The reaction of methylmagnesium iodide with 5,6-methylenedioxy-2-acetylbenzo[*b*]furan (III), which was obtained by treating 2-hydroxy-4,5-methylenedioxybenzaldehyde (IV)[2] with monobromoacetone, afforded a benzofuran derivative V, $C_{12}H_{12}O_4$, mp 65—66°C. The same compound, V, was furnished by the reaction of this Grignard reagent with 5,6-methylenedioxy-2-carbethoxybenzo[*b*]furan (VI).[3] The infrared spectrum of V exhibited an absorption due to the hydroxyl group at 3320 cm^{-1}. In its NMR spectrum (Table 1),*3 a singlet signal at δ 2.10 (1H), which easily disappeared upon deuterium exchange, and a sharp singlet at δ 1.63 (6H) provided evidence for the presence of $-C(OH)(CH_3)_2$ grouping. Moreover, V has the NMR signals at δ 5.97 (singlet, 2H, $O-CH_2-O$), 6.46 (doublet, 1H, $J=0.75$ Hz, β-hydrogen atom of benzofuran ring),[4] 6.90 (singlet, 1H, aromatic proton), and 6.97 (doublet, 1H, $J=0.75$ Hz, aromatic proton). These NMR spectral data suggest the presence of one β-proton on the benzofuran ring and that the two isolated aromatic protons are in a 1,4-relationship. Therefore, the structure of V was established as 5,6-methylenedioxy-2-(1′-hydroxy) isopropylbenzo[*b*]-furan.

The dehydration of V by heating alone afforded an isopropenyl derivative II, $C_{12}H_{10}O_3$, mp 98—99°C, in a 41% yield. The NMR spectrum of II (Table 1 and Fig. 1) showed a methyl signal, δ 2.09 (3H, doublet, $J=$Hz), and signals due to two vinyl protons at δ 5.12 and 5.70 (each 1H, finely-split signal).

The catalytic hydrogenation of II over 5% Pd-C in ethyl acetate at room temperature gave the corresponding isopropylbenzofuran VII, $C_{12}H_{12}O_3$, mp 56—57°C; its NMR spectrum exhibited signals at δ 1.29 (6H, doublet, $J=7$ Hz), 3.02 (1H, multiplet, $(CH_3)_2$=CH–), 6.89 (1H, singlet), and 6.97 (1H, broad singlet). Elvidge and Foster[4] have reported that, in the NMR spectra of benzofurans, the 3-proton couples with the 7-proton with $J=0.9$ Hz. The singlet at δ 6.89 and the broad singlet at δ 6.97 mentioned above can, therefore, be attributed to the 4- and 7-protons respectively. This assumption is in accord with the spectral data (Table 1) of 4,5-methylenedioxybenzo[*b*]furan (VIII)[3] and its 3-methyl- (IX) and 2,3-dimethyl-derivative (X) prepared from sesamol.[5]

Next, VII was further reduced over 5% Pd-C in ethanol at an elevated temperature to give 2,3-dihydrobenzofuran, XI. The NMR spectrum of XI (Table 1 and Fig. 3) showed a two-proton

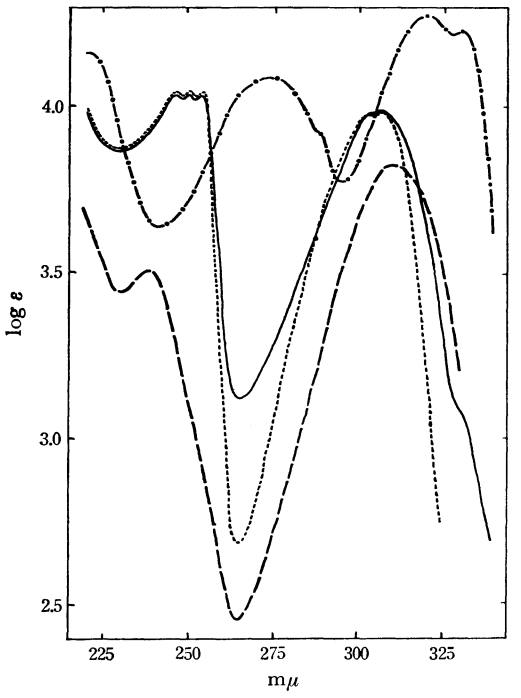

Fig. 4. Ultraviolet spectra of II (-·-·-), V (——), VII (------) and XI (— — —) in ethanol.

multiplet centered at δ *ca.* 2.9 and a one-proton multiplet centered at δ 4.46 attributable to the β- and α-protons of dihydrofuran-ring respectively. An interesting feature of the spectrum was provided by the signals (δ 0.93 and 0.99, each 3H, doublet, J=6.5 Hz) due to the two methyl groups of the isopropyl side chain; *e. g.*, these signals are quite similar to those of the isopropyldihydrofuran system in lunacrine (XII),[6] and these two methyl groups are magnetically nonequivalent.

The ultraviolet spectra of these compounds (II, V, VII, and XI) are shown in Fig. 4. The shape of the UV spectrum of V is very similar to that of VII. The bathochromic effect (about 11 mμ) observed in the spectrum of II could be explained as resulting from the isopropenyl double bond conjugated to the furan ring at the α-position. On the other hand, the spectrum of XI is very similar to that of 6-substituted-3,4-methylenedioxyanisole derivatives.[7]

Experimental*5

5,6-Methylenedioxy-2-acetylbenzo[*b*]furan (III). A hot solution of IV (mp 125—126°C)[2] (3.3 g) in absolute ethanol (40 m*l*) was treated with a solution of potassium hydroxide (1.2 g) in absolute ethanol (20 m*l*). Then, monobromoacetone (3.0 g) was stirred, drop by drop, into the hot solution over a 20-min period and the reaction mixture was refluxed for 1 hr on a steam bath. Again, potassium hydroxide (0.6 g) and monobromoacetone (1.5 g) were added to the mixture and the reaction was continued for 1 hr. The product was treated again with potassium hydroxide (0.3 g) and monobromoacetone (0.75 g). After the addition of water (20 m*l*), the organic solvent was evaporated. The resulting residue was repeatedly extracted with benzene. The combined benzene solutions were washed with a diluted sodium hydroxide solution, dried over anhydrous sodium sulfate, and evaporated. The residue was crystallized from ethanol to give colorless needles of III, mp 156.5—157°C; yield, 3.2 g. IR: 1672 (C=O); 1626, 1545, 1495 (aromatic); 1036, 945 cm^{-1} (O-CH_2-O). UV: λ_{max} mμ (log ε); 267 (3.76), 291.5 (4.00), 340 (4.27). NMR:*3,4 δ 6.05$_s$ (O-C$\underline{H}_2$-O), 2.55$_s$ (C$\underline{H}_3$CO) and Table 1.

Found: C, 64.95; H, 4.14%. Calcd for $C_{11}H_8O_4$: C, 64.70; H, 3.95%.

5,6-Methylenedioxy-2-(1′-hydroxy)isopropylbenzo[*b*]furan (V). *a) From III.* A solution of III (510 mg) in a mixture of anhydrous ether (10 m*l*) and anhydrous benzene (35 m*l*) was slowly stirred into a methylmagnesium iodide solution (from methyl iodide (1.56 g) and magnesium (270 mg) in anhydrous ether (15 m*l*)) for 0.5 hr in an ice-bath. After stirring for 1.5 hr, the reaction mixture was decomposed by the cautious addition of 1N sulfuric acid (20 m*l*). The aqueous layer was reextracted with benzene, and the combined benzene solution were washed with a 5% sodium hydrogen carbonate solution and a saturated sodium thiosulfate solution, and dried over anhydrous sodium sulfate. After the solvent had been evaporated *in vacuo*, the residue was purified by column chromatography over alumina with benzene. The elute was evaporated to yield yellow crystals. This was sublimated at 50°C *in vacuo* to give colorless crystals of V, mp 65—66°C; yield, 160 mg. IR: 3320 (OH); 1630, 1591, 1555, 1505 (aromatic); 1040, 938 cm^{-1} (O-CH_2-O). UV: λ_{max} mμ (log ε); 246.5 (4.03), 250.5 (4.03), 254.5 (4.03), 306$_{sh}$*6 (3.98), 309 (3.98), 331$_{sh}$ (3.10). NMR:*3,4 δ 5.97$_s$ (O-C$\underline{H}_2$-O); 2.10$_s$ (O$\underline{H}$); 1.63$_s$ (6H, C$\underline{H}_3$) and Table 1.

Found: C, 65.57; H, 5.29%. Calcd for $C_{12}H_{12}O_4$: C, 65.44; H, 5.49%.

b) From VI. A mixture of VI (mp 84—85°C)[3] (1.1 g) in anhydrous ether (10 m*l*) and anhydrous benzene (20 m*l*), and a methylmagenesium iodide solution (from methyl iodide (2.20 g) and magnesium (0.35 g) in anhydrous ether (10 m*l*)) was refluxed on a steam bath with stirring for 1.5 hr. The reaction mixture was then treated as above to give V, mp 65—66°C; yield, 0.55 g.

5,6-Methylenedioxy-2-isopropenylbenzo[*b*]furan (II). The hydroxy-compound V (160 mg) was heated at 150°C for 5 min in a stream of nitrogen. The viscous, orange yellow product was sublimated in a stream of nitrogen *in vacuo* at 90°C/1 mmHg to give colorless needles of II, mp 98—99°C; yield, 60 mg.

*5 All the melting points are uncorrected; the infrared spectra were measured in Nujol, while the ultraviolet spectra were measured in ethanol.

*6 sh=shoulder.

IR: 1620, 1555, 1502 (aromatic); 1038, 940 (O-C$\underline{H}_2$-O); 877 cm^{-1} ($H_2C{=}C\langle$). UV: λ_{max} mμ (log ε); 221 (4.16), 276 (4.07), 320 (4.26), 332 (4.22). NMR: *3,4 δ 6.00$_s$ (O-C$\underline{H}_2$-O); 5.70$_m$, 5.12$_m$ (each IH, $\rangle C{=}C\underline{H}_2$); 2.09$_d$ (J=1)(C$\underline{H}_3$) and Table 1.

Found: C, 71.14; H, 5.12%. Calcd for $C_{12}H_{10}O_3$: C, 71.28; H, 4.99%.

5,6-Methylenedioxy-2-isopropylbenzo[*b*]furan (VII). A solution of II (65 mg) in ethyl acetate (50 m*l*) was hydrogenated over 5% Pd-C (50 mg) at room temperature for 10 min; 1 molar equivalent of hydrogen was absorbed. After the catalyst had been filtered, the filtrate was evaporated under a weak vacuum. The residual oil was soon crystallized on cooling. This was sublimated *in vacuo* at 55°C/0.5 mmHg to give colorless prisms of VII, mp 56—57°C; yield, 57 mg. IR: 1625, 1588, 1555, 1500 (aromatic); 1036, 943 cm^{-1} (O-C$\underline{H}_2$-O). UV: λ_{max} mμ (log ε); 247 (4.04), 251 (4.03), 255 (4.04), 305 (3.97), 309 (3.97). NMR: *3,4 δ 5.96$_s$ (O-C$\underline{H}_2$-O); 3.02$_m$ (J=7)($\rangle C\underline{H}$); 1.29$_d$ (J=7)(6H, C$\underline{H}_3$) and Table 1.

Found: C, 70.39; H, 5.88%. Calcd for $C_{12}H_{12}O_3$: C, 70.57; H, 5.92%.

5,6-Methylenedioxy-2-isopropyl-2,3-dihydrobenzo[*b*]furan (XI). A solution of VII (40 mg) in ethanol was hydrogenated over 5% Pd-C at 70°C at atmospheric pressure for a few hours. After the same procedure as has been described above, the residue was crystallized from dilute ethanol to give colorless plates of XI; mp 92—93°C; yield, 37 mg. IR: 1616, 1498 (aromatic); 1047, 934 cm^{-1} (O-C$\underline{H}_2$-O). UV: λ_{max} mμ (log ε); 240 (3.51), 313 (3.82). NMR: *3,4 δ 5.85$_s$ (O-C$\underline{H}_2$-O); 1.93$_m$ (J=6.5) ($\rangle C\underline{H}$); 0.99$_d$, 0.93$_d$ (J=6.5) (each 3H, C$\underline{H}_3$) and Table 1.

Found: C, 70.09; H, 6.67%. Calcd for $C_{12}H_{14}O_3$: C, 69.88; H, 6.84%.

5,6-Methylenedioxy-3-methylbenzo[*b*]furan (IX). *a) 2-Acetyl-4,5-methylenedioxyphenoxyacetic Acid.* A mixture of 2-hydroxy-4,5-methylenedioxyacetophenone (mp 112—113°C)[8] (0.9 g), ethyl bromoacetate (0.9 g), and anhydrous potassium carbonate (4.0 g) in anhydrous acetone (100 m*l*) was refluxed for 7 hr in a steam bath, and then the inorganic precipitates were filtered off. After the filtrate had been evaporated, the residue was added to a 2N sodium hydroxide solution (60 m*l*). The mixture was heated in a steam bath for 0.5 hr and then acidified with 2N hydrochloric acid. The resulting precipitate was collected and recrystallized from ethyl acetate to give 2-acetyl-4,5-methylenedioxyphenoxyacetic acid as colorless needles, mp 205°C; yield, 0.6 g. IR: 1734, 1711, 1654 (C=O); 1620, 1500 (aromatic); 1043, 932 cm^{-1} (O-C$\underline{H}_2$-O).

