine dye-like structure due to the intramolecular proton transfer.

The photochromism of some derivatives of 1,3,3-trimethylspiro[indoline-2,2′-benzopyran] have been investigated by Fisher,[1] Lashkov,[2] Balny,[3] and the present authors.[4] It has also attracted the interest of workers in technological field photomemory, masking materials, optical switches and optical displays.

The ordinary photochromism of the spiran has been known for the conversion of a stable colorless state into a colored metastable state with ultraviolet light. The colorless modification is transformed from the colored one either spontaneously when the solution is stored in the dark, or by irradiation with visible light. The process that takes place in the photochromic system is presented as



A (colorless) B (colored)

R (**2**) -8′-COOH
(**3**) -6′-COOH
(**4**) -6′-NO_2
Δ heat

Some of these colorless photospirans are converted into colored forms when they are adsorbed on the solid surface such as silica gel or alumina, and the color can be bleached with visible light. This type of reversible photo-color change is called "reverse photochromism." The authors have found that 1,3,3-trimethylspiro[indoline-2,2′-benzopyran]-8′-carboxylic acid (**2**) shows a reverse photochromism without adsorbents. The substance **2** exhibited intense color when it was dissolved in organic solvents. The color of the solution was diminished by irradiation with either visible or ultraviolet light. The colorless species was converted into the original colored one as the irradiation was ceased.

In this paper, the properties of the compound **2** are described in comparison with a colorless isomer 1,3,3-trimethylspiro[indoline-2, 2′-benzopyran]-6′-carboxylic acid (**3**). The effects of added acid or alkali on the solution of the compound **2** or **3** are also described.

Experimental

Absorption spectra with short life were obtained with a Hitachi Rapidscan Spectrophotometer SPR-2 which scanned from 200 mμ to 700 mμ within 0.15 sec. The other experimental procedures were given in other reports.[4,5]

Results and Discussn

The compound **2** is soluble in polar solvents, but not in non-polar solvents. The isomer **3**, however, is not soluble in polar solvents but soluble in non-

polar solvents. The absorption spectra of the compound **2** and **3** in ethanol are shown in Fig. 1. The compound **2** exhibits an intense color which depends on the solvent, while the isomer **3** does not have any absorption band in visible region. The shape and the strength of the absorption band of the compound **2** in visible region is similar to that of the colored state of photospiran **4**. From the absorption spectrum and solubility, the compound **2** is assumed to have a merocyanine dye-like structure which is homologue of the colored state of the photospiran **4**.

2 Compound **3**

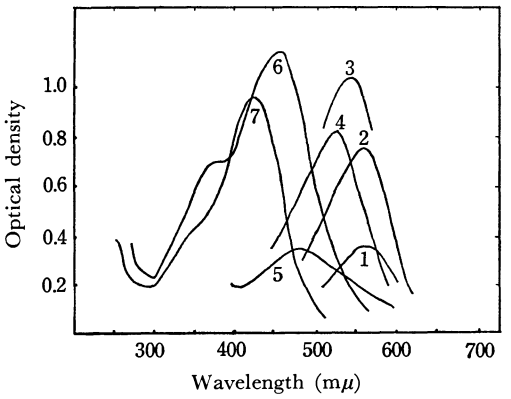

Fig. 2. Absorption spectra of **2** in various solvents.

1) ethyl acetate, 2) pyridine, 3) acetone, 4) acetonitrile, 5) *n*-butanol, 6) methanol, 7) water

The absorption spectrum of **2** in visible region is shifted towards shorter wavelength with the increase in a solvent polarity. Dependence of the spectral shift on the solvent as shown in Fig. 2 was elucidated by considering the dipole moment of the colored species. The ground state of the colored species **2** would be stabilized by interaction with the solvent dipole, but the first excited state would not be

2) —— compound **3**

stabilized. The energy difference between ground and first excited state would then increase with increasing stabilization energy. This process is shown in Fig. 3 schematically.

The absorption spectra of **2** and **3** in infrared region are shown in Fig. 4. The ν(C=O) band of COOH in 1720 cm^{-1} was observed in **3** but not in **2**. An absorption band in 1525 cm^{-1} was, however, found in **2** and it was assigned to $\nu(CO_2^-)$. The spiran band at 954 cm^{-1} that had been reported by Schiele[6] was found to be much weaker for **3** than for **2**. The 1237 cm^{-1} band of **2** that had been assigned to be ν(C=C–O)[6] was shifted towards a longer wave number. It could be the electron transfer from C to O atom of the pyran ring which increased the charge density of the O atom.[6] This fact on IR spectra gives good support to the previous assumption that the colored species of **2** has a structure like a merocyanine dye in which the pyran ring is ruptured due to the internal proton transfer.

6) C. Schiele and G. Arnold, *Tetrahedron Letters*, **1967**, 1191.

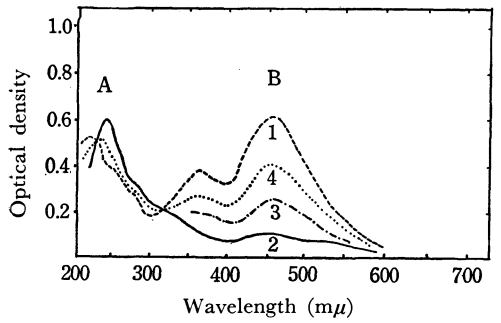

Fig. 5. The effect of irradiation on the ethanol solution **2** at room temperature.

1) Absorption spectrum of **2** in ethanol
2) After irradiation with light
3), 4) After standing the photo-bleached solution in the dark

It would be quite plausible to consider that the proton transferred structure is more favored because of energy.

The compound **2** in ethanol exhibited a deep color. The color was bleached with UV or visible light and the absorption band near the ultraviolet region was intensified. After the irradiation was stopped the color reappeared thermally. The absorption spectral changes are shown in Fig. 5. From the fact that the absorption spectrum of **2** in ethanol did not show any change at low temperature (−120 °C), the color change in the solution does not seem to be thermochromic. The photo-bleaching was performed utilizing visible light at −30°C. At this temperature, the thermal recovery to the colored one was not observed under the same condition. This behavior of the photo-bleached spiran (**2**) is quite the same as observed in the colorless spiran (**3**).

The thermal back reaction of **2** from the colorless state to the colored state followed the first order

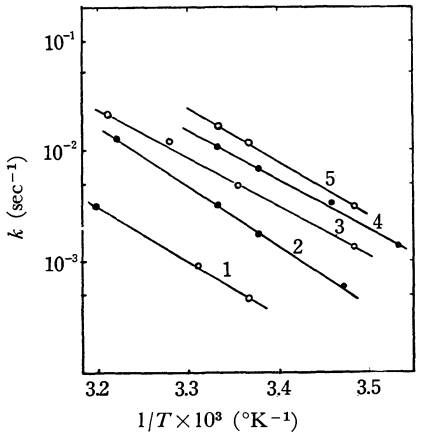

Fig. 6. Arrhenius plots for the recoloration rates of **2** in various solvents.

1) water, 2) pyridine, 3) ethanol, 4) acetone, 5) acetonitrile

TABLE 1. ACTIVATION ENERGIES FOR THE RECOLORATION OF THE COMPOUND **2**

Solvent	Activation energy kcal/mol
Water	22.6
Pyridine	25.4
Ethanol	20.2
Acetone	17.7
Acetonitrile	22.5

rate equation. The reaction rate depended on the solvent and the temperature. The temperature dependence of the rate constant in various solvents is shown in Fig. 6. The activation energies for the back reaction are presented in Table 1. The rate of thermal back reaction from colored to colorless state of photospiran (**4**) was determined in different solvents. The activation energy increased with the increasing solvent polarity. This results from the stabilization of meta-stable colored state of **4** by large polarity of the solvent. Thus, the higher the solvent polarity, the slower the thermal decoloration rate of compound **4**. On the other hand, the thermal recoloration rate of the compound **2** did not show any direct relationship with solvent polarity. This is understandable if we take into account the fact that the meta-stable form (colorless) of **2** is not sensitive. The energy scheme of the reactions are shown in Fig. 3. The colored state of spiran is assumed to have a zwitter ionic structure that is sensitive to added acid or alkali.

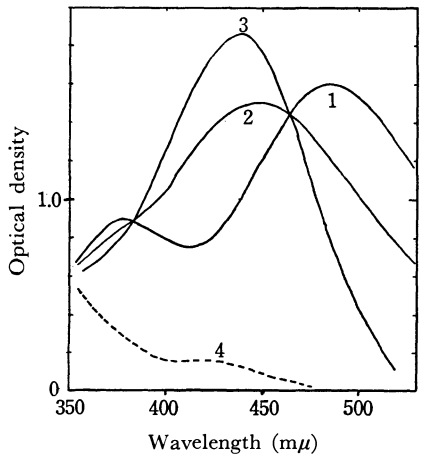

Fig. 7. Absorption spectra of **2** and malonic acid systems, and effect of irradiation with light on the systems.

3) **2**; 7.0×10^{-5} mol/l + malonic acid; 9.4×10^{-2} mol/l
4) after irradiation 3) with light.

On addition of acid into the solution of **2** the absorption spectrum of the solution shifted to the shorter wavelength. The shift was proportional to the amount of added acid. The new colored species (C) produced by adding acid into the solution **2** was bleached by irradiation with UV or visible light. The color reappeared as the irradiation was stopped. The absorption spectral change in the reverse photochromic reaction is shown in Fig. 7. In ethanol solution of **2** the absorption band in visible region diminished quickly on addition of alkali. On the other hand, in aqueous solution the absorption band at longer wavelength (560 mμ) appeared as soon as the aqueous alkaline solution was added. The absorption band at 560 mμ decreased gradually at room temperature. The shape

of the band was similar to that of the colored species of **2** in alcoholic solution. The absorption spectral changes with addition of alkali are shown in Fig. 8. The intermediate colored species was believed to have a merocyanine dye-like structure.

The solution of **3** in ethanol had an absorption band only near the ultraviolet region, and did not show any color change by irradiation with light even at a low temperature. As acid was added in the solution of **3** an absorption band in visible region appeared. The color was bleached by irradiation with visible light, but recovered thermally. The absorption spectrum of this colored species was

similar to the colored species (C) of the compound **2**. The spectral change described above is shown in Fig. 9. The reaction mechanism of the reverse photochromism about the compound **2** and the system (compound **3**/acid) are shown in Fig. 10.

The photo-bleaching efficiencies of the compound **2** and the systems (compound **2**, or **3**/maleic acid) in ethanol are given in Table 2.

Conclusion

Depending on the nature and the position of substituted groups, the derivatives of 1,3,3-trimethylspiro[indoline-2,2-benzopyran] (**1**) differ from each other to a great extent in photochromic property. 1,3,3-Trimethylspiro[indoline-2,2'-benzopyran]-8'-carboxylic acid (**2**), shows a reverse photochromism. On the other hand, the isomer **3** which is substituted at 6'-position with COOH does not exhibit either the normal or reverse photochromism. As acid is added into the solution of the compound **3**, however, the system (compound **3**/acid) shows a reverse photochromism.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 1734—1738 (1969)

Properties of Butyl Acrylate Copolymer with Metal Ionic Crosslinkage

Jun-ichi HAKOZAKI,*1 Einosuke HIGASHIMURA and Yūji HAYASHIBARA

Research and Development Department, Mitsubishi Rayon Co., Ltd., Kyobashi, Chuo-ku, Tokyo

(Received July 31, 1968)

Some properties of the butyl acrylate-acrylic acid copolymer, which has ionic crosslinkage with a mono- or divalent cation, were observed. The organic solvent resistance tends to increase with an increase in the degree of neutralization with metal ions at room temperature and at 50°C. The tensile and flow properties exhibit a linear increase with the amounts of metal ions incorporated. The activation energies of the melt viscosity were 7.5, 10.5, and 22.0 kcal/mol for 1, 1/4, and 1/2 of metal-ion equivalents respectively. The stress relaxation behavior was observed at the temperature of 92°C; it was found that relaxation at the highest rate takes place at the initial stage of the relaxation process.

As the linear polymers showing a rubbery elasticity generally have a small cohesive energy density between the molecules, there are some deficiencies of their mechanical, thermal, and chemical properties. Therefore with an eye to practical application, some attempts have been made here to improve the above-mentioned properties by crosslinking reaction. A number of ways for crosslinking reaction have been reported, such as by radiation, a chemical reaction incorporating some functional groups, vulcanization with sulfur or peroxide, and introduction of metal ions.

In recent years, many types of ionic polymers containing covalent and ionic bonds have been introduced. For example, butadiene - acrylic acid[1] and butadiene - acrylonitrile - acrylic acid copolymers[2] were vulcanized with zinc oxide. They are called carboxyl rubber. Styrene-acrylic acid[3] and α-olefin-unsaturated carboxylic acid copolymers[5] were crosslinked with monovalent and sometimes divalent cations, and so they were called "Ionomers."

This paper will deal with some properties of the butyl acrylate - acrylic acid copolymers, which has an ionic crosslinkage with a mono- or divalent cation. The properties investigated here include the temperature dependence of the organic solvent resistance, the mechanical, and viscous flow properties, and the stress relaxation behavior.

Experimental

Samples. The butyl acrylate (BA)-acrylic acid (AA) copolymer used in this study was prepared by emulsion polymerization; the BA/AA composition in this copolymer was 89/11 by mol%. The intrinsic viscosity was

around 1.0 in dioxane.

The ionic crosslinking reaction of this copolymer with a mono- or divalent cation such as sodium hydroxide or zinc acetate was performed in a solvent medium; these samples, purified with an excess of the solvent at room temperature, were dried under a vacuum at 50°C. The test specimens were prepared by compression-molding into the various types desired. Some of the properties of these samples are summarized in Table 1.

Table 1. Samples

Code	Metal	Neutralized equivalent	Molding temp. (°C)
BAA	—	0	100
BAA-Zn-1/4	Zn	1/4	150
BAA-Zn-1/2	Zn	1/2	200
BAA-Na-1/4	Na	1/4	120
BAA-Na-1/2	Na	1/2	150
BAA-Na-1	Na	1	200

Tensile Properties. The tensile properties were measured by an Instron-type tensile tester. The cross-head travel speed was 50 mm/min. The test specimens were a modified type 25 mm long, 4 mm wide, and 0.5 mm thick. A conditioning chamber was used for high-temperature tests.

Viscous Flow Properties. For the purpose of investigating the temperature dependence of the characteristics of these ionic linkages, the viscous flow deformation was measured by means of a Williams parallel-plate plastometer at various temperatures. Test specimens were compression-molded into a standard disk 4 mm diameter and 2 mm thick. The temperature range investigated was 120 to 220°C, especially 180°C, while the compression load was varied between 2 and 50 kg. Assuming a Newtonian flow, the melt viscosity, η_m(poise), was calculated by using the following equation:

$$1/h^4 = (8F/3\eta_m V^2)t + C \qquad (1)$$

where h is the thickness (cm) at time t (min) under a load of F (dyn), V is the volume of the specimen, and C is a constant.

Stress-relaxation. In oder to investigate the ionic crosslinking behavior under stress at high temperatures, the tensile stress relaxation was measured. The apparatus used was the tensile tester described above, and the temperature of the controlling chamber was 70—90°C. The stress decay with time was analysed by means of an auto-recording chart.

Results and Discussion

Organic-solvent Resistance. The organic-solvent resistance of these polymers has been observed in various solvents at room temperature and at 56°C, 6 hr after immersion in the solvents. The results are illustrated in Table 2, along with the cohesive energy density (CED) of these solvents.

Table 2. Organic solvent resistance

It has been found that the parent BA-AA copolymer can be dissolved easily in all the solvents investigated, but the solubility of ionically-crosslinked copolymers tends to decrease as the degree of neutralization with metal ions increases. Judging from the above observation, ionic crosslinkage with a divalent metal has quite a strong network structure and can not be broken at about 50°C in these solvents. In the case of small amounts of metal ions, however, they can be dissolved at high temperatures in ethanol or butanol, either of which is a hydrogen-bond-scission reagent with a cohesive energy density of about 12.

Tensile Properties. It is generally well known that the tensile propetries of elastomers change remarkably with the increase in the density of crosslinking. Table 3 shows these values measured at 23 and 93°C. The apparent density of crosslinking (ν_a) was calculated by using Eq. (2), which is based on the kinetic theory of rubber elasticity:[6]

$$f=\nu_a \boldsymbol{R} T(\alpha-1/\alpha^2) \qquad (2)$$

where f is the tensile stress; $\boldsymbol{R}$, the gas constant; T, the absolute temperature, and α, the extension ratio defined as the ratio of extended to unstrained length.

It is obvious that, at low temperatures, the tensile strength, the modulus, and the breaking energy increase, but the elongation decreases with an increase in the metal present. Therefore, these properties depend on the equivalent of metal used, *i. e.*, the degree of the neutralization of carboxylic acid. However, it seems that the values tested here are mostly somewhat lower than those of other practical rubbers. Figure 1 illustrates the variation in the tensile strength with a neutralized equivalent for both Na and Zn at room temperature. Figure 2 shows the density of crosslinking calculated from Eq. (2) against, the neutralized equivalent. It was observed that the density of crosslinking by metal ions increases exponentially with the neutralization amount for an acidic group and that there is a considerable difference between the monovalent Na and the divalent Zn. At the high temperature of 93°C, deformation by viscous flow and by a fall in tensile properties were generally observed. However in a copolymer with a large amount of metal, the retention of tensile strength is large at a high temperature, and so this type of linkage is fairly strong. The above facts suggest the following structures of the crosslinkage of these copolymers. For Zn^{2+}, it may be $-COO^-\ Zn^{2+}\ OOC^-$. For Na^+, the structure may be:

$$\begin{array}{l} -CO-O^- \cdots Na^+ \\ \quad\vdots\quad\ \vdots \\ \quad Na^+ \cdots O^- - CO- \end{array}$$

as has been suggested by Morawetz,[3] where ion-dipole interaction between two ion pairs forms a quadrupole ion. Moreover, these structures may be the cause of a higher level of tensile strength and modulus compared to those of the parent copolymer.

Viscous-flow Properties. In order to investigate the properties of the crosslinkage by metal ions introduced between the parent backbone of BA-AA copolymer, deformation under a load was measured at high temperatures by means

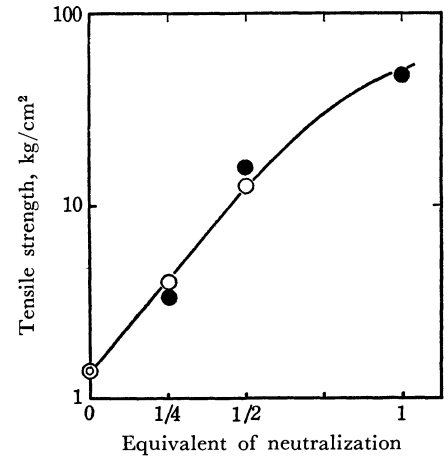

Fig. 1. Dependence of tensile strength on equivalent of neutralization.

of a Williams parallel-plate plastometer. In the measurement of the melt viscosity using various samples with different quantities of metal ions, the load and temperature were varied between 1.9—51.5 kg and 118—250°C respectively. The linear relationship between h^{-4} and t, according to Eq. (1), is shown in Fig. 3. Assuming this flow deformation to be Newtonian from the relationship shown in Fig. 3, η_m was calculated by Eq. (2); the results are listed in Table 4. η_m apparently exhibits a sharp increase with the quantity of metal ions at the same temperature. The temperature dependence of the η_m of various samples is illustrated in Figure 4. The apparent activation

energies were calculated from the gradient of these curves according to Arrhenius' equation and are shown in the last column of Table 4.

Stress-relaxation Behavior. The stress-relaxation behavior is also a good method for determining the properties of crosslinkage.

If we assume that stress relaxation at high temperatures is due to random network scission, the following relation holds between the stress decay ratio (relative stress) at a constant extension and at a constant number of crosslinking:

$$f(t)/f(0)=n(t)/n(0)=e^{-kt} \quad (3)$$

where $f(0)$ and $n(0)$ are the stress and number of

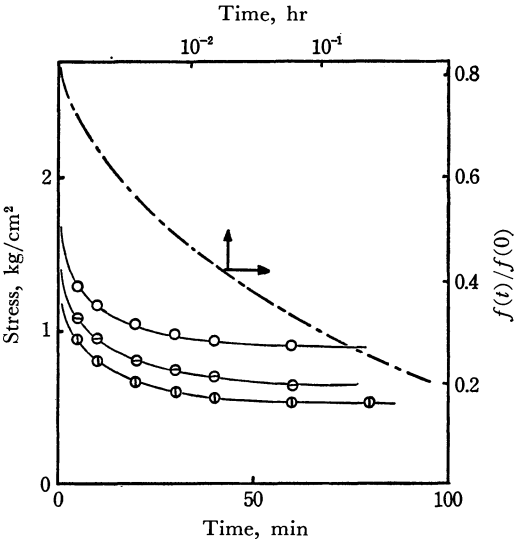

Fig. 5. Typical stress decay curve of BAA-Zn-1/2.

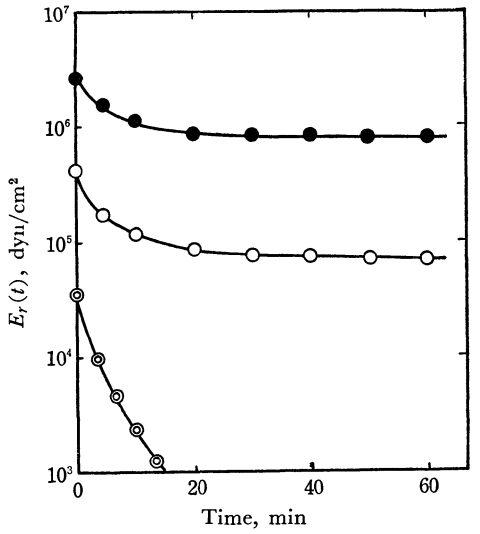

Fig. 6. Relaxation modulus *vs.* time.
◎ BAA ○ BAA-Zn-1/4 ● BAA-Zn-12

crosslinking, respectively, at the initial stage, and where $f(t)$ and $n(t)$ are those at time t. Figure 5 illustrates a typical stress decay curve with BAA-Zn-1/2 as the sample. From this figure, it can be seen that the highest rate of stress relaxation takes place at the initial stage of the relaxation process, and that this rate decreases with an increase in the metal-ion content. Figure 6 shows the change in the relaxation modulus with the time. At 92°C, the viscous flow was observed with the parent BAA copolymer, which does not contain any metal, whereas the equilibria, E_r were 10^5 and 10^6 with the copolymers containing Zn-1/4 and Zn-1/2 respectively.

We have observed that some types of relaxation take place at the initial stage of the relaxation process. These higher rate-relaxation phenomena can be considered to be due to a partial loosening of the chain entanglement or to a slippage of labile crosslinkage caused by sufficient residual interaction of acrylic acid side groups. Network linkage by divalent metal ions is relatively stable even at high temperatures. For most of the properties tested in this study, the ionically-crosslinked butyl acrylate copolymer exhibits a lower level than do other practical rubbers. However, it is considered that the above deficiencies can be improved by investigating the parent copolymer, vulcanization, the molecular size, the chemical composition of the comonomer, the carboxylate content, the vulcanizate recipe, and the types and quantities of cations.

Effect of Coexisting Minerals on Graphitization of Carbon under Pressure. III. Accelerating Effect of Calcium Hydroxide

Tokiti NODA,*1 Michio INAGAKI, Shin-ichi HIRANO and Hajime SAITO

Faculty of Engineering, Nagoya University Furo-cho, Chikusa-ku, Nagoya

(Received October 18, 1968)

The polyvinyl chloride coke was heat-treated under the pressure of 3.2 kbar at 600—850°C for 20—240 min in a simple piston-cylinder type vessel, being sandwiched between two disks of calcium hydroxide. By electron microscopic observations, particles having the six-fold symmetry diffraction pattern of graphite single crystal were found besides particles of amorphous carbon even in the specimen heat-treated at temperature as low as 600°C. Above 800°C, the sharp peak corresponding to the graphitic component appeared on (002) diffraction profiles, overlapping with the broad band of the turbostratic component. The formation of the graphitic component seems to be related to the recrystallization of coexisting calcium hydroxide, as in the case of limestone and calcium carbonate. However, the fact that a small amount of free calcium oxide formed by the decomposition of calcium hydroxide was detected in the heat-treated carbon specimens suggests a chemical theory for the accelerating effect of calcium compounds on the graphitization of carbon under pressure.

It has been found in the previous works[1,2] that the graphitization of carbon is accelerated by the heat treatments under pressure in the presence of limestone or calcium carbonate. The beginning of graphitization, that is the appearance of the component having the graphitic structure, was found to be closely related to the recrystallization of coexisting minerals.[2]

According to Wyllie and Tuttle,[3] the melting point of calcium carbonate is lowered by the addition of water. For example, the melting point of calcium carbonate, 1310°C at 1 kbar, is depressed to 1130°C by the addition of only 8 wt% of water. In our preliminary experiment, a soft carbon was heat-treated under pressure in the presence of calcium carbonate disks, which absorbed about 8 wt% of water. The graphitization of carbon was found to start at about 1000°C, about 100°C lower than that in the case of dry calcium carbonate.[2] However, we could not draw any conclusion at that time, because the exact control of the water content of calcium carbonate disks was experimentally difficult and also it was not known whether water vapor affects the graphitization of carbon or not.

In the present work, heat treatments of carbon were performed under pressure by using disks of calcium hydroxide, whose melting point is 840°C at 3 kbar,[3] in order to confirm the relation between the graphitization of carbon and recrystallization of coexisting minerals.

Experimental and Results

The carbon sample used was the polyvinyl chloride coke (PV-7) which was used in the previous works.[1,2] Disks of calcium hydroxide, 8.0 mm in

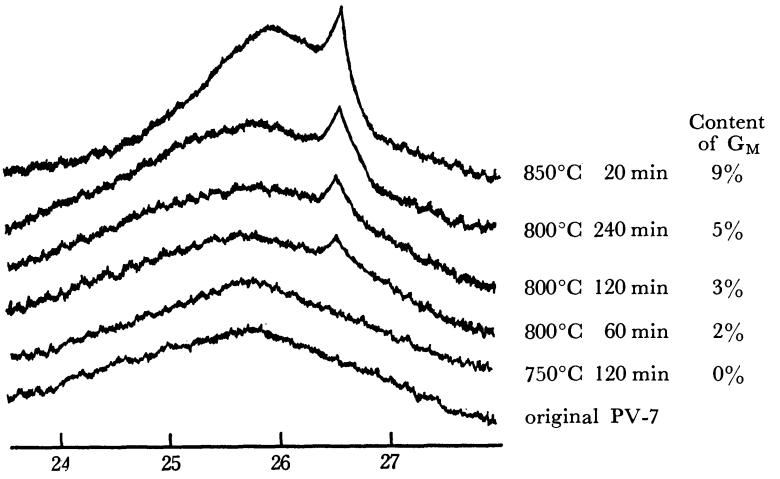

Fig. 1. Change of observed profile of (002) diffraction line with heat treatment

diameter and 3.5 mm thick, were made by compressing calcium hydroxide powder (chemical reagent grade) under 3.5 kbar. The bulk density of the disks was about 2.2 g/cm^3 (*ca.* 15% porosity). The disks and powder of calcium hydroxide were kept in an evacuated desiccator to avoid the absorption of carbon dioxide during the stroage. The heat treatments were performed at temperatures between 600 and 850°C for residence times of 20—240 min under the quasi-hydrostatic pressure of 3.2 kbar in a simple piston-cylinder type vessel. The arrangement of the pressure cell and the procedure for the heat treatments were exactly the same as used previously.[1,2] Temperature of heat treatment (HTT) was determined from input power by using the relation between temperature and input power. Pressure was calibrated by using the transition points of KNO_3 and AgI.[4]

The profile of (002) diffraction line of the central part of the heat-treated specimens was measured by using Ni-filtered Cu$K\alpha$ radiation. The same part of the specimen was dispersed in trichloroethylene by ultrasonic vibration, then supported by an evaporated carbon film, and observed by transmission electron microscope.

The carbon specimens heat-treated above 600°C were obtained as sintered cakes. In the cakes, calcium hydroxide was detected by X-ray diffraction method. The disks of calcium hydroxide recrystallized above 600°C, and were found to melt above 800°C at the part in contact with carbon specimen. Above 800°C, a small amount of calcium oxide was detected by X-ray diffraction method not only in the disks of calcium hydroxide but in the carbon specimen.

Figure 1 shows the change of observed profile of (002) diffraction line with heat treatment. Above

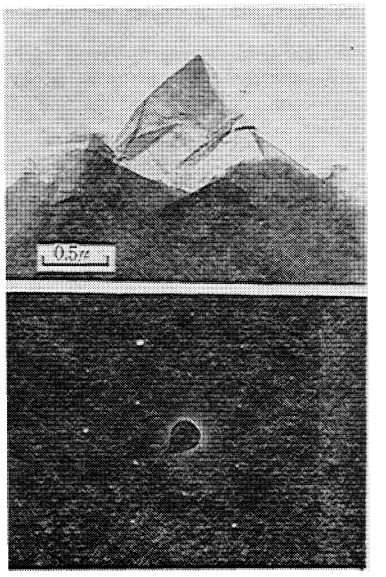

Fig. 2. Bright-field micrograph and selected area diffraction pattern of graphitic particle in carbon specimen heat-treated at 600°C for 60 min under 3.2 kbar.

800°C, a sharp peak is observed on a broad band. According to the same procedure reported previously,[1] the composite profile was separated graphically into two profiles for the graphitic component G_M and the turbostratic component A_M. The component G_M had almost constant c_0-spacing of 6.72 Å, and the component A_M of 6.90Å which was not so different from the original value. The content of the graphitic component G_M was obtained from the ratio of the area under the profile of G_M to the total area under the composite profile after the correction for the preferred orientation of crystallites in the specimen used for the X-ray measurement. The measured content of the component G_M is given for each profile in Fig. 1.

4) M. Inagaki, S. Hirano and H. Saito, *Yogyo Kyokai Shi*, **76**, 264 (1968).

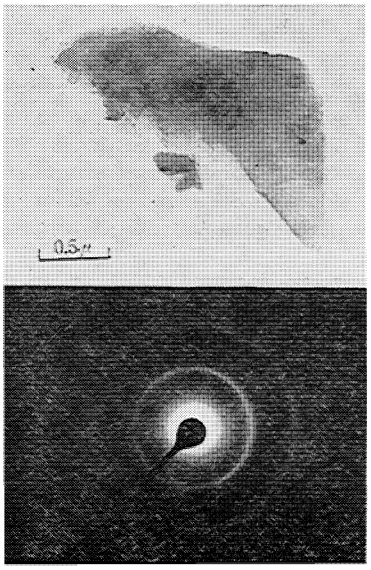

Fig. 3. Bright-field micrograph and selected area diffraction pattern of turbostratic particle in carbon specimen heat-treated at 600°C for 60 min under 3.2 kbar.

By electron microscopic observation, particles having the diffraction pattern of six-fold symmetry of graphite single crystal, were found besides particles having the turbostratic structure even in the specimen heat-treated at 600°C for 60 min. Bright-field micrographs and selected area diffraction patterns of graphitic and turbostratic particles are shown in Figs. 2 and 3, respectively.

The heat treatment above 900°C was difficult to carry out because the calcium hydroxide melts and reacts with graphite heater.

Discussion and Summary

The accelarating effect of coexisting calcium hydroxide on graphitization of carbon is more remarkable than that of calcium carbonate.[2] Even at HTT as low as 600°C, particles having the graphitic structure were found with electron microscopy. The temperature of the beginning of formation of the graphitic component is much lower than those found in the heat treatments of the same coke in the presence of limestone and calcium carbonate,[2] as well as without any minerals.[2,5] The content of the component G_M increases slightly with the increase in residence time. However, the increase in HTT seems to be more effective than the increase in residence time, when the result at 850°C for 20 min is compared with that at 800°C for 60 min.

A close relation seems to be present between the graphitization of carbon under pressure in the presence of foreign minerals and the recrystallization of the coexisting minerals, when a conclusion can be drawn from the present result together with the results of the works on the effect of calcium carbonate previously reported.[1,2] However, the fact that a small amount of free calcium oxide was found in the heat-treated specimens suggests a chemical theory of acceleration of graphitization. Active calcium oxide formed by the decomposition of calcium hydroxide can react at relatively low temperatures, *vis.*, 600°C, with amorphous carbon to form an intermediate compound, probably calcium carbide, which decomposes inversely to form stable graphite and calcium oxide. In order to verify this theory, more detailed and extensive experiments will be needed.

3-[8′-Quinolinol-(5′)-yl]alanine and Related Compounds

Konomu MATSUMURA, Takamasa KASAI and Hisako TASHIRO

Department of Chemistry, Kitasato University, Minato-ku, Tokyo

(Received February 22, 1968)

An improved method of preparing the two known compounds[1] 5-chloralyl-8-quinolinol (I) and 5-formyl-8-quinolinol (II) and preparation of 3-[8′-quinolinol-(5′)-yl]alanine (V) which, to our knowledge, has not heretofore been reported are presented in this paper. On heating a mixture of 8-quinolinol and chloral at 65°C I was formed in 93% yield. A mixture of I and a solution of sodium in cold acetone after 3 days standing at room temperature yielded the hydrolyzed product II in 67% yield. After the hydrolysis was finished the reaction mixture was filtered [the solid (A) on the filter was worked up to isolate II.]. The chloroform residing in the acetone filtrate (B) was quantitatively estimated as the following by the Cole method[2] with minor modifications. The filtrate (B) was subjected to distillation. To the distillate pyridine and concentrated sodium hydroxide solution were added. On heating, the color of the solution became red, the extinction at wavelength 490 mμ was determined and the concentration of chloroform was quantitatively estimated. In parallel to this, the following control experiment was carried out. A known amount of chloroform was mixed with a solution of sodium in acetone and the resulting solution was treated in the same manner as in the case of hydrolysis of I and the remaining chloroform was estimated by the Cole method. By this control experiment, it was found that about 91% of the chloroform initially added had been destroyed by hydrolytic fission during the treatment under the conditions specified. For interpretation of the mechanism of hydrolysis of I this percentage of chloroform was taken into account. It was indicated that the amount of produced chloroform during the hydrolysis of I was nearly equal to the calculated one from the following scheme

$$Q\text{-}CH(OH)\text{-}CCl_3 \rightarrow Q\text{-}CH(OH)^+ + -CCl_3^-$$

Q = 8-Quinolinol-(5)-yl

From this, it may be postulated that the hydrolysis of I with sodium acetonate would involve an ionic cleavage affording CCl_3^-, whose mechanism is different from that postulated for the hydrolysis of I in ethanolic potassium hydroxide solution.[1]

On condensation with hippuric acid or hydantoin, followed by treatment with hydroiodic acid and phosphorus, the compound II yielded 3-[8′-quinolinol-(5′)-yl]alanine (V).[3]

Results of Biological Study.[*1] The compound V has been found inactive in antifungal test *in vitro* (50 μg/ml of V indicated inactive against *candida albicans*) and contrary to expectation, it was toxic (tolerated dosis: 500 mg per kg body weight of a mouse either subcutaneously or intra peritoneally).

Experimental

5-Chloralyl-8-quinolinol (I). On adding chloral (22.2 g, 0.15 mol) to 8-quinolinol (14.5 g, 0.1 mol) an orange solid was formed. After standing for 3 days at room temperature until it turned to a light yellow solid, it was heated at 65°C in a water bath for 35 hr. The reaction mixture was treated with 3 N hydrochloric acid (250 ml) at 80°C until the orange reaction mass completely turned to yellow crystalline hydrochloride which was filtered after cooling. It was suspended in hot water (200 ml) and sodium acetate hydrate (40 g) was added to the suspension. The mixture was heated on a water bath (80°C) for 0.5 hr, the resulting orange yellow free base was filtered on cooling, and it was repeatedly washed

a) Dried at 115°C *in vacuo*. b) The quinolinolylalanine (V) (0.116 g, 0.005 mol) was reacted with picric acid (0.23 g, 0.001 mol) in hot water. The crude product when twice recrystallized from dilute ethanol (30%) yielded monopicrate. The mother liquor of the recrystallizations separated dipicrate on concentration. c) Vacuum-dried over potassium hydroxide at room temperature. d) Made by heating a mixture of quinolinolylalanine (V) (0.116 g, 0.0005 mol) acetic anhydride (0.5 g, 0.005 mol) and glacial acetic acid (0.5 m*l*) for 7 min at 100°C. It gave no color reaction with ferric chloride. e) Made in 66%yield by applying the Harington method of iodinating tyrosine to this compound C. R. Harington and R. V. Pitt-Rivers, *Biochem. J.*, **39**, 157 (1945). The compound is soluble in one hundred and sixty times its weight of boiling water. f) All substances melted with decomposition.

with hot water and dried on a water bath, yield 29.7 g (93%). It was pure enough for use in the next step of synthesis. For comparison a portion was recrystallized from acetone. Its identity with that obtained by the known method[1] was ascertained by IR spectra and thin layer chromatography.

5-Formyl-8-quinolinol (II). Chipped sodium (3.6 g, 0.157 mol) was added to the cooled (0°C) acetone (dried with calcium chloride and distilled, 180 m*l*). The mixture was frequently shaken until a homogeneous suspension resulted, whereupon 5-chloralyl-8-quinolinol (9.6 g, 0.03 mol) was added and the resulting mixture was stirred for a few minutes until a homogeneous paste resulted. After standing for 3 days at room temperature the resulting precipitates (A) were filtered, repeatedly washed with acetone [the combined filtrate and washings (B) were stored for the estimation of chloroform] and were dissolved in water (100 m*l*) (charcoal). On acidifying with acetic acid (50%) the filtered aqueous solution afforded a straw yellow solid (4.6 g), mp 160—173°C. A mixture of this solid product, sodium bisulfite (15 g) and water (30 m*l*) was well triturated at about 60°C. After cooling, the mixture was filtered (charcoal) and washed with water. Concentrated hydrochloric acid was added to the combined filtrate and washings (50 m*l*) and the solution was concentrated on a water bath until the odor of sulfur dioxide became faintly discernible. After standing overnight the separated solid was filtered, dissolved in hot water (100 m*l*) and the solution (charcoal) was filtered. On addition of sodium acetate (6 g) to the filtrate the free base separated, which was filtered and washed with water, yield, 3.5 g (67%); mp 176—178°C. It was recrystallized from benzene to form almost colorless prisms, mp 177—178°C. It was identified with the authentic sample of 5-formyl-8-quinolinol[1] by IR spectra and thin layer chromatography.

Estimation of Chloroform in Acetone Solution

(a) Preparation of the Standard Curve. The procedure which has been standardized for measuring the amount of chloroform is essentially similar to that of Cole[2] and the extinction at the wavelength of 490 mμ was determined by spectrophotometer.

From this, the standard curve

$E = 0.281\ C$

E: Extinction

C: g/100 m*l*

Width of the solution = 1 cm

was obtained.

(b) Estimation of Chloroform. The filtrate (B), which was originated from 0.03 mol of chloralylquinolinol (I) was acidified with dilute sulfuric acid, and distilled on a water bath. When no more distillate came out a small amount of acetone was added to the residue and the distillation was continued. The chloroform content in the total distillate was measured by Cole method using the standard curve. Found: $CHCl_3$, 0.28 g (7.8% of the theoretical). Calcd (from the reaction formula) $CHCl_3$, $119 \times 0.03 = 3.58$ g.

(c) Control Test. Chloroform (3.582 g, 0.03 mol) was added to the cooled solution of sodium (3.6 g, 0.157 mol) in acetone (180 m*l*). After 3 days standing at room temperature, the mixture was treated in the same manner as that in the hydrolysis of I. Found: $CHCl_3$, 0.31 g (8.7% of the theoretical).

2-Phenyl-4-[8'-acetoxyquinol-(5')-ylmethylene]-5-oxazolone (III). A mixture of 5-formyl-8-quinolinol

(1.73 g, 0.01 mol), hippuric acid (1.88 g, 0.0105 mol), acetic anhydride (4.6 g, 0.045 mol) and fused sodium acetate (0.8 g, 0.01 mol) was heated at 100°C for 2 hr. After cooling the reaction mixture was treated with ice water (200 m*l*). The separated yellow solid (3.6 g, mp 138—173°C) after being dried at room temperature over potassium hydroxide *in vacuo* was recrystallized from benzene (50 m*l*) to give azlactone (III). Yield, 2.9 g (80%), mp 160—188°C. It gave no color reaction with ferric chloride and can be used without further purification for the next step of synthesis. For analytical purpose, it was recrystallized from benzene. Garnet colored prisms or yellow needles melting at 192°C. Found: C, 70.26; H, 4.41; N, 7.76%. Calcd for $C_{21}H_{14}O_4N_2$: C, 70.39; H, 3.91; N, 7.81%.

2-Phenyl-4-[8′-quinolinol-(5′)-ylmethylene]-5-oxazolone. A solution of the acetoxyazlactone (III) (100 mg) in dilute ethanol (33%, 20 m*l*) was heated in a boiling water bath for one half hour. After cooling, the separated solid was filtered and crystallized from benzene to give brownish orange rods, mp 240—248°C (decomp). The solution in ethanol gives a violet brown color with ferric chloride. Found: C, 72.08; H, 3.85; N, 8.83%. Calcd for $C_{19}H_{12}O_3N_2$: C, 72.15; H, 3.80; N, 8.96%.

β-[8-Quinolinol-(5)-yl]-α-benzoylaminoacrylic Acid. A mixture of the azlactone (III) (120 mg) and 3 N hydrochloric acid (3 m*l*) was gently boiled over a free flame for 6 min until complete dissolution of the material into an orange red solution was effected. After cooling the reaction mixture was made alkaline with sodium carbonate solution, the resulting solution was acidified with acetic acid and the separated solid was recrystallized from hot ethanol to give prismatic needles of intense yellow color, mp 208—209°C (decomp). It exhibited a deep brown color with ferric chloride. Found: C, 67.45; H, 4.27; N, 8.18%. Calcd for $C_{19}H_{14}O_4N_2$: C, 68.26; H, 4.19; N, 8.38%.

5-[8′-Quinolinol-(5′-)ylmethylene]hydantoin (IV). A mixture of 5-formyl-8-quinolinol (1.73 g, 0.01 mol), hydantoin (1 g, 0.01 mol), acetic anhydride (5 g, 0.05 mol) and fused sodium acetate (0.85 g, 0.01 mol) was heated at 100°C for 5 hr. After evaporation under reduced pressure and cooling, the residue was treated with ice water. The separated solid (A) was converted to the hydrochloride by treating with hot dilute hydrochloric acid. The hydrochloride was dissolved in dilute sodium hydroxide solution and the solution was acidified with acetic acid to give the deacetylated product (1.5 g, 59%); mp 285—295°C (decomp). Without any further purification, it was used for the next step of synthesis. When crystallized from hot dioxane, it formed yellow prismatic needles, mp 198°C (decomp). It gave a violet brown color reaction with ferric chloride. Found: C, 61.54; H, 3.69; N, 16.14%. Calcd for $C_{18}H_9O_3N_3$: C, 61.18; H, 3.53; N, 16.47%.

The Hydrochloride of IV formed yellow needles and was hydrolysed in water, mp 296—300°C (decomp). Found: C, 50.41; H, 4.18; N, 13.22%. Calcd for $C_{13}H_9O_3N_3 \cdot HCl \cdot H_2O$: C, 50.40; H, 3.88; N, 13.57%.

5-[8′-Acetoxyquinol-(5′)-ylmethylene]hydantoin. The solid (A) in the preceding experiment after being dried at room temperature was treated with warm benzene. Recrystallization of the benzene insoluble solid from acetone afforded yellowish leaflets, mp 261—263°C, giving no color reaction with ferric chloride. Found: C, 60.58; H, 3.37; N, 13.95%. Calcd for $C_{15}H_{11}O_4N_3$: C, 60.61; H, 3.70; N, 14.14%.

3-[8′-Quinolinol-(5′)-yl]alanine (V).[3] A mixture of hydroiodic acid (52%, 9.8 g, 0.044 mol), red phosphorus (1 g), acetic anhydride (6.8 g) and the azlactone (III) (1.79 g, 0.005 mol) or the hydantoin (IV) (1.49 g, 0.005 mol) was gently refluxed in an oil bath for 6 hr. The subsequent treatment was almost similar to that stated in the standard procedure.[3b] The yield of the amino acid as monohydrate was 1.2 g (96%) starting from the azlactone and 1.05 g (84%) from the hydantoin. On recrystallization in five hundred times its weight of boiling water, the amino acid afforded colorless elongated plates, mp 287°C (decomp). It exhibited a violet red color with ninhydrin and a green color with ferric chloride.

The pK_2, 4.5; pK_3, 10.5, isoelectric point. 7.5, IR spectra $\nu_{cm^{-1}}^{KBr}$ 3480, 2920, 1630, 1575; 1520; 1435, 1410, 1350 and 1170. Paper chromatogram by descending technique R_f 0.3 (Solvent: Butanol-acetic acid-water, 4 : 1 : 2).

Found: C, 57.63; H, 5.54; N, 11.24%. Calcd for $C_{12}H_{12}O_3N_2 \cdot H_2O$*[2]: C, 57.60; H, 5.60; N, 11.20%.

The authors are grateful to Dr. Yoshio Matsumoto for help and advice in quantitative analysis of chloroform and measurements of pK and R_f values of the amino acid.

The Surface Rearrangement*1 of Adsorbed Hydrogen on Platinum Electrodes

Kazuo SASAKI and Shigeyuki YOSHIDA

Department of Applied Chemistry, Faculty of Engineering, Hiroshima University, Senda-machi, Hiroshima

(Received April 24, 1968)

It is an accepted fact that the adsorbed hydrogen waves (ahw) which appear in a current-potential curve obtained by a linear potential sweep experiment with a noble metal electrode are depressed by the competitive adsorption of foreign substances in the solution. This character of the ahw has been utilized to determine the surface coverage of various organic substances[1-4] as well as the carbon monoxide[3,5,6] adsorbed on platinum electrodes. The method employed in these experiment is very useful in determining the relative surface coverage of adsorbent under given conditions. However, because of the competitive adsorption of unavoidable impurities in the solution and also the spontaneous structural change in the ahw itself, it seems inadequate as a basis for discussing in detail either the kinetics of adsorption or the absolute determination of adsorbent.

In the present paper, some basic characteristics of the ahw observed in sulfuric acid solutions containing no additional substance will be described.

Experimental

Super Special Grade sulfuric acid of Wako Pure Chemicals, Ltd., was used as the electrolyte. The tap water was first purified by means of an ion-exchange column and then distilled twice in glass vessels. In order to avoid contamination by foreign anions, a mercury-mercurous sulfate electrode was used as the reference electrode. The potential values in this paper are referred to this electrode. A platinized platinum wire with an apparent area of 0.19 cm^2 was used as the test electrode. Similar results were obtained in comparative experiments with a smooth platinum electrode. Nitrogen gas was bubbled into the solution to remove any dissolved gases. The rate of potential sweep was mainly kept at 0.2 V/sec. Current-potential curves were recorded by means of an XY-recorder, Model XYR-1A, of Toa Electronic Co., Ltd.

Results and Discussion

The curve in Fig. 1 respresents the current-potential curve at the steady state of the potential sweep. The steady-state curve is obtained after repeating the cyclic potential sweep several times, but the curve deforms more or less during the first few cycles of the potential sweep depending on the conditions under which the electrode was stored before use. Once the steady state is attained, the curve form remains unchanged during further repetitions of the sweep. When the sweep is stopped at a given constant potential for a short period of time, the ahw again is deformed during several succeeding cycles of the potential sweep. Some actual observations are shown in Fig. 2. This sort of phenomenon seems to have drawn the attention of several workers,[7-9] and the simultaneous adsorption of contaminants has been held

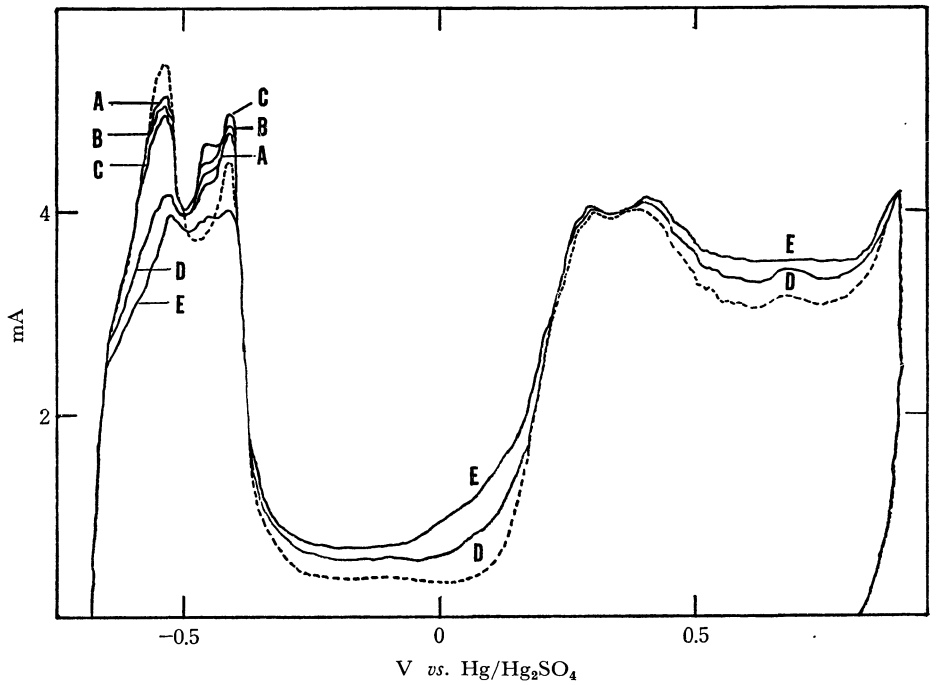

Fig. 2. Effect of the constant potential treatment.
Dashed curve indicates the steady state curve. Curve A was obtained after 5 sec. B, 10 sec; C, 20 sec; D, 25 min; E, 60 min. Curves for 5, 10 and 20 sec merge in the steady state curve at higher potential range. The potential sweep was paused at −0.68 V.

to account for the depression of ahw.[7,9] *2) A close inspection of Fig. 2 indicates, however, that there is another source of the depression of the ahw. In obtaining the curves in Fig. 2, after the steady state curve(dashed line) had been attained, the potential sweep was stopped at a desired potential (−0.68 V in this case) for various periods of time ("waiting time" will be used hereafter); then the potential sweep was carried out in order to record the full lines of the curves.

It may be seen in Fig. 2 that the left half of the double peak (peak I) diminishes monotonously with the time, while the right half (peak II) first increases and then gradually decreases. After a prolonged treatment at −0.68 V, the ahw becomes a hump-like single peak. Although the depression of the ahw can be attributed to the adsorption of contaminants, the transient increase in peak II requires explanation. Two reasons can be cited for this transient increase: 1) the steady state curve does not represent the saturation coverage of

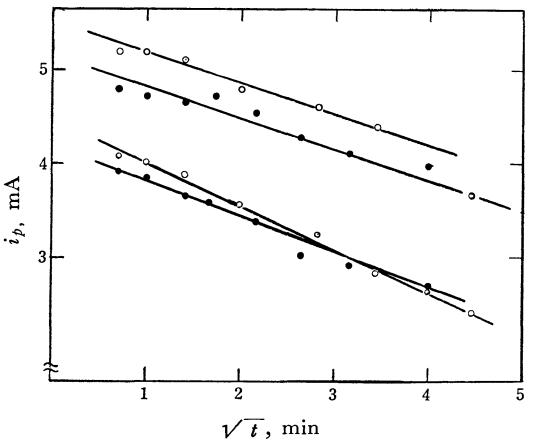

Fig. 3. Decrease in peak current with time.
Full circle: Potential sweep was paused at −0.45 V.
Empty circle: Potential sweep was paused at −0.25 V.
After the constant potential treatment, the electrode was first polarized cathodically and then reversed at −0.68 V to anodic direction. Upper two curves stand for peak I and lower two for peak II.

*2 French and Kuwana[8] found an essentially similar effect. They attributed the depression of the ahw to the deactivation of platinum atoms at the electrode surface. In the present case, however, the deactivation of the electrode surface does not seem to be the main reason. This was concluded from the fact the decrease in the ahw resulted in an increase in the quantity of electricity at the potential regions of both the double-layer charging and the surface oxide formation. The quantity of electricity recovered at these two potential regions always exceeded that at the ahw (see Fig. 2). This point will be discussed in a later paper.

hydrogen, but rather the adsorption continues during the waiting time, and 2) some of the hydrogen adsorbed at peak I migrates or rearranges*1 to a more stable form at peak II. The former explanation seems unlikely, because the transient increase only appeared in peak II, not at all in peak I.

The transient increase in peak II was not found when the sweep was paused at a potential more negative than the saddle point of the double peak. At these potentials, peak II decreased monotonously with the time. This is illustrated in Fig. 3, where the decrease in the peak current is plotted against the square root of the waiting time. Since the transient increase was found only when the potential sweep was paused at a potential range covered by peak I, it is reasonable to assume that some of the hydrogen adsorbed at peak I migrates to peak II. The following facts support this assumption. The decrease at peak I roughly holds a linear relationship with the square root of the waiting time. The square-root dependence does not, however, hold exactly, and a small deviation arises at a shorter time, as may be seen in Fig. 4.

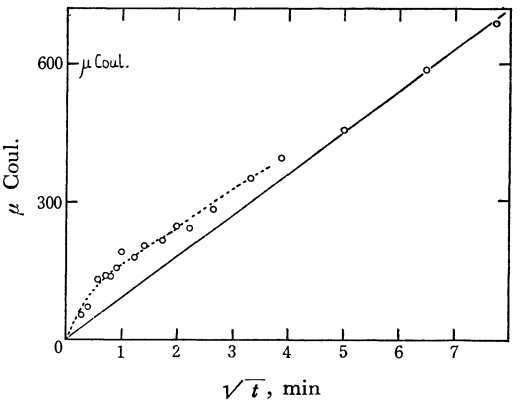

Fig. 4. Decrease of peak I with time.
Potential sweep was paused at −0.68 V.

This indicates that the decrease at peak I is caused not only by the diffusion-controlled adsorption of contaminants, but also by something else. It must be noted that the points deviating from linearity in Fig. 4 fit on a straight line when the abscissa is drawn on a logarithmic scale instead of on the basis of the square root (curve A in Fig. 5). Accordingly, the depression of peak I can be approximated by the equation:

$$\Delta q_{\mathrm{I}} = -kt^{1/2} + k' \log t \qquad (1)$$

where Δq_{I} represents the difference in the quantities of electricity between the steady state curve and the curve obtained after the waiting time, t. The negative signs in the right-hand side terms were given to express the decrease at the ahw. k should be the sum of the diffusion coefficients (not the diffusion constants) of the contaminants, and k', the rate constant of the rearrangement of the adsorbed hydrogen. The behavior of peak II in Fig. 2 suggests that there might be two counteracting processes. The curve B in Fig. 5 shows this in more detail. Of course, it is reasonable to assume the counteracting processes to be the contaminant adsorption and the surface rearrangement of the adsorbed hydrogen. Thus, the rate of change at peak II can be expressed as:

$$\Delta q_{\mathrm{II}} = -kt^{1/2} + k' \log t \qquad (2)$$

By combining Eqs. (1) and (2), the effect of the contaminant adsorption can be cancelled:

$$q_R = \Delta q_{\mathrm{II}} - \Delta q_{\mathrm{I}} = 2k' \log t \qquad (3)^{*3}$$

where one half of q_{R} represents the amount of hydrogen rearranged from peak I to peak II.

Curve C in Fig. 5 shows the difference between Δq_{II} and Δq_{I}. In accord with the expectation from Eq. (3), the curve shows a linear relationship with log t when t does not exceed twenty to thirty minutes. At a longer waiting time, the curve become flat (although this part is not seen in Fig. 5), thus indicating the equlibrium of the rearrangement. The total amount of hydrogen which takes part in the rearrangement was found to be less than 10% of the adsorbed hydrogen at saturation.

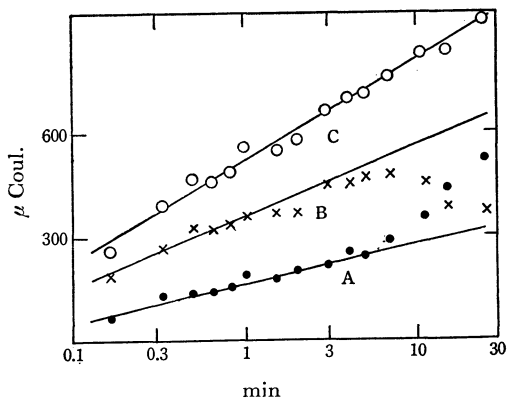

Fig. 5. Curve A: Decrease of peak I, B: Incerase of peak II C: Corrected change at peak II.

*3 In the above discussion, k' was taken to be common to both Δq_{I} and Δq_{II}. The treatment is, therefore, equivalent to assuming that no hydrogen adsorbs on vacant sites produced after the rearrangement. Actually, this is not true, since it was found that the increase in the charge at peak II (Δq_{II}) was greater than the decrease at peak I (Δq_{I}) unless the waiting time exceeded thirty seconds or so. Accordingly, Eq. (1) will require an additional term to express the adsorption on vacant sites produced after the rearrangement. Because of the present lack of experimental accuracy, however, it seems meaningless to attempt to discuss the mechanism in such detail.

In order to find the activation energy of the process, experiments were carried out at three different temperatures, 5, 25, and 40°C. The results indicated that the activation energy, if it existed, was less than 1 kcal/mol.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 1747—1749 (1969)

β-Diketone Involving Fluorine. V.[1] NMR Studies of Pivaloyltrifluoroacetone in Various Alcohols

Kimitaka SATO, Hisao OCHI[2] and Kiichi ARAKAWA[2]

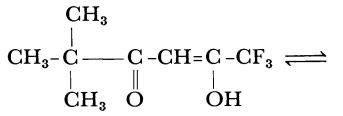
Tokyo Research Institute, Yawata Iron and Steel Co., Ltd., Kawasaki, Kanagawa

(Received May 17, 1968)

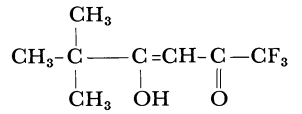
It was noted, in our previous papers,[1,3-5]— that an equilibrium existed between β-diketones involving fluorine and alcohols by the activation of the carbonyl carbon adjacent to a trifluoromethyl (CF_3-) group due to the *I* effect exerted by the fluorine atom. Such a phenomenon has already been described with β-diketones like trifluoroacetylacetone (TFA),[1,3] benzoyltrifluoroacetone (BTA), 2-furoyltrifluoroacetone (FTA), 2-thenoyltrifluoroacetone (TTA)[4] or hexafluoroacetylacetone (HFA),[1] and with alcohols like methanol, ethanol, 1-propanol, 2-propanol, allyl alcohol, propargyl alcohol, benzyl alcohol, ethylene glycol or some halohydrins. The equilibrium is affected by the steric effect and the nucleophilicity of alcoholic oxygen, therefore some changes in property are expected to be found by changing not only the variety of alcohols but also that of β-diketones. For these reasons, pivaloyltrifluoroacetone (PTA) with a bulky functional group was newly synthesized, and the behavior of that β-diketone (PTA) in alcohols and water has been studied by means of high resolution NMR spectroscopy.

Results and Discussion

The proton magnetic resonance signals of PTA appeared at 8.77 ppm due to the pivaloyl proton and at 4.01 ppm due to methine proton, but any signals which should be attributed to methylene proton did not appear. Thus PTA exists as 100% enolized structure of either Ia or Ib.



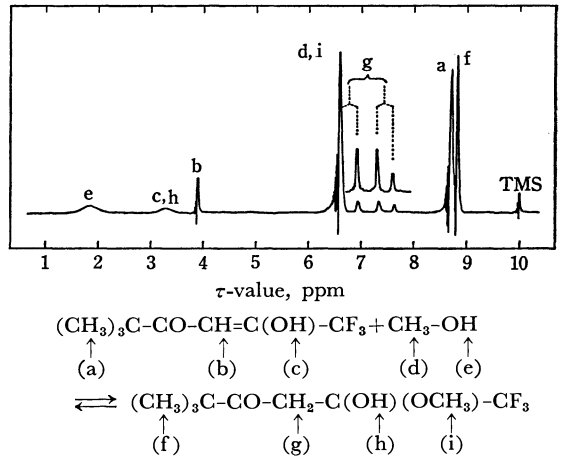
(Ia)



(Ib)

As (Ia) was probably regarded as the preferred enol form in the equilibrium (Ia) and (Ib),[6] the following discussions were carried out assuming that the structure of PTA was (Ia).

Table 1 lists the values of chemical shifts in the fluorine magnetic resonance spectra of various kinds of β-diketone-alcohol solutions mixed at the volume ratio, 1 : 1. Two signals appeared at about 76 ppm



$(CH_3)_3C$-CO-CH=C(OH)-CF_3 + CH_3-OH
(a) (b) (c) (d) (e)
⇌ $(CH_3)_3C$-CO-CH_2-C(OH)(OCH_3)-CF_3

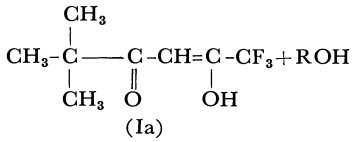
Table 1. The values of chemical shift in fluorine magnetic resonance spectra of solutions

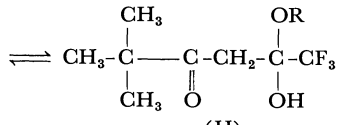
Alcohol	R	$(CH_3)_3CCOCH=C(OH)C\underline{F}_3$ (ppm)	$(CH_3)_3CCOCH_2C(OH)(OR)C\underline{F}_3$ (ppm)	II / Ia+II
(PTA)		76.0	—	—
CH_3OH	CH_3-	75.1	80.7	0.50
CH_3CH_2OH	CH_3CH_2-	75.4	81.1	0.21
$CH_3(CH_2)_2OH$	$CH_3(CH_2)_2$-	75.5	80.8	0.15
$(CH_3)_2CHOH$	—	75.5	—	—
$BrCH_2CH_2OH$	$BrCH_2CH_2$-	75.2	81.2	0.19
$CNCH_2CH_2OH$	$CNCH_2CH_2$-	74.3	80.9	0.50
$ClCH_2CH_2OH$	$ClCH_2CH_2$-	75.4	81.5	0.18
$CH_2=CHCH_2OH$	—	75.4	—	—
$PhCH_2OH$	$PhCH_2$-	75.3	80.7	0.18
H_2O	H-	74.9	84.8	0.18

and 81 ppm in the spectra of these solutions: the signal at 76 ppm was equal to PTA, $(CH_3)_3CCOCH C(OH)CF_3$, and that at 81 ppm may be due to the new reaction product(II). Figure 1 shows the case of PTA-methanol solution as an example in the PMR spectra of those solutions. Of the two signals at 8.74 and 8.84 ppm, the down-field one was apparently due to the pivaloyl proton of PTA because of having a definite intensity in spite of the values of II/(Ia+II), and the up-field one might be due to the pivaloyl proton of the new product (II). It was easily estimated that the AB-type signal at 7.11 ppm was based on methylene proton in comparison with the case of TFA[4] and the integrated ratios between the signal at 7.11 ppm and at 8.84 ppm were about 2 : 9. The signal at 6.61 ppm might be due to not only methyl proton of methanol but also methoxy proton, since that intensity was much stronger than that due to only methanol. It was thought that the broad signals at about 2 and 3 ppm must be based on some hydroxyl protons. Therefore, it was expected that the new reaction product consisted of such functional groups as pivaloyl,methoxyl, hydroxyl, methylene and trifluoromethyl in this equilibrium.

From these results, it has been deduced that the following equilibrium exists also in PTA similar to TFA, TTA, *etc.*:



(Ia)

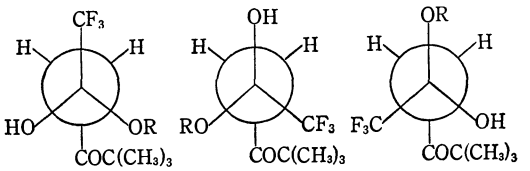


(II)

R=H-, CH_3-, CH_3CH_2-, $CH_3(CH_2)_2$-, $BrCH_2CH_2$-, $CNCH_2CH_2$-, $ClCH_2CH_2$-, $PhCH_2$-.

It was found, however, that PTA hardly reacted with isopropyl alcohol, allyl alcohol and propargyl alcohol in such equilibrium. This is probably due to the steric hindrance or the less nucleophile nature of alcoholic oxygen effective in such alcohols.

Such exceptions found in isopropyl, allyl and propargyl alcohol solutions have never been found with β-diketones like TFA, HFA, TTA, BTA and FTA reported in the previous papers.[1,3,5] This may be due to the fact that the steric hindrance of pivaloyl group mainly contributes to these phenomena. The carbon atom adjacent to the trifluoromethyl group is optically active in the new reaction product (II), which is consequently possible to take conformations IIIa, IIIb and IIIc.



(IIIa) (IIIb) (IIIc)

It seems reasonable to conclude that IIIa is the most preferred of three conformations and is major conformation in the sample solution. It was estimated that PTA hardly reacted with isopropyl, allyl and propargyl alcohols because of the considerable contribution of steric hindrance even in IIIc conformation together with nucleophilicity of alcoholic oxygen. Above-mentioned characteristics of PTA are apparently different from that of TFA, TTA and HFA.

Experimental

Measurements. A JNM C-60 high-resolution nuclear magnetic resonance spectrometer was used. Proton resonance spectra and fluorine resonance spectra were run at 60 Mc and 56.45 Mc, respectively. Each sample was dissolved in carbon tetrachloride at a concentration of 25 vol%. The temperature was maintained at 23±1°C. Tetramethylsilane (TMS: proton) and monofluorotrichloromethane ($CFCl_3$:

fluorine) were employed as the internal standards.

Materials. *Commercial alcohols and halohydrins* were used without further purification. Water was purified by passing it through an ion exchange resin.

Pivaloyltrifluoroacetone (PTA) used in this investigation was prepared in the following method, a modification of Henne's[7]: Sodium ethylate freshly prepared by treating 14 g of absolute ethanol with 7.6 g of finely dispersed sodium was dissolved in ether. To the resulting suspension was added slowly 42.6 g of ethyl trifluoroacetate in 40 m*l* of ether. Privaloylmethane, 30 g, in 30 m*l* of ether was then added, and the mixture refluxed for about six hours. On account of the avidity of the condensates for moisture, the following procedure of isolation was adopted. The reaction mixture was treated with a 50% solution of sodium bisulfide in a very slight excess over neutralization requirements, then with a saturated aqueous solution of cupric aectate (180 m*l*). The organic layer was distilled off, then 43.6 g of crystalline copper derivative, mp 85—87°C, was extracted with ether. The dry copper derivative was suspended in 500 m*l* of dry ether, in which it was partly dissolved, and was subjected to a stream of hydrogen sulfide. After removal of the cupric sulfide, the condensed compound was separated from the ether by fractional distillation, with rigorous precautions to avoid loss by volatility, to give 23.5 g of a light yellow oil, bp 129.5—130.5°C.

UV: λ_{max}^{MeOH} mμ (ε); 288 (8700).

Found: C, 49.51; H, 5.99%. Calcd for $C_8H_{11}O_2F_3$: C, 48.98; H, 5.64%.

The authors wish to express their thanks to Professor Yojiro Tsuzuki of Science University of Tokyo for his valuable discussion.

Studies on Polymorphism of Glutathione

Muneji MIYOSHI, Keishi KOTERA, Hiroyasu SEKO, Kenji MASUKAWA, Sataro IMADO and Kentaro OKUMURA

Chemical Research Laboratory, Tanabe Seiyaku Co., Ltd., Higashiyodogawa-ku, Osaka

(Received July 25, 1968)

Glutathione is known as an important constituent of all living cells, and has recently been used in clinical fields. Various synthetic routes have been reported by many investigators since Harington and Mead[1] first synthesized the tripeptide in 1935.

The crystal of glutathione is well known as a colorless needle which is easily soluble in water, and its structure has also been discussed.

However, studies on the crystallization conditions of glutathione have scarcely been reported, although some preparative methods are shown.[2-6]

In the present paper, both nuclei formation and the conditions of crystal growth of glutathione were investigated in water and ethanol-water (1 : 2), with varying supersaturated concentration and temperature respectively.

Results

Crystallization in Water System. The glutathione used in this study was repeatedly purified through Cu-salt. Paper electrophoresis did not show any spots of impurities.

Condition of nuclei formation was examined in water without seeding.

The different crystalline nuclei of the glutathione (named type B) were formed when 100% supersaturated solution (100g glutathione/100g water) was maintained above 50°C for 30 min where the crystallization conditions were quite different from those used in the previous reports.

The selective crystal growth of this new type B as well as that of the other one formed under the usual conditions (named type A) may be carried out by seeding the crystalline nuclei of each type to the supersaturated solution under usual crystallization conditions.

In the supersaturated concentrations from 27 to 50%, type A was selectively grown at 10°C after 72 hr, with or without seeding type A. If crystalline nuclei of type B were seeded to the same supersaturated solution at 10°C, only crystal of type B was grown selectively.

In the 100% supersaturated concentration, type

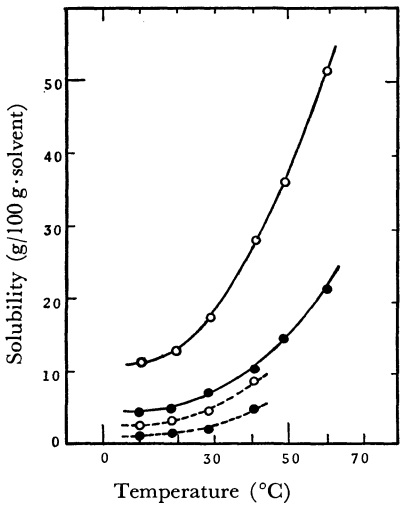

Fig. 1. Solubility curves of type A and B.

— type A
--- type B
○ H_2O
● EtOH-H_2O (2:1)

B was selectively formed with or without seeding type B, when the solution was kept for 30 min at 50°C and then for 72 hr at 30°C. However, if type A was seeded under the same condition, only type A was found in the grown crystal.

The final concentrations in the mother liquor showed 14.0% with A and 5.1% with B respectively after 72 hr at 10°C, and these results suggested that considerable differences of solubilities in water would exist between both types. In fact, these data approximately agreed with those of the solubility curves at 10°C shown below. (Fig. 1)

Crystallization in Ethanol-Water (1 : 2) System. Preparative crystallization of glutathione has been usually carried out by adding suitable amount of ethanol to the aqueous solution. Therefore the crystallization condition was also investigated in ethanol-water (1 : 2) system to check which nuclei of type A or B would be formed.

Remarkable decrease in solubilities of the glutathione (Fig. 1) was found in comparison with those in water system. In this solvent system, only the crystalline nuclei of type A were obtained under conditions in this study.

Chemical and Physicochemical Properties. The new crystalline form named type B was found to be a colorless rigid and fine crystal, while that of type A was a colorless needle.

The solubilities of both types in water were remarkably different as shown in Fig. 1.

Type B was proved to be more stable on storage at 40°C in 100% relative humidity. Thus, the amount remaining unchanged was as much as 75% for B and was only 15% for A after 17 days.

Elemental analysis, paper electrophoresis, $[\alpha]_D$, and mp of type B quite agreed with those of type A.

Both types gave completely the same patterns of NMR (in D_2O, d_6-DMSO, CF_3COOD), ORD (in H_2O) and IR (in D_2O) except IR in KBr tablets. In the pattern of IR spectra, the difference between both types was observed at absorption bands assigned to both amide and carboxyl groups. (Fig. 2)

X-ray diffraction patterns were also measured. It was found that type A showed a very strong peak at d=4.00Å while type B at d=4.19Å, and the spacing of the latter was a little longer than the former.

Discussion

On the Crystallization Conditions. From Fig. 1, the range in which the nuclei of type B were

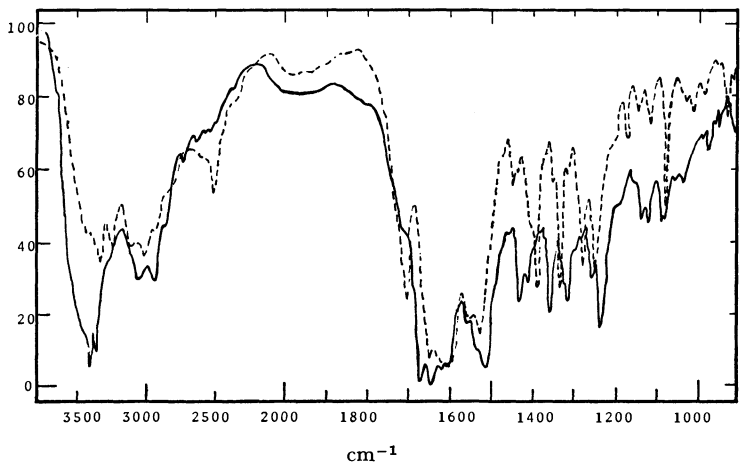

Fig. 2. Infrared spectra in KBr tablets.
---- type A —— type B

formed might exist at higher temperatures or higher concentrations, as the difference between solubility curves of type A and B was much greater. However it was practically difficult to obtain the crystal above 60°C because partial decomposition of glutathione was observed more than an hour later. It is interesting to note that the condition to form nuclei of type B must be restricted within a very small range of temperature and concentration as mentioned above.

It should also be noted that only the selective crystallization of one type took place, with seeding, even in the supersaturated solution where the other type of crystal should be formed without seeding. This fact suggests that the work of nucleus formation of both types would be unusually greater than that of crystal growing. Therefore by seeding one type of nuclei, the same type of crystal would be selectively grown, while nucleus formation of the other type might be disturbed.

Estimation of the Structural Configuration. Many papers about the polymorphism of peptides, in which two different forms are proposed, have been reported. Both of them are "the folded form" with intramolecular hydrogen bonds, and "the extended form" with intermolecular hydrogen bonds. In this connection, IR alternations due to the structural configurations of peptides have also been studied.[7-8] In IR spectra of KBr tablets obtained in this experiment, type B of the glutathione showed a lowering of absorption frequencies at amide ν_{NH} ($\Delta 116\ cm^{-1}$), amide I ($\Delta 25\ cm^{-1}$) and amide II ($\Delta 20\ cm^{-1}$) in comparison with those of type A, respectively. These results would be in satisfactory agreement with those previously reported.

As to the X-ray analysis, Wright[9] reported that the structure of glutathione was held together by a three dimensional network with intramolecular hydrogen bonds. The spacings were calculated as the orthorhombic system, using the unit cell dimensions found by Wright ($a=28.05\pm0.02$Å, $b=8.802\pm0.002$Å, $c=5.630\pm0.002$Å). The calculated value for type A agreed with the observed value in type A.

From these data, the structure of type A must be "the folded form" with intramolecular hydrogen bonds, which is well known previously, and that of the new type B would be "the extended form" with intermolecular hydrogen bonds.

Experimental

Crystallization of Type B. a) Glutathione (10 g) dissolved in water (20 ml) was concentrated to total weight 20 g *in vacuo* at 40°C. This supersaturated solution was maintained at 50°C for 30 min with mild stirring, and the solution was allowed to stand for 72 hr at 30°C. Crystal was filtered and washed with a small amount of water and dried in a desiccator under reduced pressure. Colorless, rigid and fine crystal was obtained, yield, 6.5 g. Mp 195°C (dec.), $[\alpha]_D^{20}$ −17.3° (*c* 2, H_2O). Solubility in water at 10°C, 3.67%. Elemental analysis agreed with the starting glutathione.

b) Nuclei of type B (0.2 g) were seeded to the solution of glutathione (10 g) in water (20 g), and allowed to stand for 72 hr at 10°C. The crystal formed was treated in the same way as above. Yield, 8.9 g. Mp 195°C (dec.), $[\alpha]_D^{20}$ −17.4° (*c* 2, H_2O). Solubility in water at 10°C, 3.70%.

Apparatus. IR spectra were recorded on a Hitachi IR-G Spectrometer (0.025 mm thickness. KRS-5 sample cell) in D_2O solution and in KBr tablets.

NMR spectra were obtained with an internal standard TMS, JEOL c-60 spectrometer (60 Mc) in D_2O, d_6-DMSO, and CF_3COOD.

X-Ray diffraction patterns were measured with the apparatus of D-3F type made by Rigakudenki, Ltd., in the region of $2\theta=5-40°$ with the use of Cu$K\alpha$ radiation ($\lambda=1.5418$ Å).

Synthesis and Melanogenesis of the DOPA Dimer

Yoshimori OMOTE, Yoshimori FUJINUMA and Noboru SUGIYAMA

Department of Chemistry, Tokyo Kyoiku University, Otsuka, Tokyo

(Received August 19, 1968)

It is generally accepted that, in the presence of tyrosinase, β-(3,4-dihydroxyphenyl)alanine (DOPA) yields melanin *via* cyclization to 5,6-dihydroxyindole.[1] Molecular orbital calculation[2-4] suggests that 5, 6-dihydroxyindole will polymerize oxidatively at the 4 and 7 positions, which correspond to the positions 2 and 5 of DOPA. Recently the presence of uncyclized units in DOPA melanin has been suggested by several groups of investigators,[5-7] This suggests the possibility that DOPA will polymerize at the position 2, 5, or 6 without any cyclization to 5,6-dihydroxyindole. Therefore, it is of interest to examine whether or not the dimer at the position 2, 5, or 6 of DOPA can be an intermediate of the melanogenesis of DOPA. One DOPA dimer, a novel bi-(amino acid), 5,5'-bi-[β-(3,4-dihydroxyphenyl)alanine](V), has thus been synthesized, and its melanogenesis has been examined.[8]

Elbs prepared 2,2'-diacetoxy-5,5'-diformyl-3,3'-dimethoxybiphenyl (I)[9,10] from dehydrodivanillin. The treatment of I and hippuric acid under reflux with fused sodium acetate in acetic anhydride yielded 5,5'-bi-[4-(4-acetoxy-3-methoxybenzylidene)-2-phenyloxazolone](II). Heating the oxazolone II under reflux with fused sodium acetate in methanol gave the unsaturated ester, 5,5'-bi-(methyl 4-acetoxy-α-benzamido-3-methoxycinnamate)(III). The oxazolone II showed IR absorptions at 1790 (oxazolone C=O) and 1766 (enol acetate C=O) cm^{-1}, while the unsaturated ester III showed absorptions at 1766 (enol acetate C=O) and 1720 (unsaturated ester C=O) cm^{-1}.

The catalytic hydrogenation of III with platinum oxide in acetic acid at atmospheric pressure and at room temperature afforded a saturated ester, 5,5'-bi-(methyl 4-acetoxy-α-benzamido-3-methoxydihydrocinnamate)(IV). When IV was hydrolyzed with hydrobromic acid and neutralized with ammonium hydroxide, the DOPA dimer(V) was produced as a colorless powder. Both the UV and the IR spectra, as well as the elemental analyses, favor the structure V for the DOPA dimer. Considering that the UV absorption spectrum of V is similar to that of monomeric DOPA (Fig. 1), it is probable that the two phenyl nuclei of V are almost perpendicular to one another.

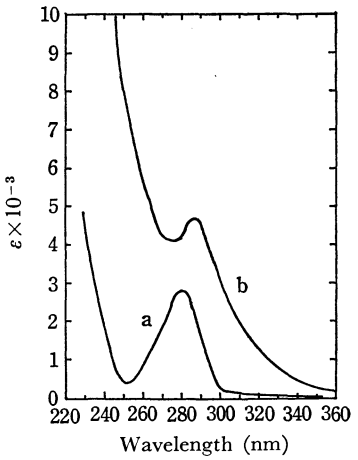

Fig. 1. Ultraviolet absorption spectra of DOPA and the DOPA dimer (V) in water.

a: DOPA b: DOPA dimer

Also, we succeeded in the direct synthesis of the DOPA dimer V from the unsaturated ester III by boiling them with hydroiodic acid and red phosphorus in acetic anhydride, as will be described in the Experimental section.

V

In the presence of atmospheric oxygen, it has been shown that DOPA and the DOPA dimer polymerized at about the same rate. In the presence of tyrosinase and atmospheric oxygen, however, the melanogenesis of DOPA was very much accelerated, while that of the DOPA dimer was accelerated only slightly. This suggests that the role of the DOPA dimer as an intermediate of enzymatic melanogenesis is rather improbable, though the possibility of a role in non-enzymatic melanogenesis can not be eliminated.

Experimental

All the melting points are uncorrected.

5,5'-Bi-[4-(4-acetoxy-3-methoxybenzylidene)-2-phenyloxazolone] (II). A mixture of 2,2'-diacetoxy-5,5'-diformyl-3,3'-dimethoxybiphenyl (I) (46 g), hippuric acid (46 g), and fused sodium acetate (24 g) in acetic anhydride (200 m*l*) was heated at 100°C for 2 hr with stirring. Into the reaction mixture ethanol (50 m*l*) was then gradually stirred, after which the mixture was kept overnight in an refrigerator. The solid substance which thus separated was filtered, and washed with a small portion of cold ethanol and then with boiling water. Treatment with chloroform-benzene gave the oxazolone II as a yellow powder (40 g); mp 287°C. Found: C, 66.13; H, 4.23; N, 4.33%. Calcd for $C_{38}H_{28}O_{10}N_2$: C, 67.85; H, 4.20; N, 4.17%. UV $\lambda_{max}^{CHCl_3}$ nm (ε) 380 (75000) and 402 (76000). IR ν^{KBr} cm^{-1} 1790, 1766, 1653 and 1593.

5,5'-Bi-(methyl 4-acetoxy-α-benzamido-3-methoxycinnamate) (III). The oxazolone II (20 g) and fused sodium acetate (9 g) in absolute methanol (250 m*l*) were refluxed for 3 hr, by which time the solid had dissolved completely. Then the solution was condensed to about one third of its initial volume; after cooling, it was poured into ice water (300 m*l*) and kept overnight in a refrigerator. The treatment of the precipitates with benzene gave III as a colorless amorphous powder (17.3 g); mp 141—145°C. Found: C, 65.62; H, 5.09; N, 3.81%. Calcd for $C_{40}H_{36}O_{12}N_2$: C, 65.21, H, 4.93; N, 3.80%. UV: λ_{max}^{EtOH} nm (ε) 225 (46600) and 295 (31000). IR ν^{KBr} cm^{-1} 3320, 1766, 1720, 1655 and 1585.

5,5'-Bi-(methyl 4-acetoxy-α-benzamido-3-methoxydihydrocinnamate) (IV). A mixture of III (2 g) in acetic acid (10 m*l*) and platinum oxide (0.05 g) was stirred with hydrogen at atmospheric pressure and room temperature for 8 hr. After the catalyst had then been filtered off, the solution was treated with active charcoal and evaporated under reduced pressure. There was thus obtained an amorphous powder of IV; mp 65—75°C. It was pure enough for the next step. Found: C, 63.32; H, 5.91; N, 3.53%. Calcd for $C_{40}H_{40}O_{12}N_2$: C, 64.85; H, 5.44; N, 3.78%. UV λ_{max}^{EtOH} nm (ε) 281 (4500). IR ν^{KBr} cm^{-1} 3400, 1770, 1753, 1653 and 1600.

5,5'-Bi-[β-(3,4-dihydroxyphenyl)alanine] (V). A solution of IV (20 g) in hydrobromic acid (47%, 100 m*l*) was refluxed for 3 hr. Then toluene (250 m*l*) was added, a Dean-Stark trap equipped with a stopcock outlet for the removal of water was inserted between the flask and the reflux condenser, and the mixture was refluxed until no more water was collected in the trap (about 8 hr). Then the hydrogen bromide salt of V, which had separated, was filtered off. It was brown and decomposed at 132°C. The salt dissolved in water (40 m*l*) was neutralized with ammonium hydroxide. The solution was evaporated to dryness. The crude DOPA dimer was boiled in water containing a little sulfur dioxide and was filtered while still hot. The filtrate was then allowed to evaporate slowly under reduced pressure to separate the pure DOPA dimer V as a colorless powder (yield 7.1 g); mp above 300°C. The color became brown and changed gradually at about 230°C from brown to black. Found: C, 55.06; H, 5.12; N, 7.08%. Calcd for $C_{18}H_{20}O_8N_2$: C, 55.10; H, 5.14; N, 7.14%. UV $\lambda_{max}^{H_2O}$ nm (ε) 287 (4700). IR ν^{KBr} cm^{-1} 3200 (broad), 1628 and 1598. The elemental analysis was carried out just after the sample had been dried at 100°C/10^{-3}—10^{-4} mmHg for 3 hr.

The DOPA dimer V was also obtained directly from III by the following reductive hydrolysis. A mixture of III (5 g), hydroiodic acid (d=1.7, 35 m*l*) and red phosphorus (3.5 g) was refluxed for 3 hr. After cooling, the unreacted phosphorus was filtered off, the solution was evaporated to dryness under reduced pressure, and water (50 m*l*) was added. The solution was extracted five times with ether (50 m*l*) in order to remove any benzoic acid and iodine, and then the aqueous solution was evaporated to dryness under reduced pressure. The residual solid was dissolved in water (10 m*l*), neutralized with ammonium hydroxide, and purified as has been described above. Yield, 1.2 g.

DOPA Melanin and DOPA Dimer Melanin. *(a) Melanogenesis by Autoxidation.* A solution of DOPA (250 mg) or the DOPA dimer (100 mg) dissolved in, respectively, 100 m*l* or 200 m*l* of a M/30 phosphate buffer at pH 6.9 was stirred in the presence of atmospheric oxygen at 25°C. Both the DOPA and DOPA dimer solutions became faint orange after one hour and then gradually turned dark over an 8-hr period. The relative rates of melanogenesis, based on the absorbancy of the solution (C=10^{-3} mol/*l*) at 550 nm (shoulder), were as follows: DOPA, 1.0 : 1.5 : 6.4 : 14.0, and the DOPA dimer, 1.0 : 1.9 : 6.6 : 13.4, after 1, 4, 8 and 16 hr respectively. Both the DOPA solution and the DOPA dimer solution produced melanin after 24 hr. Each solution was acidified, and black pigments were collected by centrifugation. The melanin thus produced was treated with concentrated hydrochloric acid at room temperature for 4 days, collected by centrifugation, washed with dilute hydrochloric acid, ethanol and finally acetone, and dried. DOPA melanin (yield, 100 mg). Found: C, 58.05; H, 3.14; N, 8.41%. DOPA dimer melanin (yield, 40 mg). Found: C, 55.00; H, 3.73; N, 7.23%.

(b) Enzymatic Melanogenesis. To a solution of DOPA (200 mg) or the DOPA dimer (200 mg) dissolved in, respectively, 100 m*l* or 500 m*l* of a M/30

phosphate buffer at pH 6.9, there was added mushroom tyrosinase (Nutritional Biochemicals Corp., 500 units/mg) (10 mg); a stream of air was then passed through for 24 hr at 35°C. The DOPA solution immediately turned red and then changed to purple within 10 min; black precipitates appeared soon after. The DOPA dimer solution changed gradually from brown to dark over an 8-hr period. After 24 hr each solution was treated as has been described above. DOPA melanin (yield, 150 mg). Found: C, 57.15; H, 3.03; N, 8.61.% DOPA dimer melanin (yield, 110 mg). Found: C, 55.16; H, 3.61; N, 7.71%.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 1754—1755 (1969)

Anionic Copolymerization of 2,3-Dimethylbutadiene and 1,1-Diphenylethylene with *n*-Butyllithium in Benzene

Heimei YUKI, Yoshio OKAMOTO and Katsutoshi SADAMOTO

Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka

(Received September 19, 1968)

Anionic copolymerization of 2,3-dimethylbutadiene (M_1) and 1,1-diphenylethylene (M_2) by *n*-butyllithium (*n*-BuLi) in tetrahydrofuran (THF) has been studied by means of NMR spectroscopy,[1] in which the rates of consumptions of the two monomers were followed. The copolymerization proceeded alternately, when the initial molar ratio of the monomers, $[M_1]_0/[M_2]_0$, was less than unity. In the present study, the copolymerization of the same monomer pair is investigated in benzene at 40°C with *n*-BuLi as an initiator.

Experimental

Meterials. 2,3-Dimethylbutadiene was synthesized by the dehydration of pinacol.[2] The monomer purified by fractional distillation was redistilled *in vacuo* from lithium aluminum hydride. Bp 69°C/760 mmHg, n_D^{20} 1.4360.

1,1-Diphenylethylene prepared from diphenylmethyl carbinol[3] was first treated with a small amount of Na-K alloy and distilled. Bp 115°C/3 mmHg, n_D^{20} 1.6085. Then *n*-BuLi was added to the monomer until the red color of its anion appeared. The monomer was redistilled from the colored mixture *in vacuo*.

Benzene purified by the usual method was redistilled in the presence of a small amount of *n*-BuLi under high vacuum before use.

n-BuLi was prepared in *n*-heptane according to the method of Ziegler.[4]

Polymerization. Copolymerization was carried out in a glass ampoule which had been previously heated with a gas burner *in vacuo*. Benzene and 2,3-dimethylbutadiene were transferred to the ampoule on a vacuum line, and then 1,1-diphenylethylene and *n*-BuLi were added with hypodermic syringes under dry nitrogen. The copolymerization was terminated by adding methanol. The polymer precipitated in methanol was filtrated, washed with methanol, and dried.

Viscosity. The viscosity of the copolymer was measured in toluene solution at 30.0°C.

Results and Discussion

The copolymerization of 2,3-dimethylbutadiene (M_1) and 1,1-diphenylethylene (M_2) by *n*-BuLi was followed in benzene at 40°C, the initial molar ratio of M_1 to M_2 being 0.683. The results are shown in Fig. 1. The copolymerization proceeded slowly to reach a constant polymer yield in about 50hr. In this period 2,3-dimethylbutadiene was completely consumed and only unchanged 1,1-diphenylethylene remained in the system. The softening point of the copolymer was about 135°C.

In Fig. 2 the plot of $\log[\eta]$ *vs.* log yield of polymer is shown. The linear relationship suggests that the

a) Molar ratio of monomers in the copolymer. Average 0.23

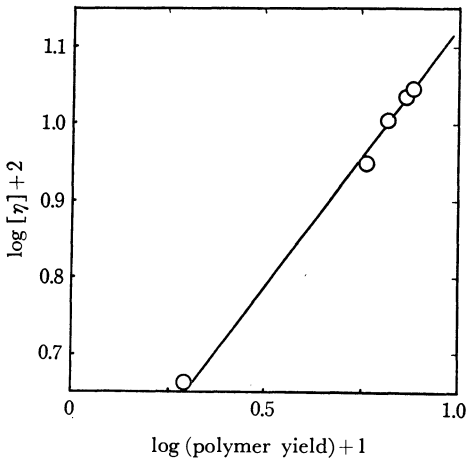

Fig. 2. Anionic copolymerization of 2,3-dimethylbutadiene (M_1) and 1,1-diphenylethylene (M_2) in benzene by *n*-BuLi.——Relationship between polymer yield and viscosity of polymer.

copolymerization proceeded without a termination and a chain transfer, probably to give a living polymer.

The copolymerization was carried out for a prolonged time and the material balance was checked in order to confirm the complete consumption of the M_1 monomer. The results are listed in Table 1. It was found that the total amount of the monomers charged, M_1+M_2 (g), was substantially equal to the sum of the polymer obtained and the unchanged M_2 monomer recovered from the mother liquor of the polymer precipitation. This fact means that 2,3-dimethylbutadiene was completely incorporated into the copolymer. The molar ratio of the monomers in the copolymer, $[m_1]/[m_2]$, can then be calculated from the polymer yield. The $[m_1]/[m_2]$ ratio decreased with a decrease in the ratio of the charged monomers, $[M_1]_0/[M_2]_0$.

The monomer reactivity ratio, r_1, is obtained by means of the integrated copolymer composition equation, assuming that the M_2 monomer does not homopolymerize and the M_1 monomer has been completely consumed.[5] The r_1 values are shown in Table 1. As a mean value, 0.23 was obtained. This indicated that 1,1-diphenylethylene is more reactive to 2, 3-dimethylbutadienyl anion than 2,3-dimethylbutadiene. In the copolymerization in THF, the r_1 value was almost zero and an alternating copolymer was obtained, when the $[M_1]_0/[M_2]_0$ ratio was less than unity.

In the copolymerizations of styrene and butadiene,[6] styrene and isoprene,[7] and 1,1-diphenylethylene (M_2) and isoprene (M_1)[8] by lithium catalysts, greater relative reactivities of conjugated dienes than the comonomers have been found in a nonpolar solvent, contrary to the less reactivities in a polar solvent. In the last pair of monomers, the r_1 values were 0.13 in THF and 37 in benzene. The relative reactivities of the two monomers against isoprene anion reversed in these two solvents. In the copolymerization of 2,3-dimethylbutadiene and 1, 1-diphenylethylene, the latter was always more reactive in both THF and benzene.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 1756—1757 (1969)

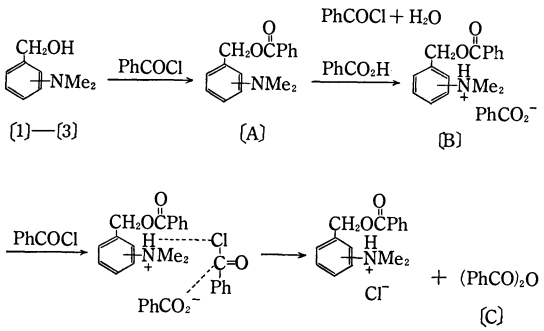
The Schotten-Baumann Reaction of Dimethylaminobenzyl Alcohols[1)]

Makoto TSUCHIYA,*[1] Hiroshi YOSHIDA, Tsuyoshi OGATA and Saburo INOKAWA

Department of Synthetic Chemistry, Faculty of Engineering, Shizuoka University, Johoku, Hamamatsu

(Received September 28, 1968)

As an extension of our previous work on the benzoylation of aliphatic *t*-aminoalcohols, we have carried out the benzoylation of such aromatic *t*-aminoalcohols as *ortho*-〔1〕, *meta*-〔2〕, and *para*-dimethylaminobenzyl alcohol 〔3〕. When the reaction mechanism proposed in a previous paper[2)] is applied to dimethylaminobenzyl alcohols, it should be written as follows:



The *t*-aminoalcohols and the *t*-amines used in this experiment are as follows: *o*-dimethylaminobenzyl alcohol 〔1〕, *m*-dimethylaminobenzyl alcohol 〔2〕, *p*-dimethylaminobenzyl alcohol 〔3〕, 2-dimethylaminocyclohexylmethanol 〔4〕, *N,N*-dimethylaniline 〔5〕, *N,N*-dimethyl-*o*-toluidine 〔6〕, *N,N*-dimethyl-*p*-toluidine 〔7〕, *N,N*-dimethyl-*o*-cumidine 〔8〕, and *N,N*-dimethyl-*p*-cumidine 〔9〕.

Results and Discussion

The Schotten-Baumann reactions of 〔1〕—〔3〕 were carried out under the same conditions as those described in a previous paper[2)] and also under other conditions using different amounts of sodium hydroxide (0.35 mol)*[2]. The results are summarized in Table 1. The yields of 〔A〕 from 〔1〕—〔3〕 were almost all the same, but the yields of 〔C〕 increased in the order of 〔1〕, 〔2〕, and 〔3〕. According to previous works,[2,3)] the yield of 〔C〕 seems to depend mainly on the basicity of 〔A〕 because of the facility of the formation of 〔B〕. In the cases of 〔1〕—〔3〕, however, the observed pK_a-values of 〔A〕[4)] decreased slightly in the order of 〔1〕, 〔2〕, and 〔3〕, as is shown in Table 1. Therefore, the yields of 〔C〕 can not simply be correlated with the basicity.

TABLE 1. BENZOYLATION OF AMINOALCOHOLS

Method	Aminoalcohol	〔A〕 (g)	Yield[a)] (%)	〔C〕 (g)	pK_a of 〔A〕
I	*o*-〔1〕	11.6	(91)	0	
	m-〔2〕	11.8	(93)	2.3	
	p-〔3〕	11.2	(88)	4.2	
II	*o*-〔1〕	11.3	(89)	7.6	2.6
	m-〔2〕	11.2	(88)	10.5	2.5
	p-〔3〕	11.4	(90)	12.1	2.4
	〔4〕	12.2	(94)	18.8	7.4

Method I : aminoalcohols 0.05 mol, benzoyl chloride 0.25 mol, sodium hydroxide 0.525 mol 10% aqueous solution.

Method II : aminoalcohol and benzoyl chloride: the same as the above, sodium hydroxide: 0.35 mol 10% aqueous solution.

a) Yield shows a crude one.

Table 2. Relation between yield of [C] and twist-angle

Dimethylaniline	λ_{max} (mμ)	ε_{max}	φ°C	[C] g[b]
[5]	250	14700	0	16.3
2-Me [6]	249	6160	50	12.0
4-Me [7]	252	14300	10	18.3
2-*i*-Pr [8]	248	4180	58	7.3
4-*i*-Pr [9]	252	14300	10	17.0
2-CH_2OCOPh [1A]	248	5960	51	7.6
3-CH_2OCOPh [2A]	255	13200	19	10.5
4-CH_2OCOPh [3A]	250[a]	14700[a]	0	12.1

a) There is no λ_{max} near 250 mμ. The value is one at 250 mμ.
b) amine 0.05 mol, benzoyl chloride 0.25 mol, sodium hydroxide 0.35 mol 10% aq. soln.

In order to obtain further knowledge on the yields of [C] in the case of weak bases, the aromatic *t*-amines of [5]—[9] were treated with benzoyl chloride under the same conditions (0.35 mol of 10% sodium hydroxide solution) as in the cases of [1]—[3]. The results are shown in Table 2. Though [6] and [8] are stronger bases[5] than [7] and [9] respectively, the *ortho* isomers, [6] and [8], gave smaller amounts of [C] than do the *para* isomers, [7] and [9], undoubtedly due to the steric hindrance in the former compounds. The degree to which the ester-group in [A] hinders the front of the nitrogen therein from the formation of [B] is possibly related to the twist-angle (φ)[6] between the *t*-amino group and the benzene ring. Just as is shown in Table 2, the yields of [C] are found to decrease as the φ values increase. This consideration was also supported by the fact that the titration curve of benzoic acid in the presence of [A] with sodium hydroxide coincided more closely with the blank titration curve without [A] in the order of [3], [2], and [1].

Finally, though there may be little difference in steric hindrance between [1] and [4], the yield of [C] from [4] was found to be more than twice that from [3].

In conclusion, the yield of [C] depends mainly on the basicity of [B], but in the case of weak bases of a similar basicity, steric hindrance has a great effect on the yield of [C].

Experimental

o-Dimethylaminobenzyl Alcohol [1]. [1] was prepared by the method of Willstätter.[7]

m-Dimethylaminobenzyl Alcohol [2]. *m*-Dimethylaminobenzaldehyde[8] was reduced with lithium aluminum hydride. Bp 127—130°C/3 mmHg, n_D^{12} 1.5710, Found: N, 9.11%. Calcd for $C_9H_{13}NO$: N, 9.27%.

p-Dimethylaminobenzyl Alcohol [3]. [3] was prepared by the method of Hass and Bender.[9]

2-Dimethylaminocyclohexylmethanol [4]. [1] was reduced in the presence of Adams platinum oxide catalyst[10] under atmospheric pressure in an ethanol solution. Bp 125—127°C/17 mmHg, n_D^{17} 1.4990, Found: N, 8.50%. Calcd for $C_9H_{19}NO$: N, 8.92%.

A Simple Treatment for the Kinetics of Radical Polymerization with Primary Radical Termination

Katsukiyo Ito and Tatsuo Matsuda

Government Industrial Research Institute, Nagoya, Kita-ku, Nagoya

(Received October 2, 1968)

Several workers have reported on the importance of primary radical termination.[1-6] Bamford, Jenkins and Johnston[7] devised a simple treatment for the kinetics of radical polymerization with primary radical termination in the following.

$$C \rightarrow 2R\cdot \qquad k_d \qquad (1a)$$

$$R\cdot + M \rightarrow X_1\cdot \qquad k_i \qquad (1b)$$

$$X_r\cdot + M \rightarrow X_{r+1}\cdot \qquad k_p \qquad (1c)$$

$$X_r\cdot + X_s\cdot \rightarrow P_r + P_s \text{ or } P_{r+s} \qquad k_t \qquad (1d)$$

$$X_r\cdot + R\cdot \rightarrow P_r \qquad k_{ti} \qquad (1e)$$

$$2R\cdot \rightarrow \text{Products} \qquad k_{tii} \qquad (1f)$$

Decomposition of the initiator C gives primary radicals R· which react with monomer M to form chain radicals X·. $X_r\cdot$ and P_r respectively denote radicals and polymer molecules containing r monomer units. In this treatment for the kinetics of radical polymerization with primary radical termination, they derived the cubic Eq. (2)

$$\frac{x^2(1+x)}{(1-x)} = \frac{2fk_dk_{ti}^2[C]}{k_sk_i^2[M]^2} = a^2 (a \geq 0), \qquad (2)$$

where

$$x = \frac{k_{ti}[X\cdot]}{k_i[M]} ([X\cdot] = \Sigma[X_r\cdot])$$

and f is initiator efficiency. Because of Eq. (2) being inconvenient for calculating the polymerization rate R_p for given values $2fk_d[C]$, the reverse procedure of calculating $2fk_d[C]$ for R_p was mainly used for simple treatment. According to this treatment, polymerizations for styrene and acrylonitrile were analyzed. On the modification of this treatment for very low monomer concentrations, Baldwin[8] analyzed radical polymerization with primary radical termination for methyl methacrylate. But this treatment is very sensitive to experimental errors at very low monomer concentrations. Furthermore, Baldwin's treatment and Bamford, Jenkins and Johnston's treatment are more complex than our treatment in the following.

In this paper, the treatment for the kinetics o radical polymerization with primary radical termination given by Bamford, Jenkins and Johnston was simplified. Using Baldwin's results,[6] Bamford, Jenkins and Johnston's results[7] and Mayo, Gregg and Matheson's results,[9] this simplified treatment was confirmed.

A Simplification for the Kinetics of Radical Polymerization with Primary Radical Termination. From Eq. (2), we obtain

$$a = x\left(\frac{1+x}{1-x}\right)^{1/2} \geq x$$

Accordingly, by the two approximations

$$\frac{1}{1-x} \cong 1 + x$$

and

$$(1 + 4a)^{1/2} \cong 1 + 2a - 2a^2$$

under the condition $x \leq a \ll 1$, Eq. (2) becomes

$$x(1+x) = a \qquad (3)$$

The solution of Eq. (3) is

$$x = \frac{1}{2}[(1+4a)^{1/2} - 1] \cong a - a^2 \qquad (4)$$

Under a condition $a \ll 1$, [X·] is given by

$$[X\cdot] = \left(\frac{2fk_d}{k_t}\right)^{1/2}[C]^{1/2}\left[1 - \frac{k_{ti}}{k_i}\left(\frac{2fk_d}{k_t}\right)^{1/2}\frac{[C]^{1/2}}{[M]}\right] \qquad (5)$$

Using Eq. (5), R_p is given by

$$R_p = k_i[R\cdot][M] + k_p[X\cdot][M] \cong k_p[X\cdot][M] = A[M][C]^{1/2}\left(1 - B\frac{[C]^{1/2}}{[M]}\right) \qquad (6)$$

where

$$A = k_p\left(\frac{2fk_d}{k_t}\right)^{1/2} \quad \text{and} \quad B = \frac{k_{ti}}{k_i}\left(\frac{2fk_d}{k_t}\right)^{1/2}$$

1) A. Chapiro, M. Magat, J. Sebban and P. Whal, *Ric. Sci.*, **25A**, 73 (1955).

2) G. Henrici-Olive and S. Olivé, *Makromol. Chem.*, **37**, 71 (1960).

3) J. C. Bevington and J. K. Allen, *Trans. Faraday Soc.*, **56**, 1762 (1960).

4) P. Hyden and H. Melville, *J. Polymer Sci.*, **43**, 201 (1960).

5) P. E. M. Allen and C. R. Patrick, *Makromol. Chem.*, **48**, 89 (1961).

6) G. M. Brunett and L. D. Loan, *Trans. Faraday Soc.*, **51**, 219 (1955).

7) C. H. Bamford, A. D. Jenkins and R. Johnston, *Trans. Faraday Soc.*, **55**, 1451 (1959).

8) M. G. Baldwin, *J. Polymer Sci.*, **A1**, 3209 (1963).

9) F. R. Mayo, R. A. Gregg and M. S. Matheson, *J. Am. Chem. Soc.*, **73**, 1691 (1951).

Eq. (6) yield a convenient linear relationship

$$\frac{R_p}{[M][C]^{1/2}} = A - AB\frac{[C]^{1/2}}{[M]} \quad (7)$$

Eq. (7) indicates that $R_p/[M][C]^{1/2}$ is constant at the low value of $[C]^{1/2}/[M]$ (a familiar relationship) and the increase of $[C]^{1/2}/[M]$ increases deviation from this familiar relationship. This conclusion is equivalent to Bamford, Jenkins and Johnston's conclusion.[7] Furthermore, using A and B in Eq. (7), $k_{ti}/k_t k_p$ is directly calculated without the knowledge of the value fk_d or k_t/k_p^2 by Eq. (8)

$$\frac{B}{A} = \frac{k_{ti}}{k_i k_p} \quad (8)$$

Applications

On the application of Eq. (7) to Baldwin's results[8] in the polymerization of methyl methacrylate (MMA) initiated by 2,2'-azobisisobutyronitrile (AIBN), a linear relationship between $R_p/[M][C]^{1/2}$ and $[C]^{1/2}/[M]$ comes into existence in the range 0 to 0.3 $(l/mol)^{1/2}$ (Fig. 1). Using A and B in this linear relationship and Eq. (8), $k_{ti}/k_i k_p$ is

$$\frac{k_{ti}}{k_i k_p} = 3.09\times10^3 \text{ mol}\cdot\text{sec}/l$$

On the application of Eq. (7) to Bamford,

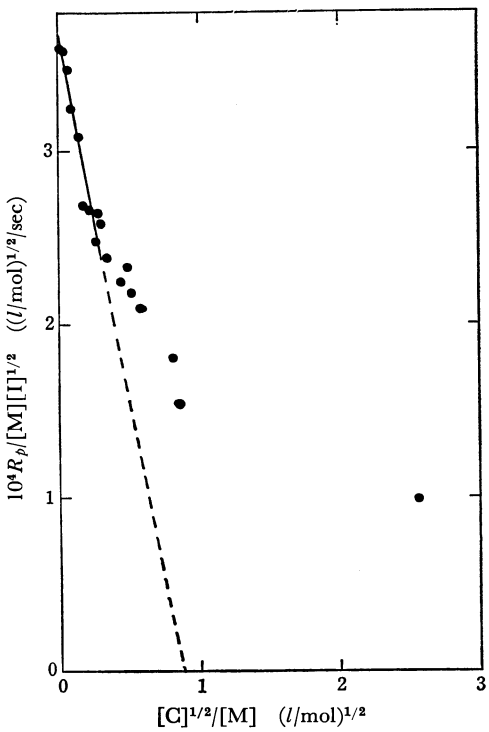

Fig. 1. Relationship between $R_p/[M][C]^{1/2}$ and $[C]^{1/2}/[M]$ for radical polymerization of MMA initiated by AIBN at 60°C.[8]

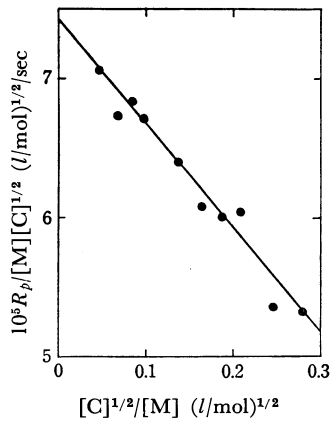

Fig. 2. Relationship between $R_p/[M][C]^{1/2}$ and $[C]^{1/2}/[M]$ for radical polymerization of styrene initiated by AIBN at 60°C.[7]

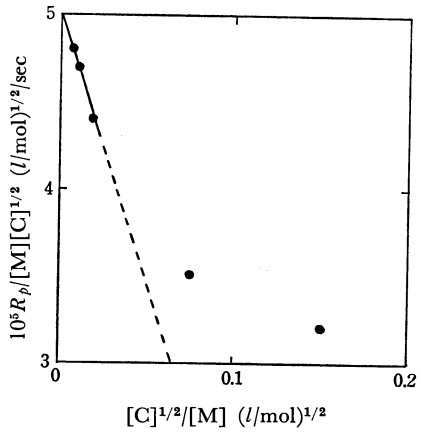

Fig. 3. Relationship between $R_p/[M][C]^{1/2}$ and $[C]^{1/2}/[M]$ for radical polymerization of styrene initiated by BPO at 60°C.[9]

Jenkins and Jonston's results[7] in the polymerization of styrene initiated by AIBN, a linear relationship between $R_p/[M][C]^{1/2}$ and $[C]^{1/2}/[M]$ comes into existence in the all experimental range (Fig. 2). $k_{ti}/k_i k_p$ for this polymerization system is

$$\frac{k_{ti}}{k_i k_p} = 1.36\times10^4 \text{ mol}\cdot\text{sec}/l$$

On the application of Eq. (7) to Mayo, Gregg and Matheson's results[9] in the polymerization of styrene initiated by benzoyl peroxide (BPO), a linear relationship between $R_p/[M][C]^{1/2}$ and $[C]^{1/2}/[M]$ comes into existence in the range 0 to 0.02 $(l/mol)^{1/2}$ (Fig. 3). $k_{ti}/k_i k_p$ for this polymerization system is

$$\frac{k_{ti}}{k_i k_p} = 1.23\times10^5 \text{ mol}\cdot\text{sec}/l$$

In conclusion, these applications indicate that a simple treatment based on Eq. (7) is very useful for discussion or calculation of $k_{ti}/k_i k_p$ for the kinetics of radical polymerization with primary radical termination.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 1760—1761 (1969)

The Mössbauer Spectrum of Iron Adsorbed on an Anion Exchange Resin

Yoshimasa TAKASHIMA, Yonezo MAEDA and Shunji UMEMOTO

Department of Chemistry, Faculty of Science, Kyushu University, Fukuoka

(Received October 2, 1968)

It is well known that iron(III) is strongly taken up on an anion exchange resin from relatively concentrated hydrochloric acid solutions. This fact can be interpreted on the basis of the results of chemical analysis, as indicating formation of negatively-charged complex ions, $FeCl_4^-$. Because of the opacity of resins, most spectroscopic techniques are not applicable to the direct investigation of chemical species sorbed on ion exchange resins. However, Mössbauer spectroscopy can be applied to such a study because penetrating γ rays are used in this technique. Several studies along this line have already been reported,[2,3] and interesting results have been obtained concerning the nature of individual species sorbed on ion exchangers.