Found: C, 55.69; H, 4.23%. Calcd for $C_{11}H_{10}O_6$: C, 55.46; H, 4.23%.

b) 5,6-Methylenedioxy-3-methylbenzo[b]furan (IX). A mixture of the above phenoxyacetic acid (0.6 g), anhydrous sodium acetate (10 g), and acetic anhydride (100 m*l*) was vigorously refluxed for 3 hr. The cooled mixture was then poured into water. The resulting precipitate was collected and recrystallized from ethanol to give IX as colorless needles, mp 56—56.5°C; yield, 0.4 g. IR: 1621, 1585, 1504 (aromatic); 1038, 939 cm^{-1} (O-C$\underline{H}_2$-O). UV: λ_{max} mμ (log ε); 248.5 (3.92), 256 (3.83), 303 (3.90), 308 (3.90). NMR: *3,4 δ 5.98$_s$ (O-C$\underline{H}_2$-O); 2.17$_d$ (J=1.5)(C$\underline{H}_3$).

Found: C, 67.92; H, 4.51%. Calcd for $C_{10}H_8O_3$: C, 68.18; H, 4.58%.

5,6-Methylenedioxy-2,3-dimethylbenzo[*b*]furan (X). To a solution of sesamol[5] (5.0 g) and 3-chlorobutanone-2 (3.9 g) in anhydrous methyl ethyl ketone (150 m*l*), anhydrous potassium carbonate (20 g) and potassium iodide (12 g) were added. The resulting mixture was refluxed for 17 hr in a steam bath, and then the inorganic precipitates were filtered off. After the filtrate had been evaporated, the residue was distilled *in vacuo* to give methyl α-(3,4-methylenedioxyphenoxy) ethyl ketone as a colorless oil, bp 163—165°C/23 mmHg; yiled, 3.0 g.

A mixture of the above ketone (3.0 g) and polyphosphoric acid (n=2.5; 18 g) was kept at room temperature for 2 days. The reaction mixture was then poured into a 2N sodium hydroxide solution. The resulting precipitate was collected and recrystallized from ethanol to give X as colorless needles, mp 82—83°C; yield, 1.5 g. IR: 1643, 1619, 1496 (aromatic); 1034, 938 cm^{-1} (O-CH_2-O). UV: λ_{max} mμ (log ε); 251 (3.96), 307 (3.95), 311 (3.95). NMR: *3,4 δ 5.96$_s$ ((O-C$\underline{H}_2$-O); 2.32$_s$, 2.07$_s$ (each 3H, C$\underline{H}_3$).

Found: C, 69.47; H, 5.14%. Calcd for $C_{11}H_{10}O_3$: C, 69.46; H, 5.30%.

The authors are indebted to Mr. Masaaki Fukumitsu for assistance with part of the experimental work. This work was supported in part by a grant-in-aid from the Ministry of Education.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 1976—1981 (1969)

The Reaction of Haloferrocenes with Copper(I) Salts in Pyridine

Masaru SATO, Takehiko ITO, Izumi MOTOYAMA, Ken-ichi WATANABE and Kazuo HATA

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya, Tokyo

(Received November 5, 1968)

The halogen exchange reaction of haloferrocene series with copper(I) salts (halide, cyanide) in an organic base was studied in comparison with that of the halobenzene series, which is regarded as a kind of nucleophilic substitution. Chloro-, bromo-, and cyanoferrocene were all obtained from iodoferrocene by this reaction in good yields. The reactivity of the ferrocene series was much higher than that of the benzene series. The order of the reactivity of halogen, I>Br>Cl, was similar to that of the benzene series. On the other hand, the substituent effects in the comparative reactivity of 1′-substituted-1-chloroferrocene with copper(I) cyanide was observed to be as follows: Et>H>Cl>Ac. This order in the ferrocene series was opposite to that in the *p*-substituted bromobenzene series: CN>Ac>Br>H>Me. In view of the electrophilic tendency in the ferrocene series and its high reactivity, the reaction mechanism is discussed.

Since the discovery of the aromaticity of ferrocene many interesting findings on the reactions of ferrocene derivatives have been reported. Ferrocene itself has a greater reactivity in the electrophilic substitution than does benzene. For example, it is acetylated with acetyl chloride and anhydrous aluminum chloride 10^6 times faster than benzene.[1] However, the nucleophilic substitution of ferrocene derivatives seems to take place with much difficulty, and few have been reported. Chloroferrocene, for example, reacts neither with potassium amide in liquid ammonia[2] nor with potassium hydroxide or potassium acetate.[3] It is interesting to note, however, that copper or copper salts have been found to participate in the reactions of haloferrocenes. The Ullmann aryl-coupling reaction of iodoferrocene took place at 60°C to afford biferrocenyl in a high yield,[4] but that of iodobenzene took place only at 200°C. The reaction of bromo- and chloroferrocene with copper(II) acetate gave ferrocenyl acetate with ease.[3] Nesmeyanov *et al.* have obtained cyanoferrocene in a good yield by the reaction of bromo- or chloroferrocene with copper(I) cyanide.[3] Thus, the substitution reactions of haloferrocenes including chloroferrocene with copper(I) salts seem to occur more easily than those of the benzene series, while the reaction of chlorobenzene with copper(I) cyanide hardly ever takes place under ordinary reaction conditions, such as with iodo- or bromobenzene.

In our previous reports,[5,6] some information on the Rosenmund-von Braun reaction of halobenzene with a complex of copper(I) cyanide and an organic base in nitrobenzene was presented, along with a discussion of the reaction mechanism. It has been reported that this reaction proceeds easily in dimethylformamide or *N*-methylpyrrolidone.[7] The reactions of halobenzene with copper(I) halides as well as with cyanide in an organic base have also been reported by Bacon and Hill.[8]

In this study, haloferrocenes were submitted to similar reactions, and the results were examined in comparison with those in the benzene series.

Syntheses of Haloferrocenes

Haloferrocenes can not be synthesized by the direct halogenation of ferrocene. Therefore, they have hitherto been obtained through the reaction of chloromercuriferrocene with halogen[9,10] or

b) Along with 37.5% recovery.

N-halosuccinimide,[11] or through the reaction of ferroceneboronic acid with copper(II) halide.[3,12] Among the haloferrocenes, however, iodoferrocene is easily obtained in a high yield by the treatment of chloromercuriferrocene with iodine.[10]

On the other hand, it is well known that iodobenzene easily undergoes a halogen exchange reaction with copper(I) halides to give bromo- or chlorobenzene in a good yield. Thus, chloro- and bromoferrocene may be expected to be successfully obtained by the reaction of iodoferrocene with copper(I) chloride and bromide respectively. The halogen exchange reactions were achieved only by refluxing the mixtures of iodoferrocene and copper(I) halides in pyridine for a few hours under an oxygen-free nitrogen atmosphere. Cyanoferrocene was also obtained using copper(I) cyanide instead of copper(I) halides.*1 The experimental results are summarized in Table 1.

Thus, these reactions are sufficiently useful as a method of synthesizing bromo-, chloro- or cyanoferrocene, since iodoferrocene is obtainable with considerable ease. On the other hand, the fact that the reaction of 1,1′-diiodoferrocene with copper(I) cyanide afforded 1′-cyano-1-iodoferrocene as the sole isolable product suggests a new method to synthesizing various 1′-substituted haloferrocenes.

The Rosenmund-von Braun Reaction of Haloferrocenes in Comparison with the Benzene Series. With a view to elucidating the character of the substitution reaction of haloferrocenes with copper(I) salts, the results of the reaction of haloferrocenes with copper(I) cyanide in pyridine under somewhat different conditions were compared with those of the same reaction with halobenzenes. The results of the experiments are shown in Tables 2 and 3. The relatively fast decomposition of iodoferrocene at 118°C may reduce the yield of cyanoferrocene to below that of benzonitrile from iodobenzene. Chloroferrocene gave a 34% yield of cyanoferrocene at 140°C (Exp. 5 in Table 2), while chlorobenzene did not react at all (Exp. 7 in Table 3).*2 A similar contrast was also evident in the reactions of bromo-compounds. In general, the higher the reaction temper-

Table 2. The reaction of haloferrocenes with copper(I) cyanide
Haloferrocenes: 0.4 g in each run, Reaction time: 2 hr

Exp. No.	Haloferrocene	CuCN (g)	Pyridine (ml)	Reaction temp. (°C)	Yield of cyanoferrocene	Recovered (%)

5	FcCl	3	3	140	34	66

A small amount of unidentified product (mp 157°C) was obtained in every case.
The formation of ferrocene by the decomposition of haloferrocenes was observed in Exps. 1, 2 and 3.

Table 3. The reaction of halobenzenes with copper(I) cyanide
Halobenzenes: 0.5 ml in each run, Reaction time: 2 hr

Exp. No.	Halobenzene	CuCN (g)	Pyridine (ml)	Reaction temp. (°C)	Yield of benzonitrile[a] (%)
1	PhI	2	10	118	98
2	PhBr	2	10	118	Trace

4	PhCl	2	10	118	—
5	PhI	3	3	140	*ca.* 100
6	PhBr	3	3	140	43[c]
7	PhCl	3	3	140	—

a) Calculated by the gas chromatographic analysis.
b) The reaction time, 10 hr.
c) When heated for 9 hr at 140—150°C, the yield was 85%.

11) R. W. Fish and M. Rosenblum, *J. Org. Chem.*, **30**, 1253 (1965).
12) A. N. Nesmeyanov, V. A. Sazonova and V. N. Drozd, *Dokl. Akad. Nauk S. S. S. R.*, **126**, 1004 (1959).

*1 Nesmeyanov *et al.*[3] performed this reaction at 135—140°C without any solvent.

*2 Chlorobenzene was hardly ever changed by heating at 140—150°C for 14 hr. Upon reaction in an autoclave at 250°C for 9 hr, the yield of the nitrile was 34%.[5]

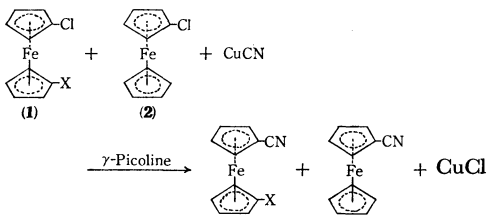
ature, the greater the increase in the yield of nitriles, and the reactivity of the halogens in both the ferrocene and the benzene series was in the same order: I>Br>Cl.*3

The ease of the displacement of halogens from the benzene nucleus was also shown to be the same order by Bacon and Hill.[8] This order is the inverse of that of the reactivities of activated aryl halides in the nucleophilic substitution. This implies that the reactions of haloferrocenes with copper(I) salts proceed in a manner similar to those of halobenzenes, at least at certain steps. On the other hand, the higher reactivity of the ferrocene series, together with that of the Ullmann coupling and Ullmann condensation of haloferrocenes,[4] suggests the contribution of a characteristic factor of ferrocene molecules to this reaction.

Effects of Substituents. In order to examine the electronic factor in this reaction, the reactions of *p*-substituted halobenzenes and of 1′-substituted haloferrocenes with copper(I) cyanide were carried out, and the effect of the substituents was discussed.

1′-Ethyl-, 1′-chloro-, and 1′-acetyl-1-chloroferrocene were synthesized, and competitive reactions of each of them with chloroferrocene were carried out in γ-picoline.*4 Similarly, the competitive reactions of *p*-methyl-, *p*-bromo-, and *p*-acetylbromobenzene with bromobenzene were all examined in the same solvent. The nitriles produced were analyzed by gas chromatography; the results are shown in Tables 4 and 5 in terms of the relative reactivity.

TABLE 4. THE RELATIVE REACTIVITY OF 1′-SUBSTITUTED CHLOROFERROCENE

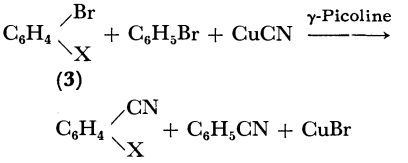


1: 0.0015 mol, **2**: 0.0015 mol, CuCN: 3.0 g, γ-Picoline: 3.0 m*l*, Biphenyl[a]: 0.0015 mol, Reaction temp.: 145°C, Reaction time: 2 hr, in N_2 atmosphere.

Exp. No.	Substituent X	Relative reactivity
1	C_2H_5	1.65
2	H	1.00
3	Cl	0.04[b]
4	$COCH_3$	—

a) Added as an internal standard in the gas chromatographic analysis.
b) Only 1′-chloro-1-cyanoferrocene was obtained.

TABLE 5. THE RELATIVE REACTIVITY OF *p*-SUBSTITUTED BROMOBENZENE



3: 0.02 mol, C_6H_5Br: 0.02 mol, CuCN: 3.0 g, γ-Picoline: 4.0 m*l*, Reaction temp.: 147°C, Reaction time: 3 hr

Exp. No.	Substituent X	Relative reactivity
1	CH_3	0.92
2	H	1.00
3	Br	1.21[a]
4	$COCH_3$	1.90
5	CN	2.03[b]

a) *p*-Bromobenzonitrile and terephthalonitrile were obtained.
b) The relative rate of *p*-bromobenzonitrile was calculated not from the direct competitive reaction, but from the result of No. 3 in this table, on the assumption that *p*-bromobenzonitrile is initially formed from *p*-dibromobenzene, followed by further substitution to terephthalonitrile.

It is very interesting that a remarkable electrophilic character was observed in the reaction of the ferrocene series, while the nucleophilic character was observed in that of the benzene series. Bacon and Hill also reported that the effect of substituents in the latter was slightly nucleophilic.[8] In view of the model proposed in our earlier paper,[5] the interaction of the cyano group with the carbon atom in benzene nuclei may be nucleophilic. Therefore, the trend and the order of substituent effcet shown in Table 5 seems reasonable. However, the nucleophilic character of this reaction, caused by the activation by the base-CuCN complex, is not as conspicuous as in an ordinary nucleophilic substitution of activated halobenzenes.

In the reactions of the ferrocene series (Table 4), the electron-withdrawing acetyl and also chloro groups exert a strong suppressive effect. The fact that dichloroferrocene only afforded a monocyano compound can be interpreted in terms of the interfering effect of a strong electron-withdrawing cyano group which has previously been substituted in another cyclopentadienyl ring. A similar result is found in the case of diiodo derivatives (Exp. 5 in Table 1). Thus, the fact that the electron-withdrawing group displays a suppressive effect on the substitution reaction of the ferrocene series, contrary to that of the benzene series,

*3 I>Br>Cl>F: Fluorobenzene is never replaced by this reaction.[5] The reactivity order was estimated on the basis of the yields of nitriles from the corresponding halides.

*4 It was used because its boiling point is higher than that of pyridine (bp 145°C).

offers an important suggestion for discussing the mechanism of this reaction in close relationship with the superior reactivity of the ferrocene series.

Discussion

The halogen exchange reaction of haloferrocene participated with copper(I) salt is considered to be a kind of nucleophilic substitution, analogous to that of halobenzene under the same conditions. Nevertheless, the displacement of halogen from the ferrocene nucleus was found to be facile in the order: I>Br>Cl, an order similar to that observed in halobenzenes. This kind of metal-assisted aromatic replacement reaction has been extensively studied by Bacon and Hill,[8] who established that the reaction was initiated by bonding between the halogen in aryl halide and copper, thus giving an "onium" structure (**4**), followed by the formation of a four-centered cyclic intermediate or an ion pair, or by a homolytic fission, and that an electron-withdrawing group on the aryl halide had only a small accelerating effect on the reaction rate.

$$ArBr + CuClL_2 \longrightarrow Ar\text{-}\overset{\oplus}{Br}\text{-}\overset{\ominus}{Cu}L_2 \quad (\mathbf{4})$$
$$\qquad\qquad\qquad\qquad\quad Cl$$

L: Ligand

It may be concluded that, within the range of conditions employed in this investigation, copper(I) salt is present in the reaction mixture in the form of a complex with a pyridine base.[5] It has also been shown that the nature of the pyridine base in the copper complex affects the rate of the substitution reaction remarkably. Under the circumstances, an electronic state of the halogen atom in aryl halide, like one of the copper atom in the complex, will seriously affect the first stage of the reaction. The cyclopentadienyl ring in ferrocene has a higher electron density than the benzene ring, so the halogen in haloferrocene may be expected to be more strongly coordinated to the copper atom than that in the corresponding halobenzene under the same conditions. The expected higher reactivities of haloferrocenes were actually observed in this investigation.

As is shown in Table 4, the effect of 1′-substituents observed in haloferrocenes was contrary to what was expected from the nucleophilic feature of this reaction. That is, the reaction was accelerated with an electron-releasing group, while it was retarded with an electron-withdrawing one.

In view of these results, the halogen exchange reaction in the ferrocene series seems to be more complicated than that in the benzene series. However, on the assumption that the principal mechanism of this reaction is not different between the two series, the anomalism observed in the substituent effect of haloferrocenes can reasonably be explained as follows: In haloferrocenes, a particular interaction between the copper(I) salt-base complex and haloferrocene precedes the formation of an "onium"-type intermediate (**4**) by an attack of the halogen in the haloferrocene on the copper atom in the complex, and exerts a controlling effect on the rate of the reaction. Since haloferrocene acts as an electron donor in this reaction, an electron-withdrawing substituent on haloferrocene retards the above-mentioned interaction, thus reducing the rate of the reaction. This explanation is consistent with the experimental results obtained in this study, and similar interaction has been observed in several members of the ferrocene series.[13] Therefore, it seems reasonable to assume a precedence of such an interaction in the halogen exchange reactions, although there is no direct evidence to support this assumption.

Further work on this subject is in progress and a more detailed discussion will be reported later.

Experimental

Materials. Commercial copper(I) chloride and bromide were used without any further purification. The copper(I) cyanide was prepared from copper(II) sulfate and potassium cyanide. Commercial pyridine, γ-picoline, and halobenzenes were purified by distillation under reduced pressure. The purity of all the organic reagents was checked by gas chromatography.

Iodoferrocene. Iodoferrocene was prepared, by a modification of the procedure reported by Shechter and Helling,[10] in a much improved yield, 71—91%; mp 48—49°C (lit. 44—45°C,[9] 49—49.5°C[4]).

Chloroferrocene. To a solution of 3.12 g (0.01 mol) of iodoferrocene in 30 m*l* of pyridine, 1.98 g (0.02 mol) of copper(I) chloride were added and then the mixture was refluxed with stirring for 3 hr under a nitrogen atmosphere. At the end of the reaction, 100 m*l* of *n*-hexane were added. Then, the reaction mixture was filtered, and the precipitate collected on a filter was washed several times with *n*-hexane. The filtrate and the washings were combined and washed with dilute hydrochloric acid and water successively. The organic layer was dried over anhydrous magnesium sulfate. After the removal of the solvent, the residual crude product was chromatographed on alumina to afford 1.95 g chloroferrocene. Yield, 88.3%; mp 56—56.5°C (lit. 58—59°C[3]).

Bromoferrocene. Following the procedure described above, bromoferrocene was prepared from iodoferrocene and copper(I) bromide in pyridine. Yield, 94%; mp 29—30°C (lit. 32—33°C[3]).

Cyanoferrocene. Iodoferrocene (3.1 g, 0.01 mol) and copper(I) cyanide (3.6 g, 0.04 mol) were treated in 20 m*l* of pyridine by the procedure used for the preparation of chloroferrocene. The crude product thus obtained was chromatographed on Florisil to give 1.75 g of cyanoferrocene. Yield, 83%; mp 106—107°C (lit.

13) V. L. Wolf and H. Hennig, *Z. Anorg. Allgem. Chem.*, **341**, 1 (1965).

107—108°C[3]). Unidentified yellow crystals were obtained as a by-product (0.15 g), mp 157—158°C.

1,1'-Diiodoferrocene. Following the procedure reported by Nesmeyanov *et al.*,[9] 1,1'-diiodoferrocene was prepared in a much improved yield. Purification by means of chromatography gave 5.77 g of 1,1'-diiodoferrocene as an orange liquid. Yield, 65.5%; bp 85°C/0.003 mmHg, n^{23} 1.6850.

1,1'-Dichloroferrocene. 1,1'-Dichloroferrocene was prepared by the reaction of 1,1'-diiodoferrocene with copper(I) chloride in pyridine following the procedure previously described for the preparation of chloroferrocene. Yield, 77.4%; mp 76—77°C (lit. 75—77°C[3]).

1'-Cyano-1-iodoferrocene. To a solution of 2.19 g (0.005 mol) of 1,1'-diiodoferrocene in 20 m*l* of pyridine, there were added 2.24 g (0.0025 mol) of copper(I) cyanide, and then the mixture was refluxed for 2 hr under a nitrogen atmosphere. After a treatment similar to that for chloroferrocene, the crude product was chromatographed on Florisil to give 0.8 g of the starting material and 0.68 g of 1'-cyano-1-iodoferrocene. The yield of the latter, 40.2%; mp 43.5—45°C.

Found: C, 39.72; H, 2.56; N, 4.25%. Calcd for $C_{11}H_8NIFe$: C, 39.20; H, 2.39; N, 4.16%.

1'-Acetyl-1-chloroferrocene. A solution of 7.6 m*l* (0.06 mol) of boron trifluoride etherate in 10 m*l* of dry dichloromethane was added to a solution of 5.5 g (0.025 mol) of chloroferrocene and 5.65 m*l* (0.06 mol) of acetic anhydride in 100 m*l* of dry dichloromethane over a 7-min period under a nitrogen atmosphere and in an ice bath. After the reaction mixture had been stirred for 30 min in the ice bath and then for 5.5 hr at room temperature, it was poured into ice water. The dichloromethane layer was washed repeatedly with water and dried over anhydrous magnesium sulfate. After the solvent had been removed, the residue was chromatographed on alumina to give 2.80 g of cholroferrocene and 3.20 g of 1'-acetyl-1-chloroferrocene. The yield of the acetyl compound, 48.6%; mp 55.5°—56.7°C (lit. 53—55°C[14]).

1'-Ethyl-1-chloroferrocene. Zinc (1.0 g) was amalgamated by stirring it with 0.1 g of mercury(II) chloride in 4 m*l* of dilute hydrochloric acid (1:20) for 10 min. After the aqueous phase had then been decanted off, a solution of 0.25 g of 1'-acetyl-1-chloroferrocene in 2.5 m*l* of conc. hydrochloric acid and 2.5 m*l* of acetic acid was added to the amalgamated zinc. The mixture was refluxed for 5 min and then cooled to room temperature. Then the zinc was filtered off and washed with ether. The filtrate was extracted with ether. The combined ethereal solution was washed with water, dilute aqueous potassium hydroxide, and water successively, and dried over anhydrous magnesium sulfate. After the ether had then been evaporated away, the residue was chromatographed on alumina with *n*-hexane, there was thus obtained 0.19 g of 1'-ethyl-1-chloroferrocene. Yield, 81.0%; bp 65—66°C/0.006 mmHg, n^{23} 1.6048.

Found: C, 58.10; H, 5.23%. Calcd for $C_{12}H_{13}ClFe$: C, 57.95; H, 5.23%.

1'-Ethyl-1-cyanoferrocene. To a solution of 0.67 g (0.0027 mol) of 1'-ethyl-1-chloroferrocene in 1.5 m*l* of γ-picoline, 1.21 g (0.0135 mol) of copper(I) cyanide were added. The reaction mixture was heated for 3 hr at 140—145°C under a nitrogen atmosphere, and cooled after the addition of 10 m*l* of pyridine at the end of the reaction. After a treatment similar to that described for the preparation of chloroferrocene, the crude product was chromatographed on silica gel to give 0.375 g of the starting material and 0.159 g of 1'-ethyl-1-cyanoferrocene. The yield of the cyano compound, 24.8%; 99—100°C/0.045 mmHg (lit. 152—156°C/5 mmHg[3]).

The Reaction of Haloferrocene with Copper(I) Cyanide (Table 2, Exp. 2). A mixture of 0.40 g of bromoferrocene, 2.0 g of copper(I) cyanide, and 10 m*l* of pyridine was stirred for 2 hr at 118°C. After the reaction was over, 30 m*l* of ether was added to the hot reaction mixture and the whole was refluxed for 10 min while being stirred well. The copper(I) salt-pyridine complex thus precipitated was filtered off and washed well with ether. The extraction with fresh ether was repeated three times in order to ensure the extraction of the product from the reaction mixture. All the ethereal solutions were then combined, washed three times with dilute hydrochloric acid and then with water, and dried over anhydrous magnesium sulfate. After the ether had been distilled off, the residue was chromatographed on silica gel with a mixture of *n*-hexane and benzene (1: 1) to give 0.10 g (32%) of cyanoferrocene, mp 106—107°C, and 0.14 g (35%) of the recovered bromoferrocene.

In the case of the reaction of chloroferrocene, the products were analyzed by gas chromatography; by this means the quantities of cyanoferrocene and the recovered chloroferrocene were determined precisely.

The Reaction of Halobenzene with Copper(I) Cyanide (Table 3, Exp. 6). A mixture of 0.5 m*l* of bromobenzene, 3.0 g of copper(I) cyanide and 3.0 m*l* of pyridine was stirred at 140°C for 2 hr. Then the reaction mixture was treated similarly as in the case of haloferrocenes. The ethereal solution thus obtained was analyzed by gas chromatography. The yield of benzonitrile was 43%.

The Competitive Reaction of Haloferrocenes (Table 4, No. 1). A mixture of 3.0 g of copper(I) cyanide, 3.0 m*l* of γ-picoline, 0.377 g (0.0015 mol) of 1'-ethyl-1-chloroferrocene, 0.336 g of chloroferrocene, and 0.203 g of biphenyl (internal standard for gas chromatography) was stirred for 2 hr at 145°C. After the reaction was over, 6 m*l* of pyridine and 20 m*l* of ether were added to the hot reaction mixture, and the whole was refluxed for 10 min while being stirred well. A copper(I) salt-pyridine complex precipitated from the reaction mixture. The precipitate was filtered off and washed with ether. To complete the collection of the product, the precipitate was extracted twice more. The ethereal solutions thus obtained were combined, washed with dilute hydrochloric acid, and then with water, and dried over anhydrous magnesium sulfate. The solution was concentrated and analyzed by gas chromatography.

The Relative Reactivities of Haloferrocenes. After the competitive reaction between chloroferrocene and 1'-substituted chloroferrocene, the yields of both nitriles were calculated from the ratio of each peak area of the nitriles to the internal standard (biphenyl). When a large excess of copper(I) cyanide over haloferrocene was used, the reaction was apparently first-order in haloferrocenes. Therefore, on the assumption

14) D. W. Hall and J. H. Richards, *J. Org. Chem.*, **28**, 1549 (1963).

that the reaction would be approximately first-order in haloferrocenes under the conditions employed in the present experiments, the rate constants were calculated from the yields of the nitriles. The relative reactivities of 1′-substituted chloroferrocene and chloroferrocene are shown in Table 4. Similarly, the relative reactivities of *p*-substituted bromobenzene and bromobenzene were found to be as shown in Table 5.