The present paper is concerned with Mössbauer spectroscopic study of iron(III) sorbed on an anion exchange resin; the study was undertaken in order to confirm the symmetry and coordination of ligands surrounding the iron atom.

Experimental

Materials. The resin sample was prepared by passing a solution containing 27 g of $FeCl_3 \cdot 6H_2O$ in 100 m*l* of 7M hydrochloric acid through a column of Dowex 1-X4 (100—200 mesh); the excess solution was removed by washing the sample with 7M hydrochloric acid. Two types of samples, wet and dry, were used for the measurements. The dry sample was prepared by drying the resin obtained above in a vacuum dessiccator.

The selected reference samples, $KFeCl_4$, NH_4FeCl_4, *etc.*, were prepared according to the procedure used by Friedman and Taube.[4]

Mössbauer Spectrometer.[5] A multichannel pulse-height analyser coupled with an instantaneous velocity measurement of the γ ray source was used. The source of radiation was ^{57}Co diffused onto metallic copper. The spectrometer was calibrated by sodium nitroprusside, and the isomer shift was expressed in mm/sec relative to the center of the nitroprusside spectrum. The measurements were performed both at room temperature and at the temperature of liquid nitrogen.

Results and Discussion

No discernible Mössbauer effect was observed for the resin samples at room temperature, but one was observed at the temperature of liquid nitrogen. Unlike the resin samples, all the reference samples showed a measurable effect, even at room temperature. All of the spectra obtained showed a fairly sharp single absorption, which is responsible for the symmetrical charge distribution around the iron atom. Table 1 summarizes the results obtained by the Mössbauer measurements of the resins and the other reference samples. The errors involved in Table 1 showing the estimation of the isomer shifts were about ± 0.02 mm/sec; the variation in the isomer shift, depending on the temperature, was estimated to be small (probably less than 0.05 mm/sec).

TABLE 1. ISOMER SHIFT

Sample	Temperature	Isomer shift* (mm/sec)	Coordination
Wet resins	liq.-N_2 temp.	0.57	
Dry resins	liq.-N_2 temp.	0.54	
$KFeCl_4$	liq.-N_2 temp.	0.54	tetrahedral, $4Cl^-$
$KFeCl_4$	room temp.	0.54	tetrahedral, $4Cl^-$
NH_4FeCl_4	room temp.	0.50	tetrahedral, $4Cl^-$
$FeCl_3$	liq.-N_2 temp.	0.73	octahedral, $6Cl^-$
$FeCl_3$	room temp.	0.70	octahedral, $6Cl^-$
$FeCl_3 \cdot 6H_2O$	room temp.	1.12 0.12	octahedral

* Relative to the center of sodium nitroprusside.

Between the values of the isomer shift for typical tetrahedral and octahedral compounds, a remarkable difference was found. Since the isomer shift reflects the degree of covalency, we may conclude from this observation that the tetrahedral compounds have more covalent bonds than the octahedral compounds.

The strong similarities between the isomer shift of the resin samples and that of the tetrahedral

compounds suggest that the iron sorbed on the anion exchange resin is in a tetrahedral environment.

It is also noticed that there is very little difference in the isomer shift between wet and dry resin samples.

This indicates that the water molecules play only a minor role in the coordination sphere of the iron sorbed on the resins.

It may be reasoned from the data on $FeCl_3$ and $FeCl_3 \cdot 6H_2O$ that the isomer shift distinctly increases as chloride ligands bound to central iron(III) ion are replaced by the less polarizable water ligands. In view of the above results, it may be concluded that the iron(III) sorbed on an anion exchanger under these experimental conditions in the undistorted tetrahedral coordination sphere which arises from chloride ligands. There are two peaks in the absorption of $FeCl_3 \cdot 6H_2O$. However, we do not yet know their exact origins.[6]

Synthetic Reactions of Aliphatic Nitro-Compounds. III. The Synthesis and Configurational Analysis of 2-Hydroxymethyl-2-aminocyclohexanediol

Shonosuke ZEN and Akiko NISHIKAI (née YASUDA)

Kitasato University, College of Pharmaceutical Sciences, Shirokane, Minato-ku, Tokyo

(Received October 8, 1968)

In a previous communication,[1] the synthesis of a cyclic amino acid, 1-amino-2,6-dihydroxycyclohexane-1-carboxylic acid (**1**), by the base-catalyzed cyclization of glutaraldehyde with ethyl nitroacetate was described. The structure of **1**, as determined by interpreting the NMR spectrum of its derivative, was designated as 2β-carboxyl-2α-aminocyclohexane-1β,3β-diol.

In order to obtain further evidence to support the above configuration, we have now synthesized the tetraacetyl derivative (**4**), mp 149—150.5°C, of 2-hydroxymethyl-2-aminocyclohexanediol-1,3 (**3**), mp 150.5—151.5°C. We prepared in the steps shown in Chart 1, and then established its configuration by means of NMR spectroscopy. The NMR spectrum*2 of **4** shown in Fig. 1, shows three sharp singlets (3 : 6 : 3 in relative intensity) resulting from one equatorial acetamido group[2] (τ 8.06), one axial acetoxy group (τ 7.92) of a acetoxymethyl*1 at the C-2 position, and two equatorial acetoxy groups[2] (τ 7.96), suggesting that these two *O*-acetyl groups have the same orientation, a *cis*-configuration. The two axial ring protons on C-1 and C-3 appear as a broad signal at about τ 4.36, while the methylene protons on C-2 appear as a singlet at τ 5.36. The proton on nitrogen in the amide group shows its signal at 4.19 τ.

As a result of the consideration of the NMR spectrum of **4**, it can be concluded that the structure of **1** takes the same configuration as that described in our previous studies.

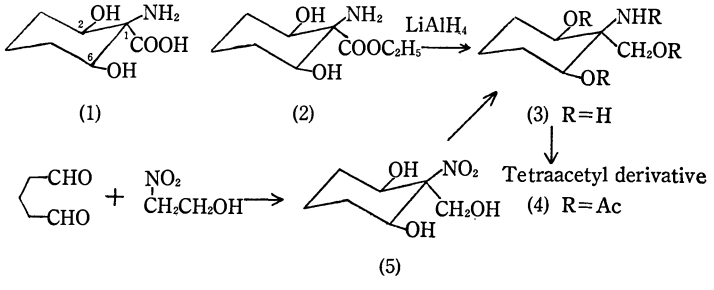

Chart. 1

2) F. W. Lichtenthaler and P. Emig, *Tetrahedron Letters*, **1967**, 557.

*1 This group corresponds to the carboxyl group of **1**.

*2 These data agree well with those of F. W. Lichtenthaler (private communication).

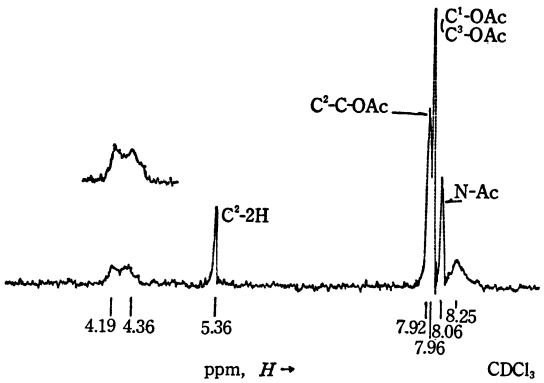

Fig. 1. NMR spectrum of tetraacetyl derivative (**4**).

Furthermore, we obtained the identical compounds, (**3** and **4**), through different steps; *i. e.*, we prepared then from 2-hydroxymethyl-2-nitrocyclo hexane-1,3-diol (**5**), mp 167—169°C, which had itself been synthesized by a cyclization of glutaraldehyde with nitroethanol under non-aqueous conditions. This fact leads to the conclusion that this cyclization proceeds in fashion analogous to Lichtenthaler's nitromethane-dialdehyde cyclization, in which the corresponding product has the *trans*-configuration.[3-5]

Experimental

2 - Hydroxymethyl - 2 - aminocyclohexanediol-1,3 (3).—Procedure-A *Prepared from 2-Ethoxycarbonyl-2-aminocyclohexanediol-1,3* (***2***). To a mixture of lithium aluminium hydride (333 mg) and dioxane (60 m*l*), 600 mg of **2**[1] was added; then the mixture was heated for 9 hr with occasional shaking under reflux, guarded by a tube containing calcium chloride, and subsequently allowed to stand overnight. Then 30 m*l* of water was added slowly, and the mixture was stirred for one hour. The precipitate thus formed was collected by filtration, and the filtrate was concentrated to dryness *in vacuo*. A yellow solid, 384 mg, was obtained in a yield of about 80%; it was crystallized from ethanol to give colorless needles, mp 150.5—151.5°C: ν(KBr), 3500, 3220 (OH) 1540 (NH), 1093 and 1050 cm^{-1} (OH). Found: C, 52.19; H, 9.35; N, 8.49%. Calcd. for $C_7H_{15}O_3N$: C, 52.17; H, 9.31; N, 8.69%.

Procedure-B *Prepared by the Reduction of 2-Hydroxymethyl-2-nitrocyclohexanediol-1,3* (***5***). 500 mg of the nitro-alcohol (**5**) was hydrogenated for 1 hr with 3m*l* of the Raney Nickel T-1[6] catalyst in 30 m*l* of ethanol at about 40°C under 55 psi of hydrogen*[3]. The filtrate from the nickel was evaporated *in vacuo* to dryness to give the crude product, light green-yellow crystals (377 mg), mp 144—146°C in a 90% yield. The sample, consisting of colorless needles for analysis obtained from ethanol, had a mp of 150—151°C.

This product was found to be identical with the above sample prepared from **2** (by procedure A) by a mixed-melting-point determination and by a comparison of their infrared spectra.

Tetraacetyl Derivative (***4***) *of* ***3***. To a solution of 50mg of **3** (prepared by Procedure A), in acetic anhydride (5 m*l*), 5 m*l* of pyridine was added, and then the mixture was allowed to stand overnight at room temperature. After the mixture was then treated as usual, an amorphous powder was obtained in a yield of 96%; it was then recrystallized from ethyl acetate-ligroin as colorless needles (mp 149—150.5°C), ν(KBr): 1740 (CO), 1640, 1560, 1250 and 1225 cm^{-1}(amide). The NMR spectrum*[4] of this compound is shown in Fig. 1.

Found: C, 54.81; H, 7.11; N, 4.34%. Calcd for $C_{15}H_{23}O_7N$: C, 54.71; H, 6.99; N, 4.25%.

The tetraacetyl derivative obtained by "procedure B" was found to be the same product (**4**) by an examination of its mp, the results of its elementary analysis, and its IR and NMR spectra.

2 - Hydroxymethyl - 2 - nitrocyclohexanediol - 1,3 (5). Freshly-distilled glutaraldehyde (3.0 g) and equimolar nitroethanol[7] (2.73 g) were dissolved in 10 m*l* of methanol. 1.5 m*l* of 3 N potassium hydroxide in methanol was then added to the mixture, which was agitated continuously at room temperature. The reaction mixture was made alkaline (pH 8.0—8.2). After two hours, it was acidified to pH 4 using a sulfuric acid. The salt thus precipitated was separated by filtration and then the filtrate was evaporated to dryness under reduced pressure.

The crystalline residue was washed with ethyl acetate to yield 1.40 g of the crude product, mp 150—160°C. After recrystallization from acetone, the analytical sample, mp 167—169°C was obtained as colorless needles. ν(KBr): 3260 (OH), 1542, 1355 cm^{-1} (C–NO_2).

Found: C, 43.79; H, 7.17; N, 7.16%. Calcd for $C_7H_{13}O_5N$: C, 43.98; H, 6.85; N, 7.33%.

The authors are indebted to Dr. Hamao Umezawa, the head of Institute of Microbial Chemistry, for his kindness for the measurements of NMR spectra.

Radiolysis of Methanol Containing Cyanogen Iodide

Hajime OGURA, Tsutomu MIYAGAWA and Masaharu KONDO

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya-ku, Tokyo

(Received October 24, 1968)

The use of cyanogen iodide as a scavenger of some intermediates formed in the radiolysis of several organic solvents has been reported by Hughes *et al.*[1,2] The present paper, in addition to reporting on the formation of iodine, which has also been studied by previous investigators, reports on the effect of cyanogen iodide on the radiolytic yield of hydrogen and formaldehyde, which are known to be the main products from irradiated methanol. The reactivity of solvated electron towards cyanogen iodide has also been determined by using nitrous oxide as a competing solute.

Experimental

Methanol was purified according to the procedure proposed by Lichtin *et al.*[3] Cyanogen iodide was prepared by the method of Goy *et al.*[4] and sublimated in a vacuum several times before use. ^{60}Co γ-irradiation was carried out at a dose rate of 1.56×10^{18} eV·ml^{-1} hr^{-1}. A deaerated solution of 5 ml prepared by the conventional vacuum technique with freeze-and-thaw cycles was sealed in a cylindrical glass cell (20 ml). Nitous oxide was taken in a calibrated volume to a definite pressure and then transferred to the irradiation vessel by using liquid nitrogen. The concentration of the gas in the solution was calculated from the solubility data.[5] The iodine was determined spectrophotometrically at 450 mμ. The formaldehyde was determined by means of chromotropic acid; however, this method could not be applied to the solutions above 10 mM ICN because of the inhibition of iodine produced by the decomposition of ICN. The amounts of hydrogen and nitrogen were determined by gas chromatography using a molecular sieve 5A column and argon as the carrier gas.

Results

Figure 1 shows the yields of hydrogen and iodine as a function of the concentration of cyanogen iodide in deaerated methanol. The radiolytic yields of these products were obtained from the initial slopes of the product-dose plots and are expressed as G-values. $G(I_2)$ appears to increase with an increase in the concentration of cyanogen iodide, but it tends to reach a limiting value of 3.2 at 5 mM ICN. The value for $G(I_2)$ reported by Hughes was slightly higher than our result. The addition of cyanogen iodide decreases the $G(H_2)$ considerably. One can obtain 5.4 for $G(H_2)$ when the solute concentration is extrapolated to zero; this is the same value as the $G(H_2)$ value for pure methanol determined by several investigators.[6-8] The yield of formaldehyde is considerably

increased by the addition of cyanogen iodide, even at a low concentration; over the concentration range investigated the yield is seen to be almost steady at about 7.6, a value which is very high compared with the value (2.3) for pure methanol.

The radiolytic yield curves for hydrogen, nitrogen, and iodine as a function of the cyanogen iodide concentration in deaerated methanol containing 5 mM N_2O are presented in Fig. 2.

A competition between cyanogen iodide and nitrous oxide for solvated electrons in methanol is obvious in Fig. 3.

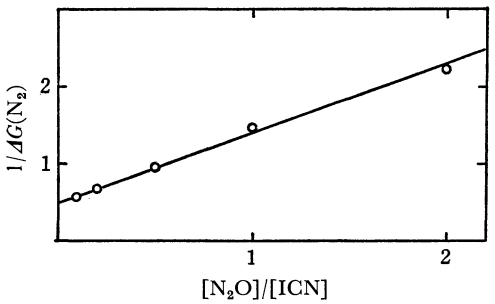

Fig. 3. $1/\Delta G(N_2)$ *vs.* $[N_2O]/[ICN]$ plotted according to Eq. (III).

Discussion

The chemical species initially produced during the absorption of ionizing radiation in methanol are usually represented as follows:

$$CH_3OH \rightsquigarrow e^-_{sol},\ H,\ CH_2OH,\ CH_3OH_2^+ \text{ and molecular products} \quad (0)$$

According to the well-established mechanism for hydrogen formation from methanol radiolysis, the following reactions are taken into consideration:

$$e^-_{sol} + CH_3OH_2^+ \rightarrow H_2 + CH_2OH \quad (1)$$

$$H + CH_3OH \rightarrow H_2 + CH_2OH \quad (2)$$

The solvated electron can react with cyanogen iodide as follows:

$$e^-_{sol} + ICN \rightarrow I + CN^- \quad (3)$$

Hughes *et al.*[1] have proposed the following reactions:

$$H + ICN \rightarrow I + HCN \quad (4)$$

$$CH_2OH + ICN \rightarrow I + HCHO + HCN \quad (5)$$

$$2I \rightarrow I_2 \quad (6)$$

The addition of cyanogen iodide decreases $G(H_2)$ effectively, as is shown in Fig. 1; this indicates that the precursor of hydrogen will react with the solute as in reactions (3) and (4). The observed increase in the yield of formaldehyde upon the addition of cyanogen iodide may be attributed to reaction (5). This reaction scheme, together with what is presented by Hughes *et al.*,[1] can afford the following meterial balance:

$$2G(I_2) = G_{e^-_{sol}} + G_H + G_{CH_2OH} = G(R) \quad (I)$$

where $G(R)$ denotes the total radical yield from methanol.*1 One can obtain 6.4 for $G(R)$ from the observed $G(I_2)$ value; this is in good agreement with the values reported by Baxendale[9] and by Lichtin.[10] As to the yield of formaldehyde, the following expression can be derived from our present reaction scheme:

$$G(CH_2O) = G_0(CH_2O) + G(R) - \Delta G(H_2) \quad (II)$$

where $G_0(CH_2O)$ denotes the molecular yield of formaldehyde and where $\Delta G(H_2)$ is the decrease in hydrogen yield due to the addition of cyanogen iodide in methanol. Taking $G_0(CH_2O)$, $G(R)$, and $\Delta G(H_2)$ to be 2.05,[9] 6.4, and 1.6—1.8 respectively, one can obtain the $G(CH_2O)$ value from (II) to be 6.7—6.9 over the concentration range of 5 to 10 mM ICN; this is nearly the same as our present data, as is shown in Fig. 1.

As may be seen in Fig. 2, $G(H_2)$ decreases gradually with an increase in the concentration of cyanogen iodide in methanol containing nitrous oxide at 5 mM. Since all the solvated electrons are scavenged by nitrous oxide at this concentration or by cyanogen iodide, the observed decrease in $G(H_2)$ may be attributed to reaction (4). It may be seen that $G(H_2)$ continues to decrease very gradually with an increase in the concentration of cyanogen iodide. This finding suggests that reaction (4) proceeds very slowly as compared with reaction (3) and that it is not so important to reduce $G(H_2)$ at the concentration of cyanogen iodide below 10 mM. When nitrous oxide is present in the system, reaction (7) will compete with reaction (3):

$$e^-_{sol} + N_2O \rightarrow N_2 + O^- \quad (7)$$

Based on simple competition kinetics, one can formulate:

$$\frac{1}{\Delta G(N_2)} = \frac{1}{G_{e^-_{sol}}}\left\{1 + \frac{k_7[N_2O]}{k_6[ICN]}\right\} \quad (III)$$

where $\Delta G(N_2)$ denotes the decrease in nitrogen yield due to the added cyanogen iodide in the presence of nitrous oxide. A plot of $1/\Delta G(N_2)$ *vs.* $[N_2O]/[ICN]$ is seen to give a straight line, as in Fig. 3. From the intercept in the ordinate, one can obtain 2.2 for Ge^-_{sol}, and from the slope

*1 In addition to these major radical products, CH_3 and OH radicals are considered to be present in very low yields, but these may be converted to CH_2OH radicals by the reaction with methanol. Therefore, these are equivalent to other radicals with regard to the formation of iodine.

10) S. V. Choi and N. N. Lichtin, *ibid.*, **86**, 3948 (1964).

of line, one can obtain k_7/k_3 for 1.9. Taking 1.3×10^{10} M^{-1}sec^{-1} for k_7,[11] k_3 is estimated to be 6.8×10^{9} M^{-1}sec^{-1}. Reactions (4) and (5) indicate that hydrogen cyanide should be produced. However, it is detected only qualitatively at the present stage because of the interference of cyanogen iodide.

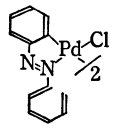
σ-Bonded Arylpalladium(II) Complex: Bis-[*N*,*N*-dimethylbenzylamine-2-*C*,*N*]-palladium

Akira KASAHARA and Taeko IZUMI*1

Department of Chemistry, College of General Education, Yamagata University, Yamagata

(Received October 23, 1968)

Recently the preparations of σ-bonded arylpalladium complexes have been investigated by several workers.[1-4] For example, Calvin and Coates[1] have prepared palladium complexes of the type of $Ar_2Pd(PEt_3)_2$ which were stabilized by π-bonding phosphine donors. Cope and Sieman[2] have found palladium(II) halides to react with azobenzenes to give the chloro-2-(phenylazo)-phenylpalladium dimer (1) as a surprisingly stable product. Furthermore, *N*,*N*-dimethylbenzylamine,[3] α-*N*,*N*-dimethylaminonaphthalene,[3] and 2-phenylpyridine[4] reacted with palladium chloride to form similar



(1)

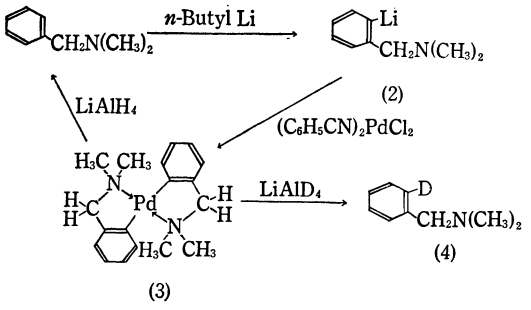


Fig. 1.

σ-bonded aryl derivatives of palladium. Recent observations[5] that *o*-lithio-*N*,*N*-dimethylbenzylamine reacts with chromium(III) chloride or cobalt(II) chloride to give complexes with carbon-to-metal σ-bonds have led us to examine a similar reaction between dibenzonitrile-dichloropalladium and *o*-lithio-*N*,*N*-dimethylbenzylamine.

Experimental[6]

Materials. *N*,*N*-Dimethylbenzylamine was obtained commercially, while dibenzonitrile-dichloropalladium was prepared by a literature method.[7] The NMR spectra were recorded with a Hitachi H-60 instrument in deuterochloroform, using tetramethylsilane as the internal standard; the peak positions were expressed in terms of τ values. The mass spectra were obtained on a Hitachi RMU-6 mass spectrophotometer. The molecular weight was determined in benzene using a Hitachi vapor-pressure osmometer.

Bis-[*N*,*N*-dimethylbenzylamine-2-*C*,*N*]-palladium(II) (3). A mixture of *N*,*N*-dimethylbenzylamine (2.70 g, 0.02 mol), *n*-butyl lithium in ether (28 m*l* containing 0.024 mol), and ether (60 m*l*) was stirred in a nitrogen atmosphere for 24 hr. The resulting mixture of *o*-lithio-*N*,*N*-dimethylbenzylamine was cooled in an ice-salt bath and then reacted with dibenzonitrile-dichloropalladium(II) (3.83 g, 0.01 mol) under a stream of nitrogen. After stirring for 6 hr at room temperature, the mixture was treated with water (50 m*l*) and extracted with methylene chloride. The extract was washed with water, dried over anhydrous magnesium sulfate, and concentrated on a rotary evaporator. The resultant red oil was triturated with petroleum ether; the yellow crystals were filtered off and recrystallized from benzene. The yield was 0.46 g (12%); mp 209—210°C (dec.). Infrared spectrum (KBr pellet): 3020, 1590, 1465, 1440, 1000, 844 and 750 cm^{-1}. NMR spectrum: 7.52 (singlet, $N-CH_3$), 7.04 (doublet, $J=10$ cps, benzylic

protons), 6.56 (singlet, N-CH_3), 6.20 (doublet, J=10 cps, benzylic protons) and 2.88—2.17 τ (multiplet, aromatic protons).

Found: C, 57.81; H, 6.62; N, 7.57%; mol wt, 368. Calcd for $C_{18}H_{24}N_2Pd$: C, 57.68; H, 6.45; N, 7.46%; mol wt, 374.8.

Reduction of Complex. General Procedure. The complex (0.2 g) to be reduced was slowly added to a stirred mixture containing 0.1 g of lithium aluminum hydride or deuteride in 30 m*l* of absolute tetrahydrofuran. The resulting black mixture was stirred at room temperature for 30 min; then water or deuterium oxide was added with cooling. The mixture was made acid with dilute hydrochloric acid, and the tetrahydrofuran was removed by evaporation under reduced pressure. After having been made alkaline with sodium carbonate, the mixture was extracted with ether. The ether solution was dried ($MgSO_4$) and concentrated by evaporation, and the product was isolated by preparative gas chromatography.

Reduction of 3 with Lithium Aluminum Hydride. This gave *N,N*-dimethylbenzylamine. The treatment of the product with methyl iodide gave the methodide as white crystals: mp 177—178°C.

Reduction of 3 with Lithium Aluminum Deuteride. This gave *N,N*-dimethyl-benzylamine-d_1. Methiodide derivative was made in the usual manner; mp 177—178°C. The mass spectrometric analysis showed that the product consisted of 92% d_1 and 8% d_0 species.

Results and Discussion

The *o*-metalation of *N,N*-dimethylbenzylamine with *n*-butyl lithium has previously been reported by Jones and his co-workers.[8] We reacted *o*-lithioamine (**2**) with dibenzonitrile-dichloropalladium in ether to give a yellow crystalline complex (**3**). The structure of **3** was assigned as follows. The elemental analysis is satisfactory, and the molecular weight measurement agrees with the assigned structure. In the infrared spectrum of **3**, the characteristic C–H out-of-plane deformation modes of a mono-substituted benzene at 770—730 and 690 cm^{-1} are absent; they are replaced by one at 750 cm^{-1} which can be assigned to a C–H deformation mode of an *ortho*-disubstituted benzene.[9] The lithium aluminum hydride reduction of **3** gave *N,N*-dimethylbenzylamine, whose mass spectrum and methiodide were identical with those of an authentic sample. On the other hand, the lithium aluminum deuteride reduction of **3** gave *N,N*-dimethylbenzylamine-d_1 (**4**). The gas-chromatographic analysis of **4** showed it to have the same retention time as an authentic sample of non-deuterated *N,N*-dimethylbenzylamine. The location of the deuterium in the *ortho*-position of the aromatic ring and, therefore the site of the carbon-to-palladium σ-bond, were indicated by the infrared spectrum of **4**, in which the characteristic absorption of an *ortho*-substituted benzene at 738 cm^{-1} was observed. Furthermore, the NMR spectrum of **3** is consistent with the proposed structure. We think that the complex **3** probably has a tetrahedral structure because the two *N*-methyl protons in the *N,N*-dimethylamino group are non-equivalent and appear as two singlets, at 7.52 and 656 τ. Moreover, the two protons in each pair of benzylic protons are also non-equivalent and appear as two doublets, at 7.04 and 6.20 τ. If the complex (**3**) were square-planar, a simple singlet pattern for the *N*-methyl protons of the *N,N*-dimethylamino group and also for the benzylic protons would be expected.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 1767—1768 (1969)

An Application of Mulliken's Theory of the Charge-transfer Complex to the Hydrogen-bonding Mechanism

Koichi TOYODA

Department of Chemistry, Faculty of Science, Kumamoto University, Kurokami-machi, Kumamoto

(Received October 28, 1968)

Recently several authors[1-4] have emphasized the importance of the charge-transfer mechanism of hydrogen bonding. Therefore, we may expect the appearance of charge-transfer bands in hydrogen-bonding systems as well as in molecular complexes. However, the present author could not find any certified charge-transfer bands for hydrogen-bonding systems except for the C. T. band of the hydrogen maleate anion found by Nagakura and his co-workers.[3] Regarding hydrogen-bonding systems, the relations between the shift of the X–H stretching vibration; the enthalpy of formation of the complex, ΔH; the excess dipole moment for the complex over the sum of the ingredients, $\Delta\mu$; the equilibrium constant of the complex, K, and the coefficients of Mulliken's theory, a and b, will be discussed here, and the C. T. band of the formic acid dimer will be estimated.

Mulliken[5] has written the wave functions for the ground and first excited states of the complex as:

$$\Psi_N = a\phi_0 + b\phi_1, \qquad \Psi_E = a^*\phi_1 - b^*\phi_0$$

In the approximation of the variation method, the following relation[6] holds:

$$aW_0 + bH_{01} = W_N(a + bS). \tag{1}$$

Here,

$$W_0 \equiv H_{00} = \int\phi_0 H\phi_0 d\tau,\ H_{01} = \int\phi_0 H\phi_1 d\tau,$$

$$S = \int\phi_0\phi_1 d\tau,$$

$$\Delta H \approx W_N = \int\phi_N H\phi_N d\tau / \phi_N{}^2 d\tau.$$

H is the exact Hamiltonian operator for the entire set of nuclei and electrons. In weak complexes, $a\approx 1$, and bS is a sufficiently small number compared with a. Therefore, Eq. (1) may be reduced to:

$$W_0 + b\beta_0 = \Delta H.$$

Here, $\beta_{01}=H_{01}-W_0S$; then, for weak complexes, $\beta_0\approx H_{01}$ will hold. If we suppose W_0 and β_0 to be approximately constant for given complexes, there is a direct relation between b and ΔH. However, there is no theoretical reason to expect W_0 and β_0 to remain constant for weak complexes, even with the same donor. On the other hand, as is well known, ΔH is given by:

$$\Delta H = -\boldsymbol{R}T \ln K + \text{constant}$$

Here $\boldsymbol{R}$ and T are the gas constant and the absolute temperature respectively. According to Mulliken,[5] for weak complexes the excess dipole moment for the complex over the sum of the acceptor and the donor, $\Delta\mu$, is given approximately by:

$$\Delta\mu \equiv \mu_M = \mu_1(b^2 + abS) \approx b^2\mu_1 \tag{2}$$

The value of μ_1, the dipole moment of the dative structure, will be quite large due to the high charge separation in the dative structure, and it will be approximately constant for weak complexes. Therefore, the following direct relation will hold:

$$\sqrt{\Delta\mu} \propto \log K$$

d) R. J. W. Le Févre and H. Vine, *J. Chem. Soc.*, **1938**, 1795. See also McClellan's Tables, p. 52.

Pimental and McClellan[7] find a proportionality between $\sqrt{\Delta\mu}$ and $\log K$ in the triethylamine-phenols and carboxylic acid dimers.

Person and Friedrich[2] have given the following equation:

$$(k_0-k_n)/k_0 \equiv \Delta k/k_0 = (1-k_1/k_0)(b^2+abS) \qquad (3)$$

If Eq. (2) is inserted into Eq. (3), the relation between Δk and $\Delta\mu$ is found to be:

$$\Delta k = [(k_0-k_1)/\mu_1]\Delta\mu$$

Here k_n, k_0, and k_1 are the X–H stretching force constants in the bonded X–H, free X–H, and $(X–H)^-$ molecules respectively. If k_0, k_1, and μ_1 are supposed to be approximately constant, there is a proportionality between Δk and $\Delta\mu$. Empirically there is a direct relation, as is shown in Fig. 1, between Δk and $\Delta\mu$ in a series of carboxylic acid dimers. The k_0, k_1, and $\Delta\mu$ values of carboxylic acid dimers are summarized in Table 1. Nakamoto *et al.*[8] have selected a constant frequency for each type of X–H stretching band; they concluded that each type of hydrogen bond shows a distinct relationship between the shift of the X–H band and the distance of the hydrogen bond. They selected 3700 cm^{-1} as the value of the free OH stretching band, so it seems reasonable to suppose that k_0 and k_1 are approximately constant.

Thereby, Mulliken's theory for the C.T. complex can be applied to hydrogen bonding systems. We may estimate 150 mμ as the approximate value for the charge transfer band characteristic of the interaction between the electron donor and acceptor in a formic acid dimer by using the following equation[9]:

$$\Delta H \approx h\nu_{CT}(b^2/a^2)$$

Kinetic Studies of the Acid-catalyzed Etherification of Ethyl Acetoacetate with Ethanol

Yoshiaki FURUYA, Iwao URASAKI, Kazuo ITOHO and Shin'ichi MIYAZAKI

Department of Industrial Chemistry, Faculty of Engineering, Kumamoto University, Kumamoto

(Received November 1, 1968)

It has been reported that the facility of the acid-catalyzed etherification of the allelotrope of *p*-nitrosophenol and *p*-benzoquinoneoxime may depend upon a special kind of keto-enol tautomerism.[1] It seemed that another system of keto-enol tautomerism could, therefore, be etherified easily with alcohols in the presence of acid as well. Actually, the acid-catalyzed etherification of ethyl acetoacetate with ethanol took place when well-dried hydrochloric acid was passed through the ethanolic solution for 10 min at −10°C; only the ethyl β-ethoxycrotonate was formed.[2]

Experimental

Materials. The ethyl β-ethoxycrotonate was prepared by refluxing a mixture of ethyl acetoacetate, acetyl chloride, and ethyl orthoformate;[3] it was recrystallized from petroleum ether after the crude product had been obtained by the removal of the other ingredients; yield 40%; mp 31°C (lit., 30°C,[2] 31°C[3]). Ethanol containing 0.16 M water was used as the reactant and solvent. The ethanolic solution of sulfuric acid was prepared from guaranteed sulfuric acid and the ethanol mentioned above.

Ultraviolet Spectrophotometry and Chemical Analysis. The reactions were followed by a Hitachi Perkin-Elmer UV-VIS spectrophotometer, model 139. The reaction product, ethyl β-ethoxycrotonate, has a broad absorption maximum at 235 mμ, while the reactant, ethyl acetoacetate, has only a small absorption in this UV region, as is illustrated in Fig. 1. Mixtures of ethyl acetoacetate, ethyl β-ethoxycrotonate, and sulfuric acid of known concentrations corresponding to 0, 20, 40, 60, 80, and 100% conversions were prepared; a plot of the difference in extinctions, $(E_{235}-E_{270})$ *vs.* $(E_{235}-E_{255})$, gave a straight line, and the calculated conversion from the values of $(E_{235}-E_{255})$ at 0 and 100% conversion agreed well, within about a 1% error, with the conversions calculated from the composition of the mixture.

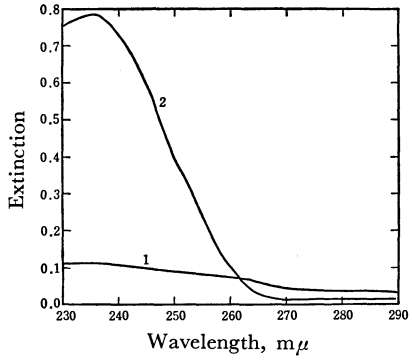

Fig. 1. Ultraviolet spectra of reactant and product in 5×10^{-5} M methanolic solution.
1, ethyl acetoacetate; 2, ethyl β-ethoxycrotonate.

Criterion of the Reaction. As the $(E_{235}-E_{270})$ *vs.* $(E_{235}-E_{255})$ plots of the actual reactions did not deviate at all from the calibration curve, it can be considered that the reaction forming ethyl β-ethoxycrotonate proceeds without any side reaction.

A Typical Run for the Rate Measurements. A solution of 2.5 m*l* of 1 N sulfuric acid in ethanol was poured into a 2.5 m*l* portion of a 1 M ethanolic solution of ethyl acetoacetate to start the reaction after both solutions had attained temperature equilibrium. Aliquots (0.1 m*l* each) were taken out at appropriate time intervals; each one was diluted with methanol to a 5×10^{-5} M total concentration of ethyl acetoacetate and ethyl β-ethoxycrotonate. The conversion percentage was calculated from the observed value of $(E_{235}-E_{255})$, and then the value of the apparent first-order rate constant, k, was calculated graphically.

Determination of the Water in the Reaction System. The water present in the reaction system was determined to be 0.20 M by the Karl Fischer method.

Results and Discussion

As the forward and reverse reactions are regarded as pseudo first-order reactions, the reaction will follow the pseudo first-order kinetics for a reversible reaction:

$$\ln [z/(z-x)] = kt, \quad (1)$$

where x and z are the concentrations of the consumed reactant at time t and at the equilibrium stage respectively. In these studies, the plots of $\log[z/(z-x)]$ *vs.* t gave a straight line, and the value of the apparent rate constant, k, was obtained graphically. Assuming the pseudo first-order rate constants for the forward and reverse reactions to be k_1 and k_{-1} respectively, the forward rate constant, k_1, can be

0.5	1.0	20	−0·6572	0.643	1.79
0.5	0.5	30	−0.3045	0.996	2.84
0.5	0.5	40	−0·3045	0.996	7.20

E_a, 6.53 kcal mol^{-1} $\Delta S^{\neq}$, −21.8 e.u.

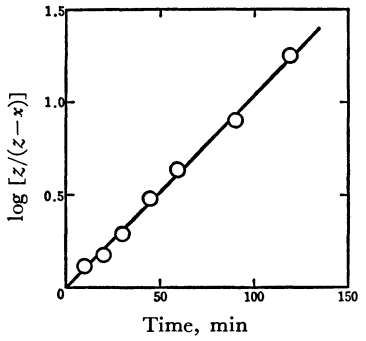

Fig. 2. The rate plots for the reversible first-order reaction at 20°C.
$[EAA]_0$: 0.5 M, $[H_2SO_4]$: 1 N z: 4.34%

obtained from the following equations[4]:

$$\ln [z/(z-x)] = (k_1+k_{-1})t = kt$$
$$z/(a-z) = k_1/k_{-1}$$

where a is the initial concentration of ethyl acetoacetate. The rate data are shown in the table.

The rate was not affected by the acidity, though the reaction does not occur without acid. The plots of log k_1 *vs.* H_0[5] gave a straight line with a slope of −0.07, as is illustrated in Fig. 3. Therefore, a proton may participate after the rate-determining step.

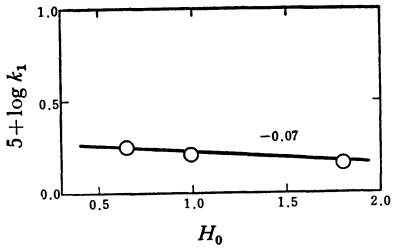

Fig. 3. The plots of log k_1 *vs.* H_0 for the etherification at 20°C.

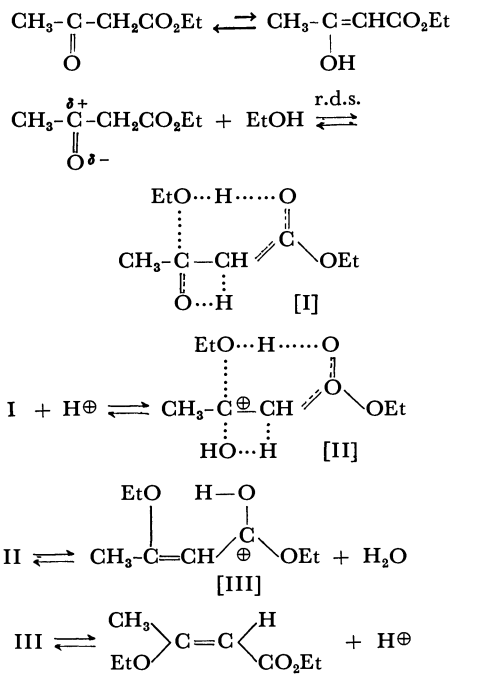
It is well known that only β-ethoxycrotonic acid is obtained by the reaction of ethanol containing sodium ethoxide with potassium β-chlorocrotonate and/or β-chloroisocrotonate[6] and also with ethyl β-chloroisocrotonate.[7] In the title reaction as well, only ethyl β-ethoxycrotonate was obtained; no ethyl β-ethoxyisocrotonate formed at all, as has been described above. Therefore, a mechanism which involves the rate-determining formation of the hydrogen-bonding complex, I, can be considered.

From these findings, the following over-all mechanism can be suggested:



The autors are grateful to Mr. T. Sonobe for his aid in performing these experiments.

Nuclear Quadrupole Resonance of Nitrogen-14 in Some Aliphatic Nitriles[1]

Shinzaburo ONDA, Ryuichi IKEDA, Daiyu NAKAMURA and Masaji KUBO

Department of Chemistry, Nagoya University, Chikusa, Nagoya

(Received November 9, 1968)

The pure quadrupole resonance of nitrogen-14 in some aliphatic nitriles was observed by means of a modified Pound-Watkins type spectrometer previously described.[2] Frequency modulation was used for the determination of resonance frequencies, while Zeeman modulation was employed for the assignment of observed resonance absorptions to ν^{I} and ν^{II}. The samples were procured from commercial sources and purified by repeated distillation. All the compounds investigated are liquids at room temperature. Therefore, they were solidified slowly in glass tubes and cooled gradually to liquid nitrogen temperature.

Since nitrogen-14 has a nuclear spin equal to unity, one can usually observe a pair of resonance lines, ν^{I} and ν^{II}, for equivalent nitrogen nuclei when the asymmetry parameter η is finite.

$$\nu^{I} = \frac{1}{4} eQq(3+\eta)$$

$$\nu^{II} = \frac{1}{4} eQq(3-\eta)$$

Here eQq denotes the quadrupole coupling constant in frequency units. From the observed resonance frequencies, the quadrupole coupling constant and the asymmetry parameter were calculated with the use of these equations as shown in Table 1.

Two sets of weak ν^{I} and ν^{II} resonance lines were observed for succinonitrile. For other compounds investigated, a single set of resonance lines was observed, indicating that all atomic sites of nitrogen are equivalent in each crystal. Accordingly, quadrupole coupling constants and asymmetry parameters can be evaluated in a straightforward manner.

Quite recently, Colligiani *et al.*[3] published the results of their comprehensive study on the ^{14}N nuclear quadrupole resonance of organic nitriles. Some of their results (propio-, butyro-, amylo-, isopropio-, glutaro-, adipo- and sebaco-nitriles) are in good agreement with ours. However, resonance frequencies ($\nu^{I}=2881.4$ and $\nu^{II}=2824.6$ kHz) observed by them for pimelonitrile do not agree with ours ($\nu^{I}=2907.7$ and $\nu^{II}=2793.3$ kHz) within experimental errors. Colligiani *et al.*[3] detected only one set of resonance lines for succinonitrile at practically the same temperature, the frequencies ($\nu^{I}=2995.7$ and $\nu^{II}=2844.7$ kHz) being in good agreement with those (2995.2 and 2844.1 kHz) of a set observed in the present investigation.

The appearance of the two sets of ν^{I} and ν^{II} lines indicates that there are two kinds of crystallographically nonequivalent nitrogen atoms in the crystals at liquid nitrogen temperature, although the two nitrogen atoms are chemically equivalent in the molecule. Unfortunately, no X-ray crystal data are available. For this compound, one-to-one correspondence cannot be made between ν^{I} and ν^{II} owing to the proximity of doublet lines. Therefore, the frequencies of the doublet lines were averaged to evaluate eQq and η.

One is tempted to consider the existence of the trans and the gauche forms in the crystals of succinonitrile. However, we could observe only a single set of ν^{I} and ν^{II} frequencies for tetramethylsuccinonitrile having a chemical formula analogous to that of succinonitrile. On the other hand, malononitrile[4] having no rotational isomers show two sets of ν^{I} and ν^{II} at liquid nitrogen temperature. These facts suggest that the nonequivalence of nitrogen atoms is due to the difference in the crystal

field rather than to the existence of different kinds of isomeric molecules.

As pointed out by Colligiani *et al.*,[3] long-chain nitriles and dinitriles show essentially the same quadrupole coupling constant and asymmetry parameter. The asymptotic value of eQq for large number of carbon atoms in a nitrile molecule is 3.80 rather than 3.81 MHz[3] as shown in Fig. 1. It is noteworthy that the asymmetry parameter is considerably large and varies over a fairly wide range in spite of the cylindrical symmetry of a single $-C\equiv N$ group. It is presumed that both the intramolecular charge distribution and the crystal field are responsible for this effect.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 1772—1773 (1969)

Simple HMO Calculation of the Substituent Effects in Tropolone Derivatives*[1]

Kimiaki IMAFUKU and Hisashi MATSUMURA

Department of Chemistry, Faculty of Science, Kumamoto University, Kurokami-machi, Kumamoto

(Received November 25, 1968)

It is well known that the observations concerning the effects of substituents on the rates and equilibrium data for the reaction of benzene derivatives are correlated by the Hammett equation.[1] Further, this equation was found to be applicable to some heterocyclic aromatic compounds, such as pyridines,[2] furans,[3] thiophenes,[4] *etc.*

For tropolone derivatives, which have a seven-membered ring structure, their dissociation constants have been reported to be linearly correlated with Hammett's substituent constants.[5] The chemical shifts of their acidic protons measured in the binary systems of tropolones-pyridine in infinite dilutions were found to be linear with their dissociation constants.[6]

On the other hand, the Hammett equation has been studied with molecular orbital theory in recent years, and it has been found that substituent constants are related to π-electron density[7] as well as localization energy[8] pertinent to reactions.

In order to explain the linearity of pK_a values

in the dissociation of tropolone derivatives with σ constants, we calculated the π-electron densities of some of 4- and 5-substituted tropolones by using the simple Hückel molecular orbital method, and examined whether or not these calculated values may be correlated with the substituent constants. The substituent constants of *m*- and *p*-positions of benzenes were used for 4- and 5-positions in tropolone derivatives, respectively.

Calculation

Treatment of Oxygen Atoms. The oxygen atoms of tropolones were treated according to Kubo *et al.*[9] The numbering of each atom is shown in Fig. 1. Although the two oxygen atoms are not

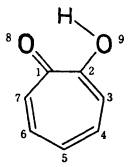

Fig. 1. The numbering for each atom.

identical, they are almost equivalent, owing to the hydrogen bonding and resonance. The molecule is assumed to be symmetrical with respect to a plane which involves the C_5-atom and the middle point of C_1- and C_2-atoms and is perpendicular to the ring. Molecular orbitals are constructed from the π-orbitals of the seven carbon atoms and of the two oxygen atoms. The number of the π-electrons which occupy these orbitals is ten.

The Coulomb integral for the oxygen atoms and the resonance integral for the oxygen-carbon bonds were obtained by repeating calculations until the dipole moment calculated for tropolone agreed reasonably with its observed value. Thus, the finally calculated dipole moment was 3.96 Debyes (observed, 3.53 Debyes[10]). The Coulomb integral for oxygen atoms and the resonance integral for the oxygen-carbon bonds were $\alpha+1.31\beta$ and 1.27β, respectively. The parameter of the Coulomb integral for the carbon atoms attached to the oxygen atoms was assumed to be one-tenth of the value of the latter atoms.

Integral Parameters for Substituents. The integral parameters for substituents were exactly those adopted by Fueno *et al.*[11] in the calculations of the molecular orbitals of benzene derivatives.

Results and Discussion

The π-electron densities q_C and q_O of C_1- or C_2-atoms and O_8- or O_9-atoms, respectively, were calculated and listed in Table 1. When these values are plotted against the Hammett substituent constants σ, linearity among them is obtained as shown in Fig. 2.

Table 1. π-Electron densities

No.	Substituent	σ	q_C	q_O
1	5-OCH_3	−0.268	0.9022	1.7196
2	5-CH_3	−0.170	0.8821	1.7065
3	4-CH_3	−0.069	0.8780	1.7031
4	H	0.000	0.8691	1.6954
5	5-Cl	0.227	0.8459	1.6696
6	5-Br	0.232	0.8431	1.6675
7	5-NO_2	0.778	0.7955	1.5970

No. of substituents are referred to Fig. 2.

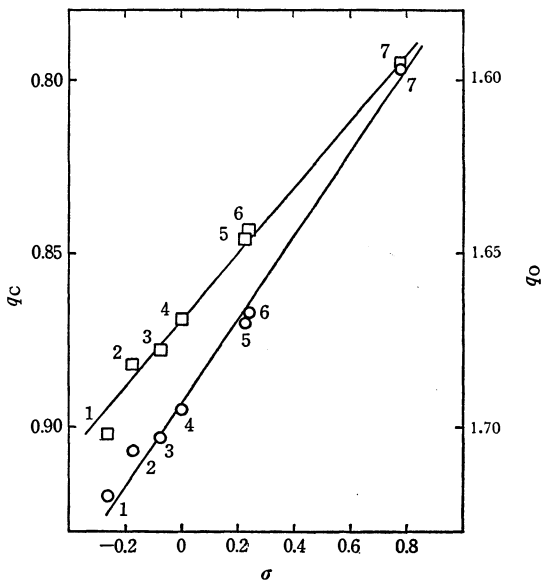

Fig. 2. The relation of π-electron densities of oxygen atoms (○) and adjacent carbon atoms (□) to substituent constants.

The linear correlations of q_C and q_O with σ are compatible with the experimental results that the pK_a values fit the Hammett plot. The linearity of q_O also illustrates the correlation of the chemical shifts of the acidic protons to the substituent constants, since their chemical shifts are influenced by the screening effect of the electrons around the oxygen atom.

Thus, it may be concluded that, for molecular orbital calculations of the seven-membered tropolone derivatives, the integral parameters for substituents obtained in benzene derivatives can be used as they are.

The authors wish to thank Dr. Koichi Toyoda of Kumamoto University for his helpful suggestions and discussions.

The authors' thanks are also due to the Ministry of Education for financial support.

The Spectrophotometric Determination of Anions by Solvent Extraction with Metal Chelate Cations. XLI.*1 Indirect Determination of β-Hydroxynaphthoic Acid by Atomic Absorption Spectrophotometry

Yuroku YAMAMOTO, Takahiro KUMAMARU, Yasuhisa HAYASHI and Susumu MATSUSHITA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima

(Received December 2, 1968)

In atomic absorption spectrophotometry, a hollow cathode lamp which emits the bright spectral lines of the element to be determined is generally used as a light source. Hence, organic compounds do not lend themselves directly to determination by conventional atomic absorption methods.

The indirect determination of some organic compounds can, however, be readily performed with this analytical tool. In our previous papers, such applications have been reported in the determination of phthalic acid[1,2] and pentachlorophenol[3]; these methods were based on the solvent extraction of ion-pairs stoichiometrically formed between the anion of the organic acid and the cationic metal chelate, such as bis(neocuproine)copper(I) or tris-(1,10-phenanthroline)iron(II), and on the subsequent determination of the metal concentration in the extracts by atomic absorption spectrophotometry, the results being related quantitatively to the associated organic compound. In connection with these investigations, this study was undertaken to establish a method for the determination of β-hydroxynaphthoic acid (3-hydroxy-2-naphthoic acid), which has until now been produced through Kolbe's reaction of β-naphthol, for industrial use, mainly as an intermediate of dyestuffs. The present procedure involves the selective extraction of tris(1,10-phenanthroline)nickel(II) β-hydroxynaphthoate into nitrobenzene, followed by the measurement of the nickel concentration in the extract by atomic absorption spectrophotometry as a function of the amount of β-hydroxynaphthoic acid initially present in the aqueous phase. The presence of β-naphthol, which has been well known as a main contaminative substance in the process of manufacturing β-hydroxynaphthoic acid, did not interfere with the determination.

Experimental

Apparatus. The atomic absorption was measured with a Hitachi Model EPU-2 spectrophotometer and a Hitachi Model 0420 atomic absorption attachment equipped with a nickel hollow cathode lamp. An air-acetylene flame was burned with a water-cooled 9-cm slot burner. The shaking for the extraction was carried out by means of an Iwaki Model KM shaker.

Reagents. All the solutions were prepared from analytical reagent-grade chemicals. A stock solution of β-hydroxynaphthoic acid (1.0×10^{-2} M) or β-naphthol (1.0×10^{-2} M) was prepared by dissolving 0.941 g of β-hydroxynaphthoic acid or 0.721 g of β-naphthol in 2 m*l* of a 6N sodium hydroxide solution and a small volume of water, and then by diluting the mixture to 500 m*l* with water. These solutions were diluted to an appropriate concentration for the experiment. A phenanthroline-nickel(II) sulfate solution (1.0×10^{-2} M) was prepared by dissolving 6.343 g of 1,10-phenanthroline ($C_{10}H_8N_2\cdot H_2O$) and 0.281 g of refined nickel sulfate ($NiSO_4\cdot7H_2O$) to a volume of 1000 m*l* with water.

Procedure. Ten milliliters of the phenanthroline-nickel(II) sulfate solution, 5m*l* of a phosphate buffer solution (1/15 M, pH 6—7), and 4 m*l* of the β-hydroxynaphthoic acid solution (2.0×10^{-3} M) were placed in a 100-m*l* separatory funnel, and then the aqueous-phase volume was adjusted to 25 m*l* with water. After 10 m*l* of nitrobenzene had been poured in, the funnel was shaken for 1 min. It was left still for about 20 min after the extraction, and then the organic phase was taken out and dried with 1 g of anhydrous sodium sulfate. The absorption due to nickel in the organic phase was then determined by the use of the atomic absorption spectrophotometer against a reagent blank used as a reference, and expressed as the initial concentration of β-hydroxynaphthoic acid in the aqueous phase. The instrument-operating conditions were as follows: a wavelength of 2320Å, slit-width of 0.20 mm, and a lamp current of 15 mA (nickel lamp). The flow rates of gases for the air-acetylene flame were 8.0 *l*/min of air and 1.5 *l*/min of acetylene. The burner height was adjusted to make the light beam pass 6 mm above the tip of the burner.

Results and Discussion

Atomic Absorption of Nickel. The effects of the variation in the composition of the air-acetylene mixture on the nickel absorption in the organic extract were studied. The absorption was nearly constant when the air-flow rate was set at a constant value, although the sensitivity was enhanc-

ed with an increase in the air-flow rate. For convenience, the gas-flow rates were adjusted to 8.0 *l*/min of air and 1.5 *l*/min of acetylene in subsequent work. Under these flame conditions, the highest sensitivity was obtained when the burner was so positioned that the radiation from the light source passed through the base of the flame 5—6 mm above the tip of the burner.

Extraction of β-Hydroxynaphthoic Acid with Phenanthroline-Nickel(II) Chelate. Among various commercially-available organic solvents tested for the extraction, nitrobenzene was found to be the most effective extractant for phenanthroline-nickel(II) β-hydroxynaphthoate. Moreover, nitrobenzene is a suitable solvent for atomic absorption spectrophotometry because it provides a stable flame during the combustion and a higher sensitivity of measurement. The extraction efficiency was estimated by extracting the ion-pair with successive 10 m*l* portions of nitrobenzene. It was found that 92% of β-hydroxynaphthoate was extracted in a single pass according to the procedure. Variations in the shaking time showed that shaking for longer than 0.5 min did not improve the extraction. The effect of the pH on the extraction is shown in Fig. 1.

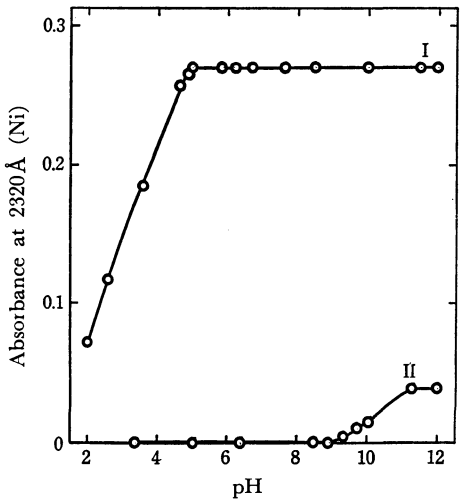

Fig. 1. Effect of pH on the extraction.
Concentration of aqueous phase: 3.2×10^{-4} M
I β-Hydroxynaphthoic acid, II β-Naphthol

The degree of the extraction of β-hydroxynaphthoate is at its maximum and is constant when the pH is held greater than 5, while β-naphtholate is only slightly extracted above pH 9. Therefore, when the method is, for instance, applied to the determination of β-hydroxynaphthoic acid in the industrial process, the pH should be in the 5—9 range in order to suppress the extraction of β-naphthol, which might contaminate the sample.

The effect of the concentration of phenanthroline-nickel(II) sulfate on the extraction of β-hydroxynaphthoate was also investigated. The absorbance of the nitrobenzene phase approached a limit when the chelate concentration was more than 1.6×10^{-3} M and when the β-hydroxynaphthoic acid concentration was kept at 3.2×10^{-4} M in the aqueous phase. Since at least a 5-fold excess (molar) of the phenanthroline chelate over β-hydroxynaphthoic acid was necessary for quantitative extractions, we decided for the sake of convenience to keep the chelate concentration at 4.0×10^{-3} M.

Calibration Curve. A plot of the absorbance due to nickel *vs.* the concentration of β-hydroxynaphthoic acid was obtained according to the procedure using varying amounts (1—5 m*l*) of the standard β-hydroxynaphthoic acid solution (2.0×10^{-3} M). As is shown in Fig. 2, this plot gives a linear relationship in the range from 8×10^{-5} to 4×10^{-4} M of β-hydroxynaphthoic acid initially present in the aqueous phase.

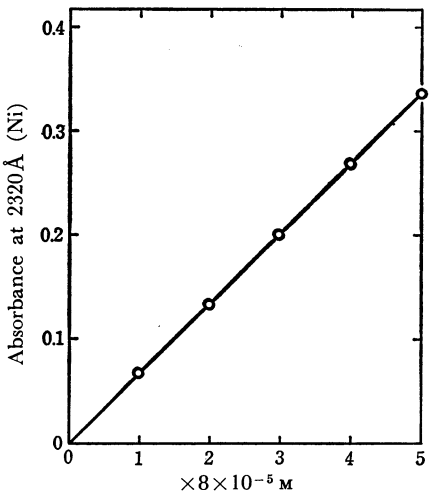

Fig. 2. Calibration curve.

Composition of Extracted Species. The continuous variation plots obtained by the atomic absorption spectrophotometric method were made in order to confirm the composition of tris (1,10-phenanthroline)nickel(II) β-hydroxynaphthoate. These plots suggested that a 1 : 2 associated ion-pair formed between the tris (1,10-phenanthroline)nickel(II) cation and the univalent anion of β-hydroxynaphthoic acid is extracted into nitrobenzene.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 1776 (1969)

A Convenient Synthesis of 3,4-Dialkyl-5-carbomethoxy-2-pyrone

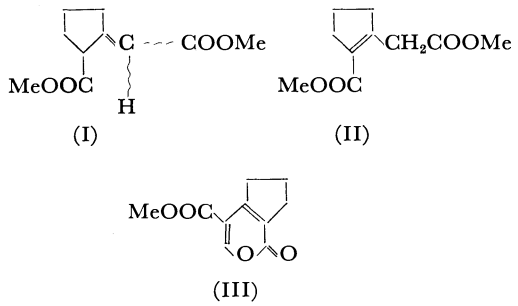
Shosuke YAMAMURA, Shuichi IWADARE, Shusi UEDA and Yoshimasa HIRATA

Chemical Institute, Nagoya University, Chikusa, Nagoya

(Received December 3, 1968)

In general, it is difficult to make 3,4-dialkyl-2-pyrone derivatives. We here describe a three-step synthesis of 3,4-dialkyl-5-carbomethoxy-2-pyrone from the β-keto ester.[1]

When heated with carbomethoxymethylene-triphenyl-phosphorane at 100—110°C for 15 hr under nitrogen, and then submitted to silica gel chromatography (Mallinckrodt, 100 Mesh), 2-carbomethoxycyclopentanone did not afford a condensation product (I), but it did afford, in a 62% yield, an isomer (II), bp 101—102°C/4 mmHg; ν_{max}^{film} 1748, 1713 and 1650 cm^{-1}; NMR spectrum (in benzene): 1.65 (2H, near q, J=7.5 cps), 2.1—2.8 (4H, br), 3.37 (3H, s), 3.40 (3H, s) and 3.73 ppm (2H, s).*1 In the presence of sodium methoxide,*2 II was treated with methyl formate at room temperature for 40 hr to afford a brown solution;[2] this solution was then cooled at 0°C and reacted with hydrogen chloride gas at 0°C for 30 min. The reaction mixture was then allowed to stand at room temperature overnight to afford, in a 41% yield, the desired pyrone (III), mp 95—96°C, the structure of which was supported by the following physical data: ν_{max}^{KBr} 1726 br, 1624 and 1548 cm^{-1}; λ_{max}^{MeOH} 291 and 265 mμ (ε, 4550 and 8025 respectively); NMR spectrum: 2.10 (2H, near q, J=7.5 cps), 2.83 (2H, t, J=7.5 cps), 3.21 (2H, t, J=7.5 cps), 3.87 (3H, s) and 8.25 ppm (1H, s).



(I) (II) (III)

Experimental

The melting point was uncorrected. The IR and UV spectra were recorded with JASCO IR-S and Hitachi-124 spectrometers respectively. The NMR spectra were obtained on a Varian Associates A-60 spectrometer. Chemical shifts for all the NMR spectra are given in ppm from an internal TMS standard, with $CDCl_3$ used as the solvent unless otherwise stated. The mass spectra were measured with a Hitachi RMU-6D mass spectrometer with an ionization energy of 70 eV.

Condensation of 2-Carbomethoxy-cyclopentanone with Carbomethoxymethylene - triphenyl - phosphorane. A mixture of the keto ester (20 g) and carbomethoxymethylene - triphenyl - phosphorane (26 g) was stirred at 100—110°C for 15 hr under nitrogen, and then cooled at room temperature to give a brown solid which was extracted with a large amount of carbon tetrachloride. The solvent was removed under reduced pressure to give a brown oil, which was then chromatographed on silica gel (200 g) and eluted with CCl_4-$CHCl_3$ (4 : 1) to afford 9.6 g of a colourless liquid (II), bp 101—102°C/4 mmHg; *m/e* 198 (M^+); NMR spectrum: 1.95 (2H, near q, J=7.5 cps), 2.4—2.9 (4H, br), 3.71 (3H, s) 3.74 ppm (5H, s) (Found: C, 60.00; H, 7.11%. Calcd for $C_{10}H_{14}O_4$: C, 60.59; H, 7.12%).

Formation of 3,4 - Dialkyl-5-carbomethoxy - 2 - pyrone. A mixture of II (14 g) and methyl formate (14 g) was slowly stirred into 400 ml of dry ether containing fresh sodium methoxide (7.0 g) at 0°C. After having been kept at 0°C for 3 hr, the reaction mixture was allowed to stand at room temperature for 40 hr with stirring; then it was cooled at 0°C and saturated with hydrogen chloride gas at 0°C for 30 min. The reaction mixture was allowed to stand again at room temperature overnight, and then extracted with a large amount of ether. The ethereal solution was successively washed with water, 5% $NaHCO_3$, and water saturated with NaCl. Finally, the solution was dried over Na_2SO_4 and the solvent was removed under reduced pressure to afford a brown solid, which was chromatographed on silica gel (100 g) and eluted with CCl_4-$CHCl_3$ (4 : 1) to give pale yellow crystals. Recrystallization from methanol afforded 5.6 g of white crystals, mp 95—96°C; *m/e* 194 (M^+) (Found: C, 62.05; H, 5.11%. Calcd for $C_{10}H_{10}O_4$: C, 61.85; H, 5.19%).

The authors are indebted to Mr. Yoshihiko Deguchi, Meijo University, for microanalyses.

SHORT COMMUNICATIONS

Cyclopropenones. III. The Reaction of Diphenylcyclopropenone and Ammonia to Afford *cis*- and *trans*-3,4-Diphenylazetidinones

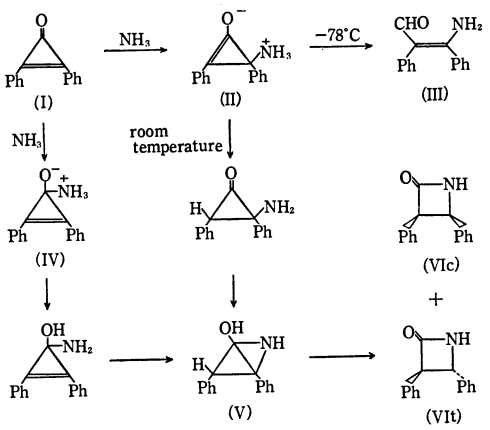
Fumio TODA, Tamio MITOTE and Katsuhiko AKAGI

Department of Industrial Chemistry, Faculty of Engineering, Ehime University, Matsuyama

(Received March, 22, 1969)

In a previous paper[1] of this series, we have reported a novel substitution reaction of diphenylcyclopropenone (I) with ammonia at −78°C to afford α-phenyl-β-amino-*trans*-cinnamaldehyde (III). When, however, the reaction was carried out at room temperature, *cis* (VIc) and *trans*-3,4-diphenylazetidinone (VIt) were obtained. This is the first instance in which azetidinone has been found to be formed from I, even though the ring-expansions of I by the reactions with hydroxylamine,[2] diazomethane,[2,3] enamine[4] and with azomethine ylid[5] to yield isoxazolone, pyridazone, cycloheptatrienone, and oxazoline respectively have been reported.

The treatment of an ether-tetrahydrofuran solution of I with ammonia at room temperature for 2 hr, followed by chromatographic separation on alumina, afforded VIc as colorless prisms (30%); mp 153°C; $\nu_{max}^{CHCl_3}$, 3410 (NH) and 1760 cm^{-1} (CO); NMR ($CDCl_3$), 2.94 (d, C_6H_5, 10H), 4.88 (d, J_{AB}= 6 Hz, H_A, 1H) and 5.13τ (d, J_{AB}=6 Hz, H_B, 1H) and (Vt) as colorless needles (30%), mp 124°C; $\nu_{max}^{CHCl_3}$, 3410(NH) and 1760 cm^{-1} (CO); NMR ($CDCl_3$), 2.62 (d, C_6H_5, 10 H), 5.34 (d, J_{AB}=3 Hz, H_A, 1H) and 5.71τ(d, J_{AB}=3 Hz, H_B, 1H). The above data were identical with those reported[6] for VIc and VIt, which were prepared in 13 and 3% yields respectively by the photochemical reaction of α-phenylcinnamamide for 70 hr.



Scheme 1

Since the treatment of an ether-tetrahydrofuran solution of III with ammonia at room temperature gave no product, and since III was recovered quantitatively, the reaction yielding VI and the reaction yielding III may be independent of each other. The reaction path leading to VI can be interpreted as is shown in Scheme 1. Of two possible reaction paths, one is the initial formation of the same intermediate (II) as in the case of the substitution reaction leading to III followed by ketonization and ring-expansion *via* the bicyclic intermediate (V). The other possible reaction path is the formation of IV by the reaction of ammonia with carbonyl carbon of I, followed by ring-expansion *via* the bicyclic intermediate (V).

On the other hand, the reactions of both I and methylamine at −78°C and at room temperature afforded the *N*-methyl derivative of VI (VII) as colorless needles (68% in both cases); mp 132°C; $\nu_{max}^{CHCl_3}$, 1750 cm^{-1} (CO); NMR($CDCl_3$), 2.94(d, C_6H_5, 10 H), 5.05 (d, J_{AB}=6 Hz, H_A, 1 H), 5.15 (d, J_{AB}=6 Hz, H_B, 1 H) and 7.09τ (d, CH_3, 3 H). Found: C, 80.85; H, 6.20%; mol wt (benzene), 246. Calcd for $C_{16}H_{15}ON$: C, 80.98; H, 6.37%; mol wt, 237. By comparing its NMR data, especially the coupling constant of the vicinal protons (J_{AB}) and the shielding effect against the phenyl protons, with those of VIc and VIt, VII was identified as the *cis*-isomer. It is not clear, however, why the *cis*-isomer was produced exclusively in this case.

The production of the *cis*-azetidinones in this series in good yields is of particular importance since these compounds are not easily obtainable by other procedures.

The Two Bitter Principles of *Isodon shikokianus* Kudo

Takashi KUBOTA and Isao KUBO

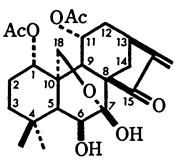
Faculty of Science, Osaka City University, Sugimoto-cho, Sumiyoshi-ku, Osaka

(Received March 24, 1969)

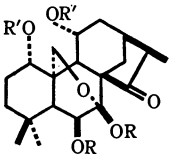
Chromatography of the ether extract of *Isodon shikokianus* Kudo yielded two crystalline bitter diterpenoid compounds, (I) $C_{20}H_{28}O_6$, mp 258—262 °C(decomp.), $[\alpha]_D^{18°}$ −45.0° (pyridine), λ_{max}^{EtOH} 238 mμ (log ε 4.04) and (II) $C_{24}H_{32}O_8$ (*m/e* 448), mp 286—288°C (decomp.), $[\alpha]_D^{22°}$ −38.6° (pyridine).

Compound I, according to its physical constants and spectral properties, is identical with the known oridonin[1] which is present in *I. trichocarpus* Kudo and *I. japonicus* Hara.

Compound II, which is found to be new and designated as shikokianin, exhibits in UV and IR spectra λ_{max}^{EtOH} 237 mμ (log ε 3.98) and ν_{max} 1720 and 1645 cm^{-1}. The IR spectrum indicated also the presence of hydroxyl groups (ν_{max}^{Nujol} 3600 and 3350 cm^{-1}, $\nu_{max}^{CHCl_3}$ 3600 and 3350 cm^{-1}) and chelated five membered ketone (1720 cm^{-1}).*1 The NMR spectrum in $CDCl_3$ showed the presence of two acetoxyl groups (8.10 and 7.90 τ, each 3H, s.), an exocyclic methylene group (4.02 and 4.54 τ, each 1H, s.), an ether type methylene group (5.60 and 6.10 τ, AB-type J=12 cps, $-CH_2-O-$), two tertiary methyl groups (8.84 τ, 6H, s., $(CH_3)_2C<$) and two hydroxyl groups (4.02 and 4.21 τ, disappeared on addition of D_2O). Catalytic hydrogenation of II on Pd-C yielded dihydroshikokianin (III), $C_{24}H_{35}O_8$, mp 266—267°C (decomp.), $[\alpha]_D^{20°}$ −61.2° (pyridine), which exhibits no UV and IR band due to double bond or NMR signal due to a secondary methyl group. Although II and III could not be acetylated with acetic anhydride and pyridine,*1 on treatment with acetic anhydride and BF_3-etherate III gave tetraacetate (IV), $C_{28}H_{38}O_{10}$, mp 187—192°C (decomp.) which exhibits no IR band due to hydroxyl group. In NMR spectrum



(II)



(III) R′=H, R=Ac
(IV) R=R′=Ac
(V) R=R′=H

IV shows four acetoxyl groups (7.86, 7.95, 7.96 and 7.99 τ, each 3H, s.) and this suggests the presence of two hydroxyl groups in III and also II itself. Dihydroshikokianin III was hydrolysed with 0.05N 50% methanolic potassium hydroxide or 1N 50% ethanolic hydrochloric acid to give the tetraol (V), $C_{20}H_{30}O_6$, mp 256—261°C (decomp.) which exhibits no signal in NMR spectrum due to acetoxyl group and reverted to III on treatment with acetic anhydride and pyridine. This indicated that the change of carbon skeleton did not take place during hydrolysis with alkali or acid. Finally, tetraol V on oxidation with periodic acid gave dihydronodosin, $C_{20}H_{28}O_6$, mp 250—252°C (decomp.) which was obtained from nodosin[2] by catalytic hydrogenation on Pd-C.

As the results of the foregoing experiments, the structural formula II including its absolute configuration is proposed for shikokianin. The assignment of α-configuration of C(11) in II was also supported by an observation that the signal of the proton attached to C(11) appeared as double doublet at 6.20 τ (J_{ax}=9 cps and J_{bx}=18 cps), as in the case of isodonal[3] (6.27 τ, d. d. J_{ax}=7 cps and J_{bx}=15 cps).

*1 These results indicated the presence of a chelated five membered ketone. Therefore the 6-hydroxyl group must be of β-configuration as oridonin.[1]

Additivity of Vicinal Circular Dichroism Contributions from Different Ligands in a Cobalt(III) Complex without Configurational Chirality

Norio KOINE and Naokazu SAKOTA

Department of Industrial Chemistry, Faculty of Engineering, Ehime University, Bunkyo-cho, Matsuyama

and Jinsai HIDAKA and Yoichi SHIMURA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka

(Received April 10, 1969)

The present communication is concerned with the additivity of the vicinal CD contributions of *trans*(*N*)-[Co(L- or D-alada)(L-ala)]$^-$, which have no chiral configuration around the central cobalt(III) ion in the first approximation. Three new complexes, *trans* (*N*)-K[Co(L-alada)(gly)]·H_2O, *trans*(*N*)-K[Co·(L-alada)(L-ala)]·$2H_2O$ and *trans*(N)-K[Co(D-alada)(L-ala)]·$2H_2O$, were prepared and separated by the method similar to that of *trans*(*N*)-K[Co(ata)(L-ala)]·$2.5H_2O$.[1],*1

The geometrical structure of these complexes was confirmed to be *trans*(*N*) one on the basis of their visible absorption spectra and from the ion-exchange column chromatographic behavior. Three geometrical isomers concerning the position or orientation of a methyl group of the coordinated L- or D-alada are possible for each of the present complexes. The NMR spectra confirmed that the complexes obtained here commonly have only one type of geometrical structure and no indication was obtained for the isolation of the other two isomers.

The good agreement of the observed CD curves (3 and 4) with the calculated ones (5 and 6) substantiates the additivity of the two vicinal contributions from the quadridentate ligand, L- or D-alada, and from the L-alaninate ligand. This result indicates that each of the asymmetric carbon atoms of the two optically active ligands independently contribute to the optical activity of the complex ion.

Interaction of Stannic Chloride with Polymethylbenzenes

Masahiro HATANO and Osamu ITO

The Chemical Research Institute of Non-Aqueous Solutions, Tohoku University, Sendai

(Received April 21, 1969)

In a number of papers, it has been found that inorganic acceptors, such as $SnCl_4$, $TiCl_4$, $VOCl_3$, and VCl_4, form charge-transfer (CT) complexes with various organic donors including aromatics.[1-5] The formation of these CT complexes has been confirmed using spectroscopic and other physicochemical methods. Since these inorganic acceptors are also a group of Lewis acids, it may be expected that the electron affinities of these inorganic acceptors, E_A, which are estimated from transition energies of CT absorption ($h\nu_{CT}$), will be of importance as effective measures of the strength of Lewis acids.

Although there have been some investigations of the CT interaction between $SnCl_4$ and aromatics as donors,[1,2,5] no CT absorption maximum has been separated; hence, the E_A of $SnCl_4$ has not yet been estimated. In the present communication we report that, in the systems of $SnCl_4$ and some polymethylbenzenes, new absorption bands were successfully separated from the absorption of the components and that these new bands were assigned and the E_A of $SnCl_4$ estimated.

Mixtures of $SnCl_4$ and hexamethylbenzene (HMB), pentamethylbenzene (PMB), durene, or mesitylene in a cyclohexane solution absorb significantly in the UV and visible region, where solutions of the individual components show negligible absorption. All the absorption spectra are summarized in Fig. 1.

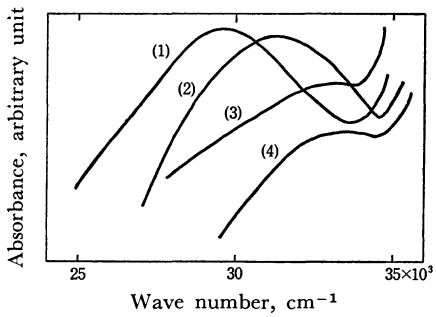

Fig. 1. Spectra of various donors with $SnCl_4$ in cyclohexane; (1), HMB (2), PMB; (3), durene; (4), mesitylene: (at 24.5°C)

The transition energies which were estimated from new absorption bands appearing in the systems of $SnCl_4$-polymethylbenzenes are also plotted against the ionization potentials (I_P) of the corresponding aromatic hydrocarbons in Fig. 2-I, where a linear relationship can be seen. The similar linear relationship of $h\nu_{CT}$ *vs.* I_P has been estsblished in the system of I_2-aromatics, as may be seen in Fig. 2-II. The transition energies of absorption bands due to σ-complexes or protonated carbonium ions of polymethylbenzenes are also plotted in Fig. 2-III against I_P.[6]

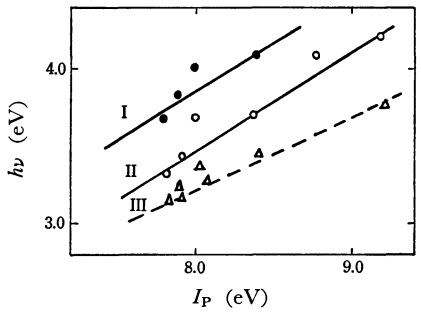

Fig. 2. Relationships between transition energies and I_P of aromatics; I, $SnCl_4$-aromatics; II, I_2-aromatics; III, σ-complexes or protonated carbonium ions of aromatics.

From the comparison of I with II and III in Fig. 2, it could be confirmed that the new absorption bands appearing in the systems of $SnCl_4$-polymethylbenzenes are due not to σ-complexes or protonated carbonium ions, but to the CT complexes of $SnCl_4$ with aromatics, as in the case of I_2-aromatics.

Using the same donor, the E_A value of any given acceptor or can be estimated by means of the following approximate equation;

$$(h\nu_{CT})_0 - (h\nu_{CT})_i = (E_A)_i - (E_A)_0$$

where the suffixes 0 and i indicate those for the standard and for any given acceptor respectively. Here, I_2 and mesitylene were chosen as the standard acceptor and donor, and the E_A of I_2 was assumed to be 1.8_0 eV; hence the E_A of $SnCl_4$ could be estimated to be 1.4_6 eV.

Determination of Volume Magnetic Susceptibility (χ_v) by NMR

Koichi HATADA, Yoshio TERAWAKI and Hiroshi OKUDA

Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka

(Received April 23, 1969)

The evaluation of χ_v by NMR has been done using a precision coaxial tubing by Zimmerman[1] or using the method devised by Bernstein and Frei.[2] The former procedure, however, is liable to be affected by the setting of the sample tube in the magnetic field, thereby introducing ambiguity into the measurement.[3,4] The latter involves a difficult arrangement of the noncoaxial tubing. In the present work we have rapidly and easily carried out an accurate determination of the χ_v value by NMR measurements using the microcell devised by Flath[5] (Fig. 1).

The measurements were done on a JNM-4H-100 spectrometer at 22.5±0.2°C, and using an internal lock system at 100 MHz. The chemical shifts were calibrated by means of the built-in frequency counter. The precision of the measurements was ±0.1 Hz. All the reagents were obtained commercially and were purified and dried by usual methods. The microcell was obtained from the Wilmad Glass Co. The sample bulb was filled with hexamethyldisilane (HMDS') up to its neck, and the space around the bulb was filled with the sample liquid or solution. At first the chemical shifts of the sample (δ_1) were measured with the spherical part of the bulb at the center of the receiver coil, using the HMDS' signal from the sphere as the lock signal. Then the bulb was put down to the bottom of the cell and the chemical shifts of the sample (δ_2) were measured by using the HMDS' signal from the cylindrical part of the microbulb as the lock signal. A good linear relation was obtained by plotting the $\delta_1-\delta_2$ value in ppm against the known values of χ_v[6] for bromoform, chloroform, benzene, and acetone.

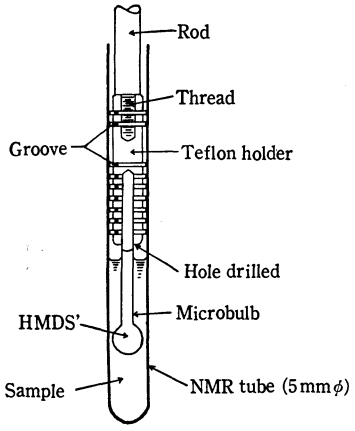

Fig. 1. Illustration of Flath's microcell.[5]

$$\delta_1 - \delta_2 = k[\chi_v(\text{sample}) - \chi_v(\text{HMDS'})] \quad (1)$$

In Eq. (1) k is the difference between the geometrical constants, $g_{cyl}-g_{sph}$, it would be $[2\pi/3-0]=2.094$ for an ideal geometry, but in practice it needs to be determined by calibration.[2,7] In the present case k was shown to be 2.245 from the slope of the linear relation described above. This value was dependent on the shape of the inner bulb, but it was independent of the outer cell and also of the time of measurement if the magnetic field homogeneity had been properly adjusted.

Using Eq. (1) the χ_v values were determined for several organic compounds. The results ($-\chi_v\times 10^6$) are: isobutyl alcohol, 0.623; acetonitrile, 0.527; toluene, 0.620; methanol, 0.523. These values are in good agreement with the results recorded in the literature[6] (0.623, 0.531, 0.620 and 0.527 respectively). The interpolation of the above plots to $\delta_1-\delta_2=0$ shows that χ_v is -0.585×10^{-6} cgs unit for HMDS'; this value has not previously been known, though it can be evaluated to be -0.568×10^{-6} using the gross estimate from Pascal's constant. The relative standard deviation in this technique is about 1.5%.

Circular Dichroism of the Square Planar Nickel(II) Complexes of [Ni(N)$_4$] Type with L-Amino Acid Amides

Takashi KOMORITA, Jinsai HIDAKA and Yoichi SHIMURA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka

(Received April 30, 1969)

In spite of its fundamental importance, the electronic spectral study has not been made enough on the ligand field bands of square planar nickel(II) complexes of [Ni(N)$_4$] type. This communication is concerned with the confirmation of the spectral correspondence between the bis(L-α-amino-acid-amidato)-nickel(II) and -palladium(II) complexes on the basis of solvent effect on the complexes. The latter has been spectroscopically determined to be the *trans* form.[1]

Bis(L-leucinemethylamidato)nickel(II) and *trans*-bis(L-leucinemethylamidato)palladium(II) were newly isolated as [Ni(L-leuma)$_2$]·H_2O[2] (Found: C, 46.58; H, 8.72; N, 15.45%. Calcd for $C_{14}H_{32}N_4O_3Ni$: C, 46.30; H, 8.88; N, 15.43%.) and [Pd(L-leuma)$_2$] (Found: C, 42.53; H, 7.78; N, 14.08%. Calcd for $C_{14}H_{30}N_4O_2Pd$: C, 42.81; H, 7.70; N, 14.26%). As is seen in Figs. 1 and 2, the negative CD bands at *ca.* 19000 cm^{-1} for then ickel-(II) and at 27100—28100 cm^{-1} for the palladium-(II) complexes change their sign to positive as the solvent changes from water or ethanol to *N,N*-dimethylformamide (DMF). The same spectral behavior was also observed for the nickel(II) and *trans* palladium(II) complexes with L-valinamidate or L- phenylalaninamidate. Furthermore, the higher wave number CD bands of the nickel(II) complexes (*ca.* 24000 cm^{-1})were affected parallel with those of the palladium(II) complexes (*ca.* 36000 cm^{-1}) by the solvents employed.

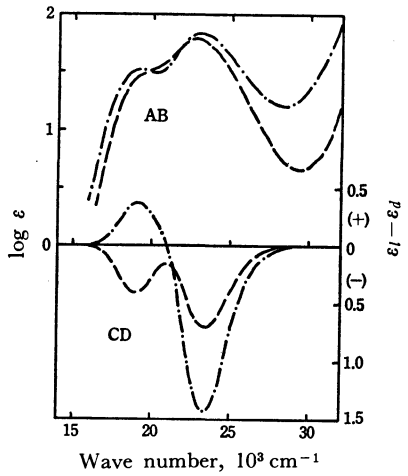

Fig. 1. Absorption (AB) and circular dichroism (CD) spectra of *trans*-[Ni(L-leuma)$_2$].
--- in ethanol, -·-· in DMF

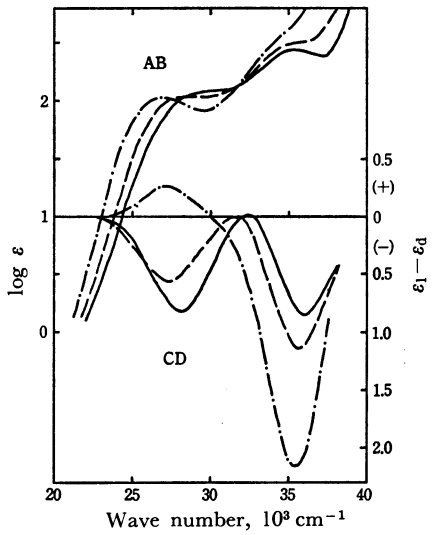

Fig. 2. AB and CD spectra of *trans*-[Ni(L-leuma$_2$].
—— in water, --- in ethanol, -·-· in DMF

The effect of the solvents on the CD of the *cis* palladium(II) complexes is distinctly different from that in the case of the *trans* complexes, especially in the higher wave number CD band (*ca.* 36000 cm^{-1}): the negative intensity of this band is lowered in the *cis* complex with L-leucinamidate or L-valinamidate as the solvent changes from water or ethanol to DMF.

These facts point out that the three nickel(II) complexes cited have the *trans* form in the solutions, and that their CD (or absorption) bands at *ca.* 19000 and *ca.* 24000 cm^{-1} correspond in electronic nature to the bands at *ca.* 28000 and *ca.* 36000 cm^{-1}, respectively, in the corresponding palladium(II) complexes.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 1783—1786 (1969)

The Yield of Hydrogen Atoms in the Vapor Phase Radiolysis of Ammonia

Masaru NISHIKAWA, Kazufumi KURODA and Niro MATSUURA

Department of Pure and Applied Sciences, The University of Tokyo, Komaba, Meguro-ku, Tokyo

(Received June 17, 1968)

γ-Radiolysis of $NH_3+C_3H_8$ mixtures was investigated at 22 ± 1°C and total pressure $\sim$50 cmHg. From the observed yield of hydrogen, H atom yield of ammonia radiolysis of $G_H=5.1$—5.8 was obtained after subtraction of contribution from the propane fraction. The value is significantly lower than that determined from the study of NH_3+D_2 and $NH_3+N_2H_4$ systems, and also that from the study of $NH_3+C_3H_8$ system reported previously. A variety of possibilities is discussed with respect to the cause of the disagreement. The effect of addition of N_2O or SF_6, which acts as an electron scavenger, was also studied. The yield of hydrogen from $NH_3+C_3H_8$ mixtures decreased appreciably, and $\Delta G(H_2)$ in the absence and presence of electron scavengers was related to the change in the neutralization process.

Similarity in the primary processes of radiation chemistry of ammonia and water has often been recognized although the observed yields of products suggest that the subsequent reactions are different. In the radiolysis of water vapor, there exists a controversy over the primary yield of hydrogen atoms. From the study of isotopic exchange in H_2O+D_2 system Firestone[1] obtained $G_H=11.7\pm0.6$, but using organic compounds as H atom scavengers Baxendale and Gilbert[2] determined $G_H=8.0\pm0.7$. To add another factor to the similarity, two different values were recently reported for the hydrogen atom yield in the radiolysis of ammonia, namely $G_H=12.5\pm1$ by Jones and Sworski[3] from the study on NH_3+D_2 and $NH_3+N_2H_4$ systems, and $G_H\gtrsim7.2$ from that on $NH_3+C_3H_8$ system by Johnson and Smic.[4] Again, the value estimated from isotopic exchange is larger than that with the use of organic scavenger. We have also been investigating the radiolysis of ammonia vapor in an attempt to determine G_H using propane as a scavenger for H atoms. The results we observed are similar to those of Johnson *et al.* However, our interpretation involving the estimation of contribution of propane fraction to the total hydrogen production indicated still another value of G_H which is lower than their value.

Experimental

Ammonia (Matheson, 99.9%), propane (>99.8%), nitrous oxide (99.9%), and sulfur hexafluoride (Matheson, >98%) were purified as described previously.[5] Gas chromatographic analysis using squalane on alumina (4.5 m) of propane thus purified indicated that no organic impurities were present at levels exceeding 10^{-3} mol%.

Irradiations were carried out in glass vessels (about 50 ml) fitted with break-seals, baked both in air and at $<10^{-6}$ mmHg before use, in a source of approximately 1000 Ci of ^{60}Co at ammonia pressure of about 50 cmHg and 22 ± 1°C.

Nitrous oxide was used for dosimetry, assuming $G(N_2)=10.0$.[6] The energy absorbed in ammonia (E_a) and in propane (E_p) were calculated using the ratio of stopping powers per molecule obtained by Meisels.[7] The dose rate used was 1.5×10^{16} eV mol^{-1}sec^{-1} in ammonia.

The non-condensable products, hydrogen and nitrogen, were analyzed by combustion in a cupric oxide furnace heated at $\gtrsim$350°C.

Results

Product yields are expressed in terms of G-values calculated for energy absorbed by ammonia, unless otherwise stated. Effect of additives on the product yields are as follows.

Propane. Hydrogen yield steadily increased from $G(H_2)=4.1$ of pure ammonia to 7.8 at 8.6 mol% of propane, while nitrogen yield was markedly depressed (Fig. 1). The increase of hydrogen yield with propane concentration suggests hydrogen production from the direct radiolysis of propane fraction in addition to scavenging H atom from

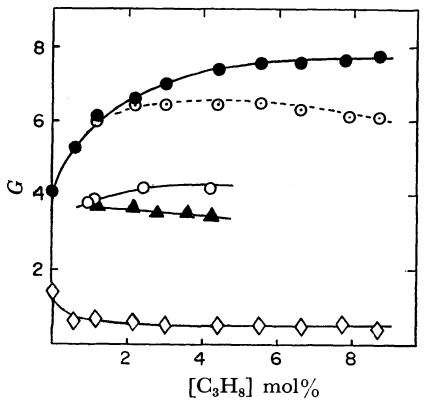

Fig. 1. G-Values of products from $NH_3+C_3H_8$ mixtures.
●, total H_2 from $NH_3+C_3H_8$; ○, H_2 corrected for contribution of C_3H_8 fraction; ○, total H_2 with N_2O ($p_{N_2O}/p_{NH_3}\cong 0.05$); ▲, total H_2 with SF_6 ($p_{SF_6}/p_{NH_3}\cong 0.005$); ◇, N_2 from $NH_3+C_3H_8$

ammonia, so that correction is necessary. The amount of hydrogen produced from propane fraction was estimated from the energy absorbed in propane taking $G(H_2)=7.5$[8] and assuming absence of energy transfer. The yield of hydrogen corrected in this manner, which is a measure of hydrogen produced in ammonia fraction, is also plotted in Fig. 1. The contribution of propane fraction to the total hydrogen can also be estimated by plotting G-values of total yield (G_t) calculated for the total energy absorbed by the mixture ($E_t=E_a+E_p$) against the fraction of energy absorbed in propane ($f_p=E_p/E_t$). The plot was utilized by Johnson and Simic,[9] and by Jones and Sworski.[3] A good straight-line relationship is demonstrated for lower f_p region where energy transfer between ammonia and propane is negligible, but at f_p higher than 0.15, $G(H_2)_t$ is seen to deviate from the straight line in Fig. 2. Extrapolation of straight portion to $f_p=0$ yields $G(H_2)^\circ=5.84\pm0.05$.

Hydrazine. At the concentration of 5.3 mol%, $G(H_2)=10.0$ and $G(N_2)=7.8$; at 7.4 mol%, $G(H_2)=9.9$ and $G(N_2)=7.6$. They are in fair agreement with the values reported by Jones and Sworski,[3] if converted into $G(H_2)_t$/fraction of stopping power of $NH_3(f_a)$ for comparison.

Sulfur Hexafluoride. $G(H_2)$ decreased from 0.91 at 0.6 mol% to 0.84 at 1.1 mol%, while $G(N_2)$ increased from 2.1 to 2.2.

Propane + Nitrous Oxide or Sulfur Hexafluoride. The effect of addition of N_2O ($p_{N_2O}/p_{NH_3}=0.05$) or SF_6 ($p_{SF_6}/p_{NH_3}=0.005$) to $NH_3+C_3H_8$ mixtures is shown in Figs. 1 and 2. The previous study indicates the concentration of N_2O

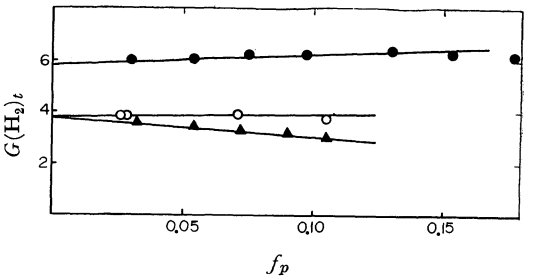

Fig. 2. Dependence of $G(H_2)_t$ on the fraction of energy absorbed by C_3H_8 ($f_p=E_p/E_t$).
●, from $NH_3+C_3H_8$; ○, with N_2O($p_{N_2O}/p_{NH_3}\cong 0.05$); ▲, with SF_6 ($p_{SF_6}/p_{NH_3}\cong 0.005$)

to be sufficient to scavenge all the electrons produced at the dose rate employed. In Fig. 2, a straight line relationship is demonstrated between $G(H_2)_t$ and f_p in both cases, extrapolation of which leads to approximately the same value, $G(H_2)^\circ\cong 3.8$. In order to see if the energy absorbed in the SF_6 in the mixture contributes to the formation of hydrogen, the concentration of SF_6 was varied to $p_{SF_6}/p_{NH_3}=0.016$ at the propane concentration of 3.6 mol%, and to 0.012 at 4.2 mol%. At both concentrations $G(H_2)_t$ increased by about 10%, indicating the presence of small contribution. It is tentatively assumed that the contribution is negligible at $p_{SF_6}/p_{NH_3}=0.005$. $G(N_2)$ is depressed from 9.8 of NH_3+N_2O (100 : 5) to 3.5 by the addition of C_3H_8 (1—3 mol%) to NH_3+N_2O mixtures.

Discussion

Hydrogen atoms react with propane by

$$H + C_3H_8 \rightarrow H_2 + C_3H_7 \quad (k\sim 2\times 10^6 M^{-1}\cdot sec^{-1})[10] \qquad (1)$$

Charge and proton transfer from NH_4^+, which is the principal ionic species in the radiolysis of ammonia,[11] to propane can be excluded on the energetic grounds because of the low ionization potential for NH_4,[12] and the high proton affinity of NH_3,[13] while on the same ground transfer from $C_3H_8^+$ to NH_3 can occur. The hydrogen yield from the radiolysis of $NH_3+C_3H_8$ mixtures may be composed of the "molecular" hydrogen from ammonia (A), that produced through reaction (1) by H atoms formed in ammonia (B), and that produced in propane fraction (C). In order to estimate the contribution of propane fraction to the hydrogen yield, it is necessary to determine the extent of energy transfer between propane and ammonia. Since this cannot be accomplished from the product analysis without the use of isotopically

labeled additives, two methods were used as the zeroth approximation, both assuming energy transfer being negligible at lower concentration range of propane. One of the methods is simply to subtract the yield of hydrogen calculated for energy absorption in propane from the total yield. A narrow range of plateau in $G(H_2)$ is seen in Fig. 1, which should be a measure of (A)+(B), *i. e.*, $G_H+G_{H_2}=6.5$. The other method is based on the equation

$$G(H_2)_t = G(H_2)_a^\circ \cdot f_a + G(H_2)_p^\circ \cdot f_p = G(H_2)_a^\circ + [G(H_2)_p^\circ - G(H_2)_a^\circ] \cdot f_p \quad (1)$$

where G_a° and G_p° are those due to energy deposited in ammonia and in propane, respectively, and f_a and f_p are the fraction of energy absorbed by ammonia and by propane in the mixture, which is given by $f_a = s_a[NH_3]/(s_a \cdot [NH_3] + s_p \cdot [C_3H_8])$ where s is the relative stopping power per unit concentration.[7] At the lower f_p region the plot of $G(H_2)_t$ *versus* f_p demonstrates a sufficiently straight line in Fig. 2, which, according to Eq. (1), indicates that the assumption may be justified. The intercept, $G(H_2)_a^\circ = 5.84 \pm 0.05$, should then be another measure of $G_H+G_{H_2}$ of ammonia. The slope of the straight line gives $G(H_2)_p^\circ = 10.4$; the value determined by Johnson and Warman is 7.5.[8] $G_{H_2}=0.74$ of ammonia radiolysis determined earlier[5] is in excellent agreement with 0.75 reported by Jones and Sworski[3] and with <0.8 by Johnson and Simic.[4] It follows that the value of G_H lies in the range of 5.1 to 5.8, which is significantly lower than those reported by Jones and Sworski and by Johnson and Simic. It is not obvious whether due corrections were made to the contribution of propane fraction to hydrogen yield by Johnson and Simic. If not, the neglect of (C), could account for most of the disagreement with their value. It is also possible that the disagreement is due to difference in the dose rate used (their dose rate is higher by a factor of 100), although it is not altogether clear how it should affect the yield in ammonia-propane system. The more serious disagreement with Sworski's value might be, at least in part, inherent in the system they used. For example, with the NH_3+D_2 system they observed G_H as high as 90 ± 66 at the ammonia pressure of 600 Torr by a fairly complicated kinetic analysis using a variety of parameters. High G-values are usually attributed to some kind of chain mechanism. In fact, very high G(HD) observed at 200°C is explained in terms of a chain mechanism involving D atoms. Since $G_H=90$ was determined at 24°C, the mechanism would probably include ionic species, if chain reactions are to be invoked. Some ambiguity, therefore, still remains in $G_H = 12.5 \pm 3.0$ at 200 Torr.

In $NH_3+N_2H_4$ system, H_2 is considered to be formed from H atoms as precursors mainly by the reaction $H+N_2H_4 \rightarrow H_2+N_2H_3$,[3] as well as a minor fraction of "molecular" H_2. Johnson and Simic observed that $G(H_2)$ of $NH_3+C_3H_8$ system is independent of temperature over the range 20—200°C at around 8.0, while that of pure ammonia increases to $G(H_2) \cong 15$ at 200°C. Similar results in the pure ammonia were observed by Jones and Sworski. Our results on the $NH_3+C_3H_8$ system at high densities ($d \sim 0.1$ g/ml) and 140°C also indicate a constant $G(H_2)$ independent of temperature and density.[14] Since the marked depression of $G(N_2)$ by propane, observed by Johnson and also in the present work, suggests scavenging of precursors of nitrogen,

$$NH_2 + C_3H_8 \rightarrow NH_3 + C_3H_7 \qquad \Delta H = -9\text{—}11 \text{ kcal/mol} \quad (2)$$

the difference in the hydrogen yield between pure ammonia and $NH_3+C_3H_8$ at elevated temperatures could be accounted for by hydrogen formation from intermediates other than H atoms which is favored at higher temperatures. At low temperatures reactions conceivable for H and NH_2 include:

$$H + H \rightarrow H_2 \quad (3)$$
$$H + NH_2 \rightarrow NH_3 \quad (4)$$
$$H + NH_3 \rightarrow NH_2 + H_2 \quad (5)$$
$$NH_2 + NH_2 \rightarrow N_2H_4 \quad (6)$$
$$H + N_2H_4 \rightarrow H_2 + N_2H_3 \quad (7)$$
$$NH_2 + N_2H_4 \rightarrow NH_3 + N_2H_3 \quad (8)$$

Reaction (5) is unimportant at $\sim$20°C because of the activation energy of 10—15 kcal/mol,[15] while it certainly is favored at elevated temperatures, resulting in the enhancecment of NH_2 concentration, hence the importance of reactions (6) and (8) over that of reaction (4). It appears, therefore, that the reactions involving NH_2 and/or species whose precursor is NH_2 might not be excluded as a source of hydrogen. One such example is seen in the reaction included by Dainton *et al.*[16] in the mechanism of radiolysis of liquid ammonia.

$$NH_2 + N_2H_3 \rightarrow NH_3 + N_2 + H_2 \qquad \Delta H = -99 \text{ kcal/mol} \quad (9)$$

Addition of hydrazine to ammonia as the scavenger for hydrogen atoms would, at the same time, increase such possibilities even at $\sim$20°C, while with propane as additive the main reaction paths are (1) and (2), which do not lead to such possibilities.

Explanation of $G_H=12.5$ analogous to what has been advanced to account for $G_H=11.7$ of water vapor in terms of the neutralization $H_3O^+ + e^- \rightarrow 2H + OH$[17] is not feasible, since if $NH_4^+ + e^- \rightarrow NH_2 + 2H$ occurs in ammonia at a higher tempera-

ture where the extent of clustering would be less than that at 20°C, hydrogen yield from $NH_3+C_3H_8$ mixtures should increase in controversy to the observation. Futhermore, the reaction

$$NH_4^+\cdot(NH_3)_2 + e^- \rightarrow 2NH_3 + NH_2 + 2H$$

is endothermic by 40 kcal/mol[18] and $NH_4^+\cdot(NH_3)_2$ is the most abundant ions observed at 1 Torr and 100°C.[19]

Sulfur hexafluoride does seem to react with H atoms as well as electrons in the radiolysis of NH_3+SF_6 mixtures, as is indicated by the marked decrease in $G(H_2)$ which approaches the value obtained using olefins as additives, although the reaction of H atoms with SF_6 is reported to be slow.[20] It is not unreasonable, since the reaction $H+NH_3\rightarrow NH_2+H_2$ does not proceed at room temperature. Other possibilities such as quenching of precursor for H atoms by SF_6 cannot be ruled out.

The reactions of SF_6 and N_2O may be considered to be solely the scavenging of electrons in the $NH_3+C_3H_8$ system, since the molar ratio N_2O/C_3H_8 and SF_6/C_3H_8 in the present work are well below those reported by Johnson and Simic[9] where the reaction of H atoms with N_2O and with SF_6 can be excluded. The decrease in the yield of hydrogen by these additives may, therefore, be assumed to be due to the change in the neutralization process of ammonium ions from ion-electron to ion-ion. The depression of the hydrogen yield, $\Delta G(H_2)=3$—4, shown in Fig. 1 (the difference was taken from the uncorrected values of $G(H_2)$ as an approximation), is of the order of $100/W$ and is consistent with the change of the neutralization process from $NH_4^++e^-\rightarrow NH_2+H$, to the ion-ion recombination, where no hydrogen is produced. On the other hand, in Fig. 2, the plot of $G(H_2)_t$ with SF_6 and with N_2O *vs.* f_p both extrapolate to $G(H_2)^\circ=3.8$. The difference in $G(H_2)^\circ$ in the presence and absence of electron scavengers in this case is only ~2, which is significantly lower than the value estimated from W-value, if it really represents the contribution of ionic processes. The increase in the $\Delta G(H_2)$ with propane concentration in Fig. 2 may suggest that these electron scavengers influence hydrogen formation in the propane fraction more strongly. In ammonia+propane system all the ions are supposed to be rapidly converted into NH_4^+ by the ion-molecule reactions before neutralization.

$$NH_3^+ + NH_3 \rightarrow NH_4^+ + NH_2 \quad (10)$$

$$NH_2^+ + NH_3 \rightarrow NH_3^+ + NH_2 \quad (11)$$

$$RH^+ + NH_3 \rightarrow NH_4^+ + R \quad (12)$$

where RH^+ represents hydrocarbon ions. The dose rate employed in the present work might be in the region where electrons can diffuse to the wall and the neutralization at wall can compete with that in the gas phase. In fact, $\sim5\times10^{11}$ eV/m*l*·sec of the present work lines in the range where Woodward and Back[21] observed the depression of hydrogen yield for a variety of hydrocarbons which was explained in terms of the stabilization of species formed by the wall neutralization. If the neutralization of NH_4^+ takes place at the wall, hydrogen is bound to be produced, although some stability was shown for the species NH_4.[12] The lower value of $G(H_2)^\circ$ estimated in Fig. 2 may be ascribed to the competition between neutralization of ammonium ions in the gas phase and at the wall. At the present stage, the experimental data are still by far insufficient to decide which of the $\Delta G(H_2)$ by electron scavengers is the true measure of the importance of ionic processes.

The slope of the straight line for $NH_3+C_3H_8+N_2O$ system gives $G(H_2)_p{}^\circ=4.5\pm0.4$ in comparison to $G(H_2)=4.9$ of the propane radiolysis in the presence of N_2O determined by Johnson and Warman.[8] The slope of the line with SF_6 as electron scavenger and the difference from the line with N_2O are still puzzling. The effect of impurities in SF_6 may be ruled out, because the discrepancy becomes larger with propane concentration if SF_6 concentration is kept constant to that of ammonia. The trend may suggest the presence of some kind of interactions between SF_6 and propane. Another possibility is the production of hydrogen by the reaction of N_2O, for example, with NH_2. $G(N_2)=9.8$ at $N_2O/NH_3=0.05$ is markedly depressed by the addition of propane to $G(N_2)=3.5$ over the concentration range of 1 to 3 mol%, suggesting the principal mode of reaction between NH_2 and N_2O is to produce nitrogen, however, reactions such as

$$NH_2 + N_2O \rightarrow N_3 + H_2O$$

$$N_3 + NH_3 \rightarrow 2N_2 + H_2 + H$$

cannot be ruled out. In any case, the study using isotopically labeled additives together with the electron scavengers is definitely necessary to obtain informations for the elucidation of the discrepancy.

We should like to acknowledge valuable discussion with Dr. K. Fueki of Nagoya University and with Dr. N. Shinohara of Yokohama City University.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 1787—1795 (1969)

Effect of Some Cationic Detergents on Macromolecularly Stabilised Emulsions with Special Reference to Sodium Alginate and Gum Arabic as Emulsifiers

Chandra PRAKASH and S. N. SRIVASTAVA

Chemical Laboratories, Agra College, Agra, India

(Received August 21, 1968)

The effect of some cationic detergents *viz.* cetyl pyridinium bromide, lauryl pyridinium chloride and phenyl trimethyl ammonium chloride has been studied on stabilised by sodium alginate and gum arabic emulsions. Zeta potentials were measured at different concentrations of cationic detergents microelectrophoretically. The particle size was determined microphotographically. With the help of zeta potential and particle size the interaction energies were calculated by summing up attraction and repulsion energies in the light of D.V.O. theory. For attraction energy the van der Waals constant was computed theoretically from the optical data and was obtained to be 6.7×10^{-14} erg. The interaction energies thus obtained gave very high energy barriers which completely obviated the occurrence of flocculation in primary minima, causing flocculation to occur in secondary minima. The theoretical degrees of aggregation were calculated and plotted at different values of A. The flocculation occurring in the system was observed haemocytometrically by counting the number of singlets and doublets and the degrees of aggregation were calculated. With the help of observed degrees of aggregation the operating value of van der Waals constant has been estimated by interpolating them into the theoretical curves, which is an indirect approach to ascertain the value of van der Waals constant. The values of A obtained are 3.0×10^{-13} and 2.6×10^{-13} erg for sodium alginate and gum arabic systems respectively. The binding parameters, number of binding sites available and free energy of adsorption have also been calculated.

Cationic detergents are the substances, generally, of high formula weight and are very specific in their surface active effects. These substances ionize in water giving positively charged long chain groups as well as anion. This positively charged part behaves as a typical polyvalent cation and hence is more efficient in flocculating negatively charged sols and emulsions. Cationic detergents produce hydrophobic surfaces, thus they have got much importance in industry. The hydrophobic groups bearing cationic polar heads are adsorbed on the surface of either negatively charged oil globules of an emulsion or solid sol particles.

A number of references on detergents are available in the literature of colloid science. Neogy and Ghosh[1] have made an exhaustive investigation of xylene-in-water emulsions stabilised by cationic detergents *viz.* cetyl dimethyl benzyl ammonium chloride, cetyl pyridinium bromide and cetyl trimethyl ammonium bromide. Recently Haydon and Phillips[2] have published some papers dealing, in general, with cationic and anionic detergents. They dealt with Gibbs equation and the surface equation of state for soluble ionized monolayers in absence of added electrolyte at the oil-water interface. They[3] studied the influence of trace of electrolytes on interfacial tension at the oil/water interface for dodecyl trimethyl ammonium bromide and sodium dodecyl sulphate systems. Haydon and Taylor[4] investigated the influence of ionic size on double layer potentials at the oil-water interface. They tested the systems for adsorbed long chain alkyl sulphates in water and of sodium dodecyl sulphate and dodecyl trimethyl ammonium bromide. Biswas and Haydon[5] studied the effect of tetradecyl trimethyl ammonium bromide on the stability of petroleum ether drops at flat surface in 0.1% bovine serum albumin solution and also compared the stability of petroleum ether drops stabilized by 0.1% bovine

serum albumin in presence of tetradecyl trimethyl ammonium bromide, with the shear moduli of elasticity of the adsorbed films. Lyklema[6] recieved the factors governing the stability of thin detergent films.

From the survey of the above literature it is concluded that a number of studies have been made covering different aspects of cationic detergents but still there is lack of quantitative data in the light of D.V.O. theory. Therefore, under the present investigation an attempt has been made to study the effect of some cationic detergents *viz.* phenyl trimethyl ammonium chloride (Ammonyx-200), lauryl pyridinium chloride and cetyl pyridinium bromide on emulsion stability in the light of D.V.O. theory and to evaluate van der Waals constant with the help of flocculation data. These studies were made in detail with sodium alginate system only and partially with gum arabic emulsion also.

Experimental

Sodium alginate and gum arabic samples were obtained from B.D.H. A pure sample (99.5%) of phenyl trimethyl ammonium chloride was obtained with the courtesy of Onyx Corporation, U.S.A. A pure sample of lauryl pyridinium chloride (LPC) was supplied by Industrial Products, Bombay, which was further crystallised with acetone. An I.C.I. sample of cetyl pyridinium bromide was used which was recrystallised with acetone.

The emulsion was prepared by dispersing 4% of petroleum ether in aqueous solution of sodium alginate or gum arabic containing 0.01% KCl initially. The counting of the drops for flocculation studies was carried out haemocytometrically as mentioned elsewhere.[7] The electrophoretic measurements were carried out in a rectangular Northrup and Kunitz flat type microcataphoretic cell mounted on the base of the Carl Zeiss Zena microscope. To minimise polarization Ag-AgCl electrodes were used, which were fitted in electrode chambers, filled with electrolyte solution of equiconducting to that of emulsion. A D.C. microammeter of Cambridge Industrial Co., Ltd., England, No. L 32132 was used for measuring the current. The microscope was focussed at stationary level which was obtained by studying the mobilities of particles at different depths which in trun gave a parabolic curve. The mobilities of the particles were measured in direct as well as reverse direction and the mean was taken. The accuracy of the apparatus was 1.0 mV.