Analytical Conditions for Gas Chromatography. Apparatus: Ohkura Model 1100. Column: 2 m×6 mm stainless-steel column packed with 10% Silicon Grease on Daichrom W with 60—80 meshes. Temperature: 180—200°C (130°C for halobenzene). Carrier gas: H_2. Flow rate: 40—60 ml/min. Relative retention time: FcH (1); Biphenyl (1.16); FcCl (1.57); 1′-Et-1-Cl-ferrocene (2.43); 1,1′-Cl_2-ferrocene (2.48); FcCN (2.77); $FcCOCH_3$ (3.45); 1′-Et-1-CN-ferrocene (4.32); 1′-Cl-1-CN-ferrocene (4.43); 1′-Ac-1-CN-ferrocene (5.23).

For the substituted halobenzenes, the following conditions were employed. Column: 2 m×6 mm stainless-steel column packed with 10% Carbowax 1500 on Chromosorb W with 60—80 meshes. Temperature: 180—190°C. Carrier gas: H_2. Flow rate: 40 ml/min.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 1981—1986 (1969)

The Reaction of Carboxylic Acids and Hydrocarbons in a Silent Electric Discharge. I. The Reaction of Acetic Acid with Ethylene*1

Teruo HIRAKI

Institute of Commodities, Faculty of Economics, Kagawa University, Takamatsu

(Received November 11, 1968)

In order to ascertain the possibility of telomerization by a silent discharge, a mixture of acetic acid and ethylene was discharged in an ozonizer under various conditions. The α-*C*-alkylation of acetic acid which was expected to result from its discharge-induced reaction with ethylene was not observed; neither propionic acid nor higher carboxylic acids were identified by gas chromatography. However, *n*-butyl acetate was obtained in a good yield. The formation of the acetate can be explained as resulting from the combination of an acetoxy radical with two molecules of ethylene. The yield of the acetate, as well as those of the liquid and gaseous products, increased with a rise in the temperature and in the voltage, with the time, and with a rise in the ratio of ethylene to the acid concentration. Besides this acetate, the liquid products were confirmed to consist of ethyl methyl ketone, acetone, acetaldehyde, hydrocarbons, and ethyl and *n*-propyl acetates. The gaseous products were carbon dioxide, carbon monoxide, C_1—C_4-hydrocarbons, and hydrogen. Judging from the relative concentration of each compound in the reaction products, it may be said that the acetoxy radical ($CH_3COO\cdot$) and the acetyl radical ($CH_3CO\cdot$) are the main intermediates in this reaction system.

No detailed study has been reported on the reaction of an acetic acid-ethylene mixture by light or radiation, not to mention by silent discharge, although a study of the radiolysis[1] of acetic acid has been made.

Acetic acid has an active hydrogen atom, as well as alcohols (primary and secondary), carbonyl compounds, hydrocyanic acid, and mercaptans. Kawamoto[2] has shown that the acrylonitrile and higher cyanides are produced by the reaction of hydrocyanic acid having an α-H with ethylene in a silent discharge, although the author could not find telomers higher than the one-to-one adduct in the discharge-induced reaction of 2-propanol and ethylene.

It would be interesting to ascertain if a silent electric discharge initiates the telomerization of acetic acid and ethylene, and if it can be employed as a means to the direct synthesis of carbonyl compounds or acetates. In the present paper, the author wishes to report the direct formation of acetates in the silent discharge, and to establish, if possible, the optimum conditions for the preparation of these compounds.

*1 The major part of these research results were presented at the 21st Annual Meeting of the Chemical Society of Japan, Osaka, April, 1968.

2) K. Kawamoto, This Bulletin, **41**, 2164 (1968).

Experimental

Materials. The acetic acid, which did not contain any impurities reducing a 0.1% potassium permanganate solution, was purified by column distillation after it had been refluxed over phosphorus pentoxide, while commercial ethylene (research grade) was used without further purification. No impurity was found by gas chromatographical analysis; the analyses of acetic acid and ethylene were performed by means of columns of DEGS (diethylene glycol succinate) and activated charcoal respectively.

Discharge Tube. The discharge tube used is shown in Fig. 1. This tube was a Pyrex tube of the Siemens type[3] with a gap length of 2.5 mm and an effective length of 45 cm. The outside (B) of the discharge tube was filled with water, while the inner tube (A) was filled with a 3% $CuSO_4$ solution. Electrodes (C) were inserted into both (A) and (B).

3) T. Matsuda, K. Oto and K. Sugino, *Nippon Kagaku Zasshi (J. Chem. Soc. Japan, Pure Chem. Sect.)*, **79**, 324 (1958).

Apparatus and Procedure. The experiment was performed in a flow system. The apparatus is shown in Fig. 2. As soon as acetic acid had been dropped, at regular time intervals, from a dropping funnel (J) into a pot, a heater (K) turned it into vapor, which was then introduced into a discharge tube (M). Ethylene coming from the reservoir (E) was passed through a solid sodium hydroxide tube (I) in order to remove the moisture in the ethylene, which was then introduced into the discharge tube along with the acetic acid vapor. The ethylene flow rate was measured by passing it through a calibrated flowmeter (F). The reaction products that passed through the discharge tube were separated into a condensable part and non-condensable gases by three traps (N) cooled to 0°C. The high tension was applied to the discharge tube from a transformer (L; capacity, 15 kV) which used a 60-cycle alternating current.

Analysis of the Products. The reaction products were identified by comparing their retention times on gas chromatography with those of authentic samples. The non-condensable products were analyzed by gas chromatography (column, 3 m activated charcoal at 100°C; carrier gas, hydrogen). For the analyses of C_3 and C_4-hydrocarbons and of hydrogen, a 3-m column of hexamethylphosphoramide and a 3-m column of molecular sieve-13X were used at 35°C (carrier gas, helium).

The condensable products were confirmed not only by gas chromatography (column, tricresyl phosphate, PEG-6000 and diethylene glycol succinate at 100°C; carrier gas, He), but also by the formation of the derivatives. Thus, ethyl methyl ketone, obtained as a fraction boiling at 80°C, was converted into its semicarbazone and 2,4-dinitrophenylhydrazone,*2 the melting points of the derivatives being 145.5—146°C and 116.8—117.3°C respectively. They showed no depression of their melting points when mixed with authentic specimens. The quantitative analysis of the liquid products was performed by gas chromatography (column, 3 m, diethylene glycol succinate at 100°C; carrier gas, helium).

Results and Discussion

The experimental conditions and the reaction products are listed in Tables 1 and 2. The main liquid products identified were acetaldehyde, acetone, ethyl methyl ketone, and ethyl, and *n*-propyl and *n*-butyl acetates. The percentage compositions of compounds shown in these tables are the average of three experiments; the fluctuations in the yields of these compounds were less than 1%. The gaseous products which were formed in this reaction were methane, ethane, acetylene, C_3 and C_4-hydrocarbons, carbon monoxide, carbon dioxide, and hydrogen.

*2 The semicarbazone and 2,4-dinitrophenylhydrazone of ethyl methyl ketone were prepared according to the procedure of R. L. Shriner, R. C. Fuson and D. Y. Curtin, "The Systematic Identification of Organic Compounds," 4th ed., John Wiley & Sons, New York (1956), pp. 218, 219.

Gaseous products: see Table 1.

* The conversion efficiency was given by (grams of reaction product per grams acetic acid used) $\times 100$.

** The yields of each compound were given by (grams of each compound per grams of total reaction product) $\times 100$.

These compounds were obtained in every run (though in the case of the decomposition of acetic acid alone, the acetylene and C_3—C_4-hydrocarbons were not formed). However, the distribution of the products depended upon the voltage of discharge, the residence time, the temperature in the tube, and the molar ratio of the reactants.

Influences of teh Molar Ratio of Ethylene to Acetic Acid on the Yield. In order to check the molar ratio effects on the discharge reaction of acetic acid and ethylene, the reaction was carried out with various ratios of the ethylene to the acetic acid concentration. As may be seen from Experiment Nos. 1—6 in Table 1, the yields of liquid products increased with an increase in the molar ratio of ethylene to acetic acid. However, the distribution of the products depended on the molar ratio of reactants as follows. (1) Acetone was obtained in the highest yield in the absence of ethylene; the acetone yield decreased when acetic acid was mixed with ethylene. Up to the molar ratio of 0.58: 1, the yield decreased almost linearly with an increase in the ratio of ethylene to acetic acid. (2) The yield of ethyl methyl ketone increased at high ratios of ethylene to the acid concentration. These facts seem to indicate that acetone is formed by the combination of an acetyl radical with a methyl radical, and ethyl methyl ketone, by the addition of an acetyl radical to an ethylene, and that the C–OH-bond breaking in the acetic acid excited by the silent discharge is rather preferred in the absence of ethylene.

On the other hand, the yield of acetates identified was lowest in the decomposition of acetic acid; it was favored by high ratios of ethylene to the acid concentration. Thus, it is thought that the acetates are formed *via* an acetoxy radical ($CH_3COO\cdot$), a radical which is produced in large quantities by the free radicals derived from the excited ethylene; the free radicals attack this acetic acid to remove a hydrogen atom in the carboxyl. However, since carbon dioxide was obtained more in the absence of ethylene than in its presence, the high yields of acetates might result from the stabilization of the acetoxy radical in the presence of ethylene. This result also suggests that the decarboxylation is rather more preferred in the discharge decomposition of acetic acid than in the reaction of a mixture of acetic acid and ethylene.

The yield of ethyl acetate was almost the same regardless of the molar ratio of the reactants. The yield of the telomer with $n=2$ (*n*-butyl acetate) increased with an increase in the molar ratio of the ethylene to the acid. Thus, it may be said that the yield of the telomer with $n=2$ is favored by a low ratio of the acetic acid to the ethylene concentration.

Influences of the Discharge Temperature, Voltage, and Time on the Reaction between Acetic Acid and Ethylene. As is shown in Table 2, when the discharge reactions were carried out at 35 and 85°C, under the reaction conditions of a 0.4: 1 molar ratio of ethylene to acetic acid, 10.5 kV, and 6 hr, the yields of the liquid products increased with a rise in the temperature. *n*-Butyl acetate (1: 2 telomer) was obtained in an especially high yield when the ozonizer was kept "warm." This fact indicates that the telomerization of this sort is much affected by the discharge temperature.

On the other hand, the yields of the liquid products increased at a high voltage of discharge; the yields of all the carbonyl compounds except acetone, and of the acetates increased (the acetone yield, on the other hand, decreased very much). This suggests that the addition reaction occurs predominantly at a high tension.

Further, it has been found that increasing the residence time increases not only the reaction rate but also the yields of all the carbonyl compounds, including acetone, and of the acetates.

Thus, it has become apparent that the yields of the liquid and gaseous products increase with a rise in the temperature, the voltage, and the time, and at high ratios of the ethylene to the acetic acid concentration (a high yield of the telomer with $n=2$, *n*-butyl acetate, is especially favored by such a ratio).

Besides *n*-butyl acetate, liquid products were confirmed to consist of ethyl methyl ketone, acetone, acetaldehyde, and ethyl and *n*-propyl acetates, plus hydrocarbons. The gaseous products were C_1—C_4-hydrocarbons, carbon monoxide and dioxide, and hydrogen.

Judging from the relative concentration of each compound in the reaction products, it may be said that the acetoxy radical ($CH_3COO\cdot$) and the acetyl radical ($CH_3CO\cdot$) are the main intermediates in this reaction system.

The Assumed Radicals and Reaction Scheme. The characteristic of the action of silent discharge on a compound seems to be the electronic excitation of the molecule. Some of the molecules may be transformed by inelastic collisions into vibrationally-excited molecules. The activated molecules thus formed are considered to change into radicals or atoms, and into a very small amount of ionized molecules, as has been reported by many workers.[4] The radicals which are assumed to be formed from acetic acid under a silent discharge and a part of the postulated reaction scheme are shown in Table 3.

These precursor radicals, II—IV, might be

formed not only by the reactions shown in this table, but also by various reactions between acetic acid and the various radicals formed. The Radical (I) seems not to be derived from acetic acid excited by the silent discharge (even if the radical were formed, the radical would be too labile to exist), since propionic acid, butyric acid, and higher carboxylic acids were not identified by gas chromatography.

When acetic acid alone was discharged in an ozonizer, acetone and carbon monoxide were obtained in good yields. Accordingly, the C–OH-bond breaking in acetic acid (Eq. (7)) seems to occur rather preferably in the case of the decomposition of the excited acetic acid.

In the present reaction system, the (6), (13) and (14) processes seem to be those for forming carbon dioxide, but the processes to give CO_2 may not necessarily be these three, because Adams *et al.*[5] have shown, by the use of a radical scavenger, that 20% of the methane obtained in the radiolysis of acetic acid passes through the "molecule" process, $CH_3COOH^* \rightarrow CH_4 + CO_2$. Moreover, Ausloos and Steacie[6] have shown that 10% of the methane produced was derived from the dissociation of the acetic acid vapor excited by light.

Comparison with Peroxide-, Light-, and Gamma-Ray-Induced Reactions. The liquid products obtained in the decomposition of the acetic acid excited by the silent discharge are similar to those obtained in the radiolysis of acetic acid as shown by Bach,[7] Johnsen,[1] and Newton.[1] However, Burr[8] has shown that, in each radiolysis of the deuteriated and tritiated acetic acids, CD_3COOH and CT_3COOH, the methane and hydrogen produced were formed through the following processes:

5) G. E. Adams, J. H. Baxendale and R. P. Sedgwick, *J. Phys. Chem.*, **63**, 854 (1959).

6) P. Ausloos and E. W. R. Steacie, *Can. J. Chem.*, **33**, 1530 (1955).

7) Bach showed that the *G*-value of the acetone formed in the radiolysis of acetic acid vapor was 0.45; N. Bach, *Proc. Intern. Conf. Peaceful Uses Atomic Energy*, United Nations, New York, **7**, 538 (1956). In addition, Johnsen showed that the *G*-values of the gaseous products were 0.35 (H_2), 3.34 (CH_4), 0.62 (C_2H_6), 0.37 (CO), and 6.0 (CO_2). Further, Newton has reported that, besides these compounds, acetaldehyde and methyl acetate are obtained in such a reaction system.

$$\cdot CH_3 + CH_3COOH \rightarrow CH_4 + \cdot CH_2COOH$$

$$\cdot H + CH_3COOH \rightarrow H_2 + \cdot CH_2COOH$$

Namely, Burr[8] proposed the formation of the $\dot{C}H_2$-COOH radical. In addition, Roland and Harmon,[9] and Coffman[10] showed that the product was $H(C_2H_4)_nR'COOH$, in which R′ is R less H; this product was not formed by the discharge when a saturated organic acid (RCOOH) with an α-H is heated to 70—80°C with ethylene and a catalyst such as benzoyl peroxide under pressure at 895—950 atm.

It has been reported by Thomas *et al.*[11] that the radical from ethylene in the electrical discharge is a vinyl radical, and that it is produced by breaking a carbon-hydrogen bond. However, since the formations of vinyl acetate and methyl vinyl ketone were not observed, the vinyl radical is considered not to be formed here; the carbon-hydrogen bond in ethylene is not broken to give the vinyl radical, but is activated to give acetylene and 1-butene. These compounds were obtained in the gaseous products.

The main conclusion to be drawn from these results is that, by using a high-frequency current to energize the ozonizer, the nature of the reaction products can be controlled by controlling the experimental conditions. In one case the major product was acetone, and in another, *n*-butyl acetate.

10) D. D. Coffman, U. S. Pat. 2433016 (1947); *Chem. Abstr.*, **42**, 2456 (1948).

11) Thomas *et al.* showed that the processes in the decomposition of ethylene excited by the silent discharge were as follows:

$$H_2C{=}CH_2 \rightarrow H_2C{=}\overset{H}{\overset{|}{C}}\text{–} + H \text{ (in extreme cases)}$$

$$H_2C{=}CH_2 \rightarrow H_2C{=}\overset{H}{\overset{|}{C}}\cdots H \xrightarrow{-H_2} HC{\equiv}CH$$

(in other cases) $\downarrow +CH_2{=}CH_2$

$$H_2C{=}\overset{H}{\overset{|}{C}}\text{–}CH_2CH_3$$

where C···H indicates an activated C–H-bond; C. L. Thomas, G. Egloff and J. C. Morrell, *Chem. Revs.*, **28**, 1 (1941).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 1986—1991 (1969)

Intramolecular Interaction between the Hydroxyl Group and the Cyclopropane Ring

Michinori Ōki, Hiizu Iwamura, Tetsuo Murayama and Isao Oka

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo

(Received November 20, 1968)

Cyclopropylcarbinol shows two absorption maxima due to the O–H stretching, the lower-frequency band being stronger than the higher. The results are interpreted on the basis of intramolecular interaction between the hydroxyl group and the cyclopropane ring. This kind of interaction is not clearly detected with 2-cyclopropylethanol, but 2,2-dicyclopropylethanol and 2-(1-methylcyclopropyl)ethanol give results which are best interpreted by assuming the presence of the interaction. It is concluded, from the findings on rigid molecules, that O–H···cyclopropane interaction is possible when the hydroxyl group approaches the edge within the plane of the ring. The steric effect of the methyl group is also discussed.

In view of the fact that the pi-electron system behaves as a proton acceptor in interaction with the hydroxyl group,[1] it seemed that it would be interesting to investigate the possible interaction between the three-membered ring and the hydroxyl group. The sigma-electrons forming the so-called "banana bond" are known to be rather mobile, and cyclopropane, oxirane, and aziridine are known to show properties like those of the pi-electron system.

A preliminary report[2] on the interaction of the oxirane ring was published by two of the present

authors (M. O. and T. M.); this paper will deal with the intramolecular interaction between the hydroxyl group and the cyclopropane ring. The first observation on this phenomenon was reported some 10 years ago,[3] and a full paper appeared recently.[4] Although the other approaches were made using different model compounds, the conclusion derived by the present authors is in good agreement with that drawn in the aforementioned literature.

The investigation of the intramolecular rather than the intermolecular interaction is convenient for deducing the geometry of the interacting molecule, since the approach of the hydroxyl group can be regulated both in direction and in site. It will be shown that the most preferred conformation of the interacting molecule is such that the hydroxyl group approaches the edge of the cyclopropane ring within the plane of the ring (II). The structure of the protonated cyclopropane rings has previously been discussed with respect to the reaction mechanisms, and it has been suggested to be edge-protonated[5] (I). Olah *et al.* also postulated, from the Raman spectrum of protonated tricyclo-[2.2.1.$0^{2,6}$]heptanes,[6] the same structure. The present authors believe that their results support the structure, since the geometry of the interacting molecule corresponds to the first step of the protonation and may be supposed to be close to the protonated structure.

Results and Discussion

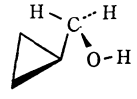
The infrared spectral data of ω-cyclopropylalkanols are collected in Table 1.

The O–H stretching absorption of cyclopropylcarbinol was reported by Schleyer *et al.*[3,4]; their results are in good agreement with those obtained in the present study. The O–H stretching spectrum of cyclopropylcarbinol shows two maxima, the band at the lower frequency being stronger than that of the higher, in contrast to the case with saturated aliphatic alcohols[7] (see Table 2).

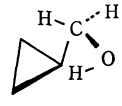
TABLE 2. ν_{O-H} DATA OF ALIPHATIC ALCOHOLS

Compound	ν_{max} (cm^{-1})	$A \times 10^{-3}$ ($mol^{-1} \cdot l \cdot cm^{-2}$)	A_l/A_h	Ref.
CH_3CH_2OH	3637.3 3627	2.8 1.6	0.56	7
$CH_3CH_2CH_2OH$	3639.7 3626	3.4 1.3	0.38	7
$(CH_3)_2CHCH_2OH$	3641.5 3628	3.6 1.8	0.50	7
$(CH_3)_2CHCH_2CH_2OH$	3639.9 3627	3.8 1.6	0.42	

The situation is similar to those of allyl alcohol[7] and benzyl alcohol[7,8]; it is best interpreted by assuming that the hydroxyl group and the cyclopropane ring interact with each other intramolecularly. The intensity of the lower-frequency band is stronger than that of the higher because of the interaction stabilizing the conformation (IV) relative to the free form (III).



(III)



(IV)

2-Cyclopropylethanol (see also Fig. 1) shows two O–H stretching absorptions also, the $\Delta\nu$ (the difference in the wave numbers of the two absorption maxima) being 14.5 cm^{-1} and the (A_l/A_h) ratio of integrated intensities being 0.48. 3-Cyclopropyl-1-propanol likewise shows two maxima, the $\Delta\nu$ and A_l/A_h values being 13.3 cm^{-1} and 0.33 respectively. The saturated alcohols in Table 2 give $\Delta\nu$ values between 10.3 and 13.7 cm^{-1} and A_l/A_h values between 0.38 and 0.56. Thus, 3-cyclopropyl-1-propanol can be considered to have no detectable intramolecular interaction, and the origin of the doublet O–H bands can be attributed to the presence of rotational isomers about the C–O bond. Although the A_l/A_h ratio of 2-cyclopropylethanol is in the range of free primary alcohols, the

7) M. Ōki and H. Iwamura, This Bulletin, **32**, 950 (1959).

8) M. Ōki and H. Iwamura, *ibid.*, **32**, 955 (1959).

$\Delta\nu$ is a little larger than the normal value. Thus, 2-cyclopropylethanol is somewhat an intermediate case.

In order to test whether there is the intramolecular interaction in 2-cyclopropylethanol, it may be necessary to change the situation to a more favorable one. This can be done in many ways. One which the authors chose at the outset was adding one more cyclopropyl group at the β-position of ethanol to form 2,2-dicyclopropylethanol. This selection was made because of a previous success in pi-electron systems: triallylcarbinol showed a very strong interaction band due to the favorable entropy factor.[9] The data shown in Table 1 and in Fig. 1 indicate an increase in A_l/A_h (2.6 instead of 0.48), although $\Delta\nu$ remains almost intact.

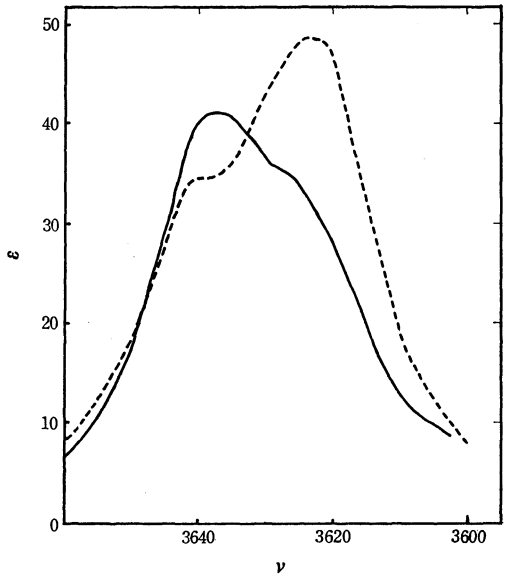


Fig. 1. ν_{O-H} Absorption bands of 2-cyclopropylethanol (——) and 2,2-dicyclopropylethanol (—·—).

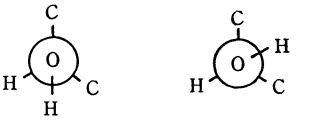
Another proof of the presence of the interaction may be obtained by increasing the electron density of the ring, for the higher electron density should facilitate the interaction. Thus, a methyl group is introduced to the cyclopropane ring. 2-(1-Methylcyclopropyl)ethanol gives a slightly increased A_l/A_h ratio, as is shown in Table 1. Although this fact alone may not be taken as positive evidence, in combination with the above results with 2,2-dicyclopropylethanol it strongly indicates the presence of the intramolecular interaction. It may be concluded that the intramolecular interaction between the hydroxyl group and the cyclopropane ring exists in 2-cyclopropylethanol derivatives, although, because of a small stabilizing energy, it can not be clearly demonstrated unless the situation is favorable for the interaction: it can also be concluded that 3-cyclopropyl-1-propanol has no detectable interaction of this kind.

Fixing the conformation of a molecule favorable for the interaction should also facilitate the interaction. In addition, a molecule with a rigid geometry should give information on the conformation of the interacting molecule. Accordingly, the infrared spectra of tricyclo[3.2.1.$0^{2,4}$]octan-6-ols[10] and related compounds were measured; the results are listed in Tables 3 and 4.

The rotational isomers are possible for secondary alcohols about the C–O axis, as is shown by V and VI. It is known[7] that the ν_{O-H} of V appears at about 3626 cm^{-1}, and that of VI, at *ca.* 3617 cm^{-1}.



All the ν_{O-H} absorption bands of tricyclo[3.2.1.$0^{2,4}$]-octan-6-ols possess similar shapes, the lower-frequency side being a little greater than the symmetrical curve. It will be convenient to use the β/α ratio introduced by Aaron and Rader[11] in discussing the band shape. Here α and β denote the segments of the half band-width of the high- and low-frequency sides of ν_{max} respectively (Fig. 2).

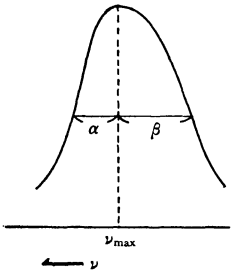


Fig. 2. Explanation of symbols α and β.

If the β/α ratio is greater than unity, the absorption band may be considered to be asymmetric, possibly indicating the presence of a small band at the lower-frequency.

An inspection of Table 3 will show that β/α value is very close to unity when no interaction of the hydroxyl group with the cyclopropane ring is possible because of the geometry of the molecule. The difference in the ratios of exo and endo isomers (VII and VIII) deserves special mention.

9) M. Ōki and H. Iwamura, This Bulletin, **33**, 1600 (1960).

10) These compounds were generously donated by Professor K. B. Wiberg, Yale University, to whom we wish to express our hearty thanks.

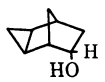
Table 3. ν_{O-H} Data of tricyclo-[3.2.1.$0^{2,4}$]octan-6-ols

Compound	ν_{max} (cm^{-1})	$\Delta\nu_{1/2}$ (cm^{-1})	β/α
	3625.2	26	0.94
	3627.1	29	1.34
	3627.2	25	1.10
	3624.0	20	1.13
	3624.0	19	1.15



(VII)

(VIII)

While the β/α value of VIII is very close to unity, that of VII is distinctly higher than anything else in Table 3. This is indicative of the presence of another band on the lower-frequency side.

It will not be unnatural to consider, from the analogous situation of 2-cyclopropylethanol, that there are some portions of molecular species which have an internal O–H···cyclopropane interaction in compound VII, but not in compound VIII. It is now apparent, therefore, that if the O–H group approaches the edge of the cyclopropane ring from the side, the O–H···cyclopropane interaction is possible, while it is impossible if O–H approaches from the upper side to the face of the ring.