From the mobility data, the zeta potentials were calculated by using the Overbeek[8] equation for symmetrical electrolytes, where the relaxation correction has been applied.

$$U = \frac{\epsilon\zeta E}{\sigma\pi\eta}\left[f_1(\kappa a) - Z^2\left(\frac{e\zeta}{kT}\right)^2 f_3(\kappa a) - \frac{\rho_+ + \rho_-}{\sigma\pi\eta e}\left(\frac{e\zeta}{kT}\right)^2 f_4(\kappa a)\right]$$

where U, velocity of the particle, ρ_+ and ρ_- the friction constants, η the viscosity of the dispersion medium, k the Boltzmann constant, e the electronic charge. $f_1(\kappa a)$, $f_2(\kappa a)$, $f_3(\kappa a)$, $f_4(\kappa a)$, the Henry functions taken from elsewhere (Overbeek *loc. cit.*).

The interfacial tension measurements were carried out with Du Nouy tensiometer No. 70535 (Central Scientific Co., Chicago, U.S.A.) having an accuracy of 0.1 dyne.

Theory of the Particle Interaction

In the frame work of D.V.O. theory the interaction energy of the colloidal particles is given by $V = V_R + V_A$, where V_A, the attraction energy, V_R, the repuslvie energy and V, the sum of the repulsive and attraction energies. The repulsive energy calculations were carried out by using an approximate expression by Derjaguin and Kussakov.[9]

$$V_R = \frac{\varepsilon a \psi^{\circ 2}}{2} \ln(1 + e^{-\kappa H}) \qquad (1)$$

where ψ° the surface potential (assumed equal to the electro-kinetic potential for the present system having ($\kappa a \gg 1$), ε is the dielectric constant in the double layer, a the particle radius, H the interparticle distance and κ the Debye-Hückel parameter.

The attraction energies were calculated, keeping in view the retardation correction, by equation due to Schenkel and Kitchener.[10]

$$\left.\begin{aligned} V_A &\approx \frac{-Aa}{\pi}\left(\frac{2.45\lambda}{120H^2} - \frac{\lambda^2}{1045H^3} + \frac{\lambda^3}{5.62\times 10^4 H^4}\right) && \text{Valid for } H > 150\text{Å} \\ V_A &\approx \frac{-Aa}{12H}\left(\frac{\lambda}{\lambda + 3.54H\pi}\right) && \text{Valid for } H < 150\text{Å} \end{aligned}\right\} \qquad (2)$$

where λ is the wavelength of the London frequency and is taken as 1000 Å, and A is the van der Waals constant.

Thus the interaction energy V can be evaluated. Therefore, knowing V, the number of particles in a shell ds around a central particle and consequently degree of aggregation or the total number of particles associated with a given central particle can be calculated[7] theoretically from the following equation.

$$D = \int 4\pi n_0 a^3 S^2 e^{-V/kT} ds \qquad (3)$$

where n_0 is the number of droplets per unit volume of the emulsion and $s=2+H/a$. The intergrand of the above expression is evaluated graphically and the integration limits are arbitrarily selected. The lower limit is readily chosen keeping in view that at sufficiently small values of s, V becomes strongly positive. Again as $s\rightarrow\infty$, $V\rightarrow 0$ and the integral tends to infinity. Therefore, the choice of the upper limit is not straightforward. In the present systems, however, V becomes strongly negative in a narrow range of s, and the value of the integral is, for any reasonable choice of the upper limit, approximately constant.

In case of the reversible or secondary minimum flocculation, as in the present system, a singlet-doublet equilibrium temporarily exists in the system and the extent of flocculation in the system can be determined from the formula.

Calculation of Binding Parameters

Binding parameters were calculated from the treatment mentioned earlier[7] and the important equations are presented below

$$\sigma_s = \frac{N_1 ev}{1+\frac{55.6}{C}\exp\left(\frac{\Delta G}{kT}\right)} \tag{4}$$

where σ_s, the charge density of the Stern layer, e the electronic charge, v valency of the cation, c the molar concentration of the added electrolyte, N_1 the binding sites per cm^2 and $-\Delta G$ is the free energy of adsorption per molecule.

This can be put in the form

$$\left.\begin{aligned} \sigma_s &= \frac{k_1 c}{1+k_2 c} \\ \text{where}\quad k_2 &= \frac{\exp\left(\frac{-\Delta G}{kT}\right)}{55.6} \\ k_1 &= N_1 k_2 ev \end{aligned}\right\} \tag{5}$$

These k_1 and k_2 are the adsorption constants which can be calculated from the following equations at the zero point of charge, which finally yields the following equations

$$\frac{1}{c} = \left(\frac{4\pi ev N_1 k_2}{\kappa\varepsilon\psi_\delta^\circ} - k_2\right) \tag{5}$$

$$\left(\frac{d\psi_\delta^\circ}{d\ln c}\right)_{\psi_{\delta=0}^\circ} = \left(\frac{\kappa\varepsilon\psi_\delta^\circ}{4\pi ev k_1} - 1\right)\psi_\delta^\circ \tag{7}$$

where v is the valency and $\left(\frac{d\psi_\delta}{d\ln c}\right)\psi^\circ_{\delta=0}$ is the slope of the log C-zeta potential curve (assuming $\psi_s^\circ=\zeta^\circ$), c is the concentration of the electrolyte at the zero point charge.

Computation of van der Waals Constant

Hamaker[11] suggested that van der Waals constant can be calculated from the following equation

$$A_{ii} = \pi^2 q_i^2 B_i \tag{8}$$

where q_i is the number of atoms of kind i contained in 1 ml of the matter. B_i is the London constant relative to the same substance, which is to be computed separately. But in the present system since the petroleum ether (p.e.), instead of being separated by a vacuum, is immersed in an aqueous medium, the net constant is given by following equation.[12]

$$A = (A_{\text{p.e.-p.e.}}^{1/2} - A_{\text{H}_2\text{O-H}_2\text{O}}^{1/2}) \tag{9}$$

The London constant, B can be calculated by four approximate formulae (a) The London equation[13]

$$B_L = \frac{3}{4}\alpha^2 h\nu_0 \tag{10}$$

Where ν_0 is the characteristic London frequency corresponding to the rotation of peripheral electrons and α is the polarisability.

(b) The Slater-Kirkwood equation[14]

$$B_{S-K} = 11.25\times 10^{-24}\cdot n^{1/2}\cdot\alpha^{3/2} \tag{11}$$

where n, number of valency electrons.

(c) The Slater-Kirkwood equation modified by Moelwyn-Hughes[15]

This new equation takes into account the effective number of dispersion electrons, S_1, thereby leading to

$$B_{S-K-M} = \frac{3}{4}\sqrt{S_1 n}\cdot h\nu_e\alpha^2$$

where ν_e, the electronic vibration frequency is given by

$$\nu_e = \frac{2532}{\sqrt{\alpha}}$$

and S_1, is given by an empirical equation,

$$S_1 = 0.39n$$

$$B_{S-K-M} = 7.8\times 10^{-24}\times n\cdot\alpha^{3/2} \tag{12}$$

(d) The Neugebaur, equation[16]

16) Th. Neugebaur, *Z. Physik*, **167**, 785 (1937).

$$B_N = -1.62\times10^{-6}\cdot\alpha\chi \qquad (13)$$

where χ being the diamagnetic susceptibility.

As mentioned before, the calculation of van der Waals constant from Eqs. (10)—(13) requires the polarisability which has been calculated from the Clausius-Mosotti equation[17] modified by Moelwyn-Hughes (*loc. cit.*),

$$\alpha = \frac{3M}{4\pi Nd}\cdot\frac{\rho^2-1}{\rho^2+1}\cdot\frac{v_0^2-v^2}{v_0^2} \qquad (14)$$

where M, the molecular weight, N the Avogadro number and ρ is the index of refraction at the London wavelength. Since the refractive index is not directly available at the London wavelength, the quantity, $\frac{v_o^2-v^2}{v_o^2}$ is the extrapolation factor for ρ determined at the frequency. The latter quantity in its turn is also determined indirectly from the dispersion equation of Sellmeier[18] *viz.*

$$\rho^2 - 1 = \frac{C\lambda_1^2}{\lambda_1^2-\lambda_0^2}$$

where λ_1 and λ_0 are respectively the wavelengths of light and of the characteristic absorption bands and C is a constant. It is obvious that to solve such equation, refractive indices at least for two wavelengths are required. For this the refractive index of petroleum ether was measured spectrometrically at 4047 Å, 4358 Å, 5461 Å and 5770 Å and corresponding indices were found to be 1.419, 1.4155, 1.408 and 1.405 respectively. Feeding these values into the above equation λ_0 can be evaluated. The value of v_0 obtained from λ_0 is 2.50×10^{15} cm/sec. This leads to a value of the extrapolation factor to be 0.957 at 5770 Å. Thus the value of ρ for the calculation of α has been taken as 1.4056 at 5770 Å.

The molecular weight of petroleum ether has been taken as 100 which agrees with the observed value (98.5) of molecular weight determined cryoscopically. The observed value of density (d) is 0.72 at 25°C. The value of α found in this manner is 1.635×10^{-23} cm^3/mol.

For calculating the London constant α, h and v_0 are available and with the proper choice of units the London constant is

$$B_{L_{p.e.}} = \frac{3}{4}(1.635\times10^{-23})^2\times6588\times10^{-27}\times2.5\times10^{15}$$
$$= 3.277\times10^{-57}\ \text{erg}\cdot\text{cm}^6$$

$$B_{S-K_{p.e.}} = 11.25\times10^{-24}\times(8)^{1/2}\times(1.635\times10^{-23})^{3/2}$$
$$= 2.10\times10^{-57}\ \text{erg}\cdot\text{cm}^6$$

where n, the number of electrons is 8, assuming that the petroleum ether molecule is composed of CH_4. Further

$$B_{S-K-M_{p.e.}} = 7.8\times10^{-24}\times8\times(1.635\times10^{-23})^{3/2}$$
$$= 4.12\times10^{-6}\times1.635\times10^{-23}$$
$$\times(-0.88\times10^{-6})\times\frac{100}{6\times10^{23}}$$
$$= 3.73\times10^{-57}\ \text{erg}\cdot\text{cm}^6$$

where the value of the specific susceptibility is -0.88×10^{-6} cgs units.[19]

The corresponding values of these constant for water with $=1.43\times10^{-24}$ cm^3/mol, $n=8$, $\chi=0.72\times10^{-6}$ cgs units as given by Verwey and Overbeek[20]

$$B_L^{H_2O} = 3.30\times10^{-59}$$
$$B_{S-K}^{H_2O} = 5.40\times10^{-59}$$
$$B_{S-K-M}^{H_2O} = 7.28\times10^{-59}$$
$$B_N^{H_2O} = 5.10\times10^{-59}$$

now by finding q (4.34×10^{21}), the number of molecules of petroleum ether contained per ml from the knowledge of its molecular weight and density with the help of Eq. (8), the van der Waals constant for petroleum ether and corresponding constants for water can be calculated and hence net attraction constant for petroleum ether drops can be estimated from Eq. (9). The results are summarised in Table 1, where in the last column a correction has been made for the reduction of London force due to its transmission through a medium whose dielectric constant is not equal to unity. This is done by dividing the constant A by 1.8, the square of the refractive index of water, 1.36. The mean of the first three readings was taken because fourth is very low.

The mean value of van der Waals constant thus obtained is 6.7×10^{-14} erg, which will be taken for calculation of interaction profiles.

Results and Discussion

(a) Particle Size. For particle size of the drops the microphotographs were taken with Olympus camera at 15×40 magnification. These were further enlarged four times. From the each photograph the size frequency curves were plotted by measuring the size of about 500 drops. The average size for sodium alginate is 1.0 μ and for gum arabic is 1.2 μ. The size frequency curve of

(b) Effect of Cationic Detergents on Zeta Potential. The zeta potentials of stabilised emulsions by sodium alginate and gum arabic were measured in the presence of cetyl pyridinium bromide (CPB, $C_{16}H_{33}C_6H_5NBr$), lauryl pyridinium chloride (LPC, $C_{12}H_{25}C_6H_5NCl$) and phenyl trimethyl ammonium chloride (Ammonyx-200, $C_6H_5N(CH_3)_3Cl$). In Fig. 2 the plots of zeta potential against log molar concentration are given for sodium alginate and gum arabic systems.

The curves obtained, in general, are of inverted S-shape. It can be seen that only LPC and CPB could reverse the charge of sodium alginate system. The effect of LPC on gum arabic emulsion was studied only. An appreciable change in zeta potential could not be observed even upto 1 mM of it. The relevant data are presented in Table 3. Ammonyx-200 could not reverse the charge even

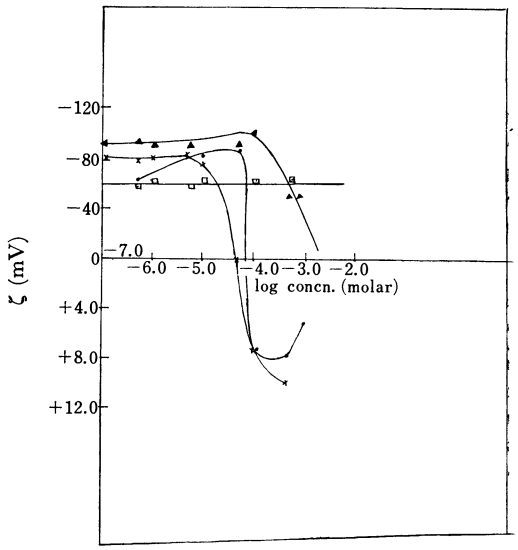

Fig. 2. Zeta potentials as a function of log concentration (molar) of cationic detergents.

(⊡) Lauryl Pyridinium chloride

upto 10^{-2}M, exhibiting thereby its weak efficacy. With increasing concentration of LPC and CPB, the zeta potential decreases continuously but at higher concentrations the charge of the system is reversed. After reversal of charge the absolute value of the zeta potential again increases with increasing concentration and the system again acquires stability, though the emulsion globules are now positively charged. During this the critical micelle concentrations of the surfactants are also reached. These variations in stability can be explained as follows. It is likely that during the addition and mixing concentrated solution of detergent to the system conditions could occur in which the micellar solution of the detergent became submicellar. The breaking down of micelles to submicelles is a very fast reaction.[21] The time required during mixing the detergent to the system is of the same order as required for breaking down of the micelles, mutual coagulation would occur between the micelles and the stabilised emulsion drops resulting in an artificial decrease in stability.

Ammonyx-200 seems to have a very weak cationic efficacy. The ζ-potential increased with increasing concentration of the detergent and then a continuous decrease is obtained. This behaviour has got close analogy with 1 : 1 electrolytes.

21) R. H. Ottwill and M. C. Rastogi, *Trans. Faraday Soc.*, **56**, 866 (1960).

(c) Determination of Flocculation Concentration and Calculation of Some Binding Constants. The flocculating concentrations obtained at the zero point of charge are presented in respective Table 2. From the flocculating concentrations it is obvious that the capacity for reversing the charge is CPB, LPC, Ammonyx-200 because the carbon chain lengths are in decreasing order and hence their CMC values are expected to be in increasing order. Therefore, the concentrations required for flocculation should be in increasing order as the carbon chain decreases.

The low flocculating concentrations are in accordance with the idea that coagulation under these conditions is due to the adsorption of the cationic surface active agent on the negatively charged drops. At low detergent concentrations adsorption appears to occur by interaction of the positively charged head group of the molecules. Thus increasing chain length decreases the available area for adsorption and hence decreases the flocculation concentration. Therefore, CPB with larger chain length is more effective than LPC. Bromide and chloride ions have little influence on the process.[21] The same interpretation can be given for Ammonyx-200 also.

The binding constant k_1, k_2, number of binding sites available N_1, and free energy of adsorption $-\Delta G$ were calculated with the help of flocculating concentration and the slope of the log concentration-zeta potential curve. The calculated values are presented in the Table 2.

From the values of the number of binding sites, in case of these detergents, it is evident that LPC and CPB are having fewer number than Ammonyx-200 which clearly shows that number of sites available would depend upon its capacity for charge reversal. Thus Ammonyx-200 could not reverse the charge in spite of adding upto 1×10^{-3}M concentration while in the case of others of the order of 10^{-5}M is quite sufficient. The low value of the free energy is in conformity with the value that Ammonyx-200 is a weak cationic detergent. The greater number of cations is required to reverse the charge if cations have got low free energy of adsorption.

(d) Interfacial Tension Measurements in Presence of Cationic Detergents. Since interfacial tension has some bearing on the stability of emulsion, it was thought of interest to make some interfacial tension measurements also in the presence of cationic detergents on sodium alginate system. The interfacial tension studies were carried out in the presence of 0.01% KCl and 0.01% sodium alginate in aqueous phase. The cationic detergents used were LPC and CPB. The interfacial tension in dynes/cm is plotted against log molar concentration in Fig. 3.

From the figure it is obvious that the interfacial tension, at lower concentrations, does not change much but at higher concentrations the fall is rapid.

(e) Interaction Energy Curves, the Degrees of Aggregation and the van der Waals Constant of the Emulsion Droplets. The interaction energies between two drops at different concentrations of Ammonyx-200, LPC and CPB have been calculated with the help of corresponding zeta potentials. These energies, for $La(NO_3)_3$, are plotted against distance in Figs. 4 and 5 choosing as representative curves for sodium alginate and gum arabic systems. The relevant data for all the curves are presented in Table 3. From the table it is obvious that the energy barrier in each

case is very high, which obviated the possibility of occurrence of flocculation in the primary minima. The observed flocculation occuring in the system is only possible in secondary minimum. All the curves are levelled off after certain time indicating the flocculation in secondary minima. To indicate the nature of flocculation occurring in the systems, the monomers and dimers were counted at different intervals. The number of monomers are plotted against time and two representative set of curves for both the systems are shown in Figs. 6 and 7. Therefore, these secondary minima, which are of main importance, are depicted separately. These secondary minima are a few kT deep. These depths though sufficient for the occurrence of secondary minima flocculation are rather insufficient to explain the observed degrees of aggregation. This apparent discrepancy may be due to not choosing the correct (operating value) of A. Therefore, an indirect method of estimating A has been adopted. To estimate van der Waals constant of the system, the theoretical degrees of aggregation were calculated at dirrerent values of A at different concentration of the detergents. These observed degrees of aggregation were interpolated in the theoretical curves, as shown in Figs. 8 and 9, and

the corresponding values of A obtained are tabulated in Table 4.

The theoretical and experimental degrees of aggregation were calculated similarly as mentioned before. The van der Waals constants for sodium alginate and gum arabic systems are 3.0×10^{-13} erg and 2.6×10^{-13} erg respectively. The van der Waals constant of petroleum ether differs from the theoretical value (6.7×10^{-14} erg) of A, probably because of the difference between adsorption of an emulsifier and that of detergent.[22] The secondary minima are plotted with the revised value of A, which are sufficiently deep to warrant reversible flocculation (Figs. 10 and 11).

The authors wish to express the thanks to Professor B. N. Ghosh, Calcutta University for kindly allowing one of them to carry out microelectrophoresis and also to the authorities of C.S.I.R., New Delhi for kindly granting a fellowship to one of them (C.P.).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 1795—1799 (1969)

Role of Doped Lithium in Nickel Monoxide in the Formation of Higher Valency Nickel Oxides by Anodic Oxidation

Hiroshi YONEYAMA and Hideo TAMURA

Department of Chemical Technology, Faculty of Engineering, Osaka University, Yamadakami, Suita, Osaka

(Received September 27, 1968)

The anodic oxidation and cathodic reduction behavior of a sintered body of lithiated nickel oxide were studied. The electrode with the higher Li content was more active than that with the lower Li content with regard to the electrochemical oxidation and reduction in the potential range between oxygen and hydrogen evolution. The quantity of the higher-valency nickel oxide having an apparent valence state of nickel ions from +8/3 to +4 formed by the anodic oxidation was estimated by measuring the quantity of electricity required for reducing it to −0.14V *vs.* SCE. This quantity is proportional to the Li content for electrodes containing more than 0.04 atom% of Li.

Lithium ions in the electrolyte have significant effects on the charge-discharge behavior of the nickel electrode in the Ni–Cd battery system;[1] for example, they increase the capacity and decrease the self-discharge. In battery systems the nickel electrode is usually prepared by "forming" nickel hydroxide, and the composition of this active mass is changed complicatedly by charge-discharge cycles.[2,3] Therefore, the role of the lithium in the behavior of the electrode during charge-discharge cycles has not yet been determined quantitatively. As, however, it has been proved that lithium ion enters into the active mass by repeated charge-discharge cycles,[3] the increase in the capacity of the electrode may be attributed to this phenomena. We have studied the oxidation and reduction behavior of a nickel monoxide electrode containing a fixed amount of lithium ions in order to clarify the relation between the lithium content and the quantity of the higher valency nickel oxides formed by anodic oxidation.

Experimental

Chemicals. All the chemicals used in this study were of a guaranteed reagent grade.

Preparation of Samples. Nickel monoxide was prepared from $Ni(NO_3)\cdot 6H_2O$ by heating it at 600°C for 4 hr in the air. NiO powder thus prepared contained the following impurities; Zn: 140, Ca: 330, Mg: 2750, Pb: 80, Cu: 920, Cr: 60, Mn: 190, Al, Si, Fe, trace (the contents are represented in ppm). This powder was mixed with a known amount of a Li_2CO_3 solution in acetic acid. After having been mixed for about 30 min with a magnetic stirrer, they were evaporated to dryness and then heated again at 600°C for a few hour in the air. The powder was formed into a tablet at 1.5 t/cm^2 (10 mm dia. 3—5 mm thick) and this tablet was sintered at 1200°C for 4 hr covered with a

thick-layer of the same powder to prevent the Li from evaporating. After sintering, platinum contacts on the end faces of the tablet were made by firing platinum powder pasted on them at 1250°C by the procedure used in the sintering.

Specific Resistivity of the Sample. The specific resistivity of the sample pieces ρ was estimated from the voltage drop V between the platinum contacts, the surface area S and the thickness L of the sample, according to the $V/I=\rho \cdot S/L$ relation, where I is the current passed through the contacts.

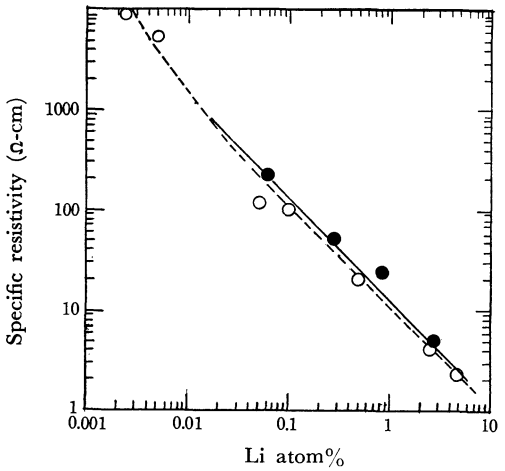

Fig. 1. Relation between Li content and resistivity at 25°C.
-●- this studies, --○-- by Verway *et al.*[4]

Li Content. The samples which were not used in the following experiments were dissolved in hot concentrated HNO_3 and the Ni was removed as nickel dimethyl glyoxim. The quantity of Li in the filtrate was measured by spectrophotometry. The relations between the resistivity and Li content in the samples were very similar to the results obtained by Verway *et al.*,[4] as is shown in Fig. 1. From these results, the Li contents of the samples used in this study were estimated from the results of the measurement of the resistivity. The resistivities and Li contents of the test electrodes are shown in Table 1.

TABLE 1. THE SAMPLES USED AS TEST ELECTRODE

Notation of electrode	A	B	C	D	E
Resistivity at 25°C (Ω-cm)	5.6	40	66	400	1800
Li content (atom %)	2.6	0.30	0.21	0.04	0.009

Cell Equipment. Before carrying out the experiment in a cell equipment, one side of the platinum contacts was erased and polished with emery papers. As these samples had a porosity of 3—10%, they were impregnated with a benzene solution of polystylene under a vacuum and then evaporated to dryness. This procedure was repeated a few times, and then the surface of the sample was slightly polished with 1000-mesh emery paper. The sample was then mounted in a glass tube with epoxy resin and used as the test electrode. Before the electrode behavior was examined, the resistance of this electrode was measured in 6N KOH by means of the impedance bridge and the effective electrode area was estimated, by the same procedure as was used in estimating the specific resistivity, assuming that the thickness of the sample piece used as the electrode was equal to an unmounted one. After being dipped in concentrated HNO_3 and then washed with de-ionized water, the electrode was placed in a conventional cell. The cell was sealed with a rubber stopper with a gas inlet and outlet. The counter electrode was a platinized platinum plate. All the measurements were carried out at 25°C in a nitrogen atmosphere and with the light shielded. The electrolyte was 0.1N NaOH.

Measurement of the Anodic-cathodic Behavior. The electrode potential was measured against the SCE. In the cathodic reduction 100 μA/cm^2 was usually chosen, while in anodic oxidation various current densities, ranging from 100 μA/cm^2 to 10 mA/cm^2 were chosen. The oxidation-reduction cycles at each electrode did not exceed 10 in this study.

Result

Figure 2 shows the electrode potential behavior of the A and the C electrodes when they were anodically oxidized immediately after the cathodic reduction in which their potential had attained that of hydrogen evolution. On the other hand, when they were cathodically reduced immediatly after the anodic oxidation for 5 min under a fixed current density, the electrode potential was gradually changed, as is shown in Fig. 3. The phase-transition potential calculated thermodynamically is also shown in these figures (the phase transition from Ni_3O_4 to $Ni(OH)_2$ or the inverse is indicated Ni_3O_4-$Ni(OH)_2$, while another transition is also indicated in a similar fashion). As these results show, if the electrode was oxidized until its potential

4) E. J. W. Verway, P. W. Haaijman, F. C. Romeijn and G. W. van Osterhout, *Philips Res. Rept.*, **5**, 173 (1950).

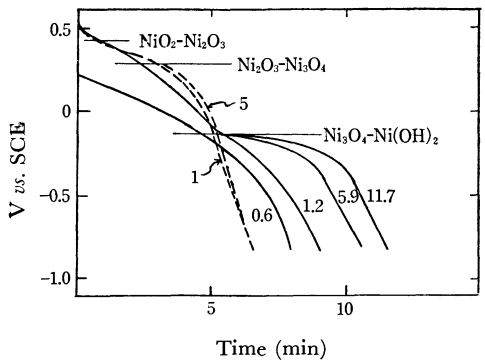

Fig. 3. Electrode potential during reduction of constant current immediatly after anodic oxidation for 5 min.
Solid line: 5.6 Ω-cm, reduction current density 590 μA/cm^2. Dotted line: 66 Ω-cm, reduction current density 200 μA/cm^2. The numbers in the figure represent current density of anodic oxidation (mA/cm^2).

was reached in the flat region, the behavior of the electrode potential during the cathodic reduction to −0.14 V was not influenced by the current density of anodic oxidation. At the A electrode (5.6Ω-cm), however, a stagnation of the potential change, indicating transformation from Ni_3O_4 to $Ni(OH)_2$[5] was observed, and its length was influenced by the anodic-oxidation-current density. This was not observed in the C electrode (66Ω-cm). These facts show that the nickel monoxide electrode, which contains a large amount of Li, has a tendency to undergo composition change more easily. The length of the stagnation of the potential change above mentioned was also influenced by the repeating cycles especially when a high current density was used in the oxidation. Therefore, in the following experiments, we studied the electrode behavior in the potential region above −0.14 V.

Figure 4 shows the potential behavior of four electrode, A (5.6Ω-cm), B (40Ω-cm), D (400Ω-cm), and E (1800Ω-cm), when they were oxidized at 100 μA/cm^2 and 1 mA/cm^2 after they had been reduced to −0.14 V. The potential rise is much faster in the electrode containing less Li, and at current densities above 1 mA/cm^2 the electrode potential reaches the flat region within 5 min. When the electrode whose potential lay in the flat region as a result of anodic oxidation was reduced mainly at 100 μA/cm^2, the quantity of electricity Q required for reduction to −0.14 V was constant for each electrode, regardless of the current density of the anodic oxidation and oxidation-reduction cycles. For example, the results obtained at the A (5.6 Ω-cm) and D (400 Ω-cm) electrodes are as shown in Table 2 while the potential

behavior of each electrode during reduction to −0.14 V is as shown in Fig. 5. When the electrodes were open-circuited after oxidation up to the oxygen evolution, the potentials of these electrode gradually fell, as Fig. 6 shows. On the other hand, when the electrodes were reduced to −0.14 V at 100 μA/cm^2, a build-up of the potential was observed after the reduction current had been interrupted at various potentials between that of oxygen evolution and −0.14 V, though at the A electrode it did not appear clearly. Even with this electrode, however, this phenomenon was observed distinctly when the reduction-current density was 10 mA/cm^2. When the reduction current was interrupted at a potential below −0.14 V, the build-up of potential was observed distinctly and the potential of the electrode easily reached −0.14 V or more, as is shown in Fig. 7.

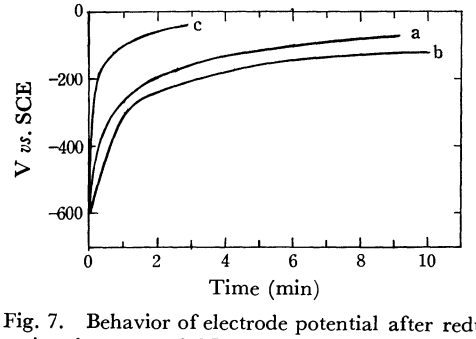

Fig. 7. Behavior of electrode potential after reduction down to −0.6 V *vs.* SCE under the reduction current density (mA/cm^2).

Discussion

The quantity of electricity Q obtained by reducing the electrode to −0.14 V is calculated to be 10—200 mC/cm^2, depending on the Li content in the electrode. Q is nearly equivalent to the quantity of the higher-valency nickel oxides, with the apparent valence state of nickel ions ranging from +8/3 to +4.

Taking the specific gravity of NiO as 6.66, the number of Ni ions per sq. cm of the NiO electrode surface is calculated to be 1.4×10^{15}/cm^2. Although the specific gravity may be changed by doping the Li, it could not be changed greatly in this study because the electrode in this study contained only 2.6 atom% Li at most. Therefore, if it is supposed that 1.4×10^{15}/cm^2 divalent nickel ions exist on the electrode surface and that all of these ions are oxidized to the tetravalent, Q is calculated to be 0.3 mC/cm^2. By comparing this calculated Q value with the experimental Q value, the nickel ions participating in the electrochemical reaction amount to 30—600 times the value calculated, depending on the Li content. This suggests the depth of the NiO ion layer from the surface participating in the reaction at potentials above −0.14 V. However, by considering the error introduced in the estimation of the specific resistivity, the true electrode area must be much larger than the apparent area, hence, the reaction is limited in the thinner surface layer of the electrode.

When NiO is oxidized electrochemically, oxygen ions enter into the NiO lattice. As the NiO electrode was confirmed to be well crystallized by X-ray diffraction, the transfer of oxygen ions into the interior of the NiO crystal may be difficult. Considering the fact that Q is constant regardless of the oxidation conditions, the formation of higher-valency oxides with apparent valence states from +8/3 to +4 is limited by some factor related to the crystal structure rather than with the rate of the diffusion of oxygen ions. This is also suggested by the results shown in Fig 3. In this figure the plateau showing a transition from Ni_3O_4 to $Ni(OH)_2$ appears at the A electrode in proportion to the current density of anodic oxidation, though the potential behavior is coincident at higher potentials. This phenomenon may indicate that oxygen ions are transfered into the NiO lattice in proportion to the electric field across the electrode in such a way that one oxygen ion is arranged into three ion pairs of Ni^{2+} and O^{2-} after the formation of the higher-valency oxides with apparent valence states of nickel ions from +8/3 to +4. Probably this structure would be energetically most stable.

Nickel hydrate is probably formed at potentials above −0.14 V, and $Ni(OH)_2$ is formed below this potential while reducing the electrode. The former can not be produced in a quantity more than the equivalent of Q, the formation of the latter is also considered to be poor, for the potential of the electrode easily fell to that of the hydrogen evolution and the recovery of the electrode potential after interrupting the reduction current at potentials lower than −0.14 V was quick as is shown in

Fig. 7. The difficulty of the formation of $Ni(OH)_2$ may be due to the same reason as in the formation of the higher-valency oxides; that is, in this case the transfer of H_2O into the NiO lattice is apparently necessary to convert NiO to $Ni(OH)_2$, and this is probably difficult. Therefore, it is probable that Ni_3O_4 was reduced to NiO on the plateau of the potential showing the conversion of Ni_3O_4 to $Ni(OH)_2$ in Fig. 3.[6]

On the basis of the finding that Q was constant on each electrode, almost all of the protons in nickel hydrate or $Ni(OH)_2$ were considered to be possibly transferred into the electrolyte when the electrode was oxidized under the experimental conditions. This is probable because the hydrate or hydroxide layer was very thin, if it was present at all.

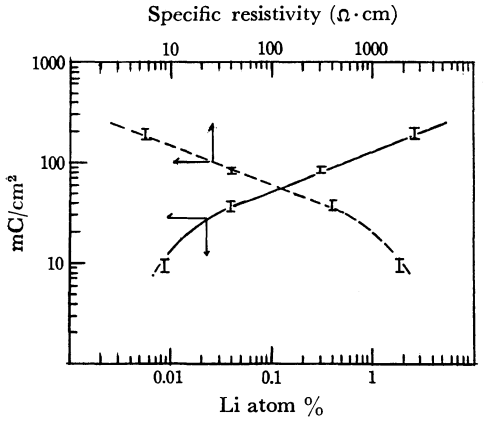

Fig. 8. Plot of Q against Li content and resistivity of the electrode.

The Q values at each electrode are plotted against the resistivity of the electrode and the Li content in Fig. 8. In the case of Li contents more than 0.04 atom%, the following relationship exists between Q and the Li content C in NiO, if allowance is made for the accuracy of Q being within ±5%.

$$\log Q = 0.40 \log C + 2.14$$

where Q is shown in mC/cm^2 and C, in atom%.

In the reduction period, diffusion of ions in the electrode-surface region is slow, especially at low Li contents, hence, Q does not indicate correctly the quantity of the higher-valency oxides with the apparent valence states of nickel ions from +8/3 to +4, especially at electrodes of low Li contents. In order to make Q exactly equivalent to the quantity of the higher valency oxides in question, the lower current density must be adopted, but if this is done the error based on self-discharge, shown in Fig. 6 will be introduced. The departure of Q at the E electrode from the above relation may be related to the error introduced by the slowness of the diffusion of ions.[7]

When Li is doped in NiO, the divalent nickel ions equal to the amount of doped Li are converted to the trivalent state. Therefore, whether Q is large or small supposedly depends on the amount of trivalent nickel ions in monoxide.

6) The potential of the transition from Ni_3O_4 to NiO is −0.142 V *vs.* SCE.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 1800—1806 (1969)

A Kinetic Study on the Homogeneous Liquid-phase Oxidation of Cumene in the Presence of Triphenylsulfonium Chloride

Katsutoshi OHKUBO, Tokio YAMABE and Kenichi FUKUI

Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received September 28, 1968)

A kinetic study of the homogeneous liquid-phase oxidation of cumene was carried out in order to clarify the characteristic behavior of triphenylsulfonium chloride as an autoxidation catalyst. The reaction proceeded with no incubation period. The experimental dependence of the rate upon catalyst and hydrocarbon concentrations and also upon the oxygen pressure was reproduced with a good analytic fit by the following equation:

$$r=k'(\mathrm{RH})^{1.27}(\mathrm{O_2})^{0.68}(\mathrm{Cat.})_0\ (e^{-at}-e^{-bt})$$ (a, b, and k' are constants).

A reaction mechanism was proposed to derive the rate equation. It seems likely from this scheme that sulfonium chloride activates molecular oxygen by means of a reversible molecular association with it.

It is well known that some transition metal compounds and some halogen compounds are effective catalysts for the liquid-phase reactions of hydrocarbons with molecular oxygen. Recently, several onium compounds, in particular sulfonium and phosphonium salts, have been found to accelerate this type of oxidation. In view of the distinguishing character[1] of the behavior of these compounds as autoxidation catalysts, a kinetic study appeared significant. In the present paper, a kinetic study of cumene oxidation catalyzed by triphenylsulfonium chloride will be reported.

The kinetic study was carried out with particular reference to the initial short reaction time. In this initial range, the decomposition of cumene hydroperoxide, which would give free radicals, was disregarded since the concentration of hydroperoxide was very low, and the product was accumulated as hydroperoxide. The dependency of the initial rate upon the catalyst and hydrocarbon concentrations, and also upon the oxygen pressure, was determined. A tentative reaction mechanism will be proposed. The stationary-state method was employed to solve kinetic equations describing the mechanism. The experimental results can be well interpreted by the proposed mechanism, in which the behavior of the sulfonium catalyst is characterized in terms of forming a complex with molecular oxygen.

Experimental

Measurement of Oxygen Absorption. The course of oxidation reaction was followed by measuring the volume changes of the oxygen absorbed; the volume was observed every minute in the initial stage of the reaction and every ten minutes thereafter.

The reaction apparatus used the one described in an earlier report.[2]

The reaction vessel was thermostatically controlled in an oil bath; the temperature range was kept constant within ± 0.05°C, and the speed of stirring was regulated at more than 500 rpm/min. The rate of oxygen absorption was found to be independent of the stirring frequency in the above range.

Preparation of Catalyst. Equimolar quantities of phenylmagnesium bromide and diphenylsulfoxide were refluxed in benzene for 48 hr to form a precipitate of triphenylsulfoxymagnesium bromide. The precipitate was triturated with 20% tetrafluoroboric acid, and the resulting crystal of triphenylsulfonium tetrafluoroborate was recrystallized from chloroform and ether to give pure colorless crystals which melted at 192—193°C. An equimolar mixture of triphenylsulfonium tetrafluoroborate and potassium chloride was kept standing for a day in ethyl alcohol. The potassium tetrafluoroborate was then filtered off and the filtrate was removed to afford colorless needles of triphenylsulfonium chloride melting at 297—298°C (recrystallized from chloroform and ether).

Found: Cl, 11.6%. Calcd for $C_{18}H_{15}SCl$: Cl, 11.9%.

Oxidation Procedure. Homogeneous solutions of triphenylsulfonium chloride in cumene were prepared in a nitrogen atmosphere. Each ten-milliliter portion of the solution contained 3.35×10^{-4}, 1.68×10^{-4}, and 0.84×10^{-4} mol/l of the catalyst; these solutions were taken as the samples of the oxidation reaction. Oxidation was carried out at the temperatures of 50, 65, 70, and 80°C, and the rates of oxygen absorption were studied by graphical differentiation of the absorption curves of oxygen. The reaction rate was regarded as

1) K. Fukui, K. Ohkubo and T. Yamabe, This Bulletin, **42**, 312 (1969).

2) K. Fukui, K. Kanai, T. Takezono and H. Kitano, *Kogyo Kagaku Zasshi* (*J. Chem. Soc. Japan, Ind. Chem. Sect.*), **67**, 1131 (1964).

corresponding to that of the formation of cumene hydroperoxide, since the moles of oxygen absorbed were equal to those of the hydroperoxide formed in the initial step of the oxidation.

Result

Oxygen Absorption and Reaction Rate. The oxygen absorption of cumene was remarkably accelerated with a sulfonium catalyst. The reaction rate reached a maximum soon after the start of the reaction, without any appreciable incubation period, and then it gradually decreased. The lowering of the temperature decreased the maximum rate and delayed the time of reaching it. A typical curve of oxygen absorption is indicated in Fig. 1, while that of the initial range in particular is shown in Fig. 2. Figure 3 shows the rate curves indicating the characteristic feature[1] of sulfonium catalysts in accelerating the oxygen absorption at the initial step. The variation of the rate (r: $mol^{-1}l^{-1}\,sec^{-1}$) with the reaction time was analyzed from these curves; it can apparently be represented by the equation:

$$r = k(e^{-at} - e^{-bt}),\ (b>a) \qquad (1)$$

where k ($mol\,l^{-1}\,sec^{-1}$), a (sec^{-1}), and b (sec^{-1}) are constants and where t (sec) is the reaction time. In Fig. 4 the curves calculated from Eq. (1) by the use of the most fitting values of a, b, and k are presented by broken lines. The values of a, b and k are summarized in Table 1. From Table 1 it can be found that the a and b constants are not much influenced by the catalyst concentration, while k is linearly dependent upon the catalyst

	0.84×10^{-4}	2.20	7.04	1.55

concentration, as will be discussed in the next paragraph.

The Variation in the Rate with the Catalyst Concentration. The effect of the catalyst on the rate of oxygen absorption was studied by the varying catalyst concentrations to 3.35×10^{-4}, 1.68×10^{-4}, and 0.84×10^{-4} mol/l. Figure 5 shows the log k *versus* log (Cat.)$_0$ plot, where (Cat.)$_0$ denotes the initial concentration of the catalyst; the plot is a straight line with a slope equal to about 1.0. The linear relation is expressed as follows: $k\propto(\text{Cat.})_0^{0.940}$ at 50°C, $k\propto(\text{Cat.})_0^{0.952}$ at 70°C, and $k\propto(\text{Cat.})_0^{0.803}$ at 80°C. From these results, the dependency of k upon (Cat.)$_0$ can be represented, at least at lower temperatures, as follows:

$$k\propto(\text{Cat.})_0 \qquad (2)$$

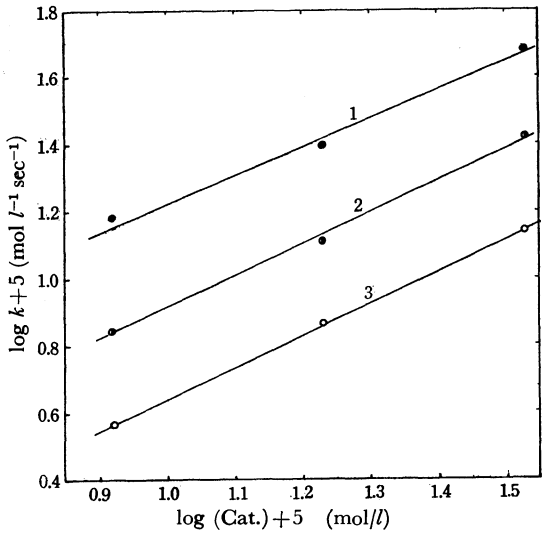

Fig. 5. The dependency of the constant, k, upon (Cat.).
-●- : at 80°C, -◑- : at 70°C, -○- : at 50°C

The Variation in the Rate with the Hydrocarbon Concentration. In order to investigate the rate dependency upon the hydrocarbon concentration, (RH), the oxidation of cumene (6.75, 6.31, 6.12, 5.03, and 3.80 mol/l) using chlorobenzene as the diluent was carried out under atmospheric pressure at 65°C in the presence of 3.35×10^{-4} mol/l of the catalyst. Figure 6 indicates the oxygen

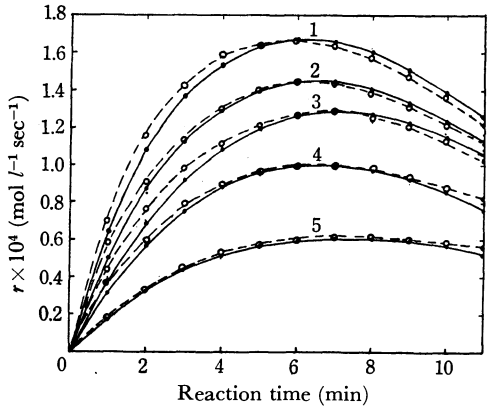

Fig. 6. Rate curves of oxygen absorption with varing concentration of cumene.

absorption rate at various hydrocarbon concentrations and shows a plot of the oxygen absorption rate against the reaction time. The most suitable values of a, b and k are listed in Table 2. Table 2

TABLE 2. THE VARIATION IN a, b AND k VALUES WITH THE HYDROCARBON CONCENTRATION

Initial hydrocarbon concentration (mol/l)	$a\times10^3$ (sec^{-1})	$b\times10^3$ (sec^{-1})	$k\times10^4$ (mol l^{-1} sec^{-1})
6.75	1.24	5.06	3.31
6.31	1.23	4.81	3.05
6.12	1.21	4.65	2.80
5.03	1.17	4.05	2.30
3.80	1.12	3.40	1.59

suggests that the a and b constants, are slightly affected by the initial value of (RH). Figure 7 shows the plot of log k against log (RH). The slope of the straight line obtained is 1.27, giving the relationship:

$$k\propto(\text{RH})^{1.27} \qquad (3)$$

The Variation in the Rate with the Oxygen Pressure. Since the liquid phase concentration of dissolved oxygen is proportional to the oxygen concentration in the gas phase, designated as (O_2),

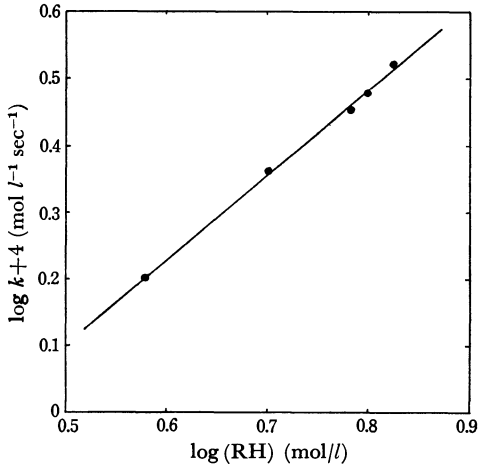

Fig. 7. The dependency of the constant, k, upon (RH) at 65°C.

the latter variable was adopted in place of the former. At a fixed cumene concentration (6.75 mol/l) and a constant temperature (65°C) in the presence of 3.35×10^{-4} mol/l of the catalyst, mixtures of oxygen and nitrogen were used for examining the effect of the oxygen concentration. Figure 8 indicates the influence of the oxygen concentration upon the rate of oxygen absorption in the initial stage of the reaction. The values of the constants (a, b and k) fitting the initial rates are listed in

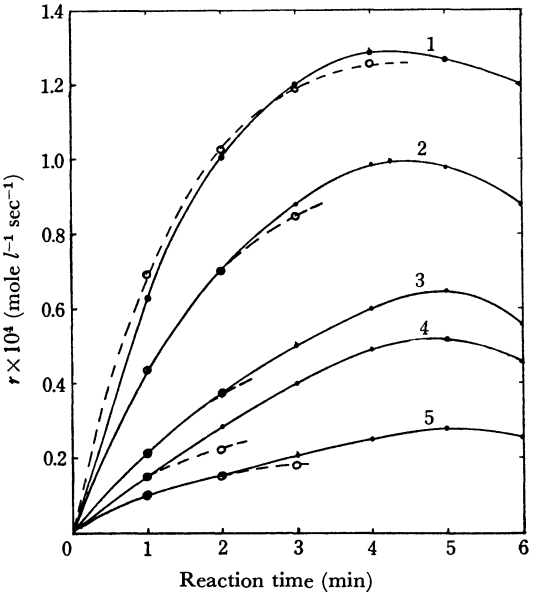

Fig. 8. Rate curves of oxygen absorption in variation with oxygen concentration

5: 0.211×10^{-2} mol/l
Broken lines at initial step are derived from Eq. (1) with specific values of a, b and k (in Table 3).

Table 3. The variation in a, b and k values with the oxygen concentration

Initial oxygen concentration (mol/l)	$a\times10^3$ (sec^{-1})	$b\times10^3$ (sec^{-1})	$k\times10^4$ (mol l^{-1} sec^{-1})
4.22×10^{-2}	1.25	10.0	1.89
2.11×10^{-2}	1.34	7.75	1.53
0.603×10^{-2}	1.36	6.60	0.793
0.422×10^{-2}	1.38	6.62	0.565
0.211×10^{-2}	1.47	6.33	0.388

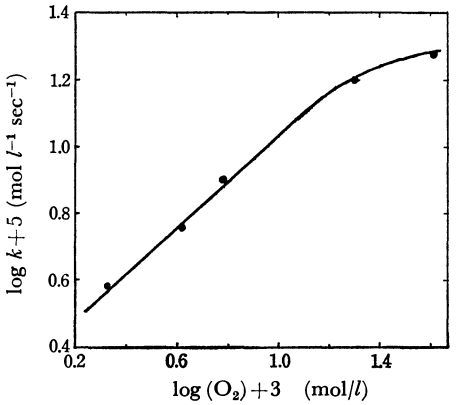

Fig. 9. The dependency of the constant, k, upon (O_2) at 65°C.

Table 3; a and b are influenced by the initial value of (O_2). Figure 9 shows the shape of the log k *versus* log (O_2) curve. The initial part of the curve is a straight line with a slope of 0.68, so that we have:

$$k\propto(O_2)^{0.68} \tag{4}$$

From Eq., (2), (3) and (4), the dependency of k upon $(Cat.)_0$, (RH) and (O_2) can be represented by:

$$k\propto(RH)^{1.27}(O_2)^{0.68}(Cat.)_0 \tag{5}$$

The rate shown in Eq. (1) may then be rewritten by the following expression:

$$r=k'(RH)^{1.27}(O_2)^{0.68}(Cat.)_0(e^{-at}-e^{-bt}) \tag{6}$$

where k' is a constant which is dependent upon neither the hydrocarbon nor oxygen concentrations, nor upon the catalyst concentration.

The Variation in the Rate with the Reaction Temperature. The reaction was studied in the temperature range from 50 to 80°C by the use of catalysts in the amounts of 3.35×10^{-4}, 1.68×10^{-4}, and 0.84×10^{-4} mol/l. Figure 10 shows the Arrhenius plots. The overall energy of activation of this process comes out to be $E_{overall}$=5.25—6.15 kcal/mol from the temperature dependence of the overall velocity constant (k).

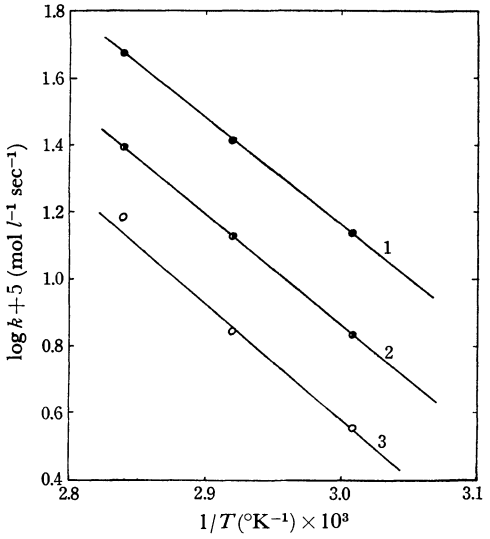

Fig. 10. Arrhenius plots of $\log k$ against $1/T$.
(1): 3.35×10^{-4} mol/l of $(C_6H_5)_3SCl$
(2): 1.68×10^{-4} mol/l of $(C_6H_5)_3SCl$
(3): 0.84×10^{-4} mol/l of $(C_6H_5)_3SCl$

It should be stressed here that, in this kinetic study, triphenylsulfonium chloride could not act as a radical source, as was discussed in a previous report.[1] Neither chloride compounds, such as alkyl chloride and hydrogen chloride, nor decomposed fragments of such catalysts as benzene, chlorobenzene, sulfide, and sulfoxide were detected.

In addition, the catalytic action of sulfonium chloride was not based mainly upon the chloride anion. This will be discussed in detail in a subsequent paper.

Discussion

The main purpose of this kinetic study was to clarify the features of the catalytic action of the sulfonium compounds. The analysis of the experimental results so far obtained would make it possible to build a tentative reaction mechanism. The nature of the reaction is most probably radical and not ionic, for the reaction is stopped by a radical inhibitor such as phenol. A "complex" formation between the catalyst and the oxygen molecule has been suggested in a previous paper;[1] such a formation would be capable of hydrogen abstraction from hydrocarbon molecules. It is worth summing up here the important experimental results:

a) The activity of the catalyst is characterized in the initial stage, in which the oxygen absorption occurs essentially with no incubation period. b) The shape of the rate curves expressed in Figs. 3, 4 and 5 suggests the involvement of a catalyst deactivation. c) The value of the overall energy of activation is relatively small. This may indicate radical reaction caused by catalytic hydrogen abstraction by the "complex."

The experimental results, then, lead to the following reaction scheme. The first step consists of the formation of a complex between the catalyst $(Cat.)_0$ and the oxygen molecule (discussed in detail in a previous report[1]):

$$Cat. + O_2 \underset{k'_c}{\overset{k_c}{\rightleftarrows}} Cat.\cdots O_2 \qquad (7a)$$

Such a complex then abstracts an active hydrogen from hydrocarbon (RH) to produce an alkyl radical (R·):

$$Cat.\cdots O_2 + RH \xrightarrow{k_1} R\cdot + Cat. + \cdot O_2H \qquad (7b)$$

followed by the usual propagation steps:

$$R\cdot + O_2 \xrightarrow{k_p} RO_2\cdot \qquad (7c)$$

$$RO_2\cdot + RH \xrightarrow{k_2} ROOH + R\cdot \qquad (7d)$$

The termination step may be described by the following scheme:

$$RO_2\cdot \xrightarrow{k_t} \text{inactive products} \qquad (7e)$$

$$Cat. \xrightarrow{k_d} \text{inactive form} \qquad (7f)$$

Terminations of other types (R·+R· or R·+RO_2·) are negligible compared to the process of (7e) at oxygen pressures above 200 mm of mercury. The disappearance of RO_2· may be a first or second-order process. Here the first-order termination is assumed for mathematical convenience. The deactivation of the sulfonium catalyst (7f) is considered to be another important process in retarding the reaction. It may be caused partly by interaction with oxidation products such as hydroperoxide. In view of the fact that more than 70% of the catalyst is recovered from the reaction mixture by the use of larger amounts of catalyst, as was reported in the previous paper,[1] it is very likely that the "deactivation" is due to the masking action*1 of some reaction products.

According to the reaction scheme discussed above, the following differential equations are obtained:

$$d(Cat.)/dt = (k_1(RH) + k_c')(Cat.\cdots O_2) - (k_c(O_2) + k_d)(Cat.) \qquad (8a)$$

$$d(Cat.\cdots O_2)/dt = k_c(O_2)(Cat.) - (k_1(RH) + k_c')(Cat.\cdots O_2) \qquad (8b)$$

$$d(R\cdot)/dt = k_1(RH)(Cat.\cdots O_2) + k_2(RH)(RO_2\cdot) - k_p(O_2)(R\cdot) \qquad (8c)$$

$$d(RO_2\cdot)/dt = k_p(O_2)(R\cdot) - (k_2(RH) + k_t)(RO_2\cdot) \qquad (8d)$$

*1 This subject will be discussed in a subsequent paper.

$$d(ROOH)/dt = k_2(RH)(RO_2\cdot) \quad (8e)$$

Assuming the stationary-state for the concentrations of R· and RO_2·, the overall rate of oxygen absorption (r) can be represented by the equation:

$$r = \frac{k_1 k_2 (RH)^2}{k_t} (Cat.\cdots O_2) \quad (8f)$$

The time change of $(Cat.\cdots O_2)$ is controlled by Eqs. (8a) and (8b), which are solved simultaneously. The solution of $(Cat.\cdots O_2)$ is introduced into Eq. (8f), giving;

$$r = \frac{k_1 k_2 k_c (RH)^2 (O_2)(Cat.)_0}{k_t(\lambda_2 - \lambda_1)} (e^{-\lambda_1 t} - e^{-\lambda_2 t}) \quad (9)$$

where:

$$\lambda_1 = \frac{1}{2}\left\{k_c(O_2) + k_c' + k_1(RH) + k_d\right\} \times \left[1 - \sqrt{1 - \frac{4k_d(k_c' + k_1(RH))}{(k_c(O_2) + k_c' + k_1(RH) + k_d)^2}}\right] \quad (9a)$$

$$\lambda_2 = \frac{1}{2}\left\{k_c(O_2) + k_c' + k_1(RH) + k_d\right\} \times \left[1 + \sqrt{1 - \frac{4k_d(k_c' + k_1(RH))}{(k_c(O_2) + k_c' + k_1(RH) + k_d)^2}}\right] \quad (9b)$$

Here the oxygen and the hydrocarbon concentrations can be assumed to be unchanged, namely, to be equal to the initial value. Equation (9) is in accordance with Eq. (1), which is obtained experimentally, and is in qualitative agreement with the rate dependency upon (RH), (O_2) and $(Cat.)_0$ shown by Eq. (6). Therefore, the a, b and k constants are correspondingly represented by;

$$a = \lambda_1 \quad (10a)$$

$$b = \lambda_2 \quad (10b)$$

$$k = \frac{k_1 k_2 k_c (RH)^2 (O_2)(Cat.)_0}{k_t(\lambda_2 - \lambda_1)} \quad (10c)$$

From Eqs. (9a) and (9b) we obtain:

$$(\lambda_1)_{(RH)=0} = \frac{1}{2}\left\{k_c(O_2) + k_c' + k_d\right\} \times \left[1 - \sqrt{1 - \frac{4k_d k_c'}{(k_c(O_2) + k_c' + k_d)^2}}\right] \quad (11a)$$

$$(\lambda_2)_{(RH)=0} = \frac{1}{2}\left\{k_c(O_2) + k_c' + k_d\right\} \times \left[1 + \sqrt{1 - \frac{4k_d k_c'}{(k_c(O)_2 + k_c' + k_d)^2}}\right] \quad (11b)$$

where $(\lambda_1)_{(RH)=0}$ and $(\lambda_2)_{(RH)=0}$ are extreme values of λ_1 and λ_2 respectively when (RH) is extrapolated to zero.

From Eqs. (11a) and (11b), it follows that;

$$(\lambda_1)_{(RH)=0} + (\lambda_2)_{(RH)=0} = k_c(O_2) + k_c' + k_d \quad (12a)$$

$$(\lambda_2)_{(RH)=0} - (\lambda_1)_{(RH)=0} = \sqrt{(k_c(O_2) + k_c' + k_d)^2 - 4k_d k_c'} \quad (12b)$$

Similarly, we get;

$$(\lambda_1)_{(O_2)=0} = k_d \quad (12c)$$

$$(\lambda_2)_{(O_2)=0} = k_c' + k_1(RH) \quad (12d)$$

Figures 11 and 12 show the plots of the values of a and b against (RH) and (O_2) respectively, giving the following extrapolated values:

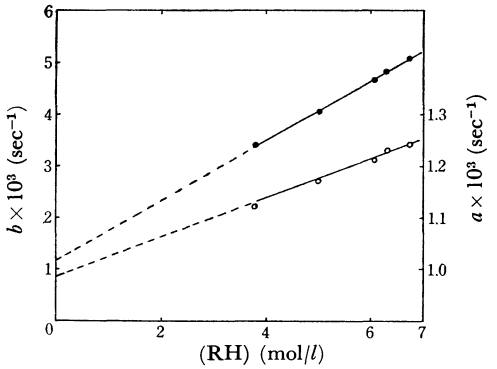

Fig. 11. The dependency of the constants, a and b upon (RH) at 65°C.
-●- : The plots of b against (RH)
-○- : The plots of a against (RH)

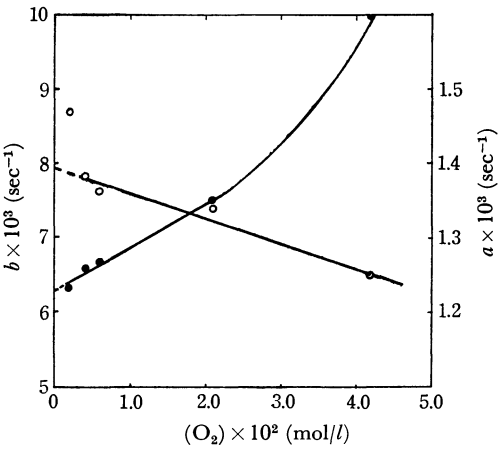

Fig. 12. The dependency of the constants, a and b, upon (O_2) at 65°C.
-●- : The plots of b against (O_2)
-○- : The plots of a against (O_2)

$$(\lambda_1)_{(RH)=0} = 0.95 \times 10^{-3}\ sec^{-1} \quad (13a)$$

$$(\lambda_2)_{(RH)=0} = 1.195 \times 10^{-3}\ sec^{-1} \quad (13b)$$

$$(\lambda_1)_{(O_2)=0} = 1.392 \times 10^{-3}\ sec^{-1} \quad (13c)$$

$$(\lambda_2)_{(O_2)=0} = 6.18 \times 10^{-3}\ sec^{-1} \quad (13d)$$

from Eqs. (12a—12d) and (13a—13d), the rate constants at 65°C can be determined to be as follows:

$k_c = 2.23 \times 10^{-2}$ mol^{-1}l sec^{-1}

$k_c(O_2) = 0.94 \times 10^{-3}$ sec^{-1}

$k_c' = 0.82 \times 10^{-3}$ sec^{-1}

$k_1 = 0.794 \times 10^{-3}$ mol^{-1}l sec^{-1}

$k_1(RH) = 5.36 \times 10^{-3}$ sec^{-1}

$k_d = 1.39 \times 10^{-3}$ sec^{-1}

From these rate constants and from the experimental values of k (shown in Table 2) under the conditions of $(O_2)=4.42 \times 10^{-2}$ mol/l and $(Cat.)_0=3.35 \times 10^{-4}$ mol/l, the value of k_2/k_t can be calculated by the use of Eq. (10c) as follows:

$$k_2/k_t = 1.79 \times 10^2 \text{ mol}^{-1}\, l$$

When this value is applied to Eq. (10c), the calculated values of k are consistent with the experimental values, as is shown in Fig. 13. These values

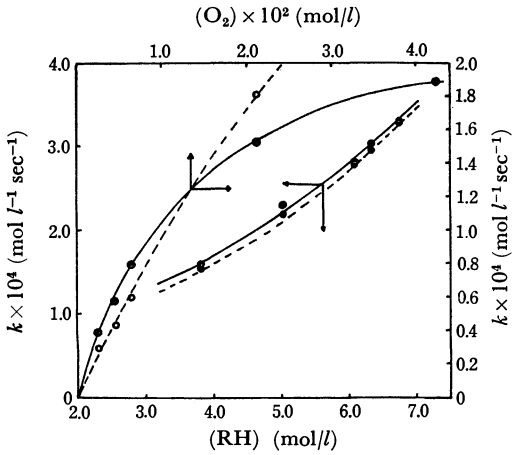

Fig. 13. The dependency of k upon (RH) and (O_2).
-◓- : k against (RH) from experimental result
-⊙- : k against (O_2) from experimental result
-●- : k against (RH) from Eq. (14a)
-○- : k against (O_2) from Eq. (14b)

of rate constants may supply the following information concerning the elementary processes involved:

a) In the case of atmospheric oxygen pressure, $k_c(O_2)$ and k_c' become comparable, so that the conversion is essentially reversible. Accordingly, the complex formations is more favored by a higher oxygen pressure.

b) The small value of k_1 implies that the hydrogen abstraction by the "complex" is a step limitting the overall rate.

c) Traylor reported[3] that the value of k_2 was nearly equal to 5.35×10^{-3} *2 mol^{-1} l sec^{-1} in cumene oxidation in the presence of t-butyl hydroperoxide at 60°C. If this value is applied to the present case, the value of k_t can be calculated to be 2.98×10^{-5} sec^{-1}. This value, small compared with k_d, indicates that the termination of peroxy-radical may not play an important role in retarding the rate. The deactivation of the catalyst may be caused by the oxidation products, such as hydroperoxide. This point will be discussed in detail in a subsequent paper.

Next, let us discuss the influence of (RH) and (O_2) upon the rate by the direct use of the values obtained above. The dependency of k upon (RH) is represented by;

$$k = \frac{4.47 \times 10^{-5}(RH)^2}{\sqrt{0.630(RH)^2 + 0.58(RH) + 5.39}} \qquad (14a)$$

under the conditions of $(Cat.)_0=3.35 \times 10^{-4}$ mol/l and $(O_2)=4.22 \times 10^{-2}$ mol/l. From a graphical fit of this expression, we also get the approximate representation;

$$k \simeq 4.47 \times 10^{-5}\,(RH)^{1.21} \text{ mol } l^{-1} \text{ sec}^{-1} \qquad (14a')$$

which reflects the experimental result of Eq. (3). Similarly, the dependency of k upon (O_2) at fixed concentrations of $(RH)=6.75$ mol/l and $(Cat.)_0=3.35 \times 10^{-4}$ mol/l can be shown as follows:

$$k = \frac{4.83 \times 10^{-3}(O_2)}{\sqrt{4.98(O_2)^2 + 3.37(O_2) + 0.229}} \qquad (14b)$$

It is obvious that such an equation can be a rough approximation of Eq. (4).

The present kinetic study afforded very favorable support to the idea, partly suggested in our previous report,[1] that the distinguishing feature of the catalyst behavior might involve a direct association with molecular oxygen, although the "complex" has not yet been isolated.

*2 The value of k_2 was converted in terms of above dimensions from the original value.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 1807—1812 (1969)

Freezing of the Droplets of Aqueous Solution Aerosols

Yuhei Uzu and Isamu Sano

Department of Chemistry, Nagoya University, Nagoya

(Received October 4, 1968)

By atomizing aqueous solutions both of electrolytes and non-electrolytes, fog droplets of 8μ in diameter were prepared, and their freezing temperatures were measured in a thermostat-like cold chamber fitted with an electrically heated platinum wire. The results were compared with that obtained with fog droplets of pure water of the same size. It was found that non-electrolytes hardly influence the freezing, whereas electrolytes do a great deal. The freezing temperature rises in the presence of an electrolyte and varies with its concentration, the highest temperatures being observed at the concentrations around 1×10^{-4}M for 1-1 type electrolytes and at lower concentrations for 1-2 and 1-3 type electrolytes. K^+ is the most effective of the alkali metal cations having the same species of anion in common, and I^- of the halide anions having the same species of cation in common. Applying the theory of nucleation, the sizes of the hydrated K^+ and the critical nucleus developed from it for ice-nucleation were estimated to be about 6 and 21 Å in radius, respectively.

The formation of ice in supercooled water is a phenomenon of great interest from the physicochemical point of view. Although some sort of coherent picture about it is now beginning to emerge, the theory seems to be far from complete and, in addition, experimental evidence is confusing. Since an investigation of the phenomenon of ice-formation provides information on the nucleation mechanism in supercooled liquids and in supersaturated solutions, much work has been done concerning the roles of insoluble and soluble substances in promoting ice-nucleation in water. It has been found for the former[1] that they would act as a catalyst. Their surface concentrates water molecules to accelerate the phase transition, mainly because of the similarity of the crystallographic structure to that of ice, and partly through the electric force fields that are ionic or non-ionic according to the nature of the constituent of surface, imperfections such as growth steps, re-entrant corners or screw dislocations.

It is questionable, however, whether soluble substances promote ice-nucleation; few reliable data are available and many of the conclusions reached are contradictory to one another. This might be attributed to the difference in the purity of the water and aqueous solutions and the characteristics of the experimental procedures.

This report deals with the effects of soluble substances, electrolytes and non-electrolytes, upon the freezing temperature of a droplet of water, and shows, in the case of electrolytes, that the concentration and valence definitely affect the freezing temperature. Additional information is given about the functions of electrolyte ions in ice-nucleation in water.

Experimental Procedure and Results

The technique has been described in detail.[2,3] The fog droplets of water or aqueous solutions whose size is 8 μ in diameter were introduced into a thermostat-like cold chamber to be supercooled and the freezing temperature was determined by making use of a heated platinum wire as a detector

of the droplets frozen.

The principal features of the results, also mentioned in our reports,[2,3] are as follows. It was found for electrolytes that a maximum appears in the change in relative freezing temperature with concentration. Some of the results are given in Fig. 1, where $\Delta T_f = T_s - T_w$ is the threshold freezing temperature of solution droplets relative to that of water droplets. The subscript symbols s and w refer to solution and water, respectively. Similar results have been obtained with other electrolytes such as $MgSO_4$, $CuSO_4$, $ZnSO_4$, $(NH_4)_2SO_4$. The results for non-electrolytes are illustrated in Fig. 2. ΔT_f takes a small negative value or zero in the concentration range studied, only becoming appreciable at higher concentrations.

Comparison of the results shown in Figs. 1 and 2 suggests that the change in relative freezing temperature found in electrolyte solution droplets might be due to the presence of ions. For a detailed study, we made measurements for 1×10^{-4} molar aqueous solutions of various electrolytes. The results are summarized in Fig. 3, in which almost all points represent the average of several measurements. It is clear that, for the 1-1 type electrolytes having the same type of cation, the relative freezing temperature rises with the size of the anion, the highest being observed for I^- and the lowest for Cl^-. For those having the same type of anion, the highest is found for K^+ among all the halides studied.

Discussion

Two models as to the mechanism of freezing of the droplets of electrolyte solutions have been advanced lately.

1) Critical nuclei for ice-formation would be formed as the consequence of water molecules being attracted to electrolyte ions owing to their electric forces to be arranged around them in a fashion more or less similar to that in ice.

2) Critical nuclei would be insoluble particles which might have been either held tenaciously in water or introduced together with solute, and, in some cases those which might have been activated through reaction with solute.[4]

The results seem to be in line with model 1. Firstly, from the observation $\Delta T_f > 0$ for electrolytes, electrolyte ions could promote either the freezing of droplets by themselves or in cooperation with insoluble particles. Secondly, the finding that ΔT_f is nought in the case of non-electrolytes is evidence that ions alone can be active to effect ice-nucleation. This is supported by the fact that there is regularity, as shown in Fig. 3, in the relation between the relative freezing temperature and the cation radius. It should be added that insoluble particles, if present in water, might have little influence upon ice-nucleation. The reasons are: (1) ΔT_f might be positive in the case of non-electrolytes, if insoluble particles accelerated ice-nucleation. (2) Fogs were prepared with purified materials, such as water subjected to redistillation[2,3] and solutions filtered through 0.1 μ pore size millipore filter. (3) For the purpose of lessening the possibility of a droplet containing insoluble particles, droplets having the mean size as small as 8 μ in diameter were used. (4) To investigate the effect of insoluble particles, some measurements were conducted of the filtered water and 1×10^{-4} molar CdI_2 solutions, and also unfiltered ones. The freezing temperatures were found to be −29.0°C and −24.3°C for the former, and −28.5°C and −24.5°C for the latter.*1

From these considerations, we are led to the conclusion that the rise in relative freezing temperature is caused by electrolyte ions and not by insoluble

particles which may be present in the droplets. Assuming that the nuclei are electrolyte ions more or less hydrated to build a layer of ice structure, we shall apply the theory of nucleation to our findings.

Macroscopic quantities such as interfacial energy have been used in the theory. Their use in assemblies containing molecules numbering from a few score to several hundreds is questionable. However, the theory is in good accord with experiment.

Application of the Nucleation Theory. According to the theory,[5] J, the rate of ice-nucleation or the rate at which the critical nuclei acquire an additional molecule to reach a size from which they grow directly toward ice particles, is given by

$$J = (kT_s/h)n \cdot 4\pi r^{*2} \exp\{-(\Delta G^* + \Delta g)/kT_s\}, \quad (1)$$

where ΔG^* is the free energy of formation of the critical nuclei or the maximum free energy necessary for their creation, Δg the free energy of activation of water molecules for self-diffusion in water or across the water-ice boundary, n the number of water molecules in contact with unit area of the surface of critical nuclei whose radius is r^*, k Boltzmann's constant and h Planck's constant.

It is apparent in Eq. (1) that the rate J is much more sensitive to the magnitudes of ΔG^* and Δg in the exponential term as compared to the pre-exponential kinetic term, the magnitude of which is of the order of 10^{28} r^{*2} $\sec^{-1}$ in the case of supercooled water as n is approximately equal to 3×10^{-8} n_0, where n_0 represents the density of water expressed in number of molecules per cm^3.

ΔG^* may be expressed as

$$\Delta G^* = (4\pi/3)(r^{*3} - r_h^3)\Delta G_v + \Delta E_{st} + 4\pi(r^{*2} - r_h^2)\sigma + \Delta E_{el}, \quad (2)$$

r_h being the radius of ions in hydrated state. ΔG_v means the change in free energy per unit volume of ice accompanying the phase transition from water to ice, ΔE_{st} the change in strain energy coming from water molecules fixed to form ice around the hydrated ions, σ the interfacial energy per unit area between the two phases, and ΔE_{el} the change in electrical energy of water molecules when they are subjected to phase transition.

Little is known about the strain energy ΔE_{st}. However, according to the structural models of liquid water, proposed theoretically by Bernal and Fowler,[6] Frenkel[7] and Frank and Wen-Yang Wen,[8] and confirmed experimentally by Dorsch and Boyd,[9] liquid water supercooled to temperatures below 4°C consists, with increasing degree of supercooling, of increasing number of molecules which constitute a structure closely resembling the structure of tridymite type ice, it follows that ΔE_{st} could be neglected.

Realizing that the hydration number of ion is 6 for K^+ and for I^-, it is difficult to imagine a surface for hydration layer. Thus the interfacial energy term, $4\pi r_h^2\sigma$ might be neglected.

For monovalent ion, the electrical energy change ΔE_{el} is calculated to be

$$\Delta E_{el} = (e^2/2D_s)(1/r_h - 1/r^*) + (e^2/2D_l) \times (1/r^* - 1/R) - (e^2/2D_l)(1/r_h - 1/R). \quad (3)$$

It is assumed herewith that there are two successive layers of water molecules around a hydrated ion. Regarding the inner layer as ice and the outer as liquid, the electrical energy which would be held by a single layer of water molecules if it were wholly in liquid state, is subtracted from the electrical energy of two layers. In this equation, D_s is the dielectric constant of the inner layer having a thickness, $r^* - r_h$, D_l the dielectric constant of the outer layer extending to the surface of the droplet with radius R and the electronic charge e. Since $R \gg r^* > r_h$, ΔE_{el} can be written in a simplified form

$$\Delta E_{el} = (e^2/2)(1/D_s - 1/D_l)(1/r_h - 1/r^*). \quad (4)$$

It is thus possible to transform Eq. (2), to a first approximation, into

$$\Delta G^* = (4\pi/3)(r^{*3} - r_h^3)\Delta G_v + 4\pi r^{*2}\sigma + (e^2/2)(1/D_s - 1/D_l)(1/r_h - 1/r^*). \quad (5)$$

Δg was estimated by McDonald[10] to be nearly constant, the value being as small as about 4×10^{-13} erg/molecule in a limited range of temperature below 0°C.

We have found that potassium iodide is most active. Thus for K^+, both r^* the size as critical nucleus and r_h the size in hydrated state were estimated by virtue of Eqs. (1) and (5).

Calculation of r^* and r_h of K^+. For this purpose, we require the relations

$$\partial \ln J/\partial r^* = 0, \qquad \partial \ln J/\partial r_h = 0. \tag{6}$$

Denoting by ΔS_v the entropy of fusion per unit volume of ice at 273°K and by $\Delta T_s(=273-T_s)$ the degree of supercooling, it follows through thermodynamical arguments that $\Delta G_v = -\Delta S_v \cdot \Delta T_s$. ΔS_v is evaluated to be approximately 1.22×10^7 erg/°K·cm^3. Denoting by ΔH_∞ the heat of fusion per unit mass of bulk ice and by ΔH_r that corresponding to the nucleus ice of radius r^*, we have thermodynamically[10] $\Delta H_r = \Delta H_\infty - (2\sigma/\rho r^*)$, where ρ is the density of ice that could be regarded to be practically independent of temperature and size. It follows that

$$\Delta G_v = -\rho/273(\Delta H_\infty - 2\sigma/\rho r^*)\Delta T_s. \tag{7}$$

By substituting Eq. (7) into Eq. (5) and carrying out differentiation, regarding T_s and Δ_g as constant, we obtain

$$2kT_s/r^* + (4\pi/3)(\rho/273)\Delta T_s\{3r^{*2}(\Delta H_\infty - 2\sigma/\rho r^*) + (r^{*3} - r_h^3)(2\sigma/\rho r^{*2})\} - 8\pi r^*\sigma - (e^2/2)\,(1/D_s - 1/D_l)1/r^{*2} = 0, \tag{8}$$

$$(4\pi/3)(\rho/273)\Delta T_s(\Delta H_\infty - 2\sigma/\rho r^*)3r_h^2 - (e^2/2)\,(1/D_s - 1/D_l)1/r_h^2 = 0 \tag{9}$$

In order to calculate r^* and r_h of K^+ from Eqs. (8) and (9), we use the following data

$T_s = 253$°K,*2 $\Delta T_s = 20$°K, $\rho = 0.92$ g/cm^3, $\Delta H_\infty = 79.7$ cal/g, $\sigma = 22$ erg/cm^2,[11] $D_s = 3$, $D_l = 96$.

As has been stated, the concentration of the solution is of the order as low as 10^{-4} mol/l, so all the above values except those for ΔT_s and consequently T_s could be approximated by the characteristics of water. It should be mentioned that the value of D_l, 96, is obtained by extrapolation of the values at room temperature down to −20°C. The result is

$$r^* = 20.6 \text{ Å}, \qquad r_h = 6.1 \text{ Å}.$$

It is of interest examine how r^* and r_h vary with σ and D_l. Using the following approximate equations instead of Eqs. (8) and (9),

$$\partial \ln J/\partial r^* \simeq \partial \ln \Delta G^*/\partial r^* \simeq (4\pi/3)(\rho/273)\Delta T_s \times \{3r^{*2}\Delta H_\infty - (2\sigma/\rho)2r^*\} - 8r^*\pi\sigma - (e^2/2)\,(1/D_s - 1/D_l)1/r^{*2} = 0, \tag{10}$$

$$\partial \ln J/\partial r_h \simeq \partial \ln \Delta G^*/\partial r_h \simeq (4\pi/3)(\rho/273)\Delta T_s \times \Delta H_\infty 3r_h^2 - (e^2/2)(1/D_s - 1/D_l)1/r_h^2 = 0, \tag{11}$$

11) L. Dufour and R. Defay, "Thermodynamics of Clouds," Academic Press, New York (1963), p. 226.

*2 The freezing temperatures actually observed for the potassium iodide solution droplets were around −20°C.

Table 1. Variation of r^* and r_h as functions of D_l and σ

D_l	D_s	σ (dyne/cm)	r^* (Å)	r_h (Å)
96	3	24	22.6	6.0
4			22.5	4.3
96	3	22	20.7	6.0
4			20.6	4.3
96	3	20	18.9	6.0
4			18.7	4.3
96	3	18	17.1	6.0
4			16.9	4.3
96	3	22	20.6	6.1

we find the results as shown in Table 1. The values given in the lowest line are obtained by Eqs. (8) and (9). They are recorded in order to confirm the accuracy of Eqs. (10) and (11).

It is seen from the table that, while the value of r^* hardly changes with D_l, it is largely dependent upon σ, being in the range of 17 to 23 Å for all the probable magnitudes of σ and in close agreement with that for supercooled water at −20°C which is shown in Table 2[12] together with those at other temperatures. As regards r_h, it remains effectively constant irrespective of the variation in σ, changing with D_l within the range of 6 Å which is usually admitted as plausible.

Table 2. Radius of the critical nucleus for ice formation in a drop of pure water

Temperature (°C)	Radius of water drop (cm)	σ (dyne/cm)	Radius of critical nucleus (cm)
0	∞	23.8	∞
−10	∞	22.8	4.20×10^7
	10^{-6}	22.8	4.88
−20	∞	21.8	2.08
	10^{-6}	21.8	2.26
−30	∞	20.7$_5$	1.38
	10^{-6}	20.7$_5$	1.46
−40	∞	19.7	1.03
	10^{-6}	19.7	1.08

The calculated values of r^* and r_h are found to be of the right order of magnitude. Further, it is known that the thickness of the ionic atmosphere around K^+ in a solution of the concentration 1×10^{-4} mol/l is approximately 300 Å. This is much larger than the radius of the critical nucleus, 21 Å. Hence we might regard K^+ alone as the center of the ice nucleus. Thus, we have ignored the presence of I^- in the solution.

12) L. Dufour and R. Defay, "Thermodynamics of Clouds," Academic Press, New York (1963), p. 150, 176.

The Influence of K^+ on the Structure of Water. There are some factors of interest. One is that a potassium iodide containing water droplet freezes, as shown in Fig. 3, at a temperature about 10°C higher than that at which a potassium iodide not containing droplet of the same size freezes. This means that the critical nucleus in water which is supposed to be only of 14 Å in radius (Table 2) might make rapid development to 21 Å if potassium iodide is present at a concentration of the order of 10^{-4} mol/*l*. It has been observed that all the cations other than K^+ freeze at temperatures lower than that for K^+ (Fig. 3). This suggests their higher ΔG^* values.

In spite of many publications on the structure of liquid water as well as electrolyte solutions, no definite conclusion has been reached. However, utilizing the information obtained herewith, we are able to give additional interpretation.

It is certain that an electrolyte ion could, owing to its ability of fixing water molecules oriented around itself through its electric forces, exhibit a function to break the structure of water. The structure breaking function should depend, firstly, on the size of ion, and secondly, on the extent of misfit. Here we have introduced the misfit as a measure of the disparity between the water structure contiguous to an ion and the ice structure to be formed from it. This might help interpret the finding that T_s for cations smaller than K^+ falls down in the same way as for those larger than K^+ (Fig. 3), the misfit being taken to be greater for an ion differing more largely in size from a water molecule. Addtional reference must be made to the finding,[13] provided by the studies of electrolyte solutions using X-ray diffraction technique, that ions such as K^+, NH_4^+ and OH^- which are close in size to water molecules have virtually no influence upon the structure of water, whereas those such as Li^+, Na^+ and Cl^- the sizes of which are decisively different from water molecules exert a more or less positive disturbance to the water structure owing to their structure breaking function. Moreover, according to the studies[14] of the self-diffusion of water in electrolyte solutions, both Cs^+ and Li^+ are the structure breakers, and this is particularly the case with Cs^+. Water molecules in the vicinity of Cs^+ display a mobility higher than that characteristic of those in pure water, indicating that the water structure has been made unstable by the presence of an ion. In the case of Li^+, water molecules are bound to the ion, yielding hydration members which are in strained state and hardly display mobility.

We conclude that an ion, which could be included in the water structure with least influence upon it and which could attract water molecules by electric forces to arrange them at least in an ice-like structure, can establish a certain extent of order in supercooled water so that it serves as a critical nucleus in ice formation. As a matter of fact, we observed that the most effective ion is K^+.

The Role of I^- in Ice-nucleation. Hitherto, we have discussed the rise in freezing temperature of water droplets in the presence of electrolytes, taking the behavior of cations alone into consideration. It might now be asked what about anions. It has been shown in Fig. 3 that, for anions having a common cation, their ice nucleability increases with the size of anion in such a way as $I^- > Br^- > Cl^-$. These anions should possess weaker electric fields around them because of their larger size as compared to cations. This might imply that it is next to impossible for anions to fix water molecules so as to form a critical nucleus. The water molecules around anions are supposed to be in situations similar to those of the water molecules around Cs^+, the size of which is large enough to impart them large mobilities. It is therefore possible for an anion to make contribution to the function of a cation in that the former allows water molecules to be taken away by the latter.

Concerning the roles of anions, there are views[15,16] worthy of mention. Anions are mostly of considerable polarizability on account of their large size, so that they might affect the structure of the surface of a water droplet as well as the structure of the interface between solid ice and liquid water. Once favored with these positions, they would act to reduce the strain there, thus facilitating ice formation. The polarizability was taken to be in the order $I^- > Br^- > Cl^-$, which is in line with that for the nucleability.

Concluding Remarks

We have examined the influence of the electrolyte concentration upon the freezing temperature of water droplets, and have indicated some of the results in Fig. 1. On the basis of these results, we conclude that there exists an optimum in electrolyte concentration, at which the droplets freeze most readily to give the highest freezing temperature. The optimums have been determined to be 1×10^{-4} mol/*l* or thereabout for 1-1 type electrolytes and to be at lower concentrations for 1-2 and 1-3 type electrolytes, though it would be necessary to make more exact determinations by future measurements for the latter two. Similar reports have been presented by some investigators[15] with a number of electrolytes, in which little account has been taken of the function of ions, and the greater part of

discussion has been given assuming the presence of insoluble particles in water.

It would be significant to search for reasons for the occurrence of the optimum in freezing temperature. It seems to us that the decrease in freezing temperature on the higher concentration side arises from the structure of water being broken down by a large number of cations so that the nuclei could grow with considerable difficulty. The finding that the optimums for 1-2 and 1-3 type electrolytes appear at lower concentrations might be attributed to the presence of more cations in water as compared with the case of 1-1 type electrolytes having the same concentration.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 1812—1819 (1969)

Evaluation of the Activation Energies of Radical Substitution Reactions in the Gaseous Phase. I. An Empirical Method Employing the Morse Function

Tsutomu KAGIYA, Yūzō SUMIDA, Tokuji INOUE and Fridrich S. DYACHKOVSKII*1

Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received October 11, 1968)

An empirical evaluation of the activation energy has been carried out for the radical substitution reaction involving polyatomic molecules. The potential energy along the reaction path is assumed to be expressed for the initial and the final systems by the two Morse functions with the coefficient "a'," which is different from the "a" in the usual Morse function of the bond. The difference between the $a'\Delta r^*$ values in the Morse functions of the initial and the final systems in the transition state is empirically determined as a function, $a_f'\Delta r_f^* - a_i'\Delta r_i^* = \beta Q$, of the reaction heat, Q. From the Morse function with "a'" and the above relation, the activation energy is calculated by using the bond dissociation energies of the initial and the final molecules. The treatment proposed is useful for the evaluation of the activation energies of many types of radical substitution reactions.

Quantitative studies aimed at evaluating the activation energy of the radical substitution reaction in the gaseous phase have been carried out from the latter half of the 1930's. Since Polanyi[1] and Horiuchi[2] found that the difference in the activation energies in a homologous reaction decreased with an increase in the difference in the reaction heats, the activation energy has been considered in relation to the reaction heat. Bagdasaryan,[3] Tikhomirova-Voevodskii,[4] and Semenov[5] have accumulated a number of the experimental data; they have indicated that the activation energies are in regular correlation with the reaction heats. It has also been found[6] that, for the homologous reactions with a similar reaction heat, the activation energy is proportional to the bond dissociation energy of the initial bond.

On the other hand, the theoretical study of the evaluation of the activation energy of the radical reaction has been started by Eyring[7] and followed by Evans and Polanyi.[1]

In the reaction involving a polyatomic molecule, however, the Evans-Polanyi treatment is so complicated that it is very difficult to evaluate theoretically each energetic term along the reaction path.

We have extended the Morse bond-energy function to a polyatomic molecule, as reported by Ogg-Polanyi.[8] The potential energy along the reaction path has been assumed to be approximately expressed by the two functions of the initial and

the final systems. The coefficient "a'" is different from the "a" in the Morse function[9] of a bond in which the presence of a radical is disregarded. Moreover, the difference between the $a'\Delta r^*$ values in the Morse functions of the initial and the final systems in the transition state was found to be proportional to the reaction heat, where Δr^* is an expansion of a bond between the ground state and the transition state.

From the Morse function with the "a'" coefficient, the $a_f'\Delta r_f^* - a_i'\Delta r_i^* = \beta Q$ relation, and the bond dissociation energies of the initial and the final bonds, an equation for the evaluation of the activation energies of radical substitution reactions is derived, and its propriety is discussed in connection with the observed values.

General Considerations

In the evaluation of the activation energy of the radical substitution reaction, we consider such reactions of the three-center type as:

$$A + BC \rightarrow AB + C \qquad (1)$$

where A, B, and C are reacting atoms or groups. As has been proposed by Evans and Polanyi,[1] the energy changes involved in the reaction can be divided into: (i) the repulsion forces between A and BC, (ii) the attraction forces of the BC molecule, (iii) the repulsion forces between C and AB, (iv) the attraction forces of the AB molecule, and (v) the perturbation energy between the states. The quantitative evaluation of each term in the reaction involving a polyatomic molecule is, however, very difficult.

In this paper, the following picture is assumed to give an approximate method for evaluating the activation energy of the reaction (1):

$$\underset{}{A + B\text{–}C} \xrightarrow{D_i^0} \underset{(a)}{(A\ B\cdots C)} \longleftrightarrow \underset{(b)}{(A\cdots B\ C)} \xrightarrow{D_f^0} A\text{–}B + C \qquad (2)$$

where (a) or (b) represents the transition state in which the potential energy of the system along the reaction path is localized on the initial B–C bond or on the final A–B bond.

Considering the above speculation in connection with the reaction process, the reaction (1) can be explained by the following three steps. (i) Until the transition state, the A radical approaches from infinity to the initial BC molecule, the BC molecule absorbs the energy of the A radical, and the B–C bond is stretched as the A–B distance decreases. (ii) In the transition state, the energy localized on the B–C bond migrates on the A–B bond. (iii) After the transition state, the energy is concentrated on the A–B bond, and the AB molecule is formed.

9) P. M. Morse, *Phys. Rev.*, **34**, 57 (1929).

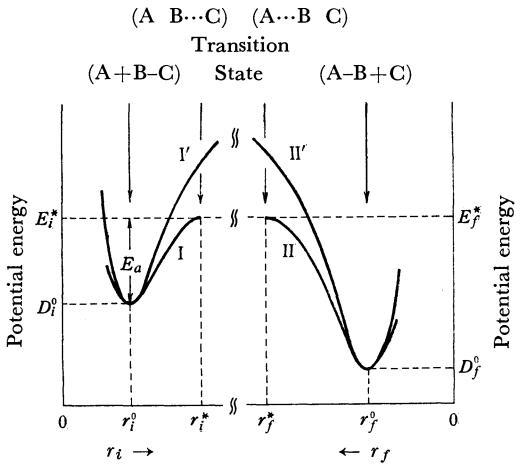

Fig. 1. The potential energy curves of the initial and the final systems along the reaction path.

We may explain the above reaction process with Fig. 1. The potential energy along the reaction path is expressed by the two curves (I and II) of the initial and the final systems, while I′ and II′ are the bond-energy curves neglecting the presence of the A and C radicals, respectively. Then, the curve I can be understood to include not only the curve I′, but also the attraction of the final bond, AB, and the repulsion between A and C.

In order to evaluate the activation energy on the basis of the above scheme, the function of the potential energy curve (I, II) along the reaction path must be determined and the conditions in the transition state must be established.

The Function of the Potential Energy Curve along the Reaction Path. As has been described before, the curve I is mainly determined by three energetic terms of the partial dissociation (the attraction) of BC, the partial formation (the attraction) of AB, and the repulsion between A and C. In consideration of these interaction energies, we assumed that the potential energy of the system along the reaction path is expressed by the two Morse functions, (3) for the initial system (curve I) and (4) for the final one (curve II):

$$E_i = D_i^0 - D_i^0(1 - e^{-a_i'(r_i - r_i^0)})^2 \qquad (3)$$

$$E_f = D_f^0 - D_f^0(1 - e^{-a_f'(r_f - r_f^0)})^2 \qquad (4)$$

where the subscripts i and f represent the initial and the final systems; E, the potential energy along the reaction path; r, the distance between the reacting components, B···C or A···B; D^0, the sum of the zero-point energy and the bond dissociation energy; r^0, the equilibrium distance of the bond, and a', the Morse constant, depending on the energetic terms described above.

Neglecting the zero-point energy in comparison with the bond dissociation energy, we can obtain, from Eqs. (3) and (4), Eqs. (5) and (6):

$$a_i'\Delta r_i^* = -\ln\left(1-\sqrt{1-\frac{E_i^*}{D_i}}\right) \quad (5)$$

$$a_f'\Delta r_f^* = -\ln\left(1-\sqrt{1-\frac{E_f^*}{D_f}}\right) \quad (6)$$

where E^* is a potential energy in the transition state and $E_i^*=E_f^*=E^*$. Equations (5) and (6) show that the activation energy can be evaluated on the basis of the "a'" coefficient and the Δr^* values.

In order to evaluate the "a'" values in Eqs. (3) and (4), we will consider the reaction (1) as a model of the radical substitution reactions. When the A radical approaches from infinity to the initial BC molecule, the Morse constant, "a_i'", of the initial system should change from the original "a_i" value to the new "a_i'" value. It is considered that this change in the "a_i'" value depends on both the attraction of AB and the repulsion between A and C. Taking into account the fact that these energetic terms are expressed as functions of a distance between the components, we postulate the new "a'" value by the following formulas:

$$a_i' = a_i(1-e^{-\gamma\cdot r_f^0}) \quad (7)$$

$$a_f' = a_f(1-e^{-\gamma\cdot r_i^0}) \quad (8)$$

where "a" is a Morse constant in the bond dissociation neglecting the presence of a radical and where γ is assumed to be a constant, regardless of the kind of reaction. The Morse constant, "a", is equal to $0.1227\omega_0\sqrt{\mu/D}$, where ω_0 is the fundamental vibrational frequency (cm^{-1}); μ, the reduced mass, and D, the bond dissociation energy (cm^{-1}), depending on both terms of the electronic energy and the energy of the repulsion between two nuclei.

In this study, it is assumed that the dissociation energy curve of a bond in a polyatomic molecule is essentially expressed by the Morse function as well as that in a diatomic molecule. For example, in computing the Morse functions of methyl halides, the methyl group is treated as a rigid unit with a mass of 15. The totally symmetric stretching vibrational frequency is used as a fundamental vibrational frequency, ω_0. The Morse constants, "a", of a bond in a polyatomic molecule, as calculated with the above characteristic values, are summarized in Table 1.

On the other hand, we can empirically evaluate the "a'" value of the exchange reaction of a hydrogen atom with a hydrogen molecule. It is known in this reaction that the activation energy is 6.7 kcal/mol; the normal distance between hydrogen atoms, 0.74 Å; the distance between hydrogen atoms in the transition state, 1.01 Å, and the bond dissociation energy of the hydrogen molecule, 103.0 kcal/mol. By substituting these values into Eq. (5) or (6), the new "a'" value along the reaction path is obtained as 1.10 $Å^{-1}$, *i. e.*, $a_i'=a_f'=a'=1.10$ $Å^{-1}$.

Table 1. The "a" constants in the Morse function

H–H	—	103	0.500	(1.85)††
				Av. 1.92±0.24

† Reported in Ref. 8.
†† Reported in Ref. 9.

With the use of the above data, *i. e.*, $a=1.85$ $Å^{-1}$, $a'=1.10$ $Å^{-1}$, and $r^0=0.74$ Å, the coefficient, γ, is determined to be 1.19 from Eqs. (7) and (8).

The Conditions in the Transition State. Taking the difference between Eqs. (5) and (6) and using the relations (7) and (8), we can derive the following equation:

$$a_f'\Delta r_f^* - a_i'\Delta r_i^* = -\ln\left(1-\sqrt{1-\frac{E_f^*}{D_f}}\right)\Big/\left(1-\sqrt{1-\frac{E_i^*}{D_i}}\right) \quad (9)$$

$$= a_f(1-e^{-\gamma\cdot r_i^0})\Delta r_f^* - a_i(1-e^{-\gamma\cdot r_f^0})\Delta r_i^* \quad (10)$$

As may be seen from Table 1, the "a" value turns out to be approximately constant; thus we may put $a_i=a_f=a_m=1.92$ $Å^{-1}$ (the average value of "a"). Moreover, since r_i^0 is nearly equal to r_f^0 in many reactions, the average value, $r_m^0=1/2(r_i^0+r_f^0)$, is employed for the value of r_i^0 and r_f^0.

$$a_f'\Delta r_f^* - a_i'\Delta r_i^* = a_m(1-e^{-\gamma\cdot r_m^0})(\Delta r_f^* - \Delta r_i^*) \quad (11)$$

When the following type of reactions is chosen as the standard reactions in computing; $R+HR'\rightarrow RH+R'$, the value of $a_m(1-e^{-\gamma\cdot r_m^0})$ is calculated to be approximately 1.40 $Å^{-1}$.

In the transition state, it is considered that the expansion of the initial bond is equal to that of the final bond in the reaction with the heat $Q=0$,

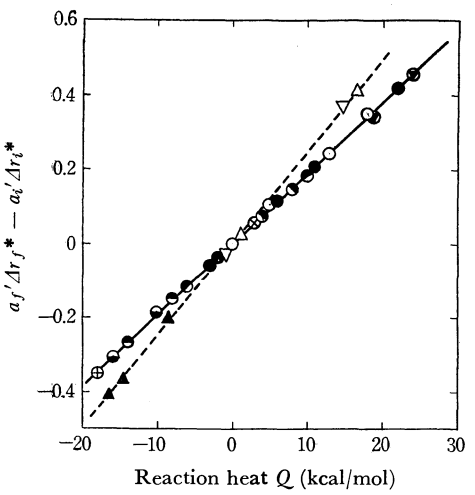

Fig. 2. Plot of the differences, $a_f'\Delta r_f^* - a_i'\Delta r_i^*$, *versus* the reaction heats.

○ H+RH→H_2+R, ⊗ D+RH→HD+R, ● CH_3+RH→CH_4+R, ◔ C_2H_5+RH→C_2H_6+R, ◐ *n*-C_3H_7+RH→*n*-C_3H_8+R, ◓ *i*-C_3H_7+RH→*i*-C_3H_8+R, ◒ *t*-C_4H_9+RH→*t*-C_4H_{10}+R, ⊕ CH_3CO+RH→CH_3CHO+R, ▼ H+RCl→HCl+R, △ H+HX→H_2+X, ▽ CH_3+HX→CH_4+X, ▲ Br+RH→HBr+R.

that it is smaller in the exothermic reaction $Q>0$, and that it is larger in the endothermic reaction $Q<0$.

On the basis of these considerations, the right side in Eq. (9) is evaluated from the experimental data and is plotted against the heat of reaction (Fig. 2). The linear relation in Fig. 2 can be expressed by the following formula for the standard reactions:

$$a_f'\Delta r_f^* - a_i'\Delta r_i^* = \beta Q = 0.0190Q \quad (Q\text{: kcal/mol}) \tag{12}$$

Therefore, $(\Delta r_f^* - \Delta r_i^*)$ is equal to $0.0136Q$.

The Evaluation of the Activation Energy. As has been described above, the potential energies along the reaction path are expressed by the two following Morse functions:

$$E_i = D_i(2e^{-a_i'\Delta r_i} - e^{-2a_i'\Delta r_i}) \tag{13}$$

$$E_f = D_f(2e^{-a_f'\Delta r_f} - e^{-2a_f'\Delta r_f}) \tag{14}$$

By substituting the conditions in the transition state, *i. e.*, $E_i^* = E_f^* = E^*$ and $a_f'\Delta r_f^* - a_i'\Delta r_i^* = 0.0190Q$, into Eqs. (13) and (14), we can derive the formulas expressing the expansions of the bond lengths and the potential energy of the bond in the transition state:

$$\Delta r_i^* = -\frac{1}{a_i'} \ln \frac{2\alpha(D_f - \alpha D_i)}{D_f - \alpha^2 D_i} \tag{15}$$

$$\Delta r_f^* = -\frac{1}{a_f'} \ln \frac{2(D_f - \alpha D_i)}{D_f - \alpha^2 D_i} \tag{16}$$

$$E^* = \frac{4\alpha(1-\alpha)D_iD_f(D_f - \alpha D_i)}{(D_f - \alpha^2 D_i)^2} \tag{17}$$

where α is equal to $\exp(0.0190Q)$. The activation energy can then be expressed by the following equation:

$$E_a = D_i - E^* = \frac{D_i((1-2\alpha)D_f + \alpha^2 D_i)^2}{(D_f - \alpha^2 D_i)^2} \tag{18}$$

Equation (18) shows that the activation energy can be calculated by using the bond dissociation energies of the initial and the final molecules. In the reaction with the heat $Q=0$, both the denominator and the numerator are zero in Eq. (18). Therefore, the activation energy of this type of reaction can be estimated by interpolating the activation energies of the reactions with $Q\neq 0$.

Results and Discussion

The expansions (Δr_i^*, Δr_f^*) of the bond lengths and the activation energies as calculated by Eqs. (15)—(18), are listed in Table 2, where they are shown in comparison with the observed values.[5,10,11]

† Calculated by Eq. (18) with β=0.0190
†† An experimental value
††† Evaluated by interpolation

The calculated values of the activation energies are in good accordance with the observed values for many, though not all, types of reactions within ±2.0 kcal/mol. It should be noted that Eq. (18) holds not only in the homopolar reactions, but also in the reactions with some ionic character.

In the reaction, R+HR′→RH+R′, with the same reaction heat and the same β value (0.0190), it is also found that the activation energy decreases with an increase in the value of D_i (or D_f). This relation may be due to the increase in the expansion, Δr_i^*, with a decrease in the dissociation energy of the initial molecule.

On the other hand, in the following reaction, in which the hydrogen atom pulls the hydrogen of hydrogen halides:

$$H + HX \rightarrow H_2 + X \qquad (19)$$

the values calculated by Eq. (18) with the standard β value are considerably larger than the observed values. This disagreement may be explained as follows. On the basis of the facts that r^0_{H-X} (1.22—1.47 Å) and r^0_{H-H} (0.74 Å) are not equal to each other and both differ from r^0_{R-H} (1.09 Å), Eqs. (11) and (12) do not hold for the reaction (19).

In our treatment, the difference in the equilibrium distances results in changes in both the Morse constant "a" and the β value. We assume that the value of $(a_f'\Delta r_f^* - a_i'\Delta r_i^*)$ is expressed by Eq. (12), which has a new β (β') value which is different from 0.0190 (Fig. 2):

$$a_f'\Delta r_f^* - a_i'\Delta r_i^* = \beta' Q \quad (Q\text{: kcal/mol}) \qquad (20)$$

The β' value is calculated with the use of the experimental data, *i. e.*, $\beta' = 0.0260$ for the reaction (19).

Moreover, in the following reaction, it is well known that the activation energy generally decreases in the order RF > RCl > RBr > RI and cannot be evaluated by Eq. (18) using the standard β value:

$$Na + XR \rightarrow NaX + R \quad (X=\text{a halogen atom}) \quad (21)$$

On the basis of the similar considerations described above, the new β values can be empirically evaluated. The following empirical relation can be obtained between β'_{R-X} and r^0_{R-X}:

$$\beta'_{R-X} = \beta'_{R-F} + 5.0 \times 10^{-5}((r^0_{R-X})^6 - (r^0_{R-F})^6) \quad (22)$$

where $\beta'_{R-F}=0.0133$ and $r^0_{R-F}=1.96$ Å. The activation energies of the reaction (21), calculated with the new β value obtained from Eq. (22), are listed in Table 3. It may also be found in Table 3 that, in the reaction (21) with the same reaction heat and a different β value, the acitvation energy decreases with a decrease in the dissociation energy of the initial bond. If the relation, $\Delta r_f^* - \Delta r_i^* = \text{constant} \times Q$, holds for the reaction (21) as well as for the standard reaction, a decrease in the dissociation energy may result in a remarkable decrease in the slope of the Morse function curve and, consequently, in that of the activation energy.

These results lead to the following conclusions. The activation energy of the radical substitution reactions can be evaluated by the method based on the Morse function. In reactions of the R+HR′→RH+R′ type, with the same reaction heat, the activation energy depends on the expansion of the bond, while in reactions of the Na+XR→NaX+R type, with the same reaction heat, the change in the activation energy depends mostly on the difference in the slope of the Morse function curve.

The authors would like to express their gratitude to Professor Kenichi Fukui for his valuable suggestions throughout this work and to Mr. Keisuke Makino and Mr. Toshihiro Tachi for their assistance in computing and in gathering of the experimental data.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 1819—1824 (1969)

The Crystal Structure of 5,5-Dimethyl-2-oxo-2-hydroxy-1,3,2-dioxaphosphorinane Monohydrate

Wataru MURAYAMA and Masatsune KAINOSHO

Central Research Laboratories, Ajinomoto Co., Inc., Suzukicho, Kawasaki

(Received November 4, 1968)

The crystal structure of 5,5-dimethyl-2-oxo-2-hydroxy-1,3,2-dioxaphosphorinane monohydrate (I) has been determined by the three dimensional X-ray diffraction method. The crystals belong to monoclinic system, with space group $P2_1$. The unit cell dimensions are; $a=9.50$, $b=5.86$, $c=8.31$ Å, $\beta=106°8'$, and two molecules per unit cell. The six-membered dioxaphosphorinane ring has a chair conformation, with P=O bond in equatorial position. The bond angles and distances of the phosphate group are similar to those found in the corresponding acyclic phosphates.

One of the most interesting roles of the molecular structure of nucleotide is the conformation around the phosphate linkage. Recently, the conformation of two naturally occurring nucleotides, inosine-5′-monophosphate and guanosine-5′-monophosphate, have been studied both in aqueous solution and in crystalline state by ^{31}P NMR measurements[1] and X-ray diffraction method,[2,3] respectively. The results, so far obtained, suggest that quite similar conformations of the phosphate fragment are preferred both in aqueous solution and in crystalline state.

Determination of the dihedral angle in P–O–C–H system by NMR method is based upon the dihedral angular sensitive nature of J_{POCH} (phosphorus-proton spin-spin coupling constant).[1,4-6] Thus, in order to determine the values of "*gauche*" and "*trans*" P–H coupling (Fig. 1) a variety of the conformationally fixed 1,3,2-dioxaphosphorinanes

were studied by NMR.[1,4–6]

During the course of our NMR studies, we realized the necessity of knowing the actual dihedral angles and bond distances in 1,3,2-dioxaphosphorinanes.[5]

The present study gives further structural information about the six-membered cyclic phosphates, for only two of the derivatives (II[7] and III[8]) were studied by X-ray diffraction method. I is a particularly informative molecule for comparison with acyclic phosphoric acid esters and for the examination of preference of P=O bond at the equatorial bond.[7,8]

Fig. 2

Experimental

5,5-Dimethyl-2-oxo-2-hydroxy-1,3,2-dioxaphosphorinane (I) can be obtained as either orthorhombic (α-form) or monoclinic crystals (β-form), when I is crystallized out from an aqueous solution. Crystal data of these two forms are given below.

α-form (orthorhombic; $P2_12_12_1$)
$a = 9.05$, $b = 6.08$, $c = 16.06$ Å,
$D_x = 1.38$, $Z = 4$.

β-form (monoclinic; $P2_1$)
$a = 9.50$, $b = 5.86$, $c = 8.31$ Å, $\beta = 106°8'$,
$D_x = 1.38$, $Z = 2$.

The structure determination by X-ray diffraction method was carried out with a crystal of the β-form. A needle-shaped crystal (elongated along the monoclinic b-axis) was mounted on a Weissenberg camera and rotated around its axis. Equi-inclination Weissenberg photographs for the five layer $0 \leq k \leq 4$ were recorded by multi-film technique with Cu$K\alpha$ radiation. The intensities were estimated visually. No corrections were made for absorption. The x and z coordinates of the phosphorus atom were determined readily from (u, 1/2, w) Harker section. The y parameter of the phosphorus atom was taken as zero. Three dimensional Fourier syntheses, based on the phase angles calculated from the position of phosphorus atom, revealed all the other peaks due to lighter atoms together with their mirror images. One set of the peaks could be picked out as real. The R-index at this stage was 0.33. Several cycles of block-matrix least squares refinements with isotropic temperature factors reduced R-index to 0.16, and following full-matrix least-squares refinements with isotropic temperature factors reduced R to 0.151. Finally, anisotropic temperature factors were introduced and several cycles of block-matrix least squares refinements were carried out. The weighting schemes at this step were $F_{max}/|F_0|$ for $|F_0| > F_{max}$, 1.0 for $F_{min} < |F_0| < F_{max}$ and 0.5 for $|F_0| < F_{min}$, where $F_{max}=20.0$ and $F_{min}=7.0$. The final R-index was 0.127.

Results and Discussion

The crystal structure projected on *bc*-plane is shown in Fig. 3. The oxygen atom of the water molecule is located in the middle of the two phosphorinane molecules, which are separated from each other by one period along the *b*-axis and a hydrogen bond system is formed along this direction. The closest intermolecular distance is 3.42 Å between C(3)-atom of the one molecule and O(3)-atom of the neighboring molecule along the *b*-axis.

The bond distances and angles in the phosphate group are generally in good agreement with the corresponding values reported for some acyclic organic phosphates. For the sake of comparison, some reported values of P–O bond distances and O–P–O angles are listed in Table 5. It should be noted that the observed values of P–OR bond distance (1.58 Å) in I coincide with calculated values based on Cruickshank's rule for P–OR bonds in RPO_4^{2-} or $R_2PO_4^-$ groups.[9] Thus, it can be concluded that the six-membered cyclic phosphate forms an ordinal ester linkage similar to that in the acyclic phosphate.

The conformation of the molecule is a chair form carrying the P–OH in axial and P=O bond in equatorial position, respectively. In the previously reported two phosphorinanes (II and III), the P=O bonds are also in equatorial and P–OPh and –Br are in axial positions.[7,8] The P–O–C angles in

the phosphorinane ring are fairly large compared with the C–C–C angle of 111° in cyclohexane.[10] Beineke[7] also pointed out that the phosphorinane rings are somewhat more flattened than the cyclohexane ring, and suggested such ring-deformation causes the reduction of the steric repulsion between the axial substituent at the phosphorus atom and the hydrogen atom at 1,3-diaxial position.

It is of interest that the S=O bond in the cyclic sulfite of 1,3-propanediol tends to favor the axial position.[11] The dihedral angle in P–O–C–C system in I is about 55°, which is considerably smaller than the dihedral angle in a strict *gauche* conformation (60°).

All of the crystallographic computations were carried out on a CDC 3600 computor with the UNICS crystallographic system programs.[12]

Solvent Effects of Charge-transfer Complexes

Jun-ichi AIHARA, Motoyuki TSUDA and Hiroo INOKUCHI

The Institute for Solid State Physics, The University of Tokyo, Roppongi, Tokyo

(Received November 7, 1968)

The solvent effects of charge-transfer complexes were examined in various solvents. During the course of investigations pertaining to aromatic-TCNE complexes, Brownstein's and McRae's formulae were found to be valid. The gas-phase spectra of these charge-transfer complexes may be regarded as the origin of the solvent effects. The anomalous behaviour of carbonyl solvent molecules was also discussed.

It has been easily assumed that increasing the solvating power of a medium for a charge-transfer (CT) complex should shift the CT-band of the absorption spectra to a lower energy region.[1] Contrary to this prediction, however, it is often found that an increase in solvent polarity results in the shift of the CT-band to higher energy region.[2] Specific interaction between the charge-transfer complex and the surrounding solvent causing these blue shifts should thus also be considered as significant in these systems.[3]

Several explanations have been proposed for these solvent effects: some of them emphasized the small heat of formation, ΔH, of the complex, which implies that the complex-binding can be looser with little change in the surroundings.[4]

Davis and Symons believed a charge redistribution in the ground state of the complex to be responsible for the blue shift in polar solvents.[3] Therefore, they concluded that the commonly-accepted concept regarding solvent shifts on the absorption spectra of charge-transfer complexes has to be abandoned. Weiss proposed that a donor-acceptor complex can be considered as an electron-hole pair in correlation with the theory of Wannier exciton, but his theory also seems to be unsuccessful.[5] One of the purposes of the present work is to reexamine the solvent effects of the charge-transfer complexes; another is to locate the absorption spectra of the gaseous complexes in the solvent diagrams for various relationships.