The same conclusion was drawn by Schleyer and his co-workers from the fact that tricyclo[3.2.1.$0^{2,4}$]-octan-8-ol derivatives (IX and X) possess bands corresponding to the interacting molecule.[4]

(IX)

(X)

Another evidence, though negative, for the geometry of the interacting molecule can be found in bicyclo[3.1.0]hexan-3-ol derivatives. The conformation of bicyclo[3. 1. 0]hexan-3-ol had been postulated by Winstein and Sonnenberg[12] to be a chair on the basis of the unusually fast solvolysis rate of the tosylate, but their suggestion was later amended to be, rather, a boat form.[13] The NMR data in hand agree with the latter, also. A rationale for this conformation may be the repulsion between axial hydrogens at the 2 and 6 positions, as revealed by the molecular model. Therefore, in thujyl alcohol[14] (XII), the hydroxyl group can not come close to the cyclopropane ring, thus eliminating the possibility of interaction. In neothujyl alcohol (XI) and *cis*-bicyclo[3.1.0]-hexan-3-ol, the interaction would be possible if the geometry were such that the hydroxyl group approached the ring from the upper side. Table 4 indicates this is not the case.

Table 4. ν_{O-H} Data of bicyclo[3.1.0]-hexan-3-ol derivatives

Compound	ν_{max} (cm^{-1})	β/α	$A\times10^{-3}$ ($mol^{-1}\cdot l\cdot cm^{-2}$)

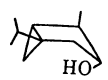
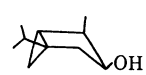
Neothujyl alcohol	3624.6	1.0	
Thujyl alcohol	3632.1 3618		2.9 0.74
Cyclopentanol	3626.1	1.1	



(XI)



(XII)

However, these facts cannot be taken as evidence for rejecting the Walsh model of cyclopropane.[15] Although, in this model, the electron density must be high at the center of the ring, this does not necessarily mean that the O–H group can approach the site. The steric repulsion must be severe in order to effect the overlapping of the orbitals concerned, thus outweighing any stabilization by the O–H··· cyclopropane interaction. The present authors

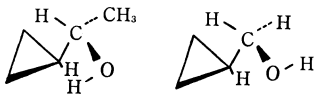
would like to reserve their conclusion on the electronic structure of the cyclopropane ring until further experimental evidence is obtained.

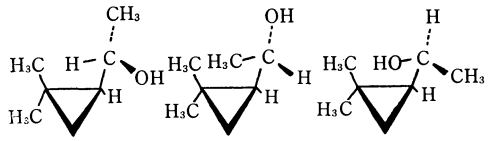
Table 5 presents the ν_{O-H} data of 1-cyclopropylethanol derivatives. It is worthy pointing out that the A_l/A_h ratio is larger with 1-cyclopropylethanol than with cyclopropylcarbinol. These results can be understood when the favorable conformation is considered.



(XIII) (XIV)

As to the conformation determined by the rotation about the C–O bond, the one (XIV) in which the hydrogen of the O–H group is in between two hydrogens, when illustrated by Newman projection, is favored in primary alcohols, probably because of the steric effect. This conformation is undoubtedly not likely in the O–H···cylopropane interaction. In secondary alcohols, the situation changes and the conformation (XIII), in which O–H can come close to the ring is not unfavorable. This very conformation is necessary for establishing the intramolecular interaction.

The introduction of two methyl groups to the position 2 of the cyclopropane ring causes the free band of 1-cyclopropylethanol to disappear. These results may be explained when steric factor of the methyl group is considered. Due to the steric effect inserted by the methyl group *cis* to the 1-hydroxyethyl, the H-inside conformation (XV) is more stable than the CH_3-inside (XVI) or the O–H-inside (XVII) conformations. Whatever conformation is taken with respect to the C–O axis in XVII, the conformation is not good at establishing the O–H···cyclopropane interaction.



(XV) (XVI) (XVII)

These circumstances must reduce the possibility of the existence of the free form. These considerations are supported by the reappearance of the free O–H absorption on the removal of the *cis*-methyl group [1-(*trans*-2-methylcyclopropyl)ethanol], as is shown in Table 5. It is, then, not surprising to find that 1-(*trans*-2-methylcyclopropyl)-1-propanol having methyl and 1-hydroxypropyl groups *trans* to each other, like the corresponding ethanol derivative, shows very small absorption for the free O–H and gives a large A_l/A_h value.

One might argue that the configuration of the alcohol may be different from that shown. However, there are many examples showing the stereochemical outcome of the Simmons-Smith reaction. For example, the reaction of methylene iodide and copper-zinc couple with 2-cyclohexen-1-ol gives bicyclo[4.1.0.]heptan-*cis*-2-ol,[16] whereas 2-cyclohexen-1-ol affords *cis*-2,3-epoxycyclohexan-1-ol on epoxidation.[17] Thus, it may be postulated that epoxidation and Simmons-Smith reaction give the same steric outcome. Then, since it has been established in this laboratory that the oxidation of 4-methyl-3-penten-2-ol with perbenzoic acid affords the threo isomer of the corresponding epoxide,[18] it is natural to consider that the Simmons-Smith reaction of 4-methyl-3-penten-2-ol will give the product of the configuration as shown (the threo isomer).

There is another possibility, that the steric effect of the methyl groups prohibits the approach of the O–H group to the cyclopropane ring in the conformation XVI. However, further study will be necessary before we can discuss this sort of steric effect of the substituents.

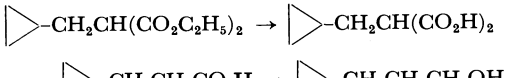
Experimental

Spectral Measurements. A Perkin-Elmer 112G single-beam grating infrared spectrometer was used for measuring the infrared absorption spectra in the 3 μ region, the spectral slit width being 0.8 cm^{-1}.

Wako special-grade carbon tetrachloride was used as the solvent. The concentrations of the alcohols were *ca.* 0.003 mol/*l*, and the length of the quartz optical cell was 2 cm. The obtained absorption band was graphically separated into two symmetrical curves.

Materials. The compounds used in this study were known compounds unless otherwise stated, and their physical constants were checked prior to measurements.

3-Cyclopropyl-1-propanol was synthesized in the following way. Cyclopropylcarbinyl bromide was condensed[19] with diethyl malonate in the presence of sodium ethoxide, and the product was hydrolyzed. The dicarboxylic acid thus obtained lost carbon dioxide on distillation, and the resulting 3-cyclopropylpropionic acid was reduced with lithium aluminum hydride.



3-Cyclopropylpropionic Acid. Diethyl cyclopropylcarbinylmalonate (27 g) was heated with 120 m*l* of 10% aqueous sodium hydroxide until a homogeneous solution was obtained. The solution was acidified with hydrochloric acid, and the dicarboxylic acid was heated

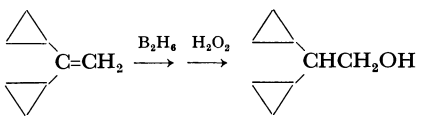
in vacuo, thus affording 3-cyclopropylpropionic acid, bp 104—105°C/17 mmHg, $n_D^{17.5}$ 1.4375, in a 69% yield. This compound had been prepared[20] by the Arndt-Eistert reaction of cyclopropylacetic acid, and the boiling point reported to be 101°C/15 mmHg.

3-Cyclopropyl-1-propanol. 3-Cyclopropylpropionic acid (13 g) in 100 m*l* of ether was added to 6 g of lithium aluminum hydride in 250 m*l* of ether. The distillation of the product gave 7 g (61%) of 3-cyclopropyl-1-propanol, bp 66°C/18 mmHg.

Found: C, 72.18; H, 12.32%. Calcd for $C_6H_{12}O$: C, 71.95; H, 12.08%.

NMR (τ): 6.40 (singlet OH), 6.47 (triplet CH_2O), 8.2—9.1 (multiplet CH_2CH_2), 9.2—10.3 (multiplet ring H).

2,2-Dicyclopropylethanol. This was prepared by the hydroboration of 1,1-dicyclopropylethylene, followed by alkaline oxidation. Considering that the hydroboration of vinylcyclopropane, followed by oxidation, has been reported to yield 97 : 3 mixture of 2-cyclopropylethanol and 1-cyclopropylethanol,[21] and considering that 1,1-dicyclopropylethylene has an enhanced steric effect, the purity of the 2,2-dicyclopropylethanol thus prepared was expected to be good. The spectral evidence supported this expectation.

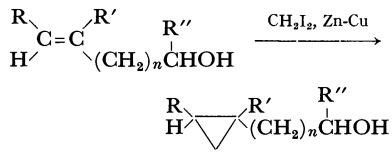


To a solution of 6 g of 1,1-dicyclopropylethylene[22] and 1 g of lithium aluminum hydride in 80 m*l* of dry tetrahydrofuran, was added 4 g of boron trifluoride etherate in 30 m*l* of tetrahydrofuran with cooling in an ice-salt bath. After the solution had been stirred for 3 hr, the excess hydride was decomposed with water. The mixture was treated with 10 m*l* of 3N sodium hydroxide and then with 10 m*l* 33% hydrogen peroxide. The distillation of the product gave 4.2 g (60%) of the crude alcohol. Redistillation afforded pure 2,2-dicyclopropylethanol; bp 106—106.5°C/41 mmHg, $n_D^{26.5}$ 1.4620.

Found: C, 76.04; H, 11.36%. Calcd for $C_8H_{14}O$: C, 76.14; H, 11.18%.

NMR (τ): 6.55 (doublet CH_2O), 7.22 (singlet OH), 9.30—10.20 (multiplet methine and ring H).

2-(1-Methylcyclopropyl)ethanol and 1-(*trans*-2-methylcyclopropyl)-1-propanol were prepared by the Simmons-Smith reaction of the corresponding olefinic alcohols.



2-(1-Methylcyclopropyl)ethanol. To a suspension of a zinc-copper couple, prepared according to LeGoff[23] from 35 g of glannular zinc in 200 ml of ether, were added 24 m*l* of methylene iodide and 16 g of 3-methyl-3-buten-1-ol in 50 m*l* of ether. After having been refluxed for 2 days, the mixture was treated in the usual manner to afford 3.5 g of the crude product (bp 52—53°C/10 mmHg). A pure sample boiled at 51—52°C/11 mmHg and possessed an n_D^{16} value of 1.4370.

Found: C, 72.18; H, 12.15%. Calcd for $C_6H_{12}O$: C, 71.95; H, 12.06%.

NMR (τ): 6.20—6.60 (multiplet CH_2O and OH), 8.59 (triplet β-CH_2), 9.00 (singlet CH_3), 9.70—9.90 (multiplet ring H).

1-(*trans*-2-Methylcyclopropyl)-1-propanol. This was similarly prepared from 4-hexen-3-ol in 49% yield. Bp 45—47°C/8 mmHg, $n_D^{18.5}$ 1.4362.

Found: C, 73.38; H, 12.40%. Calcd for $C_7H_{14}O$: C, 73.63; H, 12.36%.

Studies of the Organic Reactions of Metal Carbonyls. XVII.*1 The Reaction of Potassium Iron Carbonylates with Allyl Halide and Its Derivatives

Yoshinobu TAKEGAMI, Yoshihisa WATANABE, Takeaki MITSUDO and Toshiharu OKAJIMA

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received December 4, 1968)

The reactions of potassium iron carbonylates ($K_2Fe(CO)_4$, $KHFe(CO)_4$ and $K_2Fe_2(CO)_8$) with allyl halide and its derivatives have been studied. Allyl halide and its derivatives react readily with these carbonylates in ethyl alcohol at 30°C to give the corresponding and isomerized olefins. The reaction of allyl chloride in hydrous ethyl alcohol gives propylene in a good yield and 1,5-hexadiene as a by-product. In dry ethyl alcohol, the yield of propylene decreases. The reaction of *trans*-1-chloro-2-butene gives *trans*-2-butene (the major product), *cis*-2-butene, and 1-butene. The reaction of 1-chloro-3-methyl-2-butene and 3-chloro-3-methyl-1-butene gives 2-methyl-2-butene (the major product), 3-methyl-1-butene, and 2-methyl-1-butene. These reactions are considered to proceed *via* σ- and π-allyl iron carbonyl complexes.

Previous work in this laboratory has shown that potassium iron carbonylates, mainly $KHFe(CO)_4$, react with isoprene in alcohol to give three different monoolefins, and that the yields and the distribution of these monoolefins are remarkably affected by the reaction conditions (the solvents and the atmosphere).[1]

The present study deals with the reactions of iron carbonylates, mainly $K_2Fe(CO)_4$, with allyl halide compounds. The results obtained here indicate that allyl halide compounds react with the iron carbonyl complexes, which then decompose in such polar solvents as alcohol and water to the corresponding olefin and isomerized olefins.

Experimental

Three potassium iron carbonylates, $KHFe(CO)_4$, $K_2Fe(CO)_4$ and $K_2Fe_2(CO)_8$, were prepared according to the method described in a previous paper.[2] A 50 m*l* portion of a 0.011M $KHFe(CO)_4$, $K_2Fe(CO)_4$, or 0.0055M $K_2Fe_2(CO)_8$ solution was used in each run.

Materials. 1-Chloro-3-methyl-2-butene (A) and 3-chloro-3-methyl-1-butene (B) were prepared by bubbling hydrogen chloride into isoprene at −10°C. These products were fractionated by vacuum distillation into two fractions.*2 The allyl halides, *trans*-1-chloro-2-butene, 3-chloro-2-methyl-1-propene, iron pentacarbonyl, and the other compounds employed in this study were all commercial products.