Experimental

Naphthalene, durene, diphenyl and pyrene used in this work were recrystallized and zone-refined materials. Stilbene was twice recrystallized from ethanol. Tetracyanoethylene (TCNE) was synthesized according to the method of Ref. 6 and purified by recrystallization

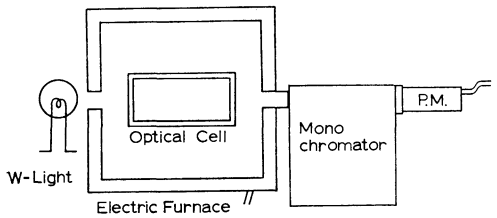
from chlorobenzene and by sublimation.

The solutions of charge-transfer complexes were prepared by mixing the respective components to appropriate concentrations. The absorption spectra were measured using a Cary Model 14 spectrophotometer.

The optical data for the charge-transfer complexes in the gas phase were obtained with an Aminco 4-8401 monochromator. TCNE and equimolecular aromatic hydrocarbon were placed in a quartz cell 7 cm or 40 cm long, which was then sealed after evacuation. The cell was heated to an appropriate temperature in a large, 50-kW electric furnace, and the absorption spectra were measured rapidly, as Fig. 1 shows schematically. The light source was a 200-W Wolfram lamp.

Survey of Gas-phase Spectra. In a previous paper, we have already reported some of the general features of the absorption spectra in the gas phase.[7] In this article, we will describe the individual characteristics in detail, as Figs. 2—7 show, in comparison with those of the carbon tetrachloride solution. The CCl_4 solvent is the most popular non-polar solvent. In general, gas-phase spectra are very similar to those in the solution in respect to shape and width. Moreover, the gaseous spectra of the complexes have no vibrational structures, such as are often found in the gaseous spectra of simple molecules. Exceptionally, the durene-TCNE complex (Fig. 3) has an asymmetric spectrum in solution.



Apparatus for Spectrophotometry

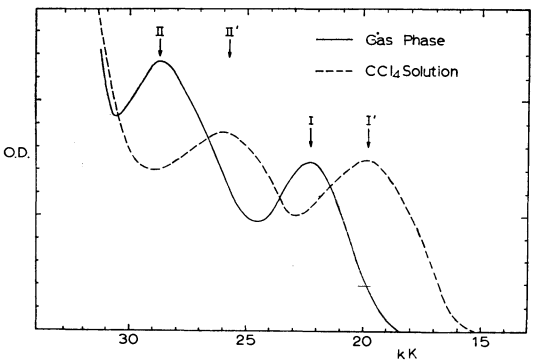

Fig. 5. The gaseous spectrum of diphenyl-TCNE.

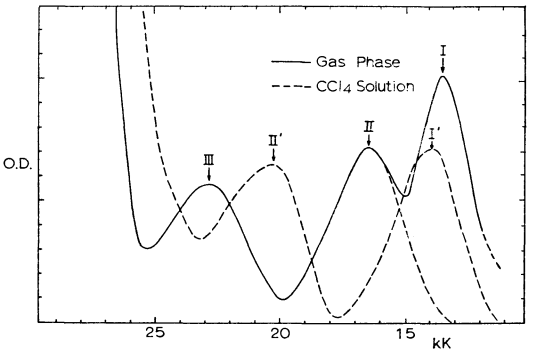

Fig. 6. The gaseous spectrum of pyrene-TCNE.

7) J. Aihara, M. Tsuda and H. Inokuchi, This Bulletin, **40**, 2460 (1967).

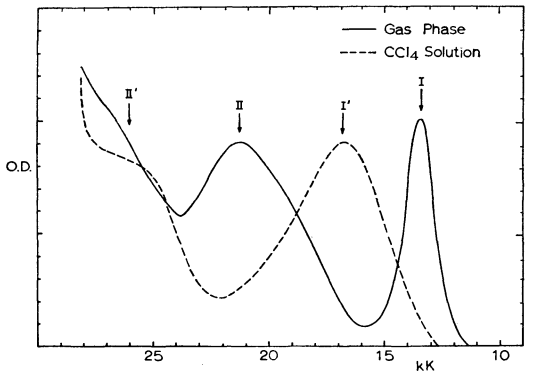

Fig. 7. The gaseous spectrum of stilbene-TCNE.

However, in the gas phase it is reproduced within the range of the structures in the solution. This suggests that the location of the 0–0 band in the gaseous spectrum is at the same position as in the solution specturm.

Therefore, the following conventional method was adopted to treat the data: the absorption maxima were taken as the position for the 0–0 band, and the peaks were assigned by comparing the spectra in carbon tetrachloride with those in the gas phase.

The absorption spectra of the naphthalene-TCNE complex are shown in Fig. 4. This complex has two charge-transfer bands, which may be interpreted as transitions from the highest occupied orbital of naphthalene to the lowest and the second lowest vacant orbitals of TCNE. The complexes of diphenyl (Fig. 5), pyrene (Fig. 6), and stilbene (Fig. 7) with TCNE are the same. The intensity ratio of the two bands is kept nearly constant between gas and solution.

Pyrene-TCNE complex has obviously different features. In the gas phase, the absorption spectra has three bands in the visible region, while in the solution only two bands are observed. In the pyrene-TCNE complex, we may except the lowest energy band for the following reasons. In the first place, the location of this band has a fairly good reproducibility, but it is poor in its intensity ratio in relation to other bands. The shapes of the first and the second bands in the solution are apparently comparable respectively to those of the second and the third bands in the gas phase. Moreover, the solvent effect to be described in the next section supports this interpretation. It is probable that the first gaseous band may be ascribed to that produced by the reaction or decomposition of the complex. An anomaly is also found in the stilbene-TCNE complex, so the first band is ommitted for the same reasons. In these two cases these phenomena appeared in nearly the same wavelength region. All the gaseous data are summarized in Table 1. Each shows a red gas-to-solution shift.

TABLE 1. THE LIST OF CT-BANDS OF TCNE CHARGE-TRANSFER COMPLEXES

Donor	CT-band (kK) in gas phase	CT-band (kK) in CCl_4 solution	Gas-to-solution shift (kK)
Toluene	27.6	24.7	−2.9
Durene	20.8	19.2	−1.6
Naphthalene	21.1	18.0	−3.1
	26.3	23.0	−3.3
Diphenyl	22.2	20.0	−2.2
	28.6	25.7	−2.9
	13.5	—	—
Pyrene	16.5	14.0	−2.5
	23.0	20.5	−2.5
	13.4	—	—
Stilbene	21.1	16.8	−4.3
	—	26.0	—

Discussion

It is very interesting to ascertain where the gaseous data are located in the solvent diagrams. As has been mentioned before, if the solvent effect is substantially abnormal, solvation itself is a theme of importance.

Several authors have attempted to relate the solvent shift of absorption spectra to the rate of the solvolysis reaction.[8] Following Kosower's idea, Brownstein developed an empirical relationship which obviously resembles the so-called Hammett rule.[9] He estimated an S-value for each solvent comparable to Hammett's σ value.

Brownstein's rule is expressed as follows.

$$SR = \frac{\nu_0 - \nu_E}{\nu_0} \tag{1}$$

where R is a constant characteristic of the system, where ν_E is the value in a given solution, and where ν_0 is the value obtained for ethanol as a standard.

To survey the general behaviour of the solvent effect of the charge-transfer bands, we adopted this rule for the naphthalene-TCNE complex. Figure 8 shows Brownstein's relation; a general correlation is found between the spectral shift and the S-value. From this validity to the complex, R is determined to be −0.433, a value which is fairly large in comparison with ordinary π–π^* or n–π^* transitions. The spectra from a gaseous specimen deviates much to the higher energy region, and so do those in ethyl-acetate and acetone. Some of these data were first cited in Refs. 2 and 10.

Next, we applied these data to the McRae relation, one of the most popular formulae of the solvent effect, expression of which is:[11]

$$\Delta h\nu \cong (AL_0 + B)\frac{n^2 - 1}{2n^2 + 1} + C\left(\frac{\varepsilon - 1}{\varepsilon + 2} - \frac{n^2 - 1}{n^2 + 2}\right) \tag{2}$$

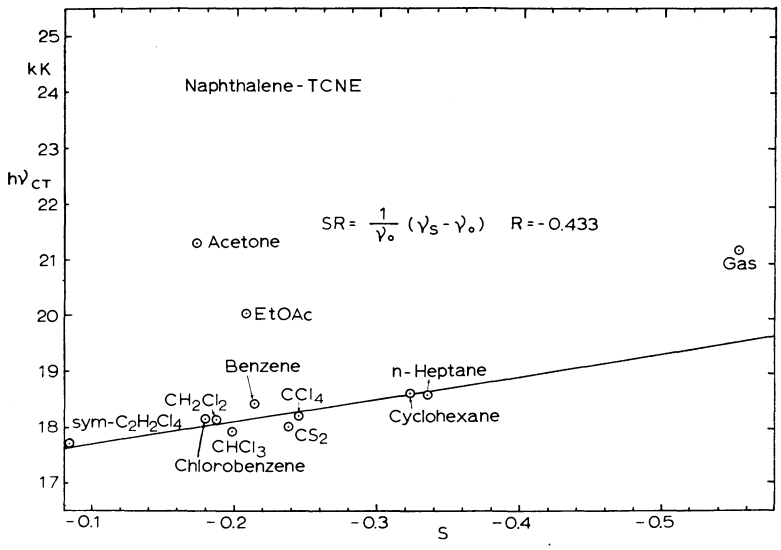

Fig. 8. The Brownstein's plots for naphthalene-TCNE.

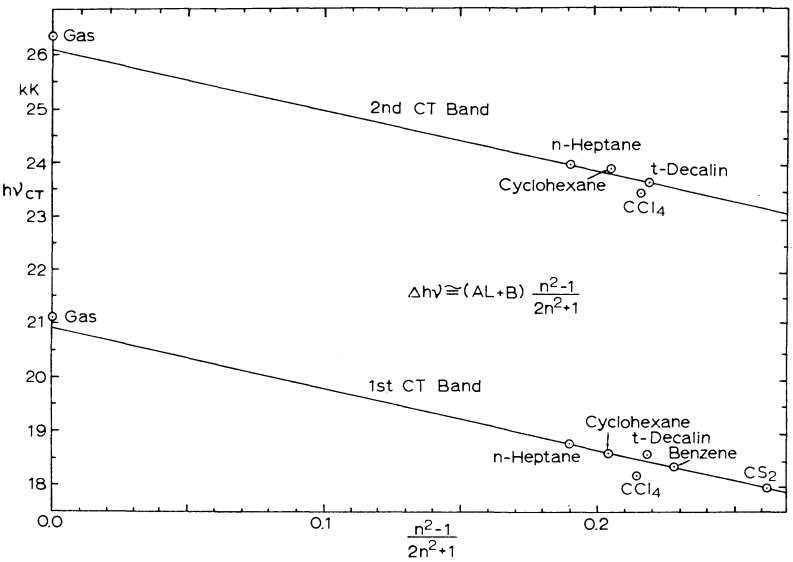

Fig. 9. The non-polar solvent effect of naphthalene-TCNE.

where n is the refractive index and where ε is the dielectric constant of the solvent. (AL_0+B) and C are constants characteristic of the solute. We plotted the absorption maxima in non-polar solvents, in which case the second term can be disregarded because $n^2 \cong \varepsilon$. The n and ε values were taken from Refs. 12 and 13. In Fig. 9 we found a fairly complete linearity between spectral shifts and $n^2-1/2n^2+1$ and obtained 11.00 kK as the (AL_0+B) value.

This means that, in these complexes, interaction between the solute-induced dipole and the solvent-induced dipole and/or between the solute dipole and the solvent-induced dipole is very large, compared to the general trend of solvent shifts. The wave numbers extrapolated to zero agree with the gaseous data.

Offen and Abidi suggested that there is no correlation between the magnitude of the shift and the refractive index or dielectric constant,[2] but this complex seems to behave normally, at least in non-polar solvents. Accordingly the nature of the complex is substantially the same in the gaseous state and in solution. Probably the large (AL_0+B)

12) A. D. E. Pullin, *Spectrochim. Acta*, **16**, 12 (1960).

value reflects the abnormal blue shift of the gas phase in Brownstein's relation.

Using this value, we tried to obtain the C-value of McRae's formula; therefore $h\nu_{CT}-(AL_0+B)\frac{n^2-1}{2n^2+1}$ is plotted against $\frac{\varepsilon-1}{\varepsilon+2}-\frac{n^2-1}{n^2+2}$ in Fig. 10. Several

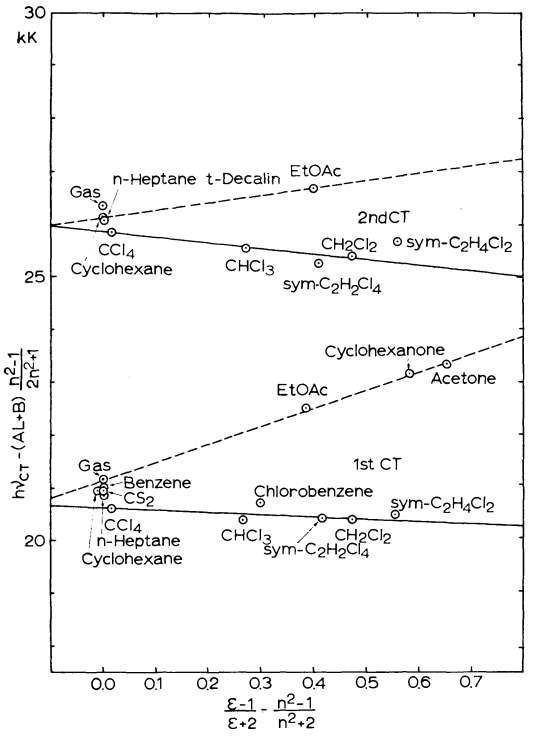

Fig. 10. The polar solvent effect of naphthalene-TCNE.

disordered solvents appeared among the polar solvents. This term indicates part of the solute dipole-solvent dipole interaction; explicitly, C is expressed as $2\mu_g(\mu_g-\mu_a)/a^3$, where μ_g and μ_a are the dipole moments of the ground state and the excited state respectively, and where a is the cavity radius of the solvent. As to the naphthalene-TCNE complex, the dipole moment of the ground state is reported to be 1.28 D, while that of the excited state can be assumed to be 10—15 D on the basis of the data of the excited hexamethylbenzene-TCNE complex.[4,14] Accordingly, the value of C must be negative in a normal case. Figure 10 shows a group of solvents which exhibit a good linear correlation between those whose gradient is -490 cm^{-1}. This group consists mainly of haloalkanes and alkenes.

For these solvents, we can estimate the charge distribution of the complex to be nearly constant.

14) G. Briegleb, J. Czekalla and G. Reuss, *Z. Physik. Chem. (Frankfurt)*, **30**, 333 (1961).

Now let us estimate the Coulomb term contributing to the charge-transfer transition. $h\nu_{CT}$ is frequently approximated by the expression;[15]

$$h\nu_{CT} = I_D - E_A - \frac{e^2}{R_{DA}} - P \qquad (3)$$

where I_D is an ionization potential of the donor, where E_A is the electron affinity of the acceptor, and where P is the polarization energy due to solvent molecules. R_{DA} indicates the distance between donor and acceptor molecules. When we apply this formula to the heptane solution, we can deduce P directly from Fig. 9 as the value of the spectral shift, 0.50 eV. The electron affinity of TCNE is 2.60 eV if we take as the standard *p*-benzoquinone, whose value, 1.40 eV, was recently determined by a magnetron method.[16] Therefore, the Coulombic ion-pair attraction term results in 2.38 eV.

Ikemoto calculated the molecular orbitals of this complex in the crystalline phase.[17] According to him, the Coulomb energy of the first band may be estimated to be 3.32 eV. The decrease in the Coulombic interaction suggests that there exists a looser complex in both the gas and the solution with a larger intermolecular distance. However, the charge distribution in the complex may be considerably different from that in the solid state, so the displacement between the two components can not be estimated straightforwardly.

From the above results, the spectral shifts may all be ascribed to a simplification of McRae's formula. The possibility of some orientational isomers in the gas phase or in the various solvents is not very important.[18] If a different form of charge-transfer isomers exists, those isomers may be expected to produce a secondary shift compared to the usual dipole-polarization shifts. The only questionable point is that the plots for the non-polar solvents in Fig. 9 are slightly displaced upward from the linearity of the regular solvents.

On the other hand, the plots for the oxygen-containing solvents are mainly dispersed to the blue side. This irregularity is in good accord with the trend in Brownstein's relationship. Generally the values found in ethyl acetate, acetone, and cyclohexanone are far remove from those in methylene chloride.[2,19] Therefore, we can conclude that these groups behave abnormally, so special theoretical attention should be given to them.

How can we examine this phenomenon? As Bayliss pointed out, this point-dipole model, in a uniform medium, is not the best approximation.[1] In the case of the charge-transfer complex especially, these solvents may change the nature of the complex.

Using the above data of the normal solvation, the cavity radius of the solvent is calculated to be 6.60±0.30 Å. This radius is quite large. In this connection the typical solvents have molecular radii in the range of from 2.0 to 4.0 Å. Therefore, a solvent which does not have a very marked partial moment may be regarded as a continuous medium.

** Determined from the dotted line in Fig. 10.

However, some polar solvent molecules will tend to become oriented so as to stabilize these partially-charged complexes through stereospecific solvation; that is, the solvent molecules around the complex may take such orientations that maximum attractions between the solvent and the solute molecules are obtained. In forming such a local field, the proper geometrical conditions of solvent molecules as well as proper polarities are necessary.[20]

Moreover, a new interaction of carbonyl compounds was reported a few years ago.[21] An oxygen atom in the carbonyl group is closely attached to the carbon atom of the same group in the neighbouring molecule. The usual van der Waals distance between them is expected to be at least 3.1 Å, according to Pauling's list of van der Waals radii.[22] However, those of chloranil, parabanic acid, and aloxan are 2.85, 2.77, and 2.79 Å respectively. Such an effect may be expected also in acetone, ethyl acetate, cyclohexanone, and so on. Carbonyl group has an ionic character of several tens per cent, too.

If we proceed to develop such an idea, the concept of a local field formed by the surroundings acting on the complex in the direction from the acceptor molecules to the donor molecules, the ground state of the complex is further polarized.[23] This explanation is somewhat related to those by Davis and Symons, and Offen and Abidi, who also suggested the enhancement of the mixing of the dative bond.[2,3] In the present case, the carbonyl solvent molecules around the complex may take such orientations as described above. It is probable that these interactions are large enough to invert the direction of the solvent shifts.[22] The dotted

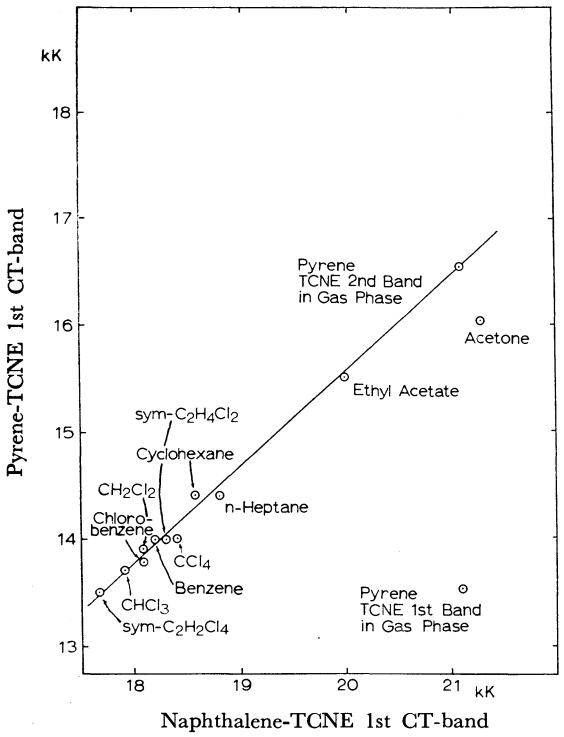

Fig. 12. The correlation between naphthalene-TCNE and pyrene-TCNE.

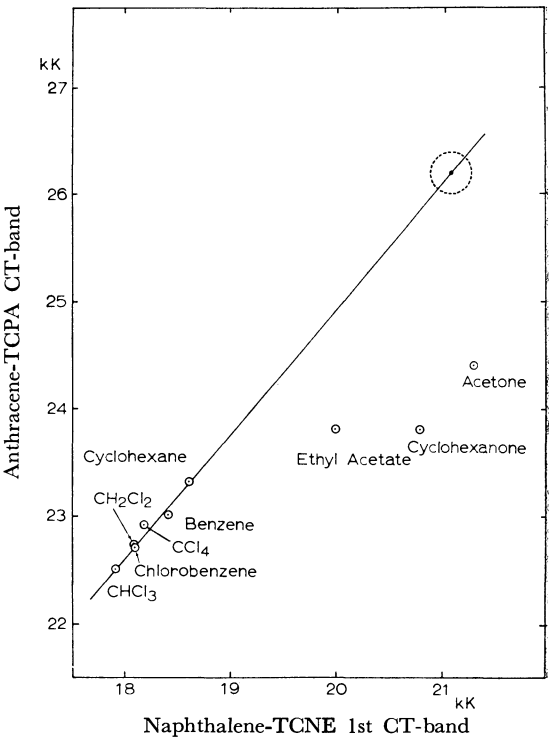

Fig. 13. The correlation between naphthalene-TCNE and anthracene-TCPA.

line in Fig. 10 suggests the possibility of such a case.

So far we have discussed mainly the naphthalene-TCNE complex, but the parallelism of solvation is widely valid among a variety of complexes.[2] In Fig. 11 another example is shown, here the first band of the gaseous pyrene-TCNE complex can be omitted as a band originating for a different reason.

We can ascertain another correlation between the spectral shifts of naphthalene-TCNE and pyrene-TCNE complexes. The results shown in Fig. 12 also give support to the above reasoning as to the first band of the gaseous pyrene-TCNE complex. The first band of the gaseous stilbene-TCNE complex is omitted for the same reason.

In Fig. 13 the correlation with a different type of complex, that is, the anthracene-TCPA (tetrachlorophthalic anhydride) complex, is examined. The gaseous spectrum of this complex could not be observed because of overlapping with that of component molecules as a result of the blue shift. However, the location of the peak is assumed to be around the dotted circle.

In both these diagrams, the carbonyl solvent behaves independently as before. We must leave further investigation of this problem to later. In this step, however, we should stress the regularity of the solvent effect and the location of gaseous spectra as a standard of that effect.

(Received November 20, 1968)

The photochemical rearrangements of phenyl acetate and *p*-substituted phenyl acetates have been studied. The quantum yields of the rearrangements of phenyl acetate in cyclohexane were independent of the irradiation time, the concentration of phenyl acetate ($<2\times10^{-2}$ mol/*l*), the temperature (20—70°C), and the presence of piperylene (a triplet quencher) or oxygen. The quantum yields for the formations of *o*- and *p*-hydroxyl acetophenones and of phenol were 0.17, 0.15, and 0.06 respectively in cyclohexane. Comparing the quantum yields for phenyl acetate rearrangements with those for *p*-methylphenyl acetate, the quantum yields for the predissociation of the O–CO bond and the back reaction, and the recombination ratio were estimated to be 0.61, 0.23, and 0.9 respectively in cyclohexane. The relative rate constants of the back reaction and the *o*- and *p*-rearrangements were parallel to the odd π electron densities of the phenoxy radical. These results have shown that the reaction scheme of phenyl acetate in the liquid phase at 2537 Å is similar to that of acetanilide.

The photochemical reactions of phenyl esters in a solution yield products of rearrangement similar to those of the Fries reaction. Anderson and Reese[1] have reported that phenyl esters rearrange to yield *o*- and *p*-hydroxyl-aryl ketones by UV irradiation. Kobsa,[2] Finnegan and Hagen,[3] and Elad *et al.*[4] have reported similar findings on the photo-Fries-rearrangement.

In the study of the photochemical reactions of acetanilide,[5-7] it has been shown that, in the liquid phase, the photochemical rearrnagement occurs *via* the predissociation by the intersystem crossing $^3\sigma_0(\text{N–C})\leftarrow S_1(\pi\pi^*)$, forming anilino and acetyl radicals which recombine efficiently in a solvent cage into the original substance, *o*- and *p*- isomers. The photochemical reactions have been examined in the vapor phase and in a rigid matrix, but no photochemical rearrangement was observed in either case.[8]

The photochemical reaction of phenyl acetate has been investigated and discussed on the basis of the mechanism of the photo-Fries-rearrangement, which was established in the study of the photochemical rearrangement of acetanilide.

Experimental

The experimental procedure and solvents were similar to those previously described.[5-7] The phenyl acetate, phenol, *p*-cresol, *p*-chlorophenol, *p*-nitrophenol and *p*-hydroxyacetophenone were Tokyo Kasei Co. G. R.-grade products. The *p*-methyl, *p*-chloro, and *p*-nitrophenyl acetates were prepared by treating the corresponding *p*-substituted phenols with acetic anhydride and were purified by distillation or by recrystallization. The 2-hydroxy-5-methyl- and 2-hydroxy-5-chloroacetophenones were produced from the corresponding phenyl acetates by means of Fries reactions and were purified by repeated recrystallization.

A low-pressure mercury lamp with a Vycor glass filter was used as the 2537 Å radiation source. Actinometry was carried out in the same way as has been described in a previous paper.[5] The light intensity at 2537 Å was 9.7×10^{14} photons $\text{sec}^{-1}\,\text{cm}^{-2}$.

The flash apparatus was an ordinary one and has previously been described.[7] The fluorescence and phosphorescence were measured by Hitachi MPF-2 and Aminco Bowman Spectrophotofluorometers respectively. In these measurements, the concentrations of the solutions were so adjusted that the values of optical density were 0.600 at 2537 Å.

Results and Discussion

Electronic Structures of Phenyl Acetate. Table 1 shows the near UV absorption band of para-substituted phenyl acetates, which are related to the $^1B_{2u}\leftarrow{}^1A_{1g}$ transition of benzene at 255 mμ and which resemble the absorption bands in the corresponding phenols (See Table 2, Figs. 2 (a), 3(a), and 4).

TABLE 1. NEAR UV ABSORPTION BANDS OF *p*-X-SUBSTITUTED PHENYL ACETATES

Substance X	λ_{max} mμ	ε_{max}
H	259	290
CH_3	266	540
Cl	269	500

Baba and Suzuki have shown that acetylation causes a blue shift and a decrease in intensity for the Band I ($^1B_2\leftarrow{}^1A_1$) of aniline, while for Band II ($^1A_1\leftarrow{}^1A_1$) it causes a red shift and an increase in intensity.[9] For the longest wavelength band ($^1B_2\leftarrow{}^1A_1$) of phenol, the acetylation also causes a blue shift and a decrease in intensity. It is believed that the acetylation to the electron-donating atom (oxygen atom) surpresses the electron migration from the oxygen atom to the phenyl group, and that the electron migration to the carbonyl group results in a shift of the n–π^* band in phenyl acetate to a shorter wavelength (blue shift), as in the case of acetanilide.[6] Therefore, the n–π^* level in phenyl acetate may lie above the lowest singlet excited state, $S_1(\pi\pi^*)$; this possibility is supported by the observation of the fluorescence (Fig. 1(a)). That is, it is reasonable to assume that the fluorescence is the emission from $S_1(\pi\pi^*)$ to S_0 because of its red shift in a polar solvent. On the other

hand, the phosphorescence which is shown in Fig. 1(b) can be assigned to the emission from the triplet state $T_1(\pi\pi^*)$ to S_0, since the phosphorescence has a long lifetime (several seconds) at 77°K.

Reaction Products. Figures 2(a), 3(a), and (4) show, respectively, the spectral changes of cyclohexane solutions of phenyl acetate, *p*-methylphenyl acetate, and *p*-chlorophenyl acetate during photolysis at 2537 Å.

The spectral change in phenyl acetate upon the irradiation at 2537 Å (Fig. 2(a)) indicates that the reaction products are *o*-hydroxyacetophenone, *p*-hydroxyacetophenone, and phenol, the absorption spectra of all of which have been measured (Fig. 2(b)). The spectral change in *p*-methylphenyl acetate indicates that not a *p*-rearrangement but an *o*-rearrangement product is obtained, plus *p*-cresol, as is shown in Fig. 3(a); Fig. 3(b) shows the absorption spectrum of each of the reaction products. The photochemical reaction of *p*-chlorophenyl acetate is similar to that of *p*-methylphenyl acetate (Fig. 4). Scarcely no spectral change was observed in an ethanol solution of *p*-nitrophenyl acetate. The substituted nitro group has an intramolecular quenching action.[7,10,11] The quantum yields for the formation of these photochemical products were measured spectrophotometrically. The molar extinction coefficients of the photochemical products are summarized in Table 2.

	Ethanol (aerated)	0.22	0	*

Φ_o, Φ_p, and Φ_{OH} are the quantum yields for the formation of *o*- and *p*-rearrangements and *p*-X-phenol respectively.

* denotes that the quantum yield for the formation of *p*-X-phenol could not be observed spectrophotometrically because of the overlapping of the absorption spectra.

change with the variation in the irradiation time and the concentration of phenyl acetate ($<2\times10^{-2}$ mol/*l*), as is shown in Figs. 5(a) and (b). Dissolved oxygen had no effect on the quantum yields, as is shown in Table 3. The addition of piperylene as a triplet quencher (E_T=2.48 eV)[5,12,13] did not affect the quantum yields of this isomerization in concentration from 10^{-4} up to 10^{-2} mol/*l*, as is shown in Fig. 5(d). There was scarcely no effect of the temperature (20—70°C) on the quantum yields of phenyl acetate photoisomerization (Fig. 5(c)), though a small temperature effect has been observed in the case of acetanilide.[7] This difference may be due to the fact that the intersystem crossing, $^3\sigma_0(O\leftarrow CO)\leftarrow S_1(\pi\pi^*)$, in phenyl acetate is quite rapid in comparison with that in acetanilide. The very small effect of the temperature on the quantum yields for phenyl acetate rearrangements is due to the high quantum yield for the predissociation of phenyl acetate, as will be described later. Of course, the effect of the temperature on the quantum yield at low temperatures (*e. g.*, at the temperature of liquid nitrogen) may be expected because of the increasing stiffness of the solvent cage at low temperatures, as has been described in a previous paper.[8]

The quantum yields decreased in polar solvents, as is shown in Table 3. However, the variation in the rearrangement quantum yields on solvents were smaller than that of acetanilide.[6] This may be due to the fact that phenyl acetate has no hydrogen atom to form a hydrogen-bond with a proton acceptor.

The features of the lowest excited singlet state and of the photochemical reaction of phenyl acetate are very close to those of acetanilide.[5-7] Its reaction mechanism involves the predissociation to phenoxy and acetyl radicals and subsequent recombination reactions between the pair radicals in a solvent cage.

Estimations of Back Reaction and Predissociation Quantum Yields. The recombination reaction between pair radicals consists of a back reaction and of *o*- and *p*-rearrangements in a solvent cage. These reactions have been shown in the photochemical rearrangement of acetanilide.[7] The quantum yield for the back reaction (Φ_B) and the predissociation (Φ_{dis}) were estimated by the method described in a previous paper.[7]

In the first approximation, the photochemical primary process in *p*-methylphenyl acetate is the same as that in phenyl acetate, because the UV absorption spectrum of *p*-methylphenyl acetate is similar to that of phenyl acetate. Therefore, Eq. (1) is given on the basis of the same assumption as was presented in a previous paper;[7]

$$\Phi^{H}_{dis} \approx \Phi^{CH_3}_{dis} \quad (1)$$

Blocked by a methyl group at the *p*-position of the phenoxyl radical, *p*-rearrangement can not occur.

12) P. E. Eaton and W. S. Hurt, *J. Am. Chem. Soc.*, **88**, 5038 (1966).
13) E. Y. Y. Lam, D. Valentine and G. S. Hammond, *ibid.*, **89**, 3482 (1967).

Thus, the values of quantum yields for the back reaction (Φ_B), the *o*-rearrangement (Φ_o), and the *p*-methylphenol formation increase.

$$\Delta\Phi_o = \Phi_o^{CH_3} - \Phi_o^{H} = 0.06 \quad (2)$$

$$\Delta\Phi_B = \Phi_\Sigma^{H} - \Phi_\Sigma^{CH_3} = 0.08 \quad (3)$$

$$\Delta\Phi_{OH} = \Phi_{OH}^{CH_3} - \Phi_{OH}^{H} = 0.01 \quad (4)$$

where:

$$\Phi_\Sigma^{H} = \Phi_o^{H} + \Phi_p^{H} + \Phi_{OH}^{H},\ \Phi_\Sigma^{CH_3} = \Phi_o^{CH_3} + \Phi_p^{CH_3} + \Phi_{OH}^{CH_3}$$

The ratio of Φ_B to 1/2 Φ_o is given approximately by:

$$\frac{\Phi_B}{\frac{1}{2}\Phi_o} \approx \frac{\Delta\Phi_B}{\frac{1}{2}\Delta\Phi_o} = 2.7 \quad (5)$$

Therefore, the values of Φ_B and Φ_{dis} may be evaluated as follows:

$$\left.\begin{aligned} \Phi_B^{H} &= \frac{1}{2}\Phi_o^{H} \times 2.7 \approx 0.23 \\ \Phi_{dis}^{H} &= \Phi_B^{H} + \Phi_\Sigma^{H} \approx 0.61 \end{aligned}\right\} \quad (6)$$

and:

$$\left.\begin{aligned} \Phi_B^{CH_3} &= \frac{1}{2}\Phi_o^{CH_3} \times 2.7 \approx 0.31 \\ \Phi_{dis}^{CH_3} &= \Phi_B^{CH_3} + \Phi_\Sigma^{CH_3} \approx 0.61 \end{aligned}\right\} \quad (7)$$

Also, the values of Φ_B^{Cl} and Φ_{dis}^{Cl} are estimated to be 0.35 and 0.69 respectively. The quantum yields for the back reaction and the predissociation are summarized in Table 4.

Table 4. Quantum yields for the back reaction (Φ_B) and the predissociation (Φ_{dis}) of *p*-X-substituted phenyl acetate at 2537 Å

Substance X	Quantum yield (Φ) Φ_Σ	Φ_B	Φ_{dis}
H	0.38	0.23	0.61
CH_3	0.30	0.31	0.61
Cl	0.34	0.35	0.69

The quantum yield for the predissociation of phenyl acetate is quite large in comparison with that of acetanilide (~0.25).[7] This means that the intersystem crossing probability for the predissociation of phenyl acetate is larger than that of acetanilide.

The recombination ratios (β) are obtained from Eq. (8):

$$\left.\begin{aligned} \beta_H &= \frac{\Phi_o^{H} + \Phi_p^{H} + \Phi_B^{H}}{\Phi_{dis}^{H}} = 0.90 \\ \beta_{CH_3} &= \frac{\Phi_o^{CH_3} + \Phi_B^{CH_3}}{\Phi_{dis}^{CH_3}} = 0.89 \\ \beta_{Cl} &= \frac{\Phi_o^{Cl} + \Phi_B^{Cl}}{\Phi_{dis}^{Cl}} = 0.88 \end{aligned}\right\} \quad (8)$$

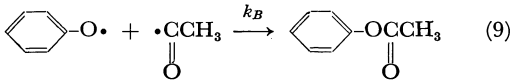
These high recombination ratios ($\beta = \sim 0.9$) indicate that the recombination reactions between phenoxy and acetyl radicals occur efficiently in a solvent cage, as do those in the photochemical rearrangement of acetanilide.[7]

No intermediate absorption was observed by means of the flash technique. The absorptions of the products appeared immediately after the flash.

From these results, the photochemical secondary processes of phenyl acetate can be given as follows:

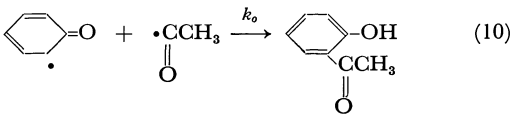
1) Recombination reaction (Main reaction)

a) Back reaction



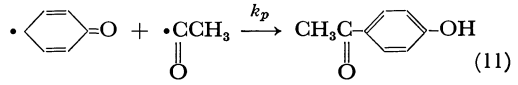
(9)

b) *o*-rearrangement



(10)

c) *p*-rearrangement



(11)

2) Hydrogen atom abstraction reaction

(12)

where k_B, k_o, and k_p are the rate constants of the back reaction, the *o*-rearrangement, and the *p*-rearrangement respectively, and where RH is a solvent molecule.

The rate constants (k_B, k_o, and k_p) for the recombination reactions between the pair radicals in a solvent cage will be proportional to the odd π electron distributions (δ) of the phenoxy radical which were obtained by Müller *et al.*[14] (Fig. 6).

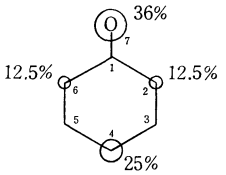


Fig. 6. Odd π electron distributions of the phenoxy radical.

$$k_B : k_o : k_p = \Phi_B : \frac{1}{2}\Phi_o : \Phi_p \quad (13)$$

$$= 1 : 0.37 : 0.65$$

$$\delta_7 : \delta_2 : \delta_4 = 1 : 0.35 : 0.69 \quad (14)$$

$$k_B : k_o : k_p \approx \delta_7 : \delta_2 : \delta_4 \quad (15)$$

From these results, it can be said that the photochemical reaction of phenyl acetate can be explained by a mechanism similar to that for acetanilide presented in previous papers.[5-7]

In conclusion, the reaction scheme of phenyl acetate at 2537 Å in the liquid phase is as follows:

$$S_0 + h\nu \longrightarrow S_1(\pi\pi^*)(^1B_2) \tag{16}$$

$$S_1(\pi\pi^*) \xrightarrow{k_s} S_0 \tag{17}$$

$$S_1(\pi\pi^*) \xrightarrow{k_F} S_0 + h\nu' \tag{18}$$

$$S_1(\pi\pi^*) \xrightarrow{k_c} T_1(\pi\pi^*) \tag{19}$$

$$S_1(\pi\pi)^* \xrightarrow{k_{dis}} \phi\text{-O}\cdot + \cdot\text{CCH}_3 \quad (\text{O}) \tag{20}$$

ϕ-O· + ·CCH$_3$ (O) → k_B → S_0; k_o → o-hydroxyacetophenone; k_p → p-hydroxyacetophenone; k_{OH} → phenol (21)

Electron Spin Resonance Studies of the Formation of Anion Radicals on γ-Irradiated Silica Gel

Yoshio YAMADA, Akinori HASEGAWA and Masaji MIURA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima

(Received November 22, 1968)

The ESR spectra assigned to the anion radicals of SO_2^-, $(TCNE)^-$ (tetracyanoethylene), and O_2^- were obtained for, respectively, sulfur dioxide, TCNE, and oxygen when these gases were adsorbed on γ-irradiated silica gel. As regards sulfur dioxide, a characteristic change in the concentration of the SO_2^- radical was observed during the post-irradiation with high-energy UV light. In the case of carbon dioxide, the CO_2^- radical was produced only when UV post-irradiation was added to γ-irradiation. The assignments were principally made in comparison with the reported g-values. Especially, the identification of the CO_2^- radical was ascertained by using ^{13}C. The analyses of the g-factor for the O_2^- radical and of ^{13}C hyperfine constants for the CO_2^- radical gave information on the interaction of the radicals on a solid surface with the cations in the adsorption center. In view of the fact that each of these molecules possesses a different degree of electron affinity, the results described above indicate that the electrons trapped in the defects of the silica gel surface transfer to the adsorbed molecules and that UV light promotes the electron transfer.

The application of ESR spectroscopy to the study of the state of molecules adsorbed on solid surfaces has been of considerable interest since it permits an analysis of the radical species produced from the molecules. The radicals detected by this method are generally classified into two types by taking the properties of adsorbents into account: (1) neutral radicals adsorbed on insulators[1,2] and (2) anion radicals on n-type semiconductors.[3-5] In respect to the radicals of the first type, the adsorbent contributes mainly to the stabilization rather than to the formation of radicals. Those of the second type are produced as a result of electron transfer from the adsorbent to the adsorbate with a high electron affinity. However, Lunsford and Jayne[6,7] have recently found that such anion radicals as CO_2^- or O_2^- are produced even on UV-irradiated magnesium oxide, an insulator. They have concluded from their studies that the trapped electrons created by UV irradiation take part in the formation of the anion radicals. All the investigations using silica gel, which is also an insulator, have, however, dealt only with neutral radicals

produced from the adsorbed-state molecules by γ- or UV-irradiation.[1,2]

In the present study, such anion radicals as SO_2^-, $(TCNE)^-$, and O_2^- were obtained from, respectively, sulfur dioxide, TCNE, and oxygen adsorbed on γ-irradiated silica gel. As for carbon dioxide, the CO_2^- radical was formed when UV post-irradiation was added to γ-irradiation.

Experimental

Materials. The method of the preparation of silica gel was described in the preceding paper.[8] Sulfur dioxide, oxygen, and carbon dioxide were purified by distillation under a vacuum. TCNE from the Wako Pure Chemical Co. was purified by sublimation.

Measurements. The silica gel was placed in a quartz tube fitted with a breakable seal and was outgassed in a vacuum of 10^{-5} Torr for 5 hr at 450—500°C. The tube was sealed off under a vacuum and then was irradiated at room temperature for *ca.* 15 hr with a ^{60}Co γ-source at a dose rate of 10^6 rad/hr. After the irradiation, the silica gel in a tube was exposed to sulfur dioxide, oxygen, carbon dioxide, or the vapor of TCNE through the breakable seal in a vacuum system. The ESR spectra were measured by a Japan Electron Optics Laboratory JES-3BS-X type ESR spectrometer operating at a cavity resonance frequency of 9400 Mc/sec with 100 kc modulation. The *g*-value was obtained by comparison with the value for DPPH. The error in *g*-value was estimated to be ±0.0002.

A high-pressure mercury lamp equipped with a Toshiba UV-D25 or VY-42 filter and also a low-pressure mercury lamp were employed in order to examine the effects of UV irradiation. UV-D25 and VY-42 filters transmit the light between 2400 Å and 4000 Å, and that between 4200 Å and 6000 Å, respectively. Carbon dioxide containing 60.8 atom% $^{13}CO_2$ which had been obtained from the Ateledyne Co., was used to identify the radical species. The TCNE anion radical was confirmed by a study of the diffuse reflectance spectra in addition to ESR spectra.

Results and Discussion

The spectrum of silica gel irradiated at room temperature is shown in Fig. 1. It was previously identified as being due to the electrons trapped in the defects.[9,10] The *g*-value (2.0009) of the spectral line is smaller than that of the free spin, and this spectrum is apt to be saturated with microwave power. These results support the above assignment.

In view of the facts that the silica gel used here has a high surface area (S=790 m²/g) and that the introduction of such a gas as sulfur dioxide results in the destruction of the defects, it seems reasonable that the electrons are trapped in the defects at the surface or its vicinity.

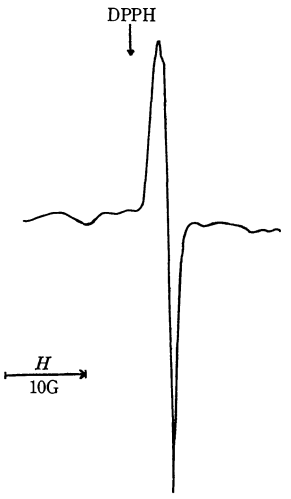

Fig. 1. ESR spectrum of γ-irradiated silica gel at room temperature.

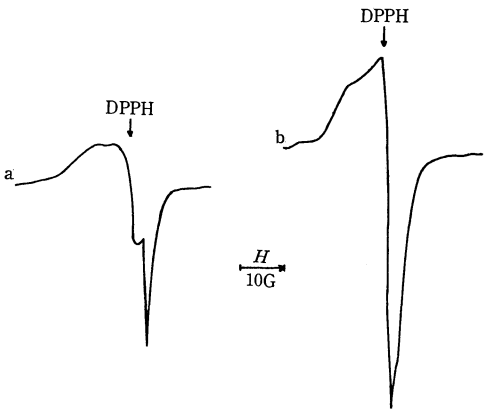

Fig. 2. (a) Spectrum recorded after sulfur dioxide was introduced at a pressure of 5 Torr to pre-irradiated silica gel, (b) spectrum recorded after sample (a) was irradiated with UV light for 5 min.

Sulfur Dioxide Adsorbed on Silica Gel. When sulfur dioxide was introduced into the silica gel at a pressure of 5 Torr, the gel, which had taken a faint violet color upon γ-irradiation, became colorless and a new ESR spectral line appeared, as is shown in Fig. 2a. This spectral line, however, did not appear on unirradiated silica gel. The values of $g_\perp$=2.0018 and $g_{//}$=2.0079 can be compared with those of the SO_2^- radical adsorbed on reduced titanium dioxide or zinc oxide.[3] On the basis of these results, the spectrum exhibited in Fig. 2a may be considered to be due to the SO_2^- radical. The formation of the SO_2^- radical on such semiconductors as titanium dioxide and zinc oxide has been interpreted as being due to the fact that the sulfur dioxide molecule, having a

high electron affinity, easily accepts an electron from the adsorbents because of the narrow energy gap between the valence and conduction bands.[11] In the case of silica gel, therefore, it is probably the trapped electrons that transfer to the adsorbed sulfur dioxide molecules, since silica gel is a typical insulator.

The signal (g=2.0009) corresponding to the electron trapped in the defect still remains, though faintly, after the adsorption. However, post-irradiation with UV light leads to the disappearance of this signal and, at the same time, to an increase in the intensity of the ESR signal due to the SO_2^- radicals. The increment in SO_2^- radicals by UV light in two different ranges of wavelengths are presented in Fig. 3 as a function of the irradiation time.

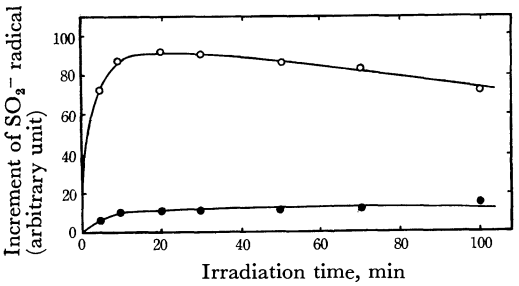

Fig. 3. The increment of SO_2^- radical by UV irradiation.

○: 2400—4000 Å (transmittance 60%)
●: 4200—6000 Å (transmittance 95%)

The illumination with light of wavelengths from 4200 Å to 6000 Å resulted in little increase in the radical. On the other hand, when light from 2400 Å to 4000 Å was used, the amount of the radical increased remarkably, though the short-wavelength light is more scattered than that of long wavelengths. Moreover, the increase in the radical reached a maximum after *ca.* 20 min and then decreased with the irradiation time. These results indicate that an energy higher than *ca.* 3 eV, which is equivalent to 4000 Å, is effective for the electron transfer. It has previously been reported that absorption spectra with peaks at 2.3, 4.1, and 5.6 eV appear on X-irradiated fused quartz,[12] the chemical composition of which is similar to that of silica gel. If these absorption bands are available to γ-irradiated silica gel, it should be mentioned, in view of the electron affinity of sulfur dioxide (2.8 eV), that even deeply-trapped electrons equivalent to 4.1 and 5.6 eV can migrate to the sulfur dioxide molecules on the surface upon UV illumination, supposing that the activation energy for the formation of the SO_2^- radical is overestimated.

The diminution in the radical concentration with the irradiation time can be interpreted if the following reactions are taken into consideration:

$$SO_2 + e^- \rightarrow SO_2^- \quad (1)$$

$$SO_2^- \rightarrow SO_2 + e^- \quad (2)$$

where e^- in Reaction (1) corresponds to an electron trapped in the defect, while that in Reaction (2) denotes an electron bleached. Namely, Reaction (2) should bring about a decrease in the radical concentration. Upon the illumination with the light from 4200 Å to 6000 Å, an appreciable increase in the radical amount was observed in the first stage, but it showed no change after *ca.* 20 min. It may be concluded from these facts that an energy less than *ca.* 3 eV contributes slightly to Reaction (1) through the transfer of the electrons trapped in the shallow potential at the first stage, but that it is inactive for Reaction (2).

TCNE Adsorbed on Silica Gel. When γ-irradiated silica gel was exposed to the vapor (10^{-2}—10^{-3} Torr) of TCNE for 10 hr, an ESR spectrum was obtained, as is shown in Fig. 4. On the other hand, no ESR signal was detected for unirradiated silica gel. The spectrum given in Fig. 4 is in good agreement with that of the TCNE anion radical formed when TCNE was adsorbed on alumina.[13] In order to identify the radical species further the reflectance spectrum of adsorbed TCNE was measured. The absorption band at *ca.* 420 mμ nearly corresponds to that of the TCNE anion radical in solution.[14] These results lead to the conclusion that the radical formed on silica gel is the TCNE anion. This is further supported by the characteristic features that TCNE has a high electron affinity and that the TCNE anion radical, as is well known, is stable even at room temperature. It seems reasonable that electron transfer is involved in the formation of the TCNE anion radical as in the case of the SO_2^- radical on silica gel. The spectral lines of the TCNE anion radical on silica gel are ill-resolved in contrast with those in solution, where four equivalent nitrogen atoms give nine lines as a result of interaction with the unpaired electron. This is explained by the fact that the anisotropy of the hyperfine structure arises from the lack of motional degrees of freedom. The signal due to the electrons trapped in the defects can scarcely be seen in Fig. 4, and the UV irradiation has no remarkable effect, different from the case of the SO_2^- radical.

Oxygen Adsorbed on Silica Gel. Oxygen was introduced at a pressure of 100 Torr to silica gel which had been irradiated by γ-ray at room temper-

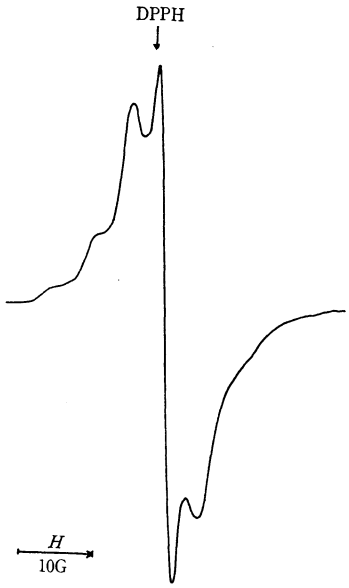

Fig. 4. Spectrum recorded after TCNE was introduced at a vapor pressure of 10^{-2}—10^{-3} Torr to pre-irradiated silica gel.

ature. A broad asymmetric spectrum appeared in addition to the signal responsible for the electrons trapped in the defects (Fig. 5a). The g-values of the new spectral line are $g_1=2.0250$, $g_2=2.0095$, and $g_3=2.0031$. Similar experiments have already been carried out by several investigators. Kazanskii *et al.*[10] showed that, for the sample outgassed at 200—300°C, the radicals formed by the cleavage of surface hydroxyl groups react with oxygens to produce the surface peroxide radicals ($g_1=2.025$, $g_2=2.002$, and $g_3=2.002$). In the case of the sample pre-treated at 500°C, however, they did not discuss the weak, different ESR spectrum formed by the introduction of oxygen to γ-irradiated silica gel. Since the present sample was outgassed at 450—500°C, the signal obtained here is considered not to be due to the surface peroxide radicals. As the matter of fact, the signal exhibited in Fig. 5a is identical with that observed under outgassing at 500°C by Kazanskii *et al.* Haul *et al.*[15] studied the effect of oxygen, nitrogen oxide, and a number of other gases on the ESR signal of irradiated silica under static and dynamic flow conditions. However, they did not find the new spectrum obtained here.

In order to elucidate the radical species corresponding to the asymmetric spectrum, a sample containing oxygen is irradiated by UV light for 30 min (Fig. 5b). The intensity of the spectral line is clearly enhanced. From these experiments and the assignment mentioned above for SO_2^- and $(TCNE)^-$, it may be concluded that the broad asymmetric spectrum is due to the O_2^- radical formed by the electron transfer from the solid to the adsorbed oxygen. This assignment is not necessarily inconsistent with the conclusions described above. The O^- radical may also be considered as a radical species. However, the g-values observed here are not suitable for the O^- radical reported,[16] and the energy required for the dissociation of O_2^- into

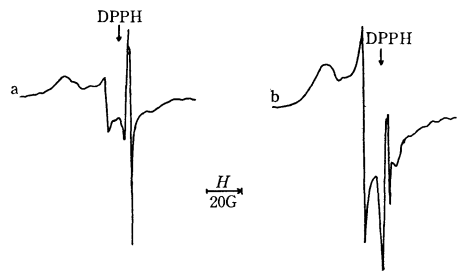

Fig. 5. (a) Spectrum recorded after oxygen was introduced at a pressure of 100 Torr to pre-irradiated silica gel, (b) spectrum recorded after sample (a) was irradiated with UV light for 30 min.

15) R. Haul, J. Karra and J. Turkevich, *J. Am. Chem. Soc.*, **87**, 2092 (1965).

$O+O^-$ is 4.1 eV,[17] an energy which is impracticable under the present experimental conditions. Therefore, the formation of the O^- radical should be excluded. After all, then, these discussions give strong evidence for our tentative identification.

Kazanskii *et al.*[5] pointed out, from their analysis of *g*-values, that the most probable state of the peroxide radical on silica gel and of O_2^- radicals on various solid surfaces is such that the O–O axis of these radicals is parallel to the surface. The analysis of the *g*-values obtained in the present case suggests that the O_2^- radical on silica gel is also adsorbed in such a situation.

Carbon Dioxide Adsorbed on Silica Gel. On the exposure of pre-irradiated silica gel to $^{12}CO_2$ gas at 100 Torr, the spectrum illustrated in Fig. 6a was observed. It is similar in shape to that of irradiated silica gel itself. With the UV irradiation, the shoulder grew, whereas the signal due to the electrons trapped in the defects was weakened (Fig. 6b). The *g*-values of the new spectral line ($g_1=g_2=2.0024$ and $g_3=1.9975$) are in complete agreement with those of the CO_2^- radical reported in a preceding paper.[8] In this case, the UV light may contribute to the electron transfer since the electron affinity of carbon dioxide is much less than those of sulfur dioxide, TCNE, and oxygen. The spectrum, which was measured under the same conditions by using a mixture of 60.8 atom% $^{13}CO_2$ and 39.2 atom% $^{12}CO_2$, is illustrated in Fig. 6c. The ^{13}C hyperfine coupling constants evaluated from this spectrum are presented in Table 1, along with the values in the literatures. At the same time the experiment of Lunsford and Jayne[6] on the CO_2^- radical on magnesium oxide was repeated. The isotropic and anisotropic hyperfine constants obtained are almost identical with their results shown in Table 1, within the limits of experimental error. The values of a_s^2 and a_p^2, which give the unpaired electron density in the 2*s* and 2*p* orbitals respectively of the carbon atom, were calculated by analogy with Ovenall and Whiffen's article.[18] These values correspond to the isotropic and anisotropic parts of ^{13}C coupling.

Coulson[19] introduced the following formula for the bond angle of such molecules as CO_2^- and NO_2:

$$\cos\theta = -\lambda^2/(2+\lambda^2) \qquad (3)$$

where θ denotes the OCO bond angle and λ, the ratio of a_s to a_p. The bond angle of the CO_2^- radical on γ-irradiated silica gel was determined by the use of Eq. (3). The value of the hyperfine splitting constant introduces some error ($\pm$8G) because of the overlapping of the anisotropies of *g*-factors and hyperfine constants. The bond angle of the CO_2^- radical on silica gel is much less than that on magnesium oxide, as is obvious from Table 1. The narrowing of the OCO bond angle of the CO_2^- radical on silica gel may be attributed to the characteristic adsorption: the separation of silicon atoms on the silica gel surface is smaller than that of magnesium atoms on the magnesium oxide surface. The narrowing of the OCO angle should also have an influence upon the molecular orbitals of the CO_2^- radical. The OCO angle of the CO_2^- radical may be expected to become narrow as the energy gaps between $3b_2$ and $4a_1$ and between $2b_1$ and $3b_2$ in the energy levels of the CO_2^- radical molecular orbital become large. Accordingly, the $4a_1 \leftarrow 3b_2$ and $2b_1 \leftarrow 3b_2$ promotions are reduced. The $4a_1 \leftarrow 3b_2$ and $2b_1 \leftarrow 3b_2$ contribute to the deviation of the values of g_1 and g_2 respectively from the value of free spin. Thus, the narrowing of the OCO angle results in the approach of g_1 and g_2 to the value of the free spin. The experimental result ($g_1=g_2=2.0024$) is consistent with these considerations.

In conclusion, it was found that the anion radicals are formed by introducing such gases as sulfur dioxide, TCNE, and oxygen to γ-irradiated silica gel. As for the CO_2^- radical, it was formed by UV irradiation in addition to γ-irradiation because carbon dioxide has a low electron affinity. The O_2^- radical seems to be adsorbed in such a state that the O–O axis is parallel to the gel surface. In addition, the analysis of the ^{13}C hyperfine constants for the CO_2^- radical gave a closer OCO angle than that of the CO_2^- radical on magnesium oxide. This finding may be ascribed to the difference in the crystal radii of the cations on the solid surface.

TABLE 1. HYPERFINE COUPLING CONSTANTS AND PARAMETERS FOR CO_2^- RADICAL

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 1841—1852 (1969)

The Electronic Spectra and the Intermolecular Interaction of Würster's Ions in Crystals

Jiro TANAKA and Masagi MIZUNO*1

Department of Chemistry, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya

(Received November 30, 1968)

The electronic spectra and the intermolecular interaction of Würster's radical have been studied for the dimer state and for the crystalline states. The polarization properties of the excited states have been investigated in detail, and the longest wavelength absorption band of the dimer has been established as having a charge-transfer character. The strength of the charge-transfer band and the shift of the monomer band in the dimer or in the crystalline states are shown to be intimately correlated with the strength of the intermolecular interactions between the stacked radicals. A theoretical analysis of the excited state of the dimer and the crystals is presented; the results are in good agreement with the experimental findings.

Würster's ions are well known to dimerize at lower temperatures in a solution. Hausser and Murrell[1] first pointed out that the origin of the longest-wavelength absorption band of the dimer is charge-transfer in nature and suggested that the ions might be stacked on each other in a solution. Suzuki, Ooshika, and their coworkers[2] extended the earlier work and found the equilibrium constant for dimerization. A similar line of experiment was carried out by Kimura, Yamada, and Tsubomura[3] recently. Kommandeur and Pott[4] discussed the nature of the electronic transition from a different viewpoint and suggested that a doubly-charged cation and a neutral molecule might be involved in the appearance of the longest-wavelength band. On the other hand, McConnell and his group,[5] however, insisted on the charge-transfer mechanism and a recent experiment by Sakata and Nagakura[6] has also supported this interpretation.

In this laboratory an X-ray structure analysis has been carried out on several Würster's salts,[7] and a combined investigation of the spectra and structure of the crystals has been attempted. The measurement of the absorption spectra with a single crystal by means of polarized light is the most reliable method for confirming the symmetry properties of the excited state if the crystal structure has already been established. In this paper we will present: (1) a theoretical treatment of the dimer interaction, (2) the findings on the crystalline absorption spectra of various Würster's salts, and (3) a discussion of the nature of the electronic transition in the crystalline state.

The longest-wavelength absorption bands of the crystals have definitely been determined to be an intermolecular charge-transfer between the stacked radicals. The appearance of the charge-transfer band in the crystalline spectra is intimately correlated with the magnitude of the intermolecular electron exchange interaction, which can be estimated by means of the overlap integrals between the molecular orbitals of the radicals. The polarization properties of the radical excited states have been determined; the findings are supported by the theoretical analysis[8] of the radical spectra. The configurational mixing between the charge-transfer state with the local excited state shifts the visible band of the radical to a shorter wavelength. It may be concluded that the electron-exchange effect between the radicals is most important in determining the optical and other electronic properties of organic free-radical crystals.

Theory of the Dimer Interaction

According to results of the X-ray crystal structure analysis, the interplanar distances between the

stacked radicals are in the range of 3.1—3.7 Å. In the region of these intermolecular distances, covalent bondings between the radicals may be expected; their strength can be estimated by the electron overlap between the half-filled molecular orbitals of the radicals. The Heitler-London approach is most appropriate for the treatment of the inter-radical interaction at these distances, since the molecular orbital method would emphasize the electron delocalization effect too much. In the following treatment we will consider only the highest singly-occupied orbital as a one-electron problem and will neglect the effects of all the other occupied orbitals. The singly-occupied highest molecular orbitals of a and bth radicals are denoted by $\psi_a{}^m$ and $\psi_b{}^m$, and vacant orbitals, by $\psi_a{}^e$ and $\psi_b{}^e$.

The orbital wave function of the singlet state may be given as follows:

Ground Configuration:

$$\Psi_G = \frac{1}{\sqrt{2(1+S_{mm}^2)}}[\psi_a{}^m(1)\psi_b{}^m(2) + \psi_b{}^m(1)\psi_a{}^m(2)]$$

Charge-transfer Configuration:

$$\Psi_{CT\pm} = \frac{1}{\sqrt{2(1\pm S_{mm}^2)}}[\psi_a{}^m(1)\psi_a{}^m(2) \pm \psi_b{}^m(1)\psi_b{}^m(2)]$$

Molecular Excited Configuration:

$$\Psi_{M\pm} = \frac{1}{\sqrt{4+2S_{me}^2+2S_{mm}S_{ee}}}[\psi_a{}^e(1)\psi_b{}^m(2) + \psi_b{}^m(1)\psi_a{}^e(2) \pm \psi_a{}^m(1)\psi_b{}^e(2) \pm \psi_a{}^m(2)\psi_b{}^e(1)]$$

where the upper sign corresponds to the symmetric state and the lower one to the antisymmetric state.

The total Hamiltonian for the system is given by;

$$H = H_a + H_b + V_{ab}$$

$$H_a = -\frac{1}{2}\nabla_1{}^2 - \sum_i \delta_i/R_{a_i 1}$$

$$H_b = -\frac{1}{2}\nabla_2{}^2 - \sum_j \delta_j/R_{b_j 2}$$

$$V_{ab} = -\sum_j \delta_j/R_{b_j 1} - \sum_i \delta_i/R_{a_i 2} + 1/r_{12} + \sum_{i,j} \delta_i\delta_j/R_{a_i,b_j}$$

where $\sum_i \delta_i R_{a_i 1}$ indicates the core attraction potentials for the first electron by the ith atomic core of the ath radical with a δ_i effective charge, which is produced by stripping off one electron from the complete radical. The molecular orbital of the radical is given by the LCAO form while the orbital energies for the isolated system are given by:

$$\psi_a{}^m = \sum_i C_i{}^m \chi_{a_j}$$

$$H_a\psi_a{}^m = \varepsilon_a{}^m\psi_a{}^m$$

$$H_b\psi_b{}^m = \varepsilon_b{}^m\psi_b{}^m$$

The overlap integral and other integrals between radicals are described by:

$$S_{mm} = \sum_i\sum_j C_i{}^m C_j{}^m \langle \chi_{a_i}|\chi_{b_j}\rangle$$

$$\langle \psi_a{}^m|1/R_b|\psi_b{}^m\rangle = \sum_i\sum_j C_i{}^m C_j{}^m \langle \chi_{a_i}|\delta_j/R_{b_j}|\chi_{b_j}\rangle$$

$$(\psi_a{}^m\psi_a{}^m|\psi_b{}^m\psi_b{}^m) = \sum_i\sum_j C_i{}^{m2} C_j{}^{m2} \langle \chi_{a_i}(1)\chi_{a_i}(1)|1/r_{12}|\chi_{b_j}(2)\chi_{b_j}(2)\rangle$$

$$S_{mm}\langle \psi_a{}^m|1/R_b|\psi_b{}^m\rangle = \sum_i\sum_j C_i{}^{m2} C_j{}^{m2} \langle \chi_{a_i}|\chi_{b_j}\rangle\langle \chi_{a_i}|\delta_j/R_{b_j}|\chi_{b_j}\rangle$$

By the use of these notations, the diagonal energy for the ground state may be given by:

$$E_{G,G} = 2\varepsilon_a{}^m - 2\langle \psi_a{}^m|1/R_b|\psi_a{}^m\rangle + (\psi_a{}^m\psi_a{}^m|\psi_b{}^m\psi_b{}^m)(1-S_{mm}^2) + \sum_i\sum_j \frac{\delta_i\delta_j}{R_{a_i,b_j}}$$
$$-2S_{mm}\langle \psi_a{}^m|1/R_b|\psi_b{}^m\rangle + 2S_{mm}^2\langle \psi_a{}^m|1/R_b|\psi_a{}^m\rangle + (\psi_a{}^m\psi_b{}^m|\psi_a{}^m\psi_b{}^m) \quad (4)$$

The diagonal energy for the molecular excited state relative to the ground state is calculated as:

$$E_{E,E\pm} - E_{G,G} = \varepsilon_a{}^e - \varepsilon_b{}^m - \langle \psi_a{}^e|1/R_b|\psi_a{}^e\rangle + \langle \psi_a{}^m|1/R_b|\psi_a{}^m\rangle + (\psi_a{}^e\psi_a{}^e|\psi_b{}^e\psi_b{}^e)(1-S_{ee}S_{mm})$$
$$-(\psi_a{}^m\psi_a{}^m|\psi_b{}^m\psi_b{}^m)(1-S_{mm}^2) - 2S_{me}\langle \psi_a{}^e|1/R_b|\psi_b{}^m\rangle + 2S_{mm}\langle \psi_a{}^m|1/R_b|\psi_b{}^m\rangle$$
$$\pm(\psi_a{}^m\psi_a{}^e|\psi_b{}^m\psi_b{}^e)(1-S_{ee}S_{mm}) \pm (\psi_a{}^e\psi_b{}^m|\psi_a{}^e\psi_b{}^m) \quad (5)$$

If we use the following approximations, which are valid for a rough calculation:

$$C_i{}^m{}^2 = C_i{}^e{}^2, \qquad S_{mm}\psi_a{}^m = S_{me}\psi_a{}^e$$
$$\langle\psi_a{}^e|1/R_b|\psi_a{}^e\rangle = \langle\psi_a{}^m|1/R_b|\psi_a{}^m\rangle \tag{6}$$

Equation (5) is reduced to:

$$E_{M,M_\pm} - E_{G,G} = \varepsilon_a{}^e - \varepsilon_b{}^m \pm (\psi_a{}^m\psi_a{}^e|\psi_b{}^m\psi_b{}^e)(1-S_{ee}S_{mm}) \pm (\psi_a{}^e\psi_b{}^m|\psi_a{}^e\psi_b{}^m)$$
$$\simeq \varepsilon_a{}^e - \varepsilon_b{}^m \pm (\psi_a{}^m\psi_a{}^e|\psi_b{}^m\psi_b{}^e) \tag{7}$$

The diagonal energy of the charge-transfer state relative to the ground state is evaluated as;

$$E_{CT,CT} - E_{G,G} = [(\psi_a{}^m\psi_a{}^m|\psi_a{}^m\psi_a{}^m) - (\psi_a{}^m\psi_a{}^m|\psi_b{}^m\psi_b{}^m)](1-S_{mm}^2) \tag{8}$$

The off-diagonal matrix element between the charge-transfer and molecular excited configurations and the ground configuration have been calculated, The results are:

$$E_{G,CT_+} = \sqrt{2}\,[S_{mm}\varepsilon_a - S_{mm}\langle\psi_a{}^m|1/R_b|\psi_a{}^m\rangle - \langle\psi_a{}^m|1/R_b|\psi_b{}^m\rangle$$
$$+ (\psi_a{}^m\psi_a{}^m|\psi_a{}^m\psi_b{}^m) + S_{mm}/R_{a,b}] \tag{9}$$
$$E_{M_\pm,CT_\pm} = \sqrt{2}\,[\pm S_{me}\varepsilon_a \mp S_{me}\langle\psi_a{}^m|1/R_b|\psi_a{}^m\rangle \mp \langle\psi_a{}^m|1/R_b|\psi_b{}^e\rangle$$
$$+ (\psi_a{}^m\psi_a{}^e|\psi_a{}^m\psi_b{}^m) \pm (\psi_a{}^m\psi_a{}^m|\psi_a{}^m\psi_b{}^e) \pm S_{me}/R_{a,b}]$$

The off-diagonal element between the molecular excited and the ground state is set equal to zero since this term has already been diagonalized.

With a view to interpretating the spectra of the dimer and the crystal, we have performed semi-empirical calculations. Three configurations, the ground, the charge-transfer, and the molecular excited state, of the lowest energy of the y axis polarization have been taken into account, where the x and y axes have been chosen to be as shown in Fig. 1.

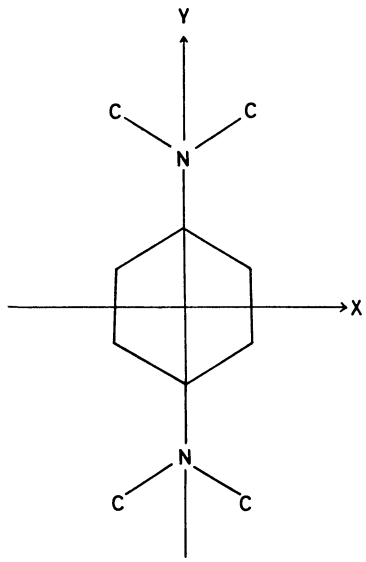

Fig. 1. The molecular axis of p-phenylenediamine.

The matrices for the symmetric (3×3) and the antisymmetric (2×2) states have been solved:

$$\begin{vmatrix} E_G & \beta & 0 \\ \beta & E_{CT_+} & \beta' \\ 0 & \beta' & E_{M_+} \end{vmatrix} = 0 \tag{10}$$

$$\begin{vmatrix} E_{CT_-} & \beta'' \\ \beta'' & E_{M_-} \end{vmatrix} = 0$$

Here the terms $S_{G,CT}\,E$, $S_{CT_+,M_+}\,E$, and $S_{CT-M_-}\,E$ are neglected in order to simplify the calculation. The actual calculation of the matrix elements is rather complicated; therefore, we have used semi-empirical values for the diagonal and off-diagonal elements. The diagonal element for the molecular excited state is taken from the peak of the absorption spectra in a solution. The energy of the charge-transfer state can be calculated by Eq. (8); however, the value is about 1 eV larger than the value envisaged from the dimer spectra in a solution. Therefore, we have used values which will fit the observed dimer spectra, 1.9 eV for the p-phenylenediamine cation dimer, 1.7 or 1.8 eV for Würster's red and 1.6 eV for Würster's blue dimers. The off-diagonal elements have been examined in detail; it is found that they are related to the overlap intergrals between the relevant molecular orbitals. In order to make a spectral assignment and an interpretation, we have used several sets of tentative matrix elements, β, β', and β''; the numerical values are tabulated in Table 1.

The results of the calculation are presented in

Tables 2 and 3. In Table 2 the wave functions are presented; by the use of these functions we can estimate the oscillator strength for each transition; their components are as shown in Table 3. Here the structure of the dimer is taken from the results of the crystal structure analysis.

The electronic absorption spectra of the Würster's dimer have been studied by several people; the results of Suzuki *et al.*[2] are shown in Fig. 2. In this figure the spectra of *p*-phenylenediamine and Würster's blue cation are presented; the monomer band (curve 1) consists of R, X, and Y bands, while the dimer spectra (curve 2) show a new longer wavelength charge-transfer (CT) band and shifted R′, X′, and Y′ bands. The splitting between the CT and R′ bands and the intensities are greatly dependent on the magnitude of the intermolecular interaction. In Table 3 the calculated oscillator strengths are presented; it is there shown that the intensity ratio for the CT and R band is so sensitively dependent on the magnitudes of the matrix elements that we might be able to estimate the strength of the interaction accurately by comparing the observed and calculated values. In Fig. 3 the results of the calculation are illustrated; the appearance of

the strong CT band and the large blue shift of the R band are intimately correlated with the intermolecular interaction. In Table 3 it may be seen that the case I corresponds to the p-phenylenediamine cation dimer in a solution, while the case II explains the Würster's red dimer and the case IV or V agrees well with Würster's blue dimer in a solution. The selected values of the off-diagonal matrix elements are quite reasonable from the point of view of steric repulsion, since the dimethyl group will hinder the stacking of the radicals.

In the next section several examples of crystal absorption will be presented, in which the change in the components of transition moments is exemplified by the intensity of the polarization spectra.

The ground-state stabilization energies, calculated as in Table 2, are intimately correlated with the singlet-triplet separation energies of the radical crystals. The experimental results on the magnetic susceptibilities of these crystals will be discussed in a separate paper.

Crystalline Absorption Spectra

The crystals of Würster's blue perchlorate, blue iodide, blue bromide, and red bromide were synthesized by the method of Michaelis and Granick.[9] Small crystals of microscopic size were selected under a polarization microscope for the spectral measurements, and the orientation of the crystalline axis was determined by taking X-ray photographs. The spectra were measured using a microspectrophotometer consisting of a Carl Zeiss monochromator and an Olympus microscope. Some of these crystals are unstable at room temperature; therefore, the measurements were carried out as soon as possible after preparation.

i) Würster's Blue Perchlorate. The crystals of Würster's blue perchlorate show a brownish metallic reflection, hexagonal or square in rhomb shape. The crystalline structure has been analysed by Turner and Albrecht;[10] their results, as yet unpublished, have been confirmed in this laboratory. The crystal belongs to the orthorhombic system of the P_n2_n space group with lattice constants of $a=5.98$, $b=10.21$, and $c=10.23$ Å. It includes two molecules in a unit cell; the projection of molecules onto the *ac* plane is depicted in Fig. 4. There were two crystalline types, the developing *ac* plane and the developing *ab* plane. The crystalline absorption measured on the *ac* plane is shown in Fig. 5; it is remarkable that the charge-transfer band is very weak in crystals. It appears at 11500 cm^{-1} with its polarization along the *a* axis. In Fig. 6 another spectra with an *ab* plane developing is presented; the band has no component along the *b* axis. These two results have shown that the charge transfer band is polarized along the direction of the *a* axis; in this direction the lines connecting the centers of the stacked radicals are parallel. In view of the theoretical results, the charge-transfer transition should have a polarization parallel to the line connecting the center of the donor and the acceptor molecules. In the present system the Würster's ion acts as both the electron donor and the acceptor by itself; therefore, the polarization of the charge transfer band may be expected to be found only along the *a* axis. Therefore the weak 11500 cm^{-1} band is confirmed to be predominantly charge-transfer in character. It is very interesting that, in a solution at a lower temperature, the intensity of the charge-transfer band of the dimer was larger than in a crystal. The fact that the intensity of the charge-transfer band is greatly dependent on the overlapping of pi-electrons suggests that the stacking of radicals might be more effective for the dimer in a solution than in a crystal. Recent experiments by Anderson[11] and Sakata and Nagakura[6] have shown that the intensity of the charge transfer band increases

markedly below the transition point of the crystal. However, at room temperature, the crystalline spectrum is much like the spectrum of the radical monomer in a solution; therefore, the succeeding band may be regarded as representing the polarization characteristics of the radical excited states. In the 15000—20000 cm^{-1} region, the R-band is not observed along the *b* axis on the *ab* plane. If the polarization of this band is the short axis of the radical (the *x* axis in Fig. 1), it should be very strong along the *b* axis. The observed result is contrary to this prediction; therefore, the transition moment must be on the long axis (*y* axis). This is in harmony with our theoretical results presented in a separated paper.[8] The observed dichroic ratio, $I_a : I_c$ was 0.7 : 1.0, while the calculated value, assuming the long-axis polarization, is 1.3 : 1.0. The agreement is not perfect; however, the last choice of a polarization vertical to the benzene ring is not acceptable since the R-band is undoubtedly a pi-pi transition and so its transition moment must be on the plane of the benzene ring. The deviation of the dichroic ratio might result from a mixing with other excited states. In the calculation presented in Table 3, the intensity ratio for the CT and R band is evaluated. The observed value is 0.063 : 1, while the value calculated by means of the parameter (IX) is 0.06 : 1. This agreement suggests that interaction parameters as small as $\beta=0.08$ eV are valid for this crystal.

In the *b* axis spectrum a peak is observed at 25500 cm^{-1}, it corresponds to the X-band in the monomer spectrum. This band is not observed along either the *a* axis or the *c* axis; therefore, its polarization is confirmed to be the short axis of the radical. This result is also consistent with our prediction of the sequence of the excited state energy levels. In the range of 26000—34000 cm^{-1} a very broad band is observed along the spectra of both the *a* and *c* axes. This is correlated to the Y-band in a solution, and the polarization may safely be regarded as being to the long axis of the radical. In a higher energy region at about 38000 cm^{-1} another peak is observed; it is the W-band, and its polarization is also the long axis of the radical. Summarizing these results, it may be concluded that the polarizations of the radical excited states for R, Y, and W bands are *y* axis, while that for the X-band is *x* axis. Although the longest wavelength charge-transfer band is not as prominent in crystals, its polarization is perfectly on the line connecting the radicals, consistent with the theoretical results, shown in Table 3.

ii) Würster's Blue Iodide. The crystal structure of Würster's blue iodide is very much like that of blue perchlorate; the structure has recently been determined by De Boer, Vos, and Huml.[12] The crystal belongs to the orthorhombic system; the space group is *Pnnm* with $Z=2$. The unit cell dimensions are $a=5.919$, $b=9.855$, and $c=9.901$ Å. The projection of molecules onto the *ab* plane is shown in Fig. 7.

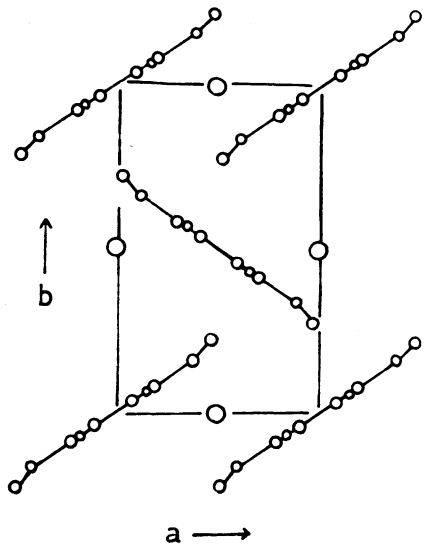

Fig. 7. Projection of Würster's blue iodide crystal onto the *ab* plane.

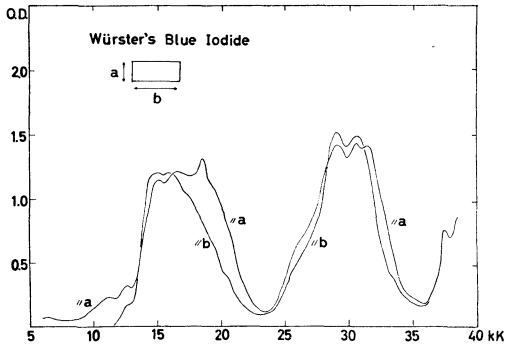

Fig. 8. The crystalline absorption spectra of Würster's blue iodide on the *ab* plane.

The crystalline absorption spectrum has been measured on the *ab* plane (Fig. 8). Although the inclination of the long axis to the *a* axis is decreased by 2.5° as compared to Würster's blue perchlorate, the spectrum is very close to the *ac* plane spectrum of perchlorate. The charge-transfer band is found at 11200 and 12500 cm^{-1}. The theoretical analysis presented above showed that the transition moment for this band is on the *a* axis of the crystal. The broad R-band is observed around the 14000—21000 cm^{-1} region and it showed several peaks which may be supposed to be due to the vibrational progressions. The X band is not obvious on this plane, but a little shoulder was found at 26000 cm^{-1}. The Y band is observed in the 28000—33000 cm^{-1}

12) J. L. De Boer, A. Vos and K. Huml, *Acta Cryst.*, **B24**, 542 (1968).

range; the polarization results are consistent with the previous conclusions drawn from the perchlorate crystalline spectrum.

In the iodide crystal the intensity ratio for the CT and R bands is found to be 0.052 : 1. This result suggests that the weakest interaction parameters will be valid for this crystal; however, the magnetic results show that the interaction might be slightly larger than in the perchlorate crystal. The overlap integral between the highest occupied orbitals will be discussed in the last section; it supports the idea of rather bigger parameters for this crystal.

Different crystalline modifications of Würster's blue iodide have been reported by Hughes and Hush.[13] In this experiment it has also been found that the other crystalline form is sometimes found in crystals obtained from a methanol solution. However, these crystals are rather unstable and rare; therefore, this form is not reported on in this paper.

iii) Würster's Blue Bromide. The crystal of Würster's blue bromide was obtained as brown-black needles, and a small, thin crystal was dark blue in light polarized parallel to the elongation axis and pale reddish in light polarized in the perpendicular direction. The crystal structure is now under investigation in this laboratory, while the space group and the cell constants have been determined to be as follows:

Crystal Data: Orthorhombic, Cmcm, $a=9.54$, $b=19.27$, $c=7.03$ Å, $z=4$.

The preliminary crystal structure results show that the elongation axis is the c axis, the benzene ring is perpendicular to the c axis, and the y-axis of the radical is parallel to the b axis. The projection of molecules onto the ab plane is shown in Fig. 9, and the projection onto the bc plane, in Fig. 10. The crystalline absorption spectra have been measured on the ac and bc planes by a polarized light; the results are shown in Figs. 11 and 12. In the range of 8000—15000 cm^{-1}, where a charge-transfer transition is expected, a broad peak is observed along both the b and c axes, but not along the a axis, where a weak absorption tail is observed. The transition moment of the charge-transfer transition is on the line connecting the stacked radicals; therefore, it has components along the c and b axes, but not along the a axis. The observed intensity ratio for the CT and R bands is about 0.55 : 1, while the calculated values are 0.35 : 1—0.5 : 1. The values of the intensity ratio for the perpendicular (c axis) and parallel (b axis) directions are 1.35 : 1 for the CT band and the calculated values are 1.2 : 1—1.7 : 1, in fairly good agreement with the observed values.

The next strong band is observed particularly along the b axis in the 15000—23000 cm^{-1} region;

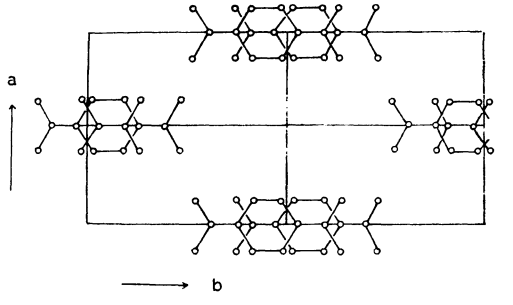

Fig. 9. Projection of Würster's blue bromide crystal onto the ab plane by the preliminary X-ray results.

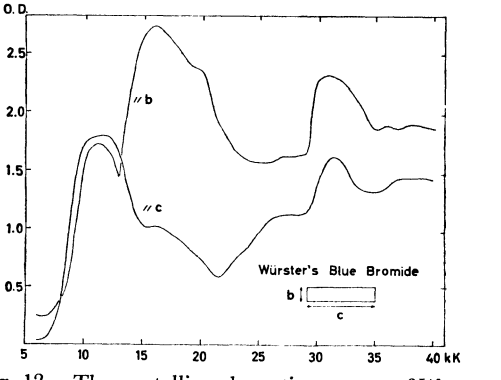

Fig. 12. The crystalline absorption spectra of Würster's blue bromide on the bc plane.

13) G. K. Hughes and N. S. Hush, *J. Proc. Roy. Soc. N.S.W.*, **81**, 48 (1947).

it may be regarded as an R-band mixed to some extent with the CT band. The R-band originally has its own polarization parallel to the long axis of the radical; however, the mixing with the charge-transfer configuration will result in some component along the out-of-plane of the benzene ring. The observed weak peak at 18000 cm^{-1} in the *c* axis direction may be explained on this basis. The intensity ratio observed is 0.02 : 1 for the *c* axis-to-*b* axis polarization, while the value calculated by the model IV is 0.005.

In the 26000 cm^{-1} region the next peak is found for the *a* axis spectrum; it may safely be assigned to the short-axis polarized X band.

As has been discussed above, if we increase the intermolecular interaction, the intensity of the charge-transfer band will be increased and the splitting between the CT and R bands will be enlarged. Judging by this criterion, the strength of the interaction in the Würster's blue bromide crystal is an intermediate case compared to the blue perchlorate and red bromide.

Another crystalline form of Würster's blue bromide has been obtained by rare chance. It was transparent when observed along the elongation axis and dark black in the perpendicular direction. The spectra have been recorded, but the crystalline data have not yet been obtained; therefore, we will not here discuss the spectral results in detail.

iv) Würster's Red Bromide. The crystals of Würster's red bromide (*N,N*-dimethyl-*p*-phenylenediamine bromide) have been prepared as dark green needles. The thin crystals are dark green in light polarized parallel to the elongation axis, and pale green in light polarized in the perpendicular direction. The crystalline structure has been analyzed in this laboratory[7]; it has been found that the radicals are stacked at equal distances from each other, with unusually short interplanar spacing in the one-dimensional column. The intermolecular interaction is extraordinary large in this crystal, and the spectra are quite different from that of other types of Würster's salt.

The thin crystal develops the *ac* plane; its absorption spectra have been measured by a polarized light. The spectra are presented in Fig. 13, while the projection of radicals on the *ac* plane is shown in Fig. 14. The projection on the *ab* plane is also

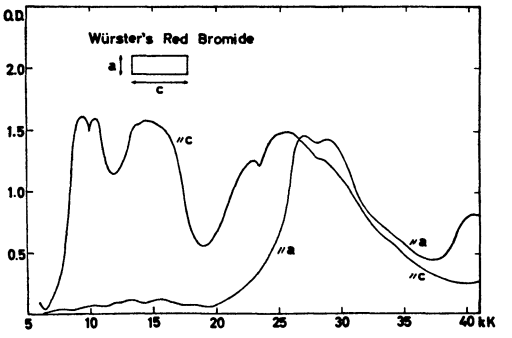

Fig. 13. The crystalline absortion spectra of Würster's red bromide on the *ac* plane.

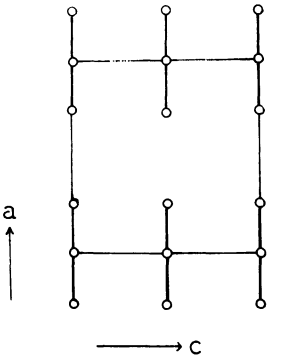

Fig. 14. Projection of Würster's red bromide crystal onto the *ac* plane.

depicted in Fig. 15. The broad strong bands are observed along the *c* axis in the 7000—18000 cm^{-1} region, which consists of two prominent peaks. The polarization of this band is definitely in the direction of the out-of-plane of the benzene ring; therefore, this band must be charge-transfer in origin. The next broad band observed along the *c* axis starts at 18000 cm^{-1} and extends to the 40000 cm^{-1} region. The polarization characteristic of this band may be understood if we assume that extensive mixing occurs between the charge transfer and the R-excited configurations. Since the long axis of the radical is parallel to the crystalline *b* axis, the R′ band can not be observed along the *c* axis unless the configurational interaction with the charge transfer state takes place. The calcula-

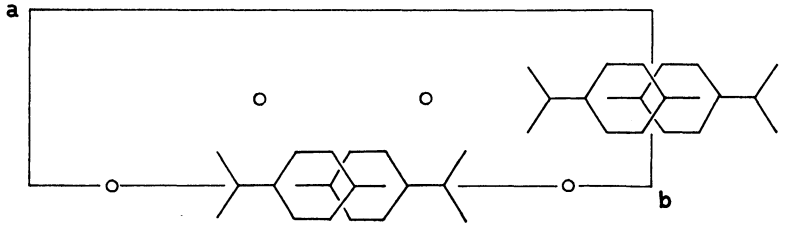

Fig. 15. Projection of Würster's red bromide crystal onto the *ab* plane.

tions of the previous section showed that the R′ band has a fairly strong component in out-of-plane direction as a result of the large mixing of the CT and R states. The intensity ratio for the out-of-plane direction of the CT and R′ bands is calculated to be 1.5 : 1, while the observed value is 0.9 : 1.

Although the first charge-transfer band might be accompanied by several vibrational progressions, it is quite noteworthy that it shows two peaks, one in the 9500 cm^{-1} region and another in the 13500 cm^{-1} region. The splitting of this band is an indication of the strong radical-radical interaction in the one-dimensional column in the crystal. A possible explanation of this band splitting will be given in the last section.

The short-axis polarized band is observed along the *a* axis, and it appears in the 25000—33000 cm^{-1} region. It is assigned to the X band; this is in conformity with the previous findings on other Würster's salts.

v) *p*-Phenylenediamine Bromide. The crystals of *p*-phenylenediamine bromide have been obtained as dark brown microcrystals. The crystalline data could not be obtained with this crystal, however, since it is not large enough for X-ray examination. The crystalline absorption spectra have been measured by a polarized light for the elongation axis and in the perpendicular direction (Fig. 16).

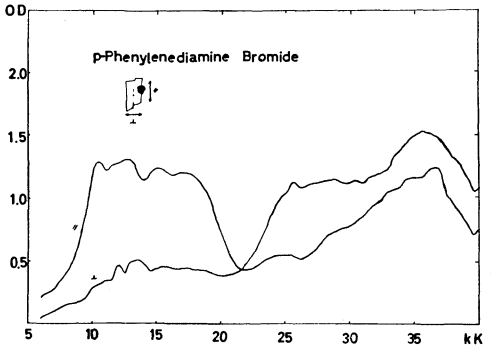

Fig. 16. The crystalline absorption spectra of *p*-phenylenediamine bromide.

The crystalline absorption bands are similar to that of Würster's red bromide, but it is remarkable that the absorption bands are broader than those of any other Würster's crystals. This means that the intermolecular interaction is the largest in this series of radical salts. This finding is supported by the experimental results[2,3] on the solution and by the calculation, and it is consistent with the steric considerations. The crystal structure is not yet known; therefore, our results will not be discussed further.

Interaction between Radicals and Crystalline Spectra. The effects of the intermolecular interaction are most significant in radical salt crystals than in any other type of molecular crystals since the unpaired electron on each radical will make a bonding between the radicals. The covalent force bind the radicals close to each other, while the exchange repulsion of the closed-shell electrons, including the so-called steric repulsions, increase the radical-radical distances. The positive charge carried on each ion is also repulsive in the present system. The analysis of these intermolecular forces might be difficult, however, the actual crystal structure represents a counterbalance of these several composite forces.

However, the tendency toward binding is shown by the formation of the radical dimer in a solution. It has been observed in Würster's radical, the ethylphenazyl radical,[1-3] the tetracyanoquinodimethane anion,[14] and pyridinium radicals[15] to form dimers in solutions, particularly at low temperatures. Characteristic of the aromatic radical dimer system is the appearance of a new absorption band in the longer-wavelength region. This band appears regardless of the charges on the radical; therefore, interaction between the unpaired electrons must be essential for the appearance of the new band. The interaction with the singly-occupied orbital is greatly dependent on the relative interatomic distances and orientations. Therefore, the present system of Würster's radicals will provide typical cases to be investigated, cases where the interplanar spacings are somewhat different from crystal to crystal: spectral and crystallographic data have accordingly been assembled.

The origin of the new band has been explained above in terms of the charge-transfer mechanism. Although we believe that the Heitler-London approach is most valid for discussions of the inter-radical electronic interactions, for the stronger dimers at shorter intermolecular distances the molecular orbital method is also illuminating. The appearance of the longer-wavelength absorption band can be explained simply in terms of a transition from the bonding to the antibonding orbital (*cf.* Fig. 17).[3] The inclusion of the ionic structures and

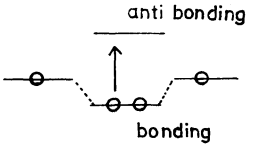

Fig. 17. Molecular orbital description of the radical-radical interaction.

the appearance of the new band which is polarized in the out-of-plane direction are naturally predicted by this method. However, the defect of this

approach is its incapability of explaining the appearance of a weak charge-transfer band in nearly the same energy region. Therefore, the molecular orbital method is limited only for cases of the stronger interaction.

According to both theories the strength of the electronic interaction can be roughly estimated by means of the magnitude of the overlap integrals. The overlap integrals of the radical pair evaluated for several crystals are shown in Table 4. The atomic orbitals used are those of the Hartree-Fock AO of Clementi[16] and the calculations were carried out at the Computation Center of the University of Tokyo. The results of the calculation have also been compared with the parametrs of the interaction estimated in the previous sections. They are listed in Table 5 where it is found that a rough correlation exists between these values.

The intensities of the CT band and the R band are mostly determined by the extent of the mixing of the CT configuration with other configurations. Each state can be described as a mixture of three configurations, Ψ_G, Ψ_{CT}, and Ψ_M, as Table 2 shows. The transition moments consist of terms proportional to $\langle\Psi_{CT}|\boldsymbol{r}|\Psi_{CT}\rangle$ and $\langle\Psi_G|\boldsymbol{r}|\Psi_M\rangle$; therefore, the directions of the transition moments are determined by the extent of the mixing of these configurations. In Würster's blue perchlorate, where the overlap integral is the smallest, the intensity of the charge-transfer band is the weakest. Würster's blue bromide shows an intermediate case in both absorption intensity and calculated overlap integral. In Würster's red bromide the charge-transfer band is extraordinarily large and the overlap integral is the largest.

The appearance of the broad and doublet structure of the CT band of the red bromide and *p*-phenylenediamine bromide crystals is puzzling; it must be intimately connected with the large electron overlap between the radicals. These absorption band are, of course, associated with the vibrational structures; however, we believe that the large breadth might be due to an electronic effect. Now let us discuss this effect by considering only the unpaired electrons on each radicals, as is shown in Fig. 18. There are two sites in the one-dimensional radical column in a unit cell; we will denote the unpaired orbitals in the ith cell by φ_i and θ_i. The wave function for the ground configuration (no charge-transfer structure) is:

$$\Phi_0 = \frac{1}{\sqrt{2N!}}\mathcal{A}\prod_{i=0}\varphi_i(i)\theta_i(2i)$$

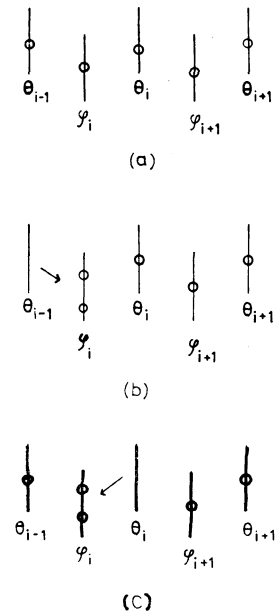

Fig. 18. Unpaired electrons on radicals in the one-dimesional crystal.

(a) ground configuration (b) left to right charge transfer state (b) right to left charge transfer state.

16) E. Clementi, *IBM Journal*, **9**, 2 (1965).

where N is the number of unit cells considered and where $\mathfrak{a}$ is the antisymmetrizer. There are two kinds of charge-transfer states; one is from the left site to the right site, and the other is from right to left. The crystalline charge-transfer states which satisfy the requirements of translational symmetry are given by:

$$\Psi_{CT}(\rightarrow, \pm) = \frac{1}{\sqrt{2}} \sum_i \left(\frac{\Phi_0}{\theta_{i-1}} \varphi_i \pm \frac{\Phi_0}{\varphi_i} \theta_i \right)$$

$$\Psi_{CT}(\leftarrow, \pm) = \frac{1}{\sqrt{2}} \sum_i \left(\frac{\Phi_0}{\theta_i} \varphi_i \pm \frac{\Phi_0}{\varphi_i} \theta_{i-1} \right)$$

There are also symmetric and antisymmetric combinations; therefore, four different kinds of excited states altogether must be considered. The plus combinations are optically active along the *c* axis in Fig. 18, while minus combinations are active along the *b* axis. The right- and left-directed charge-transfer states which have degeneracy will combine again; only the two states shown below are optically active, being active along the *b* and *c* axes respectively.

$$\Phi_{CT}(a, \perp) = \frac{1}{\sqrt{2}} [\Psi_{CT}(\rightarrow, -) + \Psi_{CT}(\rightarrow, -)]$$

$$\Phi_{CT}(a, //) = \frac{1}{\sqrt{2}} [\Psi_{CT}(\rightarrow, +) - \Psi_{CT}(\leftarrow, +)]$$

The inactive excited states are obtained by the following combinations;

$$\Phi_{CT}(i, \perp) = \frac{1}{\sqrt{2}} [\Psi_{CT}(\rightarrow, -) - \Psi_{CT}(\leftarrow, -)]$$

$$\Phi_{CT}(i, //) = \frac{1}{\sqrt{2}} [\Psi_{CT}(\rightarrow, +) + \Psi_{CT}(\leftarrow, +)]$$

Now let us concern ourselves with the *c* axis polarized spectrum. Here, there are two relevant states, $\Phi_{CT}(a,//)$ and $\Phi_{CT}(i, //)$. The splitting of these two states is given by the off-diagonal element, $\langle \Psi_{CT}(\rightarrow,+)|H|\Psi_{CT}(\leftarrow,+) \rangle$. This element has not terms proportional to the first order in the nearest neighbor electron overlap. However, the electron-electron interaction of a dipolar type appears and the splitting is given by:

$$\langle \varphi_i(1)\theta_{i-1}(1)|1/r_{12}|\varphi_i(2)\theta_i(2) \rangle.$$

The numerical estimation of this value gives a stabilization of the active state amounting to 0.75 eV (6000 cm^{-1}) relative to the inactive state. The splitting of the band observed in the crystalline spectra is of just the same order of magnitude; therefore, it is conceivable that the inactive state appears by means of the intensity borrowing through the vibrational or other kinds of perturbations.

The alternative approach to the understanding of the spectral characteristics is by the band theory, which is an extension of the molecular orbital method. We believe, however, that it will be inadequate for the present system of crystals, and so it will not be discussed further.

Kinetics of the Transition of Titanium Dioxide Prepared by Sulfate Process and Chloride Process

Akira SUZUKI* and Ritushi TUKUDA**

* *Government Chemical Industrial Research Institute, Tokyo, Shibuya-ku, Tokyo*
** *Shonan Sekisui Stock Company, Mutsuzaki Kumanodo, Sakura-shi, Chiba*

(Received December 3, 1968)

The kinetics of the phase transformation of anatase to rutile was studied by means of X-ray diffraction. Samples of anatase were prepared by sulfate and chloride processes. The kinetic data could well be expressed by the equation

$$\alpha = 1 - e^{-bt^n},$$

where α is the fraction of anatase transformed in time t, and b and n constants. The activation energy of the phase transformation is 105 kcal/mol for the sample prepared by the sulfate process, and 107 kcal/mol for the sample prepared by the chloride process. These values of activation energy are compared with those previously obtained.

The kinetics of the transition of polymorphic compounds such as silicon dioxide,[1] titanium dioxide,[2-7] germanium dioxide,[8] zirconium dioxide,[9] ferric oxide[10] or calcium carbonate[11] has been previously investigated. The rate of the transition of these compounds is complicated by the variable processes of the preparation of samples, the size of sample particles, the surrounding atmosphere and the presence of impurity, *etc.*

Titanium dioxide is prepared by the sulfate process or by the chloride process on an industrial scale. In the present study the rate of the transition of anatase to rutile has been measured using samples prepared by both processes. It might be interesting to compare the kinetic data of the two samples and to compare them with the data obtained by previous investigators.

Experimental

Samples. The samples of anatase were prepared by the two following processes.

(1) Sulfate Process. Sulfuric acid solution of titanium was prepared from purified titanium tetrachloride and extra pure grade sulfuric acid by the method previously reported.[5] Concentrations of total sulfuric acid and titanium were 670 g/*l* and 100 g/*l* respectively. The sulfuric acid solution of titanium was poured into a beaker, which was set in an autoclave. The solution was hydrolyzed at 160—170°C for 2hr in the closed autoclave. The precipitated gel was washed several times with sulfurous acid and deioned water, and the product thus obtained was heated at 100°C for 12hr and then at 700°C for 2hr.

(2) Chloride Process. Pure titanium dioxide (anatase) can be prepared by the following reaction between pure titanium tetrachloride and oxygen at 650°C.

$$TiCl_4 + O_2 = TiO_2 + 2Cl_2$$

The method of preparing the sample was as follows. Pure titanium tetrachloride was brought into the silica tube, nitrogen being used as a carrier gas. Nitrogen was passed through the liquid of pur titanium tetrachloride in a reservoir and brought into the silica tube. Oxygen preheated at 500°C was added to titanium tetrachloride-nitrogen mixture at the entrance of the silica tube. The temperature of the reservoir was controlled to 100—120°C, and that of the silica tube at 650±2°C. Titanium dioxide (anatase) formed was collected.

Properties of Sameples. Physical properties of anatase prepared by the two processes were examined by means of electron microscopy, the B.E.T. and picnometric method. The results are shown in Table 1 with those of rutile described below. A small number of crystals (~0.5 μ) with tetragonal habit were observed among the particles prepared by the chloride process. X-ray diffraction lines of rutile were not observed in the

diffraction patterns of the samples. The relative intensities of all peaks of anatase agree well with those of an A.S.T.M. card.

Procedures of the Determination of the Kinetic Data. For the kinetic runs, samples were set in the sintered alumina boats and heated in a tube electric furnace. The heating procedure was the same as that already described.[5]

The composition of anatase-rutile mixtures was analyzed by the X-ray diffraction method using the Geiger Counter X-ray Diffractometer. Magnesium oxide was used as an internal standard. The weight ratio of magnesium oxide and the anatase-rutile mixture was 1 : 4. The d values of the peak used to compare the intensity were 3.521 Å and 2.106 Å, for anatase and magnesium oxide respectively. Figure 1 shows the calibration curve determined as follows: The I_A/I_{MgO} ratio was measured for a series of ten samples of anatase-rutile magnesium oxide mixture with a definite mixing ratio and the average value of this ratio was plotted against the anatase % in the anatase-rutile mixture. A series of five determinations of the I_A/I_{MgO} ratio for each sample-magnesium oxide mixture was made in the case of the determination of anatase content in the samples after partial transformation.

Results and Discussion

The two samples prepared by the sulfate process and by the chloride process were transformed to rutile after heating at 1050°C for 3 hr, and anatase was not detected in these samples. The properties of these two kinds of rutile are shown in Table 1, and their particle sizes, specific surface areas and

Table 1. Physical properties of anatase and rutile types of titanium dioxide

Process of the preparation of sample	Sulfate process		Chloride process	
	Anatase	Rutile	Anatase	Rutile
Particle form	round	round	angular, round, tetragonal habit	round
Particle size (μ)	0.2—0.3	0.5—0.7	0.05—0.3	0.5—0.7
Specific surface area (m^2/g)	16	1.6	34	1.6
Specific gravity	3.77*	4.14	3.63*	4.10

Each rutile type sample was prepared from respective anatase type sample by heating at 1050°C for 3 hr.
* The difference in the specific gravities of the two kinds of anatase is difficult to explain, and seems to be attributed to the difference in the crystal growth during preparation.

specific gravities were almost the same. A small number of crystals with tetragonal habit were detected when the sample prepared by the chloride process was heated at 830°C for the longer time. It may indicate that transformation in these crystals begins later than that in other crystals.

The diffraction lines of anatase decreased and those of rutile increased monotonously in their intensities during the transformation and the relative intensities of all peaks of anatase or rutile agreed well with those of A.S.T.M. card.

The experimental results of the transformation rate studied over the temperature range between 800 and 880°C are shown in Figs. 2 and 3. From Figs. 2 and 3, it can be seen that in the early stage of the reaction carried out at the same temperature the transformed amount of the samples prepared by the sulfate process is lower than that of the samples prepared by the chloride process. These

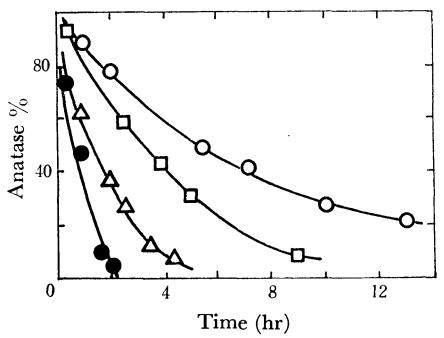

Fig. 2. Plots of anatase % as a function of time at different temperatures (Sulfate process).
-○- 820°C -□- 840°C
-△- 860°C -●- 880°C

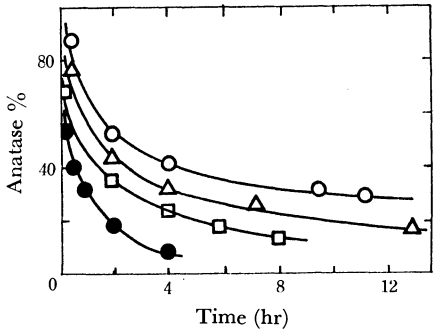

Fig. 3. Plots of anatase % as a function of time at different temperatures (Chloride process).
-○- 800°C -△- 820°C
-□- 840°C -●- 860°C

results would be explained by the fact that particles with small size are contained in the sample prepared by the chloride process. Experimental results in which the transformation rate of the sample with small particle size is larger than that of the sample with large particle size were published previously.[1,5]

It is well known that the following kinetic equation describes the process of the reaction proceeding through nucleation and crystal growth.[12,13]

$$\alpha = 1 - e^{-bt^n}, \tag{1}$$

where α is the fraction of material transformed in time t, and b and n constants. Differentiating Eq. (1), we get

$$\frac{d\alpha}{dt} = nbt^{(n-1)}(1-\alpha). \tag{2}$$

This is a first-order equation for $n=1$.
From Eq. (1), we get

$$\ln(1-\alpha) = -bt^n, \tag{3}$$

or

$$t = \left\{\frac{-\ln(1-\alpha)}{b}\right\}^{1/n}. \tag{4}$$

From Eqs. (2) and (4), we have

$$\frac{d\alpha}{dt} = nb^{1/n}\{-\ln(1-\alpha)\}^{(n-1)/n}(1-\alpha)$$
$$= k\{-\ln(1-\alpha)\}^{(n-1)/n}(1-\alpha), \tag{5}$$

where $k=nb^{1/n}$.
k is a constant, and may be defined as the rate constant of kinetic equation (5).
From Eq. (3) we have

$$\ln\{-\ln(1-\alpha)\} = \ln b + n\ln t. \tag{6}$$

12) M. Avrami, *J. Chem. Phys.*, **7**, 1103 (1939); *ibid.*, **8**, 212 (1940).
13) B. V. Erofeev, *Doklady Akad. Nauk S. S. S. R.*, **52**, 515 (1946).

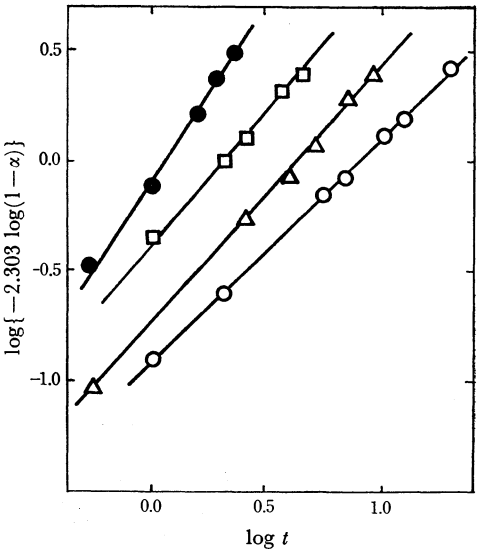

Fig. 4. Plots of $\log\{-2.303\log(1-\alpha)\}$ as a function of $\log t$ at different temperatures (Sulfate process).
-○- 820°C -△- 840°C
-□- 860°C -●- 880°C

Thus, b and n can be obtained from the curves of the figure in which data are plotted with the coordinates $\ln\{-\ln(1-\alpha)\}$ and $\ln t$. As shown in Figs. 4 and 5, experimental data fit the relationship of Eq. (6) reasonably well except for the data of the early stage in the reaction for the sample prepared by the chloride process.

Table 2. Values of n, b and k at different temperatures

Preparation process of anatase	Constant	Temperature (°C) 800	820	840	860	880
Sulfate process	n	—	0.961	1.16	1.21	1.61
	b	—	0.135	0.189	0.440	0.811
	k (t^{-1})	—	1.20×10^{-1}	2.75×10^{-1}	6.14×10^{-1}	1.41
Chloride process	n	0.344	0.432	0.492	0.621	—
	b	0.522	0.580	0.733	1.10	—
	k (t^{-1})	5.21×10^{-2}	1.20×10^{-1}	2.62×10^{-1}	7.40×10^{-1}	—

Values of n, b and k calculated from the curves of Figs. 4 and 5 are shown in Table 2. Table 2 indicates that there is not a large difference between k of the sample prepared by the sulfate process and that of the sample prepared by the chloride process at the same temperature. Attention should be paid to the fact that the data in the early stage of the transition for the sample prepared by the chloride process do not fit the relationship of Eq. (6). This fact may be related to a wide distribution of particle size in the sample prepared by the chloride process as shown in Table 1.

In the model presented by Avrami,[12] b depends on temperature, shape and growth rate of the new phase and nucleation frequency, and n has a value from 1 to 4 according to the variety of habit of the new phase.

In the present study the values of n varied in the vicinity of unity over the temperature range between 820 and 860°C among the samples prepared by the sulfate process as shown in Table 2. It is interesting to consider that the kinetic data followed the first-order law fairly well, when the sample prepared by the hydrolysis of sulfuric acid solution of titanium at 90—100°C was used.[5]

The values of n were all below unity for the samples prepared by the chloride process as shown in Table 2. Deviation from the values of n in the Avrami expression was observed.[9,14,15] Such a deviation might be related to the following facts.

1) The small number of nuclei occur and/or the samples with small particle size are used.[14]

2) The edgewise impingement of new phase occurs.[15]

Such situations may exist in the transition of anatase to rutile for the samples prepared by the chloride process.

Arrhenius plots of log k against $1/T$ are shown in Fig. 6. The activation energies estimated from Fig. 6 are 107 and 105 kcal/mol for the samples prepared by the sulfate process and by the chloride process respectively. Thus, both values of activation energies in this work are almost the same.

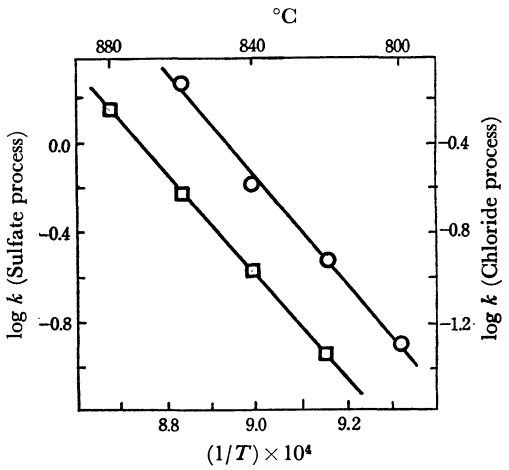

Fig. 6. Arrhenius plots of log k against $1/T$.
-□- Sulfate process
-○- Chloride process

Several values of the activation energy for the anatase-rutile transformation were reported, and are listed in Table 3 with those in the present study. Sullivan and Cole[2] investigated the relation between the kinetics of the anatase-rutile transformation and the preparing conditions of anatase for the first time. They used four hydrated titanium dioxide samples obtained by the hydrolysis of industrial titanium sulfate. Though the details of preparing conditions, *e. g.* drying temperature, were not described, the values of activation energy obtained in their investigation are almost the same as those obtained in the present study. Yaganarasimhan and Rao pointed out that the activation energy of the transition of anatase prepared by sulphate hydrolysis (No. 5 in Table 3) is considerably higher than that of pure anatase (No. 2, 3, 6 in Table 3). It seems certain that the activation energy of the transition of anatase prepared by the sulfate process differs from that of pure anatase. However, attention should be paid to the effect of the drying temperature of the sample (anatase) on the activation energy of the transition. It is shown

by Suzuki and Kotera[5] that it is difficult to dehydrate completely the titania gel prepared by the hydrolysis of an aqueous solution of titanium salt and the crystal growth of anatase is incomplete, if titania gel is dried at a relatively low temperature. The precipitated titania gel prepared by hydrolysis of the sulfuric acid solution of titanium contains sulfate ion probably as sulfuric acid adsorbed on the surface of the gel. To remove the adsorbed sulfuric acid completely, it is necessary to heat the gel at considerably high temperature. The assumption that the adsorbed sulfuric acid could be removed with difficulty only by means of washing is partly supported by our preliminary experiments where pH of the suspensions prepared by mixing an equal amount of deioned water with two kinds of anatase dehydrated at 100°C and 700°C were 2.5 and 5.5 respectively. Meanwhile, it is interesting to note that the activation energies of the transition of anatase to rutile are not so different if the drying temperature of anatase is considerably high (No. 4, 6, 8, 9 in Table 3). These results suggest that the rate-determining reaction in transformation of anatase to rutile would be independent of the sample preparation. Shannon and Pask[7] also investigated the transition of the three commercial anatase powders to rutile and obtained various activation energies from 94 to 204 kcal/mol (Table 3). These results suggest that commercial anatase contains various impurities, thus causing variation in activation energies.

The authors wish to thank Dr. Y. Kotera of this Institute for his valuable discussions.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 1858—1861 (1969)

Electronic Absorption Spectra of Unstable Species Formed by the Ultraviolet Irradiation of *N,N*-Dimethylaniline at 77°K

Satoshi ARIMITSU, Katsumi KIMURA*1 and Hiroshi TSUBOMURA

Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka

(Received December 3, 1968)

Electronic absorption spectra of unstable species formed by the ultraviolet irradiation of *N,N*-dimethylaniline (DMA) were studied in various rigid matrices at 77°K. It was concluded that there are two unstable species which exhibit similar absorption spectra in the visible and the near ultraviolet regions. These species were identified with the cation radical $\left(\left[\bigcirc\!\!\rangle\text{-}N(CH_3)_2\right]\right)^+$ and the neutral radical $\left(\bigcirc\!\!\rangle\text{-}\dot{N}(CH_3)\right)$, based on various experimental results concerning solvent effect, electron attachment, stimulated emission by the infrared light, *etc.* The molar extinction coefficient of the cation at 470 mμ was found to be about 1200 (l/cm·mol).

Studies on the primary photochemical processes of aromatic compounds have been made by use of electronic absorption spectroscopy and ESR technique.[1-9] It has been concluded that there are mainly two different types of processes.[10] One is photoionization and the other is photodissociation. Photoionization occurs predominantly for compounds having relatively low ionization potentials such as *p*-phenylenediamine and its methyl-derivatives.[11,12] On the other hand, photodissociation occurs prevalently for compounds having relatively high ionization potentials such as toluene and *p*-hydroquinone derivatives.[6,13]

Ultraviolet irradiation of *N,N*-dimethylaniline (DMA) in EPA (a mixture of ether, isopentane and ethanol) rigid matrix was investigated previously by Lewis *et al.*[3] and by Porter and co-workers.[4-6] They reported two absorption maxima at 3166 and 4590 Å, which they assigned to the *N*-methylanilino radical and the DMA^+ cation, respectively. Porter and his collaborators made flash-photolytic experiments on DMA in liquid paraffin solution at room temperature, and obtained absorption bands at 3140 and 4000 Å which were assigned tentatively to the *N*-methylanilino radical.[8]

Recently we have studied the triplet-triplet absorption spectrum of DMA using the flash technique at room temperature.[14] The studies reported here were made to identify the carriers of the absorption bands arising from the ultraviolet irradiation of DMA in the low temperature matrix.

Experimental

Materials. Commercial G. R. grade DMA and *N*-methylaniline (NMA) were purified by distillation from zinc powder under reduced pressure, and kept in a deoxygenated condition. Solvents used as transparent organic matrices were ethanol, MP (1 part methylcyclohexane, 1 part isopentane) and liquid paraffin. Ethanol was purified by fractional distillation. Ether and isopentane were dried with sodium for a day and purified by distillation. Methylcyclohexane and liquid paraffin were purified by passing through a 100 cm column of activated silica gel. About 10^{-3} molar solutions were used in most experiments. All samples examined were deaerated by the freeze-pump-thaw technique.

Apparatus. Absorption spectra were measured with

a Cary Spectrophotometer, Model 15. The solution in a cylindrical quartz cell 1.3 cm in diameter was immersed in liquid nitrogen contained in a quartz dewar. Photolysis was carried out with a 250-W Ushio high pressure mercury lamp through a Toshiba UV-D25 filter transparent in the wavelength from 250 to 400 mμ. A 500-W Xe-lamp was used as an infrared light source together with a Toshiba IR-D1A filter transparent in the infrared region. Emission spectra and emission decay were measured with an Aminco-Bowman Spectrofluorimeter or a Nalumi RM-23 spectrometer.

Results

Absorption Spectra of Irradiated DMA. When DMA was illuminated in the ultraviolet region at the temperature of liquid nitrogen, the matrix colored yellow. It showed sharp bands in the near ultraviolet region and relatively broad absorption bands in the visible region as shown in Fig. 1. These absorption bands disappeared when the matrix was warmed and did not reappear by refreezing at 77°K. Figure 1 shows the absorption spectra obtained for DMA irradiated in ethanol, MP and liquid paraffin at 77°K.

In the case of non-polar matrices such as MP, illumination of the irradiated DMA in the infrared region diminished the C_1 (~470 mμ) and C_2 (~334 mμ) bands as shown by curves 3) and 3') in Fig. 1 and at the same time the sample emitted blue light.

When a mixture of DMA and diphenyl in a rigid

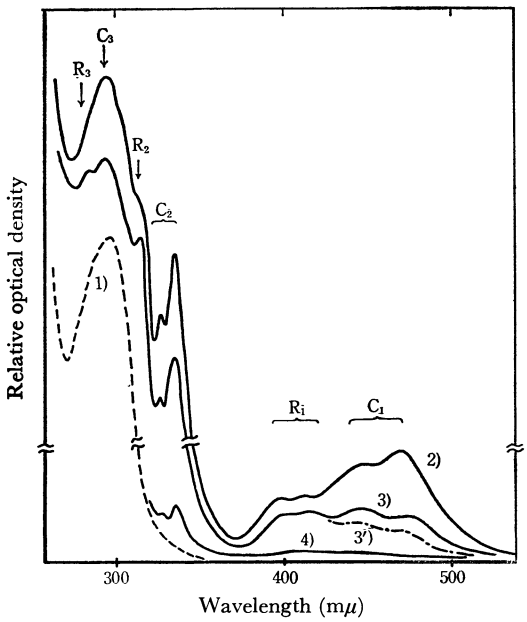

Fig. 1. Electronic absortion spectra of DMA irradiated in various matrices at 77°K. 1: before irradiation; 2, 3, 4: after irradiation in ethanol, MP and liquid paraffin, respectively; 3': same as 3, after photobleaching by infrared light.

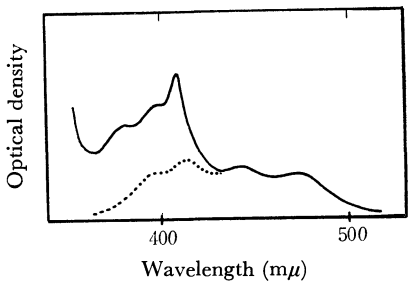

Fig. 2. Electronic absorption spectrum of a mixture of DMA and diphenyl in MP solution irradiated by UV-light at 77°K.

MP matrix was illuminated in the ultraviolet region, a spectrum shown in Fig. 2 was obtained. The absorption band near 400 mμ is identical with that of diphenyl anion.[15,16] When the UV-irradiated sample was treated with infrared light, it was found that the absorption band of the diphenyl anion decreased in intensity slightly, together with C_1 and C_2 bands.

Emission Spectra of Irradiated DMA. A

weak emission was observed from DMA irradiated in the non-polar MP matrix even after irradiation was terminated. The emission was stimulated either by illuminating the irradiated matrix in the infrared region or by warming. These luminescence spectra are given in Fig. 3, together with the ordinary emission spectrum of DMA excited by ultraviolet light at 77°K. From Fig. 3, it may be seen that these luminescence spectra are fluorescence and phosphorescence of DMA. The decay of the delayed luminescence at 410 mμ was found to fit in approximately with the first order kinetics with a half-life, $\tau_e = 23$ min.

Absorption Spectra of Irradiated NMA. For the purpose of identifying the absorption bands obtained in the case of DMA, we studied the ultraviolet irradiation of *N*-methylaniline (NMA) by a similar procedure. Figure 4 shows the absorption spectra obtained in the case of NMA irradiated in ethanol and MP matrices at 77°K. New absorption bands in the visible and the near ultraviolet regions faded out by warming the matrices. In the case of non-polar matrices such as MP, illumination of the irradiated NMA in the infrared region diminished C_1' (~450 mμ) band and the spectrum changed from 3) to 3') as shown in Fig. 4. At the same time, the sample emitted light. Thermoluminescence and delayed luminescence are observed also in the case of the irradiated NMA.

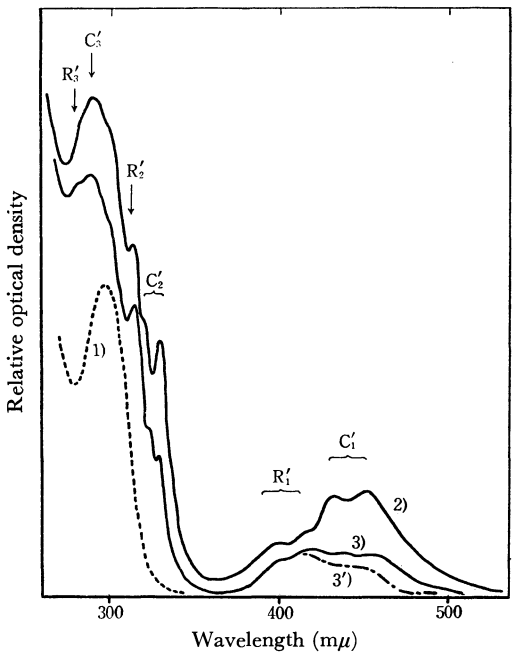

Fig. 4. Electronic absorption spectra of NMA irradiated in various materices at 77°K.
1: before irradiation; 2,3: after irradiation in ethanol and MP matrices; 3′: same as 3, after photobleaching by infrared light.

Discussion

From inspection of the spectra 2) and 3) in Fig. 1, it may be seen that the absorption spectrum changed with solvents; namely band C_1 is as strong as band R_1 in the non-polar solvents, but much stronger in the polar ones. This shows that there are at least two different species showing absorption in the wavelength region 400—500 mμ. Band C_2 is also stronger in polar medium than in non-polar ones and the ratio of the intensity of the C_2 band to that of the C_1 band is nearly constant. Considering the fact that photoionization occurs more easily in polar solvents than in non-polar ones as observed in the case of *N,N,N′,N′*-tetramethyl-*p*-phenylenediamine (TMPD),[10] absorption bands C_1 and C_2 may be ascribed to the DMA^+ cation.

When the DMA irradiated in MP matrix was illuminated in the infrared region, bands C_1 and C_2 decreased in intensity, while the intensity of band R_1 remained the same. This result is quite reasonable, because the action of the infrared light is supposed to excite the electrons trapped in the matrix, to make them mobile till some of them recombine with their parent molecular cations. The diphenyl anion formed in the MP matrix also provides a conclusive proof for the formation of the DMA^+ cation. The luminescence stimulated by the infrared light, together with the thermoluminescence, of the irradiated DMA is much stronger in the phosphorescence component compared with the emission of the same sample excited by ultraviolet light. A similar phenomenon is observed for the luminescence of photoionized TMPD.[17,18]

As a results of the experimental analaysis mentioned above, it may be concluded that the absorption bands C_1 and C_2 are assigned to the DMA^+ cation.

Similarly, from the experimental results on the absorption and emission spectra of the UV-irradiated NMA, the absorption bands C_1' and C_2' shown in Fig. 4 may be assigned to the NMA^+ cation.

It is a little bit more difficult to provide enough evidence for establishing the assignment of the bands which we call R_1 and R_2 for the species formed from DMA and R_1' and R_2' for the species formed from NMA. From the extensive work done by Porter and his group, it has been concluded that fission of the β-bond in the side chain is the main consequence of the photolysis of aromatic compounds. It has also been empirically noticed that a hydrogen atom in the substituent is more easily

photodissociated than a methyl group. Thus, photolysis of  –$CH(CH_3)_2$ and  –$C(CH_3)_3$ both yield  –$\dot{C}(CH_3)_2$.[19] By applying these results to our case, we see that the most probable species formed from the irradiated DMA, except DMA^+ cation, must be  –$\dot{N}(CH_3)$, and the radical expected from the irradiated NMA must also be  –$\dot{N}(CH_3)$.

Bands R_1 and R_1' were not affected by illumination in the infrared light after ultraviolet irradiation at 77°K and their intensities are mostly indifferent to the change of the solvents. It can be seen from our results that bands R_1 and R_2 for DMA is in good agreement with bands R_1' and R_2' for NMA. Thus, it seems quite probable that the species relevant to these bands is *N*-methylanilino radical  –$\dot{N}(CH_3)$.

It is also difficult to assign bands C_3 and R_3 shown in Fig. 1. Band C_3 is observed both in ethanol and MP, but band R_3 is observed only in MP. Therefore, we may tentatively assign bands C_3 and R_3 to the DMA^+ cation and *N*-methylanilino radical, respectively. As a result of a similar reasoning, the absorption bands C_3' and R_3' shown in Fig. 4 may be assigned to the NMA^+ cation and *N*-methylanilino radical, respectively.

N-methylanilino radical and DMA^+ cation are π-isoelectronic species and hence they should have very similar electronic spectra. Similarities in the electronic spectra between radicals and cations have been demonstrated in our previous work on *p*-disubstituted aromatics.[12] Therefore, with respect to this view, our conclusion that the C_1, C_2, C_3 bands are for the cation and the R_1, R_2, R_3 bands are for the radical is more reasonable than the assignment of previous authors.

We have found that the weak delayed luminescence emitted from the UV-illuminated DMA shows exponential decay at 77°K. If electrons trapped in the matrix were to migrate in the medium and combine with any of the positive ions distributed at random, the decay of the emission would be of the second order. On the other hand, if the electron returns mostly to its parent positive ion, the decay curve of the emission would be of the first order, in agreement with the experimental results mentioned above.

We also tried to estimate the molar extinction coefficient of DMA^+ cation. In the case where a dilute ethanol solution of DMA was irradiated at 77°K, it was observed that only the absorption bands assigned to the DMA^+ cation appeared noticeably at the initial stage of irradiation, and the ratio of radical to cation gradually increased as the irradiation was continued. It was also observed that, for a short time of irradiation, the decrease of DMA absorption at 300 mμ was nearly propotional to the increase of DMA^+ absorption at 470 mμ. If radical formation is neglected for this short UV-irradiation time, the molar extinction coefficient of DMA^+ cation at 470 mμ is found to be about 1200 (l/cm·mol).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 1862—1870 (1969)

A Theory of the Gel-forming Polymerization of Polyvinyl Compounds

Kenichi FUKUI and Tokio YAMABE

Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received December 9, 1968)

A theory of the molecular-size distribution of the cross-linked polymers to be formed from a mixture of vinyl monomers with a distribution of functionalities by radical polymerization is presented. It is assumed that all the unconverted vinyl groups are equireactive to the propagation, which proceeds without cyclization. The distribution is obtained by applying the statistical theory of gel formation with multifunctional interunit junctions, which are, in this case, equivalent to cross-linking chains. The general theory is applied to three practical cases; the curing reaction of unsaturated polyesters, the polymerization of polyvinyl compounds, and the copolymerization of vinyl and divinyl compounds.

A theory of gel formation by the radical copolymerization of divinyl compounds with monovinyl compounds was originally presented by Flory[1] and subsequently by Stockmayer[2] under principal assumptions which will be presented at the outset of the next section. In the first place, Flory[1] tried to explain the gel point of the polymerization. In his theory, he regarded every doubly-converted divinyl monomer as a single tetrafunctional monomer, each functional group of which was able to react independently with the vinyl groups of other monomers. According to this concept, a polymerization of this type is equivalent to the condensation reaction of tetrafunctional and bifunctional monomers.

Then he applied the results obtained in the case of the condensation to the case of this polymerization only in order to obtain the gel point. This interpretation, however, disregards the fact that the mechanism differs essentially from the condensation reaction in that polymerization and cross-linking are concomitant rather than consecutive. (This type of polymerization is usually called "cross-polymerization.") Hence, he hesitated to adopt, in the case of cross-polymerization, the molecular-size distribution of the copolymers obtained by the condensation. Subsequently, Stockmayer[2] treated this case with the following concept: every cross-link of the copolymers is equivalent to the cross-link between chains which would be obtained by cutting the middle of every doubly-reacted divinyl monomer of the copolymers. Thus he also reduced the polymerization to the cross-linking of primary-chain molecules, in any arbitrary size distribution, where the gel point was as presented by Eq. (1). Then he concluded that Eq. (1) was also valid in this case if another assumption was made.*1

$$\rho_c = \frac{1}{w_2 (P_w - 1)} \tag{1}$$

where ρ_c is the fraction of converted vinyl groups at the gel point, where P_w is the weight-average size of the cross-linking chains, and where w_2 is the weight fraction of the divinyl monomers. In the same paper, he demonstrated that, according to the same interpretation, the distribution for the cross-linking of primary chains might be also employed in the present case. Stockmayer's concept is, however, not only based on the unnatural interpretation mentioned above, but is also quite invalid for such simple cases as the cross-polymerization of trivinyl compounds.

By the use of another method, not by statistical methods, but by solving kinetic equations, Ohiwa[3] first obtained a reasonable size distribution of polymers obtained by the cross-polymerization of f-vinyl monomers. In his theory, the critical value is presented by Eq. (2) under the same assumptions as ours:

$$\rho_c = \frac{1}{(f-1)(P_w - 1)} \tag{2}$$

Thus, in the cross-polymerization or copolymerization of primary polyvinyl compounds, the gel

2) W. H. Stockmayer, *J. Chem. Phys.*, **12**, 125 (1944).

*1 This assumption was that, at any instant, the fraction of material involved in active growing chains is negligible compared to the amounts of stable polymers and residual monomers.

3) M. Ohiwa, *Nippoin Kagaku Zassi (J. Chem. Soc. Japan, Pure Chem. Sect.)*, **76**, 508, 684 (1955).

point can at any rate be predicted by the Flory method[1] of the expectation value or by the other methods described above. However, the molecular-size distribution of the polymers and the post-gelation relationships have not been presented except for a few special cases treated by Ohiwa.[3]

On the other hand, a number of experiments[4] have qualitatively supported these theories with respect only to the critical value, ρ_c. Some remarkable quantitative deviations from the theoretical value which had been attributed to the effect of cyclization reactions were fairly well explained by modified theories including this effect.[4,5]

The present paper will present an exact and reasonable size distribution and the post-gelation relationships in the cross-polymerization of polyvinyl compounds, in any arbitrary distribution of their vinyl groups. Help was not sought from unnatural explanations nor by solving complicated kinetic equations. Only the statistical theory of gel formation with multifunctional interunit junctions developed by the present authors[6] was applied to the case. The basic concept is that a cross-linking chain is to be regarded as an interunit junction. This general theory is employed in three practical cases; the curing reaction of unsaturated polyesters, the polymerization of polyvinyl compounds, and the copolymerization of vinyl and divinyl compounds.

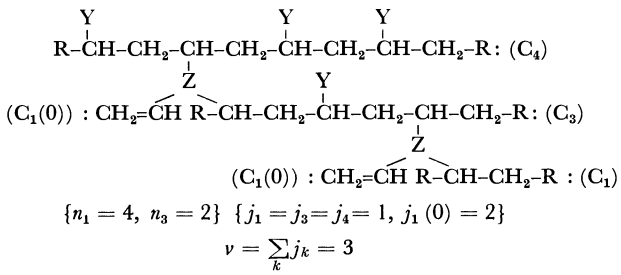
The Size Distribution and the Gel Point

The present treatment is based on the following usual assumptions in the first approximation: (1) all of the vinyl groups in polymers and primary molecules are equally reactive, and (2) no kind of intramolecular reaction leading to a cyclic structure occurs. Also, it is assumed that: (3) the distribution of cross-linking chains follows the Flory distribution[1] during the entire course of the polymerization. The last assumption is, however, not essential. Other distributions are also applicalbe, if desired.

The initial system treated here is generally composed of primary molecules with any arbitrary distribution of their vinyl groups, say, N_1 mono-, N_2 di-,$\cdots$, N_s s-vinyl compounds. The weight fraction, w_s, of the s-vinyl compounds is, then:

$$w_s = \frac{sN_s}{F}, \quad F = \sum_s sN_s$$

Now, to speak of a single polymeric molecule, it is constructed of chains (called "cross-linking chains" in this paper) formed by the polymerization of some vinyl groups, each in different primary molecules. A simple case can be visualized thus:



The cross-polymerization of vinyl compounds (CH_2=CHY) and trivinyl compounds ($[CH_2=CH]_3Z$) is illustrated in the above scheme, where C_k represents a cross-linking chain formed by the polymerization of k vinyl groups, where $C_1(0)$ is an unconverted vinyl group, and where R stands for one of the terminators or initiators produced from, for example, the catalysts. The description of any single polymer requires, therefore, the specification of the number of primary molecules of each kind and the number of crosslinking chains of each size. We denote the numbers of primary molecules by n_1, n_2, n_3,$\cdots$, n_s, and the numbers of cross-linking chains by j_1, j_2, j_3,$\cdots$, j_k, *etc.* For brevity, any particular set of these numbers is represented by the symbols $\{n_s\}$ and $\{j_k\}$. The number of unconverted vinyl groups, $j_1(0)$, can be obtained from the $\{n_s\}$ and $\{j_k\}$ as presented by Eq. (7). The symbol $m(\{n_s\}; \{j_k\})$ will be used for the mole fraction of polymers described by a particular set $\{n_s\}$ and $\{j_k\}$.

In this paper, the results obtained by the use of our previous general theory[6] are directly employed to derive the distribution of the molecular size. The essential point of the present paper is based on the reasonable concept that any cross-linking chain is to be regarded as a kind of interunit junc-

5) M. Gordon, *J. Chem. Phys.*, **22**, 610 (1954); R. N. Haward, *J. Polymer Sci.*, **14**, 535 (1954); C. A. J. Hoeve, *ibid.*, **21**, 1, 11 (1956).

6) K. Fukui and T. Yamabe, This Bulletin, **40**, 2052 (1967).

tion as defined in the previous paper.[6] Therefore, a C_k-chain corresponds to a k-functional interunit junction. Unconverted vinyl groups should be distinguished from C_1-chains, although, according to the definitions, both are monofunctional interunit junctions; they are treated here as different monofunctional interunit junctions.

According to the third assumption, the total number of C_k-chains, J_k, in the system is presented as follows:

$$J_k = F\rho\alpha^{k-1}(1-\alpha)^2$$

where ρ is the fraction of converted vinyl groups and where α is the probability of chain propagation. The probability of the formation of a C_k-chain, p_k, is then given from the definition of Eq. (8) in Ref. 6 as follows:

$$p_k = \frac{kJ_k}{F} = k\alpha^{k-1}(1-\alpha)^2\rho \quad (k = 1, 2, 3, \cdots) \tag{3}$$

Hence, ρ can be rewritten as:

$$\rho = \sum_k p_k$$

The fraction of unconverted vinyl groups, $p_1(0)$, can then be simply expressed as:

$$p_1(0) = 1 - \sum_k p_k = 1 - \rho \tag{4}$$

From Eq. (48) in Ref. 6 and Eqs. (3) and (4), the distribution of the molecular size of the polymeric species can readily be obtained as follows:

$$m(\{n_s\};\{j_k\}) = \frac{(\sum_s (s-1)n_s)!\,(\sum_s n_s - 1)!}{(\sum_s (s-1)n_s - \sum_k j_k + 1)!} \times \rho^{\sum_k j_k}(1-\rho)^{\sum_s (s-1)n_s - \sum_k j_k + 1} \times \alpha^{\sum_s n_s - 1}(1-\alpha)^{2\sum_k j_k} \prod_k \frac{k^{j_k}}{j_k!} \prod_s \frac{w_s{}^{n_s}}{n_s!} \tag{5}$$

where $\{j_k\}$, $j_1(0)$, and $\{n_s\}$ satisfy the following relations:

$$\sum_k (k-1)j_k = \sum_s n_s - 1 \tag{6}$$

$$j_1(0) = \sum_s (s-1)n_s - \sum_k j_k + 1 \tag{7}$$

From this distribution, we can easily obtain the mol fraction, $m(\{n_s\};\nu)$, of polymers containing $\sum_k j_k = \nu$ cross-linking chains;

$$m(\{n_s\};\nu) = \sum_{\sum_k j_k = \nu} m(\{n_s\};\{j_k\}) = \frac{(\sum_s (s-1)n_s)!\,(\sum_s n_s + 2\nu - 1)!}{(\sum_s (s-1)n_s - \nu + 1)!\,(2\nu-1)!\,\nu!} \times \rho^{\nu}(1-\rho)^{\sum_s (s-1)n_s - \nu + 1} \times \alpha^{\sum_s n_s - 1}(1-\alpha)^{2\nu} \prod_s \frac{w_s{}^{n_s}}{n_s!} \tag{8}$$

The gel point is characterized by the following equation (see Eq. (19) in Ref. 6):

$$1 = (\lambda_w - 1)(\mu_w - 1)$$

where:

$$\lambda_w = \sum_s s w_s$$

$$\mu_w - 1 = \sum_k (k-1)p_k$$

or by the use of the weight-average chain length, P_w:

$$\mu_w - 1 = \rho(P_w - 1)$$

Hence, the fraction, ρ_c, of converted vinyl groups at the gel point is represented by:

$$\rho_c = \frac{1}{(\lambda_w - 1)(P_w - 1)} \tag{9}$$

This expression can be used for any arbitrary distributions of chain length and includes the previous results (Eqs. (2) and (3)) in their most simple case. In the present case, P_w is equal to $(1+\alpha)/(1-\alpha)$; hence, Eq. (9) is reduced to:

$$\rho_c = \frac{1-\alpha}{2\alpha(\lambda_w - 1)} \tag{9'}$$

The number- and weight-average molecular sizes can immediately be obtained from the results of the previous paper as follows respectively:

$$\langle \sum_s s n_s \rangle = \frac{\sum (\sum_s s n_s)\, m(\{n_s\};\nu)}{\sum m(\{n_s\};\nu)} = \frac{\lambda_n}{1-\alpha\rho\lambda_n} \tag{10}$$

$$\langle (\sum_s s n_s)^2 \rangle = \frac{\sum (\sum_s s n_s)^2 m(\{n_s\};\nu)}{\sum (\sum_s s n_s)\, m(\{n_s\};\nu)} = \frac{(1-\alpha+2\alpha\rho)\lambda_w}{1-\alpha-2\alpha\rho(\lambda_w - 1)} \tag{11}$$

or, more generally:

$$\langle (\sum_s s n_s)^2 \rangle = \frac{\lambda_w [1+\rho(P_w - 1)]}{1-\rho(\lambda_w - 1)(P_w - 1)} \tag{11'}$$

where $\lambda_n = 1/\sum_s (w_s/s)$

Likewise, the number- and weight-average degrees of polymerization are, respectively:

$$\langle (\sum_s n_s) \rangle = \frac{1}{1-\alpha\rho\lambda_n} = \frac{\langle (\sum_s s n_s) \rangle}{\lambda_n} \tag{12}$$

and:

$$\langle (\sum_s n_s)^2 \rangle = \frac{1-\alpha+2\alpha\rho}{1-\alpha-2\alpha\rho(\lambda_w - 1)} = \frac{\langle (\sum_s s n_s)^2 \rangle}{\lambda_w} \tag{13}$$

These average numbers are, of course, only valid until the gel point is reached.

Relationships after the Gel Point

The relative abundances of cross-linking chains and of various primary species in the sol and in the gel fractions may be easily determined by applying

our previous general theory[6] to the present case. The results of the previous theory will be used here after without further remark. The characteristic equation defined by Eq. (26′) in Ref. 6 is presented in this case as:

$$x = \sum_s w_s u^{s-1} \tag{14}$$

$$u(x) = p_1(0) + \sum_k p_k x^{k-1} \tag{15}$$

which, on substituting the expression given by Eq. (3) for p_k, reduces to:

$$u(x) = 1 - \rho + \rho\left(\frac{1-\alpha}{1-\alpha x}\right)^2 \tag{15′}$$

where ρ is the over-all fraction of polymerized vinyl groups beyond the gel point. It is proved that the lowest real positive root, x_1, of this equation is equal to unity before the gel point, and less than unity after that point. With x_1 or $u_1 = u(x_1)$, the sol fraction $w_s^{(sol)}$ of s-vinyl compounds is given by:

$$w_s^{(sol)} = w_s u_1^s \quad (s = 1, 2, \cdots) \tag{16}$$

Hence, the total fraction, W_{sol}, of the sol is:

$$W_{sol} = \sum_s w_s u_1^s \tag{17}$$

which, by the use of Eq. (14), reduces to:

$$W_{sol} = x_1 u_1 \tag{17′}$$

Finally,

$$W_{sol} = x_1\left[1-\rho\left(1-\left(\frac{1-\alpha}{1-\alpha x_1}\right)^2\right)\right] \tag{17″}$$

The weight fraction, $w_s'^{(sol)}$, of the sol consisting of s-vinyl primary compounds is:

$$w_s'^{(sol)} = w_s^{(sol)}/W_{sol} = w_s u_1^s/W_{sol} \tag{18}$$

The number- and weight-average values of s in the sol fraction are then, respectively:

$$\lambda'_n = 1/\sum_s (w_s'^{(sol)}/s) \tag{19}$$

and:

$$\lambda'_w = \sum_s s w_s'^{(sol)} \tag{20}$$

Similarly, the fraction of C_k-chains in the sol is given by:

$$p_k^{(sol)} = p_k x_1^k \tag{21}$$

Hence, the fraction of the sol consisting of C_k-chains, $p_k'^{(sol)}$ is expressed by:

$$p_k'^{(sol)} = p_k^{(sol)}/W_{sol} = p_k x_1^k/W_{sol} \tag{22}$$

The number- and weight-average lengths of the chains in the sol are, then, respectively:

$$\langle k_n\rangle^{(sol)} = 1/(\sum p_k'^{(sol)}/k) = \frac{1}{1-\alpha x_1} \tag{23}$$

and:

$$\langle k_w\rangle^{(sol)} = \sum_k k p_k'^{(sol)} = \frac{1+\alpha x_1}{1-\alpha x_1} \tag{24}$$

The fraction of polymerized vinyl groups in the sol, ρ', is obtained from the definition as follows:

$$\rho' = \sum_k p_k'^{(sol)} = 1 - \frac{(1-\rho)}{1-\rho+\rho\left(\frac{1-\alpha}{1-\alpha x_1}\right)^2} \tag{25}$$

or:

$$\rho' = 1 - \frac{(1-\rho)}{u_1} \tag{25′}$$

which shows, on the contrary, the fraction of unconverted vinyl groups of the sol $p'^{(sol)}_{1(0)}$ to be $1-\rho'$.

Furthermore, from these equations, the number- and weight-average molecular sizes in the sol are, respectively:

$$\langle(\sum_s s n_s)\rangle^{(sol)} = \frac{\lambda'_n}{1-\alpha\rho'\lambda'_n} \tag{26}$$

and:

$$\langle(\sum_s s n_s)^2\rangle^{(sol)} = \frac{(1-\alpha+2\alpha\rho')\lambda'_w}{1-\alpha-2\alpha\rho'(\lambda'_w-1)} \tag{27}$$

Likewise, the number- and weight-average degrees of polymerization are, respectively:

$$\langle(\sum_s n_s)\rangle = \frac{1}{1-\alpha\rho'\lambda'_n} \tag{28}$$

and:

$$\langle(\sum_s n_s)^2\rangle = \frac{1-\alpha+2\alpha\rho'}{1-\alpha-2\alpha\rho'(\lambda'_w-1)} \tag{29}$$

It is noteworthy that these equations (Eqs. (26) and (29)) possess the same forms as Eqs. (10) and (12) after the replacement of λ_n, λ_w, and ρ in Eqs. (10) and (13) by λ'_n, λ'_w, and ρ' respectively.

The weight fraction of s-vinyl compounds in the gel, $w_s^{(gel)}$, is then obtained by the difference:

$$w_s^{(gel)} = w_s - w_s^{(sol)} = w_s(1-u^s) \tag{30}$$

Hence,

$$W_{gel} = 1 - W_{sol} \tag{31}$$

Likewise, the weight fraction, $p_k^{(gel)}$, of C_k-chains in the gel is:

$$p_k^{(gel)} = p_k - p_k^{(sol)} = p_k(1-x_1^k) \tag{32}$$

The fraction of vinyl groups in the gel which have polymerized, ρ'', is:

$$\rho'' = \frac{\sum_k p_k^{(gel)}}{W_{gel}} = \frac{1-\left(\frac{1-\alpha}{1-\alpha x_1}\right)^2}{1-x_1\left[1-\rho+\rho\left(\frac{1-\alpha}{1-\alpha x_1}\right)^2\right]}\cdot\rho \tag{33}$$

Namely,

$$\rho'' = \frac{2\alpha-(1+x_1)\alpha^2}{(1-\rho)\alpha^2 x_1^2+\alpha(2-2\rho+\alpha\rho)x_1+1}\cdot\rho \tag{33′}$$

Similarly, the number- and weight-average lengths of the cross-linking chains with which the gel is constructed are, respectively:

$$\langle k_n\rangle^{(\mathrm{gel})} = \frac{\sum_k p_k^{(\mathrm{gel})}}{(\sum_k p_k^{(\mathrm{gel})}/k)} = \frac{1-\alpha^2 x_1}{(1-\alpha)(1-\alpha x_1)} \tag{34}$$

$$\langle k_w\rangle^{(\mathrm{gel})} = \frac{\sum_k k p_k^{(\mathrm{gel})}}{\sum_k p_k^{(\mathrm{gel})}} = \frac{1+(1+x_1)\alpha-6x_1\alpha^2+x_1(1+x_1)\alpha^3+x_1{}^2\alpha^4}{(1-\alpha)(1-\alpha x_1)(1-\alpha^2 x_1)} \tag{35}$$

These relationships for the gel may afford some information to make clear the structure of the gelled network polymers, which we will discuss in detail elsewhere. It should be noticed here however that, before the gel point, the number-average length of the cross-linking chains maintains a constant value:

$$\langle k_n\rangle = \frac{1}{1-\alpha}$$

and that even beyond the gel point the same value remains as an average over the whole system containing the sol and the gel, while the average length in the sol and in the gel are different from each other, as Eqs. (23) and (34), respectively, indicate. This is a consequence of the preferential acquisition of larger molecules by the gel.

Near the gel point, both x_1 and u_1 may be slightly smaller than unity; these can then be written as:

$$x_1 = 1-\varepsilon \qquad 1 \gg \varepsilon > 0 \tag{36}$$

$$u_1 = 1-\delta \qquad 1 \gg \delta > 0 \tag{37}$$

By substituting the x_1 of Eq. (36) into Eqs. (14) and (15) and by neglecting the terms of a higher order than ε and δ, these factors may be approximated by:

$$\varepsilon \cong \frac{[2\alpha\rho(\lambda_w-1)+\alpha-1](1-\alpha)}{\alpha^2\rho[2\rho\lambda_z+3(\lambda_w-1)]} \tag{38}$$

$$\delta \cong \frac{[2\alpha\rho(\lambda_w-1)+\alpha-1](1-\alpha)}{\alpha\rho[(1-\alpha)\lambda_z+3\alpha(\lambda_w-1)^2]} \tag{39}$$

where $\lambda_z=\sum_s (s-1)(s-2)w_s$. Furthermore, if ρ is expressed by the following equation, which may be employed to define Δ,

$$\rho = \rho_c(1+\Delta) \qquad 1 \gg \Delta > 0 \tag{40}$$

ε and δ can then be rewritten in other expressions:

$$\varepsilon \cong \frac{2(1-\alpha)(\lambda_w-1)^2}{(1-\alpha)\lambda_z+3\alpha(\lambda_w-1)^2}\cdot\Delta \tag{38'}$$

$$\delta \cong \frac{2(1-\alpha)(\lambda_w-1)}{(1-\alpha)\lambda_z+3\alpha(\lambda_w-1)^2}\cdot\Delta \tag{39'}$$

By the use of ε and δ, we can obtain the relationships available near the gel point as follows:

$$\rho' \cong \rho_c\left[1-\frac{\alpha(\lambda_w-1)^2-(1-\alpha)[2(\lambda_w-1)+\lambda_z}{(1-\alpha)\lambda_z+3\alpha(\lambda_w-1)^2}\cdot\Delta\right] \tag{41}$$

$$\rho'' \cong \frac{1}{\lambda_w}+\frac{\lambda_w-1}{\lambda_w{}^2}\left\{1-\frac{(\lambda_w-1)(3\alpha\lambda_w-\alpha-2)}{(1-\alpha)(\lambda_z+3\alpha(\lambda_w-1)^2}\right\}\Delta \tag{42}$$

$$\lambda_n' = \lambda_n[1-(\lambda_w-\lambda_n)\delta] \tag{43}$$

$$\lambda_w' = \lambda_w\left[1-\left(\lambda_w-\frac{\lambda_z}{\lambda_w}\right)\delta\right] \tag{44}$$

$$W_{\mathrm{sol}} = 1-\lambda_w\delta \tag{45}$$

$$\langle k_n\rangle^{(\mathrm{sol})} = \frac{1}{1-\alpha}\left(1-\frac{\alpha}{1-\alpha}\varepsilon\right) \tag{46}$$

$$\langle k_w\rangle^{(\mathrm{sol})} = \frac{1+\alpha}{1-\alpha}-\frac{2\alpha}{(1-\alpha)^2}\varepsilon \tag{47}$$

$$\langle k_n\rangle^{(\mathrm{gel})} = \frac{1+\alpha}{1-\alpha}-\frac{\alpha}{(1-\alpha)^2}\varepsilon \tag{48}$$

At incipient gelation, it holds that $\rho''=1/\lambda_w$ and $\rho'=\rho_c$; that is, the converted fraction of the vinyl groups of the first increment of gel is $[(\lambda_w-1)/\lambda_w]\cdot(P_w-1)$ times as large as that of the sol. Similarly, $\langle k_n\rangle^{(\mathrm{sol})}=P_n$, $\langle k_n\rangle^{(\mathrm{gel})}=\langle k_w\rangle^{(\mathrm{sol})}=P_w$, and, in addition:

$$\langle k_w\rangle^{(\mathrm{gel})} = P_z \tag{49}$$

where $P_n=1/(1-\alpha)$, and $P_z=(1+4\alpha+\alpha^2)/(1-\alpha)^2$.

It is noticeable that, at incipient gelation, the number-average chain length of the gel is equal to the weight-average chain length of the sol.

These general relationships has thus been obtained for the partitioning of the components between the sol and the gel obtained by the cross-polymerization of primary molecules with any arbitrary distribution. Tractable expressions are also, of course, obtained for certain specified primary distributions. Three special cases will be discussed below.

Curing Reaction of Unsaturated Polyesters

As the first example of the specified distribution of the vinyl groups of primary molecules, let us consider the curing reaction of unsaturated polyesters. In this case we may employ the Flory distribution for the distribution of primary chains (linear unsaturated polyesters):

$$w_s = s(1-\gamma)^2\gamma^{s-1} \tag{50}$$

where γ is the fraction of converted functional groups in condensation reaction, such as, for instance, between glycol and maleic anhydride. Once the distribution has been determined thus, all the relationships obtained in the previous section can be expressed with observable quantities, such as α, γ, and ρ.

In the first place, we will try to obtain the mole fraction $m(n, p; \nu)$ of polymers constructed by ν

cross-linking chains connecting the n primary chians which had p vinyl groups at all in the initial state. From the definition,

$$m(n, p; \nu) = \sum m(\{n_s\}; \nu) \tag{51}$$

where the summation should cover all non-negative integers, $\{n_s\}$, satisfying the conditions; $\sum_s n_s = n$ and $\sum_s s n_s = p$. Simple manipulations lead to the following distribution:

$$m(n,p;\nu) = \frac{1}{(p+n-\nu)} \binom{n+\nu-1}{n} \binom{p+n-1}{\nu} \binom{p+n-\nu}{2n-1} \times \rho^{\nu}(1-\rho)^{p-n-\nu+1}\alpha^{n-1}(1-\alpha)^2(1-\gamma)^{2n}\gamma^{p-n} \tag{51'}$$

If the number of converted vinyl groups, $i=\nu+n-1$, and the number of cross-links in the polymer, $j=n-1$, are employed instead in the above distribution, it is consistent with the distribution obtained by Ohiwa[3] with the aid of the kinetic method. He demonstrated that it is different from that of the case of cross-linking by the condensation reactions of primary chins.

By substituting the relationships available for the present case into Eqs. (9′) and (13),

$$\lambda_n = \frac{1}{1-\gamma}, \quad \lambda_w = \frac{1+\gamma}{1-\gamma} \tag{52}$$

we obtain:

$$\rho_c = \frac{(1-\alpha)(1-\gamma)}{4\alpha\gamma} \tag{53}$$

$$\langle p \rangle = \frac{1}{1-\gamma-\alpha\rho} \tag{54}$$

$$\langle p^2 \rangle = \frac{(1+\gamma)(1-\alpha+2\alpha\rho)}{(1-\alpha)(1-\gamma)-4\alpha\gamma\rho} \tag{55}$$

$$\langle n \rangle = \frac{1-\gamma}{1-\gamma-\alpha\rho} \tag{56}$$

$$\langle n^2 \rangle = \frac{(1-\gamma)(1-\alpha+2\alpha\rho)}{[(1-\alpha)(1-\gamma)-4\alpha\gamma\rho](1+\gamma)} \tag{57}$$

which are, of course, valid only before the gel point.

The characteristic equation (Eq. (14)) is now simply:

$$x = \left(\frac{1-\gamma}{1-\gamma u}\right)^2 \tag{58}$$

or, alternatively:

$$u = \frac{1}{\gamma}\left[1 - \frac{(1-\gamma)}{\sqrt{x}}\right] \tag{58'}$$

From Eqs. (15′) and (58), it follows that:

$$\rho = \frac{1-\gamma}{\alpha\gamma} \frac{(1-\alpha x_1)^2}{(x_1+\sqrt{x_1})(2-\alpha-\alpha x_1)} \qquad (\rho \geqq \rho_c) \tag{59}$$

from which x_1 or u_1 can be obtained for a given value of ρ as well as α and γ, even if numerically. To get the sol fraction or other fractions presented in the previous section one need, then, do nothing but do the numerical calculations using this x_1.

The sol fraction is now simply:

$$W_{\text{sol}} = \frac{x_1 - (1-\gamma)\sqrt{x_1}}{\gamma} \tag{60}$$

In this case, the number- and weight-average sizes of the primary chains in the sol decrease as the reaction proceeds beyond the gel point, following the relations:

$$\lambda_n' = \frac{1}{1-\gamma u_1}, \quad \lambda_w' = \frac{1+\gamma u_1}{1-\gamma u_1} \tag{61}$$

These are, however, constant until the gel point, as is shown in Eq. (52). From Eqs. (28) and (29), the number- and weight-average degrees of polymerization are presented with $\gamma' = \gamma u_1$ and ρ', or, equivalently, u_1 and ρ (since, from Eq. (25′),

$$\langle n \rangle^{(\text{sol})} = \frac{1-\gamma'}{1-\gamma'-\alpha\rho'} \tag{62}$$

and

$$\langle n^2 \rangle^{(\text{sol})} = \frac{(1-\alpha+2\alpha\rho')(1-\gamma')}{[(1-\alpha)(1-\gamma')-4\alpha\gamma'\rho'](1+\gamma')} \tag{63}$$

At incipient gelation, ε and δ can now be obtained from Eq. (28′) and Eq. (39′) respectively:

$$\varepsilon \cong \frac{2(1-\alpha)}{6(1-\alpha)(\gamma/[1+\gamma]^2+3\alpha} \cdot \Delta \tag{64}$$

and:

$$\delta \cong \frac{(1-\alpha)}{6(1-\alpha)(\gamma/[1+\gamma])^2+3\alpha} \cdot \frac{(1-\gamma)}{\gamma} \cdot \Delta \tag{65}$$

Hence, from Eq. (45):

$$W_{\text{sol}} \cong 1 - \frac{(1-\alpha)}{6(1-\alpha(\gamma/[1+\gamma])^2+3\alpha} \cdot \frac{1+\gamma}{\gamma} \cdot \Delta \tag{66}$$

The approximation used in deriving these equations is, of course, based on the condition that the Δ defined by Eq. (40) is sufficiently small compared to unity and, hence, valid only very near the gel point. In curing reactions, however, ρ is usually small since ρ_c is sufficiently small; the primary chain length is, therefore, great (*cf.* Eq. (9)). This situation leads Eq. (66) to another approximation:

$$x_1 \cong W_{\text{sol}} \tag{67}$$

When we apply this approximation to Eq. (25), ρ' nearly becomes:

$$\rho' \cong \rho\left(\frac{1-\alpha}{1-\alpha W_{\text{sol}}}\right)^2 \tag{68}$$

which is useful apart from the gel point as long as ρ is small.

Similarly, from Eq. (33), ρ'' is:

$$\rho'' \cong \rho \frac{\alpha[2-\alpha(1+W_{\text{sol}})]}{(1-\alpha W_{\text{sol}})^2} \tag{69}$$

At incipient gelation $\rho'' \cong (P_w - 1)\rho'$, as has been pointed out at the end of the preceding section.

Polymerization of Polyvinyl Compounds

In this section, the case of the polymerization of f-vinyl monomers will be treated as the second example of the general case. Polyallyl compounds as well as polyvinyl compounds are also valid for the monomer, since allyl groups polymerize much like vinyl groups. In fact, some kinds of diallyl or triallyl esters are used to produce some thermosetting resins.

Now, from Eq. (8), the mole fraction $m(n; \nu)$ of polymers composed of n monomers connected by ν cross-linking chains can be immediately presented by:

$$m(n;\nu) = \frac{(fn-n)!(n+2\nu-1)!}{(fn-n-\nu+1)!(2\nu-1)!\nu!n!} \times \rho^{\nu}(1-\rho)^{fn-n-\nu+1}\alpha^{n-1}(1-\alpha)^{2\nu} \quad (70)$$

The gel point is simply:

$$\rho_c = \frac{(1-\alpha)}{2\alpha(f-1)} \quad (71)$$

The number-average degree of polymerization is given by:

$$\langle n \rangle = \frac{1}{1-f\alpha\rho} \quad (72)$$

Its weight-average degree of polymerization is:

$$\langle n^2 \rangle = \frac{1-\alpha+2\alpha\rho}{1-\alpha-2(f-1)\alpha\rho} \quad (73)$$

These equations (Eqs. (70) and (73)) agree with that obtained by the kinetical method.[3] Formulas derived in quite a different manner have proved to be a special case of the present general theory.

The sol fraction or the composition of the gel can be calculated by means of the root of the characteristic equation, x_1, which, for this case, is presented by:

$$x = \left[1-\rho+\rho\left(\frac{1-\alpha}{1-\alpha x}\right)^2\right]^{f-1} \quad (74)$$

This root, x_1, is usually obtained by numerical calculations. For the simplest case (f=2), it is obtained explicitly as follows:

$$x_1 = \frac{(2-\alpha\rho) - \sqrt{[\alpha\rho+4(1-\alpha)]\alpha\rho}}{2\alpha} \quad (\rho \geqq \rho_c) \quad (75)$$

The relation between x_1 and ρ is shown in Fig. 1 for the cases of f=2 and 3, and α=0.8.

The sol fraction, W_{sol}, is simply:

$$W_{sol} = x_1^{\frac{f}{f-1}} \quad (76)$$

which is shown in Fig. 2 for the case of f=2 and 3.

Likewise, the relationships of the number-average lengths of the cross-linking chains in the sol and in the gel are drawn in Fig. 3 according to Eqs. (23) and (34). This figure may afford information about the structure of the gel and about the difference between the sol and the gel.

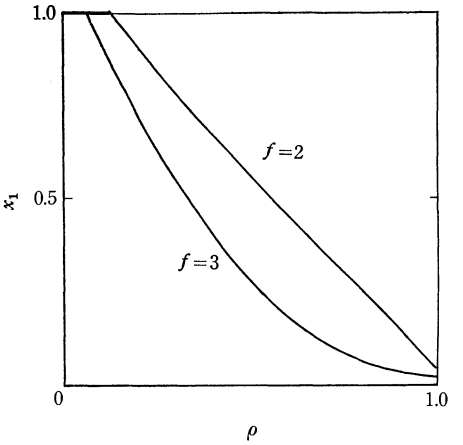

Fig. 1. The relationships between x_1 and ρ (α=0.8).

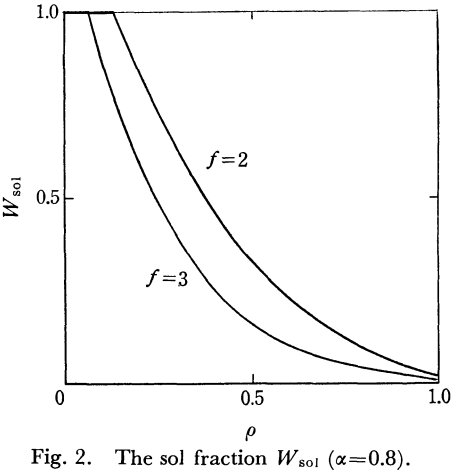

Fig. 2. The sol fraction W_{sol} (α=0.8).

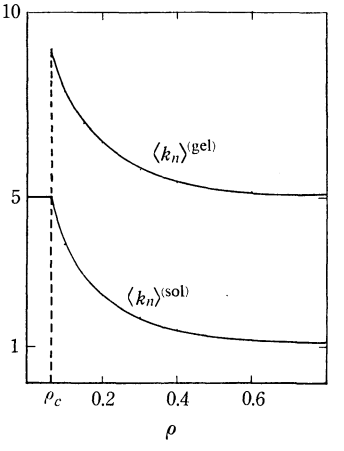

Fig. 3. The number average lengths of crosslinking chains in the sol and in the gel.

Copolymerization of Vinyl and Divinyl Monomers

Lastly, let us treat the case of the copolymerization of vinyl and divinyl monomers, which we discussed in the introduction of this article. The general relationships for calculating the distribution obtained by cross-polymerizing primary molecules of any arbitrary distribution have been derived in the first section. Then, in the present case, the molecularsize distribution of Eq. (8) reduces to:

$$m(n_1,n_2;\nu) = \frac{(n_1+n_2+2\nu-1)!}{n_1!(n_2-\nu+1)!(2\nu-1)!\nu!} \times \rho^{\nu}\cdot(1-\rho)^{n_2-\nu+1}\alpha^{n_1+n_2-1}(1-\alpha)^{2\nu} \times w_1^{n_1}\cdot w_2^{n_2} \quad (77)$$

This is, therefore, the exact and reasonable distribution first obtained by the present authors.

The number- and weight-average molecular sizes are, respectively:

$$\langle(n_1+2n_2)\rangle = \frac{2}{2-w_2-2\alpha\rho} \quad (78)$$

and:

$$\langle(n_1+2n_2)^2\rangle = \frac{(1-\alpha+2\alpha\rho)(1+w_2)}{1-\alpha-2\alpha\rho\cdot w_2} \quad (79)$$

The gel point is now given from Eq.(9′) by:

$$\rho_c = \frac{1-\alpha}{2\alpha w_2} = \frac{1}{w_2(P_w-1)} \quad (80)$$

which coincides with Eq. (1) obtained by Flory[1] and by Stockmayer.[2] It is of interest to see that this Eq. (1) derived from quite different considerations, is also obtained as a special case of the more general theory. This equation shows that, since $\rho_c \leqq 1$, w_2 should be larger than $(1-\alpha)/2\alpha = 1/(P_w-1)$ for the attainment of the gel point (even if intramolecular reactions are excluded); otherwise the gelation does not occur at any extent of polymerization reaction. Such a situation is fully discussed in another paper.*

The polymer conversion, W_p, is given by:

$$W_p = 1 - [w_1(1-\rho) + w_2(1-\rho)^2] \quad (81)$$

since the monomers should be excluded from the polymers. Hence, the fraction of the unconverted vinyl groups in polymers, $R_{u.s.}$, is:

$$R_{u.s.} = \frac{W_p-\rho}{W_p} = \frac{w_2(1-\rho)}{1+w_2(1-\rho)} \quad (82)$$

At the initial stage of the reaction, Eq. (81) reduces to:

$$R_{u.s.} \cong \frac{w_2}{1+w_2} \quad (83)$$

The charactristic equation can now be rewritten in the following form:

$$x = w_1 + w_2\left[1-\rho+\rho\left(\frac{1-\alpha}{1-\alpha x}\right)^2\right] \quad (84)$$

which, after simple manipulation, gives:

$$x_1 = \frac{(2-\alpha w_2\rho) - \sqrt{[4(1-\alpha)+\alpha w_2\rho]\alpha w_2\rho}}{2\alpha} \quad (85)$$

Hence:

$$u_1 = \frac{(2-\alpha w_2\rho) - \sqrt{[4(1-\alpha)+\alpha w_2\rho]\alpha w_2\rho}}{2\alpha w_2} \quad (86)$$

where the relation $(1-x_1)=w_2(1-u_1)$ is used to obtain the u_1 from the x_1.

At incipient gelation, from Eqs. (38′) and (29′):

$$x_1 = 1 - \frac{2(1-\alpha)}{3\alpha}\cdot\Delta \quad (85')$$

$$u_1 = 1 - \frac{2(1-\alpha)}{3\alpha w_2}\cdot\Delta \quad (86')$$

On the other hand, near complete conversion ($\rho\cong 1$), these may be approximated as follows:

$$x_1 = 1 - w_2\rho + \frac{(1-\alpha)^2}{w_2\rho} \quad (85'')$$

$$u_1 = 1 - \rho + \frac{(1-\alpha)^2}{w_2^2\rho} \quad (86'')$$

where it is supposed that $w_2 \gg (1-\alpha)$. It should be remarked that, in Eqs. (85″) and (86″) near the full conversion, $x_1\cong 1-w_2=w_1$, whereas $u_1\cong 0$. The latter value means that both monomers are almost entirely changed into gel near the full conversion since $W_{sol}=w_1u_1+w_2u_1^2$. On the other hand, the former indicate that in the gel the monovinyl monomers do not take part in the unit of branches extending to infinity as it ought to. These situa-

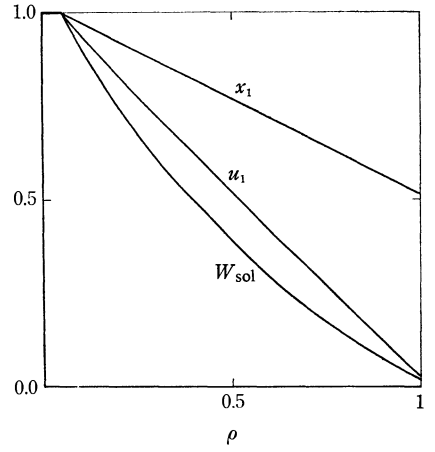

Fig. 4. The relationships between x_1, u_1, W_{sol} and ρ (W_2=0.5, α=0.95).

*2 T. Yamabe and K. Fukui, This Bulletin, to be submitted.

tions, visualized in Fig. 4, may reflect the difference between the meanings of x_1 and u_1, as will be discussed in the Appendix.

Appendix

Recently, Dobson and Gordon[7] presented a theory of branching processes and of the statistics of rubber elasticity by adopting the stochastic theory of cascade processes. As an example, they treated vulcanization by cross polymerization and obtained the same equation (see Eq. (4) in Ref. 7) as Eq. (14) in this paper:

$$x = \sum_s w_s u^{s-1} \tag{A-1}$$

where u was as presented by the following equation (translated into our notations (see Eq. (43) in Ref. 7):

$$u = 1 - \rho + \rho(1 - \alpha + \alpha x)^2 \tag{A-2}$$

This is, however, in disagreement with the corresponding equation (Eq. (15)) of the present paper; namely,

$$u = 1 - \rho + \rho\left(\frac{1-\alpha}{1-\alpha x}\right)^2 \tag{A-3}$$

Apparently, Eq. (A-2) was derived on the basis of the same concept as Flory's with regard to the cross-linking chain; hence, as has been discussed above, it is not reasonable and does not represent the characteristic features of the polymerization. Figure A-1 indicates the remarkable difference between $1-\alpha+\alpha x$ and $(1-\alpha)/(1-\alpha x)$, a difference equivalent to the difference between Eq. (A-2) and Eq. (A-3).

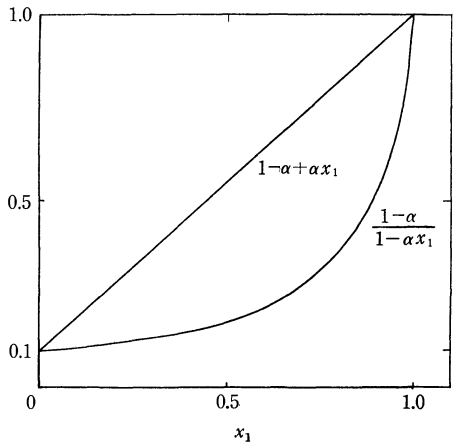

Fig. A-1. Functions $1-\alpha+\alpha x_1$ and $(1-\alpha)/(1-\alpha x_1)$ ($\alpha=0.9$).

Equation (A-2) is, however, approximated by Eq. (A-1) for $\alpha x \ll 1$, since:

$$\frac{1-\alpha}{1-\alpha x} \approx 1 - \alpha + \alpha x$$

Such an approximation is valid only for $x \ll 1$. The other case, that $\alpha \ll 1$, is almost meaningless since no polymer is obtained in this case. Therefore, the theory presented by Dobson and Gordon should be reformulated by our treatment. A paper on this subject will be presented elsewhere.

Raman Effect in Ferroelectric Sodium Nitrite Crystal. II. Dependence of B_2 Type Phonon Spectrum on Propagation Direction

Masamichi TSUBOI,* Minoru TERADA** and Teruo KAJIURA***

* *Faculty of Pharmaceutical Sciences, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo*

** *Mitsubishi Atomic Power Industries, Inc., Omiya, Saitama*

*** *Japan Electron Optics Laboratory, Company, Nakagami, Akishima, Tokyo*

(Received December 16, 1968)

The Raman spectra corresponding to the (bc) component (B_2 type vibrations) of the polarizability tensor in the ferroelectric sodium nitrite crystal (C_{2v}^{20}) have been observed with various directions of the phonon propagation. It has been found that one of the B_2 Raman lines at 160 cm^{-1} splits into two components when the phonon propagates in a direction 45° from the c axis in the ac plane. This splitting has been ascribed to an interaction of a B_2 and B_1 type lattice-vibrations whose frequencies are accidentally equal to each other in the phonon propagation direction now in question.

A great improvement has been made in the Raman spectroscopy of crystals by the introduction of laser light sources. We can now easily distinguish Raman lines corresponding to different components of the polarizability tensor of a crystal, if its single crystal with a size greater than or comparable to the diameter of the laser beam is available. In addition, we can now examine whether each of the Raman frequencies changes depending upon the direction of the phonon propagation. In an ionic crystal, an appreciable frequency difference is often observed between the transverse and longitudinal waves of the same mode of vibration.[1,2] Such a frequency difference is observed only for an optical mode and is considered to be caused by a long-range electric field.[3,4]

We have been examining the Raman effect of ferroelectric sodium nitrite crystal (C_{2v}^{20}—*Im2m*) by use of helium-neon and argon ion lasers. In our previous paper,[5] we reported Raman frequencies observed with the orientations of the incident and scattered beams which allow the frequencies of the transverse waves to appear. In a further experiment, different frequencies have been found in general for different orientations. As was once reported by Tramer,[6] a marked shift (from 1230 to 1360 cm^{-1}) in one of the B_2 frequencies has been observed on changing the direction of the phonon propagation from a axis to c axis in the ac plane. One of the other two B_2-type Raman lines, on the other hand, shows a peculiar behavior in a similar change of the phonon propagation direction. This peculiar behavior will be described below with an interpretation for it.

Experimental

The single crystals of sodium nitrite ($NaNO_2$) used in our experiment were kindly provided by Dr. S. Hirotsu and Mr. K. Suzuki, Tokyo Institute of Technology. Final data were taken on two $NaNO_2$ crystals. One of the crystals was cut so that each of the a, b, and c axes is parallel to a sample edge. The other was cut so that the b axis is parallel to a sample edge and the a and c axes are parallel to a sample face and at 45°C to the sample edges.

Each Raman spectrum was recorded a number of times by use of three different setups: (1) a Perkin-Elmer LR-1 Raman Spectrometer with a 10 milliwatt He-Ne laser, (2) a Spex 1400-II Double-monochromator in combination with a 30 milliwatt He-Ne laser made by Japan Electron Optics Laboratory, Company, and (3) a Spex 1400-II Double-monochromator in combination with a 50 milliwatt argon ion laser made by Japan Electron Optics Laboraty, Company. Each laser beam is completely polarized along a certain direction. The scattered beam from the crystal was sent to the monochromator slit through a polarizer so that only a particular component of the scattered beam can be observed.

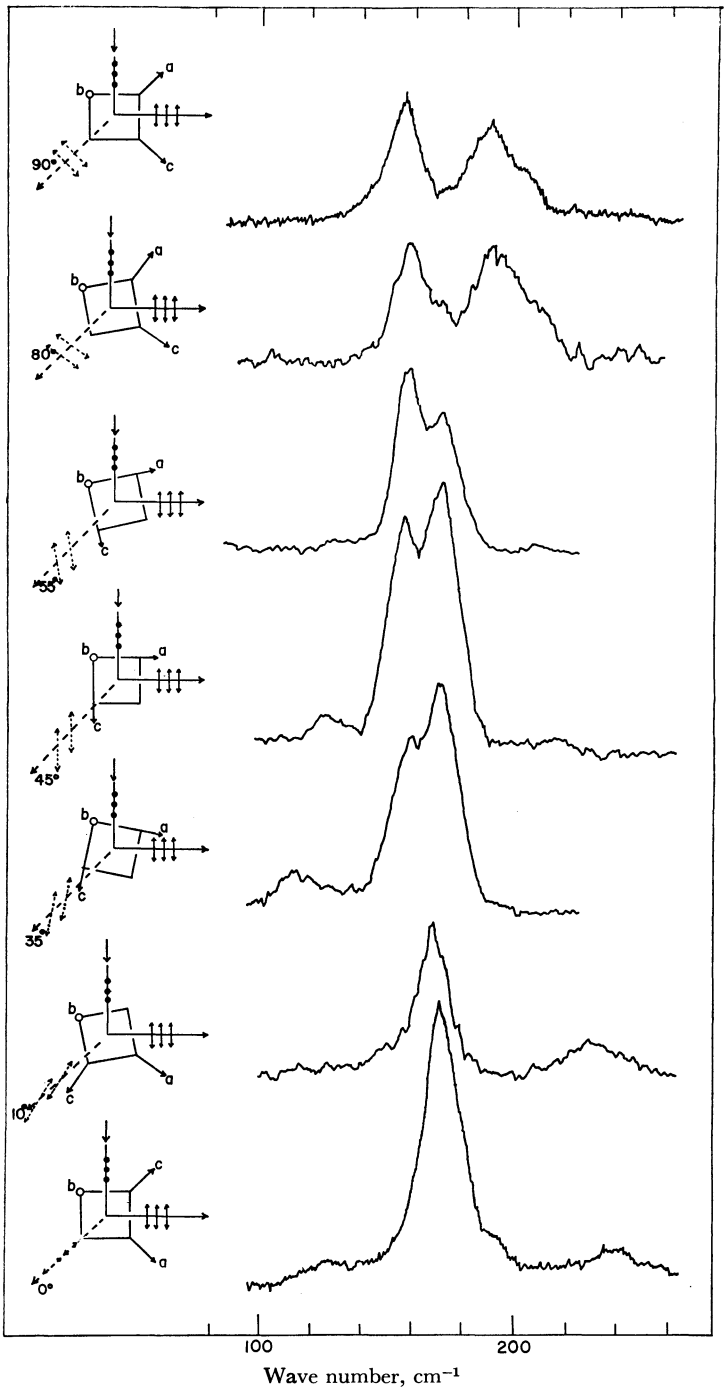

Fig. 1. Raman spectra of $NaNO_2$ crystal (C_{2v}^{20}) observed at room temperature. Orientations of the incident and scattered beams and their electric vectors are given in the left side of each spectrum. The broken lines indicate the direction of the phonon propagation and the direction of its electric polarization.

Result and Interpretation

Figure 1 shows the Raman spectra of the $NaNO_2$ crystal (C_{2v}^{20}) with various orientations in the 100—260 cm^{-1} region recorded at room temperature. Here, the incident and scattered beams are always set so that the Raman lines corresponding to the (bc) component in the polarizability tensor should appear. In this setting there should appear only the B_2-type vibrations, in which the dipole oscillation takes place along the c axis. The single crystal was placed so that the phonon propagation direction is in the ac plane and makes an angle θ indicated in the figure with the c axis. When θ is 90° (transverse wave) the B_2 Raman lines are at 157 and 190 cm^{-1}, while when θ is 0° (longitudinal wave) they are at 172 and 236 cm^{-1}. When θ is 55—35° the first Raman line splits into two at 157 and 171 cm^{-1}.

The splitting just stated is considered to be caused by B_1 vibration whose frequency comes accidentally in the vicinity of 165 cm^{-1}. In fact, there is a B_1 vibration whose frequency was located by Axe[7] at 149 cm^{-1} for the transverse wave and at 193 cm^{-1} for the longitudinal wave. It is true that any vibration belonging to the B_2 species cannot interact with a vibration belonging to the B_1 species as far as

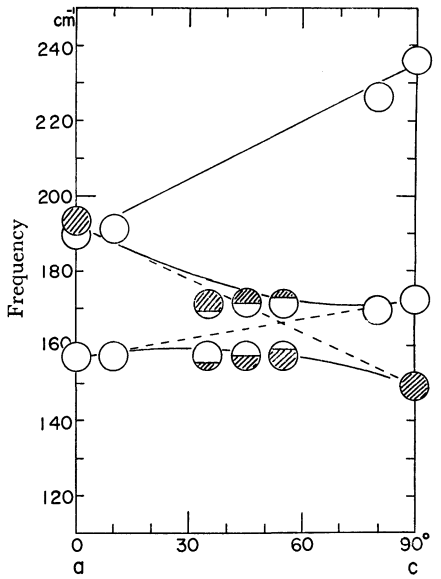

Fig. 2. Frequencies of a few Raman-active vibrations of $NaNO_2$ crystal plotted against the phonon propagation direction.

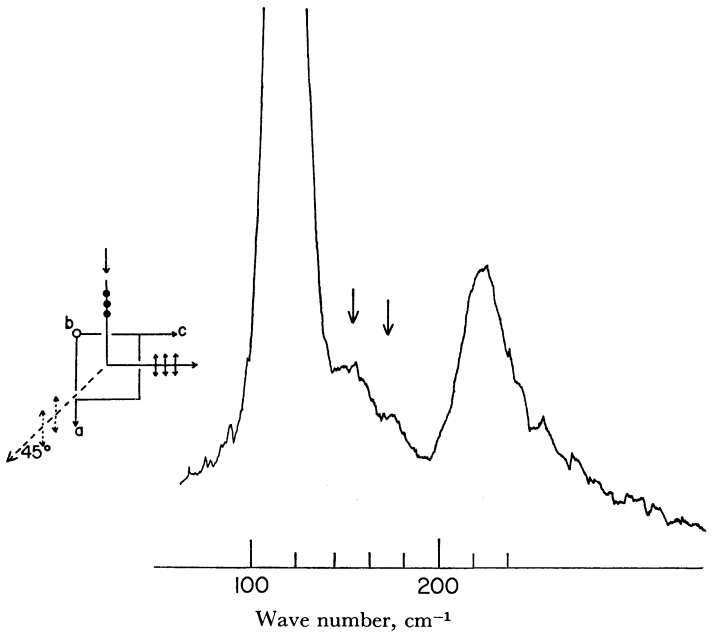

Fig. 3. Raman spectrum of $NaNO_2$ crystal (C_{2v}^{20}) observed at room temperature. Orientations of the incident and scattered beams and their electric vectors are shown in the left side of the figure. The broken lines indicate the direction of the phonon propagation and the direction of its electric polarization. A strong Raman line observed at 120 cm^{-1} is assigned to the A_2 type vibration.

7) J. D. Axe, *Phys. Rev.*, **167**, 573 (1968).

these symmetry classifications are strictly valid. Actually, however, these are so only for vibrations whose wavevectors are exactly zero. What we are observing in the Raman spectra are vibrations with small but appreciable amounts of phase difference between the adjacent two unit cells, and therefore, an approximate "B_1" vibration may interact with an approximate "B_2" vibration through, for example, a long-range electric field. Figure 2 shows a relation of the frequencies of the Raman-active lattice vibrations with the direction of its phonon propagation direction in the ac plane. The broken lines indicate the frequencies expected when there were no interaction between the "B_1" and "B_2" vibrations, and the solid lines are what are expected when there is an interaction. The circles indicate the observed frequencies; white circles are those corresponding to the (bc) component (B_2-type vibration) and black circles to the (ba) component (B_1-type vibration) of the polarizability tensor. The partly-white, partly-black circles indicate Raman lines which are considered to have partly B_2 and partly B_1 character. The relative intensities observed of the doublet Raman lines in Fig. 1 may be taken as indicating the relative amount of the B_2 character, becuase the incident and scattered beams are set here so that almost only B_2 vibrations should appear.

On the basis that both of the 157 and 171 cm^{-1} Raman lines are due to lattice vibrations which have halfway B_2 and halfway B_1 character, these Raman lines should appear not only in a B_2 type phonon spectrum but also in a B_1 type phonon spectrum. This has been found to be actually the case as shown in Fig. 3. Here, the incident and scattered beams are set so that only Raman lines corresponding to the (ba) component (B_1 type vibrations) of the polarizability tensor should appear. The propagation direction of the phonon should be 45° with the a axis in the ac plane. Besides the Raman lines at 225 cm^{-1} (assigned to a B_1 vibration), there are two weak Raman lines observed at nearly 157 and 171 cm^{-1}, which are indicated by two arrows in Fig. 3. This result supports our interpretation of the splitting of the Raman line.

Solution Properties of Poly-*m*-chlorostyrene

Kimiyoshi MATSUMURA

Department of Chemistry, Aichi Kyoiku University, Nagoya

(Received December 19, 1969)

The solution properties of poly-*m*-chlorostyrene in toluene and butanone were measured by the light-scattering and viscosity methods. The dependencies of the second virial coefficients, the end-to-end distances, and the intrinsic viscosities on the molecular weights were not very different from those of the other polystyrene derivatives. It was made clear that the unperturbed dimension of poly-*m*-chlorostyrene was larger than that of poly-*p*-chlorostyrene, and similar to that of poly-*o*-chlorostyrene. The relationships between poly-*m*-chlorostyrene and solvents (toluene and butanone) were similar to those between polystyrene and poly-*o*-chlorostyrene and the solvents, but the reverse of that between poly-*p*-chlorostyrene and the latter; that is, compared with butanone, toluene was a "good" solvent for poly-*m*-chlorostyrene.

A number of reports on the solution properties of polystyrene and its derivatives, mainly *p*-substituted polymers, have been made.

In this paper, by light-scattering and viscosity measurements of poly-*m*-chlorostyrene solutions, the effects of the substituted position of the chlorine atom on the polymer chain are compared with the findings concerning poly-*o*-chlorostyrene and poly-*p*-chlorostyrene.

Experimenta

Sample. *m-Chlorostyrene.* *m*-Chlorostyene was prepared from *m*-chlorophenylmethylcarbinol, which had been obtained by the Grignard reaction of *m*-chlorobenzaldehyde and methylbromide,[1] by dehydration with potassium bisulfate; bp 56—58°C/7 mmHg.

1) L. A. Brooks, *J. Am. Chem. Soc.*, **66**, 1295 (1944).

Polymer. The monomer was polymerized by heating it in a sealed tube at 90°C for 60 hr without any initiator. The conversion rate was about 85%.

The polymer was dissolved in benzene (*ca.* 20 g/*l*), and the solution was fractionated at 35°C by successive precipitation with methanol. Thirteen fractions were obtained from 25 g of the polymer. Each fraction was redissolved in benzene, reprecipitated with methanol, and dried under reduced pressure.

Solvents. The toluene was washed successively with sulfuric acid, water, a solution of sodium hydroxide, and water. The purified toluene was refluxed with metallic sodium and distilled; bp 110.4—110.6°C.

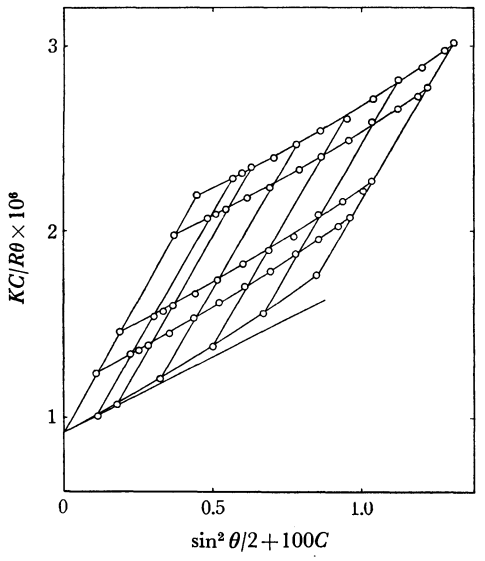
The butanone was boiled with potassium permanganate for a day, dried with magnesium sulfate, and distilled; bp 79.2—79.5°C.

Measurements. For the measurements of the light-scattering of the solutions, a Shimadzu photometer was used. The measurements were performed at 35°C with toluene solutions and at 30°C with butanone solutions, by the use of the 436 mμ wavelength and the angular range covering 40—135°. The increments of the refractive index of the solution with the concentration, dn/dc, were measured at each temperature with the wavelength of 436 mμ.

For the viscosity measurements of the solutions with both solvents, a modified Ubbelohde viscometer was used. At 30°C the flow time of toluene was 270.1 sec in this viscometer. The measurements were performed at 30°C.

Results and Discussion

Results. By the light-scattering measurements, the weight average molecular weight, M_w, the second virial coefficient, A_2, and the root-mean-square end-to-end distance of the polymer chain, $\langle L^2\rangle^{1/2}$, were obtained by the Zimm plot for each fraction according to the ordinary method.



Fit. 1. Zimm plot for poly-*m*-chlorostyrene fraction 2 in butanone at 30°C.

An example of the Zimm plot for Fraction 2 of poly-*m*-chlorostyrene in butanone at 30°C is shown in Fig. 1. The observed values of dn/dc were 0.118 ml/g in a toluene solution at 35°C and 0.211 ml/g in a butanone solution at 30°C for the wavelength of 436 mμ.

As Figs. 2 and 3 show, the intrinsic viscosity,

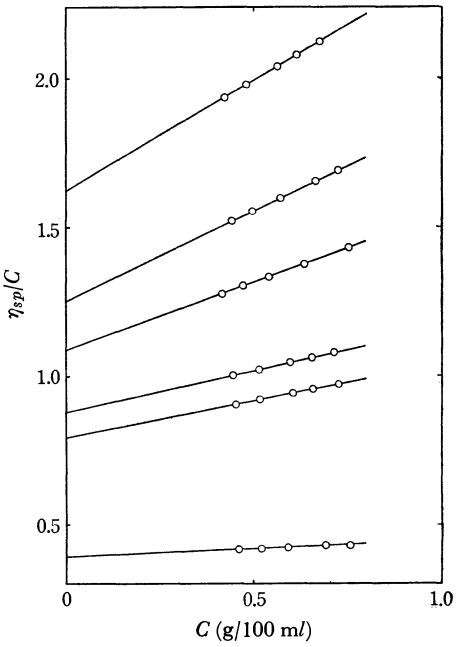


Fig. 2. Relation between reduced viscosity and concentration of poly-*m*-chlorostyrene in toluene at 30°C.

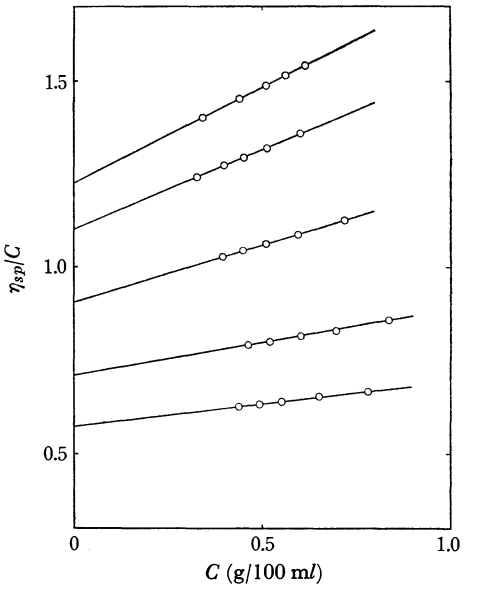

Fig. 3. Relation between reduced viscosity and concentration of poly-*m*-chlorostyrene in butanone at 30°C.

$[\eta]$, and the Huggins constant, k', are obtained through the viscosity measurements.

These results are shown in Tables 1 and 2.

The molecular-weight dependencies of $[\eta]$, A_2, and $\langle L^2\rangle^{1/2}$ are calculated by the log-log relations of M_w to these values; they are shown in Figs. 4, 5, and 6. By the least-squares method, these relations are found to be as follows:

$$[\eta] = 1.19\times10^{-4}\cdot M_w^{0.68} \text{ (dl/g)}$$
in toluene at 30°C,
$$= 1.71\times10^{-4}\cdot M_w^{0.64}$$ in butanone at 30°C,
$$A_2 = 26.5\times10^{-3}\cdot M_w^{-0.33} \text{ (mol·cc/g}^2\text{)}$$
in toluene at 35°C,
$$= 1.54\times10^{-3}\cdot M_w^{-0.17}$$ in butanone at 30°C,
$$\langle L^2\rangle^{1/2} = 0.60\times M_w^{0.54}(\text{Å})$$ in toluene at 35°C,
$$= 0.31\times M_w^{0.58}$$ in butanone at 30°C.

Discussion. The relations of M_w to $[\eta]$, A_2, and $\langle L^2\rangle^{1/2}$ for poly-*m*-chlorostyrene in toluene and butanone are not very different from those for the other polystyrene derivatives.

Stockmayer and Fixman[2] proposed the following equation, by which the unperturbed dimension of the polymer chain could be deduced from the experimental values of the intrinsic viscosities and the molecular weights of the polymer in a good solvent:

$$[\eta]/M^{1/2} = K_\theta + 0.51B_0\Phi\cdot M^{1/2},$$

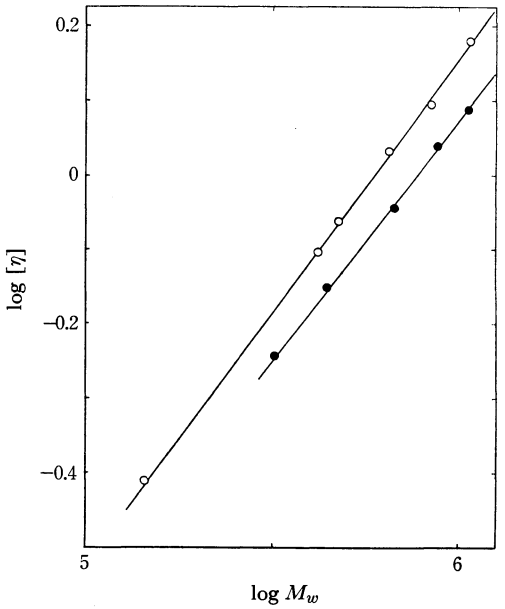

Fig. 4. Molecular weight dependencies of the intrinsic viscosities for poly-*m*-chlorostyrene at 30°C: open circle, toluene solution; colsed circle, butanone solution.

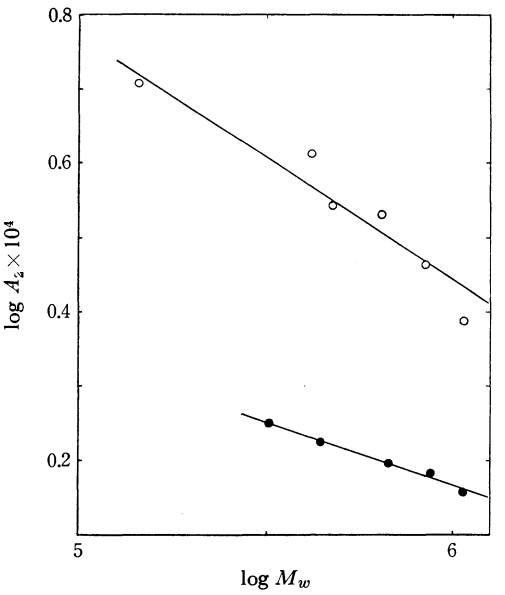

Fig. 5. Molecular weight dependencies of the second virial coefficients for poly-*m*-chlorostyrene: open circule, toluene solution at 35°C; closed circle, butanone solution at 30°C.

2) W. H. Stockmayer and M. Fixman, *J. Polymer Sci.*, **C1**, 137 (1963).

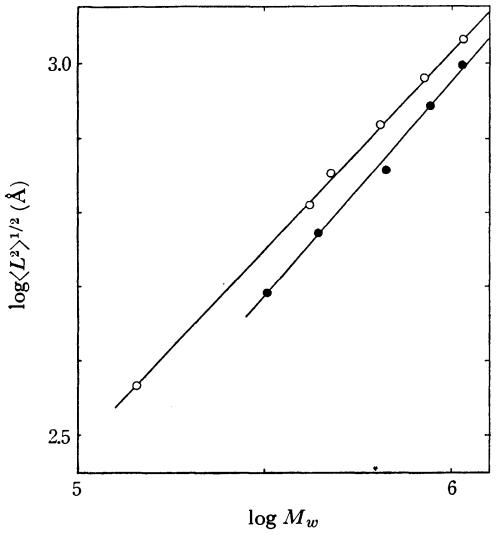

Fig. 6. Molecular weight dependencies of the end-to-end distances for poly-*m*-chlorostyrene: open circle, toluene solution at 35°C; closed circle, butanone solution at 30°C.

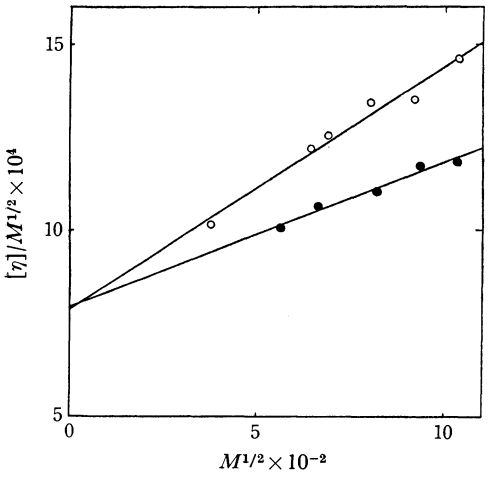

Fig. 7. Viscosity plots for poly-*m*-chlorostyrene in toluene (open circle) and in butanone (closed circle) at 30°C, by the Stockmayer-Fixman equation.

where $K_\theta=[\eta]_\theta/M^{1/2}=\Phi_0(\langle L^2\rangle_0/M)^{3/2}$, where $[\eta]_\theta$ is the intrinsic viscosity at the theta state, where $\langle L^2\rangle_0$ is the unperturbed dimension of the polymer chain, and where Φ_0 is the Flory parameter at the theta state, for which the value of 2.87×10^{21} is assumed in this paper.

As is shown in Fig. 7, the K_θ values for poly-*m*-chlorostyrene in toluene and butanone calculated by the above equation are 7.89×10^{-4} and 7.93×10^{-4} respectively; the least-squares method was used for the extrapolation to obtain the K_θ values. These values show an excellent agreement with each other and give $(7.91\pm 0.02)\times 10^{-4}$ (dl/g) as the average value.

On the basis of the K_θ value, the value of $(\langle L^2\rangle_0/M)^{1/2}$ was found to be 0.651 (Å), and the value of σ, $(\langle L^2\rangle_0/\langle L^2\rangle_f)^{1/2}$, in which $\langle L^2\rangle_f$ is the mean-square end-to-end distance, assuming a fixed valence angle of 109.5°, but a completely free internal rotation for the polymer chain; this value is obtained as 2.48.

The σ value for poly-*m*-chlorostyrene, 2.48, is slightly larger than that obtained for poly-*p*-chlorostyrene by the light-scattering measurement, 2.23,[3] and by the osmotic pressure measurements, 2.15[4] and 2.30.[5] This result shows that the chain of poly-*m*-chlorostyrene is considered to be more extended than that of poly-*p*-chlorostyrene. As the σ value for poly-*m*-chlorostyrene is also slightly larger than that for poly-*o*-chlorostyrene, 2.41,[6] the chain of the former polymer seems to be more extended than that of the latter. However, as the difference between both σ values is exceedingly small, the extension of the poly-*m*-chlorostyrene chain may be considered to be similar to that of poly-*o*-chlorostyrene.

The large σ value of poly-*m*-chlorostyrene shows that either the steric repulsion or the electrostatic repulsion, or both the repulsions, exist between the neighboring side groups, unlike the case of poly-*p*-chlorostyrene, for which no electrostatic repulsion is seen in the findings on various *p*-substituted polystyrenes.[7] The difference in σ value between these two polymers is surely caused by the difference in the substituted positions of the chlorine atoms on the phenyl group. Of course, at present, it is impossible to decide which of the two types of repulsions has the more effect on the dimensions of poly-*m*-chlorostyrene. For this purpose, it becomes necessary to measure the solution properties of *m*-substituted polystyrene, in which no electrostatic interaction occurs between the substituents. In addition, experiments under the theta conditions are necessary.

The effect of the solvent on the polymer-chain dimensions is measured by the $(\langle L^2\rangle/\langle L^2\rangle_0)^{1/2}$ ratio. A solvent which has a large value of the ratio has a strong interaction with the polymer segment; as a result of this, the polymer chain is considered to be extended greatly compared with the unperturbed state. That is, such a solvent is one of the "good" solvents. Table 3 shows the $(\langle L^2\rangle/\langle L^2\rangle_0)^{1/2}$ ratios for polychlorostyrene and polystyrene with the same degree of polymerization,

Table 3. The effects of solvents on the expansion of polychlorostyrene and polystyrene at the same degree of polymerization $P_w=7220$

Polymer	Solvent	Temp. (°C)	$\left(\frac{\langle L^2\rangle}{\langle L^2\rangle_0}\right)^{1/2}$
Poly-*m*-chlorostyrene	Toluene	35	1.61
	Butanone	30	1.45
Poly-*o*-chlorostyrene	Toluene	35	1.48
Poly-*p*-chlorostyrene	Toluene	room temp.	1.57
	Butanone	room temp.	2.05
Polystyrene	Toluene	room temp.	1.36
	Butanone	room temp.	1.04

$P_w=7220$, which corresponds to the molecular weight of 10^6 for polychlorostyrene, in toluene and butanone at about 30°C. The ratio, 1.61, for poly-*m*-chlorostyrene in a toluene solution; this is similar to that of poly-*p*-chlorostyrene in toluene, but larger than that for a butanone solution, 1.45, which is itself similar to that of poly-*o*-chlorostyrene in toluene. From a comparison of these values, it is considered that toluene is a "good" solvent for poly-*m*-chlorostyrene compared with butanone. These relationships between poly-*m*-chlorostyrene and solvents (toluene and butanone) are similar to those of polystyrene and poly-*o*-chlorostyrene*1 and the reverse to that of poly-*p*-chlorostyrene.

The relations between M_w and $[\eta]$, A_2, and $\langle L^2\rangle^{1/2}$ also give a means by which to know whether or not a solvent is a "good" solvent for a polymer. As Figs. 3, 4, and 5 shows, the observed values of $[\eta]$, A_2, and $\langle L^2\rangle^{1/2}$ of the toluene solution are larger than those of a butanone solution at the same molecular weight of poly-*m*-chlorostyrene. These relationships between poly-*m*-chlorostyrene and solvents support the above conclusion when compared with the $(\langle L^2\rangle/\langle L^2\rangle_0)^{1/2}$ ratio.

The author wishes to express his thanks to Professor Akira Kotera for his helpful discussions, and to Dr. Takahide Saito for his encouragement. The author is also indebted to Professor Tomoji Inoue for the use of the instrument for the experiments.

*1 It has been observed by the author that butanone is a theta solvent for poly-*o*-chlorostyrene.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 1878—1881 (1969)

The Dipole Moments of Diphenyl Sulfide, Sulfoxide, Sulfone, and Their Derivatives

Yoshio TOSHIYASU,*1 Yoshio TANIGUCHI, Ko KIMURA, Ryoichi FUJISHIRO, Masakuni YOSHIHARA,*2 Waichiro TAGAKI*2 and Shigeru OAE*2

Department of Chemistry, Faculty of Science, Osaka City University, Sumiyoshi-ku, Osaka

(Received December 27, 1968)

The electric dipole moments of diphenyl sulfide, sulfoxide, and sulfone and their derivatives were determined in benzene solutions at 25°C. The observed moments are used to estimate the mesomeric moments on the assumption of the vector addition of group moments. The mesomeric moments of the phenylmercapto, phenylsulfinyl, and phenylsulfonyl groups are estimated to be −0.12, 0.10, and 0.44 D, respectively. The steric effect of ortho-substituents is also discussed on the basis of the dipole moment data.

Quantum chemical considerations[1] and spectral investigations[2] both lead to the conclusion that the delocalization of π-electrons from benzene ring to the vacant 3d-π orbitals of a sulfur atom is important for aryl sulfoxides and sulfones. The chemical evidence[3] is in conformity with this prediction.

*1 Present address: Science Education Institute of Osaka Prefecture, Sumiyoshi-ku, Osaka.

*2 Permanent address: Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sumiyoshi-ku, Osaka.

1) W. E. Moffitt, *Proc. Roy. Soc. (London)*, **A200**, 409 (1950); H. P. Koch and W. E. Moffitt, *Trans. Faraday Soc.*, **47**, 7 (1951).

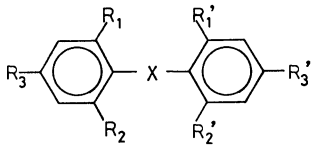
3) C. C. Price and S. Oae, "Sulfur Bonding," Ronald Press, New York (1962); E. L. Wehry, *J. Am. Chem. Soc.*, **89**, 41 (1967).

Contrary to the cases of sulfoxides and sulfones, the chemical behavior of diphenyl sulfides[4] was interpreted in terms of the electron-donating conjugation of the sulfur atom, just like that of diphenyl ethers. Craig and others,[5] however, concluded that both the sulfur 3p and 3d orbitals are utilized in the sulfur-carbon bonding of aryl sulfides. The electric dipole moments of diphenyl sulfide, sulfoxide, and sulfone, and some of their derivatives were already reported,[6] but the available data are not sufficient to discuss the nature of sulfur-carbon bonding in aryl sulfides, sulfoxides, and sulfones. This paper will describe the observed dipole moments of diphenyl sulfide, sulfoxide, sulfone, and their derivatives, such as:



X: S, SO, SO_2

$R_1=R_1'$, $R_2=R_2'$: H, CH_3

$R_3=R_3'$: H, CH_3, OCH_3

The mesomeric moments of these compounds are estimated by comparing the present data with the observed moments of relevant aliphatic sulfides, sulfoxides, and sulfones. The contribution of the vacant 3d orbitals of sulfur atoms to conjugation will be discussed, together with the steric effect of substituents.

Experimental

The preparation of all the materials used in this work was described elsewhere.[7] Benzene was used as a solvent throughout this work, and purified by fractional distillation through a 100-cm column packed with stainless-steel helices after being shaken with concentrated sulfuric acid.[8]

The measurements of the dielectric constants, ε, the specific volumes, v, and the square of the refractive indices, n^2, were carried out by the same apparatus and method as in a previous work.[9] All the data were obtained at 25 ± 0.02°C. In the present investigation, the weight fraction, w, of solutes covers up to about 0.02.

Results and Discussion

The observed values of ε's, v's, and n^2's are, fairly well within the range of experimental errors, expressed by the linear equations of w's. The results are summarized in Table 1. The molecular polarizations, P's, were obtained from these experimental data according to the Halverstadt-Kumler's method.[10] The molecular refractions, R_D's, for the sodium D line were used to estimate the total distortion polarizations. They were assumed to be

equal to 1.05 R_D. The polarization values and dipole moments, μ's, are tabulated in Table 2, together with the dipole moments of the relevant alkyl sulfur compounds. The mesomeric moments of diphenyl sulfides, sulfoxides, and sulfones were calculated on the basis of the following two assumptions: (1) the difference in dipole moments between diphenyl sulfur compounds and the relevant dialkyl ones is due to delocalization, and the vector subtraction of the latter dipole moments from the former gives the mesomeric moments, and (2) the valence angles[11] of the aryl sulfur compounds

depicted in Fig. 1 are used to calculate the mesomeric moments per carbon-sulfur bonding.

It is not a reasonable assumption to divide the conjugation of bis-*p*-methoxyphenyl sulfur compounds in two methoxyphenyl and one diphenyl sulfur part. However, the approximate mesomeric moments of carbon-sulfur bonding are determined by taking the vector subtraction of the group moment of anisole, which is shown in Fig. 2. In order to calculate the mesomeric moment of BI (or BII), it is necessary to estimate the S–O bond moment. This was done by the use of the dipole moment of dialkyl sulfide, that of BI (or BII), and that of dialkyl sulfoxide. The mesomeric moments thus calculated are tabulated in Table 3, together with those of anisole and one of its derivatives.

Table 3 clearly shows that the conjugative effect operative in AI or AII is the same as that of thioanisole, although the mesomeric moment of AI or AII is considerably smaller than that of thioanisole. The conformation[12] of diphenyl sulfide is similar to that of diphenyl ether.[13] It may be inferred that the maximum conjugation of diphenyl sulfide is inhibited by the twisting of two benzene rings. On

the other hand, the mesomeric moments of BI and CI are directed in the opposite sense of those of A's.

As Moffitt[1] and others[2] pointed out, the 3d vacant orbitals of sulfur atoms contribute to the conjugative effect, which is enhanced by methoxy substituents at the para positions. There is a possibility of this type of conjugation in aryl sulfides,[5] also. As far as the ground state is concerned, the increase in the effective positive charge of sulfur atoms[2] is a necessary condition for this type of conjugation. This condition is fulfilled for aryl sulfoxides and sulfones. Any conclusion about the contribution of the vacant 3d orbitals of aryl sulfides to the conjugative effect, however, can not be drawn from the dipole moment measurements alone, but it is evident that the electron-withdrawing conjugation of the sulfur atoms of aryl sulfides is negligible or at least much less than the electron-donating one.

As already stated, the two benzene rings of diphenyl sulfide are twisted about 40° out of the C–S–C plane.[14] This may be due to the steric effect. Hence, the steric hindrance by methyl substituents at the ortho positions may not be observed appreciably. The dipole moment of dimesityl sulfide is not so much different from that of diphenyl sulfide. This is true for aryl sulfoxides and sulfones, although the decrease in the dipole moment of dimesityl sulfone relative to that of diphenyl sulfone amounts to 0.11 D. The change in the valence angle is probably, at least in part, responsible for this decrease in the dipole moment.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 1881—1885 (1969)

Derivatographic Studies on Transition Metal Complexes. I. Deaquation-Anation Reaction of Aquopentaammine-chromium(III) Complexes*1

Ryokichi TSUCHIYA, Yoriko KAJI, Akira UEHARA and Eishin KYUNO

Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa

(Received August 13, 1968)

By using a Derivatograph, the simultaneous analyses in TGA, DTA and DTG on the several aquopentaamminechromium(III) complexes were attempted. The enthalpy changes, ΔH, in the deaquation-anation processes of aquopentaamminechromium(III) nitrate, chloride, bromide, iodide, sulfate and sulfite were calculated as 11.9, 6.1, 9.0, 10.8, 13.8 and 12.8 kcal/mol, respectively, the activation energies, $E^{\neq}$, in the corresponding processes of the nitrate, chloride, bromide, sulfate and sulfite were obtained by the DTG curve analysis as 18, 28, 38, 36 and 33 kcal/mol, and those in the nitrate, chloride, bromide, iodide, sulfate and sulfite were obtained by the DTA curve analysis as 14, 25, 36, 19, 39 and 32 kcal/mol, respectively.

A number of thermochemical studies on the metal complexes by means of thermogravimetric analysis (TGA) with a thermobalance[1] or by means of the dissociation pressure method[2] have been reported. Since the application of the differential thermal analysis (DTA) alone to the solid phase reaction of the metal complexes in the field of thermochemical studies can not give satisfactory information on the reactions, owing to the ambiguity of the stoichiometric relation in it, simultaneous measurements of DTA, TGA and derivative thermogravimetric analysis (DTG) are indispensable for obtaining a consistent interpretation for the reactions. Nevertheless, such a technique for the simultaneous measurements of TGA and DTA was never applied until several years ago.[3]

The simultaneous measurements of TGA and DTA with a Derivatograph on the transition metal complexes with a single sample was undertaken.

*1 Presented at the 17th Symposium on Coordination Compounds of the Chemical Society of Japan, Hiroshima, December, 1967.

1) M. Mori and R. Tsuchiya, This Bulletin, **33**, 841 (1960); N. Tanaka and M. Nanjo, *ibid.*, **37**, 1330 (1964).

2) M. Mori and R. Tsuchiya, *ibid.*, **32**, 467 (1959).

3) W. W. Wendlandt and J. L. Bear, *J. Inorg. Nucl. Chem.*, **22**, 77 (1961).

As the first series of derivatographic studies, the deaquation-anation reaction of aquopentaamminechromium(III) complexes was investigated with the above equipment and a comparison of the thermal properties between them and the corresponding cobalt(III) complexes was also made.

Experimental

Materials. The aquopentaamminechromium(III) nitrate (I) was prepared by the methods proposed by one of the authors.[4] The corresponding chloride (II), bromide (III), iodide (IV), sulfate (V) and sulfite (VI) were prepared by adding ammonium chloride and hydrochloric acid, potassium bromide and hydrobromic acid, potassium iodide, sodium sulfate and potassium hydrogen sulfite to aquopentaamminechromium(III) nitrate I as a starting material, respectively;[4] they were identified by the chemical analysis and the infrared absorption spectra.

Measurements. The TGA, DTA and DTG curves were automatic-photographically recorded with a single sample in a constant nitrogen stream with a Metrimpex Derivatograph Typ-OD-102 made in Hungary,[5] which is a most useful equipment for the simultaneous measurements of the above three curves. Five hundred milligrams of samples were used in each measurement unless otherwise stated. The particle size of the samples was within the range between 100 and 200 mesh. The heating rate was about 1°C per minute. IR and far-IR spectra of the samples, both before and after the deaquation-anation reactions, were measured with a JASCO Model IR-E IR Spectrophotometer and a Hitachi EPI Far-IR Spectrophotometer, respectively.

Results and Discussion

The derivatograms, containing T, TGA, DTA and DTG curves, recorded for the complexes, II, III and IV, are shown in Fig. 1, and those for I, V and VI are shown in Fig. 2. In these figures, TGA curves are recorded in the lower part of the chart and the other T, DTA and DTG curves are in the upper part. Recordings of DTA and DTG were operated so as to be approximately expanded within the upper part of the chart by adjusting the sensitivity of the galvanometer.

That the aquopentaamminechromium(III) complexes, $[Cr(H_2O)(NH_3)_5]X_3$ (X=halogenide, nitrate, sulfate or sulfite anion), give rise to the deaquation-anation reaction, that is, they lose the coordinated water to yield acidopentaamminechromium(III) complexes, $[CrX(NH_3)_5]X_2$, is well known.[6] The first dropping of the TGA curves and the simultaneous appearance of the endothermic peaks in DTA curves for the complexes concerned shown in Figs. 1 and 2 suggest the occurrence of such deaquation-anation processes in the solid phase.

The temperatures at which the deaquation of the aquopentaamminechromium(III) complexes begins, appearing in TGA curves, T, and the temperatures at which endothermic peaks show the maximum in DTA curves, T_m, for the respective reactions, shown in Figs. 1 and 2 are summarized in Table 1.

It is found from this table that the temperature at which the deaquation starts becomes higher in the order of I<II<III<IV<V<VI. This order is not in good agreement with that proposed by Wendlandt *et al.*[3] for the complexes, I, II, III and IV, but it is approximately in agreement with that reported by Tanaka *et al.*[7] for hexaamminenickel(II) complexes, so far as the nitrate, chloride, bromide and iodide are concerned. The sequence obtained in this work is approximately parallel to the increasing order of the ionic radii of the counter-anions entering into the coordination sphere after

Table 1. The temperatures, T, at which the complexes begin to be deaquated and the peak temperatures, T_m (°C)

Complex	T	T_m
I	40	85
II	60	82
III	68	95
IV	70	125
V	100	134
IV	120	140

the deaquation. It may suggest the apparent increasing order of the thermal stability against the deaquation-anation reaction among the above aquopentaammine complexes concerned.

The enthalpy change, ΔH, in the deaquation-anation reaction per mole of sample is expressed as below in terms of the peak area, A, formed by DTA curves.

$$\Delta H = \frac{K}{N} A, \qquad (1)$$

where K is a constant containing the conductivity of the sample and depending upon the structure of the equipment and the heating conditions, and N is the numbers of moles of sample, *i. e.*, the value of the mass divided by the molecular weight of the sample. The ratio, $\Delta H/A$, should be, therefore, the function of the dehydration temperature of the materials.

In order to confirm these relationships, the values of $\Delta H/A$ were plotted against the peak temperatures of DTA curves in the dehydration reactions in Fig. 3 for barium chloride dihydrate, cobalt(II) sulfate heptahydrate, copper(II) sulfate pentahydrate, nickel(II) sulfate heptahydrate, ammonium aluminum alum, potassium chromium(III) alum, copper(II) sulfate monohydrate and cobalt(II) sulfate pentahydrate. Since these plottings lie approximately on a smoothed curve, it may be appropriate to select copper(II) sulfate pentahydrate as a standard sample to determine the constant K in Eq. (1).

By comparing the peak area in the DTA curves in the deaquation-anation reaction of aquopentaamminechromium(III) complexes concerned with that appearing in DTA in the dehydration of copper(II) sulfate pentahydrate, and applying ΔH= 13.6 kcal/molH_2O as the mean value of the enthalpy change per one mole of water calculated from the total enthalpy change[8] in the liberation of the first four moles of water from copper(II) sulfate pentahydrate, the enthalpy change in the deaquation-anation reaction desired can be determined.

These values, ΔH, for the aquopentaamminechromium(III) complexes obtained by the above method are listed in Table 2, together with those for the aquopentaamminecobalt(III) complexes cited from reference.[9]

It is seen in this table that the values of ΔH for the complexes, I, II and III, are in remarkably good agreement with those for the corresponding

cobalt(III) complexes, respectively, and the increasing order of the values, ΔH, such as in II$<$III$<$IV$<$I$<$VI$\lesssim$V, is approximately parallel, except for the nitrate, I, to the order of their increasing thermal stability presumed by the deaquation-anation temperatures, T or T_m, listed in Table 1.

Up to date, the kinetic analysis has, in general, been performed by the isothermal method, but it is very troublesome, though accurate, owing to the necessity of, at least, several measurements of the quantity concerning the reactants or products at various temperatures. On the contrary, the kinetic analysis in the thermal decomposition processes became very advantageous, if the DTG curve is applied, because it will be possible by using only one curve obtained by the temperature-elevating method.

The rate constant, k, is given by the equation[10]

$$k = \frac{(A/N_0)^{n-1}(-\mathrm{d}x/\mathrm{d}t)}{(A-a)^n}, \qquad (2)$$

where N_0 is the number of mole of the sample at the time at which the DTG peak appears, A and a are the total peak area and the area swept up till the time, t, respectively, $\mathrm{d}x/\mathrm{d}t$ is the displacement of the DTG curve from the base line at time t, that is, parallel to the rate of the weight change,

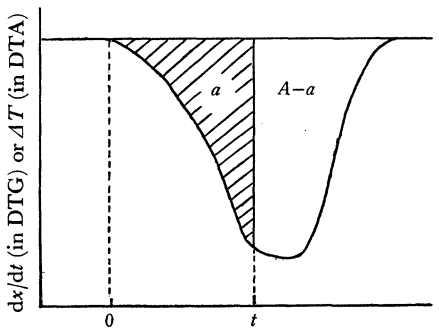

Fig. 4. Kinetic analyses on the basis of DTG and DTA curves.

and n is the reaction order, as shown in Fig. 4.

If the reaction proceeds in the first order, Eq. (2) is simplified as

$$k = \frac{-\mathrm{d}x/\mathrm{d}t}{A-a}. \qquad (3)$$

The logarithm values of the rate constant for the deaquation-anation reaction in the aquopenta-ammine complexes, I, II, III, V and VI, are calculated by using Eq. (3) and they are plotted against the reciprocal of the absolute temperature, which are shown in Fig. 5.

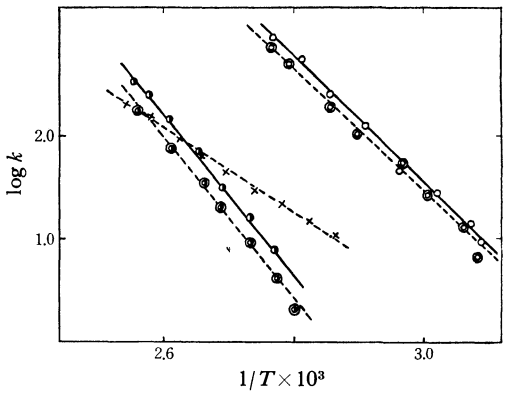

Fig. 5. Arrhenius plots, $\log k - 1/T$, for the deaquation-anation reactions of aquopentaamminechromium(III) chloride (○◎), bomide (◐◑) and iodide (×), from DTG (——) and from DTA (------).

Another available method of kinetic analysis is the use of the DTA curve. The rate constant is given by the equation[11]

$$k = \left(\frac{KAV}{N_0}\right)^{n-1} \frac{C_p(\mathrm{d}\Delta T/\mathrm{d}t) + K\Delta T}{\{K(A-a) - C_p\Delta T\}^n}, \qquad (4)$$

where V is a volume of a sample, ΔT is the temperature difference between the sample and the inert material, $\mathrm{d}\Delta T/\mathrm{d}t$ expresses the slope of DTA curve at time t, and C_p is the molecular heat of the sample. ΔT is corresponding to $\mathrm{d}x/\mathrm{d}t$ in the case of DTG curve shown in Fig. 4, and other terms are identical to the corresponding ones noted in Eq. (2).

It will be difficult to find the value of the rate constant from Eq. (4), since the molecular heat is not generally known. However, when the terms containing the molecular heat in Eq. (4) are negligibly small and the reaction is assumed to proceed in the first order, Eq. (4) is simplified as

$$k = \frac{\Delta T}{A-a}. \qquad (5)$$

Equation (5) can be formerly obtained by replacing $-\mathrm{d}x/\mathrm{d}t$ in Eq. (3) by ΔT, and the analytical

10) N. G. Dave and S. K. Chopra, *Z. Physik. Chem.*, **48**, 257 (1966).

11) H. J. Borchardt and F. Daniels, *J. Am. Chem. Soc.*, **79**, 41 (1957).

processes are quite the same in both DTG and DTA curves.

Arrhenius plots obtained for the chloride, bromide and iodide as the representatives by using Eq. (5) are also shown in Fig. 5, together with the plots by DTG analysis. The activation energies, $E^{\neq}$, obtained from the Arrhenius plots in the case of DTG and DTA analyses are summarized in Table 3.

Table 3. Activation energies, $E^{\neq}$, in the deaquation-anation reactions of aquopentaamminechromium(III) and that of one of the cobalt(III) complexes

Complex	$E^{\neq}$ kcal (from DTG)	$E^{\neq}$ kcal (from DTA)	$E^{\neq}$ by Wendlandt[3]
I	18	14	16
II	28	25	18
III	38	36	31
IV	—	19	18
V	36	39	—
VI	33	32	—
$[CoH_2O(NH_3)_5]Cl_3$			22[12]

In this table, the activation energies in the deaquation-anation reactions of aquopentaamminechromium(III) halides and nitrate reported by Wendlandt *et al.*[8] and that of the corresponding aquopentaamminecobalt(III) chloride reported by one of the authors[12] are also included, which was, however, obtained by the isothermal kinetic measurement different from those in the present work by the dynamic temperature-elevating method.