Reaction Procedure. To the solution of the potassium iron carbonylate, a certain amount of allyl halide or its derivatives was added, and then the mixture was agitated vigorously at 30°C under an atmospheric pressure of nitrogen or carbon monoxide. After a certain reaction time, the reaction flask was connected with a cold trap immersed in liquid nitrogen and fitted with a vacuum pump. The gases in the reaction flask were collected in the trap at 30 mmHg. The trap was allowed to warm to room temperature and then heated to 80°C, and the gas evolved was submitted to analysis. The liquid reaction mixture was analyzed at the same time.

Analytical Procedures. The reaction products were gas-chromatographed. For the gaseous products, a column packed with active carbon (0.3 cmϕ, 3 m) or a column packed with dimethylsulfolan (0.3 cmϕ, 5 m) was used. For the liquid products, a Golay R 45 column (0.25 mmϕ, 45m) and a column packed with SE 30 on a chromasorb were used.

Results and Discussion

The Reactions of $K_2Fe(CO)_4$ and $K_2Fe_2(CO)_8$ with Allyl Halides. Table 1 summarizes the results of these reactions, which were carried out under an atmosphere of carbon monoxide or nitrogen at 30°C. $K_2Fe(CO)_4$ reacts readily with allyl chloride, while the light-brown reaction mixture immediately turns dark red, and then yellow brown. As the reaction products, propylene (the major product) and 1,5-hexadiene are obtained.

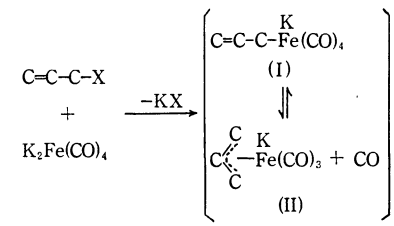
The yield of propylene amounts to about 2 mol*3 in hydrous ethyl alcohol (Exp. 1). However, in dry ethyl alcohol the yield of propylene decreases to 1 mol (Exp. 2). In both cases the yield of 1,5-hexadiene is almost 0.2 mol. Comparing Exp.1 with Exp. 3, the nitrogen atmosphere seems to be little more favorable to the production of propylene than the carbon monoxide atmosphere. Under carbon monoxide some side reactions, such as a carbonylation reaction, occur. The infrared spectrum of the reaction mixture treated with an alcoholic solution of iodide and hydrogen chloride has a band at 1738 cm^{-1} characteristic of an ester, indicating that some acyl-iron carbonyl complex is formed.

$KHFe(CO)_4$ and $K_2Fe_2(CO)_8$ also react with allyl chloride to give propylene and 1,5-hexadiene (Exps. 4 and 5), but the yields of propylene are less than that of the reaction of $K_2Fe(CO)_4$. The order of the reactivity of the iron carbonylates to the substitution reaction seems to be: $K_2Fe(CO)_4 > KHFe(CO)_4 > K_2Fe_2(CO)_8$.

As Exps. 6 and 7 show, allyl bromide and iodide also react with $K_2Fe(CO)_4$. However the yields of propylene are less than half of that of the reaction of allyl chloride.

The reaction of $K_2Fe(CO)_4$ with allyl halide is considered to proceed *via* σ- and π-allyl iron carbonyl complexes and to follow the following reaction scheme:



$$\xrightarrow{\text{solvent}} C{=}C{-}C \quad (1)$$

In the first step, $K_2Fe(CO)_4$ reacts with allyl halide to give the σ-allyl complex (I). This complex seems then to be converted to the π-allyl complex (II) with an evolution of carbon monoxide. These complexes may be unstable in an alcoholic solution, thus abstracting hydrogen from the solvent and giving propylene in a good yield. This reaction scheme is supported by the fact that, under nitrogen, a considerable amount of carbon monoxide evolves (Exps. 1 and 2).

When 1 mol of water is present in the reaction system, a considerable amount of carbon dioxide also evolves (Exp. 1). Thus, the water present in the system is more favorable to the formation of propylene and carbon dioxide. This fact seems to indicate that the water acts as one of the hydrogen sources and that a reaction between the water and carbon monoxide occurs to give hydrogen and carbon dioxide:

$$H_2O + CO \rightarrow 2(H) + CO_2 \quad (2)$$

This reaction mechanism is, however, not yet completely clear.

In dry tetrahydrofuran and in dry benzene the iron carbonylate is less reactive and the yield of propylene decreases to lees than half of that in dry ethyl alcohol (Exps. 8 and 9). These solvents are unsuitable for this reaction because the iron carbonylate is insoluble in benzene and only slightly soluble in THF. In these solvents, the formation of 1,5-hexadiene is also retarded.

The Reaction of *trans*-1-Chloro-2-butene and 3-Chloro-2-methyl-1-propene. The results of the reactions are summarized in Table 2. All of the reactions were carried out at 30°C in ethyl alcohol. *trans*-1-Chloro-2-butene reacts with $K_2Fe(CO)_4$ to give *trans*-2-butene (the major product), *cis*-2-butene, and 1-butene. The yield of the

*3 Hereafter mol means mole per mole of $Fe(CO)_4^{2-}$.

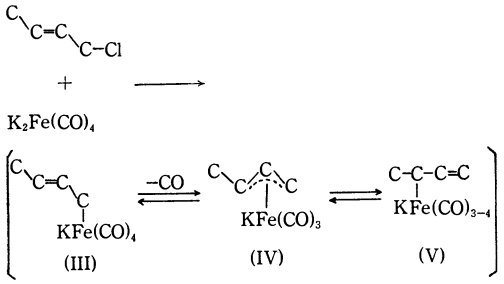
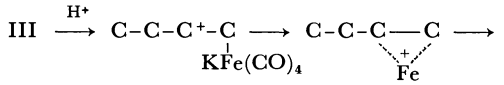
olefins amounts to 1.1 mol. The distribution of these monoolefins is approximately independent of the atmosphere, the presence of water, and the reaction time (10—240 min). After 4 days (Exp. 14), however, the percentage of *trans*-2-butene increases to 70%, while those of 1-butene and *cis*-2-butene decrease to 15% and 15% respectively, showing that under these conditions the isomerization among the butenes slowly occurs. This reaction is considered to proceed *via* σ- and π-allyl iron carbonyl complexes and to follow the following reaction scheme:



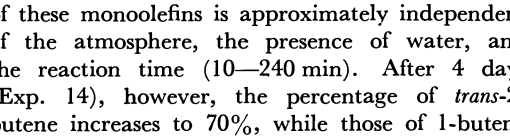
(3)

Thus, two σ-allylic compleexs (III and V) and one π-allylic complex (IV) are possible. For the formation of 1-butene, two routes from the complexes III and V are probable.
From the complex III:



(4)

From the complex V:



(5)

The π-allylic structure can reasonably be considered to be more stable than the σ-allyl structures. σ-Allyl manganese carbonyl has been suggested to decompose in the presence of an acid to give propylene in a way similar to that of Eq.(4).[3] In this case the reaction was carried out in a neutral or a rather basic solution. Moreover, it is safe to conclude that the complex III is more stable and more dominant than the complex V, which has a structure with larger steric hindrance. Accordingly, the route (5) is more probable for the formation of 1-butene. The complexes III and V seem to give 2-butene and 1-butene respectively. This consideration is supported by the facts that the percentages of 2-butenes are larger than that of 1-butene and that the isomerization among the the butenes occurs slowly under the conditions employed.

3-Chloro-2-methyl-1-butene also reacts with $K_2Fe(CO)_4$ to give 2-methylpropene in a good yield (Exp. 15).

The Reaction of 1-Chloro-3-methyl-2-butene and 3-Chloro-3-methyl-1-butene. The results of the reactions are summarized in Table 3. All of the reactions were carried out in ethyl alcohol at 30°C.

As Table 3 shows, 1-chloro-3-methyl-2-butene and 3-chloro-3-methyl-1-butene react with $K_2Fe(CO)_4$ and $KHFe(CO)_4$ to give three different

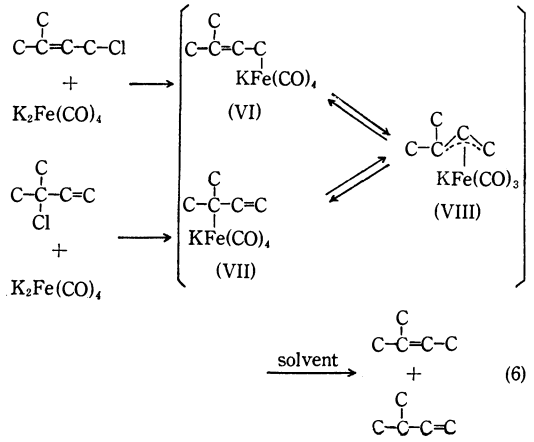
monoolefins, 2-methyl-2-butene (C), 3-methyl-1-butene (A), and 2-methyl-1-butene (B). At a high mole ratio ($RX/Fe(CO)_4^{2-}=3.0$), the distribution of the olefins is almost independent of the reaction conditions (the atmosphere, the presence of water, and the reaction time 1.5 hr —2 day). Under these conditions the olefin C is predominant, its percentage amounting to 85—90%; the olefins seem to be almost in an equilibrium because the distribution of the olefins remains unchanged with an increase in the reaction time.

When the mole ratio is 1.0 (Exps. 21 and 26), the olefins A and C predominate in the initial stage of the reactions. In this case the percentage of the olefin A amounts to 20%.

Judging from the similarity between the reactions of 1-chloro-3-methyl-2-butene and 3-chloro-3-methyl-1-butene, these reactions seems to have the same intermediates. Thus, the following reaction scheme seems reasonable:



(6)

In these cases, two σ-allyl complexes and one π-allyl complex are possible. The complex VI may be more stable than the complex VII because the tertiary structure of the latter has a larger steric hindrance. Accordingly, the equilibrium between them may be much more favorable to the complex VI. Thus, starting with even 3-chloro-3-methyl-1-butene under the conditions employed, the complex VI seems to be readily formed, giving the olefin C as the major product. The formation of the π-complex VIII is supported by the evolution of carbon monoxide.

This work was supported in part by The Kawakami Foundation, to which our thanks are due.

Anionic Telomerizations of Styrene with Butylamines*1

Teruzo ASAHARA, Manabu SENŌ, Sadayoshi TANAKA and Norio DEN

Institute of Industrial Science, The University of Tokyo, Roppongi, Minato-ku, Tokyo

(Received December 5, 1968)

The anionic telomerizations of styrene with *n*-butylamine, *s*-butylamine, *t*-butylamine and isobutylamine catalyzed by sodium metal were investigated. The structures of the products were discussed by the NMR spectra obtained in carbon tetrachloride and identified to be *N*-butyl-2-phenylethylamines and *N*-butyldi(2-phenylethyl)amines. The general reaction scheme was proposed and interpreted with the concept of the anionic telomerization, where amine acts as a telogen and styrene as a taxogen.

The concept of telomerization was introduced for reactions of the type

$$XY + nM \rightarrow XM_nY$$

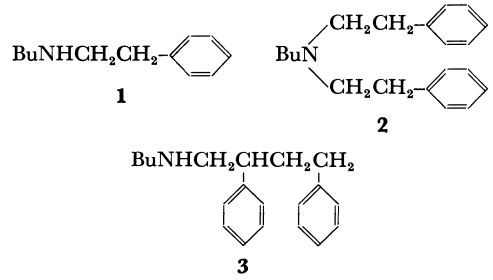
by Harmon in 1945.[1] Radical telomerizations have been actively investigated by many reseachers in the USA, Japan, USSR, Israel, *etc.*, and those of ethylene with carbon tetrachloride in particular. On the contrary, only a few papers on anionic and cationic telomerizations have appeared.

The hydrogen atoms attached to the nitrogen atom in ammonia NH_3, primary amines RNH_2 or secondary amines RR'NH are weakly acidic[2] and subject to the attack of strong alkalis such as sodium metal, phenyl potassium and *n*-butyllithium to form alkali amides. Some of these can add to styrene[3] or initiate the anionic polymerization of styrene.[4] Hence it was supposed that on taking one of the amines as a telogen and styrene as a taxogen, an anionic telomerization would take place with sodium metal as a catalyst.

In this paper investigation in telomerization of styrene with butylamines and the NMR spectra of the resulting *N*-butyl-2-phenylethylamines and *N*-butyldi(2-phenylethyl)amines are presented. Moreover, the reaction mechanism is discussed with the proposed scheme from the standpoint of anionic telomerization.

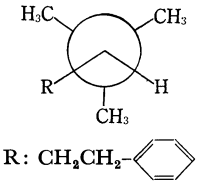
Results and Discussion

Reaction Products. Each of the butylamines $BuNH_2$ was reacted with syrene in the presence of sodium metal as a catalyst to produce N-butyl-2-phenylethylamine (**1**) and *N*-butyldi(2-phenylethyl)amine (**2**), but *N*-butyl-2,4-diphenylbutylamine (**3**) was not obtained.



The reaction products are listed in Table 1, where column 1 shows the amines used and column 4 the reaction products isolated.

Structures of the Reaction Products. Figures 1, 2, 3 and 4 show the proton NMR spectra of the reaction products. The assignments of the signals to the protons are listed in Table 2. In the compound **2c** there is one conformation about a single bond between the nitrogen and the carbon (e), in which three methyl groups are not equivalent in the conformation.



The splitting of the methyl singlet of the protons (f) into two signals would be caused by the restricted rotation about the single bond between the nitrogen and the carbon (e). If the rotation is as free as in the compound **1c**, three methyl groups would become equivalent in the NMR and show a single methyl singlet. The splitting of the phenyl

protons (a) in the compound **2c**, which does not appear in the compound **1c**, is perhaps due to the different conformations that are brought about by the restricted rotations about single bonds between carbons (b) and (c) and between carbon (c) and nitrogen. The IR spectra and the NMR spectra are consistent with the structural formulas illustrated in Table 1.