That nitrate has the smallest value of activation energy supports the fact that nitrate has the lowest dissociation temperature of all the complexes treated in this paper and undergoes deaquation most easily.

Although the methods to obtain the activation energy employed by authors in this study and by Wendlandt *et al.*, so far as the nitrate and the halides are concerned, are different from each other, the data by two groups of workers are in satisfactory agreement with one another except for those of the chloride.

12) M. Mori, R. Tsuchiya and Y. Okano, This Bulletin, **32**, 1029 (1959).

If these deaquation-anation reactions belong to S_N1 reaction, *i. e.*, the rate-determining step in these reactions consists in the deaquation process such as

$$N_5Cr\text{–}OH_2 \longrightarrow N_5Cr + OH_2\,, \qquad (a)$$

where N_5Cr expresses $Cr(NH_3)_5$ group, the activation energies in these reactions should be approximately close to each other. But it is not always the case as shown in Table 3. When the rate of the anation process such as,

$$N_5Cr + X \longrightarrow N_5CrX\,, \qquad (b)$$

where X expresses halide ions, nitrate, sulfate or sulfite anions, is larger than that of the deaquation process, (a), the deaquation-anation reaction will belong to S_N1 reaction owing to the rate-determining step of (a) as described above, whereas the rate of the process (b) is smaller than that of the process (a), the reaction will belong to S_N2 reaction due to the rate-determining step of (b).

The fact given in Table 3 that the activation energies in the deaquation-anation reactions of the bromide, sulfate and sulfite are, above all, larger than those of the chloride, iodide and nitrate, suggests that the deaquation-anation reactions in the former complexes, the bromide, sulfate and sulfite, include, to some extent, the tendency of S_N2 reaction, at least, at the earlier step of these reactions, differing from those in the latter complexes. The reason for this may be attributed to the larger ionic radii of the bromide, sulfate and sulfite anions, but a more decisive reason is not clear.

That the activation energy for the aquopentaamminechromium(III) chloride is slightly larger than that for the corresponding cobalt(III) chloride as shown in the table may be due to a somewhat larger force constant in $Cr\text{–}OH_2$ in the former complex than that in $Co\text{–}OH_2$ in the latter one.[13]

The authors wish to express their appreciation to the Ministry of Education for the financial support granted for this research.

Derivatographic Studies on Transition Metal Complexes. II.*1 Thermal Reaction in the Solid State of Chromium(III) and Cobalt(III) Aquo-EDTA-like Complexes*2

Ryokichi Tsuchiya, Akira Uehara and Eishin Kyuno

Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa

(Received August 13, 1968)

The thermal reaction processes in the solid state of the following chromium(III) and cobalt(III) aquo complexes with EDTA or the related aminopolycarboxylic acids were investigated by means of derivatography: [CrHedta(H_2O)] (I), [CrHpdta(H_2O)]·H_2O (II), [CrHtmta(H_2O)]·H_2O (III), [Cr(OH)Hapda(H_2O)$_2$] (IV) and [Co(OH)Hapda(H_2O)$_2$] (V) (edta, pdta, tmta and apda are the abbreviated forms of ethylenediaminetetraacetate, propylenediaminetetraacetate, trimethylenediaminetetraacetate and ammoniapropionicdiacetate anions, respectively.). With complex I, the carboxylate anion free from coordination to metal coordinated when the dehydration took place at *ca.* 280°C. It resulted in the change of the coordination number of EDTA from quinquedentate to sexadentate. In the case of complexes II and III, the transition appeared below *ca.* 100°C where the coordinated water molecule in the coordination sphere is thermally expelled to the outer sphere as the protonated form due to the coordination of a carboxylate anion. PDTA and TMTA (conjugated acids of pdta and tmta respectively) also changed from quinquedentate to sexadentate ligands in this step. Of complexes IV and V, the coordinated hydroxo group was excluded as a water molecule together with the hydrogen in a free carboxylate anion at *ca.* 140°C to make the coordination number of APDA(conjugated acid of apda) change from terdentate to quadridentate. The activation energies and the enthalpy changes in each thermal reaction process were determined by the analysis of their derivatograms.

The thermal behaviors in the deaquation-anation reaction of a series of the aquopentaamminechromium(III) complexes in the solid phase have been discussed on the basis of the data obtained from "Derivatograms" in the preceeding paper.*1 One merit in the simultaneous measurements of TGA and DTA curves by "Derivatograph" is being able to deduce whether the enthalpy change appearing in the DTA curve is due to the weight loss of the sample or due to only the phase change. The combination of the IR data concerning the samples before and after the thermal reactions with the results obtained by Derivatograph may give detailed information about the structural transformations in the reactions.

Several aquo complexes of chromium(III) and cobalt(III) with EDTA or the related ligands, PDTA, APDA or TMTA were prepared. Investigations were carried out (1) to obtain information on the structural change in the successive, thermal reaction processes for these complexes and (2) to determine, if possible, the enthalpy changes and the energies of activation concerning the respective reactions. The ligands used in this study are given in Fig. 1.

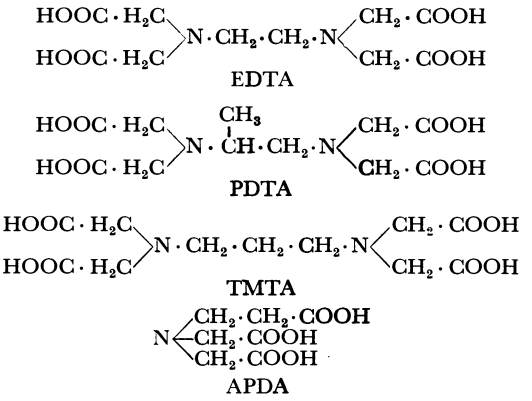

Fig. 1. Rational formulas of the ligand.

and IR spectral measurement.

Hydrogen propylenediamine tetraacetato aquo chromium(III) Monohydrate: [CrHpdta(H_2O)]·H_2O (II). The preparation was carried out by the same method[1] and the chemical formula was checked by elemental analysis and IR spectra.

Hydrogen trimethylenediaminetetraacetatoaquochromium(III) Monohydrate: [CrHtmta(H_2O)]·H_2O (III). Thirteen grams of chromium(III) chloride hexahydrate were dissolved in 100 m*l* of water and then 15 g of TMTA were added. After the solution was heated on a water bath at about 80°C for a while, 25 g of potassium hydrogencarbonate was added little by little. After being evaporated to half the volume by aeration, the solution was when necessary, quickly filtered and the filtrate was kept to stand for a while. When red crystals were deposited, they were filtered and washed with a small amount of ethanol-water (1:1) mixture and then with ethanol-ether (1:1) mixture and air-dried. Yield about 18 g. The product was recrystallized in water.

Found: C, 33.77; N, 6.95; H, 4.69%. Calcd for [CrHtmta(H_2O)]·H_2O: C, 33.75; N, 7.16; H, 4.61%.

Hydroxohydrogenammoniapropionicdiacetatodiaquochromium-(III): [Cr(OH)Hapda(H_2O)$_2$] (IV). This was prepared by the method reported previously[2] and the identification was carried out in a way similar to that described above.

Hydroxohydrogenammoniapropionicdiacetatodiaquocobalt(III): [Co(OH)Hapda(H_2O)$_2$] (V). Twelve grams of cobalt-(II) chloride hexahydrate were dissolved into 100 m*l* of water and another 100 m*l* of water containing 10 g of APDA neutralized with 10 g of potassium hydrogencarbonate was added, and then the mixture was heated on a water bath for about one hour. The clear pink solution obtained was oxidized by 10 m*l* of 10% hydrogen peroxide solution to produce the cobalt(III) complex. After the pH of the solution was adjusted to 2—3, the solution was stood for a few hours. Purple crystals were obtained. The products were recrystallized from its concentrated aqueous solution. Yield about 5 g.

Found: C, 26.49; N, 4.72; H, 4.65%. Calcd for [Co(OH)Hapda(H_2O)$_2$]: C, 26.65; N, 4.44; H, 4.47%.

Derivatographic Measurement. The derivatograms of these complexes expressing simultaneously the results of thermogravimetric analysis (TGA), differential thermal analysis (DTA) and derivative thermogravimetric analysis (DTG) were obtained with a Metrimpex Derivatograph Typ-OD-102 made in Hungary. All the experiments were carried out in a nitrogen stream under the heating rate of 1°C/min, and 500 mg of the sample was used in each run. The analyses of derivatograms for each reaction process were carried out in a manner similar to that explained in a previous paper.*[1]

IR Measurement. The IR spectra were measured with a JASCO Model IR-E Spectrophotometer in Nujol mull state for the samples in the successive, appropriate heating steps appointed from the derivatograms.

Conductivity Measurement. The conductivities of the samples were determined with a Yokogawa Universal Bridge BV-Z-13A.

Result and Discussion

Dehydration Mechanisms in Aquo-EDTA-Like Complexes. Some chemical properties of the samples, I—V, including their IR data are shown in Table 1. Their IR spectra show two characteristic bands near at 1730 and 1640 cm^{-1} which correspond to those assigned by Busch and Bailar[3] in cobalt(III) EDTA complex to the stretching vibration concerning the non-coordinated and coordinated carboxylate anions, respectively. In complexes III, IV and V, above all, the band at 1730 cm^{-1} is shifted to about 1690 cm^{-1} probably due to the stronger interaction between the non-coordinated carboxylate and the neighboring, coordinated H_2O or OH group.[2]

Table I. Some chemical properties of complexes

Complex	IR ($\nu_{C=O}$)(cm^{-1})		Molar conductivity* (mho cm^{-1})	pH**
	-COOH	-COO-M		
I	1738 (s)	1640 (vs)	211.6	2.5
II	1728 (s)	1635 (vs)	278.1	2.6
III	1685 (s)	1630 (vs)	153.8	4.2
IV	1690 (s)	1640 (vs)	2.8	6.4
V	1689 (s)	1640 (vs)	3.2	6.2

* 1.0×10^{-3} mol/*l* aqueous solution was used.
** 1.0×10^{-2} mol/*l* aqueous solution was used.

The lower values of pH and the higher values of the conductivities in complexes, I, II and III, show that they dissociate, to a great extent, into the hydrogen ion and complex anion. But complexes IV and V are all non-electrolytic species in aqueous solution.

The derivatograms for each complex, I—V, are shown in Figs. 2 and 3. The IR spectra of the samples taken at the appropriate step of the thermal reaction processes appearing in the derivatograms were measured. They are shown in Fig. 4.

Complex I loses one mole of the coordinated water about 280°C as seen in Fig. 2, and Fig. 4-a shows that the absorption peak at 1738 cm^{-1} assigned to the non-coordinated carboxylate disappears after the heating at 280°C. It may suggest that, in complex I, the non-coordinated carboxylate comes into the coordination to metal as soon as one water molecule is liberated at the temperature.

In the case of complex II, a small but distinct endothermic change is observed in the DTA curve just before the TGA curve begins to show any weight decrease of the sample as seen in Fig. 2. Fig. 4-b shows that the band assigned to the non-coordinated carboxylate also disappears but the band assigned to the coordinated one remains

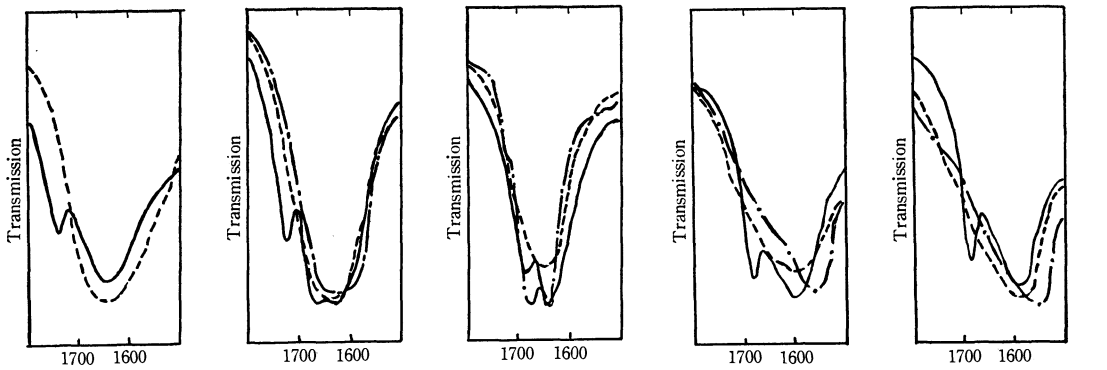

Fig. 4. Infrared spectra.

upon heating at *ca.* 95°C. In this step, PDTA anion behaving as a quinquedentate ligand may turn to a sexadentate ligand in the same way as EDTA in complex I. However, differing from I, the change occurring in the coordination number in complex II is due not to the complete liberation of water molecule from the complex, but probably to the separation of water molecule from coordination sphere in the complex itself, without any weight loss.

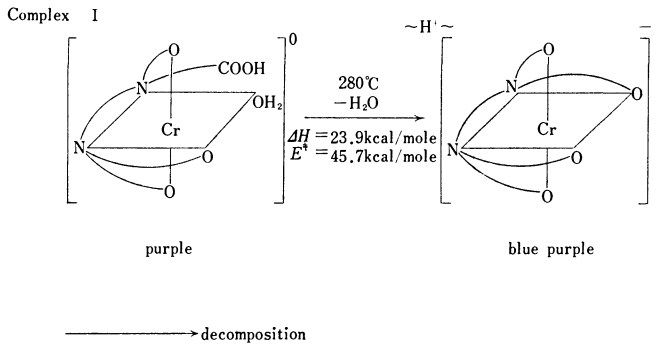
Above 95°C, the weight loss of the sample begins, and two moles of water are successively liberated up to 220°C, which are shown by TGA and DTA curves in Fig. 2. The IR spectrum concerning the carboxylate stretching vibration at 200°C is shown to be similar to that at 95°C as seen in Fig. 4-b,

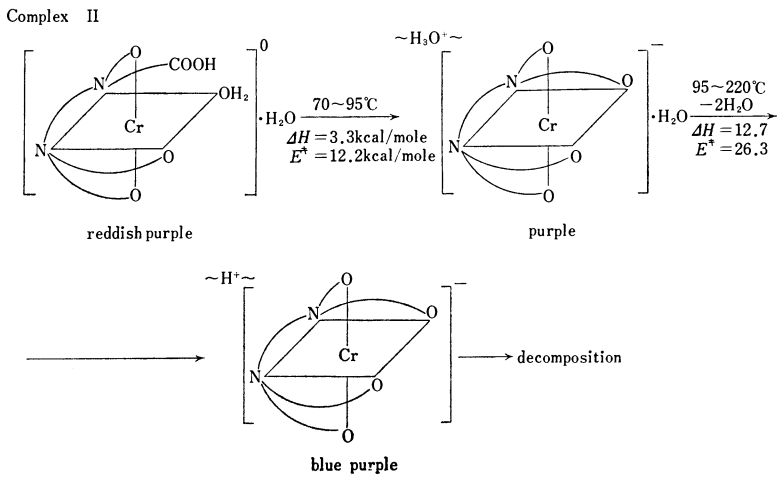
which may indicate no structural change in the coordinated PDTA molecule.

As shown in Fig. 2, in the case of complex III, a small change on the DTA curve also appears at relatively low temperature region, 60—80°C, without giving any weight loss in TGA curve, where the complex shows only a slight color change from red to reddish-violet. The sharp band at 1685 cm^{-1} in IR spectra at room temperature could not be detected in the sample at 80°C as seen in Fig. 4-c, giving the verification that a coordinated carboxylate may come out from the coordination sphere as H_3O^+ in this step, resulting in the coordination of the carboxylate ion, where TMTA molecule turns from a quinquedentate ligand to a sexadentate one. At 90—220°C the DTA curve shows a split peak, probably due to the stepwise liberation of two moles of water from the intermediate, H_3O-[Crtmta]·H_2O. Further decomposition begins to proceed at about 280°C and a small exothermic peak appears immediately before decomposition, its significance not being so clear. The reappearance of the peak assigned to the non-coordinated carboxylate in IR spectra in Fig. 4-c may suggest the formation of the ionic intermediate, but its structure is unknown.

The derivatogram for complex IV in Fig. 3 shows the relatively small, distinct changes in both DTA and DTG curves at 130—160°C corresponding to the weight loss for just one mole of water, and they are accompanied by the great sharp peaks in DTA and DTG at 160—210°C corresponding to the liberation of two moles of water. The IR spectra of IV at 160°C and 210°C, as shown in Fig. 4-d, do not give the band assigned to the non-coordinated carboxylate which was presented at 1690 cm^{-1} at room temperature. These results may suggest that APDA which acted as a terdentate ligand keeping one of the carboxylate group non-coordinated behaves as a quadridentate at 160—210°C owing to the liberation of the first one mole of water which comes from the coordinated OH^- and H^+ of the free carboxylate group.

With complex V, it is found in Fig. 3 that one mole and another two moles of water are gradually liberated, successively. The IR spectra of V at 150°C and 180°C in Fig. 4-c also give no band assigned to non-coordinated carboxylate group





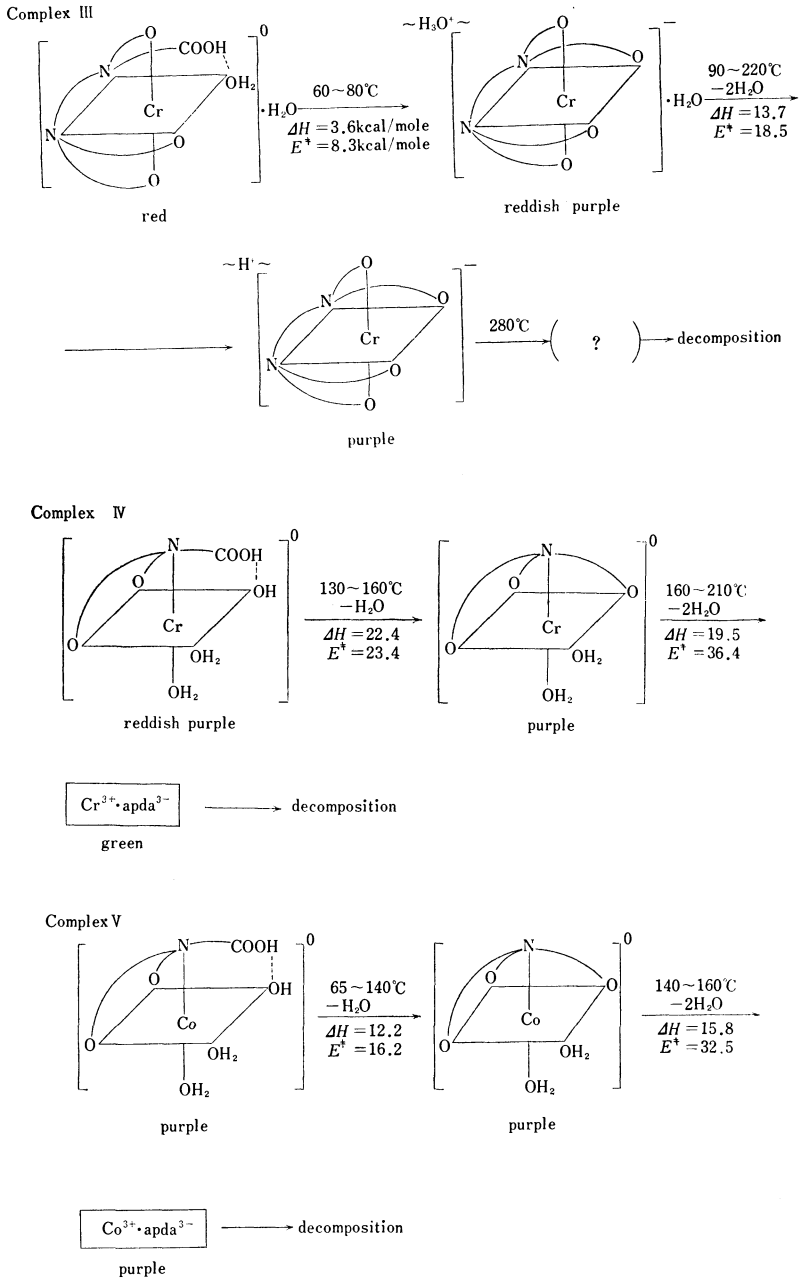


Fig. 5. Possible thermal reaction schemes.

which appeared at room temperature in the same way as those of complex IV. It may suggest that, in complex V also, APDA turns to a quadridentate ligand from a terdentate one at 150°C. The possible thermal reaction schemes for complexes, I—V, are proposed in Fig. 5.

Enthalpy Change and Activation Energy. The enthalpy changes, ΔH, for each step of the thermal decomposition of these complexes were estimated from DTA in the same way as described previously.*1 The activation energies, E^*, for the corresponding steps were calculated by using DTA[4] or DTG[5] curves and by applying the Arrhenius plots to this calculation. The representative Arrhenius plots, $\log k$ *vs.* $1/T$, where k is the rate constant for complexes III and IV are shown in Fig. 6-a, b and Fig. 7-a, b, respectively. The values

of ΔH and E^* obtained above are given in the corresponding processes in Fig. 5.

The enthalpy changes in the first step of the thermal reaction of complexes II and III, where the coordinated water came out from the coordination sphere to the outer sphere without the liberation of water molecules from the solid phase of the complexes, are obtained in the range of ΔH=3.3—3.6 kcal/mol. On the other hand, those in the second step, where one mole of water was expelled, are estimated within the range of ΔH=12.7—13.7 kcal/mol. Complex III in particular indicates a small exothermic change as ΔH=5.6 kcal/mol at about 280°C. The activation energy for III in the first dehydration process including the transition, 26.8 kcal/mol, is smaller than that in the corresponding process in complex I, 45.7 kcal/mol. It is likely due to the fact that TMTA can coordinate to metal as a sexadentate ligand with less strain than EDTA, owing to a six-membered ring in it.

The activation energies in the first dehydration process for complexes IV and V are approximately close to the respective enthalpy changes. The lower temperature at which the dehydration beings, the smaller enthalpy changes and the lower activation energies in the first and second dehydration processes on cobalt(III) complex V than those on chromium(III) complex IV may indicate that the former is thermally less stable than the latter.

Mixed Conduction in Stabilized Zirconia at a Low Oxygen Partial Pressure*1

Kazushi HIROTA

Department of Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received October 11, 1968)

The electromotive force of the oxygen concentration cell, O_2 gas|stabilized zirconia|Fe(+C)-melt+COgas, was measured at 1900°K as a function of the carbon concentration in iron melt, and the transference number of the stabilized zirconia was calculated. The transference number of the ions in the stabilized zirconia partition is less than unity over the whole range of carbon concentration. When the results are compared with the equations derived from plausible models, a reasonable coincidence is obtained.

In the stabilized zirconia crystals, the mobility or the diffusion coefficient of the oxygen ion is exceptionally large at temperatures far from the melting point,[1,2] while those of the metal ions are negligibly small.[3] The stabilized zirconia, therefore, has practically only one kind of charge carrier at an elevated temperature.[4,5]

This ideal character as an ionic conductor disappears at very low oxygen partial pressures due to the partial reduction of zirconia. Kiukkola and Wagner[4] first showed that the electronic conduction is negligible in comparison with the oxygen ion conduction at oxygen partial pressures as low as $10^{-21.5}$ atm at 870°C.

Vest and Tallan[6] have since reported on the transference number of the oxygen ion in calcia-stabilized zirconia, determined by their polarization method, as a function of the oxygen partial pressure at 1000°C, and have reported a transference number of less than 0.5 at 10^{-16} atm, for example.

Schmalzried[7] has measured the electromotive force of the cell, air|ZrO_2(+CaO)|Ca+CaO, at temperatures from 700 to 1000°C and has shown that, at 1000°C for example, the average transference number of oxygen ions in the zirconia electrolyte is about 0.5 when the oxygen partial pressure is 10^{-35} atm at one side of the electrolyte, while the other side is air.

Baker and West[8] have measured the electromotive force of the cell, H_2+H_2O|solid electrolyte|H_2+H_2O, over the range of temperatures from 1000 to 1600°C. They thought that their results for calcia-stabilized zirconia were consistent with those of Schmalzried. However, the numerical coincidence in their transference number for the zirconia electrolyte is only apparent, because the difference in oxygen partial pressure between air and a hydrogen-steam mixture at the reference electrodes must result in a difference in the transference number in the zirconia for the same oxygen partial pressures at the other side of the electrodes.

Tretyakov[9] has measured the electromotive force of the cell, air|ZrO_2(+CaO)|Cr+Cr_2O_3, or Mn+MnO, at temperatures from 600 to 1600°C and has given the relation;

$$\log P_{O_2}^* = -60.5 \cdot 10^3/T + 19.5$$

where $P_{O_2}^*$ (in atm) is the partial pressure of oxygen gas at which the transference number of the ion in the zirconia becomes 0.5.

As one can see, these findings on the transference number cited above do not coincide with each other.

In these investigations, the measurements were done at several fixed oxygen partial pressures, or under several sets of limited conditions; the results were then extended to more general expressions by

adopting plausible, but not decisive, models for mixed conduction.

For the use of zirconia as a solid electrolyte, it is necessary to establish facts on the transference number over a wide range of oxygen partial pressure; such facts will make it possible to calculate the region of oxygen partial pressure in which the electronic conduction can be neglected.

Richardson and Dennis[10] and Rist and Chipman[11] have given a reliable value for the activity coefficient of carbon in liquid iron. In this system, the equilibrium:

$$C(\text{in Fe melt}) + O(\text{in Fe melt}) = CO(\text{in gas phase}) \quad (1)$$

can be expected. Therefore, one may calculate the activity of oxygen from the carbon concentration in the iron melt and the partial pressure of CO in the gas phase in equilibrium with the iron melt. This system can cover a wide range of oxygen partial pressures at low oxygen partial pressures, and has a relatively large buffer action in reaction to the leak of oxygen. Therefore, this system was used in the following experiment.

Similar cells, iron melt|stabilized zirconia|reference oxygen activity, have been reported by many investigators. They have given the relation between the electromotive force of their cells and the O in the iron melt, in the region where the average transference number of the stabilized zirconia was assumed to be unity.[12] In their measurments, the iron melts were in contact with such inert gases as argon gas; this may result in the serious scattering of the observed values.

Experimental

The electromotive force of the cell; O_2 gas|stabilized zirconia|Fe(+C), CO gas, was measured at 1900±2°K. Commercial zirconia tubes, Zr-23 of the Degussa Co., Ltd., were used in the cell as the stabilized zirconia partition. The results of the wet analysis of the tubes used are listed in Table 1, together with their change in chemical composition with use in the measurements. The arrangement of the cell is shown in Fig. 1. The cell was hung in a vertical-tube furnace, and then CO gas, mixed with from 0% to 3% of CO_2 gas, was made to flow upwards through the furnace at the flow rate of 2 cm/sec.

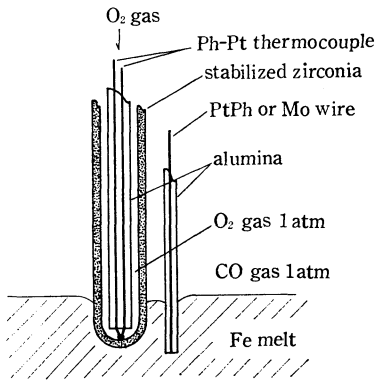

Fig. 1. Schematic illustration of cell arrangement.

The furnace used was a resistance-type furnace. A wire of 60%Pt-40%Rh alloy was wound round an alumina tube (40 mm in diameter, Al-23, of the Degussa Co., Ltd.), coated with fine powder of pure alumina (99.9% pure, Alcoa Co., Ltd.) and surrounded with the same powder about 15 cm thick for thermal insulation. The thermocouple for temperature control was fixed close to the wire. The temperature controllers used were the EC-51 type of the Ohkura Electric Co., Ltd. The center of the furnace, about 18 cm wide, was kept at 1900±2°K during operation.

The electromotive force was measured between a Pt-Rh wire of the thermocouple at the inside of the zirconia tube and a Pt-Rh wire or Mo wire immersed in the iron melt outside the zirconia tube. Because of the use of molybdenum wire, a correction of the electromotive force of the cell, corresponding to the thermoelectromotive force, was made. The dissolution rates of these wires in the iron melt were so high that the time available for the measurement of the electromotive force was about ten seconds for each measurement. The contamination of the iron melts from these wires was about 0.3% in atm ratio; this contamination was assumed to be negligible.

The 6%Rh94%Pt-30%Rh70%Pt thermocouple used in the cell was checked with the gold point, the diopside point, and the palladium point both before and after the experiment. No change in electromotive force was found.

Table 1. Chemical compositions of stabilized zirconia tubes used in the measurement

11) A. Rist and J. Chipman, "The Physical Chemistry of Steelmaking," ed. by J. F. Elliott, John Wiley and Sons, New York (1958), p. 3.

12) For example, W. A. Fischer and W. Ackermann, *Arch. Eisenhüttenwes.*, **36**, 643 (1965); Y. Matsushita and K. Gotō, *Transactions, I. S. I. J.*, **6**, 131 (1966).

Each iron sample was prepared by mixing 99.9% pure iron powder with graphite powder of a spectroscopic grade. The iron sample was placed in an alumina crucible, and was elevated slowly in the furnace. Then, the zirconia tube was immersed in the iron melt thus obtained and kept at 1900±2°K for ten minutes or more, after which the electromotive force was measured.

After the measurement, the sample was quenched immediately by lowering the crucible in the gas flow. A half of each sample pellet (about 30 g in weight) thus obtained was made into chips by a shaper or a diamond cutter and a hammer. The carbon concentration was measured by the method prescribed in JIS G-1211-2.3 (1963), *i. e.* the volume metric method. A standard sample of U. S. National Bureau of Standards, Cat. No. 12h (0.41 wt% carbon) was analyzed to check the carbon analysis; the value of 0.43 wt% carbon was thus obtained.

The immersion of the zirconia tube in a high-carbon iron melt results in numerous fine cracks on the zirconia surface. The cracks enlarge upon repeated exposure to the heating, immersing, and cooling cycle. Thus, the gas-tightness of the zirconia tube was lost in the work on high-carbon specinens. The effect of cracks on electromotive force was also examined; it was found that immediately after the stirring of the iron melt, the electromotive force of the cell was independent of the cracks, even if the cracks were not small.

The exposure of zirconia tubes to air at a high temperature results in a reaction between the zirconia and the iron drops retained on the surface of the zirconia tube; it also results in a decrease in the electromotive force. When this reaction is avoided, no detectable change in the appearance of the zirconia tube results from repeated coolings, heatings, and immersions in low-carbon iron.

Results and Discussion

1) Average Transference Number in Zirconia Partition. The relation between the carbon concentration of the iron melt and the electromotive force of the cell is plotted in Fig. 2. The values scatter about ±5 mV in electromotive force and about 10% in carbon concentration from the calculated line, shown as a solid line in Fig. 2.

The important part of this scattering, perhaps, results from the fact that the iron melt is not homogeneous, a condition which itself results partly from the transfer of carbon from or to gas phase, and partly from the permeation of oxygen through the zirconia partition. It was found that the stirring of the iron melt produced, sometimes, a fluctuation in the magnitude of the electromotive force. The contamination of the zirconia by the iron oxide during the measurements was negligible in comparison with the iron oxide originally present. The error resulting from the presence of iron oxide may be smaller than the other errors, since the correlation between the iron concentration and the electromotive force was not observable in contamination of this magnitude.

From the results shown in Fig. 2, the average

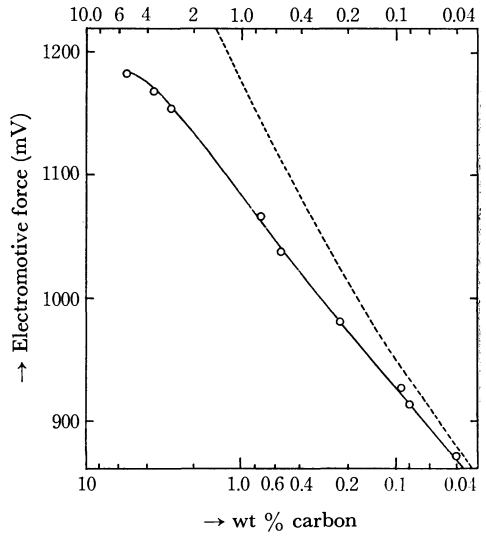

Fig. 2. Electromotive force of the cell as a function of carbon concentration in iron melt at 1900±2°K.

----- calculated from Eq. (6) when $\bar{t}_{ion}=1$,
○○ measured electromotive force,
—— calculated from Eqs. (6), and (10) or (11) giving $A=1$ and $B=1.7\cdot10^3$.

transference number of the oxygen ion in the zirconia partition, $\bar{t}_{ion}$, was calculated as follows. The electromotive force of the cell, E, may be expressed by the use of $\bar{t}_{ion}$:

$$E = \bar{t}_{ion}\cdot E_{cal},$$

$$E_{cal} = -(RT/4F)\int_0^{\ln P} d(\ln f_{O_2}) \qquad (2)$$

where P is the fugacity of molecular oxygen, which is in equilibrium with the oxygen in the iron melt, where R, T, and F are the gas constant, the absolute temperature, and the Faraday constant respectively, and where f_{O_2} is the fugacity of O_2.

Rist and Chipman[11] have given the carbon concentration in the carbon-iron system as a function of the partial pressures of CO and CO_2, P_{CO} and P_{CO_2} as follows;

$$\log \gamma_c = 4450(1-N_{Fe}^2)/T$$
$$\log K = -7280/T + 7.98$$
$$\log K' = \log K + \log \gamma_c$$
$$K' = P_{CO}^2/P_{CO_2}\cdot N_C, \qquad (3)$$

where N_C and N_{Fe} are the mole fractions of carbon and iron in the iron melt and where γ_C is the activity coefficient of carbon.

The standard free energy change of the reaction,

$$CO + (1/2)O_2 = CO_2 \qquad (4)$$

has previously been given as −28220 cal/mol at

1900°K.[13] The fugacity of molecular oxygen can, then, be given as a function of P_{CO} and P_{CO_2} when the system is in equilibrium.

$$-\ln P = 2\cdot\ln(P_{CO}/P_{CO_2}) + 14.95 \qquad (5)$$

From Eqs. (2), (3), and (5) and from the fact that $P_{CO}=1$, one may give the electromotive force of the cell as a function of the carbon concentration in the iron melt:

$$E = \bar{t}_{ion}[(\log N_C - 2.34\,N_{Fe}^2)/5.305 + 1.835] \qquad (6)$$

When $\bar{t}_{ion}=1$, Eq. (6) gives the broken line shown in Fig. 2. The average transference number, $\bar{t}_{ion}$, was calculated on the basis of Eq. (6) from the measured electromotive force of the cell; it is given in Fig. 3 as a function of the carbon concentration.

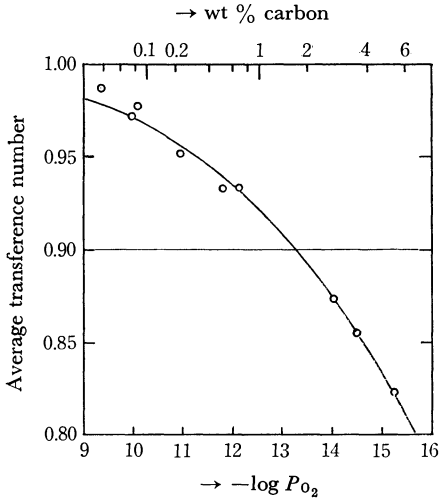

Fig. 3. Average transference number, $\bar{t}_{ion}$, of zirconia partition at 1900°K.

○○ measured values,
—— calculated with Eq. (10) or (11) giving $A=1$ and $B=1.7\cdot10^3$.

2) Oxygen Permeation Resulting from Electronic Conduction. In Fig. 3 the depression in the transference number of the oxygen ion is shown over the whole range of carbon concentration. Such a depression in transference number must, theoretically, restrict the application of Eq. (6). In the experiment, the electromotive force is measured when the external current of the cell is zero. However, this does not mean that the ionic current in the zirconia partition is zero. The electronic current and the ionic current might be equal in absolute value and opposite in current direction. The consequent leakage or permeation of oxygen may result in the disturbance of the equilibrium of the system. Therefore, Eq. (6) can be applied only when the equilibration rate within the iron melt is sufficiently large in comparison with the transport of oxygen through the zirconia partition.

The electrical resistance of the stabilized zirconia partition per square centimeter was about 10 ohm. Therefore, the leakage rate, corresponding to the carbon concentration from 10^{-4} to 10^{-2} mol/cm^3, may be from 10^{-8} to 10^{-7} mol/sec·cm^2. The temperature of the system is so high that the distrubance of this magnitude was ignored in these measurements.

3) Transference Number of the Oxygen Ion in the Zirconia Electrolyte. It is well recognized that, in a sufficiently low oxygen partial pressure region, the zirconia becomes dark in color, diminishes in weight, and changes in volume as the partial reduction proceeds. It is reasonable, therefore, to doubt whether the partial reduction of zirconia has any effect on the ionic conductivity under the present experimental conditions. Two models, as examples, were compared with the experimental results from this point of view:

$$\text{Model 1:}\quad \sigma_I = C_1 + C_2 f_{O_2}^{-1/4},\quad \sigma_e = C_3 f_{O_2}^{-1/4}$$
$$\text{Model 2:}\quad \sigma_I = C_1 + C_2 f_{O_2}^{-1/4},\quad \sigma_e = C_3 f_{O_2}^{-1/4}$$

where C_1, C_2, and C_3 are the constants and where σ_I and σ_e are the ionic and electronic conductances respectively. Model 1 corresponds to the case where the loss of an oxygen ion results in two additional defects in the electrolyte; *i. e.*, each electron remained needs to be trapped in the defect of the crystal lattice near the oxygen-deficient zirconium ion. Model 2 means that the loss of an oxygen ion results in one additional defect in the crystal lattice.

From the relation:

$$E = \int[\sigma_I/(\sigma_I + \sigma_e)]\mathrm{d}E_{cal} \qquad (9)$$

one may obtain the following relations for these models:

Model 1:

$$(1 - \bar{t}_{ion}) = A_1\ln[(P^{-1/4} + B_1)/(1 + B_1)]/\ln P^{-1/4},$$
$$A_1 = C_3/(C_3 + C_2),\ B_1 = C_1/(C_3 + C_2) \qquad (10)$$

Model 2:

$$(1-\bar{t}_{ion}) = A_2\ln[(P^{-1/4}+B_2)(1+D)/(P^{-1/4}+D) \times (1+B_2)]/\ln P^{-1/4},$$
$$A_2 = (C_3/2C_2)/[(C_3/2C_2)^2 - C_1/C_2]^{1/2},$$
$$B_2 = C_3/2C_2 - [(C_3/2C_2)^2 - C_1/C_2]^{1/2},$$
$$D = C_3/2C_2 + [(C_3/2C_2)^2 - C_1/C_2]^{1/2} \qquad (11')$$

or, in a good approximation:

$$(1 - \bar{t}_{ion}) = A_2\ln[(P^{-1/4} + B_2)/(1 + B_2)]/\ln P^{-1/4} \qquad (11)$$

13) Natl. Bur. Standards Series. III. March, 1949, and June, 1948 or "Thermochemistry for Steelmaking," Vol. 1, ed. by J. F. Elliott and M. Gleiser, Addison-Wesley Pub. Co., Reading, Mass. (1960).

Equation (10) or (11) may be rewritten in this form:

$$\frac{(1-\bar{t}_{\mathrm{ion},1})\log P_1^{-1/4}}{(1-\bar{t}_{\mathrm{ion},2})\log P_2^{-1/4}} = \frac{\log[(P_1^{-1/4}+B)/(1+B)]}{\log[(P_2^{-1/4}+B)/(1+B)]} \tag{12}$$

where B is B_1 or B_2, corresponding to Model 1 or 2, and where $\bar{t}_{\mathrm{ion},1}$ and $\bar{t}_{\mathrm{ion},2}$ are the transference numbers when $P=P_1$ and $P=P_2$ respectively. The left side of Eq. (12) is an observable quantity; it is plotted against log P_1 in Fig. 4, where P_2 is the

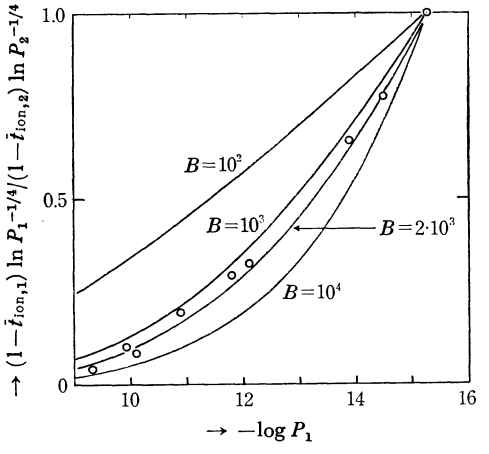

Fig. 4. Evaluation of B in Eq. (12).
○○ calculated with left side of Eq. (12)
—— calculated with right side of Eq. (12)

fugacity of oxygen in carbon-saturated iron. The right side of Eq. (12) gives the lines in Fig. 4, corresponding to the values of B. Judging from Fig. 4, B must be about 2.10^3, perhaps in the range:

$$1.7\cdot10^3 \leqq B \leqq 2\cdot10^3 \tag{13}$$

One may, then, estimate the probable value of A:

$$1.0 \leqq A \leqq 1.1 \tag{14}$$

It is obvious from their definitions that $A_1 \leqq 1 \leqq A_2$. If A_1, $A_2=1$, then $C_2/C_1=0$. Since A is very close to unity, C_2/C_1 is not larger than $1.3\cdot10^{-8}$ when Model 2 holds true, which means that the ionic conductivity, σ_I, is constant within the range of experimental error under the present experimental conditions. Therefore, we cannot choose between Models 1 and 2 on the basis of only the present results. This means that the concentration of additional defects resulting from the loss of oxygen is rather negligible in comparison with the concentration of magnesium oxide. This finding may consistent with the fact that the stabilized zirconia is doped deeply and has a large concentration of lattice defects.

The transference number was reproduced from these constants when $B=1.7\cdot10^3$ and $A=1$, for example; it is given by a solid line in Fig. 3. The electromotive force of the cell, E, was calculated from the same constants; it is given by a solid line in Fig. 2. The coincidence between the calculated and measured values seems to be satisfactory.

From these constants, the "true" transference number, $\sigma_I/(\sigma_I+\sigma_e)$, can also be calculated as a function of the oxygen fugacity; it is shown in Fig. 5. According to Tretyakov's empirical equation, which is the only finding available at this temperature, $-\log P_{O_2}^*$ is 12.3 for calcia-stabilized zirconia at 1900°K. The corresponding value, $-\log f_{O_2}$ at $\sigma_I/(\sigma_I+\sigma_e)=0.5$, is about 12.8 for magnesia-stabilized zirconia in Fig. 5. It seems that these two values coincide very well with each other in spite of the difference in the chemical composition of the electrolytes.

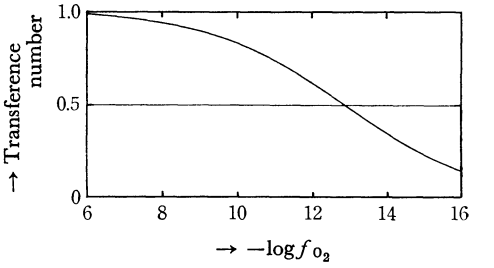

Fig. 5. Transference number, $\sigma_I/(\sigma_I+\sigma_e)$, of stabilized zirconia as a function of oxygen fugacity at 1900°K, when $C_2/C_1=0$ and $C_1/C_3=1.7\cdot10^3$, *i.e.* $B=1.7\cdot10^3$ and $A=1$.

The partial reduction of zirconia may result not only in electronic conduction but also in a volume change or in a response-time increase in electromotive force. The penetration of partial reduction in the zirconia partition can be calculated as follows. It is obvious that:

$$\mathrm{d}E = (1/\sigma_e)\, i\, \mathrm{d}l, \tag{15}$$

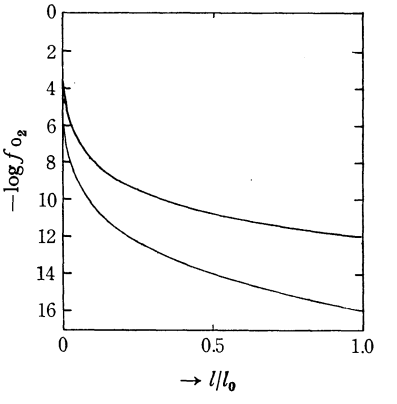

Fig. 6. Oxygen fugacity in zirconia partition calculated with $C_1/C_3=1.7\cdot10^3$ and $C_2/C_1=0$. l_0 is the thickness of the partition, and l is the length vertical to the partition.

where i is the electronic current in zirconia and where l is the length parallel with the electronic current. At the steady state, i is independent of l. From Eqs. (2), (9), and (15), the following equation can be derived:

$$-idl = \frac{\sigma_I\sigma_e}{\sigma_I + \sigma_e} \cdot \frac{RT}{4F} \cdot d(\ln f_{O_2}) \qquad (16)$$

The result calculated from Eq. (16) is shown in Fig. 6. The result shows that the partial reduction penetrates deeply into the partition.

This experiment was supported by the Central Research Laboratory of Hitach, Co. Ltd. The writer wishes to express his thanks to Dr. N. Ono, Mr. A. Kurabayashi, Dr. S. Abe and Professor T. Katsura for their valuable discussions and encouragement during this investigation.

The writer also wishes to express his thanks to Professor A. Muan and Professor Yu. D. Tret'yakov for their kindness in reading the manuscript and in making kind suggestion.

Synthetic Hydrogen-containing Ultramarine Phases

Yasushi KUBO and Goro YAMAGUCHI

Institute of Industrial Science, The University of Tokyo, Roppongi, Tokyo
Department of Industrial Chemistry, The University of Tokyo, Hongo, Tokyo

(Received October 15, 1968)

Hydrogen was analyzed on synthetic sulfur-containing sodalite-type sodium aluminosilicates. Specimens synthesized from the $NaAlSiO_4$-Na_2S system in a H_2 or N_2 atomsphere or in a N_2-S_2 atmosphere contained hydrogens which were introduced by ion-exchange during water-washing. Specimens synthesized from the same system in H_2S-containing atmospheres also contained hydrogens introduced from the synthetic atmosphere. The latter specimens had the formula: $Na_8Al_6Si_6O_{24}S \cdot xH_2S \cdot yS$, which was characterized by a constant number of sodium ions (eight per unit cell), whereas the former contained variable numbers of sodium ions according to the duration of water-washing. A difference in correlation between the sulfur content and the lattice constant was observed between these two series of specimens, indicating different manners of existence of the hydrogen.

In previous papers,[1,2] two sorts of sulfur-containing sodalite-type sodium aluminosilicates, designated sulfosodalite and leuco-ultramarine, were reported on. The former was synthesized by heating a $NaAlSiO_4$-Na_2S mixture at temperatures of from 850 to 950°C in a H_2 or N_2 atmosphere with no sulfur vapor pressure, while the latter was synthesized in a N_2 atmosphere with a sulfur partial pressure of from 0.75 to 1.0 atm. Almost all of the sulfur was contained in a sodalite-type aluminosilicic framework as the monosulfidic ion S^{2-} in the former compound, and in the latter, as the disulfidic ion S_2^{2-}. The nomenclature was based on this fact. According to the results of these papers, the formulae for these compounds were $6NaAlSiO_4 \cdot xNa_2S$ and $6NaAlSiO_4 \cdot xNa_2S_2$ respectively, and solid solutions were formed continuously between these phases.

The present paper has two objects. First, a fact overlooked in the previous papers[1,2] is reported —that the specimens previously analysed contained some hydrogen. Second, the syntheses of new sorts of sulfur-containing sodalite-type sodium aluminosilicates which also contain hydrogens but which are different from the compounds mentioned above will be reported. These new compounds will be reported. These new compounds will be synthesized by heating the $NaAlSiO_4$-Na_2S system in atmospheres containing H_2S. The composition and lattice constant will be determined, and a comparison made between these two series of synthetic hydrogen containing ultramarine phases.

Experimental

Specimens. The sulfosodalite and leuco-ultramarine specimens to be examined here are those which have been prepared in the previous investigations.[1,2] They were synthesized from the starting mixture of

1) G. Yamaguchi and Y. Kubo, This Bulletin, **41**, 2641 (1968).
2) G. Yamaguchi and Y. Kubo, *ibid.*, **41**, 2645 (1968).

the $NaAlSiO_4$-Na_2S system. The details of the method of preparation were given in those papers. The former specimens were obtained by heating the mixture in a H_2 or N_2 atomosphere at temperatures of from 850 to 950°C. The latter specimens were prepared by heating the mixture in a N_2-S_2 atmosphere at various sulfur partial pressures, from 0.25 to 1.00 atm. To indicate these specimens, the system of specimen symbols used in the previous papers will be employed in this paper.

It was found that, when the starting mixture was heated in a H_2-H_2S or H_2S-S_2 atmosphere, sodalite-type phases were also obtained. Specimens of these new phases were prepared by almost the same method as that used for the above-described specimens, except that the atmosphere system was changed. Details of these specimens will be given in a subsequent paper, which will also treat the relationship between the synthetic conditions and the compositions of these phases.

Analyses. After they had been synthesized, all the specimens were immersed in water as soon as they had cooled and were taken out of the furnace of the synthetic apparatus. They were fully washed with water until no alkali could be detected by a phenolphthalein indicator, and then dried at 110°C. Subsequently, a carbon disulfide extraction was made in order to remove completely the free sulfur condensed on the specimen.

The procedure for the determination of the chemical composition of the sodalite-type phase involves two processes; chemical analysis for every component and the determination of the yield of the sodalite-type phase by the X-ray diffraction method. The details of these processes were given in a previous paper.[1)]

The amount of hydrogen present in the specimen was determined by measuring the amount of water which was liberated when the specimen was heated in an O_2 gas stream at about 800°C. For this purpose, an element-analysis apparatus, Shimadzu UM-3, was employed. About an 80-mg portion of the specimen was placed in the combusting system of the apparatus. Prior to oxidation, the specimen was heated at about 170°C in a N_2 gas stream for 1 hr in order to fully remove the water absorbed on the surface of the specimen. The gas stream was then changed to that of O_2 gas, and the temperature was raised to about 800°C. Any SO_3 gas which may have been produced by this treatment was trapped by Ag meshes, and the water was absorbed with magnesium perchlorate. The results obtained were found to be sufficiently reproducible.

X-Ray Diffraction Measurements. The lattice constant was determined by a diffractometer measurement using Cu-$K\alpha$ radiation. MgO powder was added as an internal standard. The diffraction (444), (710, 550, 543), or (721, 633, 552) of the sodalite-type phase, at 2θ values of about 73°, 74° and 77.5° respectively, was measured at the scanning speed of 0.25°/min; calibration was made using the diffraction, (311) or (222), of MgO, at 2θ values of 74°41.52′ and 78°38.52′ respectively on the same diffractometer trace.

Results and Discussion

Specimens Synthesized in a H_2 or N_2 Atmosphere. The results of the analyses of several typical specimens are given in Table 1. The content of every component is represented by the number per unit cell. Lattice constants are also given in the last column of the same table.

Although there must not have been any water in the reaction system, $NaAlSiO_4$-Na_2S, in either the H_2 or N_2 atmosphere, the sulfosodalite specimens liberated considerable amounts of water (about 1 to 1.3%) when heated in O_2 gas. In a previous paper,[1)] it was remarked that, in these specimens, the sodium content determined from the residual Na_2SO_4 was always less than that expected from the charge balance with anions. Thus, in that paper, the content given by the latter method, *i. e.*, that determined indirectly from the ionic charge balance, was adopted as more reliable. The liberation of water as revealed in the present experiment strongly indicates that hydrogen is another constituent of the cations in these specimens. It may be seen that, by taking the hydrogen content into account, the balance of ionic charges between the cations, $Na^+ + H^+$, and the S^{2-} anion is greatly improved. (The sign of the "Charge Balance," + or −, in Table 1 indicates an overbalance of cations or anions respectively). Thus, the inconsistency observed in the sodium analysis can be attributed to the presence of hydrogen. Here the values given as the Na^+ content and the total Na content in Table 2 of a previous paper[1)] are cor-

rected to those given in Table 1 of the present paper.

The hydrogen seems to have originated from the process of washing with water after synthesis. Just after having been synthesized and cooled, the sulfosodalite phase may have contained more than eight Na^+ ions per unit cell. It is rather natural that the excess sodium ions should be easily ion-exchanged in water. This may have occurred to various extents according to the duration of water-washing; the sodium content, which apparently varies at random in Table 1, seems to indicate such conditions. As can also be seen in the table, the content of the cations, $Na^+ + H^+$, usually overbalances that of the anion, S^{2-}. This may indicate that some hydration has also occurred in these specimens.

Specimens Synthesized in a (N_2, S_2) Atmosphere. The results of analyses for two other specimens, U-H (950°C, $P_{S_2}=0.50$ atm) and U-O (950°C, $P_{S_2}=1.00$ atm), are also given in Table 1. These specimens are characterized by a low hydrogen content, indicating that these specimens are more stable than sulfosodalite when washed in water.

Specimens Synthesized in a (H_2S, H_2) or (H_2S, S_2) Atmosphere. For specimens synthesized in atmospheres of various gas compositions, the analytical results are given in Table 2 in the same manner of representation as in Table 1. The second and the third columns of the table give, respectively, the synthetic temperature and the mixing ratio of two gases in atmosphere. The relation between the synthetic conditions and the composition is not treated here, but will be discussed in a separate paper. Lattice constants are also given in the last column.

The hydrogen content in these specimens is much larger than in the sulfosodalite and leuco-ultramarine of the preceding section. Furthermore, it must be pointed out that the number of Na^+ ions per unit cell is almost constant at eight, corresponding to the ideal number of cation sites per unit cell of the sodalite-type structure. The rather large deviations from eight in the SH5-A2 and SH6-A3 specimens may be attributed to an enlarged experimental error due to lower yields of the sodalite-type phase in these specimens. The same phenomenon as in sulfosodalite, that the content of cations, $Na^+ + H^+$, exceeds that of the anion, S^{2-}, is also observed in these specimens, indicating the possibility of some hydration in the water-washing process. However, if the secondary effect by water-washing is elim-

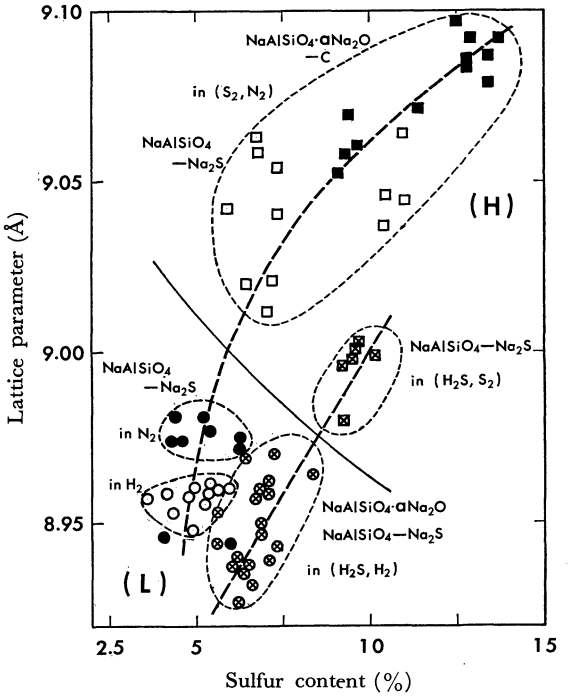

Fig. 1. Simultaneous plot of lattice parameter and sulfur content for sulfur-containing sodalite-type sodium aluminosilicates formed in every system. Two series of correlations are recognizable as shown by two broken line curves. Difference in chemical and physical characteristics are somewhat remarkable between two regions (L) and (H).

inated, the formula of the sodalite-type phase may be expressed by; $6NaAlSiO_4 \cdot Na_2S \cdot xH_2S \cdot yS$ or $Na_8Al_6Si_6O_{24}S \cdot xH_2S \cdot yS$. Thus, the composition of this compound can be represented by two characteristic values, x and y.

In the end case of $x=1$ and $y=0$, the formula becomes $Na_8Al_6Si_6O_{24}(SH)_2$, corresponding exactly to the homostructure of sodalite $Na_8Al_6Si_6O_{24}Cl_2$. In fact, in the specimen with a composition near this, the intensity distribution of the power X-ray diffraction was almost the same as that of sodalite. Thus, this compound may be named hydrosulfosodalite.

Relationship between the Total Sulfur Content and the Lattice Constant. On numbers of sulfur-containing sodalite-type phases, synthesized in various reaction systems and under various conditions by the method described above, the lattice constant (in A) was plotted against the total sulfur content (in percentages). The resulting diagram is given in Fig. 1. Since the lattice constant is not determined by the single factor of the total sulfur content, the plotted points scatter over a certain range even at the same total sulfur content. A separated region, however, proper to specimens of every atmosphere system is formed in the diagram. Furthermore, two series of correlations are clearly recognizable; they are shown by two broken lines. In these correlations, it is seen that specimens synthesized in atmospheres containing H_2S have a lattice constant smaller by about 0.8% at the same total sulfur content than that of specimens synthesized in atmospheres not containing H_2S.

Since the lattice constant was measured on specimens washed fully with water, the ion-exchange of excess Na^+ ions in the latter specimens with protons of water must have proceeded to a considerable extent; some of the specimens had almost the same Na^+ ion content as the former specimens, as can be seen in Table 1. Nevertheless, there is a difference in lattice constant between these two series of specimens. This indicates that there is some essential difference in the manner of existence between the hydrogen introduced into the former specimens from the synthetic atmospheres containing H_2S and that introduced by ion-exchange into the latter specimens, which were formed originally as alkali-rich phases in synthetic atmospheres not containing H_2S. Further details, however, have not yet been made clear.

The authors wish to thank Mr. M. Yuyama and Mr. K. Ohara of our laboratory for their aid in this investigation, and Mr. A. Miyashita, Japan Chemical Co., for his help with the hydrogen analysis.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 1901—1908 (1969)

Polarographic Reduction of Cobalt(II) in Acetonitrile in the Presence of Acetate Ions

Eiki ITABASHI and Shigero IKEDA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka

(Received October 28, 1968)

The effect of the nature and the concentration of the supporting electrolyte on the polarographic reduction of cobalt(II) acetate in acetonitrile has been investigated. An acetonitrile solution of cobalt(II) acetate yields a two-step and a three-step reduction wave in 0.05M $LiClO_4$ and in 0.05M $NaClO_4$ solution, respectively. The same solution gives ill-defined reduction waves in the presence of quaternary ammonium perchlorates, such as $(CH_3)_4NClO_4$, $(C_2H_5)_4NClO_4$, or $(n\text{-}C_4H_9)_4NClO_4$. The $Co(CH_3CN)_n^{2+}$, $Co(OAc)^+$, and $Co(OAc)_3^-$ species are present in a solution containing alkali metal perchlorate electrolyte. $Co(OAc)^+$ and $Co(OAc)_3^-$ are the predominant species in a quaternary ammonium perchlorate solution. The reduction potential becomes more negative with increase in the number of acetate ions coordinated to cobalt(II). The reduction potential of cobalt(II) acetate becomes less negative upon the addition of alkali metal perchlorate to the quaternary ammonium perchlorate supporting electrolyte. This effect is caused by the dissociation reaction of cobalt(II) acetate, in which an acetate ligand is transferred to the alkali metal ion.

The supporting electrolyte effects on the non-aqueous inorganic polarography have been reported by several investigators, especially Murray and Hiller,[1] who have done extensive work on the polarography of a number of metal acetylacetonates in acetonitrile and have found that the reduction potentials were shifted to less negative potentials by the addition of lithium perchlorate to the tetraethylammonium perchlorate supporting electrolyte. They concluded that this effect was due to the chemical reaction of the electrode reduction product, in which an acetylacetonate ligand was transferred to the lithium ion.

The present authors have previously reported on the supporting electrolyte effects on the polarographic reduction of nickel(II) in acetonitrile containing small amounts of glacial acetic acid.[2] The reduction potentials of nickel(II) acetate become less negative and the limiting current decreases with an increase in the radius of the cation of the supporting electrolyte. These effects have been explained by taking into consideration of the dissociation reaction of nickel(II) acetate. Nickel(II) acetate is dissociated into $Ni(CH_3CN)_n^{2+}$ or $Ni(OAc)^+$ by the addition of a supporting electrolyte.

Such a dissociation reaction upon the addition of a supporting electrolyte may also be expected in other acetato metal complexes.

The present paper is concerned with the supporting electrolyte effect on the polarographic behavior of cobalt(II) acetate in acetonitrile.

Experimental

Reagents. Acetonitrile and glacial acetic acid were purified by procedures which have been described previously.[2] Hexaaquocobalt(II) perchlorate, $Co(H_2O)_6(ClO_4)_2$, was prepared and recrystallized by the procedure given in the literature.[3] The analysis of $Co(H_2O)_6(ClO_4)_2$ gave the following results: Found: Co, 17.2±1.8; ClO_4, 52.6±1.3%. Calcd for $Co(H_2O)_6(ClO_4)_2$: Co, 16.11; ClO_4, 54.36%. A guaranteed reagent cobalt(II) acetate, $Co(CH_3COO)_2\cdot 4H_2O$, was recrystallized from an aqueous solution containing 5M acetic acid. The analysis of the salt gave the following results: Found: Co, 22.0±1.0; C, 19.21; H, 5.83%. Calcd for $Co(CH_3COO)_2\cdot 4H_2O$: Co, 23.66; C, 19.29; H, 5.67%.

A tetra-*n*-butylammonium acetate, $n\text{-}Bu_4NOAc$, was prepared by neutralizing an alcoholic solution of tetra-*n*-butylammonium hydroxide with acetic acid, after which the salt was recrystallized from benzene. The analysis of the salt gave the following results: Found: C, 71.48; H, 13.63; N, 4.48%. Calcd for $(n\text{-}C_4H_9)_4NCH_3COO$: C, 71.71; H, 13.03: N, 4.65%.

A dried tetramethylammonium perchlorate (Me_4NClO_4), tetraethylammonium perchlorate (Et_4NClO_4) and tetra-*n*-butylammonium perchlorate ($n\text{-}Bu_4NClO_4$) were prepared by the same procedure as has been described previously.[2] The water content of the polarographic solution containing supporting electrolyte and the depolarizer was determined by Karl Fisher titration to be *ca.* 20 mM.

2) S. Ikeda and E. Itabashi, This Bulletin, **41**, 1844 (1968).

3) N. A. Matwiyoff and S. V. Hooker, *Inorg. Chem.*, **6**, 1127 (1967).

Procedures. The polarograms and current-time (*i-t*) curves of an individual drop at the constant potential were recorded with the circuit which has previously been described.[2]

The alternating current (*a. c.*) polarograms were recorded with a Yanagimoto PA-102 polarograph.

The dropping mercury electrode had an *m* value of 1.33_4 mg/sec and a drop time of 4.98 sec in a deaerated 0.1M sodium perchlorate acetonitrile solution at −0.80 V *vs.* SCE and at a mercury height of 60 cm.

The potential of the DME was measured against a saturated calomel electrode (SCE).

The cell equipment was the same as has been reported on previously.[2] The dissolved oxygen in the solution was removed by bubbling pure nitrogen gas through the solution. Measurements were made at 25±0.1°C. In the following section, "current" (denoted *i* in the figures) means the maximum current observed just before the mercury drops.

Results

Cobalt(II) acetate $Co(OAc)_2 \cdot 4H_2O$ does not dissolve in an acetonitrile solvent alone, but it dissolves easily in the same solvent containing small amounts of glacial acetic acid.*1 Typical polarograms for an acetonitrile solution of cobalt(II) acetate containing 0.4% glacial acetic acid and various supporting electrolytes are given in Fig. 1.

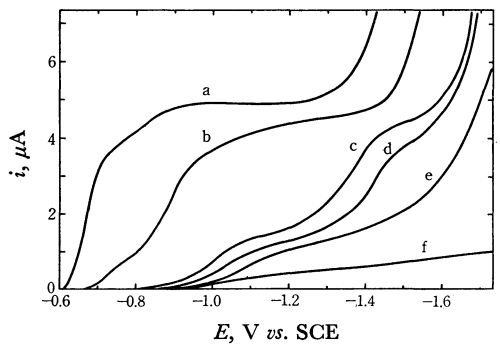

Fig. 1. Effect of supporting electrolyte on the polarograms of Co (II).

(e) 0.05M *n*-Bu_4NClO_4; (f) no electrolyte

The polarographic data on cobalt(II) acetate in various supporting electrolyte solutions are summarized in Table 1. An acetonitrile solution of cobalt(II) perchlorate in the same solvent containing 0.4% glacial acetic acid gives a reversible reduction wave, as is shown in Table 2. The polarographic behavior of cobalt(II) perchlorate in acetonitrile has been studied by several investigators. Their results are also listed in Table 2.

*1 When cobalt(II) acetate was dissolved in acetonitrile containing small amounts of glacial acetic acid, cobalt(II) was present in the solution almost as $Co(OAc)_2(HOAc)_n(H_2O)_{4-n}$. The potentiometric titration of an acetonitrile solution of cobalt(II) acetate with anhydrous perchloric acid indicated that two moles of acetato ions are coordinated to cobalt(II), as in the previously-reported case of $Ni(OAc)_2 \cdot 4H_2O$.[2]

Alkali Metal Perchlorate Systems. In a 0.05M lithium perchlorate electrolyte solution, cobalt(II) acetate is reduced in two steps.

Cobalt(II) acetate in a 0.05M sodium perchlorate electrolyte solution gives three ill-defined steps.

A. c. polarograms of cobalt(II) acetate in the same solution show three peaks which correspond to the above-mentioned three steps of the d. c. polarograms. The limiting current of the first (at −0.82 V) and the second (at −1.16 V) steps, named from positive to negative potentials, are found to be partially kinetic-controlled, but that of the third step (at −1.30 V) is diffusion-controlled.

The total wave height of the three steps is proportional to the concentration of cobalt(II) acetate up to 2.5 mM. In both lithium and sodium perchlorate electrolyte solutions, the reduction current increases at potentials more negative than −1.35 V and −1.45 V *vs.* SCE, respectively, as is shown in Fig. 1.

The rising potential of the hydrogen ion reduction wave obtained in a 0.05M lithium perchlorate containing 0.4% glacial acetic acid is observed at −1.76 V *vs.* SCE. The reduction potential of hydrogen ion becomes less negative with an increase in the concentration of cobalt(II) acetate. As a result, the increase in the reduction current obtained at potentials more negative than −1.35 V *vs.* SCE may be caused by the catalytic reduction of the hydrogen ion.

Quaternary Ammonium Perchlorate Systems. Cobalt(II) acetate in tetramethyl- and tetraethyl-ammonium perchlorate electrolyte solutions gives a double step in a d.c. polarogram, but an a.c. polarogram shows a single peak, one which corresponds to the first step of a double wave.

The exponent of the *i-t* curve for the first step has a value of 0.45. On the other hand, that for the second step obtained at relatively low concentrations of cobalt(II) acetate has values of 0.67 and 0.71 in 0.05M tetramethyl- and tetraethyl-ammonium perchlorate electrolyte solutions, respectively, as is shown in Table 1. The exponent value of the *i-t* curve of the second step is close to that of 0.67 to be expected for a pure kinetic-controlled electrode mechanism.[6]

The *i-t* curve for the second step obtained at the concentrations of cobalt(II) acetate higher than 0.5 mM, shows an irregular shape (*cf.* Fig. 2).

When the concentrations of cobalt(II) acetate are greater than 1.0 mM, the second step shows a peak current. The residual current in a quaternary ammonium perchlorate electrolyte solution containing 0.4% glacial acetic acid begins to rise at about −1.7 V *vs.* SCE. These findings indicate that the second step in tetramethyl- and tetraethylammonium perchlorate electrolyte solutions does not correspond to the reduction of cobalt(II) acetate, but to the catalytic reduction of hydrogen ion.

The effect of the concentration of glacial acetic acid on the polarograms was investigated. No appreciable change in the reduction wave was observed up to 4% in volume. In the experiments described in the following section, the concentration of glacial acetic acid was maintained at 0.4% in volume unless otherwise stated.

Effect of Mixed Electrolytes. The step-by-step addition of lithium perchlorate to quaternary ammonium perchlorate electrolyte solutions containing cobalt(II) acetate causes the reduction potential to become less negative, a single wave to split into a double wave and the wave height of both waves to increase. Figure 3 shows polarograms of an acetonitrile solutions of cobalt(II) acetate containing various concentrations of lithium perchlorate and tetramethylammonium perchlorate at the ionic strength of 0.05.

Table 3 shows the exponent of *i-t* curve of the limiting current plateau for the double wave observed in the presence of various concentrations of lithium perchlorate. The exponent of the *i-t*

curve decreases with an increase in the concentration of lithium perchlorate up to about 10 mM.

There is no appreciable change in the wave height and in the exponent of the *i-t* curve upon the further addition of lithium perchlorate.

Effect of the Concentration of the Supporting Electrolyte. The d.c. and a.c. polarograms for an acetonitrile solution of cobalt(II) acetate in the presence of various concentrations of sodium perchlorate are shown in Figs. 4-a and -b, respectively.

Ill-defined reduction waves change to well-defined waves with increase in the concentration of sodium perchlorate. The a.c. polarogram obtained in 0.05M sodium perchlorate exhibits three peaks. The increase in the concentration of sodium perchlorate causes the height of the first peak to increase and that of the third one to decrease. The height of the peak is almost independent on the concentration of sodium perchlorate up to 0.5M, but the peak disappears upon further increases in the concentrations of the electrolyte. In the 1M sodium perchlorate electrolyte solution, a single peak is observed at the potential of −0.80 V *vs.* SCE.

When lithium perchlorate was employed as the supporting electrolyte, an a. c. polarogram with two peaks was observed at concentrations of lithium perchlorate lower than 0.2M.

With an increase in the concentration of lithium perchlorate, the height of the first peak increases and that of the second decreases.

A single peak corresponding to the first peak is observed when the concentration of lithium perchlorate is greater than 0.5M.

The d. c. and a. c. polarograms obtained in quaternary ammonium perchlorate electrolyte solutions, on the other hand, are not greatly influenced by the concentration of electrolytes. An increase in the concentration of the electrolyte causes the reduction potentials to become more negative and reduces the wave height, however.

Effect of Acetate Ions. Figure 5 shows polarograms of cobalt(II) perchlorate in a 0.05M tetra-*n*-butylammonium perchlorate solution containing 0.4% glacial acetic acid and various concentrations of tetra-*n*-butylammonium acetate.

An acetonitrile solution of cobalt(II) perchlorate, in the absence of tetra-*n*-butylammonium acetate, gives a reversible reduction wave with the half-wave potential of −0.62 V *vs.* SCE in 0.05M tetra-*n*-butylammonium perchlorate. The addition of tetra-*n*-butylammonium acetate causes the single wave to split into a double wave and the wave

height of both steps to decrease.

When the concentration of tetra-*n*-butylammonium acetate is greater than 1 mM, the first step ceases to exist and an irreversible wave corresponding to the second step is observed. The irreversible wave also vanishes at concentrations of tetra-*n*-butylammonium acetate higher than about 2 mM.

In the presence of glacial acetic acid, the polarographic behavior of cobalt(II) at potentials more negative than −1.7 V *vs.* SCE is not clear because of the discharge of hydrogen ions produced by the dissociation of acetic acid.

The effect of acetate ion on the polarograms of cobalt(II) perchlorate in the absence of glacial acetic acid was also investigated. The results are reproduced in Fig. 6.

When the $[OAc^-]/[Co(II)]$ ratio is less than 2,

0.80[b]	0.19	0.32	
1.00[b]	—	0.40	
1.20[b]	—	0.44	
1.40[b]	—	0.56	

three waves are observed. The first two waves are similar to those observed in the presence of glacial acetic acid. The reduction potential of the third step observed at potentials more negative than −2.2 V *vs.* SCE becomes more negative values and the wave height increases with an increase in the concentration of tetra-*n*-butylammonium acetate. When the $[OAc^-]/[Co(II)]$ ratio is greater than 2, but less than 3, cobalt(II) is precipitated.

When the $[OAc^-]/[Co(II)]$ ratio is greater than 3, an ill-defined reduction wave is observed. The nature of the limiting current for the three steps is shown in Table 4.

The limiting current of the first step is diffusion-controlled. The exponent of the i-t curve for the second and third steps, on the other hand, increases with an increase in the concentration of tetra-*n*-butylammonium acetate. This indicates that the process has an appreciable contribution from a kinetic controlled electrode mechanism.[7]

Plots of the wave height against the $[OAc^-]/[Co(II)]$ ratio and the concentration of tetra-*n*-butylammonium acetate are given in Fig. 7.

The wave height of the first step decreases linearly with the increase of the concentrations of tetra-*n*-butylammonium acetate, becoming zero at the point where the $[OAc^-]/[Co(II)]$ ratio is equal to 2. The total wave height of the first two steps

(a), 1st wave; (b), (a)+2nd wave; (c), (b)+3rd wave.

(curve b in Fig. 7) also decreases almost linearly with the concentration of tetra-n-butylammonium acetate to about 1 mM, but it deviates from the line at higher concentrations of tetra-n-butylammonium acetate containing 0.4% glacial acetic acid. In the absence of glacial acetic acid, the limiting current of the second step becomes zero at concentrations of tetra-n-butylammonium acetate higher than 1.5 mM. If curve b in Fig. 7 extrapolated to the point where the current is zero, the extrapolated point corresponds to [OAc⁻]/[Co(II)]= 3.0. The wave height at the potential where the third step is observed in the absence of glacial acetic acid (curve c in Fig. 7), on the other hand, is nearly proportional to the concentrations of tetra-n-butylammonium acetate to about 2 mM.

Discussion

The polarographic reduction of cobalt(II) perchlorate in acetonitrile containing acetate ions is dependent on the concentration of acetate ions. When the [OAc⁻]/[Co(II)] ratio is less than 2, the plots of the limiting current in relation to the acetate ion concentration indicate that the first step (wave I) involves the reduction of uncomplexed cobalt(II), while the second step (wave II) involves that of $Co(OAc)^+$. When the $Co(H_2O)_6(ClO_4)_2$ compound is dissolved in acetonitrile in the absence of acetate ions, cobalt(II) is present in the solution almost as $Co(CH_3CN)_6^{2+}$ ions.[8]

An acetonitrile solution of cobalt(II) perchlorate reacts with acetate ions to form $Co(OAc)_2$, which then dissociates into $Co(OAc)^+$ and $Co(OAc)_3^-$. $Co(OAc)_2$ is an electroinactive species; an acetonitrile solution of cobalt(II) acetate, in the absence of any supporting electrolyte, gives no apparent reduction wave, as Fig. 1 shows.

$$Co^{2+} + 2OAc^- \rightleftarrows Co(OAc)_2 \quad (1)$$

$$2Co(OAc)_2 \rightleftarrows Co(OAc)^+ + Co(OAc)_3^- \quad (2)$$

$$\text{Wave I: } Co^{2+} + 2e + Hg \rightleftarrows Co(Hg) \quad (3)$$

$$\text{Wave II: } Co(OAc)^+ + 2e + Hg \longrightarrow Co(Hg) + OAc^- \quad (4)$$

where the coordinated acetonitrile molecules were omitted for the sake of simplicity.

The third step (wave III) observed in the absence of glacial acetic acid can be attributed to the reduction of $Co(OAc)_3^-$ produced by reaction (2):

$$\text{Wave III: } Co(OAc)_3^- + 2e + Hg \longrightarrow Co(Hg) + 3OAc^- \quad (5)$$

When the [OAc⁻]/[Co(II)] ratio is greater than 2, but less than 3, an acetonitrile solution of cobalt(II) in the presence of 0.4% glacial acetic acid gives a single irreversible wave corresponding to the wave II.

The over-all reaction can be represented by the equilibrium reaction (6) and the electrode reaction (4):

$$Co(OAc)^+ + 2OAc^- \rightleftarrows Co(OAc)_3^- \quad (6)$$

The reduction wave of $Co(OAc)_3^-$ is not observed because of the discharge of hydrogen ions. The kinetic nature of the limiting current may be due to the equilibrium reaction (6).

When the [OAc⁻]/[Co(II)] ratio is greater than 3, an ill-defined reduction wave corresponding to the wave III is observed in the absence of glacial acetic acid. The limiting current of wave III receives an appreciable contribution from the kinetic-controlled electrode mechanism, judging from the results of the measurement of the i-t curve, shown in Table 4.

Although this kinetic mechanism is uncertain, wave III, under the proposed conditions, involves the reduction of $Co(OAc)_3^-$ but not of $Co(OAc)_4^{2-}$; wave III is also observed when the [OAc⁻]/[Co(II)] ratio is less than 2. The partial electrochemical reactions may be written as in the reactions (7) and (5):

$$Co(OAc)_3^- + OAc^- \rightleftarrows Co(OAc)_4^{2-} \quad (7)$$

The $Co(OAc)_4^{2-}$ species may be unstable in the solution, if present at all.

Acetate ion yields a double anodic dissolution wave of mercury, as is shown in Fig. 8. The total limiting current is diffusion-controlled and is proportional to the concentration of acetate ions. In the presence of cobalt(II) perchlorate, the dissolution wave is not observed until the [OAc⁻]/[Co(II)] ratio exceeds 3, as is shown in Fig. 9. The curves a and b in Fig. 9 show the plots of the wave height

8) B. J. Hathaway, D. G. Holah and A. E. Underhill, *J. Chem. Soc.*, **1962**, 2444.

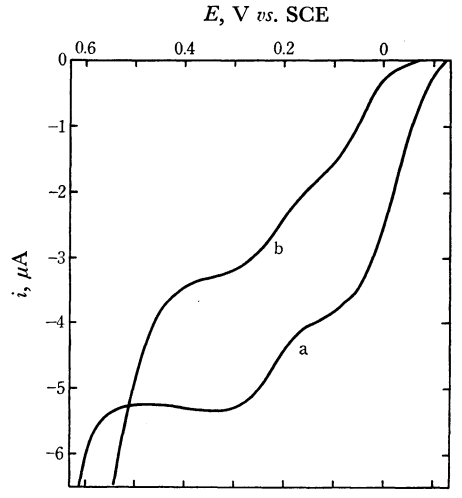

Fig. 8. Anodic dissolution waves of mercury for acetate ion in 0.05M n-Bu_4NClO_4 solution in the absence (a) and the presence (b) of 0.5 mM $Co(H_2O)_6(ClO_4)_2$.
[n-Bu_4NOAc]: (a), 1.0 mM; (b), 2.0 mM

against acetate ion concentrations in the absence and in the presence of cobalt(II), respectively. These results indicate that $Co(OAc)_4^{2-}$ is unstable and dissociates easily into $Co(OAc)_3^-$.

From the above arguments, the change in the reduction wave for an acetonitrile solution of cobalt(II) acetate in the presence of small amounts of glacial acetic acid can be said to be due to the variety of electroactive species of cobalt(II) in the solution.

The reduction wave for an acetonitrile solution of cobalt(II) acetate in the presence of quaternary ammonium perchlorate corresponds to the reduction of the $Co(OAc)^+$ which is produced by the dissociation reaction (2).

An acetonitrile solution of cobalt(II) acetate in the absence of any supporting electrolyte does not show any apparent reduction wave. This indicates that cobalt(II) acetate, in the absence of any supporting electrolyte, is only slightly dissociated in acetonitrile and that the dissociation reaction is accelerated by the presence of a supporting electrolyte; also, neutral cobalt(II) acetate $Co(OAc)_2$ is electroinactive at the DME.

The reduction waves of cobalt(II) acetate in alkali metal perchlorate supporting electrolyte solutions are dependent on the concentration of the electrolyte.

When the concentration of lithium perchlorate is less than 0.2M, a double wave corresponding to the reduction of $Co(CH_3CN)_n^{2+}$ and $Co(OAc)^+$ is observed, while a single wave corresponding to the reduction of $Co(CH_3CN)_n^{2+}$ is observed at concentrations of lithium perchlorate higher than 0.5M. The a.c. polarogram also suggests that two electroactive species are present in the solution containing 0.05M lithium perchlorate. The solution equilibria in a lithium perchlorate electrolyte solution can probably be represented by the following sequence:

$$2Co(OAc)_2 \rightleftarrows Co(OAc)^+ + Co(OAc)_3^- \quad (2)$$

$$Co(OAc)_3^- + 2Li^+ \rightleftarrows Co(OAc)^+ + 2LiOAc \quad (8)$$

$$Co(OAc)^+ + Li^+ \rightleftarrows Co^{2+} + LiOAc \quad (9)$$

The wave height of a double wave observed at relatively low concentrations of lithium perchlorate or that of a single wave at concentrations of electrolyte higher than 0.5M is proportional to the concentration of cobalt(II) acetate.

These findings indicate that $Co(OAc)_2$ and $Co(OAc)_3^-$ are only slightly present in lithium perchlorate electrolyte solutions. As a result, the predominant reaction participating in the electrode process of cobalt(II) acetate in lithium perchlorate electrolyte solutions may be presented by the reaction (9).

Three ill-defined steps are observed in a 0.05M sodium perchlorate electrolyte solution. The a.c. polarograms obtained in the same solution also show three peaks. These results show that three electroactive species of cobalt(II) are present in the solution. The solution equilibria of cobalt(II) acetate in a 0.05M sodium perchlorate electrolyte solution may be described by the following sequence:

$$2Co(OAc)_2 \rightleftarrows Co(OAc)^+ + Co(OAc)_3^- \quad (2)$$

$$Co(OAc)_3^- + 2Na^+ \rightleftarrows Co(OAc)^+ + 2NaOAc \quad (10)$$

$$Co(OAc)^+ + Na^+ \rightleftarrows Co^{2+} + NaOAc \quad (11)$$

Three steps are responsible for the reductions of $Co(CH_3CN)_n^{2+}$, $Co(OAc)^+$, and $Co(OAc)_3^-$, and the reduction potential becomes more negative with an increase in the number of coordinated acetate ions.

When the concentration of sodium perchlorate exceeds about 0.5M, the predominant species is $Co(CH_3CN)_n^{2+}$. When the concentration of sodium perchlorate is less than 0.2M, $Co(OAc)^+$ and $Co(OAc)_3^-$ are the predominant species.

The reduction potential of cobalt(II) acetate becomes less negative upon the addition of alkali metal perchlorate to the quaternary ammonium perchlorate supporting electrolyte solutions, and the wave height also increases, as is shown in Fig. 3. This effect may be attributed to the increases in the concentrations of $Co(CH_3CN)_n^{2+}$ and $Co(OAc)^+$, presented by reactions (8) and (9).

The authors wish to thank the Ministry of Education for the financial support granted for this research.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 1908—1915 (1969)

New Methods of Preparing the Mixed Cyano Cobalt(III) Complexes*1

Nobufumi MAKI and Shukichi SAKURABA

Department of Chemistry, Faculty of Engineering, Shizuoka University, Johoku, Hamamatsu

(Received November 1, 1968)

The following new cyano cobalt(III) complexes have been prepared by treating the corresponding chloro complexes with silver cyanide: *cis*-$[Co(CN)_2dip_2]NO_3 \cdot 7H_2O$, *cis*-$[Co(CN)_2dip_2]_2SO_4 \cdot 12H_2O$, *cis*-$[Co(CN)_2en(NH_3)_2]NO_3$, $[Co(CN)_3en(NH_3)] \cdot H_2O$, and *trans*-$[Co(CN)dg_2(NH_3)] \cdot \frac{1}{2}H_2O$. This method has also been used in the preparation of the following compounds: *cis*-$[Co(CN)(NO_2)en_2]NO_3 \cdot H_2O$,*2 *cis*-$[Co(CN)(SO_3)en_2]$, *trans*-$[Co(CN)(SO_3)en_2]$, *cis*-$[Co(CN)(OH_2)en_2]SO_4 \cdot 2H_2O$,*2 *cis*-$[Co(CN)_2en_2]NO_3$,*2 *cis*-$[Co(CN)_2pn_2]NO_3$,*2 *cis*-$[Co(CN)_2phen_2]NO_3 \cdot 6H_2O$,*2 and *cis*-$[Co(CN)_2phen_2]Cl \cdot 4H_2O$. Another new method has been attempted in dimethyl sulfoxide or an acetonitrile-water solution by the step-by-step substitution of a chloro ligand with a CN^- ion *via* the monocyanomonochloro complex of the $[Co(CN)Cl\ N_4]$-type; we thus succeeded in obtaining these dicyano-ammine complexes, *trans*-$[Co(CN)_2(NH_3)_4]NO_3 \cdot H_2O$, *trans*-$[Co(CN)_2en(NH_3)_2]Cl \cdot H_2O$, and *cis*-$[Co(CN)_2(NH_3)_4]NO_3 \cdot H_2O$. The methods of preparing the following new complexes are also described: *trans*-$Na[Co(CN)_2dg_2] \cdot 2H_2O$, *trans*-$K[Co(CN)_2dg_2] \cdot \frac{3}{2}H_2O$, *trans*-$(NH_4)_2[Co(CN)dg_2(SO_3)] \cdot 4H_2O$, and *trans*-$H[Co(CN)dg_2Cl] \cdot 4H_2O$. The absorption spectra in the visible, ultraviolet, and infrared regions have been measured.

The direct substitution of diacido-cobalt(III) complexes, $[CoX_2N_4]$, with CN^- ions has heretofore been considered to be difficult. For example, the $[Co(CN)_2en_2]^+$ ion could be obtained only *via* the $[Co(S_2O_3)_2en_2]^-$ ion.[1] When the dichloro complex is treated with potassium cyanide, a disproportionation occurs to produce such precipitates as $[Co\ en_3][Co(CN)_5OH]$. One of the reasons for this is certainly the hydrolysis of potassium cyanide in solution, and another, the difference in bonding character between Co–Cl and Co=C=N$^-$. The method of Rây and Sarma[1] is based on the similarity in coordinate bond character between Co–S_2O_3 and Co=C=N$^-$ in the sphere of the bis(ethylenediamine)cobalt(III) complex. Their method, however, is invalid for the preparation of dicyano-bis(2,2′-dipyridyl) and dicyanobis(1,10-phenanthroline)cobalt(III) complexes.

Recently, Yoneda *et al.*[2] have succeeded in obtaining the *trans*-$[Co(CN)_2en_2]Cl$ complex in dimethyl sulfoxide. In such a non-aqueous solution, the substitution occurs only gently and is not accompanied by the disruption of the complex, since the dissociation and hydrolysis of potassium cyanide are depressed to some extent.

Regarding the cobalt(III) complexes of the cyano-ammine series, Konya *et al.*[3] have reported the preparation of *cis*- and *trans*-$[Co(CN)_2(NH_3)_4]Cl$. Independently of their work, other methods of preparing the nitrates of these isomers have been attempted and will be described in the present

*1 Presented at the 18th Symposium on Coordination Chemistry, Kyoto, October 18, 1968.

*2 The complex cation is known, but has not yet been reported as a compound.

report. On the other hand, Shibata *et al.*[4] reported the syntheses of $[Co(CN)(NH_3)_5]Cl_2$ and $[Co(CN)_3(NH_3)_3]$, while Siebert[5] independently described the preparation of the former, $[Co(CN)(NH_3)_5]X_2$ (X=Cl, Br, NO_3, ClO_4 or $\frac{1}{2}SO_4$). By the successive substitution method of the tricarbonatocobaltate(III) complex developed by Shibata *et al.*[4] an odd number of CN^- ligands is introduced into the coordination sphere of the ammine cobalt(III) complex in the presence of active charcoal. Recently, Kuroda[6] reported a similar method of preparing the dicyano complex, *cis*-$[Co(CN)_2en_2]ClO_4$, *via* the carbonato complex, $[Co(CO_3)en_2]ClO_4$. Several years ago, Cambi and Daglia[7] reported the isolation of $K_2[Co(CN)_5(NH_3)]$. The complexes of *cis*- and *trans*-$M[Co(CN)_4(NH_3)_2]$, however, are now still missing members in this series.

Several other papers dealing with the mixed cyano cobalt complexes are listed as Ref. 8—10.

In the present work, the direct substitution of chloro ligands has been found to be possible in water provided that the cyanide ions are present in a very dilute concentration. For this purpose, we have adopted the silver cyanide, the solubility of which in water is $2.2\cdot10^{-5}$ g/100 g water at 20°C, and have succeeded in obtaining directly the mixed ligand complexes of cyano-cobalt(III), as listed in the synopsis.

On the other hand, the syntheses of ammine complexes with a *trans*-configuration have been carried out in dimethyl sulfoxide with potassium cyanide. The following complexes were obtained: *trans*-$[Co(CN)_2(NH_3)_4]NO_3\cdot H_2O$ and *trans*-$[Co(CN)_2en(NH_3)_2]Cl\cdot H_2O$.

The present paper will deal with the preparation methods and the absorption spectra of these cyano cobalt(III) complexes.

Experimental

Preparation of *cis*-$[Co(CN)_2en_2]NO_3$ (anhydrous). Twenty grams of *trans*-$[CoCl_2en_2]NO_3$ were suspended in 700 m*l* of distilled water, mixed with 20 g of AgCN, and heated on a water bath (90°C) for three hours. The color of the solution changed from green to yellow. The solution was then filtered, concentrated by evaporation, and allowed to stand. On cooling, yellow crystals separated from the solution; they were recrystallized once from hot water. Found: Co, 19.98; C, 24.49; N, 33.49; H, 5.63%. Calcd for $[Co(CN)_2en_2]NO_3$: Co, 20.10; C, 24.58; N, 33.44; H, 5.50%.

The dicyanobis(propylenediamine)cobalt(III) nitrate was analogously prepared by treating *trans*-$[CoCl_2pn_2]NO_3$ (20 g) with AgCN (20 g) in 500 m*l* of water below 60°C for half an hour. The orange-yellow filtrate was concentrated *in vacuo* below 50°C with a rotatory evaporator. Finally the complex was precipitated from the concentrated solution with the addition of ethanol. Found: Co, 18.22; C, 30.04; N, 30.21; H, 6.26%. Calcd for $[Co(CN)_2pn_2]NO_3$: Co, 18.35; C, 29.91; N, 30.52; H, 6.28%.

The perchlorate, *cis*-$[Co(CN)_2en_2]ClO_4$, was analogously prepared: 20 g of *trans*-$[CoCl_2en_2]ClO_4$ were treated with 20 g of AgCN in 600 m*l* of water at 90°C for three hours. The complex has no crystallization water. Found: Co, 17.90; C, 21.78; N, 25.34; H, 4.90%. Calcd for $[Co(CN)_2en_2]ClO_4$: Co, 17.83; C, 21.80; N, 25.42; H, 4.88%.

Preparation of *cis*-$[Co(CN)_2(NH_3)_4]NO_3\cdot H_2O$. Forty grams of *trans*-$[Co(CN)Cl(NH_3)_4]NO_3$[11] were mixed with 29 g of AgCN in 400 m*l* of acetonitrile containing 5% of water at room temperature and then heated on a water bath (50—60°C) for three hours. The temperature of the solution was kept below 60°C during the reaction. No smell of ammonia was recognized. The suspension was then filtered, and the residue was repeatedly washed with water. The orange-yellow water solution was concentrated *in vacuo* below 50°C with a rotatory evaporator. Orange-yellow crystals separated from the solution when it was allowed to stand overnight. The crude complex was recrystallized from hot water containing a trace of acetic acid. Found: Co, 22.65; C, 9.11; N, 37.69; H, 5.70%. Calcd for $[Co(CN)_2(NH_3)_4]NO_3\cdot H_2O$: Co, 22.74; C, 9.27; N, 37.84; H, 5.45%.

Preparation of $[$*cis*-$Co(CN)_2en(NH_3)_2]NO_3$. This complex was quite analogously prepared. That is, 60 g of *trans*-$[CoCl_2en(NH_3)_2]NO_3$[12] were treated with 80 g of AgCN in 500 m*l* of acetonitrile containing 5% of water at 80°C for three hours. Found: Co, 21.97; C, 18.04; N, 36.88; H, 5.31%. Calcd for $[Co(CN)_2en(NH_3)_2]NO_3$: Co, 22.06; C, 17.99; N, 36.70; H, 5.28%.

Preparation of *cis*-$[Co(CN)_3en(NH_3)]\cdot H_2O$. Sixty grams of *trans*-$[CoCl_2en(NH_3)_2]Cl\cdot H_2O$[12] were treated with 100 g of AgCN in 500 m*l* of acetonitrile containing 10% of water at 90°C for ten hours. Large yellow crystals were obtained. Found: Co, 25.41; C, 25.92; N, 36.15; H, 5.66%. Calcd for $[Co(CN)_3en(NH_3)]\cdot H_2O$: Co, 25.39; C, 25.87; N, 36.21; H, 5.65%.

Preparation of *cis*-$[Co(CN)_2dip_2]NO_3\cdot 7H_2O$.[13] Fifteen grams of *trans*-$[CoCl_2dip_2]NO_3$[14],*3 were treated with 10 g of AgCN in 500 m*l* of water on a water bath

*3 dip=2,2′-dipyridyl; $C_{10}H_8N_2$.

(80°C) for three hours. Lustrous, needle-shaped yellow crystals were obtained from the filtrate. The crude complex was recrystallized from hot water. Found: Co, 9.51; C, 43.15; N, 15.97; H, 5.03%. Calcd for $[Co(CN)_2dip_2]NO_3 \cdot 7H_2O$: Co, 9.64; C, 43.22; N, 16.04; H, 4.95%.

The solubility of the complex in water was 1.0904 g/100 g water (25°C). The corresponding sulfate was obtained by using *trans*-$[CoCl_2dip_2]_2SO_4$ (anhydrous) instead of *trans*-$[CoCl_2dip_2]NO_3$ as the starting complex. Found: Co, 10.12; C, 45.54; N, 14.45; H, 5.01%. Calcd for $[Co(CN)_2dip_2]_2SO_4 \cdot 12H_2O$: Co, 10.17; C, 45.60; N, 14.50; H, 4.88%.

Preparation of *cis*-$[Co(CN)_2phen_2]NO_3 \cdot 6H_2O$.[13],*4 Twenty grams of *trans*-$[CoCl_2phen_2]NO_3$[15] were treated with 15 g of AgCN in 500 m*l* of water at 70—80°C for three hours. The suspension was then filtered and concentrated by evaporation. When the solution was allowed to stand, silky yellow crystals deposited on the wall of the beaker. Found: Co, 9.11; C, 48.39; N, 15.17; H, 4.67%. Calcd for $[Co(CN)_2phen_2]NO_3 \cdot 6H_2O$: Co, 9.19; C, 48.68; N, 15.29; H, 4.40%.

The solubility of the complex in water was 0.6736 g/100 g water; in absolute methanol, 0.1952 g/100 g methanol; and in absolute ethanol, 0.0111 g/100 g ethanol at 25°C.

The chloride of the complex was obtained by treating the nitrate with a solution of potassium chloride, for the chloride of the complex is less soluble in water than the nitrate. Found: Co, 10.08; C, 54.07; N, 14.66; H, 4.52%. Calcd for $[Co(CN)_2phen_2]Cl \cdot 4H_2O$: Co, 10.18; C, 53.95; N, 14.52; H, 4.18%.

Preparation of *cis*-$[Co(CN)(NO_2)en_2]NO_3 \cdot H_2O$. The orange-red crystals of *cis*-$[CoCl(NO_2)en_2]NO_3$[16] (60 g) were treated with 30 g of AgCN in 500 m*l* of water at 80—90°C for an hour. The color of the solution changed from red to yellow. The solution was then filtered, concentrated by evaporation, and allowed to stand. Bright yellow crystals deposited. The yield was 84% of theory. Found: Co, 17.69; C, 18.03; N, 29.65; H, 5.67%. Calcd for $[Co(CN)(NO_2)en_2]NO_3 \cdot H_2O$:[17] Co, 17.80; C, 18.13; N, 29.61; H, 5.48%.

Preparation of *trans*-$[Co(CN)(SO_3)en_2]$. Twenty grams of *trans*-$[CoCl(SO_3)en_2] \cdot H_2O$[18] were treated with 10 g of AgCN in 500 m*l* of water at 90°C for three hours. Brownish-yellow crystals were thus obtained. Found: Co, 20.53; C, 20.89; N, 24.77; H, 5.78%. Calcd for $[Co(CN)(SO_3)en_2]$: Co, 20.66; C, 21.06; N, 24.56; H, 5.66%.

Preparation of *cis*-$[Co(CN)(SO_3)en_2]$ (anhydrous). The complex was prepared by the following two methods: (1) To a solution in which *trans*-$[Co(CN)(SO_3)(NH_3)_4] \cdot 2H_2O$[6] (30 g) had been completely dissolved there were added 135 m*l* of 10% ethylenediamine under continuous stirring; the solution was then heated and evaporated on a water bath for three hours. The reaction took place, evolving ammonia. The yield was 54% of theory. Found: Co, 20.37; C, 21.22; N, 24.56; H, 5.71%. Calcd for $[Co(CN)(SO_3)en_2]$: Co, 20.66; C, 21.06; N, 24.56; H, 5.66%.

(2) Analogously, 20 g of *cis*-$[CoCl(SO_3)en_2] \cdot 3H_2O$ were treated with 10 g of AgCN in 500 m*l* of water at 90°C for three hours. The *cis*-$[Co(CN)(SO_3)en_2]$ complex (anhydrous) was obtained from the filtrate. Found: Co, 20.68; C, 20.97; N, 24.83; H, 5.91%. Calcd for $[Co(CN)(SO_3)en_2]$: Co, 20.66; C, 21.06; N, 24.56; H, 5.66%.

Preparation of *trans*-$[Co(CN)dg_2(NH_3)] \cdot {}^1/_2H_2O$.[*5] The complex was prepared by the following three methods:

(1) Thirty-four grams of *trans*-$[CoCldg_2(NH_3)] \cdot H_2O$[19] were treated with 20 g of AgCN in 500 m*l* of water at 90°C for three hours. Bright brownish-yellow crystals were obtained from the filtrate. The crude product was recrystallized from hot water containing acetic acid. Found: Co, 17.33; C, 32.00; N, 24.51; H, 5.38%. Calcd for $[Co(CN)dg_2(NH_3)] \cdot \frac{1}{2}H_2O$: Co, 17.27; C, 31.68; N, 24.63; H, 5.32%.

(2) To 15.0 g of *trans*-$[Co(CN)(OH_2)(NH_3)_4]Cl_2$[6] in 150 m*l* of water there were added 14.4 g of dimethylglyoxime. The mixture was heated on a water bath for three hours. The reaction proceeded, evolving ammonia, according to the following scheme:[20]

$$[Co(CN)(OH_2)(NH_3)_4]^{2+} + 2dgH \rightarrow [Co(CN)dg_2(NH_3)] + 3NH_3.$$

Every half hour during the reaction, 5—7 g of ammonium acetate were added to the solution. A total of 20 g of ammonium acetate was used. Lustrous orange-yellow crystals separated from solution when it was allowed to stand. The product was filtered and washed with 80% ethanol to eliminate traces of unreacted dimethylglyoxime. The yield was more than 82% of theory. Found: Co, 17.21; C, 31.44; N, 24.89; H, 5.45%. Calcd for $[Co(CN)dg_2(NH_3)] \cdot \frac{1}{2}H_2O$: Co, 17.27; C, 31.68; N, 24.63; H, 5.32%.

(3) A solution of 400 m*l* containing 27 g of potassium cyanide was mixed with a solution of 100 g of $[Codg_2(NH_3)_2]Cl \cdot 5H_2O$[21] dissolved in 400 m*l* of water and heated on a water bath for an hour at 90°C. The insoluble orange-yellow crystals which were deposited from the solution were filtered and washed with cold water several times and then with ethanol. The crude complex was recrystallized from hot water containing acetic acid. Found: Co, 17.22; C, 31.43; N, 24.78; H, 5.40%. Calcd for $[Co(CN)dg_2(NH_3)] \cdot \frac{1}{2}H_2O$: Co, 17.27; C, 31.68; N, 24.63; H, 5.32%.

Preparation of *trans*-$K[Co(CN)_2dg_2] \cdot {}^3/_2H_2O$.[22] The complex was prepared by the following two methods:

(1) A solution (200 m*l*) containing 13.7 g of potassium cyanide was mixed with a solution of 50 g of

*4 phen=1,10-phenanthroline; $C_{12}H_8N_2$.

$[Codg_2(NH_3)_2]Cl\cdot 5H_2O$[21] dissolved in 300 m*l* of water under stirring and then heated on a water bath until the reaction mixture had been evaporated to one-third of its former volume. From the smell of ammonia evolved, it could be discerned that the following reaction was in progress:

$$[Codg_2(NH_3)_2]Cl\cdot 5H_2O + 2KCN \rightarrow K[Co(CN)_2dg_2]\cdot \tfrac{3}{2}H_2O + 2NH_3 + 2KCl.$$

During the course of the reaction, insoluble orange-yellow crystals deposited. These crystals were ascertained to be the *trans*-$[Co(CN)dg_2(NH_3)]\cdot \tfrac{1}{2}H_2O$[19] complex by the elementary analyses and by the study of the absorption spectra in the IR, UV, and visible regions.[23] These crystals of the cyano-ammine complex were filtered off during the reaction, and the filtrate was further concentrated by evaporation. On cooling, large needle-shaped yellow crystals were obtained. Found: Co, 14.41; C, 29.63; N, 20.55; H, 4.32; K, 9.50%. Calcd for $K[Co(CN)_2dg_2]\cdot \tfrac{3}{2}H_2O$: Co, 14.47; C, 29.49; N, 20.63; H, 4.21; K, 9.60%.

Sodium salt of the complex was obtained by using sodium cyanide instead of potassium cyanide. Found: Co, 14.63; C, 29.97; N, 20.14; H, 4.49%. Calcd for $Na[Co(CN)_2dg_2]\cdot 2H_2O$: Co, 14.73; C, 30.01; N, 20.00; H, 4.53%.

(2) Seventy-eight grams of *trans*-$[Co(CN)dg_2(NH_3)]\cdot \tfrac{1}{2}H_2O$[19] were suspended in 800 m*l* of water containing 16 g of potassium cyanide. To the suspension there were stirred 25 g of active charcoal. Then the suspension was warmed on a water bath for ten hours at 40—50°C. The substitution occurred gently and slowly, evolving ammonia, below 50°C. The charcoal was filtered off, and the filtrate was concentrated by evaporation at 60—70°C until needle-shaped yellow crystals were deposited. Found: Co, 14.39; C, 29.61; N, 20.40; H, 4.10%. Calcd for $K[Co(CN)_2dg_2]\cdot \tfrac{3}{2}H_2O$: Co, 14.47; C, 29.49; N, 20.63; H, 4.21%. The aiming dicyano complex was very soluble in water, while the starting of the monocyanoammine complex was insoluble. Therefore, the isolation was easy and complete.

Preparation of *trans*-$(NH_4)_2[Co(CN)dg_2(SO_3)]\cdot 4H_2O$. To a solution (1.2 *l*) containing 40 g of *trans*-$[Co(CN)(SO_3)(NH_3)_4]\cdot 2H_2O$[6] there were added 50 g of dimethylglyoxime (dgH). The mixture was then boiled at 100°C for three hours. The reaction took place, evolving ammonia. No deposition of metallic cobalt was observed. After cooling, the solution was filtered to eliminate the unreacted dimethylglyoxime, and then the filtrate was further concentrated by evaporation on a water bath at 80°C. When it was allowed to stand, orange-yellow crystals separated from the solution; they were filtered and washed with ethanol and ether. The crude product was recrystallized from hot water. Found: Co, 11.50; C, 21.33; N, 19.07; H, 6.32%. Calcd for $(NH_4)_2[Co(CN)dg_2(SO_3)]\cdot 4H_2O$: Co, 11.71; C, 21.47; N, 19.48; H, 6.01%.

Preparation of *trans*-$H[Co(CN)dg_2Cl]\cdot 4H_2O$. Thirty grams of *trans*-$(NH_4)_2[Co(CN)dg_2(SO_3)]\cdot 4H_2O$ were dissolved in 500 m*l* of water. To this solution there were added 300 m*l* of concentrated HCl. The temperature of the solution was maintained at 50—60°C for ten hours under continuous stirring. The reaction proceeded, evolving sulfur dioxide. The yellow precipitates were separated from the solution when the reaction was over. The mixture was filtered and washed several times with ethanol and ether. The crude complex was purified by treating it again with 200 m*l* of concentrated HCl at 60°C. Above 90°C, it could be seen that the CN-ligands were partly replaced with Cl^- ions to produce the $H[CoCl_2dg_2]$ complex. The residue was filtered and washed with concentrated HCl, ethanol and ether. Found: Co, 13.69; C, 25.69; N, 16.73; H, 5.50%. Calcd for $H[Co(CN)dg_2Cl]\cdot 4H_2O$: Co, 13.91; C, 25.51; N, 16.53; H, 5.47%.

Preparation of *cis*-$[Co(CN)(OH_2)en_2]SO_4\cdot 2H_2O$. Into 150 g of the *trans*-$[Co(CN)(SO_3)en_2]$ obtained previously there were stirred, drop by drop, 150 m*l* of concentrated H_2SO_4 in ice. The reaction occurred immediately, evolving SO_2 and yielding a viscous liquid of $[Co(CN)(SO_4)en_2]$, which tends to aquate in water. The aimed-at aquo complex was precipitated from the solution with the addition of methanol. The yield was 38%. Found: Co, 16.48; C, 17.01; N, 19.83; H, 6.40%. Calcd for $[Co(CN)(OH_2)en_2]SO_4\cdot 2H_2O$: Co, 16.59; C, 16.90; N, 19.71; H, 6.24%.

Preparation of *trans*-$[Co(CN)_2(NH_3)_4]NO_3\cdot H_2O$. Dried crystals of potassium cyanide were ground into fine powder in a porcelain mortar, and 3.00 g of them were dissolved in 500 m*l* of dimethyl sulfoxide at 60°C. Then the solution was transferred into a three-necked flask equipped with a reflux condenser and a mechanical stirrer. To this solution there were added 11.66 g of *trans*-$[Co(CN)Cl(NH_3)_4]NO_3$.[11] The suspension was heated on a water bath at 70—85°C for three hours. When the solution was then allowed to stand overnight, orange-yellow crystals were deposited from the solution; they were filtered and washed with acetone several times. The crude complex was recrystallized from hot water below 50°C. The yield was 53.4% of theory. Found: Co, 22.51; C, 9.08; N, 37.72; H, 5.60%. Calcd for $[Co(CN)_2(NH_3)_4]NO_3\cdot H_2O$: Co, 22.74; C, 9.27; N, 37.84; H, 5.45%.

Preparation of *trans*-$[Co(CN)_2en(NH_3)_2]Cl\cdot H_2O$. This complex was prepared according to the following reaction steps:

$$\textit{trans}\text{-}[Co(CN)(SO_3)(NH_3)_4]\cdot 2H_2O \xrightarrow{en} \textit{cis}\text{-}[Co(CN)(SO_3)en(NH_3)_2] \xrightarrow{HCl} \textit{cis}\text{-}[Co(CN)Clen(NH_3)_2]Cl \xrightarrow[\text{in DMSO}]{KCN} \textit{trans}\text{-}[Co(CN)_2en(NH_3)_2]Cl\cdot H_2O.$$

(1) Thirty grams of *trans*-$[Co(CN)(SO_3)(NH_3)_4]\cdot 2H_2O$[5] were dissolved in 100 m*l* of a water solution containing 8.6 g of ethylenediamine, and then the mixture was heated on a water bath (80°C) for two hours. The complex was once dissolved completely in solution, and then again deeper-colored yellow or brown crystals separated from the solution as a result of the reaction. The reaction mixture was further heated on a water bath for three or four hours, filtered while in a hot state, and washed several times with hot water, ethanol, and ether. The *cis*-$[Co(CN)(SO_3)en(NH_3)_2]$ complex (12 g) was thus obtained; it was used for the next reaction without further purification, since it was insoluble in water.

23) Previously, it was speculated that these crystals were the $[Co(dgH)_3]\cdot 2.5H_2O$ complex, but this speculation should be corrected; *cf.*, Ref. 22.

(2) Thirty grams of *cis*-$[Co(CN)(SO_3)en(NH_3)_2]$ (anhydrous) were dissolved in 300 m*l* of concentrated HCl and heated on a water bath at 80—85°C for five hours. The color of the solution changed from orange-yellow to red. At last, the solution became a half of its former volume. The solution was once filtered. To the filtrate there were added, drop by drop, 200 m*l* of absolute ethanol under ice cooling. Then, fine red crystals were separated from the solution. The *cis*-$[Co(CN)Cl\,en(NH_3)_2]Cl$ complex is pure enough to be used for the next procedure without further recrystallizations.

(3) Dried powder of potassium cyanide (2.30 g) was completely dissolved in 300 m*l* of dimethyl sulfoxide at 70—80°C in a flask which equipped with a reflux condenser and a mechanical stirrer. Then, 6.0 g of *cis*-$[Co(CN)Cl\,en(NH_3)_2]Cl$ were added in small portions to the solution and the mixture was heated at 80°C for an hour. The yellow solution soon became muddy as the reaction proceeded. The reaction mixture was allowed to stand overnight, filtered and washed with acetone several times. The crude complex was recrystallized from hot water below 60°C. Found: Co, 22.63; C, 18.50; N, 32.61; H, 6.39%. Calcd for $[Co(CN)_2en(NH_3)_2]Cl\cdot H_2O$: Co, 22.79; C, 18.58; N, 32.49; H, 6.24%.

Preparation of *trans*-$[Co(CN)_2en_2]NO_3$. This complex was prepared by the method of Muto *et al.*[2] That is, 4.68 g of *trans*-$[CoCl_2en_2]NO_3$ were treated with 3.00 g of KCN in 500 m*l* of dimethyl sulfoxide for three hours at 70°C. The crude complex was recrystallized from hot water below 60°C. Found: Co, 20.22; C, 24.39; N, 33.43; H, 5.69%. Calcd for $[Co(CN)_2en_2]NO_3$: Co, 20.10; C, 24.58; N, 33.44; H, 5.73%.

Measurements. The absorption spectra in the visible and ultraviolet regions were determined with a Beckmann DU spectrophotometer. The IR spectra were recorded on a Perkin-Elmer grating infrared spectrophotometer, model 337, with a KBr-pellet. The proton spectra were recorded on a Hitachi-Perkin-Elmer high resolution NMR spectrometer, model R-20. As a solvent for the NMR measurements we used 99.75% D_2O at 35°C.

Results and Discussion

The Method of Syntheses. The CN^- ion is located at the end position of the spectrochemical series and has the strongest coordinating ability among the cobalt(III) complexes of the Werner type. Hence, the attack on the acido-cobalt(III) complexes by the cyanide ions causes the ligands with lesser coordination ability to be expelled totally or partly from the coordination sphere and results in an overall rearrangement of the ligands; *i. e.*, a disproportionation occurs, since the ligands in general tend to surround a cobalt with bonds of the same nature or similar covalent character as far as possible.

The results of the preparations, however, suggest that the substitution of chloro ligands is possible even in a water solution by the use of silver cyanide. When the cyanide ions are present in a very dilute concentration, the substitution can take place only without any accompanying disproportionation, because the silver ion leaves the reaction system as a precipitate of AgCl and the equilibrium of silver cyanide moves in the direction of dissociation to supply Ag^+ or CN^- ions.

For the preparation of dicyano-ammine complexes, the attempts to let the dichloro-ammine complexes cited below react with AgCN have failed due to the disruption of the complex used: *cis*-$[CoCl_2(NH_3)_4]NO_3$, *trans*-$[CoCl_2(NH_3)_4]NO_3$, and *trans*-$[CoCl_2tn_2]NO_3$.*6

In addition to these complexes, the substitution of the following complexes with KCN in a dimethyl sulfoxide has been attempted, but all attempts have failed, and for the same reason: *trans*-$[CoCl_2pn_2]NO_3$,*7 *trans*-$[CoCl_2dip_2]NO_3$, *trans*-$[CoCl_2phen_2]NO_3$, and *trans*-$[CoCl_2(NH_3)_4]NO_3$.

Accordingly, for obtaining dicyano-ammine complexes the step-by-step substitution method *via* the monocyano-monochloro complex of the $[Co(CN)ClN_4]$-type has been adopted and found to be suitable for replacing a chloro ligand with a CN^- ion without disrupting the complex, as has been described previously.

In connection with this, the method using silver cyanide always gave rise to the *cis*-isomer rather than the *trans*-isomer, even if a *trans*-isomer was used as the starting complex, except in the case of the preparation of *trans*-$[Co(CN)(SO_3)en_2]$, in which the method using silver cyanide carried out in a water solution gave a *trans*-isomer. On the other hand, the method using KCN in dimethyl sulfoxide always gave a *trans*-isomer.

The dimethylglyoximato-cobaltate(III) complex, $H[CoCl_2dg_2]$, did not react with AgCN because the aquation of the complex was too rapid to allow the replacement of the Cl-ligands with CN^- ions within the sphere of coordination. The disruption of the complex used is ascribed to the formation of diaquocobalt(III) cyanide, $[Co(OH_2)_2dg_2]CN$. Thus, the substitution with CN^- ions has to take place within the sphere of coordination.

Absorption Spectra in the Visible and Ultraviolet Regions. Table 1 shows the numerical data of the absorption maxima of the cobalt(III) complexes measured.

In the table, the first two absorption bands are assigned to ligand-field bands. The third, or last, strong band can be attributed to a charge-transfer caused by the ligands, such as CN and SO_3.

Figures 1 and 2 show that the first spin-allowed band of dicyano cobalt(III) complexes of the

s=strong; m=medium; w=weak

Figure 3 shows the spectra of *cis*-dicyano-bis(2,2′-dipyridyl) and -bis(1,10-phenanthroline)cobalt(III) complexes, and of their ligands, respectively. The absorption spectrum of the latter complex agreed above all with that reported by Favini and Paglia[10] as a whole, but it did not necessarily coincide in detail, especially with regard to the presence of a small peak at around 27—29 kK.

Figure 4 shows the absorption spectra of the monocyano-cobalt(III) complexes prepared by the method using silver cyanide in water. The spectra quite agreed with those obtained by Ohkawa *et al.*[8] and by Chan and Tobe.[9]

Infrared Absorption Spectra. Table 2 lists the frequencies of the C≡N stretching vibrations measured for the mixed cyano cobalt(III) complexes.

Generally, a complex with a *trans*-configuration exhibits only one C≡N stretching band, while some of the complexes with a *cis*-configuration show two or more of their C≡N stretching bands split by the lowering of the symmetry, although there are some exceptions.

The differentiation between *cis*- and *trans*-isomers for bis(ethylenediamine)cobalt(III) complexes has been made in the infrared spectra of the CH_2-rocking vibrations in the region of 870—900 cm^{-1}. According to Baldwin,[24] the complexes with a *cis*-configuration show two bands, while those with a *trans*-structure exhibit one. Table 3 shows the frequencies of the CH_2-rocking vibrations in the regions measured.

Hughes and McWhinnie[25] suggested there is a correlation between the structure of the steric isomers and the complexity of that part of the

Table 3. Frequencies (cm^{-1}) of absorption bands in the regions of 870—900 cm^{-1} of the complexes of $[Coen_2XY]$-type

Compound	Frequency (cm^{-1})

The Chemistry of Protactinium. VII. The Stability of Protactinium(V) in Perchloric Acid and TTA-Benzene Solutions

Shin Suzuki and Yasushi Inoue

The Research Institute for Iron, Steel and Other Metals, Tohoku University, Katahira-cho, Sendai

(Received December 17, 1968)

With a view to understand the reasons for the confusion in published works as to the chemical behavior of protactinium(V) in a perchloric acid solution, the effect of the contact time and the stability of the perchloric acid solution of the pentavalent protactinium in the TTA-benzene extraction have been investigated in relation to the methods of preparing the solution. Four sample solutions, prepared by various methods, were used, and definite differences among them were observed. Two of them have been confirmed to be very stable and not to suffer a change in their distribution ratios with the time of standing, while the others are unstable-that is, their distribution ratios decrease with standing, thereby reaching a constant value which agrees with that of the former two. However, the value consistent with that obtained from backward extraction is not this constant value but the value obtained from fresh solutions of the latter type. Protactinium species in the TTA-benzene solution are also not stable, and their distribution ratios increase with standing. This increase in the distribution ratio is mainly due to the formation of unstrippable species. The mechanism of this irreversible change is assumed, from the indirect evidence of extraction experiments and absorption spectroscopy, to be the irreversible dehydration of $Pa(OH)_2T_3 \cdot HT$ to form $PaOT_3 \cdot HT$ in the organic phase. These unfavorable features of the extraction equilibrium should be taken into account in interpreting the results obtained by TTA extraction experiments.

As a result of an investigation by TTA-benzene extraction and by the ion exchange and filtration methods, of the chemical behavior of protactinium in a perchloric acid solution, it was concluded that $PaO_m(OH)_n^{5-2m-n}$ (where $2m+n=3$ and 4) was the predominant species present in a perchloric acid solution of 0.3—2.0M when the concentration of protactinium was lower than 10^{-6}M.[1] When the protactinium concentration was higher than 10^{-5}M, however, quite different behavior was observed. For example, when a perchloric acid solution which was made 10^{-7}M in protactinium by diluting a 10^{-5}M solution which had been prepared in advance was subjected to TTA extraction, the log-log plot of the distribution ratio and the TTA activity in the organic phase were different from those obtained with a solution which was directly made 10^{-7}M in protactinium concentration. In the former case, the distribution ratio decreased remarkably with the time. In the filtration experiments, the percentage of the removal of protactinium from a perchloric acid solution by membrane filters increased with a decrease in the pore sizes. However, this effect was especially noticeable when the protactinium concentration was as high as 10^{-5}M. In the same kind of experiments with Tōyō Roshi No. 5C filter paper (the finest filter for quantitative use), virtually no effect of aging was observed in the case of either carrier-free or 10^{-7}M protactinium solutions, while in the case of a 10^{-5}M solution the removal increased with the aging time, attaining a value of 45% after 80 days. The results can be understood in terms of the formation of colloidal aggregates to a great extent. These observations suggest that the method of preparation and the concentration of protactinium both affect the nature of protactinium in a perchloric acid solution. Much of the confusion in published works which has been pointed out previously[1] may be attributed to these facts. Furthermore, the contact time required to attain a constant distribution ratio in the TTA-benzene extraction system was different with different authors; that is, in a previous experiment by the present authors, only 30 min was long enough to attain a constant distribution ratio,[1] while Kolarich and his co-workers reported that a one-day contact was necessary to reach an extraction equilibrium.[2] This also constitutes one of the very important keys to solve the reasons for the discrepancies among the results obtained by various experimenters.[1]

The purpose of the present study is to investigate the effect on the TTA extraction behavior of the method of the preparation of the perchloric acid

solution of protactinium. In the course of the investigation, interesting results regarding the stability of the protactinium species in the TTA-benzene solution have been obtained.

Experimental

Reagents and Apparatus. *^{231}Pa and ^{233}Pa.* Stock solutions of these isotopes in hydrochloric-acid and hydrofluoric-acid mixtures were prepared by the methods reported previously.[3] The concentration of protactinium in the ^{231}Pa solution was determined by gravimetry by using protactinium pentoxide as a weighing form.

Benzene was purified by distillation, and doubly-distilled water was used throughout this experiment. The acidity of the solution was determined by titration with a standard sodium hydroxide solution. The other chemicals, such as the thenoyl trifluoroacetone (TTA), perchloric acid, hydrofluoric acid, and aluminum perchlorate, were of the highest purity. For the solvent extraction procedure, a Iwaki universal mechanical shaker, Model V-S was used. A Kōbe Kōgyō Model PS-400 well-type scintillation probe coupled with a Kōbe Kōgyō Model SA-400 scaler was used for the gamma-ray assay.

Procedures. All the experiments were carried out at room temperature. Ordinary separatory funnels made of glass were used for the solvent extraction. To eliminate distortions of the experimental results related to the adsorption on glass, the walls of the funnels were preliminarily saturated with protactinium by shaking the test solution for a time sufficient for adsorption equilibrium to be reached. Care was taken to ascertain the material balance in each experiment; each value given is the average of the results of at least two determinations. For all the solvent extractions except for Fomin's method,[4] 5-m*l* portions of the aqueous and organic phases were used, and after the separation of the two phases, a 2-m*l* aliquot of each phase was placed in a polyethylene test tube and its γ radioactivity counted; the distribution ratio was calculated by means of the usual relationship.

$$D = \frac{\gamma \text{ activity per ml of the organic phase}}{\gamma \text{ activity per ml of the aqueous phase}}$$

Forward Extraction. Four perchloric acid solutions of protactinium prepared by the various methods to be described below, were used. Examinations of the effect of contact time and of the stability of the solution, and analysis by Fomin's method, were carried out for each of the solutions.

No. 1: Aliquots of ^{231}Pa and ^{233}Pa stock solutions (total, 5 m*l*) and 30 m*l* of concentrated perchloric acid were transferred into a platinum dish and heated on a hot plate until the white fumes of perchloric acid appeared. Then the mixture was violently heated directly on a gas burner for five minutes. After cooling, 13 m*l* of concentrated perchloric acid were added. This solution was then diluted to 250 m*l* with distilled water. The concentrations of protactinium and of perchloric acid in this solution were 10^{-7} and 1.38 M respectively.

No. 2: Aliquots of ^{231}Pa and ^{233}Pa stock solutions (total, 5 m*l*) and a small amount of concentrated hydrofluoric acid were transferred into a platinum dish and evaporated almost to dryness, initially on a hot plate and finally on a water bath. The residue was then dissolved by heating it with 2.31 m*l* of 1.17M hydrofluoric acid. Then 95 m*l* of a 5.28M perchloric acid solution and 2.5 m*l* of a 3M aluminium perchlorate solution were added, in this order, and the mixture was diluted with distilled water to 500 m*l*. The concentrations of protactinium, perchloric acid, fluoride ions, and aluminum ions in this solution were 5×10^{-8}, 1.05, 0.005, and 0.015M respectively.

No. 3: Aliquots of ^{231}Pa and ^{233}Pa stock solutions (total, 5 m*l*), a few milliliters of concentrated hydrofluoric acid, and 2 m*l* of concentrated perchloric acid were placed in a platinum crucible, and the mixture was heated until the white fumes of perchloric acid appeared. Heating was then continued until the volume of the solution was reduced to about 1 m*l*. The residual solution was transferred to a polyethylene bottle, and 1 m*l* of concentrated perchloric acid was added to the crucible. The solution was then reduced to 0.5 m*l* by heating it on a hot plate; the residual solution was combined with the solution in the same bottle. The procedure was repeated until all the activity was removed from the crucible. The concentrations of protactinium and of perchloric acid in this solution were 8.7×10^{-6} and 8.48M respectively. Before use, this solution was diluted to 10^{-7}M with respect to protactinium with perchloric acid of a suitable concentration, to make 1.00M in acidity.

No. 4: Aliquots of ^{231}Pa and ^{233}Pa stock solutions (total, 5 m*l*) and a small amount of hydrofluoric acid were transferred into a platinum dish and evaporated almost to dryness, initially on a hot plate and finally on a water bath. The residue was dissolved out of the dish by heating it with concentrated perchloric acid until all the activity on the dish had been removed. The solution was then diluted to 250 m*l* with distilled water. The concentrations of protactinium and of perchloric acid in this solution were 10^{-7} and 0.998M respectively.

Backward Extraction. Aliquots of ^{231}Pa and ^{233}Pa stock solutions were transferred into a platinum dish and heated to dryness on a hot plate. The residue was dissolved in 0.64 m*l* of 1.17M hydrofluoric acid, and then 0.948 m*l* of a 5.28M perchloric acid solution and 1.7 m*l* of a 1.33M aluminum perchlorate solution were added, in this order. The solution was diluted to 50 m*l* with distilled water. A protactinium solution in TTA-benzene was then prepared by extracting protactinium from 25 m*l* of this solution with 75 m*l* of a 0.1M TTA-benzene solution for 25 min. The concentration of protactinium in the TTA-benzene solution thus prepared was 0.98×10^{-7}M. The backward extraction was performed by bringing into contact 5-m*l* portions of this solution and of the perchloric acid solution of definite concentration which had been pre-equilibrated with the 0.1M TTA-benzene solution.

Fomin's Method.[4] The percentage of inextractable forms (P) which were not in rapid equilibrium with extractable forms, and the distribution ratio of extractable forms, D_t, were determined by Fomin's method. The essence of this method consists of the measurement of

3) S. Suzuki and Y. Inoue, This Bulletin, **39**, 490 (1966).

4) V. V. Fomin, E. P. Mairova, M. I. Krapivin and V. G. Yudina, *Zh. Neorg. Khimiya*, **3**, 2113 (1958).

two or more distribution ratios in successive extractions:

$$D_t = \frac{D_n}{VD_{n+1}} + D_n - \frac{1}{V} \quad (1)$$

$$P = \frac{D_t - D_n}{(1+VD_n)D_t} \quad (2)$$

where D_n is the distribution ratio which is obtained in the nth extraction and where V is the ratio of the volumes of the organic and aqueous phases.

In practice 15-m*l* portions of both phases were first brought into contact. The $D_1(1/D_1)$ ratio was calculated, and then a 10-m*l* portion of the aqueous (organic) phase was placed in contact with 10-m*l* portion of the new organic (aqueous) phase to determine the $D_2(1/D_2)$ ratio. Finally, a 5-m*l* portion of the aqueous (organic) phase was shaken with a 5-m*l* portion of the new organic (aqueous) phase to determine the $D_3(1/D_3)$ ratio. From Eqs. (1) and (2), two sets of $D_t(1/D_t)$ and P values, one by using $D_1(1/D_1)$ and $D_2(1/D_2)$ and the other by using $D_2(1/D_2)$ and $D_3(1/D_3)$, were calculated. As an example, Table 1 shows one of these sets of results. The last column on the table (P_c) shows the P values, which should be in a $1/D_2-1/D_3$ couple, as calculated from the results of the $1/D_1-1/D_2$ couple. The experimental and calculated values agree within experimental error.

Results

The Results from Forward Extraction. *The Relation between the Method of Preparation and the Rate of Extraction.* The effect of the contact time on the distribution ratio is shown in Figs. 1 and 2. No significant difference in the curves with different methods of preparation is observed. In the case of No. 3, however, a contact time of only 1 min is sufficient to achieve a constant distribution ratio, while about 10 min is necessary in the cases of No. 1 and No. 4. As is clearly shown in Fig. 2, in the case of No. 2 the trend is slightly different: D reaches a maximum after a short contact time and then decreases with an increase in the contact time, finally reaching a constant. These tendencies hold irrespective of the aging time of the solution; Fig. 2 shows an example. From the above results, it can be said that 20 min of contact is sufficient to attain a constant distribution ratio in a forward extraction, regardless of the method of preparation.

The Effect of Aging Time on the Distribution Ratio. As is shown in Fig. 3, for some time after preparation Nos. 1 and 3 show constant distribution ratios which coincide with the values obtained from the backward distribution of a fresh solution of protactinium in TTA-benzene. The value from No. 1 begins to decrease 20 days after preparation and reaches a constant after 40 days of standing. The value from No. 3 begins to decrease 10 days after preparation and reaches a constant after 20 or 30

days of standing. On the other hand, the Nos. 2 and 4 samples are stable for about 2 months and no change in distribution ratios beyond the limits of the experimental error are observed. Interestingly enough, these constant distribution ratios are nearly the same as those obtained from No. 3 and No. 1 after a long period of standing (if normalized to the value which will be obtained in 1M perchloric acid).

The Results from Backward Extraction. *The Effect of the Contact Time.* The effect of the contact time on the distribution ratio from the backward extraction which was carried out by using a freshly-prepared protactinium solution in 0.1M TTA-benzene was investigated; the results are shown in Fig. 4. The stripping solution was 1M perchloric acid. It is apparent from Fig. 4 that the distribution ratio reaches a constant after 5 minutes' contact. The value of the distribution ratio coincides fairly well with that obtained by the forward extraction of a freshly-prepared No. 1 sample.

The Effect of Aging Time on the Distribution Ratio. A TTA-benzene solution of protactinium was stored in a brown bottle in the dark, and the change in the distribution ratio during standing was followed. The protactinium in a 0.1M TTA-benzene solution was stripped by a 1M perchloric acid solution. It is apparent from Fig. 5 that at first the distribution ratio decreases remarkably with standing; it shows a minimum at 30 min and then increases a little before reaching a constant. This constant value continues for about five hours. Then the distribution ratio increases continuously. After 2 weeks of standing, nearly all the protactinium becomes unstrippable. Essentially the same phenomenon is observed when carrier-free ^{233}Pa is used. When hydrochloric or sulfuric acid is used as the stripping reagent, virtually the same phenomenon is observed, as is shown in Fig. 6.

Fomin's Method. As one of the methods for understanding the rather peculiar behavior observed in the stripping, Fomin's method was applied. The relation between the standing time and the percentage of unstrippable species (P) is shown in

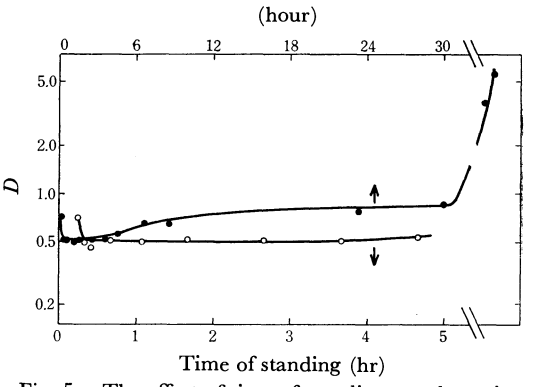

Fig. 5. The effect of time of standing on the stripping of Pa. I.

4: Aq. phase, 1M HCl; Org. phase, 10^{-7}M Pa in 0.1M TTA-benzene

Fig. 7. The P value for a fresh Pa-TTA-benzene solution is only 2—3%. It increases remarkably with standing and reaches 80 or 90% after 2 months of standing, irrespective of the protactinium concentration or the kind of stripping reagent. The $1/K_t$ value decreases slowly with the time of standing, as is shown in Fig. 8. It is clear from these results that the reason for the decrease in stripping is mainly the formation of unstrippable species, but also partly the increase in the distribution ratio (K_t) of the strippable species.

The Relation between the Distribution Ratio and the Perchloric Acid Concentration as Determined by Backward Extraction. The distribution ratio was determined as a function of the perchloric acid concentration by using a fresh solution of protactinium in 0.1M TTA-benzene. As is clearly shown in Fig. 9, the curve obtained was nearly the same as that shown in Fig. 6 of the second report of this series.[1] As has been described earlier, the values of the distribution ratio agree with those from the forward extraction which is made by using either a No. 1 or No. 3 solution.

Absorption Spectra of the Pa-TTA Complex. As another way to understand the peculiar behavior in stripping, the change in the absorption spectrum with standing was traced. The protactinium concentration was about 3×10^{-5}M. An absorption

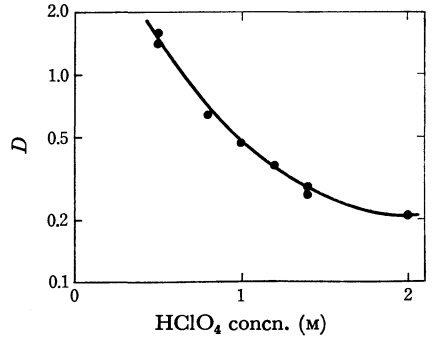

Fig. 9. Distribution ratios determined by stripping as a function of $HClO_4$ concentration.
TTA concn.: 10^{-1}M, Pa concn.: 10^{-7}M

maximum was observed at 410 mμ. The spectrum did not change except for a slight decrease in absorbance with standing. As is shown in Table 2, the absorbance at 410 mμ decreases by 10% after 51 days of standing.

Table 2. The effect time of standing on the absorbance of Pa in TTA-benzene solution
TTA: 0.1M Pa: *ca.* 3×10^{-5}M

Time (day)	Absorbance at 410 mμ
0	0.705
3	0.697
5	0.683
12	0.691
20	0.688
51	0.630

Discussion

In the equilibration experiment, it is obvious that a contact time of longer than half an hour makes no sense for the following reasons. In the forward

extraction, the distribution ratio reaches a constant value within 20 min of contact time, irrespective of the method used to prepare the perchloric acid solution of protactinium. Five minutes' contact is long enough to get a constant value from backward extraction. Another important thing is the peculiar behavior of the stripping, which makes it impossible to establish a true equilibrium because of the unfavorable formation of unstrippable species.

The method of preparing No. 3 corresponds in protactinium concentration to that shown in Fig. 5b of the second report of this series,[1] but the method used to prepare the stock solution is different. From this comparison it may be concluded that a protactinium solution with a concentration as high as 10^{-5}M is unstable. Besides, the solution prepared by such method as No. 1 is unstable regardless of the protactinium concentration.

The change in the absorption spectrum of protactinium(V) in a hydrochloric acid solution has been ascribed to the onset of hydrolysis, which is accompanied by the disappearance of solvent extractability.[5] The extractability of protactinium from a nitric acid solution decreases with standing, a fact which has been ascribed to the formation of inextractable species.[6,7] Even in the case of a fresh solution, the amount of protactinium in inextractable forms comprises 3%.[7] These phenomena have been ascribed to the formation of colloidal aggregates in the aqueous phase, which is not in rapid equilibrium with monomeric forms. Similar behavior was observed in our previous experiment in perchloric acid solution. About 17% and 44% of protactinium in 0.5 and 3.1M perchloric acid solutions respectively were unadsorbable species on cation exchange resin, and consistent results were obtained in the filtration experiments. No such phenomenon could, however, be observed in the TTA extraction.[1]

The same kind of investigation was undertaken in this experiment with relation to both the methods of preparing the protactinium solutions and their aging. It is evident that, in all the cases examined, the distribution coefficient remains unchanged in successive extraction. Therefore, the change in the distribution ratio with the time of standing is directly related to the change in K_t value. This difference between TTA extraction and other methods can be explained by the existence of a dynamic equilibrium in the TTA extraction; this in turn destroys the colloidal aggregates to some degree by means of the strong chelating action of TTA. It is obvious from these results that the extraction behavior differs greatly with the method of preparation, even in such a dilute solution as 10^{-7}M; nearly the same distribution ratio is obtained regardless of the method of preparation when the solution has been aged for longer than a month. However, the value consistent with that obtained from back extraction is not this value but the value obtained from fresh No. 1 and No. 3 samples. These observations suggest that the method of preparing either No. 1 or No. 3 is suitable from the standpoint of extraction equilibrium; however, No. 3 can not be considered to be very appropriate because of its unique behavior, discussed in a previous report. From the above considerations, about a 30-min contact of a fresh No. 1 sample with a TTA-benzene solution is most suitable for the investigation. It should be noted, however, that this statement of experimental conditions takes no cognizance of the thermodynamically-stable state of protactinium in a perchloric acid solution.

In any case these difficulties should be taken into account in interpreting the results.

There are many possibilities for interpreting the interesting behavior observed in stripping. One possibility is the polymerization of the extracted Pa-TTA chelate in the organic phase. However, this may be rejected on the basis of the fact that this phenomenon is observed irrespective of the protactinium concentration. Besides, the rate of the formation of the unstrippable species is faster in carrier-free ^{233}Pa than in 10^{-7}M protactinium. This obviously mitigates against this possibility. Another possibility is the decomposition of the chelate by some such means as thermal or radiation decomposition. This possibility is not warranted either because the rate of decrease in absorbance is too slow to interpret the rather drastic increase of unstrippable species. The last possibility is a minor and irreversible change of the extracted compounds in the organic phase. If the TTA chelate of protactinium is assumed to be absent in the aqueous phase, the extracted species should be $Pa(OH)T_4$, according to the second report of this series.[1] Strictly speaking, though, this form is not general enough; as alternate forms species like $Pa(OH)_2T_3 \cdot HT$ and $PaOT_3 \cdot HT$ are possible. If we consider that the first form participates in the extraction equilibrium and irreversibly undergoes dehydration to form the second form, which is naturally assumed to be more hydrophobic than the first form, the peculiar stripping behavior may be understood. Of course, there is no direct evidence for this hypothesis. Further study to support this hypothesis is being undertaken and will be reported on in the near future.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 1922—1926 (1969)

The Kinetic Studies of the Acid-catalyzed Etherification of the Tautomers of *p*-Nitrosophenol and *p*-Benzoquinoneoxime with Ethanol in Dioxane

Yoshiaki FURUYA, Iwao URASAKI, Kazuo ITOHO and Akiyoshi TAKASHIMA

Department of Industrial Chemistry, Faculty of Engineering, Kumamoto University, Kumamoto

(Received April 17, 1968)

The rates of the acid-catalyzed reversible etherification of the allelotrope of *p*-nitrosophenol and *p*-benzoquinoneoxime with ethanol in dioxane-forming *p*-nitrosophenetole have been measured by ultraviolet spectrophotometry. The rate of the forward reaction was expressed as the sum of the second- and the third-orders over a fairly large concentration region of the allelotrope and of ethanol. The plots of the logarithm of the apparent forward second-order rate constant against $-\log(C_{BH^+}/C_B)$ gave a straight line with a slope of -0.95. A probable mechanism involving the rate-determining formation of a σ-complex by the nucleophilic attack of the hydroxyl O-atom of ethanol on the α-carbon of the hydroxyl group of protonated *p*-nitrosophenol, and also the rate-determining deprotonation from the oxime group of the σ-complex by the allelotrope of *p*-nitrosophenol, was postulated.

The introduction of a nitroso group at the para position of phenol facilitates the etherification of the phenolic hydroxyl group.[1] The investigation of the optimum reaction conditions for the formation of *p*-nitrosophenetole has previously been reported by one of the present authors.[2] It has been considered, on the basis of synthetic results, that the facile equilibrium between the allelotrope of *p*-nitrosophenol and its ether presumably depends on the powerful activating effect of the protonated nitroso group.[3] However, the kinetics of this reaction was expressed as the sum of the second and third-orders under the conditions of these studies. It is interesting to investigate the reaction mechanism expressed by two terms.

Experimental

Materials. The allelotrope of *p*-nitrosophenol was prepared according to Bridge's method[4] and then recrystallized from benzene; yield 67%, mp 134°C (decomp). The ethanol was refluxed over calcium oxide for several hours and then rectified; bp 78.3°C. The dioxane was boiled under reflux for 7 hr with 10% of its volume of 1N aqueous hydrochloric acid, a slow stream of air being passed in through the condenser in order to remove the acetaldehyde formed. The organic layer was separated after treatment with potassium hydroxide and then distilled from the sodium; bp 101°C. The dioxane solution of sulfuric acid was prepared from guaranteed sulfuric acid and the anhydrous dioxane obtained as above.

Ultraviolet Spectrophotometry and Chemical Analysis. The reactions were followed by means of a Hitachi Perkin-Elmer UV-VIS spectrophotometer, model 139. The absorption maxima of the allelotrope and *p*-nitrosophenetole were 300 and 343 mμ respectively. Dioxane solutions of the allelotrope, *p*-nitrosophenetole, sulfuric acid, and ethanol of known concentrations (corresponding to 0, 20, 40, 60, 80 and 100% conversion) were prepared; a plot of the difference of extinction, $(E_{370}-E_{315})$ *vs.* $(E_{343}-E_{315})$, gave a straight line, and the conversion calculated from the values of $(E_{343}-E_{315})$ at 0 and 100% conversion agreed well (within a 1% error) with the conversions obtained from the composition of the solution.

Criterion of the Reaction. As the $(E_{370}-E_{315})$ *vs.* $(E_{343}-E_{315})$ plots of the actual reaction did not deviate at all from the calibration curve obtained above, it can be considered that the reaction forming *p*-nitrosophenetole occurs without any side reaction.

The reaction mixtures obtained using ethyl mercaptan and/or ethanol were extracted with ether; they were washed with water in order to eliminate the acid and then dried. The solutions were examined by means of gas chromatography employing a Yanagimoto gas chromatograph, model GCG-550FTP, operated with an F.I.D. and a 1.5-m column packed with 1.5% SE-30 coating Celite 545, using nitrogen with a flow rate of 45 ml/min from 50 to 150°C and with a programing rate of 12°C/min and a chart speed of 1 cm/min. The retention times of the authentic samples in ether and the two ethereal solutions prepared as described above are as follows:

	—	—	—	—	—	—	4.55	6.55

A Typical Run for the Rate Measurements. A solution of 0.25 m*l* of 2N sulfuric acid in dioxane was poured into a solution of 4.75-m*l* portions of both 0.211M allelotrope and ethanol in dioxane in order to start the reaction after both solutions had attained temperature equilibrium. Aliquots (each 0.1 m*l*) were taken out at appropriate time intervals; each one was diluted with methanol to a 5×10^{-5}M total concentration of the allelotrope and *p*-nitrosophenetole. The conversion percentage was calculated from the observed value of $(E_{343}-E_{315})$, while the values of the apparent forward second-order rate constant, k_2', were calculated graphically.

Determination of the Water in the Reaction System. The remaining water in the reaction system was determined to be 0.2M by the Karl Fischer method.

Measurement of the Isotope Effect. The preparation of the dioxane containing heavy water was carried out as follows: the water present in dioxane as a reaction solvent was removed by distillation after the solvent had been heated under reflux with metal sodium. Heavy water, D_2O, was added, and then removed as above. These procedures were repeated three times. The dioxane containing the usual water was treated in the same manner.

The mobile hydrogen in the allelotrope of *p*-nitrosophenol was exchanged with deuterium as follows: the allelotrope (1.01 g, 0.0082 mol) was dissolved in a mixture of absolute methanol (11.2 g, 0.35 mol) and deuterium oxide (0.94 g, 0.047 mol), after which the mixture was allowed to stand for 4 hr at room temperature. Then the medium was removed under reduced pressure. These procedures were repeated three times. It was determined by infrared analysis*1 that some of the mobile hydrogen in the allelotrope was exchanged with deuterium by the above treatment.

As alcohol, the usual alcohol and tetradeuteriomethanol were used for the usual reactions and for the reactions of the deuterio-compounds respectively. *p*-Nitrosoanisole, as an authentic sample, was prepared by the acid-catalyzed reaction of *p*-nitrosophenol with methanol and was recrystallized 3 times from petroleum ether; mp 24°C.

The rate constants, k_2 and k_3, were expressed as k_{2H} and k_{3H} for the usual reactions of the allelotrope with methanol and as k_{2D} and k_{3D} for the reactions of the deuterio-allelotrope with tetradeuteriomethanol in the presence of dideuteriosulfuric acid in dioxane containing deuterium oxide only.

*1 For this analysis, the potassium bromide tablet method was used. The intermolecular hydrogen bonding band in 3450 cm^{-1} was decreased and the hydroxyl stretching band in 2780 cm^{-1} was increased in the case of this sample.

Results and Discussion

A typical rate plot of the reaction at 60°C is shown in Fig. 1. The reaction follows the second-order reversible kinetics:

$$dx/dt = k_2'(a-x)(b-x) - k'_{-2}(c+x)x, \qquad (1)$$

where *a*, *b*, and *c* are the initial concentrations of the allelotrope, ethanol, and water respectively, and where *x* is the concentration of the consumed reactant at time *t*. The following equation is obtained by integrating Eq. (1):

$$\log\frac{x+m}{z-x} = \frac{ab(c+2z)-(a+b+c)z^2}{2.303z(c+z)}k_2't + \log\frac{m}{z} \qquad (2)$$

where:

$$m = \frac{ab(c+z)}{ab-(a+b+c)z}$$

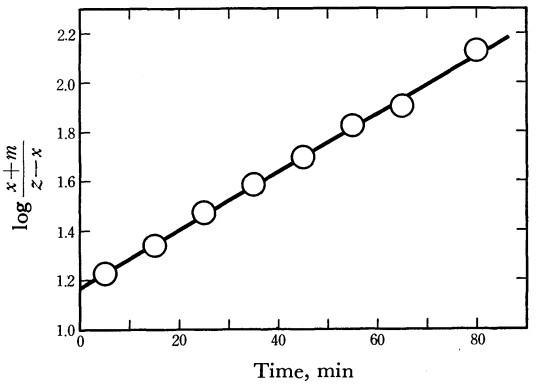

Fig. 1. The reversible second-order rate plot for the acid-catalyzed etherification of the allelotrope in dioxane at 60°C.
Concn. of H_2SO_4: 0.1N
Initial concn. of the allelotrope: 0.2M
Initial concn. of H_2O: 0.2M
Initial concn. of C_2H_5OH: 0.3M

and where z is the concentration of the consumed reactant at equilibrium. The plots of $\log(x+m)/(z-x)$ *vs.* t gave a straight line, and the value of the forward rate constant, k_2', was calculated from the slope. Here, the plots for the reversible second-order reaction, $\log(x+m)/(z-x)$ *vs.* t, bear a close resemblance to that for the reversible first-order reaction, $\log z/(z-x)$ *vs.* t. Therefore, we have misapprehended the reaction order in a previous report.[5] During repeated measurements, the first-order rate constant, k_d', has scarcely ever been found.

On the variation of the initial concentration of the ethanol, the apparent forward second-order rate constant, k_2', holds constant, as is obvious in Fig. 2. The plots of the k_2' rate constant against the initial concentration of the allelotrope gave a straight line with a definite slope, a line which did not pass through the point of origin, as is shown in Fig. 3. Thus, the forward rate equation may be given by:

$$v_{\text{forward}} = k_2'[\text{Allelo.}][\text{Ethanol}]$$
$$= \{k_2 + k_3[\text{Allelo.}]\}[\text{Allelo.}][\text{Ethanol}] \quad (3)$$

The rate was also affected by the acidity of the reaction medium. The indicator ratio, C_{BH^+}/C_B, at 373 mμ for each medium was determined spectrophotometrically using *p*-nitroaniline. The values of $\log k_2'$ were plotted against $-\log(C_{BH^+}/C_B)$ instead of H_0. As is illustrated in Fig. 4, a straight line with a slope of -0.95 was obtained. Therefore, both the k_2 and k_3 rate constants should involve the term of h_0.

It has been reported that the ratio of quinoidal (keto) and benzenoid (enol) forms in an equilibrium was determined by the difference in hydrogen-bond fission in the aggregated molecules.[6] The present authors have thought that the promoting forces are protonation and/or deprotonation. As the tendency of protonation to the nitroso group on the benzenoid form, I, is larger than that to the carbonyl group in the quinoidal form, II,[5] the rate of the formation of II is larger than that of I. An analogous situation holds in a protic solvent such as alcohols. In the case of an aprotic solvent such as dioxane, deprotonation is probably the promoting force. As deprotonation from the O-atom of the oxime group in II may be more difficult than that from the hydroxyl group in I, and as protonation to the

6) E. Havinga and A. Schors, *Rec. trav. chim.*, **69**, 457 (1950).

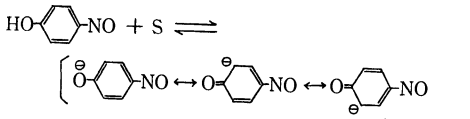
[I]

[II]

nitroso group in **I** is easier than that to the carbonyl group in II,[5] the allelotrope probably exists largely in the quinoldal form. These presumptions agree well with the experimental results.[6]

The allelotrope seems to be in the monomolecular state, mostly in dioxane ranging from 0.1 to 0.3M.[7] Therefore, the intermediate of tautomerism is the protonated *p*-nitrosophenol in an acidic and/or protic solvent and the deprotonated *p*-nitrosophenol anion, IV, in an aprotic solvent:

[III]



[IV]

The participation of the proton in this reaction system can be considered to be as follows:

(4)

(5)

(6)

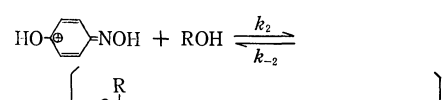
When two equilibria, (4) and (5), occur in a reaction mixture, the slope of the straight line obtained from the plots of $\log k_2'$ *vs.* H_0 should be -1. Considering the relationship of H_0 and J_0,[8] the value of the slope should be smaller than -1 when the (5) and (6) equilibria take place. As has been described above, the plots of $\log k_2'$ against H_0 gave a straight line with a slope of -0.95. Thus, the protonation to ethanol will give a protonated ethanol, not an ethyl cation.

Now, the pK_{BH^+} values of ethanol, dioxane, and the allelotrope are -2.5,[9] -4.4,[10] and -3.4[11] respectively. Thus, the order of the ease of the protonation is as follows: ethanol > the allelotrope > dioxane.

The ethyl cation, $C_2H_5^+$, is not formed under the reaction conditions described above. Hence, we may conclude the attack of protonated *p*-nitrosophenol on the hydroxyl O-atom of ethanol. This can be assumed also from the fact that a new peak, which is probably due to *p*-nitrosothiophenetole, is found by gas chromatography in the reaction mixture using ethyl mercaptan. If the ethereal O-atom of *p*-nitrosophenetole is derived from *p*-nitrosophenol, *p*-nitrosothiophenetole should not be formed by the reaction of *p*-nitrosophenol with ethyl mercaptan whose C–S bond is firm. Therefore, the promoting force of the reversible reaction forming *p*-nitrosophenetole from the allelotrope does not depend on the protonated ethanol, but on protonated *p*-nitrosophenol. Thus, the reaction will be promoted by a nucleophilic attack of the hydroxyl O-atom of ethanol on the α-C of the hydroxyl group of protonated *p*-nitrosophenol.

In constructing the second term of Eq. (3), the following three cases can be considered: (1) the formation of a π-complex between a molecule of protonated ethanol and the allelotrope, (2) the existence of the dimer of the allelotrope, and (3) the behavior of the allelotrope as a base in the deprotonation step. The formation of π-complex was scarcely observed at all under these reaction conditions. Also, the molecular association of the allelotrope was not found by the freezing-point-depression method, as has been mentioned above. Thus, the allelotrope can be expected to behave as a base in the deprotonation step from the σ-complex, V. For caution's sake, the kinetic isotope effects of hydrogen were also examined. The ratios of k_{2H}/k_{2D} and k_{3H}/k_{3D} were 0.83 and 2.58 respectively.

Therefore, we may consider that the first and second terms correspond to Steps (7) and (8) respectively. The value of k_2 is comparable to that of k_3. When the proton is abstracted by strong



[V]

(7)

(8)

7) From the molecular weight of the allelotrope obtained by the freezing-point-depression method, scarcely no molecular association was found.

8) M. A. Paul and F. A. Long, *Chem. Revs.*, **57**, 1 (1957).

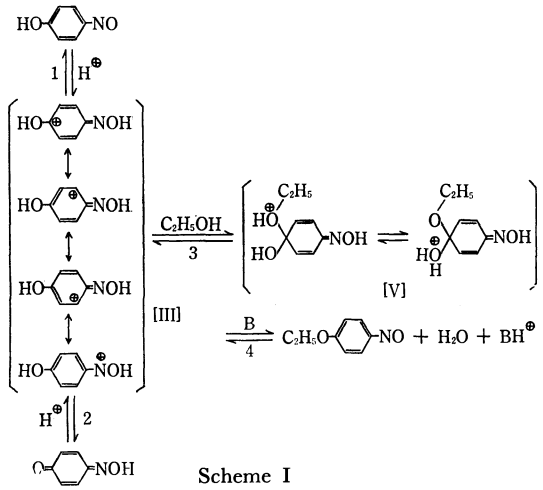
9) It was presumed that the pK_{BH^+} value of ethanol was nearly equal to that of methanol; *cf.* N. C. Deno and J. O. Turner, *J. Org. Chem.*, **31**, 1969 (1966).

10) H. Lemaire and H. J. Lucas, *J. Am. Chem. Soc.*, **73**, 5198 (1951).

11) According to our measurements using the UV method.

bases, such as water and alcohol, the value of k_3 in Step (8) becomes very large. Thus, Step (7) controls the rate in a pathway participated in by a strong base; this step is expressed as the first term in Eq. (3). This is demonstrated also by the fact that the k_2' rate constant does not contain the concentration of ethanol; moreover, the isotope effect was not observed. On the other hand, in the case of the deprotonation by a weak base such as the allelotrope of *p*-nitrosophenol, it is obvious, from the kinetics and isotope effect, that Step 8 determines the rate.

From these findings the following probable mechanism may be suggested (Scheme I).



Scheme I

B: H_2O, C_2H_5OH, the allelotrope, dioxane and HSO_4^-, *etc.*

Proton NMR Studies of Substituent Effects. The Hammett-type Relationship in *meta*- and *para*-Substituted Formanilides*1

Jun NIWA

Chemical Laboratory, Department of General Education, Nagoya University, Chikusa-ku, Nagoya

(Received July 20, 1968; in revised form December 25, 1968)

The spectral analyses of 23 *meta*- and *para*-substituted formanilides in dimethyl sulfoxide have proved that they exist in an equilibrium of *cis*- and *trans*-forms of restricted rotational isomers in the solvent. The chemical shifts of the protons on the formanilides are strongly dependent on the polar nature of the substituent. In the *cis*-form, the chemical shifts of both the imino and the formyl protons correlate with the Hammett σ^0. In the *trans*-form, a plot of the chemical shifts of the formyl protons against the σ^0-constants reveals a good correlation in the case of *meta*-derivatives, but serious deivations for the *para*-substituents, both for the electron-releasing conjugative substituents and for the electron-withdrawing conjugative substituents. The deviations for both types of substituents are in the direction to be anticipated for any important extra conjugative interaction between the *para*-substituent and the side-chain. The Yukawa-Tsuno equation is precisely applicable to these shifts when we assume that this system has the same *r*-value for both types of substituents; the relation is expressed as:

$$\Delta\delta = -12.0(\sigma^0 + 1.12\Delta\bar{\sigma}_R) + 0.5.$$

where $\Delta\bar{\sigma}_R=\sigma^+-\sigma^0$ for the electron-releasing conjugative substituents and where $\Delta\bar{\sigma}_R=\sigma^--\sigma^0$ for the electron-withdrawing conjugative substituents ($r=0.993$, $s=0.8$). From the solvent effect on the substituents, such as NH_2, OH, and COOH, their σ^0-values in dimethyl sulfoxide are proposed. It is also deduced that this solvent effect affects principally the part of the inductive contribution in the overall substituent effect.

It has been extensively verified that the respective Yukawa-Tsuno equation, either (1) or (2), can be applied to the electrophilic or the nucleophilic reaction of the side-chain derivatives of benzene whenever the opportunity arises for a strong conjugative interaction between the substituent

*1 Presented in part at the 21th Annual Meeting of the Chemical Society of Japan, Osaka, March, 1968.

and the reaction site:[1]

$$\log k/k_0 = \rho(\sigma^0 + r\Delta\bar{\sigma}_R^+) \quad (1)$$

where $\Delta\bar{\sigma}_R^+ = \sigma^+ - \sigma^0$, or:

$$\log k/k_0 = \rho(\sigma^0 + r\Delta\bar{\sigma}_R^-) \quad (2)$$

where $\Delta\bar{\sigma}_R^- = \sigma^- - \sigma^0$. Yukawa and Tsuno[1] have also suggested that if the σ^+- and σ^--values[2,3] are used as a common reference of the substituent constants in a series of side-chain derivatives, Eqs. (1) and (2) will turn to:

$$\log k/k_0 = \rho(\sigma^0 + r\Delta\bar{\sigma}_R) \quad (3)$$

where $\Delta\bar{\sigma}_R = \sigma^+ - \sigma^0$ and $\sigma^- - \sigma^0$.

Meanwhile, in NMR studies, a number of correlations have been noted between the reactivity parameters and the chemical shifts of the protons on benzene derivatives. In such a situation, it has been reported that Eq. (1) or (2) can be precisely applied to the side-chain derivatives.[4],*2 However, no work has been reported on the series of compounds in which Eq. (3) commonly holds both for the electron-releasing conjugative substituent and for the electron-withdrawing conjugative substituent.

In the present study, we have measured the chemical shifts of protons on the side-chain of 23 *meta*- and *para*- substituted formanilides dissolved in dimethyl sufoxide, where they exist in an equilibrium of *cis*- and *trans*-forms of restricted rotational isomers. This paper will describe how the substituent effect on the chemical shifts of protons on each isomer has been investigated from the viewpoint of the Hammett-type relationship. Especially, we will reveal that the Yukawa-Tsuno equation (3) is commonly applicable to the chemical shifts of the formyl proton of the *trans*-form for both types of substituents mentioned above when we assume that this system has the same *r*-value for the above substituents, and we adopt the σ^+- and σ^--values as a common reference of the substituent constants.

Moreover, from the investigation of the solvent effect on the substituents, such as NH_2, OH, and COOH, which form a strong hydrogen bonding with dimethyl sulfoxide, their σ^0-values in this solvent will be proposed. We will also discuss which part of the inductive and mesomeric contributions of the overall substituent effect this solvent effect has an influence on.

Experimental

Materials. *The substituted and the unsubstituted formanilides* used in the present study were prepared from formic acid*3 and the appropriate substituted anilines*4 according to the literature methods. The *p*-aminoformanilide was prepared by reducing *p*-nitroformanilide by iron dust in diluted formic acid. All the melting points or the boiling points of the formanilides, except for the compounds described below, agreed with the value described in the literature. *m*-Hydroxy derivative, mp: 112.7—113.2°C; *m*-Fluoro derivative, mp: 61.0—62.0°C; *p*-Fluoro derivative, mp: 66.0—66.5°C; *m*-Acetyl derivative, mp: 98.5—99.5°C; *p*-Acetyl derivative,

mp: 106.0—107.0°C. These compounds were confirmed by elemental analysis and by a study of the IR spectra.

*Dimethyl Sulfoxide.**4 This was distilled under reduced pressure after having been refluxed with calcium hydride for a few hours, avoiding any uptake of atmospheric moisture, and was stored over Linde-3A molecular sieves[5] (bp: 61°C/3 mmHg).

All the sample solutions were left standing for about 48 hr at room temperature after the sample tube had been sealed, so as to reach equilibrium completely.

Measurement of NMR Spectra. All the spectra were obtained on a JNM C-60 spectrometer. The prove temperature was maintained at 20.0±0.5°C. The chemical shift was measured by relating it to the resonance peak of 0.5 mol% benzene added as an internal reference by the side-band technique. Since, in every case, the signal of benzene appeared 159.7±0.5 cps down field from the low-field ^{13}C–H satellite of dimethyl sulfoxide, it was confirmed that benzene could be utilized as an internal reference. The proton signals were independent of the concentration, ranging from 5 to 0.5 mol%, and of addition of a small amount of water. In Table 1 the chemical shifts of the protons of 23 *meta*- and *para*-substituted formanilides at a 5 mol% concentration are given relative to formanilide itself. The precision of the measurement was within about ±0.5 cps for the chemical shifts of the formyl protons, while, within about ±0.8 cps for the imino protons.

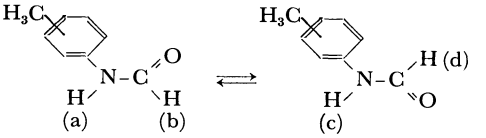
Results and Discussion

Analyses of Spectra of *meta*- and *para*-Substituted Formanilides. From the observation of near-infra-red absorption spectrum and the measurement of apparent dipole moment of formanilide in carbon tetrachloride solution, Mizushima *et al.*[6] have indicated that it exists in two forms—*cis*- and *trans*-forms of restricted rotational isomers, which are caused by a partial double-bond character of the C-N bond. Recently, inspecting the NMR spectra of formtoluidides in carbon tetrachloride, measured at 60 Mc and 100 Mc, Nishiyama and Yamada[7] proved that the *cis*- and *trans*-forms of the formtoluidide existed in an equilibrium:



(I) *cis*-Form (II) *trans*-Form

On the basis of the above informations, we analysed the spectra of *meta*- and *para*-substituted formanilides at several concentrations in carbon tetrachloride, benzene, acetone, and dimethyl sulfoxide. The formanilides, except for the formtoluidides and the unsubstituted formanilide, were too sparingly soluble in such non-polar solvents as carbon tetrachloride and benzene for the spectra to be examined. As an example, the spectra of form-*p*-toluidide at 5 mol% in carbon tetrachloride and dimethyl sulfoxide are shown in Figs. 1 and 2.

The spectrum of Fig. 1 shows the same pattern as that obtained by Nishiyama and Yamada,[7] and it reveals that the formtoluidide exists in the *cis*- and *trans*-forms in carbon tetrachloride. They were assigned by comparing, with each other, the coupling constants between the imino and the formyl protons of them. The resonance signals, (a) and (c), were assigned to the imino protons of the two forms, because their line width may be broadened due to a relaxation phenomenon involving the ^{14}N

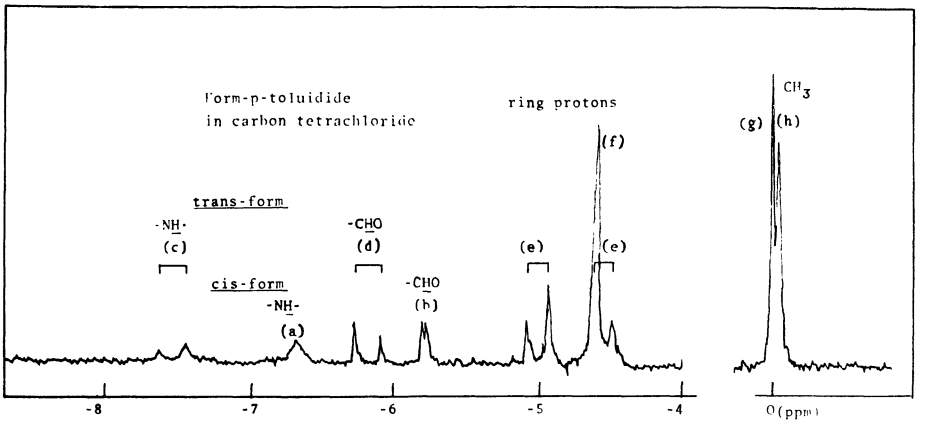

Fig. 1. Proton resonance spectrum (60 Mc/sec) of form-*p*-toluidide at 5 mol% in carbon tetrachloride at 20.0±0.5°C. The chemical shifts shown are relative to the methyl group of the *cis*-form.

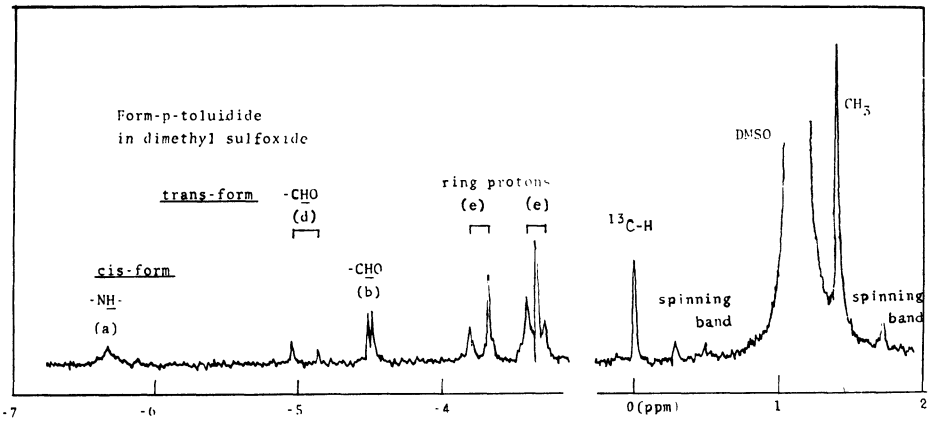

Fig. 2. Proton resonance spectrum (60 Mc/sec) of form-*p*-toluidide at 5 mol% in dimethyl sulfoxide at 20.0±5°C. The chemical shifts are shown relative to the low-field ^{13}C–H satellite of dimethyl sulfoxide.

quadrupole.[8] The signal (a) also shifted variably depending on the kind of solvents. The resonance signals, (b) and (d), were assigned to the formyl protons of the two forms, because they gave sharp resonance lines and the shift by variation of solvents little occured. The signal (a) of the imino proton was ascribed to belong to the *cis*-form, and the signal (b), to arise from the proton of the formyl group in the *cis*-form, which was a doublet due to the spin-spin coupling with the imino hydrogen. The value of the coupling constant was 2.2 cps, which was consistent with that obtained for the *cis*-proton of some kinds of amides (J_{cis}=2.1 cps for formamide[9] and J_{cis}=1.8 cps for formtoluidide[7]). The signals, (c) and (d), were assigned to belong, respectively, to the imino and the formyl protons of the *trans*-form, because they were the doublet due to the spin-spin coupling between the *trans*-protons, and the value of the coupling constant was 11.3 cps (J_{trans}=11.4 cps, both for formamide[9] and for formtoluidide[7]).

Figure 2 shows the spectrum of the form-*p*-toluidide in dimethyl sulfoxide. All the resonance signals, except for that of the imino proton of the *trans*-form, correspond with those in carbon tetrachloride solution. When a small amount of dimethyl sulfoxide was added in the carbon tetrachloride solution of the formtoluidide, the signal (a) of the imino proton of the *cis*-form shifted to the lower field, whereas that of the *trans*-form, (c), remained almost constant. As the concentration of the dimethyl sulfoxide increased, the signal (a) approached to the signal (c). Accordingly, in dimethyl sulfoxide, the signal (c) may be concealed behind the signal (a). The low-field shift

of the signal (a) by the addition of dimethyl sulfoxide may be due to the hydrogen bonding between the imino hydrogen of the *cis*-form and the molecule of dimethyl sulfoxide. The independence of the concentration of the dimethyl sulfoxide in the case of the chemical shift of the imino proton of the *trans*-form may be ascribed to that the associated molecules of the *trans*-form make the ring dimer (See Fig. 11).

Although Figs. 1 and 2 do not so distinctly the doublet of the resonance signals of the ring protons, the spectrum of form-*p*-anisidide shows the typical AB-type doublet of the protons on the *para*-disubstituted benzene ring (Fig. 3). The signal (e) was ascribed to belong to the *cis*-form, while the signal (f), to the *trans*-form, from their relative intensities. In Fig. 1 the two resonance signals, (g) and (h), of the methyl protons, which appeared at slightly different positions, corresponded with the *cis*- and *trans*-forms respectively.

When the spectra in carbon tetrachloride (Fig. 1) and benzene are compared with those in dimethyl sulfoxide (Fig. 2) and acetone, the intensities of all resonance signals of the protons of the *trans*-form in the latter solvents are much smaller than those of the *cis*-form. This shows that the *cis*- and *trans*-forms exist in an equilibrium, and that the equilibrium inclines toward the *cis*-form in the polar solvent. The effect of varying the concentrations in carbon tetrachloride showed that the equilibrium favored the *cis*-form as the concentration increased.*5 The substituent effect on the

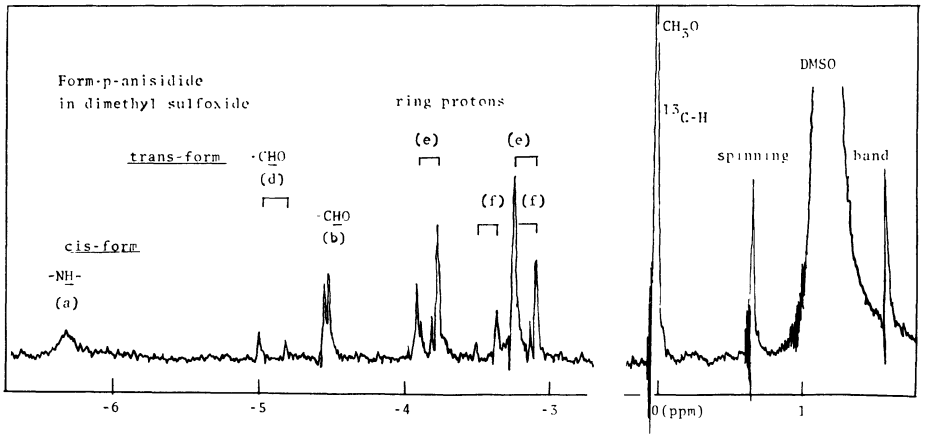

Fig. 3. Proton resonance spectrum (60 Mc/sec) of form-*p*-anisidide at 5 mol% in dimethyl sulfoxide at 20.0±0.5°C. The chemical shifts shown are relative to the low-field ^{13}C–H satellite of dimethyl sulfoxide.

10) T. Yonezawa and I. Morishima, This Bulletin, **39**, 2346 (1966).

equilibrium in dimethyl sulfoxide showed a trend that the *trans*-form was favored by the electron-releasing substituent. These results may be all explained by assuming an asymmetric polarized structure for the *cis*-form (Fig. 7), while, a non-polarized structure for the *trans*-form (Fig. 11), as will be discussed in detail later. The representative spectra of *meta*- and *para*-substituted formanilides in dimethyl sulfoxide are shown in Figs. 3 and 4.

Substituent Effect on the *cis*-Form. *(i) Correlation of the Chemical Shift of the Imino Proton with the σ^0-Constant.* Although the ^{14}N quadrupole makes the measurement of accurate chemical shifts difficult by broadening the imino proton signal, this disadvantage is offset by the wide range of the chemical shifts observed (about 70 cps). This enhanced sensitivity of the substituent effect on the imino proton signal can be understood in terms of hydrogen bonding to the solvent molecule.

In Fig. 5, the relative chemical shifts of the imino protons are plotted against the σ^0-values. The correlation is expressed by Eq. (4), which was derived from a least-squares fit of the data:

$$\Delta\delta = -40.3\sigma^0 + 2.1 \qquad (4)$$

for all the 18 substituents except five: *p*-NH_2, *m*-OH, *p*-OH, *m*-COOH and *p*-COOH. The correlation coefficient and the standard deviation have the respective values of 0.988 and 2.1. The plots for *p*-COOH and *m*-COOH are excluded from the figure, for their σ^0-values have not been established. The plots for such substituents as *p*-NH_2, *p*-OH, and *m*-OH deviate greatly above the correlation line. These substituents, whether in the *meta*-position or the *para*-position, are apparently much more electron-releasing than the ordinary σ^0-values predict. The effect may be a reflection of the alteration of the substituent by the specific solvation. The σ^0-values of these substituents in dimethyl sulfoxide, calculated from the regression line, are: -0.67 for *p*-NH_2, -0.41 for *p*-OH, -0.16 for *m*-OH, 0.50 for *p*-COOH, and 0.11 for *m*-COOH. The reliability of these σ^0-values will be examined in the succeeding sections.

This aspect of the substituent effect on the imino proton reveals that there is no extra conjugative interaction between the substituent and the side-chain in the *cis*-form. This result suggests that, the amide group not in the plane of the aromatic ring, can not interact with the aromatic *pi*-electron system. When we assume an asymmetric polarized structure for the *cis*-form, the departure from planarity can be explained as due to the steric repulsion between the hydrogen of the aryl group, in the ortho position shown, and the C–O$^-$ group,*6 The molecule of the *cis*-form is shown schematically in Fig. 7.

(ii) Correlation of the Chemical Shift of the Formyl Proton with the σ^0-Value. It is expected that the

cis-Form *trans*-Form

Fig. 7. The *cis*- and *trans*-forms of *m*- and *p*-substituted formanilides. The radii of the circles correspond to the van der Waals' radii of the atoms.

*6 This type of steric repulsion has been suggested for formanilide by Mizushima *et al.* (Ref. 6).

chemical shifts of the formyl protons correlate with the σ^0-values, because even those of the imino protons exhibit no significant conjugative interaction between the substituent and the imino group. Thus, as is shown in Fig. 6, the relative chemical shifts can be expressed as:

$$\Delta\delta = -10.4\sigma^0 + 1.0 \qquad (5)$$

for all the 18 substituents except for five substituents mentioned above. The values of r*[7] and s*[7] were 0.974 and 0.8 respectively. This lack of good correlation is to be expected since the formyl protons of all the formanilides have a small spread of total chemical shift (about 16 cps). When the σ^0-values in dimethyl sulfoxide are used for the substituents mentioned above, all their plots fall close to the correlation line, as is shown by the dotted circles in the figure.

Substituent Effect on the *trans*-Form. Application of the Yukawa-Tsuno Equation to the Chemical Shift of the Formyl Proton. In the *trans*-form, a plot of the chemical shifts of the formyl protons against the Hammett σ^0-constants reveals a good correlation in the case of the *meta*-derivatives, as is shown in Fig. 8. This relation can be expressed as:

$$\Delta\delta_m = -12.0\sigma^0 + 0.5 \qquad (6)$$

In this case, too, the plots for *m*-OH and *m*-COOH fall close to the *meta*-correlation line when their σ^0-values in dimethyl sulfoxide are used. The ρ-value is compatible with the ρ-value (-10.4) in the case of the formyl proton in the *cis*-form, as is to be expected from the fact that the distance between the substituent and the proton observed is not very different in the two cases. As is shown in Table 1, however, the formyl protons of all the *trans*-forms have quite a large spread of total chemical shift (about 37 cps) compared with the case of the formyl proton of the *cis*-form. This must be a reflection of a strong extra conjugative interaction between the substituent and the side-chain in the *trans*-form.

It is characteristic that all the plots for the electron-releasing conjugative substituents at the para-position, such as *p*-NH_2, *p*-$N(CH_3)_2$, and *p*-CH_3, deviate seriously from the *meta*-correlation line in the direction to be predicted by the σ^+-value,[2] whereas those for the electron-withdrawing con-

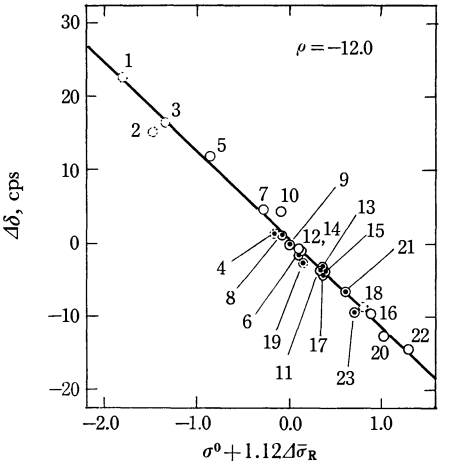

Fig. 10. Correlation of the chemical shifts of the formyl protons of the *trans*-forms with the Yukawa-Tsuno equation. Numbered points correspond to entries in Table 1. Substituents, $N(CH_3)_2$, NH_2, OH, and COOH are shown by dotted circles.
⊙: *mreta*-substituent ○: *para*-sbustituent

jugative substituents, such as *p*-$COCH_3$, *p*-CN, and *p*-NO_2, deviate considerably in the direction of the σ^--value.[3] When the σ^+-values are used for the former substituents and the σ^--values for the latter, all the plots except that for *p*-$N(CH_3)_2$ fall near the correlation line, but the correction seems yet to be insufficient. This result suggests that the Yukawa-Tsuno equation (3) may be applicable to the chemical shifts of the formyl protons if we adopt the σ^+-values for the former substituents and the σ^--values for the latter as a common reference of substituent constants, and if we assume that this system has the same *r*-value for both types of substituents. Thus, a good correlation is obtained as:

$$\Delta\delta = -12.0(\sigma^0 + 1.12\Delta\bar{\sigma}_R) + 0.5 \qquad (7)$$

for the 16 substituents, as is shown in Fig. 10. The values of r*[7] and s*[7] were 0.993 and 0.8 respectively. A plot for the *p*-fluoro derivative deviates somewhat above the correlation line, as has been observed by Yukawa and Yamada.[4] in the chemical shifts of the ethynyl protons in *meta*- and *para*-substituted phenylacetylenes.

When the σ^0-values in dimethyl sulfoxide and the ordinary $\Delta\bar{\sigma}_R$-values*[8] are used, the plots for *p*-NH_2, *p*-OH, and *p*-COOH*[9] fall close to the correlation line. Only the plot for *p*-$N(CH_3)_2$ deviates greatly down from the correlation line. Yukawa and Tsuno[10] have indicated a good correlation between the chemical shifts of *para*-protons on monosubstituted benzenes and the $\Delta\bar{\sigma}_R$-values, but in this case, too, the plot for *p*-$N(CH_3)_2$ deviates considerably from the correlation line. From the correlation line, the $\Delta\bar{\sigma}_R{}^+$-value for *p*-$N(CH_3)_2$ is calculated as -0.93. When this value is used in the present case, the plot for *p*-$N(CH_3)_2$ falls near the correlation line, as is shown by dotted circle, (2), in Fig. 10. The origin of the difference between the two $\Delta\bar{\sigma}_R{}^+$-values, one of which has been derived from the reactivity data and the other from the NMR data, is not yet evident.

The characteristic aspect of the substituent effect in the case of the *trans*-form is in contrast to the situation in the *cis*-form, and it implies that the aryl and the amide groups constitute a expanded conjugated system over the whole molecule. When we assume an asymmetric polarized structure for the *trans*-form (Fig. 7), this is explained as follows. First, in the *trans*-form, the aromatic ring and the amide groups lies in the same plane, because of the lack

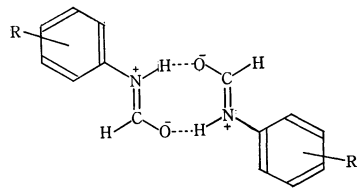

Fig. 11. The ring dimer of the molecules of the *trans*-form of *m*- and *p*-substituted formanilides.

of the steric interaction between the aryl and the amide groups. Second, as is shown schematically in Fig. 11, the molecules of the *trans*-form associate to make the ring dimer.*[10] All of these effects may cause that the formal charges on the nitrogen atom of the imino group and the oxygen atom of the C–O group are distributed along the bonds in the molecule, and that the composite *pi*-electron systems are delocalized along the entire body of the planar molecule.

Solvent Effect on Three Substituents, NH_2, OH, and COOH. Equation (7) shows that the normal $\Delta\bar{\sigma}_R$-values can also be applied in dimethyl sulfoxide to the substituents, such as NH_2, OH, and COOH, which form a strong hydrogen bonding with the solvent molecule. This result suggests that this specific solvation does not affect the term of the conjugative interaction. On the other hand, their σ^0-values in dimethyl sulfoxide differ remarkably from their normal σ^0-values. Which, then, the inductive or the mesomeric contribution of the σ^0-constant, does this solvation influence? We will now attempt to answer this question.

The σ^0-constant separated by Yukawa and Tsuno[1] is shown in Eq. (8):

$$\sigma^0 = \sigma_i + \sigma_\pi \qquad (8)$$

where the σ_i and σ_π terms are called the *sigma*-inductive and *pi*-electronic effects respectively. When the σ_i-and σ_π-values*[11] are used, Eq. (3) generally turns to:

$$\log k/k_0 = \rho(\sigma_i + r\sigma_\pi) \qquad (9)$$

where $\sigma_\pi = \sigma_\pi{}^+$*[12] and $\boldsymbol{r} = 1 + 2.4r$ for the electron-releasing conjugative substituent, and $\sigma_\pi = \sigma_\pi{}^-$*[12] and $\boldsymbol{r} = 1 + 1.2r$ for the electron-withdrawing conjugative substituent. Here, we will assume that this solvation affects only the term of the inductive effect by forming hydrogen bonding with the substituent group. Then. Eq. (8) can be expressed as:

$$\sigma^0_{(DMSO)} = \sigma_{i(DMSO)} + \sigma_\pi \qquad (10)$$

From Eq. (10), the σ_i-values in dimethyl sulfoxide are calculated to be: -0.25 for *p*-NH_2, -0.07 for

*[8] See Table 2.

*[9] Although the $\Delta\bar{\sigma}_R{}^-$ value for *p*-COOH has not been established, there may be little difference between the $\Delta\bar{\sigma}_R{}^-$ values for *p*-COOH and *p*-COOR. Therefore, the $\Delta\bar{\sigma}_R{}^-$ value for *p*-COOR (0.28) is used in this case.

11) Y. Yukawa and Y. Tsuno, "Jikken Kagaku Koza" (Handbook of Chemical Experiments), Supplemental Vol. 12, ed. by the Chem. Soc. Japan, Maruzen Co., Tokyo (1967), p. 462.

*[10] The presence of the ring dimer for formanilide has been suggested by Mizushima *et al.* (Ref. 6).

*[11] See Table 2.

*[12] $\sigma_\pi{}^+ = 0.415\Delta\bar{\sigma}_R{}^+$ and $\sigma_\pi{}^- = 0.81\Delta\bar{\sigma}_R{}^-$ (Ref. 1). If $0.415\Delta\bar{\sigma}_R{}^-$ is adopted, the plots for *p*-CN, *p*-$COCH_3$, *p*-COOH, and *p*-NO_2 fall on the correlation line.

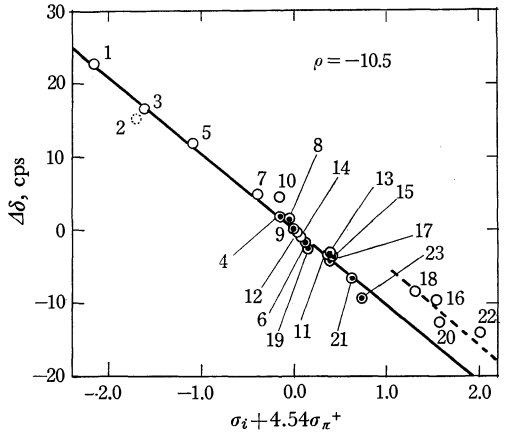

Fig. 12. Correlation of the chemical shifts of the formyl protons of the *trans*-forms with the equation, $\Delta\delta=\rho(\sigma_i+r\sigma_\pi)$. Numbered points correspond to entries in Table 1.
⊙: *meta*-substituent ○: *para*-substituent

p-OH, and 0.27 for *p*-COOH. If Eq. (9) holds for all the *para*-substituents which are electron-releasing conjugative, the use of these σ_i-values will prove the above assumption to be appropriate.

Figure 12 shows that Eq. (9) fits well for all the substituents mentioned above; the relation can be expressed as:

$$\Delta\delta = -10.5(\sigma_i + 4.54\sigma_\pi^+) \qquad (11)$$

In view of the error in the measurement of each chemical shift, we are probably justified in concluding that this ρ-value is almost equal to the ρ-value (−12.0) for the *meta*-derivatives. When the σ_π^--values are used for the electron-withdrawing conjugative substituents, *p*-$COCH_3$, *p*-CN, *p*-COOH, and *p*-NO_2, their plots fall on the other line. However, this result may be reasonable in view of the definition of the σ_π^--value.*[12] This fact does not essentially affect the above discussion. Accordingly, it may be concluded that this type of solvation influences not the mesomeric contribution but the inductive contribution of the substituent effect.

We wish to express our indebtedness to Mr. Mitsuru Yamazaki of Nagoya University for the measurement of the NMR spectra. Thanks are also due to Mr. Shozo Masuda of Tokyo University for his elemental analyses of the samples.

Macro Chelate Rings. I. Synthesis of 2,7-Dimethyl-4,5-bis-(salicylideneaminomethyl)acridone as a Quadridentate Chelating Agent and Its Metal Complexes

Hisashi OKAWA and Tamotsu YOSHINO

Department of Chemistry, Faculty of Science, Kyusyu University, Hakozaki, Fukuoka

(Received August 5, 1968)

2,7-Dimethyl-4,5-bis(salicylideneaminomethyl)acridone, which may form a quadridentate metal complex involving a ten-membered chelate ring, was synthesized by a sequence of steps and characterized. A monomeric cobalt(II) complex of the ligand was isolated and examined.

A number of six- or less-membered metal chelates have been synthesized, but there have been few, if any, characterized complexes with eight- or more-membered chelate rings in spite of the interest in the configuration of the complex.

In order to find a suitable metal complex which is sterically controlled for our ultimate object of making an asymmetric synthesis of an organic compound, we attempted to synthesize a novel quadridentate chelating agent, 2,7-dimethyl-4,5-bis-(salicylideneaminomethyl)acridone (I), which may form a ten-membered chelate ring in addition to two six-membered chelate rings by complex formation.

As is generally known, a purely organic macro ring compound is considered to be difficult to obtain without the selection of a suitable cyclization reaction and strict reaction conditions. In chelate compounds as well, an eight- or more-membered solitary chelate ring would not seem to form a stable metal complex because of the extreme weakness of the chelate effect. A considerably stable inner complex, however, may be formed if a macro chelate ring is fortified with an adjoining six-mem-

bered chelate ring on each side. Actually, some stable chelates of the ligand derived from salicylaldehyde and hexamethylenediamine have been obtained.

From this fact it seems possible to isolate a metal chelate of the liganed (I) in a stable form. However, no chelating agent similar to our ligand has ever been synthesized. The hydrogen atom attached to the nitrogen atom in the acridone nucleus may hinder the complex formation. Moreover, the ligand is unique in that the two phenolic oxygen atoms and two azomethin nitrogen atoms in the ligand molecule can not coordinate to the four sites of a square, planar central atom, as shown by a model consideration. Therefore, it seems necessary for the chelate to take a tetrahedral or octahedral configuration.

Therefore, in this work the synthesis of 2,7-dimethyl-4,5-bis(salicylideneaminomethyl) acridone (I) was explored as well as the complex formation.

Results and Discussion

The synthetic scheme of the organic moiety is shown in Chart 1. As the starting material, 2,7-dimethylacridone (V), in which the most reactive sites of acridone are blocked by methyl groups, was prepared by the Jourdan-Ullmann-Goldberg method from *p*-bromotoluene and 2-amino-5-methylbenzoic acid, which had been synthesized by a new method. Since the aminomethyl derivatives of acridone were not known, several routes were attempted. Among these, only direct aminomethylation was successful. 2,7-Dimethylacridone (V) was treated with *N*-hydroxymethylphthalimide or *N*-hydroxymethylbenzamide in concentrated sulfuric acid, and the condensation product (VI or VII) was hydrolyzed with hydrobromic acid to give 2,7-dimethyl-di(aminomethyl)acridone dihydrobromide (VIII). The di(aminomethyl)derivative was stable only in its salt form; the isolation of the free diamine was unsuccessful. Because of the instability of free diamine, the positions of the substitution were tentatively assigned to the 4 and 5 positions by analogy with the electrophilic substitutions of 2,7-dichloro and 2,7-dibromoacridone.[1] This 2,7-dimethyl-4,5-di(aminomethyl) acridone dihydrobromide was treated with salicylaldehyde to give 2,7-dimethyl-4,5-bis(salicylideneaminomethyl)acridone (I), the structure of which was confirmed by elementary analysis; its infrared spectrum supported the existence of a chelated azomethin group at 1625 cm^{-1}.

The compound (I) formed metal complexes with several metal salts, such as cobalt(II) and nickel(II) acetates. Of these the cobalt(II) complex (IX) was so stable as to be isolable in a pure state;

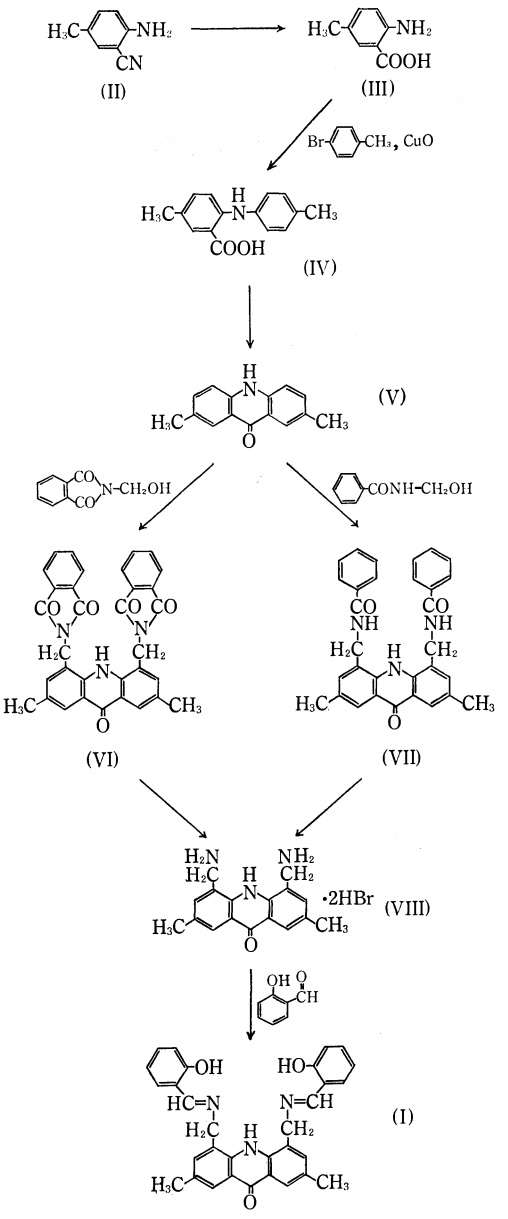

Chart 1.

its structure was determined by elementary analysis, by molecular-weight determination by vapor pressure in methanol, and by the shift of the C=N strectching vibration from 1625 to 1620 cm^{-1}. On the other hand, no recognizable shifts of the C=O and N–H stretching vibrations in the acridone nucleus were observed upon complex formation, the respective peaks being at 3270 and 1625 cm^{-1}. This fact means that the acridone nucleus does not change to the 9-hydroxyacridine nucleus upon prototropy; accordingly, the nitrogen atom in the acridone nucleus does not participate in the complex formation. The quinquedentate structure shown

(IXa) (IXb)

Chart 2.

in formula (IXb) could thus be excluded, and the quadridentate structure (IXa) was chosen as that of the cobalt(II) complex (Chart 2*1). The hydrogen atom attached to the nitrogen atom in the acridone nucleus was, unexpectedly, shown not to hinder the complex formation. Although the cobalt(II) complex did not have sufficient stability because of the steric strain probably due to the macro ring, our experiments have shown that the matal complex involving a ten-membered chelate ring is possibly so stable as to be isolable in a pure state.

Experimental

2-Amino-5-methylbenzonitrile (II). A mixture of 3-bromo-4-aminotoluene (186 g, 1 mol) and cuprous cyanide (100 g, 1.1 mol) in *N,N*-dimethylformamide (250 m*l*) was refluxed. Cuprous cyanide was dissolved within about 10 min. After a period of 3 hr, the reaction mixture was poured into a solution of sodium cyanide (200 g) in water (700 m*l*). The entire mixture was heated on a water bath for 1 hr and then cooled. The upper organic layer was separated, and the aqueous layer was extracted with benzene (300 m*l*). After the combined mixture of the organic layers had been dried over anhydrous sodium sulfate and the solvent had been removed by distillation, the residue was subjected to vacuum distillation; a fraction (97 g) boiling at 94—102°C/2 mmHg and solidifying immediately on cooling was collected to give 2-amino-5-methylbenzonitrile. A sample crystallized from ethanol consisted of colorless needles with a mp of 60—61°C.

The compound obtained by this new method was identified by the coincidence of our description with that of Findeklee's report.[2]

2-Amino-5-methylbenzoic Acid (III). 2-Amino-5-methylbenzonitrile (61 g, 0.5 mol) was hydrolyzed in a solution prepared by adding ethanol (500 m*l*) to a solution of sodium hydroxide (80 g) in water (100 m*l*). The sodium salt which separated after 7 hr was collected and dissolved in water (500 m*l*). The aqueous solution was neutralized with hydrochloric acid to give 2-amino-5-methylbenzoic acid, the subsequent crystallization of which from benzene gave colorless needles with a mp of 173°C.

The product was identified by the coincidence of our descritpion with that of Findeklee's report.[3]

2-(*p*-Tolylamino)-5-methylbenzoic Acid (IV). A mixture of 2-amino-5-methylbenzoic acid (40 g, 0.25 mol), *p*-bromotoluene (43 g, 0.25 mol), copper(II) oxide (0.5 g), and anhydrous potassium carbonate (18 g) in quinoline (100 m*l*) was refluxed at 240°C for 3 hr. After the excess *p*-bromotoluene and quinoline had been removed by steam distillation, the remaining dark-brown reaction mixture was boiled with active charcoal (5 g) for 5 min and then filtered. The filtrate, on acidification with hydrochloric acid, separated a dark yellowish green precipitate which was then crystallized from ethanol to give pale yellow prisms (50 g) with a mp of 184—186°C.

Found: C, 74.89; H, 6.36; N, 5.87%. Calcd for $C_{15}H_{15}NO_2$: C, 74.67; H, 6.27; N, 5.80%.

2-Amino-5-methylbenzoic acid and excess *p*-bromotoluene formed yellow crystals of 2-bis(*p*-tolyl)amino-5-methylbenzoic acid, which in turn yielded *N*-*p*-tolyl-2,7-dimethylacridone with a mp of 217—219°C.

2,7-Dimethylacridone (V). A solution of 2-(*p*-tolylamino)-5-methylbenzoic acid (50 g) in concentrated sulfuric acid (200 m*l*) was heated on a water bath for 4 hr. After having been cooled, the reaction mixture was poured onto ice. The yellow precipitate was collected by filtration. After any impurities had been removed by boiling with a 10% aqueous sodium carbonate solution, the insoluble residue was crystallized from dioxane or acetic acid to give yellow needles (28 g) with a mp of above 300°C. The overall yield from 2-amino-5-methylbenzoic acid was 55%.

Found: C, 80.99; H, 5.99; N, 6.58%. Calcd for $C_{15}H_{13}NO$: C, 80.69; H, 5.87; N, 6.27%.

The use of an excess of sulfuric acid led to the formation of a compound of an unknown structure, the composition of which was close to $C_{15}H_{14}NO_5SNa$.

2,7-Dimethyl-4,5-bis(phthalimidomethyl)acridone (VI). 2,7-Dimethylacridone (2.23 g, 0.01 mol) and *N*-hydroxymethylphthalimide (3.54 g, 0.023 mol) were dissolved in concentrated sulfuric acid (50 m*l*), and then the solution was left standing at room temperature for a week. The reaction mixture was then poured onto ice to give a yellow precipitate; this precipitate was collected by suction, treated in a 10% sodium bicarbonate solution (300 m*l*), collected by filtration, and washed with water and then with ethanol. The yield was almost quantitative. An analytical sample was crystallized from acetic acid to give pale yellow needles with a mp of above 300°C.

Found: C, 72.93; H, 4.46; N, 7.46%. Calcd for $C_{33}H_{23}N_3O_5$: C, 73.19; H, 4.28; N, 7.76%.

The use of a large excess of *N*-hydroxymethylphthalimide resulted in the formation of an insoluble substance, of an unknown structure, apparently containing more than two, probably six, phthalimidomethyl groups.

Found: C, 69.11; H, 3.88; N, 7.89%. Calcd for $C_{69}H_{43}N_7O_{13}\cdot H_2O$: C, 69.29; H, 3.79; N, 8.20%.

2,7-Dimethyl-4,5-bis(benzamidomethyl)acridone (VII). A mixture of 2,7-dimethylacridone (1.1 g, 0.005 mol) and *N*-hydroxymethylbenzamide (1.8 g, 0.012 mol) in concentrated sulfuric acid (50 m*l*) was left standing at room temperature for ten days, and then the reaction mixture was poured onto ice. The yellow precipitate was collected by filtration. After having been boiled in a 10% aqueous sodium bicarbonate solution, it was collected, washed with water, and crystallized from a methanol-dioxane mixture to give pale yellow needles (2.2 g) with a mp of above 300°C.

Found: C, 75.81; H, 5.82; N, 8.42%. Calcd for $C_{31}H_{27}N_3O_3$: C, 76.03; H, 5.56; N, 8.58%.

*1 Two water molecules which may be coordinated to the cobalt atom are eliminated in this chart.

2) W. Findeklee, *Ber.*, **38**, 3544 (1905).

3) W. Findeklee, *ibid.*, **38**, 3555 (1905).

2,7-Dimethyl-4,5-di(aminomethyl)acridone Dihydrobromide (VIII). A mixture of 2,7-dimethyl-4,5-bis(phthalimidomethyl)acridone (5 g) in acetic acid (50 m*l*) and 40% hydrobromic acid (50 m*l*) was refluxed in an oil bath for 2 days. The yellow needles (400 mg) which separated were collected by filtration and washed with a small amount of ethanol.

Found: C, 43.87; H, 4.86; N, 8.98%. Calcd for $C_{17}H_{21}N_3OBr_2$: C, 44.27; H, 5.03; N, 9.11%.

This dihydrobromide (200 mg) was also obtained in a comparable yield by refluxing 2,7-dimethyl-4,5-bis-(benzamidomethyl)acridone (2 g) in a mixture of acetic acid (30 m*l*) and 40% hydrobromic acid (30 m*l*) for 7 hr. In this case, the reaction time could be shortened for a comparably easy hydrolysis. These dihydrobromides were confirmed to be the same by the coincidence of the two infrared spectra.

The diamine seemed to be stable only in its salt form; attempts to isolate the free diamine failed, giving only a black paste.

2,7-Dimethyl-4,5-bis (salicylideneaminomethyl)-acridone (I). An acidic solution of 2,7-dimethyl-4,5-di(aminomethyl)acridone dihydrobromide (50 mg) and salicylaldehyde (50 mg) in 50% ethanol (30 m*l*) was neutralized with a 10% sodium bicarbonate solution to separate dark pink needles; these needles were collected by filtration and recrystallized three times from dioxane to give pink needles (30 mg) with a mp of 227—229°C. UV (ethanol): 31600 (6770), 25600 (5460) and 24700 cm^{-1} (ε 6190). IR (KBr disk): 3270 (N–H) and 1625 cm^{-1} (C=O and C=N).

Found: C, 76.24; H, 5.63; N, 8.51%. Calcd for $C_{31}H_{27}N_3O_3$: C, 76.05; H, 5.56; N, 8.58%.

Cobalt(II) Complex of 2,7-Dimethyl-4,5-bis(salicylideneaminomethyl)acridone (IX). A mixture of 2,7-dimethyl-4,5-bis (salicylideneaminomethyl) acridone (30 mg) and cobalt(II) acetate tetrahydrate (25 mg) in ethanol (25 m*l*) was heated on a water bath for 3 hr to give a reddish-brown precipitate; this precpitate was collected by filtration and washed with a small amount of ethanol. It was soluble in pyridine, dioxane, and *N,N*-dimethylformamide. UV (ethanol): 20000 (2100), 17500 (1100) and 7300 cm^{-1} (ε 480). IR (KBr disk): 3270 (N–H), 1625 (C=O) and 1620 cm^{-1} (C=N).

Found: C, 64.29; H, 4.77; N, 7.21; Co, 10.15%, mol wt, 590 (methanol). Calcd for $C_{31}H_{25}N_3O_3Co\cdot 2H_2O$: C, 63.92; H, 5.02; N, 7.21; Co, 10.12%, mol wt, 582.5.

Nickel(II) Complex of 2,7-Dimethyl-4,5-bis(salicylideneaminomethyl)acridone (X). A mixture of 2,7-dimethyl-4,5-bis (salicylideneaminomethyl) acridone (30 mg) and nickel(II) acetate tetrahydrate (25 mg) in ethanol (25 m*l*) was heated on a water bath for 1 hr. The precipitate was collected by filtration and washed with a small amount of ethanol to give a yellowish-brown powder.

Found: C, 63.37; H, 4.57; N, 7.53%. Calcd for $C_{31}H_{25}N_3O_3Ni\cdot 2H_2O$: C, 63.94; H, 5.02; N, 7.22%.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 1937—1941 (1969)

Secondary Structure of Poly-L-arginine and Its Derivatives*1

Tadao HAYAKAWA, Yoshiyuki KONDO and Hiroyuki YAMAMOTO

Institute of High Polymer Research, Faculty of Textile Science and Technology, Shinshu University, Ueda

(Received August 12, 1968)

The conformations of poly-$N^{\omega,\omega'}$-dicarbobenzyloxy-L-arginine, poly-N^{ω}-carbobenzyloxy-L-arginine, and poly-L-arginine hydrobromide were studied by means of their infrared spectra (IR), X-ray photographs, optical rotatory dispersions (ORD), and circular dichroisms (CD). The presence of the α-helical conformation in poly-$N^{\omega,\omega'}$-dicarbobenzyloxy-L-arginine and poly-N^{ω}-carbobenzyloxy-L-arginine was confirmed by X-ray photographs and by their IR spectra. The ORD and the CD curves of these polymers were found to be characteristic of the α-helical conformation. It was also found that these polypeptides have a random coil conformation in trifluoroacetic acid. In the (2-chloroethanol : trifluoroacetic acid) solvent system, the typical helix-coil transition of poly-N^{ω}-carbobenzyloxy-L-arginine was observed at 20—30% trifluoroacetic acid. The ORD and the CD curves of poly-L-arginine showed that the polymer took a random coil structure in the pH range from 2.7 to 11.0. However, when the pH is increased from 11.0 to 11.5, the spectra gradually change into the α-helix structure. Moreover, the polypeptide predominantly took the α-helix structure at pH 12.5. From the ORD and CD data, the polypeptide can be considered to have a right-handed α-helix conformation.

Considerable interest has recently been shown in the secondary structure of many synthetic polypeptides and proteins in the solid state and in solution. The protamins are strongly basic proteins which have high arginine contents, and their con-

*1 Presented at the Annual Meeting of the Society of Polymer Science of Japan, Tokyo, May, 1968.

formations have been found by the NMR[1] and the ORD[2,3] measurements to be almost random coil structures in aqueous solutions. However, the physicochemical properties of poly-L-arginine and its derivatives have not been reported. Recently we have prepared poly-L-arginine as an useful model of the protamins and have also prepared, by the NCA method,[4] two kinds of protected polyarginine as intermediates. In this paper, the physical properties and the secondary structure of poly-$N^{\omega,\omega'}$-dicarbobenzyloxy-L-arginine, poly-N^{ω}-carbobenzyloxy-L-arginine, and poly-L-arginine hydrobromide in the solid state and in solution will be discussed using the date obtained from the IR spectra, the X-ray analyses, and the ORD and CD.

Experimenta

Materials. Poly-$N^{\omega,\omega'}$-dicarbobenzyloxy-L-arginine (I), poly-N^{ω}-carbobenzyloxy-L-arginine (II), and poly-L-arginine hydrobromide (III) were prepared by the NCA method described in a previous paper.[4] The degree of polymerization of these polypeptides is found to be *ca.* 70 by carboxyl end-group analysis.

Measurements. The IR spectra were recorded by the use of the potassium bromide-pellet technique on a Jasco IR spectrophotometer, Model DS-301. The X-ray diffraction photographs were taken with a Rigaku-denki Geigerflex, using a Cu-target. The ORD and CD were measured on a Jasco Model ORD/UV-5 ORD recorder with a CD attachment at room temperature, using the cells with light paths of between 0.1 and 100 mm. The aqueous solutions of poly-L-arginine for the ORD and CD measurements were prepared by dissolving poly-L-arginine hydrobromide in water and by adjusting the pH with 0.1N NaOH.

Results and Discussions

IR Studies and X-Ray Analyses. The IR absorption spectra of I, II, and III showed absorptions at 1655 cm^{-1} (Amide I) and 1545 cm^{-1} (Amide II), suggesting that the polymer could have the α-structure (Fig. 1). The absorption shoulder at 1545 cm^{-1} and the other absorptions at 1515cm^{-1}, 1615 cm^{-1} and 1725 cm^{-1} of the polymers I and II may be due to the influence of the protected guanido group in polyarginine. The spectrum of III is simplified in all regions because of the removal

of the protecting group of the guanido group and showed absorptions at 1655 cm^{-1} and 1540 cm^{-1}. X-ray analyses of the polymers I, II, and III were also carried out. The X-ray diffraction patterns of I and II indicated the presence of a 18 Å reflection. Similarly, the X-ray photograph of poly-γ-benzyl-L-glutamate[5] in the α-helix structure shows the presence of a 13 Å reflection. This could be interpreted as indicating that a helix-helix interval of an α-helical polypeptide is broadened from 13 Å to 18 Å for poly-L-arginine derivatives (I and II) because of the bulky side chain. Poly-L-arginine hydrobromide (III) gives an almost amorphous photograph.

Optical Rotatory Dispersion and Circular Dichroism. *Poly-$N^{\omega,\omega'}$-dicarbobenzyloxy-L-arginine.* The ORD curves of poly-$N^{\omega,\omega'}$-dicarbobenzyloxy-L-arginine in tetrahydrofuran (THF), in dioxane, in 2-chloroethanol, and in trifluoroacetic acid (TFA) are shown in Fig. 2. In THF and in dioxane, the polypeptide exhibits a positive Cotton effect, with a strong peak at 245—247 mμ, followed by a deep trough at 233 mμ; the crossover point lies at 240 mμ. A second positive Cotton effect can be expected below 220 mμ with the crossover point at 222 mμ, but this is not clearly evident from the ORD curves. The CD curves of the polypeptide in THF and in dioxane are recorded in order to resolve

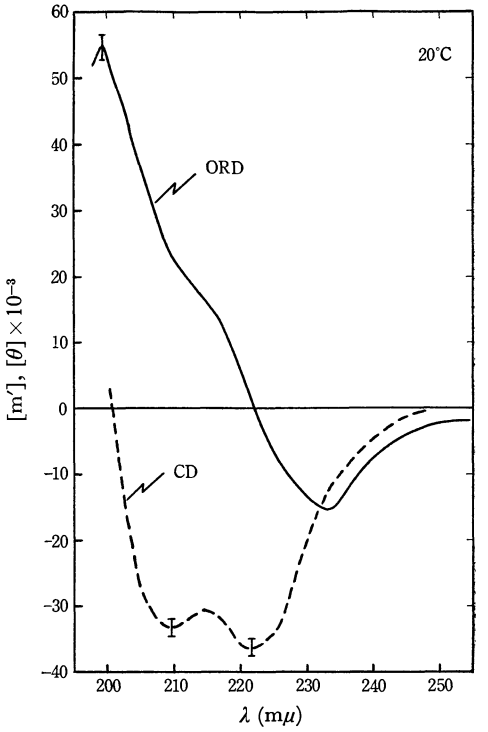

Fig. 4. ORD and CD of poly-N^{ω}-carbobenzyloxy-L-arginine in 2-chloroethanol.

any possible overlapping of Cotton effects in this region. The CD curves are shown in Fig. 3. The CD curves of the polypeptide reveal a strongly positive dichroism centered at 235 mμ in the wavelength range 250—200 mμ. Two negative dichroism bands, at 221 mμ and 214 mμ, are observed for these solutions; a positive dichroism band can also be expected below 200 mμ. The positive dichrosim band at 235 mμ can be assigned to the π–π^* exciton transition of the benzyl group. The negative ellipticity band at 221 mμ appears to be the n–π^* peptide electronic transition associated with the α-helical conformation of polypeptide, while the negative band at 214 mμ and the positive band below 200 mμ are to be assigned to the parallel-polarized and perpendicular-polarized π–π^* exciton transitions of the peptide groups respectively.[6] These dichroism bands are found in approximately the same positions and have the same signs and magnitudes as those observed in right-handed α-helix polypeptides. From these CD and ORD measurements, this polypeptide can be considered to have a right-handed α-helix conformation in THF and in dioxane.[6] When TFA and 2-chloroethanol are used as the solvents (Fig. 2), the peak at 245 mμ disappears. The ORD and the CD curves of the polypeptide in 2-chloroethanol (Figs. 2 and 3) are characteristic of the random coil conformation; there is a 238 mμ trough, a 226 mμ peak, and a 205 mμ trough in the ORD curve, and

a small negative dichroism band at 230 mμ, a small positive dichroism band at 217 mμ, and a large negative dichroism band at 202 mμ in the CD curve. These results suggest that the phenyl groups near the backbone of the main chain exist in a dissymmetric environment in helix-supporting solvents (THF, dioxane). In TFA and in 2-chloroethanol, the polypeptide exists as a random coil and the dissymmetry is lost.[7]

Poly-N^{ω}-carbobenzyloxy-L-arginine. The ORD and the CD curves of poly-N^{ω}-carbobenzyloxy-L-arginine in 2-chloroethanol are shown in Fig. 4. The polymer has a 233 mμ trough and a 199 mμ peak, with a shoulder near 213 mμ, on the ORD curve; it also has two negative dichroism bands, at 222 and 210 mμ.[6] These spectra suggest that the polypeptide has a right-handed α-helix structure. The Moffitt-Yang plot for poly-N^{ω}-carbobenzyloxy-L-arginine in mixed solvents (TFA-2-chloroethanol) is shown in Fig. 5. The ORD of this polypeptide in (TFA : 2-chloroethanol) solutions fits the Moffitt-Yang equation. The coefficient of the second term, b_0, is found to be dependent on the mol% of TFA. In 100% TFA, b_0 is zero and a_0 is −310, while in 100% 2-chloroethanol b_0 is −600 and a_0 is +360.

over, the helix-coil transition of the polypeptide in mixed solvents typically takes place at 20—30% TFA (Fig. 6). The helical contents are calculated by two methods[8,9]: a) from the b_0 value for the Moffitt-Yang plot, and b) by using the magnitude, $[m']_{233}$, in the ultraviolet-region ORD measurements.

Poly-L-arginine. The ORD curves of poly-L-arginine as a function of the pH in aqueous media are shown in Fig. 7. In the pH range 2.7—11.0, the polypeptide is in a random coil structure which has a 238 mμ trough, a 227 mμ peak, and a 205 mμ trough. However, when the pH is increased from 11.0 to 11.5, a remarkable change in the ORD spectrum is observed: the peak at 227 mμ disappears and the trough at 238 mμ shifts to 233 mμ. The solubility of the polypeptide decreases at pH values higher than 12.0. Therefore, ORD and CD measurements were carried out in methanol-water media. In the pH range 12.3—12.5, the polypeptide has predominantly the α-helix conformation: a trough with $[m']_{233}\cong -9000$, a crossover point at 221 mμ, and a shoulder near 214 mμ. However, the magnitude of the $[m']_{233}$ value for the polypeptide is smaller than the magnitude of the $[m']_{233}\cong -15000$ values of poly-L-glutamic acid (pH 4)[9] and poly-L-lysine (pH 11)[10] in aqueous solutions. When the pH is increased to 12.6, the polypeptide precipitates. It could be assumed that the coil-helix transition of the polypeptide takes place in this solution (pH 12.5), but this was not evident from the ORD spectra. The CD curves of the polypeptide as a function of the pH are shown in Fig. 8. In the pH range 2.7—11.0 the CD spectrum shows the same curve as that observed in the ORD; *i. e.*, the polypeptide shows the characteristics of a random coil, a small negative dichroism band at 230 mμ, and a small positive dichroism band at 218 mμ, while a large negative dichroism band may be anticipated below 200 mμ. In the pH range 11.5—12.0 the CD spectrum shows that the polypeptide partially takes the α-helix structure.

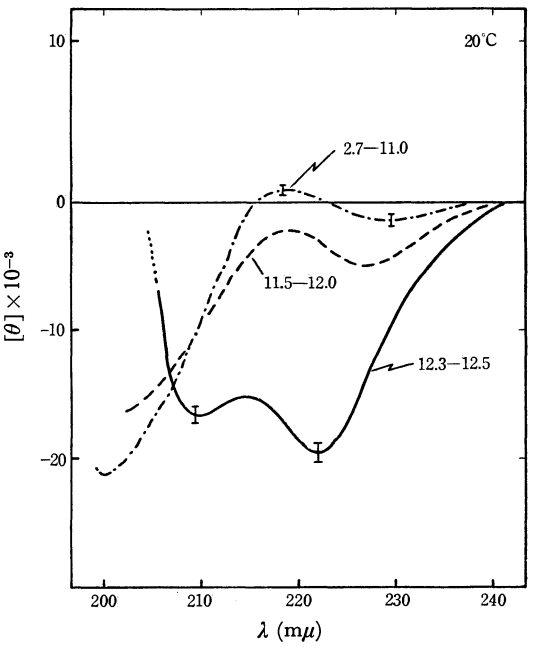

Fig. 8. CD of poly-L-arginine as a function of pH in aqueous media.
pH 2.7—11.0 (-·-·-), pH 11.5—12.0 (----) and pH 12.3—12.5* (——).
*: water-methanol (2 : 1, v/v).

The polypeptide has predominantly the right-handed α-helix conformation between the pH values of 12.3 and 12.5: two negative dichroism bands, at 222 and 209 mμ, with $[\theta]_{222}\cong -19000$ and $[\theta]_{209}\cong -17000$ values respectively. However, the $[\theta]_{222}$ and the $[\theta]_{209}$ values are smaller than those of usual polypeptides.[6,10] These results may be assumed to indicate either that the polypeptide mingle with some random coil conformation or that the molecular weight of the polypeptide is much smaller than that of usual polypeptides.

The authors wish to express their thanks to the Kaishin Kisei Domei of this Faculty for its financial support.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 1942—1947 (1969)

Studies on Stable Free Radicals. III.*1 Reactions of Stable Nitroxide Radicals with *S*-Radicals Derived from Benzenethiols and Thiamine

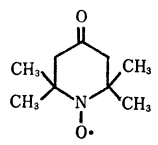
Keisuke MURAYAMA and Takao YOSHIOKA

Central Research Laboratories, Sankyo Co., Ltd., Shinagawa-ku, Tokyo

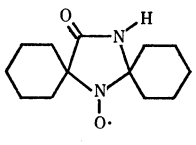
(Received September 5, 1968)

The reaction of the extremely stable free radical, 2,2,6,6-tetramethyl-4-oxopiperidine-1-oxyl (I), was carried out with benzenethiols (IV). The formation of diphenyl disulfides (VI), benzenesulfinic acids (VII), and 1-(*p*-substituted benzenesulfinyl)-2,2,6,6-tetramethyl-4-oxopiperidines (X) from the above reaction shows that the radical (I) can act as a hydrogen-abstracting agent, an oxidizing agent, and a radical scavenger. Possible mechanisms for the coupling reaction of the radical (I) with the *S*-radicals (V) to give the sulfinamides (X) were discussed. A substituent effect was observed in the formation of the disulfides (VI). The *N*-oxyl radical (I) and another stable free radical, such as 2,6-di-*t*-butyl-4-methylphenoxyl radical (XXV), were shown to react with the *S*-radical (XVII) derived from thiamine (XIV) to give new types of thiamine derivatives, *S*-(2,2,6,6-tetramethyl-4-oxopiperidino)thiamine (XX) and *S*-(2,6-di-*t*-butyl-4-methylphenoxy)thiamine (XXVI) respectively.

Many studies of the synthetic methods and physical properties of extremely stable *N*-oxyl radicals have recently been reported.[2,3] However, few papers have reported the roles of such radicals as oxidizing agents, hydrogen-abstracting agents, or radical scavengers. Especially, there have been few studies of the reactivities of radicals by means of isolating the coupled products of the radicals with the other free radicals.[1,4] In the preceding paper[1] we studied the reactive sites in such radicals as 2,2,6,6-tetramethyl-4-oxopiperidine-1-oxyl (I) and cyclohexane-1-spiro-2′-(4′-oxoimidazolidine-1′-oxyl)-5′-spiro-1″-cyclohexane (III) from the structure of the coupled products of I and III with a *C*-radical derived from α,α′-azo-bis(isobutyronitrile) (ABIN).



(I)



(III)

Chart 1

In this paper the authors wish to report that the radical (I) can act as a hydrogen-abstracting agent, an oxidizing agent, and a radical scavenger, by using the fact that the radical (I) reacts with benzenethiols (IV) to give diphenyl disulfides (VI), benzenesulfinic acids (VII), and 1-benzenesulfinyl-2,2,6,6-tetramethyl-4-oxopiperidine (X). Most importantly, the fact that the radical (I) acts as a radical scavenger is very interesting because this result can be applied to other experiments to determine whether a reaction proceeds *via* a free radical intermediate or not.

Todd and Sykes,[5] and Yurugi[6] have studied the pyrolysis of thiamine disulfide (XVIII) and the reaction of the *S*-anion (XV) of thiamine (XIV) with potassium ferricyanide to give thiochrome (XIX). Although they have postulated a reaction mechanism involving an *S*-radical intermediate in the above reaction, no coupled products of the *S*-radical (XVII) of thiamine with other free radicals have been obtained. We applied the reaction of the free radical (I) with the *S*-radical derived from benzenethiol to the case of another *S*-radical (XVII) derived from thiamine (XIV).

Results and Discussion

The reaction of the *N*-oxyl radical (I) with various benzenethiols (IV) was found to proceed

vigorously in the absence of a solvent at room temperature. This reaction took place even at −55°C in an ethereal or a chloroform solution to give the disulfides (VI), the substituted benzenesulfinic acids (VII), and 1-(*p*-substituted benzenesulfinyl)-2,2,6,6-tetramethyl-4-oxopiperidines (X), as Chart 2 shows. Two reduction products, 2,2,6,6-tetramethyl-4-oxopiperidine (XII) (*ca.* 35% yield) and 1-hydroxy-2,2,6,6-tetramethyl-4-oxopiperidine (XI) (*ca.* 6% yield), were also isolated.

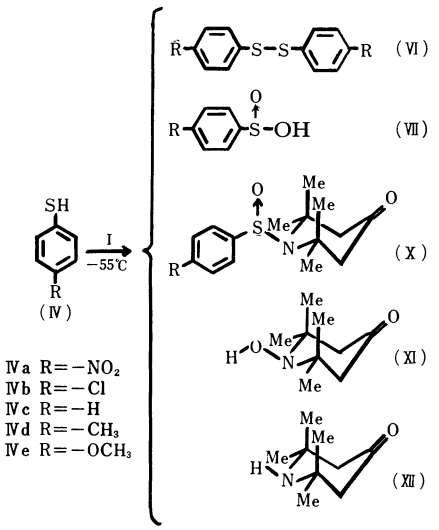

Chart 2[7-9]

The structural assignments of these products were based on the results of the elemental analyses and spectral data. The melting points of the products were identical with those of normal products produced by the independent syntheses of X from the corresponding sulfinyl chlorides and XII, or that of authentic samples.

Our preliminary communication showed that, in our NMR studies of the amides X, four methyl protons of the amides X gave rise to two broad absorptions indicative of magnetic non-equivalence.[10]

The reaction mechanism can be formulated as is shown in Chart 3. The sulfhydryl hydrogen of thiols (IV) was abstracted by the radical (I). The *S*-radicals (V) thus obtained then dimerized to give the dimer (VI). The *N*-oxyl radical (I) or (II) can further react with *S*-radicals (V) to give intermediate, (VIII) or (IX), which, on isomerization, furnish amides (X).

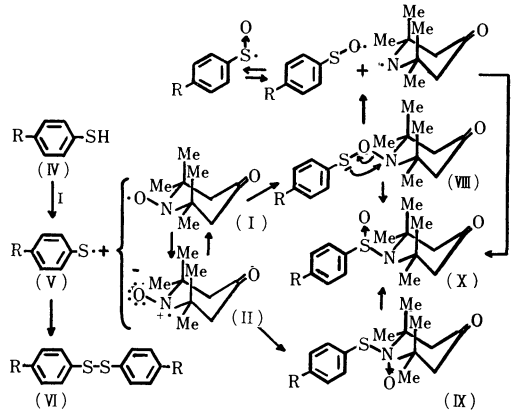

Chart 3[7-9]

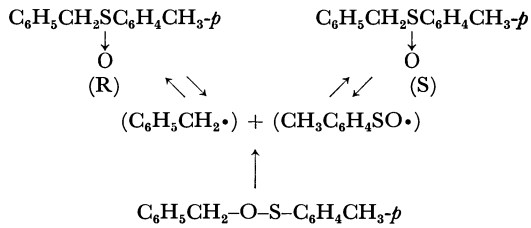
The formally analogous thermal rearrangement of sulfenates to sulfoxides has been reported in racemization studies of optically-active sulfoxides by Mislow *et al.*,[11] who have proposed the following homolytic dissociation mechanism:



Similar mechanisms involving an –O–N< bond cleavage in VIII may also be possible.

Sulfinic acid formation, *i. e.*, VII, can hardly be explained by the hydrolysis of the sulfinamides (X), since the reaction of the *N*-oxyl radical (I) with the thiols proceeds in anhydrous media. The details of this reaction mechanism will be presented elsewhere.

Thus, the *N*-oxyl radical (I) appears to have the properties of a hydrogen-abstracting agent, an oxidizing agent, and a radical scavenger. The change of the *p*-substituent on the phenyl group from hydrogen to $-NO_2$, $-Cl$, $-CH_3$, or $-OCH_3$ had only a small effect. Table 1 shows that such an electron-donating group as *p*-OCH_3 tended to decrease the yield of the disulfides (VI). The yield was determined by UV-intensity measurements (λ_{max}) after separation using silica gel-column chromatography. This fact can be explained in terms of the small effect of the substituents on the stability

7) In this chart a piperidine ring was conveniently shown in a chair form as represented for the amine XII by Aroney *et al.*[8] However, Rozantzev and Cur'yanova[9] proposed a twist and a boat form for the *N*-oxyl radical (I) and 1,4-dihydroxy-2,2,6,6-tetramethylpiperidine respectively.

TABLE 1. *p*-SUBSTITUENT EFFECT ON THE YIELD OF DIPHENYL DISULFIDE

Substituent (*p*)	$-NO_2$	-Cl	-H	$-CH_3$	$-OCH_3$
Yield (%)	55.0	51.5	51.5	52.0	30.5

of the *S*-radical, or on the rate of the hydrogen-abstraction from benzenethiols.

These results appeared to be inconsistent with those proposed by Kooyman *et al.*,[12] who have studied the hydrogen-abstraction reaction by the 1-methyl-1-cyanoethyl radical from substituted benzenethiols (ρ-value: -0.4). However, a direct comparison is impossible because of the uncertainty of the reaction mechanism; in the system studied, there was no evidence that the disulfides were kinetically-controlled products.

Since the free radical (I) was found to exhibit the property of a radical scavenger, we considered using it in the reaction of the radical (I) with the *S*-radical of thiamine (XIV) in a thiol form in order to investigate whether the reaction proceeds *via* a free radical intermediate (XVII) or not. As is

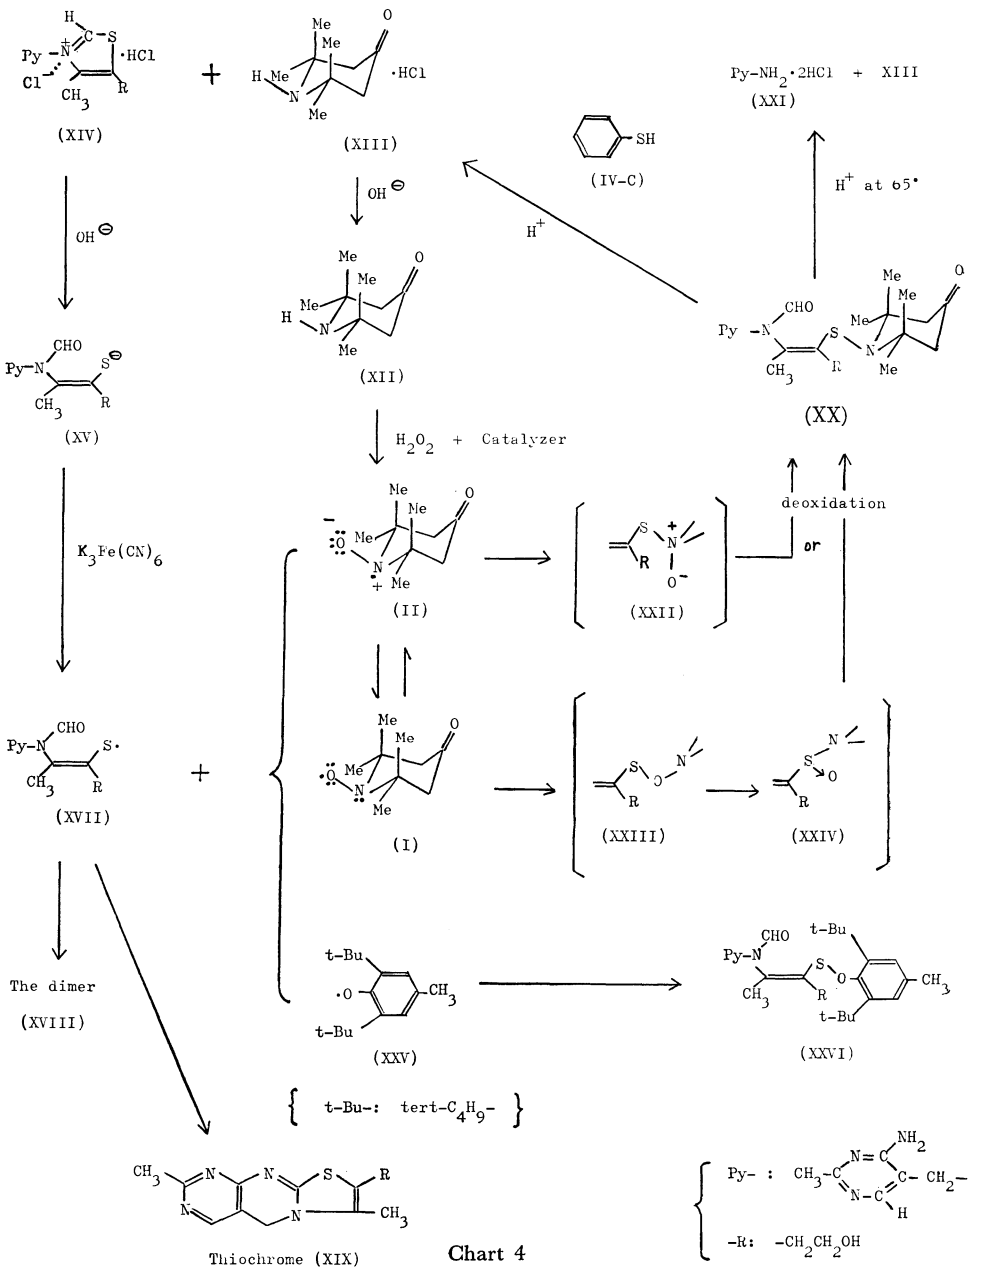

Chart 4

12) Y. Schaafsma, A. F. Bickel and E. C. Kooyman, *Rec. Trav. Chim.*, **76**, 180 (1957).

summarized in Chart 4, thiamine (XIV) was transformed into the *S*-anion (XV) by normal procedures.[13] This *S*-anion (XV) was oxidized with a 1-equivalent electron-abstracting agent, potassium ferricyanide, at 5°C to give the corresponding *S*-radical (XVII).[14] The reaction of the *N*-oxyl radical (I) with the *S*-radical (XVII) was expected to give a coupled product, a new thiamine derivative.[15] From the results of elemental analyses, the UV, IR, NMR, and mass spectra, and the R_f-value in paper chromatography and a thiochrome test,[16] (to be shown in the Experimental section), the structure of the isolated product, $C_{21}H_{33}N_5O_3S$, was deduced to be *N*-[(4-amino-2-methyl-5-pyrimidyl)methyl]-*N*-{4-hydroxy-1-methyl-2-[(2,2,6,6-tetramethyl-4-oxopiperidino)thio]-1-butenyl}-formamide (XX). Further, the hydrolysis of the new derivative, XX, with hydrochloric acid gave 2-methyl-4-amino-5-aminomethylpyrimidine dihydrochloride (XXI) and 2,2,6,6-tetramethyl-4-oxopiperidine hydrochloride (XIII). The reduction of XX with benzenethiol and hydrochloric acid gave thiamine hydrochloride (XIV) and 2,2,6,6-tetramethyl-4-oxopiperidine hydrochloride (XIII) quantitatively. These results are consistent with the structure XX. However, the above observations could not ascertain whether or not a sulfenamide group, –S–N<, was present in this molecule XX. Strong support for the existence of the sulfenamide group was given by the mass spectrometric fragmentation of XX using a high-resolution double-focussing mass spectra; the large fragment peaks at *m/e* 122.073, 186.098, and 249.136 corresponded with $C_6H_8N_3^+$, $C_9H_{16}NOS^+$, and $C_{12}H_{17}N_4O_2^+$ respectively, as is shown in Chart 5. Therefore, the isolated product, XX, was deduced to be a deoxy-form of the expected normal coupled product. Further, the structure of XX was established by X-ray analysis.[17]

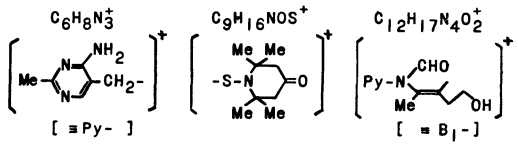

Chart 5

In the reaction of benzenethiols with the *N*-oxyl radical, the coupled products were isolated as sulfinamides, –S(=O)–N<, as has been described above.

On the other hand, the coupled product of the *N*-oxyl radical (I) with the *S*-radical (XVII) of thiamine was found to be a sulfenamide, –S–N<, (XX), which was considered to have been produced *via* a normal coupling intermediate, XXII, XXIII, or XXIV. The difference between the two cases will be reported on elsewhere.

Sulfenamides have been produced by Dunbar and Rogers by the following procedure.[18] Although the thiamine derivative in the RSO_2–S–R′ form could not be detected in our laboratory, the thiol-sulfonate, RSO_2–S–R, can be produced by the reaction of the *N*-oxyl radical (I) with the disulfide (XVIII). Therefore, it is possible to consider that

$$RSO_2\text{–}S\text{–}R' + 2\ HN\langle^{R''}_{R'''} \rightleftharpoons R'\text{–}S\text{–}N\langle^{R''}_{R'''} + RSO_2^{\ominus}\cdot{}^{\oplus}H_2N\langle^{R''}_{R'''}$$

the sulfenamide (XX) of thiamine was produced by such a process.

In order to exclude the possibility of the formation of the sulfenamide (XX) by such a course, and in order to prove the existence of the *S*-radical (XVII) of thiamine, it was felt necessary to carry out the reaction of XVII with a free radical other than the *N*-oxyl radical (I). The phenoxyl radical, the 2,6-di-*t*-butyl-4-methylphenoxyl radical (XXV), was chosen as the other free radical. As expected, the *S*-radical (XVII) of thiamine reacted with the phenoxyl radical (XXV) to give a coupled product XXVI, mp 197°C (from MeOH) and the disulfide XVIII under almost the same conditions as those used for the reaction of the *N*-oxyl radical (I) with the *S*-radical (XVII) of thiamine. The molecular formula of $C_{27}H_{40}N_4O_3S$, (XXVI) was assigned to the coupled product of the *S*-radical (XVII) with the phenoxyl radical (XXV) on the basis of the elemental analysis. The structures XXVI-a, XXVI-b, and XXVI-c were reasonable for the coupled products (XXVI), as Chart 6 shows.

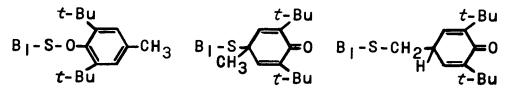

Chart 6

The UV spectrum of the product (XXVI) showed λ_{max}^{EtOH} 235 mμ (log ε 4.22) and 276 mμ (log ε 4.03) (shoulder) in an ethanol solution. The thiochrome test for the product (XXVI) was negaitve. After the reduction of the product (XXVI) with cysteine, the test was positive. Since a thiamine alkylsulfide with the partial structure of =C–S–C could not be

generally reduced with cysteine, the structures XXVI-b and XXVI-c may be excluded.[19]

Thus, the reaction of thiamine in the thiol form with potassium ferricyanide was understood to proceed *via* a free radical intermediate. In these results the existence of new types of thiamine derivatives was established.

Experimental

All the melting points were uncorrected.

The NMR spectra were obtained by means of a Varian A-60 NMR spectrometer, using tetramethylsilane as the internal standard at 32°C.

The mass spectra were obtained using a JEOL-JMS-OlS mass spectrometer with an ionizing voltage of 70 eV.

The paper chromatograms of thiamine derivatives were run with an *n*-butanol - acetic acid - water mixture (4 : 1 : 5) on Toyofilter paper No. 51, using the ascending technique, while spots were detected by spraying with a dilute Dragendorff reagent.

Materials. The benzenethiol (IV-c), *p*-nitro- (IV-a), *p*-chloro- (IV-b), and *p*-methylbenzenethiol (IV-d) used in this work were obtained from the Tokyo Kasei Kogyo Co., Ltd. Compound IV-a was twice recrystallized from dichloroethane after the solution of the corresponding potassium salt of IV-a had been treated with active charcoal at 5°C under a nitrogen atmosphere and then neutralized with a 10% hydrochloric acid solution to furnish an almost pure compound (IV-a). The other thiols, (IV-b), (IV-c), and (IV-d), were purified by distillation under diminished pressure. The *p*-methoxy derivative (IV-e) was prepared by the general method described in the literature.[20]

2,2,6,6-Tetramethyl-4-oxopiperidine-1-oxyl (I) was prepared by the oxidation of the corresponding amine (XII) by hydrogen peroxide in the presence of sodium tungstate and ethylenediaminetetraacetic acid (EDTA).[3]

General Procedure for the Reaction of *p*-Substituted Benzenethiols (IV) with 2,2,6,6-Tetramethyl-4-oxopiperidine-1-oxyl (I). Into a solution of 0.01 mol of IV in 15 m*l* of anhydrous chloroform, maintained at an internal temperature of −55——60°C with stirring under a dry nitrogen atmosphere, there was slowly added, drop by drop, a solution of 0.01 mol of I in 5 m*l* of anhydrous chloroform. After the addition was completed, the stirring was continued for 1 hr at −55°C; then the internal temperature was gradually raised to room temperature. The reaction mixture was allowed to stand at room temperature for 10 hr, and then the solvent was evaporated under diminished pressure at 30°C. The oily residues or crude crystals were chromatographed on 100 g of silica gel activated at 150°C for 2 hr. By using anhydrous *n*-hexane as the eluting solvent, *p*-substituted diphenyl disulfides (VI) were isolated. Then 1-(*p*-substituted benzenesulfinyl)-2,2,6,6-tetramethyl-4-oxopiperidines (X) (*ca.* 10%), 2,2,6,6-tetramethyl-4-oxopiperidine (XII) (*ca.* 35%), and 1-hydroxy-2,2,6,6-tetramethyl-4-oxopiperidine (XI) (*ca.* 6%) were eluted with benzene. Lastly, the salts of 2,2,6,6-tetramethyl-4-oxopiperidine with *p*-substituted benzenesulfinic acids (VII) was eluted with methanol. The disulfides (VI) were recrystallized from ethanol to give analytically-pure samples which were identical with authentic samples. The sulfinamides (X) were recrystallized from ethanol or ether to give analytically-pure samples which were identical with the normal samples produced by the reaction of *p*-substituted benzenesulfinyl chloride with 2,2,6,6-tetramethyl-4-oxopiperidine (XII) in dry triethylamine at 50°C. The sulfinamides (X) are listed in Table 2.

The benzenesulfinates of VII (*ca.* 20%) obtained from the last fraction were recrystallized from ethanol to give analytically-pure samples which were identical with authentic samples.

***N*-[(4-Amino-2-methyl-5-pyrimidyl)methyl]-*N*-{4-hydroxy-1-methyl-2-[(2,2,6,6-tetramethyl-4-oxopiperidino)thio]-1-butenyl}formamide (XX). [Abbr., *S*-(2,2,6,6-Tetramethyl-4-oxopiperidino)thiamine].** Into a mixture of 33.4 g (0.1 mol) of thiamine hydrochloride (XIV) and 17.0 g (0.1 mol) of the *N*-oxyl radical (I) in 100 m*l* of water, there was slowly added a solution of 12 g of sodium hydroxide in 50 m*l* of water at 5°C with vigorous stirring. After the reaction mixture was allowed to stand at 20°C for 30 min, a solution of 32.9 g (0.1 mol) of potassium ferricyanide in 100 m*l* of water was added at 5°C with vigorous stirring. The crude crystals which were separated after several hours were then filtered and washed with cold water three times. The crude product was recrystallized from wet

methanol to afford colorless prisms with a mp of 179°C (monohydrate). The monohydrate was dried at 105—110°C for 10 hr under diminished pressure to give an analytically-pure sample (mp 179°C). Found: C, 57.78; H, 7.76; N, 16.29; S, 7.39%. Calcd for $C_{21}H_{33}N_5O_3S$: C, 57.91; H, 7.64; N, 16.08; S, 7.36%. UV λ_{max}^{EtOH} mμ (logε): 235 (4.17); 276 (3.77) (shoulder). IR cm^{-1} ($CHCl_3$ solution, 1.0 m/m NaCl, Grating):[21] ν_{O-H} 3620; $\nu_{as\ N-H}$ 3480; $\nu_{s\ N-H}$ 3335; $\nu_{C=O}$ 1715. NMR (τ) (in d-6 DMSO):[22] 2.08 (1H, singlet); 2.13 (1H, singlet). R_f (paper chromatography):[23] 0.70. The thiochrome test was negative, but became positive after reduction with cysteine.[24] High-resolution double-focussing mass spectra: molecular ion peak, *m/e* 435.230=$C_{21}H_{33}N_5O_3S$; large fragment peaks, *m/e* 122.073=$C_6H_8N_3^+$; *m/e* 186.098=$C_9H_{16}NOS^+$; *m/e* 249.136=$C_{12}H_{17}N_4O_2^+$.

The Hydrolysis of *S*-(2,2,6,6-Tetramethyl-4-oxopiperidino)thiamine (XX). A solution of 0.87 g (0.002 mol) of XX in 2 m*l* of methanol containing 0.5 g (0.005 mol) of concentrated hydrochloric acid (35% aq) was refluxed for 2 hr, and then the solvent was evaporated under diminished pressure. Scratching induced the oily residue to solidify upon the addition of absolute ethanol. The mixture thus obtained was filtered, and the solid was recrystallized from wet ethanol; mp 265—270°C (bubbling). Found: C, 34.25; H, 5.73; N, 26.48; Cl, 33.40%. Calcd for $C_6H_{12}N_4Cl_2$: C, 34.12; H, 5.69; N, 26.54; Cl, 33.65%. This compound was identical with authentic 4-amino-2-methyl-5-aminomethylpyrimidine·2HCl (XXI).[25] The filtrate was evaporated under diminished pressure. The oily residue, when scratched in ethyl acetate, gave a yellow semi-solid. After this semi-solid was filtered off, the filtrate was treated with fresh ethyl acetate to furnish a white precipitate which was then separated by filtration. To a suspension of this solid in ethyl acetate on a water bath, a small amount of ethanol was added until the solid dissolved. This solution was cooled at −30°C to give white crystals. This crystalline product was neutralized with potassium hydroxide in a methanol solution to give 2,2,6,6-tetramethyl-4-oxopiperidine (XII), which was identical with an authentic sample.

The Reduction of *S*-(2,2,6,6-Tetramethyl-4-oxopiperidino)thiamine (XX) with Benzenethiol. Into a mixture of 4.4 g (0.0101 mol) of XX and 4.4 g (0.0400 mol) of benzenethiol in 30 m*l* of methanol, 2.1 g of a 35% aqueous solution of hydrochloric acid (0.0101 mol) were slowly added, drop by drop, with stirring at 10°C. After the mixture had stood for 10 hr at 20°C, the solvent was evaporated under diminished pressure. The residue solidified upon being scratched in a small amount of ethanol (about 10 m*l*). As the solid was a mixture of thiamine hydrochloride (XIV) and diphenyl disulfide (VI), the solid was purified by fractional crystallization from ethanol. Thiamine hydrochloride monohydrate, mp 235°C was crystallized out first, and then the diphenyl disulfide, mp 61°C was obtained. These substances were identical with authentic samples. After the above filtrate was evaporated under diminished pressure, the residue, upon the addition of a small amount of ethyl acetate with scratching, furnished a small amount of a solid. The solids (crude VI and XIV) were removed, and then to the filtrate there was added a further amount of ethyl acetate. This solution deposited white crystals after standing for several hours. These crystals were treated with potassium hydroxide in methanol to afford 2,2,6,6-tetramethyl-4-oxopiperidine (XII), which was identical with an authentic sample.

***N*-[(4-Amino-2-methyl-5-pyrimidyl)methyl]-*N*-{4-hydroxy-2-[(2,6-di-*t*-butyl-4-methylphenoxy)thio]}-formamide (XXVI).** [*S*-(2,6-Di-*t*-butyl-4-methylphenoxy)thiamine]. To a solution of 6.7 g (0.0199 mol) of thiamine hydrochloride (XIV) in 50 m*l* of water, with the internal temperature maintained at 5°C by effective stirring under a nitrogen atmosphere, there was slowly added, drop by drop, a solution of 2.4 g (0.06 mol) of sodium hydroxide in 10 m*l* of water. After the addition was completed, stirring was continued for 1 hr at 20°C to afford the *S*-anion (XV) of thiamine (XIV), which was, for convenience, named the "-$S^{\ominus}$-solution." Separately, to a mixture of 4.4 g (0.020 mol) of 2,6-di-*t*-butyl-4-methylphenol in 20 m*l* of benzene and 4.4 g (0.110 mol) of sodium hydroxide in 20 m*l* of water, while controlling the internal temperature at 5°C by effective stirring (nearly an emulsion) under a nitrogen atmosphere, there was slowly added, drop by drop, a solution of 6.5 g (0.0198 mol) of potassium ferricyanide in 20 m*l* of water. After the addition was completed, stirring was stopped. The benzene-layer was carefully separated under a nitrogen atmosphere with a large pipette. Immediately, a portion of the benzene solution in the large pipette was slowly added, drop by drop, to the "-$S^{\ominus}$-solution" with effective stirring at 5°C (nearly an emulsion) under a nitrogen atmosphere; meanwhile, a solution of 6.6 g (0.0205 mol) of potassium ferricyanide in 20 m*l* of water was alternately added in an approximately equivalent amount to the above benzene solution. After this alternating addition was completed, the benzene layer was separated by means of a large pipette as soon as possible. Subsequently the benzene solution which separated was allowed to stand for several hours; the crude crystalline product was isolated and then recrystallized from methanol, mp 197°C. Found: C, 64.52; H, 8.04; N, 10.98; S, 6.26%. Calcd for $C_{27}H_{40}N_4O_3S$: C, 64.80; H, 8.00; N, 11.20; S, 6.40%. UV λ_{max}^{EtOH} mμ (logε): 234.5 (4.22); 276.5 (4.03). Thiochrome test: negative, but positive after reduction with cysteine.

21) These values were disagreement with the standard value in nonpolar dilute solution becuase of the measurement in concentrated chloroform solution.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 1948—1954 (1969)

Reaction of Xanthates with *t*-Amines. VI. The Reaction Mechanism

Hiroshi Yoshida

Department of Synthetic Chemistry, Faculty of Engineering, Shizuoka University, Hamamatsu

(Received September 11, 1968)

It was previously reported that xanthate reacted with *t*-amine to give quaternary ammonium salt at room temperature, and dithiolcarbonates at elevated temperatures. Precise study showed that these reaction products are formed by the following three reactions: the alkylation of *t*-amine with xanthate affords quaternary ammonium salt and the reaction of xanthate with quaternary ammonium salt yields dithiolcarbonate, while there is transesterification between thiolesters and quaternary ammonium salt. The rate constants and equilibrium constants of these reactions were calculated.

Xanthates are known to react with ammonia, prim-, and *s*-amines to give thioncarbamates and mercaptans:[1)]

$$ROCS_2R' + HNR''_2 \rightarrow ROCSNR''_2 + R'SH$$

However, no work has yet been reported on the reaction of xanthates with *t*-amines. In previous papers[2)] the present author has reported that xanthates react with *t*-amines at room temperature to give quaternary ammonium salts, and at elevated temperatures (70—80°C) to yield dithiolcarbonates and a small amount of ammonium salts. For example, *n*-propyl methylxanthate reacts with triethylamine thus:

$$MeOCS_2\,n\text{-Pr} + Et_3N \rightarrow Et_3\overset{\oplus}{N}(Me)\overset{\ominus}{S}COSMe + Et_3\overset{\oplus}{N}(Me)\overset{\ominus}{S}COS\,n\text{-Pr} + MeSCOSMe + MeSCOS\,n\text{-Pr} + n\text{-PrSCOS}\,n\text{-Pr}$$

The present paper will deal with the formation of the products obtained by the reaction of xanthates with *t*-amines by the following three successive reactions:

i) Alkylation of *t*-amines with xanthates (to give quaternary ammonium salts).

ii) The reaction of xanthates with the quaternary ammonium salts (to yield dithiolcarbonates).

iii) Transesterification between thiolesters (xanthates and/or dithiolcarbonates) and the quaternary ammonium salts.

Results and Discussion

t-Amine, a nucleophile, reacts with ordinary carboxylic esters to yield quaternary ammonium salts.[3),4)] Alkyl acylates are cleaved at their alkyl-

oxygen bond to afford the corresponding sulfides[5-7] by means of the action of mercaptides, while thiolacylates undergo ester interchange reactions[5,6] with mercaptides as a result of the nucleophilic attack of mercaptide ions on the carbonyl group. As has previously been reported,[2d] the alkylation of *t*-amines with xanthates resembled the Menschutkin reaction. At elevated temperatures xanthates react with *t*-amines to yield the rearranged dithiolcarbonates and a small amount of ammonium salts. As is shown in Table 1, not only xanthates but also thionesters give the rearranged thiolesters when they are treated with triethylamine or with the corresponding ammonium slats. The reactivity of alkyl thionesters decreased in the order: methyl$\gg$ ethyl$>$*n*-propyl with respect to the alkyl group. When thionesters were heated under similar conditions without any amines or ammonium salts, no detectable change was observed. These preliminary experiments indicated that ammonium salts formed in the initial step attack thionesters to give thiolesters.

Alkylation of *t*-Amines with Xanthates (to give Quaternary Ammonium Salts). It has been reported that the reaction of *t*-amines with ordinary esters yields quaternary ammonium salts at elevated temperatures.[3,4] Hammett and Pfluger[3b] have reported that the rates of the methylation of trimethylamine by various esters increase with an increase in the strength of the acid. However, no work has been reported on the reaction of *t*-amines and thion- or thiol-esters. In a previous paper,[2d] the kientics of the reaction of *S*-alkyl, -aryl, and -aralkyl xanthates with various amines in benzene has been reported (Table 3). The rates of the reaction of various esters with trimethylamine are compared with those of xanthates in Table 2. The rate constants (observed or extrapolated from higher temperatures) for the quaternization of trimethylamine with methylesters in benzene at 30°C are shown in Table 3. As the table shows, thionesters are more active than the corresponding oxygen-esters. The difference in activation energy between dimethylcarbonate and dimethylthioncarbonate, and that between methyl *p*-nitrobenzoate and methyl *p*-nitrothionbenzoate, are 5.2 and 3.6 kcal/mol respectively (Table 3); therefore, the activation energy of the alkylation of trimethylamine with an ordinary ester is 4—5 kcal/mol greater than the corresponding thionester which rearranges to form the thiolester. The summation of the bond energies shows that thion-thiol rearrangement should be exothermic, amounting to

nearly 20 kcal/mol.[8] O'Connor and Nace[9a] have reported that the activation energies for the pyrolysis of the ethylcarbonate and methylxanthate of cholesterol are 41.0 and 32.9 kcal/mol respectively. This difference in activation energy (8.1 kcal/mol) is in good agreement with that between dimethyl carbonate and methyl methylxanthate for alkylation (7.7 kcal/mol. Table 3). The substitution of an electron-accepting group for the carbonyl carbon of the esters leads to an increase in the rate of alkylation (positive ρ values in Table 3). The ρ factor is +0.467 for the pyrolysis of *S*-benzyl cholesterylxanthates,[9a] and +0.82 for the alkylation of trimethylamine with *S*-benzyl methylxanthates. The difference may be due to the fact that the former is a cyclic *cis* intramolecular elimination reaction,[9c] and the latter, an S_N2. The smaller reactivity of dimethyl thioncarbonate than that of methyl methylxanthate may be due to the electron-releasing resonance effect of the methoxy group.[10]

Thus, the greater reactivity of xanthates may be based on the decreased activation energy due to the electron-accepting mercapto group and to thion-thiol rearrangement.

The Reaction of Methyl Methylxanthate (I) with Tetramethyl Ammonium Dithiocarbonate $Me_4\overset{\oplus\ominus}{N}SCOSR$ (II). The reaction product between I and trimethylamine gave no rearranged product in benzene. On the other hand, it gave dimethyldithiolcarbonate under homogeneous conditions in dimethylformamide (DMF) or dimethylsulfoxide (DMSO), even at room temperature. The rate constants of the following reactions in DMF at 30°C were determined by measuring the rates of the disappearance of I (the transesterification, described in the following section, was disregarded):

$$Me_3N + MeOCS_2Me \xrightarrow{k_2} Me_4\overset{\oplus\ominus}{N}SCOSMe \quad (1)$$

$$Me_4\overset{\oplus\ominus}{N}SCOSMe + MeOCS_2Me \xrightarrow{k_2'} Me_4\overset{\oplus\ominus}{N}SCOSMe + MeSCOSMe \quad (2)$$

The rate equations are:

$$d[X]/dt = -k_2[X][A] - k_2'[S][X]$$

$$d[S]/dt = k_2[X][A]$$

The concentrations are related thus:

$$[S] + [A] = [A_0]$$

$$[S] + [X] + [T] = [X_0]$$

where [X], [A], [S], and [T] indicate the concentrations of I, trimethylamine, II (R=Me), and dimethyl dithiolcarbonate respectively, and where $[A_0]$ or $[X_0]$ indicate the initial concentration. Put $[X_0]=[A_0]$; then, upon integration:

$$\left.\begin{aligned} x &= [(\kappa-1)/\kappa]\alpha + (1/\kappa)\ln\alpha + 1/\kappa \\ \tau &= \int_\alpha^1 \frac{d\alpha}{\alpha[(\kappa-1)\alpha + \ln\alpha + 1]} \\ \tau &= -\ln x \qquad (\kappa = 1), \end{aligned}\right\} \quad (3)$$

where $\tau=[A_0]k_2't$, $\kappa=k_2/k_2'$, $x=[X]/[X_0]$, and $\alpha=[A]/[A_0]$. x and τ, as functions of α for various κ's, can be calculated by Eq. (3); and x plotted against τ in Fig. 3.

The reaction (2) is pseudo-first-order, and the apparent first-order rate constant is proportional to the concentration of II (R=Me) (Fig. 2). The slope of the line gives k_2'. Equimolar reactions of I with trimethylamine proceed; data typical of those shown in Table 8 are plotted in Fig. 3, where they give $\kappa=0.19$. The results, summarized in Table 4, indicate that, toward I, $MeSCOS^-$ is a stronger nucleophile than trimethylamine by a factor of 5. As has been shown previously (Table 1), xanthates react with triethylamine to yield dithiolcarbonates at elevated temperatures. At lower temperatures crystalline quaternary ammonium salts have little reactivity, while at elevated temperatures they melt and dissolve in the reagent and react with xanthates. Trimethylamine reacts

II (R=Me)	DMF	30	k_2' 0.186	155

esters has been reported by many workers, almost all of them concerned with intramolecular reactions (for example, the Schönberg rearrangement[12] or the thermal rearrangement of xanthates[13]). It was confirmed that the reactions of thionesters (such as xanthates and thionbenzoates) with *t*-amines to form thiolesters are second-order and that the initially-formed thiolate ions (monoalkyl dithiolcarbonate and thiolbenzoate ions) react as strong nucleophiles with thionesters to give rearranged thiolesters.

Transesterification between Thiolesters and II. It is well known that transesterification occurs when an ester is heated with alcohol in the presence of acid or base. Although some works[5-7,14] have reported the transesterification of thiolesters, the kinetics or equilibrium has not been investigated. The reaction between II and thiolesters in benzene (heterogeneous conditions) produced no detectable change, but the mixture of II and thiolesters in DMF or DMSO came to equilibrium in a few

minutes at room temperature. Table 5 shows that the amount of ammonium salts produced depends on thiol groups and not on the structure of the thiolesters (*i.e.*, xanthate, trithiocarbonate, and dithiolcarbonate).

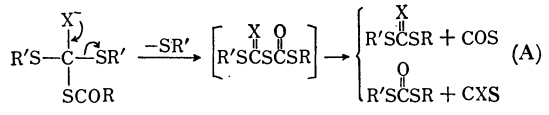
The following equilibrium can be derived from Table 5:

$$Me_4\overset{\oplus\ominus}{N}SCOSMe + (Ester)\text{-}SR \rightleftarrows Me_4\overset{\oplus\ominus}{N}SCOSR + (Ester)\text{-}SMe$$

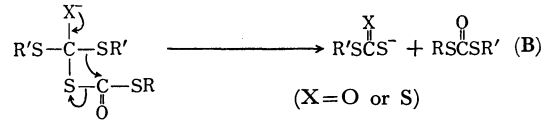
$$K = [Me_4\overset{\oplus\ominus}{N}SCOSR][(Ester)\text{-}SMe]/[Me_4\overset{\oplus\ominus}{N}SCOSMe][(Ester)\text{-}SR]$$

The slope of the straight line obtained by plotting $\log K$ *vs.* σ^* for R ($\rho^*=+2.2$) is shown in Fig. 4. The positive ρ^* value indicates that the equilibrium of the reaction depends on the relative basicities of $RSCOS^-$.[15]

The explanation that these reaction products are formed by an S_N2 attack of $RSCOS^-$ on the carbonyl carbon of the thiolester seems improbable, since the reaction of dialkyl trithiocarbonate (X=S) and II gave no trithiocarbonate ion ($RSCS_2^-$), while this ion should be formed in any reaction by mechanism (A) or (B):



(A)



(B)

The reaction of methyl *n*-propylxanthate with potassium ethylmercaptide was found to yield ethyl *n*-propylxanthate by ester interchange under similar conditions (Table 5). Thus, it seems plausible that the mercaptide ion initially formed by the reaction (C):[16]

$$RSCOS^{\ominus} \rightleftarrows RS^{\ominus} + COS \qquad (C)$$

attacks the carbonyl carbon of the thiolesters to yield transesterification products. Thiolesters do not react with monoalkyl trithiocarbonate. The

15) Although free acids RSCOSH are not known, their pK_a values should give postive ρ^* for R groups considering the data of xanthic acids [V. Hejl and J. Pecher, *Chem. Zvensti*, **21**, 261 (1967); *Chem. Abstr.*, **67**, 85514 (1967); H. Majima, *Chem. Abstr.*, **56**, 2201f (1962)] and mercaptans [D. L. Yabroff, *Ind. Eng. Chem.*, **32**, 257 (1940); M. M. Kreevoy, E. T Happer, R. E. Duvall, H. S. Wilgus, III, and L. T. Ditsch, *J. Am. Chem. Soc.*, **82**, 4899 (1960)].

16) Although in a literature [Houben-Weyl "Methoden der Organischen Chemie" 9, Georg Thieme Verlag, Stuttgart (1955), p. 807] the salt is described to be unknown, the treatment of potassium ethylmercaptide with carbonyl sulfide in DMF or in benzene was found to yield $EtSCOS^-K^+$. The structure of the salt was determined by VPC analysis of the reaction product [EtSCOSMe] with methyl iodide. This finding also seems to suggest reaction (C).

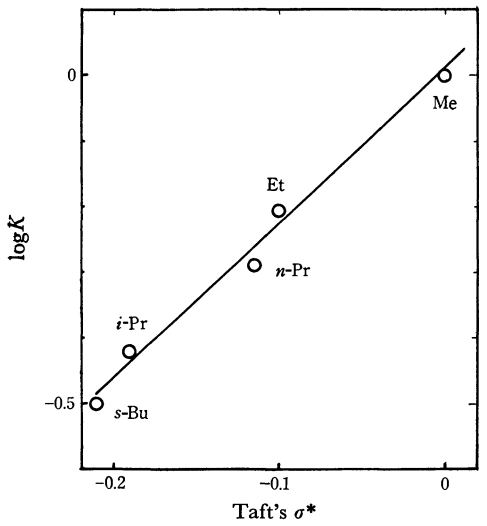


Fig. 4. The relation between Taft's σ^* and log K.

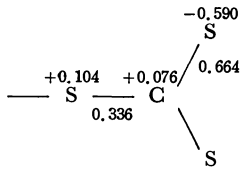
resonance energy[17] calculated by the author leads to the conclusion that the stability of the trithiocarbonate ion is greater than that of the dithiolcarbonate ion (II).

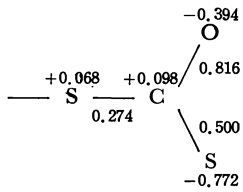
17) LCAO MO calculation of carbonate ions were carried out according to the procedure of M. J. Janssen [*Rec. Trav. Chim.*, **79**, 1066 (1960)] using following parameters.

	Coulomb integral (α_x)	Resonance integral (β_{C-x})
-S-	$\alpha+\beta$	0.6β
=S	$\alpha+0.5\beta$	
-O-	$\alpha+2.5\beta$	1.2β
=O	$\alpha+1.0\beta$	

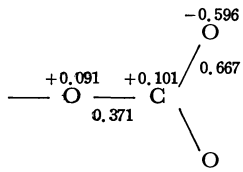
The procedure was repeated until consistent result was obtained. The results was as follows:



RE = 0.950β



RE = 0.220β



RE = 1.860β

Experimental

Materials. The newly-prepared compounds are shown in Table 6, together with the previously-reported ones.[2]

Kinetic Determination in Benzene. The accurately-weighed ester was dissolved in dry benzene. The concentration of trimethylamine in benzene was determined by titration.[18] The solution (the initial concentrations of the reagents were 0.2—0.5N) was sealed in stoppered test tubes (reactions at 25—35°C) or in ampoules (above 45°C). After appropriate times, ampoules were removed from the bath and cooled; the ammonium salts produced were collected on a glass filter, washed with ether, and then weighed. First-order rate constants with respect to esters and trimethylamine are shown in Tables 1 and 2.

The structure and purity of ammonium salts were tested as previously.[2] The newly-prepared ammonium salts are shown in Table 6. The physical constants of the *S*-methylesters obtained by the reaction of ammonium salts with methyl iodide agreed with those of authentic samples (Table 6).

Kinetic Determination in DMF. The concentrations of trimethylamine in DMF were determined by potentiometric titration,[18] while the solutions of methyl methylxanthate (I) and ammonium salts were prepared by dissolving accurately-weighed amounts of the solute in dry DMF. The solutions of ammonium salt are not stable at elevated temperatures, exhibiting a slight yellow color in a few hours at 50°C. Thus, the solutions should be prepared just before use.

The reaction rate was determined spectrometrically by measuring the rate of the disappearance of I (λ_{max} =275.5 mμ, ε=9020, ethanol). In the reaction, dimethyl dithiolcarbonate (λ_{max}=248 mμ, ε=4420, ethanol) was obtained in 60—80% yields. The reaction of I with tetramethyl ammonium dithiocarbonate $Me_4NSCOSR$ (II) was of a pseudo-first-order, and the rate constants were proportional to the concentration of II (R=Me) (Fig. 2). A typical example is shown in Table 7.

The rate constant, k_2, for the reaction of trimethylamine and I in DMF is obtained by the use of the curves shown in Fig. 3, which are drawn from data typical of those in Table 8. The data are listed in Table 4.

Determination of Equilibrium Constants. An equimolar mixture of II and thiolester (accurately weighed) in DMF (a 10% solution) was sealed in a stoppered test tube filled with nitrogen, and then left for 15 min at 50°C to let it come to equilibrium. Then the mixture was divided into two equal parts. To one part was added a large amount of a mixture of dry benzene and ether 1:1 (v/v), and the resulting precipitates (ammonium salts) were washed thoroughly with the solvent. The composition of the precipitates was determined by VPC after treating them with methyl iodide. The second part was poured into cold water and extracted with ether. The ethereal extract (thiolesters), after having been dried over sodium sulfate, was analyzed by VPC. The ratio of the products is listed in Table 5.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 1955—1958 (1969)

Reactions of Cycloalkanone Oxime *p*-Toluenesulfonates

Tadashi SATO and Hirohisa WAKATSUKA

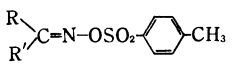
Department of Applied Chemistry, Waseda University, Shinjuku-ku, Tokyo

(Received September 24, 1968)

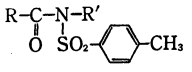
The reactions of cyclohexanone and cyclopentanone oxime *p*-toluenesulfonates were studied. It was found that cyclohexanone oxime *p*-toluenesulfonate (IIIa) afforded a tetrahydroazepine derivative (Va), while cyclopentanone oxime *p*-toluenesulfonate (X) afforded *δ*-valerolactam *p*-toluenesulfonate (XIII), when both compounds were heated in benzene.

The rearrangement of ketoxime *p*-toluenesulfonates (I) into *N*-*p*-toluenesulfonamides (II) has been known as one type of Beckmann rearrangement and has been extensively studied. The rearrangements of cyclohexanone and cyclopentanone oxime *p*-toluenesulfonates have been reported by Heldt[1] and by Grob *et al.*[2] Cyclohexanone oxime *p*-toluenesulfonate (IIIa) is thermally unstable and defragnates at room temperature, particularly when its purity is not high. In connection with our studies of pyrolysis, we carried out reactions with these compounds and obtained results different from those reported.

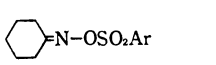
Heldt reported that when IIIa was left standing in dry chloroform at 25°C for one year, it yielded a compound (named Compound A)to which the structure IV could be assigned. He showed that Compound A melted at 124.6—125°C, and had strong bands at 1710 and 1640 cm^{-1} in its infrared spectrum.



I

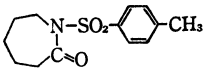


II



IIIa: Ar=H_3C-

b: Ar=



IV

We refluxed IIIa in dry benzene for 3 hr, and obtained in a 54% yield a compound (named Compound B) which showed characteristics similar to those of Compound A.*1 Compound B melted at 124°C and had strong bands at 1720 and 1640 cm^{-1} in its infrared spectrum. However, Compound B was confirmed to be 6-(3,4,5,6-tetrahydro-2*H*-azepin-7-ylamino)-hexanoic acid *p*-toluenesulfonate (Va) by the following evidence. The *p*-toluenesulfonyl moiety was assumed to be combined with the tetrahydroazepine moiety through salt-type linkage, not through sulfonamide-type linkage as is the case for the structure IV, because *p*-toluenesulfonic acid was immediately isolated as an addition compound with 2,4-dinitrophenylhydrazine (DNPH), upon the addition of a DNPH reagent[3] to Compound B. When Compound B was dissolved in 18% hydrochloric acid and the solution was concentrated *in vacuo* at room temperature, hydrochloride Vb crystallized out. Vb showed infrared bands at 1720 and 1640 cm^{-1} and had a pK_a value of 4.45. Furthermore, Vb was identical with the authentic sample prepared from *ε*-caprolactam and phosgene.[4] From the reaction

2) C. A. Grob, H. P. Fischer, W. Raudenbusch and J. Zergenyi, *Helv. Chim. Acta*, **47**, 1003 (1964).

*1 The identity of Compounds A and B was not established because neither Compound A nor its complete spectrum was available. The differences in elemental analyses between the two compounds were: C, 0.01—0.73; H, −0.02—0.07; N, 0.50—0.52%.

3) R. L. Shriner, R. C. Fuson and D. Y. Curtin, "The Systematic Identification of Organic Compounds," 4th ed., John Wiley & Sons, New York, N. Y. (1956), p. 219.

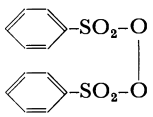
4) H. R. Meyer, *Kunststoffe-Plastics*, **3**, 160 (1956); *Chem. Abstr.*, **52**, 11781f (1958).

mixture of IIIa in benzene we isolated as by-products ε-caprolactam, *p*-toluenesulfonic anhydride (VI), and a compound with a mp of 123°C (named Compound C). Compound C showed only one absorption band at 1685 cm^{-1}, in the carbonyl region in the infrared spectrum; it was thus obviously different from Compounds A and B. The structure IV was assigned to Compound C because it was identical with the product obtained by the thermal dehydration of 6-(*p*-toluenesulfonamido)-hexanoic acid (VII).

The same results were obtained when chloroform or carbon tetrachloride was used in place of benzene as the solvent for the reaction of IIIa.

When cyclohexanone oxime benzenesulfonate (IIIb) was refluxed in benzene for 3 hr, a benzenesulfonate derivative, Vc, corresponding to Va was obtained. Vc was converted into the hydrochloride Vb by treating it with 18% hydrochloric acid. Diphenyl sulfone (VIII) was isolated in this case as the sole by-product. It was found that benzenesulfonyl peroxide (IX), when refluxed in benzene, afforded VIII. These facts induced us to suggest that the reaction IIIb→Vc proceeded through a

VIII

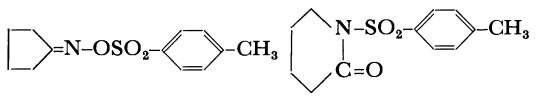


IX

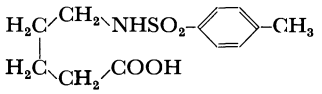
radical fission in IIIb, although no further experimental evidence was obtained. The same type of reaction as those of IIIa→Va and IIIb→Vc has been reported by Oxley and Short[5] with benzophenone oxime *p*-toluenesulfonate.

The reaction of cyclopentanone oxime *p*-toluenesulfonate (X) was studied next. Grob and his coworkers[2] reported that when X was allowed to stand for 3.5 hr at 23°C in 80% ethanol containing an equivalent amount of triethylamine, it yielded δ-valerolactam and *N*-*p*-toluenesulfonyl-δ-valerolactam (XI, mp 144—145°C). Heldt[1] reported that the heating of X in glacial acetic acid at 35°C for 2 hr yielded a compound with a mp of 151—152°C (named Compound D); he assigned the structure XII to this compound.

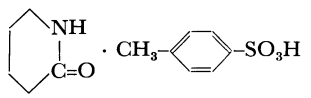
When X was refluxed in benzene for 3 hr, an oil was obtained which, on standing in the air, crystallized to give a compound with a mp of 147°C (named Compound E). Compounds D and E were found to be identical by synthesizing Compound D according to the method reported by Heldt. It was found, however, that the assignment of the structure XII to Compound D, made by Heldt, was unacceptable, because the authentic compound with the structure XII (mp 92°C, named Compound F) which was prepared from 5-aminopentanoic acid



X XI



XII



XIII

XIV

and *p*-toluenesulfonyl chloride was different from Compounds D and E*[2]. The structure XII for Compound F was confirmed by the fact that Compound F afforded XI (mp 144—145°C), upon thermal dehydration under the same conditions as those used for the dehydration of VII into IV. The infrared spectrum of XI was identical with that of IV.

It was concluded that the structure XIII should be assigned to Compounds D and E, because Compound E was prepared by just mixing δ-valerolactam and *p*-toluenesulfonic acid in acetone and afforded XIV on hydrolysis.

Reactions with other types of ketoxime *p*-toluenesulfonates are now being studied.

Experimental

Reaction of Cyclohexanone Oxime *p*-Toluenesulfonate (IIIa) in Benzene. A solution of cyclohexanone oxime *p*-toluenesulfonate (IIIa)[1] (5 g) in 50 m*l* of dry benzene was refluxed for 4 hr. The solution gradually turned yellow and then brown. The benzene was then evaporated *in vacuo*, and water was added. 0.3 g of a solid material was filtered out (solid: named M), and the filtrate was concentrated *in vacuo*. Acetone was added, and the solution was left to stand overnight. A solid material appeared which was recrystallized from a mixture of dioxane and 2-methoxyethanol to afford 2 g of pure Va, mp 124°C.

Found: C, 57.16; H, 7.57; N, 7.12%. Calcd for $C_{19}H_{30}O_5N_2S$: C, 57.29; H, 7.54; N, 7.04%.

IR spectrum (cm^{-1}): 1720 (s), 1640 (vs), 1217 (vs), 1160 (vs).

When a small amount of Va was added to the 2,4-dinitrophenylhydrazine reagent (DNPH),[3] an addition compound of DNPH and *p*-toluenesulfonic acid, mp

5) P. Oxley and W. F. Short, *J. Chem. Soc.*, **1948**, 1514.

*2 Heldt[1] reported that when δ-valerolactam was treated successively with 95% sulfuric acid, with aqueous sodium hydroxide, and with *p*-toluenesulfonyl chloride, crystals with a melting point of 143.5—144.5°C resulted. To these crystals he assigned a structure of XII in the monohydrated form. We followed his method, but we obtained Compound F, mp 92°C.

213°C, was obtained. This material did not show a melting point depression on admixture with an authentic sample of the addition compound.

The solid M obtained above was immediately recrystallized from ligroin to afford 0.2 g of crystals; mp 127°C (mother liquor: named N). The compound was found to be identical with the authentic sample of *p*-toluenesulfonic anhydride (VI)[6] from a study of its infrared spectrum and by a mixed-melting-point determination. The mother liquor N was then evaporated *in vacuo*, and water was added. The solution was kept overnight at room temperature, and the water was evaporated *in vacuo*. Ligroin was added to the residue and a small amount of an insoluble material (*p*-toluenesulfonic acid) was removed with charcoal. The ligroin was evaporated *in vacuo*, and a solid material was obtained. The material was recrystallized from ligroin to afford a compound with a mp of 121°C. The compound was found to be *N*-*p*-toluenesulfonyl-ε-caprolactam (IV) by a study of its infrared spectrum and by a mixed-melting-point determination with the authentic sample.

The Conversion of Va into the Hydrochloride Vb. A solution of Va (1 g) in 10 m*l* of 18% hydrochloric acid was concentrated *in vacuo* at temperature below 40°C, and then acetone was added to the residue. The solid material which appeared was recrystallized from a mixture of dioxane and 2-methoxyethanol to afford Vb, mp 150°C. This compound was found to be identical with the authentic sample of Vb by a study of its infrared spectrum and by a mixed-melting-point determination.

6-(3,4,5,6-Tetrahydro-2*H*-azepin-7-ylamino)-hexanoic Acid Hydrochloride (Vb). This compound was prepared in the following modification of a method described in the literature.[4] To a stirred solution of phosgene (4 g) in 10 m*l* of chloroform, there was added, drop by drop, ε-caprolactam (4.5 g) in 10 m*l* of chloroform at a temperature between 30°C and 40°C. After the addition was complete, the reaction mixture was stirred for an additional 3 hr at a temperature between 30°C and 40°C, and then the chloroform was evaporated *in vacuo*. When a small amount of ether was added, a solid appeared. This solid was filtered and dissolved in 50 m*l* of 18% hydrochloric acid. The solution was then refluxed for 30 min and concentrated *in vacuo*. Upon the addition of acetone to the residue, a solid was obtained which was recrystallized from a mixture of dioxane and 2-methoxyethanol to afford Vb, mp 148°C (lit[4] mp 152—153°C).

Found: C, 54.88; H, 8.85; N, 10.53%. Calcd for $C_{12}H_{22}N_2O_2 \cdot HCl$: C, 54.86; H, 8.76; N, 10.68%.

IR spectrum (cm^{-1}): 1730 (s), 1645 (vs), 1155 (vs).

NMR spectrum (in CF_3COOH): δ 7.6 (broad, 2H), δ 3.5 (multiplet, 4H), δ 2.7 (multiplet, 4H), δ 1.8 (multiplet, 12H).

pK_a: 4.45.

***N*-*p*-Toluenesulfonyl-ε-caprolactam (IV).** 6-(*p*-Toluenesulfonamido)hexanoic acid (VII)[1] (2 g) was heated in a small still under a vacuum (1 mmHg) at 125°C for 15 hr. The residue was then stirred in a 5% sodium bicarbonate solution for 2 days. The insoluble material was recrystallized from a mixture of water and acetone to afford a small amount of IV, mp 123°C.

Found: C, 58.43; H, 6.31; N, 5.32%. Calcd for $C_{13}H_{17}NO_3S$: C, 58.43; H, 6.34; N, 5.24%.

IR spectrum (cm^{-1}): 1685 (vs), 1354 (vs), 1170 (vs).

Cyclohexanone Oxime Benzenesulfonate (IIIb). To a stirred solution of cyclohexanone oxime (5.6 g) in 10 m*l* of pyridine, benzenesulfonyl chloride (8.8 g) in 15 m*l* of pyridine was added, drop by drop, at such a rate that the reaction temperature did not exceed 0°C. After the addition was complete, the reaction mixture was stirred for an additional 3 hr at 0°C. The reaction mixture was poured into a mixture of ice and sulfuric acid (containing 8 g of sulfuric acid). The yellow oil was immediately extracted with 80 m*l* of benzene. The benzene solution was washed with water two times and dried over anhydrous sodium sulfate in a refrigerator overnight. The solution was then used directly for the next process.

Reaction of Cyclohexanone Oxime Benzenesulfonate (IIIb) in Benzene. The benzene solution of cyclohexanone oxime benzenesulfonate (IIIb) obtained above was refluxed for 4 hr. The benzene was then evaporated *in vacuo*, and water was added. The solid material was filtered out (solid: named P), and the filtrate was evaporated *in vacuo*. Acetone was added to the residue, and the solution was left to stand overnight. The solid material thus obtained was recrystallized from a mixture of dioxane and 2-methoxyethanol to afford 2.4 g of Vc, mp 99°C.

Found: C, 56.27; H, 7.26; N, 7.06%. Calcd for $C_{18}H_{28}N_2O_5S$: C, 56.25; H, 7.30; N, 7.30%.

IR spectrum (cm^{-1}): 1720 (s), 1640 (vs), 1215 (vs), 1165 (vs), 1125 (vs).

Compound Vc was converted to the hydrochloride Vb in the same way as was Va converted into Vb.

The solid P was recrystallized from ligroin to afford a small amount of diphenyl sulfone (VIII), mp 121°C (lit[7] mp 125°C).

Found: C, 66.14; H, 4.60%. Calcd for $C_{12}H_{10}O_2S$: C, 66.06; H, 4.59%.

The infrared spectrum of this material was identical with the published spectrum of VIII.[8]

Reaction of Benzenesulfonyl Peroxide (IX) in Benzene. A solution of benzenesulfonyl peroxide (IX)[9] (3 g) in 30 m*l* of benzene was refluxed for 2 hr and then evaporated *in vacuo*. The residue was recrystallized from ligroin to afford 1 g of diphenyl sulfone (VIII), mp 121°C.

Reaction of Cyclopentanone Oxime *p*-Toluenesulfonate (X) in Benzene. A solution of cyclopentanone oxime *p*-toluenesulfonate (X)[1] (2 g) in 20 m*l* of dry benene was refluxed for 3 hr. The benzene was then evaporated *in vacuo*. The solid material which appeared when the solution was left in the air was recrystallized from dioxane to afford 1.9 g of δ-valerolactam *p*-toluenesulfonate (XIII), mp 147°C. The compound was found to be identical with the authentic sample by a study of its infrared spectrum and by mixed-melting-point determination.

δ-Valerolactam *p*-Toluenesulfonate (XIII). To a solution of δ-valerolactam (2.3 g) in 10 m*l* of acetone

6) H. Meyer, *Monatsh. Chem.*, **34**, 573 (1913).

there was added a solution of *p*-toluenesulfonic acid (4 g) in 20 m*l* of acetone. The solid material which appeared was recrystallized from dioxane to afford 6 g of XIII, mp 147°C.

Found: C, 53.34; H, 6.56; N, 4.79%. Calcd for $C_{12}H_{17}NO_4S$: C, 53.14; H, 6.30; N, 5.17%.

IR spectrum (cm^{-1}): 2300 (w), 1685 (s), 1220 (vs), 1120 (vs), 1025 (vs), 1000 (s).

Reaction of Cyclopentanone Oxime *p*-Toluenesulfonate (X) in Acetic Acid. This reaction was carried out under conditions identical with those described by Heldt.[1] Crystals with a mp of 147°C were obtained; they were identical with the authentic sample of XIII. Repeated recrystallizations from glacial acetic acid did not raise the melting point.[1]

Hydrolysis of δ-valerolactam *p*-Toluenesulfonate (XIII). A solution of δ-valerolactam *p*-toluenesulfonate (XIII) (2 g) in 20 m*l* of water was refluxed for 2 hr. The water was then evaporated *in vacuo*; an oily residue, which soon solidified, was recrystallized from dioxane to afford 2 g of 5-aminopentanoic acid *p*-toluenesulfonate (XIV), mp 142°C. The compound was found to be identical with the authentic sample of XIV by a study of its infrared spectrum and by a mixed-melting-point determination.

5-Aminopentanoic Acid *p*-Toluenesulfonate(XIV). δ-Valerolactam (1 g) and *p*-toluenesulfonic acid (2 g) were dissolved in 50 m*l* of water. The solution was refluxed for 5 hr, and the water was evaporated *in vacuo*. An oily material soon solidified. Recrystallization from dioxane afforded 3 g of XIV, mp 142—142.5°C.

Found: C, 49.87; H, 6.73; N, 4.55%. Calcd for $C_{12}H_{19}NO_5S$: C, 49.83; H, 6.57; N, 4.84%.

IR spectrum (cm^{-1}): 1700 (s), 1215 (vs), 1164 (vs), 1115 (s), 1025 (s), 1000 (s), 810 (m).

5-(*p*-Toluenesulfonamido)pentanoic Acid (XII). To a solution of 5-aminopentanoic acid hydrochloride[10] (2.5 g) in a sodium hydroxide solution (1.4 g of sodium hydroxide in 7.5 m*l* of water), there was added a solution of *p*-toluenesulfonyl chloride (3.5 g) in 15 m*l* of acetone below 30°C. The solution was then stirred for 3 hr and neutralized with hydrochloric acid. The solution was freezing-dried, and the residue was extracted with ethyl acetate. After the ethyl acetate had been evaporated, the residual solid was recrystallized from water. Crystals with a mp of 92°C (1.25 g) were obtained.

Found: C, 53.44; H, 6.38; N, 5.21%. Calcd for $C_{12}H_{17}NO_4S$: C, 53.14; H, 6.30; N, 5.17%.

IR spectrum (cm^{-1}): 1686 (s), 1330 (s), 1155 (vs).

***N*-*p*-Toluenesulfonyl-δ-valerolactam (XI).** This compound was prepared by the dehydration of XII in the same way as was VII dehydrated into IV. Recrystallization from a mixture of benzene and ligroin afforded crystals of XI, mp 140°C (lit[2] mp 145°C).

IR spectrum: 1675 (vs), 1350 (vs), 1170 (vs), 825 (s), 675 (s).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 1959—1963 (1969)

Kinetic Study of the Polymerization of Diallyl Carbonate*1

Akira MATSUMOTO, Katsutoshi TAKASHIMA and Masayoshi OIWA

Department of Applied Chemistry, Faculty of Engineering, Kansai University, Senriyama, Suita-shi, Osaka

(Received October 2, 1968)

The polymerization of diallyl carbonate was carried out at 60°C, benzoyl peroxide being used as the initiator; here it has been discussed kinetically from the point of view of cyclopolymerization. The rate of polymerization, R_p, was not proportional to the square root or the first power of the initiator concentration, (I), but $R_p/(I)^{1/2}$ and $(I)^{1/2}$ bore a linear relationship. The rate of polymerization, the residual unsaturation, and the degree of polymerization decreased with a decrease in the monomer concentration. The relation between the rate of polymerization over the degree of polymerization, $R_p/\bar{P}_{n,0}$ and the monomer concentration, (M), was also linear, as in $R_p/(I)^{1/2}$ and $(I)^{1/2}$. The ratio of the rate constant of the unimolecular cyclization reaction to that of the bimolecular propagation reaction of the uncyclized radical, K_c, was estimated to be 4.0 mol/*l* from the dependence of the residual unsaturation on the monomer concentration.

It is well known that diallyl-compounds undergo cyclopolymerization.[1-9] It seems, however, that there have been few detailed studies of kinetic treatment on the basis of cyclopolymerization.

Holt and Simpson[1] have studied, with a number of diallyl esters, the statistical theory of gelation; they have found that the conversion at the gelation point was greater than would be calculated for the formation of networks from tetrafunctional monomers, and that the divergence from theory could be partly explained as resulting from a loss of unsaturation by cyclization. In their report they also proposed a reaction scheme for the polymerization of the diallyl ester; however, the kinetics based on the scheme were not clarified in detail, for their consideration contained the assumption that the reactivities of the uncyclized radical with an adjacent pendant double bond and of the cyclized radical were equivalent.

On the other hand, we have presented in detail the kinetics of the polymerization of diallyl phthalate;[10] in this paper the two radicals mentioned above were individually treated.

In the present experiment, the polymerization of diallyl carbonate was carried out; by employing the kinetic equations derived in a previous paper, we will kinetically discuss our results from the standpoint of cyclopolymerization.

Experimental

Materials. The diallyl carbonate was prepared by the ester exchange reaction of diethyl carbonate with allyl alcohol according to the procedure of Adelson and Dannenberg.[11] A portion of clean sodium (about 4 g) was cut into small pieces and then added to 230 g of absolute allyl alcohol. After all the sodium had been dissolved, 120 g of diethyl carbonate was added; the mixture was refluxed under a Vigreux column, and then ethyl alcohol was taken off overhead. The residue was taken up in 100 m*l* of benzene, and water-washed several times, after which the benzene was distilled off. The residue was distilled under reduced pressure and then redistilled just before use; bp 90—91°C/50 mmHg, d_4^{20} 0.969 (lit,[11] bp 95—97°C/57—61 mmHg). The purity of the diallyl carbonate was confirmed by the complete disappearance of the absorption due to the ethyl group in its NMR spectrum.

The benzoyl peroxide (BPO) was purified by repeated precipitations from a chloroform solution by the addition of methanol.

The benzene was washed thoroughly with concentrated sulfuric acid and then with distilled water until it became neutral; it was then dried on calcium chloride and distilled over metallic sodium.

Polymerization Procedure. Polymerizations were carried out in glass ampoules (10—50 ml capacity), using dry benzene as the solvent and BPO as the initiator. Measured amounts of diallyl carbonate, BPO, and benzene were placed in a glass ampoule, which was then degassed twice in the usual manner and flushed with nitrogen. The ampoule was then sealed under a vacuum and transferred into a thermostat regulated at the desired temperature.

After a definite reaction time, the ampoule was removed from the thermostat and the polymer was separated by pouring the contents into a tenfold volume of methanol containing hydroquinone, and also by centrifuging.

The polymer thus obtained was then washed repeatedly with methanol and dried *in vacuo* until a constant weight was attained. The conversion was calculated on the weight of the dry polymer obtained.

The polymer was then purified by dissolving it in benzene and by subsequent reprecipitation in methanol.

Analyses of the Polymer. The residual unsaturation of the purified polymer was determined by the method of Simpson *et al.*[12]; the polymer was dissolved in benzene, saponified in excess alcoholic potassium hydroxide, and neutralized with hydrochloric acid, and then the free allyl alcohol was determined by the bromide-bromate technique. Tests on pure diallyl esters showed that this could be done within an estimated error of ±1.5%. The results were expressed as percentages of pure diallyl carbonate.

The molecular weight of the polymer was measured with a vapor-pressure osmometer, Hewlett Packard 302.

Results and Discussion

Kinetics of the Diallyl Ester. In a previous paper,[10] the kinetics of the polymerization of diallyl phthalate was discussed in detail on the basis of cyclopolymerization; the kinetic equations were derived by assuming steady-state conditions, conditions which were based on the following reaction scheme:

Decomposition: $\mathrm{I} \longrightarrow 2\mathrm{R}\cdot$ $2k_d(\mathrm{I})$

Initiation: $\mathrm{R}\cdot + \mathrm{M} \longrightarrow \mathrm{M}\cdot$ $2k_i(\mathrm{R}\cdot)(\mathrm{M})$

Cyclization: $\mathrm{M}\cdot \longrightarrow \mathrm{M_c}\cdot$ $k_c(\mathrm{M}\cdot)$

Propagation:
$\mathrm{M}\cdot + \mathrm{M} \longrightarrow \mathrm{M}\cdot$ $2k_p(\mathrm{M}\cdot)(\mathrm{M})$
$\mathrm{M_c}\cdot + \mathrm{M} \longrightarrow \mathrm{M}\cdot$ $2k_{cp}(\mathrm{M_c}\cdot)(\mathrm{M})$

Chain transfer:
$\mathrm{M}\cdot + \mathrm{M} \longrightarrow \mathrm{P} + \mathrm{M}\cdot$ $2k_{t_1}(\mathrm{M}\cdot)(\mathrm{M})$
$\mathrm{M_c}\cdot + \mathrm{M} \longrightarrow \mathrm{P} + \mathrm{M}\cdot$ $2k_{t_2}(\mathrm{M_c}\cdot)(\mathrm{M})$

Re-initiation: $\mathrm{M}\cdot^* + \mathrm{M} \longrightarrow \mathrm{M}\cdot$ $2k_i'(\mathrm{M}\cdot^*)(\mathrm{M})$

Stabilization: $\mathrm{M}\cdot^* + \mathrm{M}\cdot^* \longrightarrow \mathrm{M}^* - \mathrm{M}^*$ $k_{t_3}(\mathrm{M}\cdot^*)^2$

where I denotes an initiator; M, a diallyl ester monomer; P, the polymer; R·, the initiator radical; M·, the uncyclized radical; $\mathrm{M_c}\cdot$, the cyclized radical, and M·*, the degraded radical.

If a steady state is assumed for the different types of radicals, Eqs. (1)—(4) can be obtained:

$$(\mathrm{R}\cdot) = fk_d(\mathrm{I})/k_i(\mathrm{M}) \tag{1}$$

$$(\mathrm{M}\cdot) = \frac{2fk_d(\mathrm{I}) + 2k_i'(2fk_d(\mathrm{I})/k_{t_3})^{1/2}(\mathrm{M})}{2k_{t_1}(\mathrm{M}) + k_ck_{t_2}/(k_{cp} + k_{t_2})} \tag{2}$$

$$(\mathrm{M_c}\cdot) = \frac{\{k_c/2(k_{cp} + k_{t_2})(\mathrm{M})\}\{2fk_d(\mathrm{I}) + 2k_i'(2fk_d(\mathrm{I})/k_{t_3})^{1/2}(\mathrm{M})}{2k_{t_1}(\mathrm{M}) + k_ck_{t_2}/(k_{cp} + k_{t_2})} \tag{3}$$

$$(\mathrm{M}\cdot^*) = (2fk_d(\mathrm{I})/k_{t_3})^{1/2} \tag{4}$$

The rate and the degree of polymerization were then obtained as Eqs. (5) and (6), in which it was assumed that the dimer, M*–M*, produced by stabilization was present in the polymer recovered.

$$\begin{aligned} R_p &= 2k_i(\mathrm{R}\cdot)(\mathrm{M}) + 2(k_p + k_{t_1})(\mathrm{M}\cdot)(\mathrm{M}) \\ &\quad + 2(k_{cp} + k_{t_2})(\mathrm{M_c}\cdot)(\mathrm{M}) + 2k_i'(\mathrm{M}\cdot^*)(\mathrm{M}) \\ &= \{2fk_d(\mathrm{I}) + 2k_i'(2fk_d(\mathrm{I})/k_{t_3})^{1/2}(\mathrm{M})\} \\ &\quad \times \left\{1 + \frac{2(k_p + k_{t_1})(\mathrm{M}) + k_c}{2k_{t_1}(\mathrm{M}) + k_ck_{t_2}/(k_{cp} + k_{t_2})}\right\} \end{aligned} \tag{5}$$

$$\begin{aligned} \bar{P}_{n,o} &= R_p/\{2k_{t_1}(\mathrm{M}\cdot)(\mathrm{M}) + 2k_{t_2}(\mathrm{M_c}\cdot)(\mathrm{M}) + k_{t_3}(\mathrm{M}\cdot^*)^2\} \\ &= \left\{1 + \frac{2(k_p + k_{t_1})(\mathrm{M}) + k_c}{2k_{t_1}(\mathrm{M}) + k_ck_{t_2}/(k_{cp} + k_{t_2})}\right\} \\ &\quad \times \left\{\frac{fk_d(\mathrm{I}) + k_i'(2fk_d(\mathrm{I})/k_{t_3})^{1/2}(\mathrm{M})}{2fk_d(\mathrm{I}) + k_i'(2fk_d(\mathrm{I})/k_{t_3})^{1/2}(\mathrm{M})}\right\} \end{aligned} \tag{6}$$

Here f denotes the efficiency of the initiation of the chain radicals by R·.

On the other hand, the rate of the formation of the pendant double bonds in the polymer is given by:

$$\begin{aligned} \mathrm{d}m/\mathrm{d}t &= 2k_i(\mathrm{R}\cdot)(\mathrm{M}) + 2k_p(\mathrm{M}\cdot)(\mathrm{M}) - k_c(\mathrm{M}\cdot) \\ &\quad + 2k_{cp}(\mathrm{M_c}\cdot)(\mathrm{M}) + 4k_{t_1}(\mathrm{M}\cdot)(\mathrm{M}) \\ &\quad + 4k_{t_2}(\mathrm{M_c}\cdot)(\mathrm{M}) + 2k_i'(\mathrm{M}\cdot^*)(\mathrm{M}) \\ &= \{2fk_d(\mathrm{I}) + 2k_i'(2fk_d(\mathrm{I})/k_{t_3})^{1/2}(\mathrm{M})\} \\ &\quad \times \left\{2 + \frac{2(k_p + k_{t_1})(\mathrm{M})}{2k_{t_1}(\mathrm{M}) + k_ck_{t_2}/(k_{cp} + k_{t_2})}\right\} \end{aligned} \tag{7}$$

By combining Eqs. (5) and (7), the following equation was obtained for evaluating K_c, the probability of cyclization which is characteristic of each monomer.

$$\left(F - \frac{2\beta}{1 + 2\beta}\right)^{-1} = \frac{(1 + 2\alpha)(1 + 2\beta)}{1 + 3\alpha + 2\alpha\beta} + \frac{(1 + 2\beta)^2}{2(1 + 3\alpha + 2\alpha\beta)(1 + \beta)} \cdot K_c \cdot \frac{1}{(\mathrm{M})} \tag{8}$$

12) W. Simpson, T. Holt and R. J. Zetie, *J. Polymer Sci.*, **10**, 489 (1953).

where F is the ratio of the amount of the residual pendant double bonds in the polymer to that of the polymerized diallyl ester monomer, $dm/d(M)$, while α, β, and K_c are k_{t1}/k_p, k_{t2}/k_{cp}, and k_c/k_p respectively.

If the kinetic chain length is sufficiently large and if the dimer, M*–M*, produced by stabilization is not present in the polymer recovered, the loss of the monomer by the initiation, chain transfer, and re-initiation reactions is negligible compared with that by the propagation reaction. The above equations may, therefore, be simplified as follows:

$$R_p = 2k_p(M\cdot)(M) + 2k_{cp}(M_c\cdot)(M)$$
$$= \{2fk_d(I) + 2k_i'(2fk_d(I)/k_{t3})^{1/2}(M)\} \times \left\{\frac{2k_p(M) + k_ck_{cp}/(k_{cp}+k_{t2})}{2k_{t1}(M) + k_ck_{t2}/(k_{cp}+k_{t2})}\right\} \quad (9)$$

$$\bar{P}_{n,o} = R_p/\{2k_{t1}(M\cdot)(M) + 2k_{t2}(M_c\cdot)(M)\}$$
$$= \frac{2k_p(M) + k_ck_{cp}/(k_{cp}+k_{t2})}{2k_{t1}(M) + k_ck_{t2}(k_{cp}+k_{t2})} \quad (10)$$

$$dm/dt = 2k_p(M\cdot)(M) - k_c(M\cdot) + 2k_{cp}(M_c\cdot)(M)$$
$$= \{2fk_d(I) + 2k_i'(2fk_d(I)/k_{t3})^{1/2}(M)\} \times \left\{\frac{2k_p(M) - k_ck_{t2}/(k_{cp}+k_{t2})}{2k_{t1}(M) + k_ck_{t2}/(k_{cp}+k_{t2})}\right\} \quad (11)$$

From Eqs. (9) and (11) we obtain:

$$(1-F)^{-1} = \frac{1}{1+\beta} + \frac{2}{K_c}\cdot(M) \quad (12)$$

The combination of Eqs. (9) and (10) gives:

$$R_p/\bar{P}_{n,o} = 2fk_d(I) + 2k_i'(2fk_d(I)/k_{t3})^{1/2}(M) \quad (13)$$

Polymerization Results. The bulk polymerization of diallyl carbonate was investigated under different initiator concentrations at 60°C; the time-conversion curves are shown in Fig. 1. The initial rates of polymerization as calculated from the slope of the straight lines shown in Fig. 1 are summarized in Table 1; they are not proportional to the square root or to the first power of the initiator concentration, as had been expected from Eq. (9).

Table 1. Influence of the initiator on the rate of polymerization of diallyl carbonate (in bulk, at 60°C)

(I) mol/l	$R_p\times10^5$ mol/l·sec	$(R_p/(I)^{1/2})\times10^5$ (mol/l)$^{1/2}$·sec^{-1}	$(R_p/(I))\times10^5$ sec^{-1}
0.4	6.84	10.24	16.2
0.2	3.64	8.13	18.2
0.1	2.05	6.47	20.5
0.06	1.44	5.91	24.1

The influence of the monomer concentration was studied by measuring the rate of polymerization, the residual unsaturation, and the degree of poly-

Table 2. Results of polymerization of diallyl carbonate at 60°C ((BPO)=0.2 mol/l, in benzene)

(M) mol/l	$R_p\times10^5$ mol/l·sec	R_{us}[a]	$\bar{P}_{n,o}$[b]	$(R_p/\bar{P}_{n,o})\times10^7$ mol/l·sec
6.82	3.64	0.379	77	4.72
4.54	3.12	0.341	75	4.16
3.41	2.47	0.306	67	3.69
2.27	2.05	0.253	63	3.25
1.70	1.82	0.237	56	3.25
1.14	—	0.224	51	—

a) The residual unsaturation is the degree of unsaturation of the molecule expressed as a percentage of pure diallyl carbonate and was obtained by the analysis of the polymer less than 10% conversion.

b) The initial degree of polymerization was obtained by the extrapolation from the experimental results shown in Fig. 2.

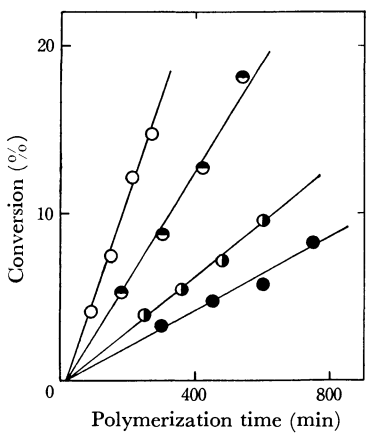

Fig. 1. Time-conversion curves in the bulk polymerization of diallyl carbonate at 60°C.
(I)=0.4(○), 0.2(◓), 0.1(◑), 0.06(●) mol/l

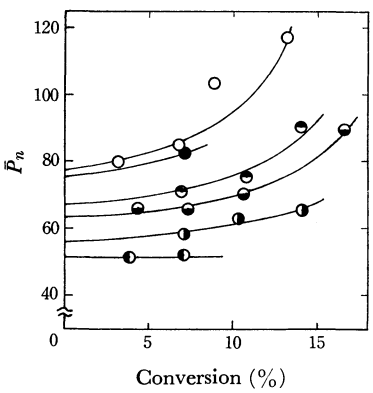

Fig. 2. Dependence of the degree of polymerization on conversion.
Polymerization temperature, 60°C
(I)=0.2 mol/l; (M)=6.82(○), 4.54(●), 3.41(◓), 2.27(◒), 1.70(◑), 1.14(◐) mol/l

merization at a constant initiator concentration ((I)=0.2 mol/l) at 60°C. The results obtained are given in Table 2.

The conversion dependence of the degree of polymerization is shown in Fig. 2. It had a tendency to increase with an increase in the conversion, and to become smaller with a decrease in the monomer concentration. Similar tendencies were observed in the previous work[10] for the polymerization of diallyl phthalate. These results may be attributed to an increase in the probability of the crosslinking reaction as the polymerization proceeds.

The values of the initial degree of polymerization, $\bar{P}_{n,o}$, as extrapolated from the experimental results shown in Fig. 2, are plotted against the monomer concentration in Fig. 3.

In Fig. 4, the relation between the residual unsaturation of the polymer, R_{us}, and the monomer concentration is plotted. Both $\bar{P}_{n,o}$ and R_{us} tend to decrease with a decrease in the monomer concentration.

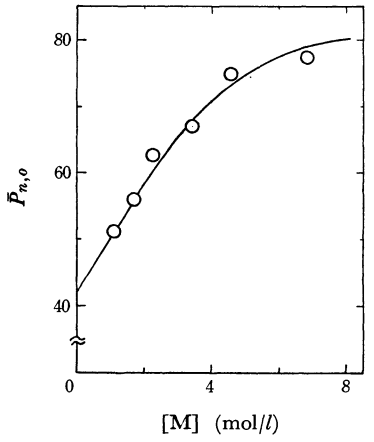

Fig. 3. Dependence of the initial degree of polymerization on monomer concentration.
Polymerization temperature, 60°C, (I)=0.2 mol/l

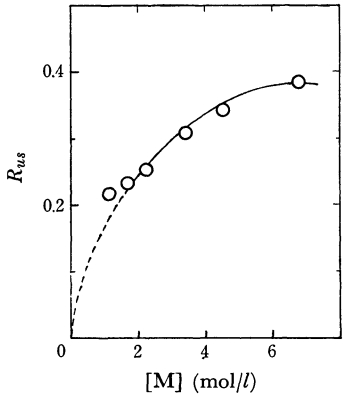

Fig. 4. Relation between the residual unsaturation and the monomer concentration.
Polymerization temperature, 60°C, (I)=0.2 mol/l

Also, as is shown in Figs. 2 and 3 and in Table 2, the initial degree of polymerization was sufficiently large; therefore, as has been mentioned above, the simplified kinetic equations, *e. g.*, Eqs. (9)—(12), can be used instead of the more elaborate ones, *e. g.*, Eqs. (5), (6) and (8), for the polymerization of diallyl carbonate.

Dependence of the Degree of Polymerization on the Initiator and Monomer Concentrations. From Eq. (10) it may be kinetically expected that the degree of polymerization will be independent of the initiator concentration. The degree of polymerization of the polymers obtained under different initiator concentrations, *e. g.*, (I)=0.4, 0.2, 0.1, and 0.06 mol/l, were determined to be 86, 82, 86, and 83 respectively; they were nearly identical, regardless of the initiator concentration. The polymers analyzed were all of about 5% conversion. This agreement between the kinetics and the experimental results may support the idea that the use of the simplified kinetic equations is justifiable.

On the other hand, the dependence of the initial degree of polymerization on the monomer concentration is shown in Fig. 3. By comparing the results with Eq. (10), we obtained the following results : $(\bar{P}_{n,o})_{M\to 0}=k_{cp}/k_{t2}\simeq 42$, $(\bar{P}_{n,o})_{M\to\infty}=k_p/k_{t1}\simeq 80$. These results suggest that the reactivities of the uncyclized radical and the cyclized radical are not equivalent. If the reactivities of the two radicals are equivalent, as has been shown by Holt and Simpson,[1] the degree of polymerization should be independent of the monomer concentration.

Influence of the Initiator and Monomer Concentrations on the Rate of Polymerization. When the monomer concentration is kept constant and the initiator concentration is varied, it may be kinetically expected from Eq. (9) that $R_p/(\mathrm{I})^{1/2}$ *vs.*

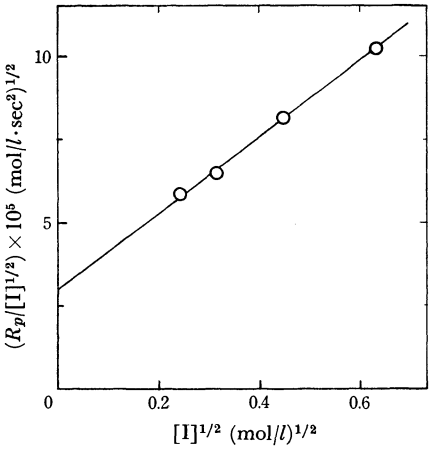

Fig. 5. Plot of $R_p/(\mathrm{I})^{1/2}$ *vs.* $(\mathrm{I})^{1/2}$.
Polymerization temperature, 60°C
(M)=6.82 mol/l

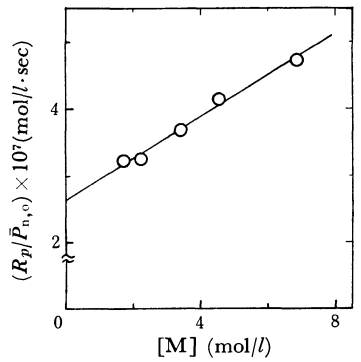

Fig. 6. Plot of $R_p/\bar{P}_{n,o}$ *vs.* (M).
Polymerization temperature, 60°C
(I)=0.2 mol/l

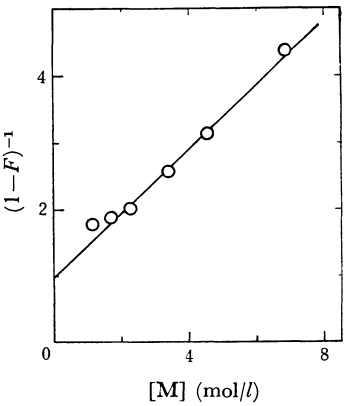

Fig. 7. Plot of $(1-F)^{-1}$ *vs.* (M).
Polymerization temperature, 60°C
(I)=0.2 mol/l

$(I)^{1/2}$ will be a straight line.*2

Similarly, if the initiator concentration is kept constant and the monomer concentration is varied, a linear relationship between $R_p/\bar{P}_{n,o}$ and (M) may be expected from Eq. (13).

These results are plotted in Figs. 5 and 6, in which the fit of the experimental data to the linear relationship is fairly good. From the slope and the intercept of the straight line shown in Fig. 5, fk_d and $k_i'/k_{t3}^{1/2}$ were estimated to be 0.74×10^{-6} sec^{-1} and 0.23×10^{-4} $(l/mol\cdot sec)^{1/2}$ respectively, while in Fig. 6, fk_d and $k_i'/k_{t3}^{1/2}$ were 0.67×10^{-6} sec^{-1} and 0.30×10^{-4} $(l/mol\cdot sec)^{1/2}$, values in good agreement with the values in Fig. 5.

Estimation of K_c. The ratio of the rate constant of the unimolecular cyclization reaction to that of the bimolecular propagation of the uncyclized radical, K_c, was evaluated by applying Eq. (12) to the experimental measurements of the dependence of the residual unsaturation on the monomer concentration.

The plot $(1-F)^{-1}$ *vs.* (M) is shown in Fig. 7; it has a good linear relationship, as was predicted by Eq. (12). K_c was estimated to be 4.0 mol/l from the slope of the straight line.

On the other hand, if the uncyclized and cyclized radicals were not individually treated as by Holt and Simpson,[1] the following equation would be obtained:

$$(1-F)^{-1} = (2k_p/k_c)(M)$$

It is obvious, however, that this equation is not sufficient to account for the experimental data shown in Fig. 7.

In cyclopolymerization, K_c is the critical factor determining the microstructure of the polymer; it may be interpreted as twice the monomer concentration necessary for the rate of the bimolecular propagation reaction to equal that of the unimolecular cyclization.[13] Thus, the monomer concentration of diallyl carbonate required for the two processes to proceed at an equal rate is 2.0 mol/l, which corresponds to about a 70% dilution of the pure monomer.

*2 Eq. (9) can be written as follows:

$$\frac{R_p}{(I)^{1/2}} = \{2fk_d(I)^{1/2} + 2k_i'(2fk_d/k_{t3})^{1/2}(M)\} \times \left\{\frac{2k_p(M) + k_ck_{cp}/(k_{cp}+k_{t2})}{2k_{t1}(M) + k_ck_{t2}/(k_{cp}+k_{t2})}\right\}$$

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 1964—1967 (1969)

The Basicities of Substituted Diphenyl Sulfoxides[1)]

Shigeru Oae, Kazuo Sakai and Norio Kunieda

Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sumiyoshi-ku Osaka

(Received October 11, 1968)

The basicities of nine *meta*- and *para*-substituted diphenyl sulfoxides have been determined spectrophotometrically in sulfuric acid media. The pK_{BH^+} values thus obtained indicate that these sulfoxides possess rather weak basicities (pK_{BH^+}; -3.67——-5.74). and these pK_{BH^+} values gave a good correlation with Brown-Okamoto's σ^+ values, ($\rho=-2.00$), instead of σ-values. These observations seem to suggest a considerable conjugative interaction between phenyl groups and sulfoxide group of these diphenyl sulfoxides.

Sulfoxides have been considered to be weakly basic because of their physical and chemical behavior, the remarkable solvating power of cationic species, semipolar nature of the S–O linkage, *etc.* But the basicities of only a few alkyl sulfoxides have hitherto been determined.[2)]

Recently, Andersen and his co-workers[3)] determined the basicities of *meta*- and *para*-substituted phenyl methyl sulfoxides by the potentiometric titration in acetic anhydride, and gave the pK_{BH^+} values which can be nicely correlated by Hammett's σ values with a large ρ value of -3.79. More recently, Haake and Cook[4)] determined the pK_{BH^+} values of phenyl methyl sulfoxide and dimethyl sulfoxide, -3.45 and -2.7 respectively, by the measurements of NMR chemical shift of methyl group and they showed the values to be considerably larger than those of Andersen's[3)] and earlier workers'.

During the course of our studies on the acid-catalyzed oxygen exchange reactions,[5)] we were interested in the basicities of diaryl sulfoxides and synthesized nine substituted diphenyl sulfoxides and determined their basicities. The measurements of the basicities of these substituted diphenyl sulfoxides were carried out spectrophotometrically in sulfuric acid media in a fashion similar to that described by Hammett[6)] and other workers,[7)] taking advantage of our earlier finding that sulfoxides ionize in a concentrated sulfuric acid in a following manner,[8)] since the UV spectra of diaryl sulfoxides are quite different from those of the corresponding protonated species.

$$R_2SO + H_2SO_4 \rightleftarrows R_2\overset{+}{S}OH + HSO_4^- \quad (i\text{-facter}=2) \qquad (1)$$

The pK_{BH^+} values for the substituted diphenyl sulfoxides thus obtained are listed in Table 2, and are found to be nicely correlated by Brown-Okamoto's[9)] σ^+ values, with ρ value of -2.00.

Experimental and Results

The Substituted Diphenyl Sulfoxides were prepared by the oxidation of the corresponding sulfides with the bromine complex of pyridine and water in acetic acid according to the same procedure as described in our previous paper.[10)] Their melting and boiling points (°C) were *p*-CH_3O, 60—60.5°C, lit,[11)] 55—57°C; *p*-C_2H_5O, 71— 72°C; *p*-CH_3, 69—70°C, lit,[11)] 71—72°C; *m*-CH_3, 44.5—45.5°C, lit,[11)] 46—47°C; H, 70—71°C, lit,[11)] 71°C; *p*-Cl, 44—45°C, lit,[11)] 45—46°C; *p*-I, 106—107°C, lit,[12)] 106°C; *p*-Br, 62—62.5°C; *m*-Cl, 165—

Sulfuric Acid. Concentrations of sulfuric acid - water media were determined by titrating with a standard alkali solution. The H_0 values used here are Long and Paul's[13] with the corrections above 60% of concentrations given by Jorgensen and Harter.[14]

Measurement of pK_{BH^+}. The UV spectra of the sulfoxides in sulfuric acid media ranging from 0% to 91.3% acid were measured with a Hitachi EPS-2U model Spectrophotometer. The wave lengths and intensities of the absorption maxima of the unprotonated (A_B) and protonated (A_{BH^+}) forms of the sulfoxides are listed in Table 1. We can see from these UV charts, for example, shown in Fig. 1 that the intensities of the absorption maxima of the unprotonated sulfoxides increase while those of the protonated sulfoxides decrease with the decrease of the concentration of sulfuric acid.

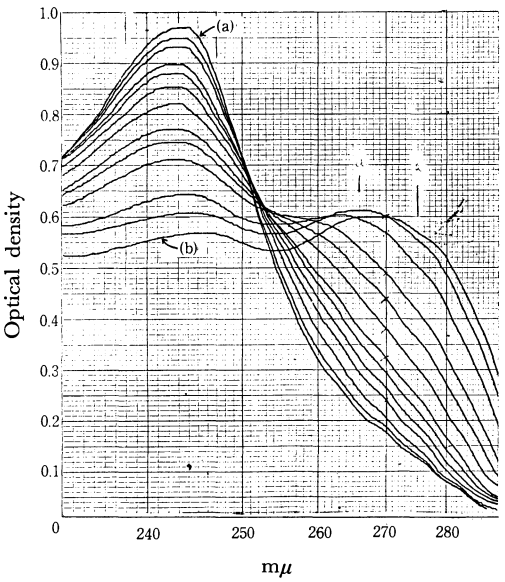

Fig. 1. UV chart of *p*-bromophenyl phenyl sulfoxide in sulfuric acid.
(a), in water and (b), in 90.2% sulfuric acid

Hammett used the following equation (Eq. (2)) to estimate the pK_{BH^+} values of such weak bases as acetophenone, benzoic acid and others in sulfuric acid media,[6a] but the equation could not be used for the measurement of pK_{BH^+} values of several other compounds[15] which do not behave as ideal Hammett bases,[7a,16] since a gradient of log [BH^+]/[B] *vs.* $-H_0$ for a non-Hammett base is not unity. Although numerous compounds have been shown to behave as Hammett bases, many compounds are not so, and our compounds were also found to be non-Hammett bases. In such cases it is more prudent to use the following equation (Eq. (3)) for the pK_{BH^+} calculation of the non-Hammett bases,[7a,16] namely substituted sulfoxides in this case.

$$pR_{BH^+} = H_0 - \log \frac{[BH^+]}{[B]} \qquad (2)$$

$$pK_{BH^+} = H_0 - n \log \frac{[BH^+]}{[B]} \qquad (3)$$

Incidentally this equation has been used for the estimation of pK_{BH^+} values of amides,[7a,b] acetophenone,[7b] benzoic acid,[7b] benzaldehyde,[7b] phosphine oxides,[16] phosphine sulfides,[16] and phenyl methyl sulfoxide,[4] *etc.*

In the spectrophotometric determination, [BH^+] and [B] can be rewritten as [$A-A_{BH^+}$] and [A_B-A] respectively, where A is an absorbance of a sulfoxide in sulfuric acid media of an adequate concentration. When the values of log[BH^+]/[B] obtained are plotted against H_0 values according to Eq. 3, one gets a straight line from which *n* and the pK_{BH^+} value can be obtained. This method was quite useful for the determination of pK_{BH^+} of most of the sulfoxides. However, we could not measure the pK_{BH^+} values of *para*- and *meta*-nitrophenyl phenyl sulfoxides by this method, since the absorption maxima of the UV spectra for the unprotonated and protonated forms of these sulfoxides are too near to be measured with reliable accuracy.

The *n*-values for the substituted diphenyl sulfoxides were found to be larger (1.8—2.4) than unity, like those for benzamide (1.51),[7b] acetophenone (1.37),[7b] benzaldehyde (1.22),[7b] benzoic acid (1.20),[7b] phosphine oxides

Acetophenone[c]	6.30±0.18	1.50±0.11	250—310

a) The correlation coefficient of all these values gave more than 0.990.
b) This is the wave length of UV spectra used to determine A.
c) These compounds were used as the standard of the pK_{BH^+} values of the sulfoxides.

(1.43—2.21),[16] *etc.*, indicating that the diphenyl sulfoxides also do not behave as Hammett bases. Recently Haake and Cook[4] also reported large n-values for phenyl methyl sulfoxide (1.62) and dimethyl sulfoxide (1.61).

All our pK_{BH^+} data of the substituted diphenyl sulfoxides obtained are listed in Table 2. Although we have also calculated the pK_{BH^+} values of our compounds by the method described by Davis and Geissmann,[17] these values are identical to those in Table 2.

Stretching Frequency of S–O Bond for Substituted Diphenyl Sulfoxides. The infrared spectra were determined in a set of 0.20 mm fixed path cells by means of JASCO-IR-C Infrared Spectrophotometer while the concentration of a sulfoxide was maintained as 0.05 mol/l in carbon tetrachloride. The stretching vibrations of S–O bonds of these substituted diphenyl sulfoxides obtained are listed in Fig. 2, and are found to be in a good correlation with Hammett σ values, with a correlation coefficient, r=0.990.

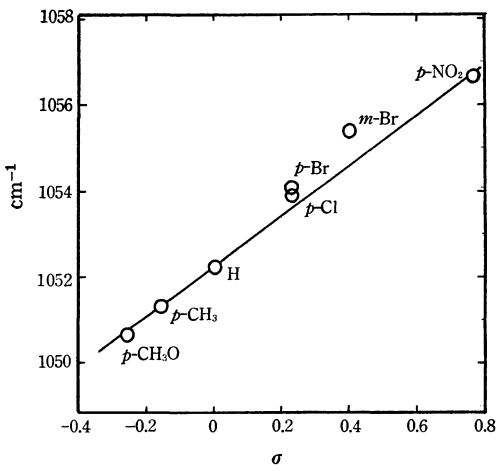

Fig. 2. Stretching frequencies of the S–O bond substituted diphenyl sulfoxides plotted against σ values.

Discussion

The pK_{BH^+} values of the diphenyl sulfoxides listed in Table 2 reveal that these sulfoxides possess rather weak basicities, and even the strongest base of this series, *i. e.*, p-anisyl phenyl sulfoxide, has its pK_{BH^+} of only −3.67. Recently, the pK_{BH^+} values of diphenyl sulfoxide has been measured in acetic anhydride by titration with perchloric acid by Andersen and his co-workers,[3] but their pK_{BH^+} value (−3.58) is considerably larger than that of ours (−4.97).[20] The pK_{BH^+} values of several other organic oxides are also listed in Table 3 for comparison.

Table 3. pK_{BH^+} Values of organic oxides

Compound	pK_{BH^+}		
$(C_6H_5)_2SO$	−4.97[a]	−3.58[b]	
$(C_6H_5)S(O)CH_3$	−0.488[b]	−3.45[c]	−3.60[d]
$(CH_3)_2SO$	0.911[b]	0[f]	−2.7[c]
$(C_6H_5)_2P(O)CH_3$	−3.2[c]		
$(C_6H_5)C(O)CH_3$	−6.15[e]	−6.30[a]	−6.51[c]

The basicities of the sulfoxides resemble more closely those of the carbonyl compounds and phosphine oxides than those of the amine and arsine oxides. Probably a substantial 2p–3dπ interaction may be in operation between the two ends of the S–O bond to diminish the basicities of the sulfoxide as in the cases of carbonyl compounds and phosphine oxides. It is known incidentally that the basicity of an oxide would be diminished

19) R. Stewart and K. Yates, *ibid.*, **80**, 6355 (1959).

20) The pK_{BH^+} value for phenyl methyl sulfoxide of Haake and Cook[4a] and ours[4b] which was measured by NMR in sulfuric acid media, are also smaller than that of Andersen and his co-workers'[3] which was measured by potentiometric titrations in acetic anhydride.

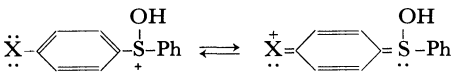
not only the semipolar character but also by the π-bonding character of the oxide bond.[21]

For example, the C–O bond of the carbonyl compounds which display the weakest basicities among several organic oxides possess almost complete π-bonding character, while the N–O and As–O bonds of amines and arsine oxides are known to be of a semipolar nature and quite basic.

It is interesting to note that the basicities of diphenyl sulfoxide is markedly smaller than that of dimethyl sulfoxide. In the case of dimethyl sulfoxide,[22] perhaps both electron-donating inductive and hyperconjugative effects of two methyl groups increase the electron density of the sulfoxide S–O linkage to enhance the basicity, while the low basicity of diphenyl sulfoxide may be due to the electron-withdrawing inductive effect of two phenyl groups which reduce the electron density of the S–O bond.

When the pK_{BH^+} values for the *meta*- and *para*-substituted diphenyl sulfoxides thus obtained were plotted against Brown–Okamoto's[9] σ^+ values, a good straight line was obtained with the correlation coefficient $r=0.990$, and the ρ value of -2.00.[24] Incidentally it is known that the plotting of the same pK_{BH^+} values against Hammett's σ values gives a very poor correlation, $r=0.920$.

These σ^+-correlations and the magnitude of ρ value of the diphenyl sulfoxides closely resembled those of substituted acetophenones (For $\sigma^+-pK_{BH^+}$; $\rho=-2.17$ ($r=0.983$). For $\sigma-pK_{BH^+}$; $\rho=-2.22$ ($r=0.903$))[19] and benzaldehydes (for $\sigma^+-pK_{BH^+}$; $\rho=-1.85$ ($r=0.994$)).[25] This suggests that similar resonance effects by the same substituents are possible for all these compounds. The two extremely delocalized formula for the protonated form of *p*-substituted diphenyl sulfoxides would be depicted as shown below.



Since the sulfur atom can expand its valence shell beyond octet using its 3d orbitals, the C–S bond between the aromatic carbon atom and the sulfur atom could have another π bonding (2p–3d type) upon the protonation to create a discrete positive charge on the sulfur atom and the formation of this 2p–3dπ bonding may call for a large resonance effect of the substituent.

In the case of the unprotonated sulfoxides, however, such a large demand for resonance effect of substituent would be negligible, since the sulfur atom bears only a fraction of a positive charge and hydrogen bonding to the terminal oxygen atom would give only a perturbation on the electron localization along the C–S linkage. Therefore, the S–O stretching frequency would be very slightly affected by the resonance effect of the substituents.

21) The bond moment; average value $\mu_{SO}=3.0$ D and the shorter bond length; 1.45 Å (average) also indicate a considerable double bonding of sulfoxides. [See C. C. Price and S. Oae, "Sulfur Bonding," Chapter 4, Ronald Press Co., New York, N. Y. (1962).]

22) The dipole moments of diphenyl sulfoxide and dimethyl sulfoxide were 4.08 (D)[12] and 4.3 (D)[23] respectively, which also show a larger inductive effect of methyl substituents.

23) A. J. Parker, "The Use of Dipolar Aprotic Solvents in Organic Chemistry," in "Advances in Organic Chemistry," Vol. 5, ed. by R. A. Raphael, E. C. Taylor and H. Wynberg, Interscience Publishers, N. Y. (1965), p. 3.

24) The value for *p*-anisyl phenyl sulfoxide was found to be slightly lower than that predicted by the σ^+ values. This deviation would be caused by the solute-solvent hydrogen bonding in sulfuric acid acting to reduce the resonance effect of *p*-CH_3O group.[5a]

The Mechanism of the Alkaline Decomposition of Triarylsulfonium Bromide with Phenyllithium[1]

Yong He Khim and Shigeru Oae

Department of Apllied Chemistry, Faculty of Engineering, Osaka City University, Sumiyoshi-ku, Osaka

(Received October 11, 1968)

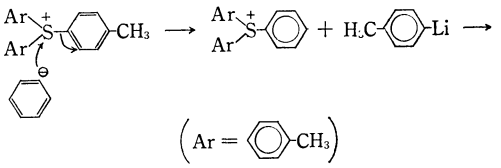
Tritolylsulfonium bromide was subjected to alkaline decomposition in order to clarify the mechanism of the reaction of triarylsulfonium bromide with phenyllithium in ether. Diaryl sulfides, diaryls, and other aryl derivatives were obtained and the combined yield was nearly quantitative. On the basis of the ratio of the products formed in the reaction, the alkaline decomposition is considered to proceed through two mechanistic routes, *i. e.*, one involving the nucleophilic attack of phenyl anion on the sulfur atom (about 70%) and the other the "benzyne" route (about 20%).

The reaction of triarylsulfonium halide with phenyllithium has been studied by Franzen[2] and later by Andersen.[3] However, their experimental procedures are not identical and the results they obtained are also somewhat different. The mechanisms suggested are also entirely different.

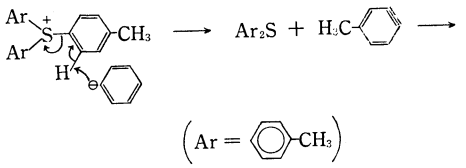
Franzen reported that triphenylsulfonium bromide exchanges phenyl groups with phenyllithium very rapidly and involves the initial formation of an unstable tetravalent sulfur intermediate and the succeeding extrusion of the phenyl group. On the other hand, Andersen proposed a mechanism involving "benzyne" intermediate on the basis of their observation that the addition of phenyllithium to diphenyl sulfoxide in ethyl ether gives diphenyl sulfide and diphenyl.

Franzen and Joschek[4] later also presented evidence that tri-(2-methoxyphenyl)sulfonium chloride reacted with phenyllithium to give the corresponding aryne though in poor yield. Meanwhile, Sheppard[5] suggested that the reaction between phenylsulfur trifluoride with phenyllithium to give both phenyl sulfide and diphenyl proceeds *via* the initial formation of tetraphenylsulfur intermediate by the replacement of the fluorines by phenyl groups, similar to the reaction between triarylsulfonium halide and aryllithium. However, the mechanisms of all these reactions have remained totally unclarified. In addition to the two mechanistic pathways hitherto mentioned, *i. e.*, the one involving the tetravalent sulfur intermediate and the other which includes "benzyne" intermediate, there are two other possibilities; namely, the reaction may proceed *via* the initial nucleophilic attack of phenyllithium on the carbon atom (mechanism 3) or may proceed *via* an intramolecular decomposition (mechanism 4). All these possible mechanisms are schematically illustrated with tolyldiphenylsulfonium compound as shown below.

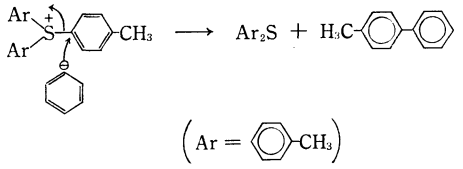
1) Nucleophilic attack on sulfur atom.



2) Benzyne mechanism.



3) Aromatic S_N reaction.



4) Intramolecular decomposition.

5) W. A. Sheppard, *J. Am. Chem. Soc.*, **84**, 3058 (1962).

In order to make a choice among these possible mechanistic pathways for the reaction between triarylsulfonium compound and aryllithium, we have undertaken detailed analyses of the products formed in the reaction between tritolylsulfonium compound and phenyllithium. This paper will describe a detailed account of the investigation. In the previous studies by both Franzen and Andersen there was a technical difficulty in choosing a plausible mechanism, since the yields of reaction products in both cases were entirely different. However, by the use of tritolylsulfonium compound with phenyllithium, one can readily test the "benzyne" mechanism (Mechanism 2) and the intramoleclular decomposition (Mechanism 4), since the "benzyne" mechanism will require the formation of both *m*- and *p*-substituted ditolyls, while the intramolecular decomposition mechanism (4) will give tolyl bromide and diaryl sulfide.

Results and Discussion

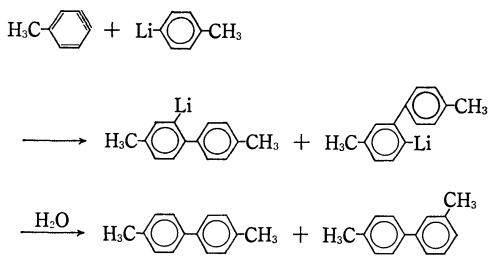
The products obtained are shown in Table 1. The reaction of tritolylsulfonium bromide with phenyllithium was carried out in boiling ether and after the reaction was completed the reaction mixture was carbonated. The products contained in ether layer were carefully fractionated by gas chromatography and identified by comparing their mp, infrared and NMR spectra with those of the authentic samples. A typical gas chromatogram of the products formed is shown in Fig. 1. One finds peaks of *p*-ditolyl sulfide, phenyl *p*-tolyl sulfide, ditolyl, *p*-methyldiphenyl, diphenyl, phenetole, phenol, and *p*-tolyl bromide in the vapor phase chromatogram. However, ditolyl and diphenyl sulfide were obtained as a mixture without being well-separated and their products ratio was determined by NMR spectra. Further, through the careful inspection of the infrared absorption spectra it was found that ditolyl consists of a mixture of two isomers, *i. e.*, *p,p'*-dimethyldiphenyl and *m,p'*-isomer in the ratio of about 1:3. Since *m,p'*-dimethyldiphenyl is formed only through the "benzyne" route (mechanism 2) through which nearly the same amount of *p,p'*-isomer would be also formed. Therefore, the "benzyne" route shown below would account for approximately 20% of the products formed in the reaction. Tolyllithium being a stronger nucleophile than phenyllithium, apparently reacts preferentially with "benzyne" formed. When the reaction was performed in the presence of a 2.0 molar equivalent of lithium thiophenoxide, a nucleophile which reacts more rapidly than phenyl-

Table 1. The reaction of tritolylsulfonium bromide with phenyllithium in ether

Sulfide group (yield %)	Diaryl group (yield %)	Aryl group (yield %)	Carboxylic acid (yield %)	Other product** (yield %)
 (57)	 * (20)	 (small)	 (26)	 (5–8)
 (33)	 (29)	 (1–2)		 (~3)
 (7)				(3–5)

* The molar ratio of *m*- and *p*-isomers is about 1:1.

** All the products result in the formation of phenyllithium.



lithium with benzyne,[6] diphenyl sulfide (8%) and ditolyl (21%) were obtained. These yields of the two products do not differ much, regardless of the absence or presence of thiophenoxide in the reaction system. If the lithium thiophenoxide can compete with tolyllithium in the addition reaction to "benzyne," the yield of diphenyl sulfide would increase and the yield of ditolyl would decrease. If phenyllithium could compete with tolyllithium in addition to "benzyne," both *p*-methyldiphenyl and its *m*-isomer would be obtained; however, no such *m*-isomer could be detected. *p*-Tolyl phenyl sulfide and diphenyl sulfide are undoubtedly the products formed by the collapse of the tetravalent sulfur intermediate as shown below, while di-*p*-tolyl sulfide is formed not only *via* this route but also by other routes. The mechanistic route involving the aromatic nucleophilic substitution on the carbon atom with the phenyllithium with ditolyl sulfide as the leaving group (mechanism 3) could explain the formation of ditolyl sulfide and *p*-methyldiphenyl, but not that of *p*-tolyl phenyl sulfide. Therefore, this route, (mechanism 3) is rather unlikely.

Judging from the distribution of the whole product and the yields of tolyl compounds formed from the sulfonium bromide, the mechanism involving the nucleophilic attack on the sulfur atom (mechanism 1) seems to account for about 75% of the products formation. Previously Franzen calculated the portion of the reaction through the mechanistic route 1 only from the amount of benzoic acid formed by the carbonation in the reaction of triphenylsulfonium bromide with phenyllithium. By the use of tritolylsulfonium bromide with phenyllithium for the reaction, one can now include other tolyl compounds such as methyldiphenyl, ditolyl and toluene as the products formed by the mechanistic route 1.

In view of the substantial formation of ditolyl the exchange of aryl group *via* route 1 undoubtedly takes place very fast. Meanwhile, the formation of tolyl bromide could be explained in terms of the intramolecular decomposition[7] though the yield (2%) is very poor (mechanism 4). Another possible route for the formation of tolyl bromide would be the addition of bromide to aryne formed by the route 2.

Besides, diphenyl,[8,9] phenetole[10] and phenol[9] were obtained. These undoubtedly result from the reaction of phenyllithium formed in the reaction of bromobenzene with lithium in diethyl ether, since all these compounds can be found among the reaction mixture before the addition of the sulfonium salt and the amounts remain the same even after the addition of the salt.

Experimental

Starting and Authentic Materials. Tritolylsulfonium bromide was prepared[11] from ditolylethoxysulfonium tetrafluoroborate[12] and tolyl Grignard reagent. mp 244—245°C (decomp.). *m*- And *p*-methyldiphenyls were prepared from the reaction of the corresponding diazonium salt with benzene and (*m*,*p*'- and *p*,*p*'-) dimethyldiphenyls were also obtained similarly. Diphenyl sulfide, phenyl tolyl sulfide and di-*p*-tolyl sulfide were prepared by the reaction of the corresponding aryldiazonium salts with thiophenolate.

The Reaction of Tritolylsulfonium Bromide with Phenyllithium. Tritolylsulfonium bromide (2.14 g, 0.0056 mol), in 10 m*l* of anhydrous ethyl ether was added to the ethereal solution of phenyllithium (0.024 mol) prepared from bromobenzene and lithium under a nitrogen stream. After the reaction mixture was refluxed for 45 min, it was poured onto dry ice, and hydrolyzed with 5% of hydrobromic acid. The ethereal layer was extracted with 10% sodium carbonate solution, and aqueous extract was acidified to isolate the mixture of benzoic and toluic acids. *p*-Toluic acid (0.2 g) was seperated by careful recrystallization from an alcohol-water mixture. The ethereal layer was washed, dried and fractionated by vapor phase chromatography. The identification and the determination of the yields of the products were performed using quantitative vapor phase chromatography and by comparison of their infrared spectra with those of authentic samples. The isolated compounds from the organic layer and their yields are shown in Table 1.

Meanwhile, the direct hydrolysis of the reaction mixture, after it was refluxed for 50 min, gave the products in almost same yields. However, in this case toluene (22%) was obtained instead of toluic acid.

The Reaction of Tritolylsulfonium Bromide with Phenyllithium-Thiophenoxide Mixture. Thiophenol (1.76 g, 0.008 mol) in 5 m*l* of anhydrous ethyl ether was added to the ethereal solution of phenyllithium (0.024 mol) and the mixture was kept stirring for 10 min at 40°C. Tritolylsulfonium bromide (1.4 g, 0.004 mol) in 10 m*l* of anhydrous ethyl ether was added to this mixture. After the reaction mixture was refluxed for 80 min, poured into ice water, acidified with 5% hydrobromic acid, and the ethereal layer was separated. The ether extract of the water layer was combined with it. Distillation of the organic layer gave almost the same products, and their yields in the case where only phenyllithium was used are shown in Table 1. The purities and yields of the products were checked by the usual quantitative vapor phase chromatography. (Diphenyl sulfide 8%, ditolyl 21%, toluene 20%.)

Synthetic Studies of Sesamol Derivatives. XI.*1 Synthesis of 5,6-Methylenedioxy-2-isopropenylbenzo[*b*]furan*2

Kenji FUKUI, Mitsuru NAKAYAMA and Sachihiko TANAKA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashi Sendamachi, Hiroshima

(Received October 25, 1968)

5,6-Methylenedioxy-2-isopropenylbenzo[*b*]furan, an analogue of the naturally-occurring 5,6-dimethoxy compound, has been synthesized by the dehydration of the corresponding 2-(1′-hydroxy)isopropyl derivative, which was obtained from 2-hydroxy-4,5-methylenedioxybenzaldehyde. By the catalytic hydrogenation of the benzofuran, its 2-isopropyl derivative and its 2-isopropyl-2,3-dihydrofurano-compound were prepared. The NMR spectra of these compounds have been compared.

Recently, a new naturally-occurring benzofuran derivative, 5,6-dimethoxy-2-isopropenylbenzo[*b*]-furan (I), has been isolated from *Ligularia stenocephala* Matsum. *et* Koidz. by Takahashi *et al.*[1] 5,6-Methylenedioxy-2-isopropenylbenzo[*b*]furan (II), an analogue of I containing a methylenedioxy group instead of two methoxyl groups, has a substitution pattern found in several naturally-occurring flavonoids, isoflavonoids and coumestans; it could, therefore, be expected to occur in nature. It was considered useful to synthesize II and record its properties in order to help in the identification of the compound when it is discovered. In continuation of a series of synthetic studies of sesamol deriv-