General Reaction Scheme. The reaction scheme is considered as follows. The initiation reaction may be the addition of sodium to styrene **4**, and product **5** transmetalates with the primary amine to give sodium amide **7**.

$$2Na + CH_2{=}CH\text{-}C_6H_5 \longrightarrow CH_2NaCHNa\text{-}C_6H_5 \quad (1)$$

4 **5**

$$5 + 2RNH_2 \rightleftarrows CH_3CH_2\text{-}C_6H_5 + 2RNHNa \quad (2)$$

6 **7**

Sodium amide **7** is able to react with styrene, and the resulting sodium salt **8** changes into the amide **7** by reaction (4), thus a cycle of reactions is formed.

$$7 + 4 \longrightarrow RNHCH_2CHNa\text{-}C_6H_5 \quad (3)$$

8

$$8 + 6 \underset{}{\overset{k_1}{\rightleftarrows}} RNHCH_2CH_2\text{-}C_6H_5 + 7 \quad (4)$$

1

Compound **8** reacts with the secondary amine **1** as well as the primary amine **6**, and amide **9** adds to styrene.

$$8 + 1 \underset{}{\overset{k_2}{\rightleftarrows}} 1 + RNNaCH_2CH_2\text{-}C_6H_5 \quad (5)$$

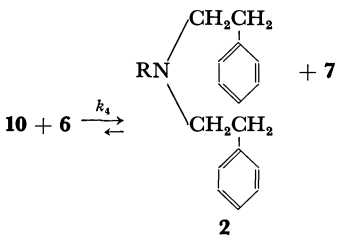
(6)

10

Compound **10** transmetalates with amines **6** and **1**.

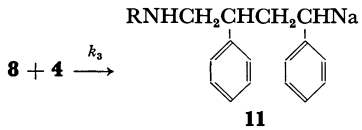


(7)

2

(8)

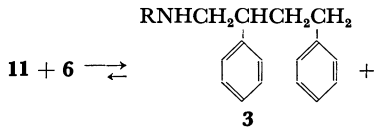
The organometallic compound **8** has a possibility to react with **4**, besides **6** and **1**, *i.e.* the propagation reaction may also take place.



(9)

11

Compound **11** reacts with amines **6** and **1**.



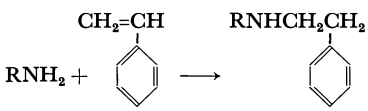
(10)

3

(11)

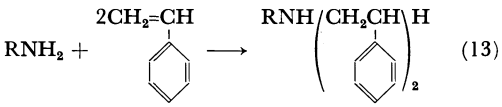
It may be understood from the reaction scheme that compounds **1**, **2** and **3** should be prepared in the reaction of amines and styrene catalyzed by sodium metal.

Anionic Telomerization. The reactions described in the preceding section can be interpreted as follows. We obtain Eq. (12) on combining Eqs. (3) and (4),



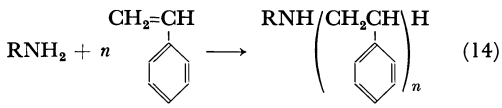
(12)

and Eq. (13) on combining Eqs. (3). (9) and (10).



(13)

If RNH_2 acts as a telogen and styrene as a taxogen, the telomerization reaction may be expressed as follows,

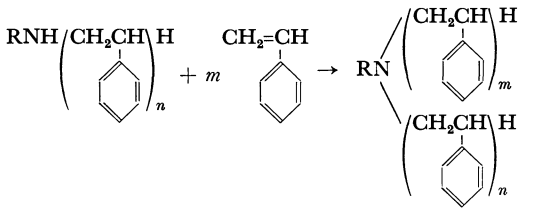


(14)

12

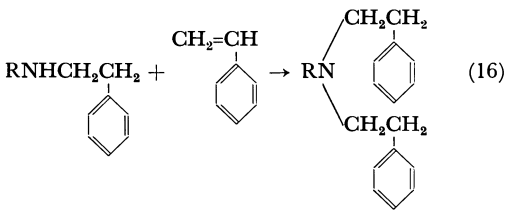
and the homolog **12** is obtained as a telomer. Hence, it is considered that Eqs. (12) and (13) are special cases of Eq. (14) and the products **1** and **3** are the telomers with $n=1$ and $n=2$, respectively. The secondary amine **12** has still an acidic hydrogen attached to the nitrogen atom and so **12** can react as a telogen. Therefore, another telomerization reaction may occur in RNH–CH_2=CH system,

i.e.,



13 (15)

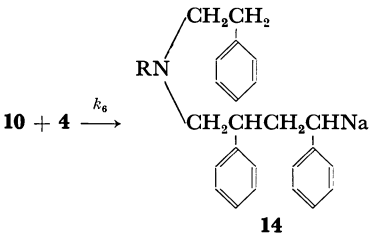
From Eqs. (6) and (8), Eq. (16) is obtained.



(16)

Reaction (16) is a special case of the telomerization reaction (15) and product **2** is one of the telomers **13**. Thus, the reaction products **1**, **2** and **3** may be interpreted as telomers in the telomerization reactions (14) and (15), and some part of the residue which remained undistilled in vacuum distillation is supposed to be a mixture of telomers **13** with $m+n \geqq 3$.

Reaction Scheme and Reactivity of Amines. Suppose k_1, k_2, k_3, k_4, k_5 and k_6 are the rate constants of reactions (4), (5), (9), (7), (8) and (17), respectivery. Compound **8** reacts with **6**, **1** and **4**, and so reactions (4), (5) and (9) are competitive each other. Other competitive reactions consist of reactions (7), (8) and (17).



(17)

14

If k_3 [CH_2=CH] is smaller than k_1 [RNH_2] or

k_2 [$RNHCH_2CH_2$], the main product is not **3** but

1, while if k_3 [CH_2=CH] is greater than k_1[RNH_2]

and k_2 [$RNHCH_2CH_2$], product **3** and its higer

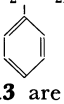
homologs  H ($n=2,3,\cdots$) areformed.

From similar consideration, if k_6[CH_2=CH] is smaller

than k_4[RNH_2] or k_5 [$RNHCH_2$=CH_2], product **12**

is hardly prepared, but compound **2** is prepared. On the contrary, if k_6 [CH_2=CH] is greater than

k_4[RNH_2] and k_5[$RNHCH_2CH_2$], compound **12**



and its higher homologs **13** are formed.

Under the reaction conditions adopted, the rate of the chain transfer reaction may be considered to be faster than that of the propagation one, since compound **2** was obtained but not compound **3**, *i.e.* the amines with acidic hydrogens reacted more easily with the organosodium compound **8** than styrene.

Experimental

Physical Data. For mass spectral analysis, a Hitachi RMU-6D mass spectrometer was employed with the electron beam energy at 80 eV. The molecular weight determination by vapor pressure osmometry was car-

ried out in benzene at 37°C on a Hewlett Packard Model 302 vapor pressure osmometer. IR spectra were recorded on a Hitachi Perkin-Elmer 125 grating infrared spectrophotometer. Proton NMR spectra were obtained on a Japan Electron Optics Lab. JNM C-60 HL spectrophotometer using tetramethylsilane as internal standard in carbon tetrachloride.

Materials. Styrene was dried over anhydrous magnesium sulfate for a day or two and was distilled under reduced pressure. Amines were dried over sodium hydroxide and were collected by distillation under atmospheric or reduced pressure according to their boiling points.

General Procedure for Preparation. A primary amine and finely sliced sodium were placed in a four-necked round-bottomed flask, provided with a mechanical stirrer, a reflux condenser, a dropping funnel and an inlet of nitrogen. The flask was heated to a prescribed temperature in an oil bath. The oil was agitated mechanically and its temperature was controlled by a thermostat. Styrene was added dropwise to the amine for from one hour to three, and thereafter the mixture was kept standing for reaction for a further three to five hours. Then the solution was cooled to room temperature and the alkali was decomposed by adding an equivalent amount of methanol and was neutralized by a 0.1N hydrochloric acid. A small amount of benzene was added to this reaction mixture and the resulting solution was washed with water, dried over sodium carbonate and distilled *in vacuo*.

***N*-Butyl-2-phenylethylamine (1a) and *N*-Butyldi-(2-phenylethyl)amine (2a).** To 21.1 g of *n*-butylamine and 0.7 g of sodium which were heated to 46.0 ±0.5°C, 31.2 g of styrene was added dropwise during 3 hr and the reaction was carried out for a further 3 hr. To the reaction mixture that was cooled to room temperature were added 3.1 m*l* of methanol and 5.0 m*l* of water. Then the solution was neutralized with hydrochloric acid, diluted with 50 m*l* of benzene and washed with 50 m*l* of water, and the organic layer was separated, dried and distilled *in vacuo* to give **1a** (14.0 g, 26.3%) and **2a** (19.8 g, 23.5%). The other reactions were carried out in similar procedures.

Characterization of Reaction Products. Table 3 summarizes the results on the characterization of the reaction products. Column 1 lists the molecular formula and structural formula of these compounds. Columns 2 and 3 show the result of the elementary analysis. The

weight percents were calculated for the molecular formula described in column 1. Satisfactory agreement with measured values confirms the expected structures. Columns 4, 5 and 6 report the molecular weights which were calculated, determined by the mass spectrometry and measured by the vapor pressure osmometry, respectively. The theoretical molecular weight was calculated for the molecular formula listed in column 1. These molecular weights agree with one another, and support the molecular formula proposed. The refractive indices of these compounds are listed in column 7. Whether the product has the group -NH- or not was confirmed by IR spectra. Wave numbers of the absorption peak due to the -NH- stretching vibration are described in column 8.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 2005—2013 (1969)

Organic Reactions under High Pressure. IV. Effect of Pressure on the Competitive Nitration of Benzene and Monosubstituted Benzenes. Dependence of the Substitutent Effect on the Pressure

Tsutomu ASANO

Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto

(Received December 12, 1968)

Partial rate factors for the nitration of six monosubstituted benzenes with nitric-sulfuric acid in acetic acid at 45°C have been determined over the 1—2000 kg/cm² pressure range. The ρ value for this reaction changed from −7.22 (1 kg/cm²) to −6.92 (2000 kg/cm²). This pressure dependency of the ρ value was not expected for this type of reaction. This phenomenon is interpreted in terms of the dependence of the degree of solvation of the transition states on the substituents. An abnormal deactivation due to pressure has been observed in the case of biphenyl. This deactivation has been attributed to an increase in the deviation from the coplanarity of the two phenyl groups. The dependence of the *ortho* : *para* ratios on the pressure is also discussed.

Since the last decade, pressure effects on the rates and product distributions of organic reactions have been extensively studied, and the results have offered much useful information about the reaction mechanisms.[1] The high-pressure technique is an especially powerful tool by which to investigate the solvation and steric hindrance in transition states.

For a liquid-phase reaction, the effect of pressure on the rate constant, k, can be expressed by Eq. (1);

$$(\partial \ln k/\partial P)_T = -\Delta V^{\neq}/RT \qquad (1)$$

where $\Delta V^{\neq}$ is the volume of the activation of the reaction, that is, the difference in the partial molar volumes between the transition state and the initial state. In considering the molecular theory of activation volumes, it is convenient to follow Evans and Polanyi[2] and to split $\Delta V^{\neq}$ into two terms:

$$\Delta V^{\neq} = \Delta_1 V^{\neq} + \Delta_2 V^{\neq} \qquad (2)$$

The change in the volume of the reacting molecules when they form the transition state is represented by $\Delta_1 V^{\neq}$, while $\Delta_2 V^{\neq}$ represents the accompanying change in the volume of the surrounding solvent. The magnitude of $\Delta_2 V^{\neq}$ is mainly determined by the difference in the total charge and in its distribution in the initial and transition states.[3] As a result, reactions in which the slow step leads to the formation of ions from neutral molecules and those in which ions combine to form neutral molecules have larger $\Delta_2 V^{\neq}$ values. On the other hand, reactions in which ions participate without either increasing or decreasing the net charge of the system have smaller $\Delta_2 V^{\neq}$ values. On the basis of this electrostriction theory, Ellis *et al.*[4] considered the effect of the pressure on the ρ value of the Hammett equation and predicted as follows:

1) For example, see E. Whalley, "Advances in Physical Organic Chemistry," Vol. 2, ed. by V. Gold, Academic Press, London and New York (1964), p. 93.

2) M. G. Evans and M. Polanyi, *Trans. Faraday Soc.*, **31**, 875 (1935).

3) S. D. Hamann "Physico-Chemical Effects of Pressure," Butterworths Scientific Publications, London (1957), Chapters 8 and 9.

4) A. J. Ellis, W. S. Fyfe, R. I. Rutherford, A. Fischer and J. Vaughan, *J. Chem. Phys.*, **31**, 176 (1959).

(A) For a reaction between an ion and a neutral molecule, pressure changes should have little effect on the value of ρ.

(B) For a reaction between ions or between neutral molecules leading to a dipolar transition state, the magnitude of ρ should be influenced by a change in the pressure.

In the case of B, the validity of the prediction was shown by examinations of the pressure effect on the dissociation constants. Fischer *et al.*[5] measured the pK values in water at 25°C of a number of substituted benzoic and phenylacetic acids over the pressure range from 1 to 3000 bars. In both series, the ρ values decreased with an increase in the pressure, as had been predicted. Imoto *et al.*[6] investigated the effect of the pressure on the rate of the saponification of ethyl benzoates in aqueous dioxane over the 1—1000 kg/cm^2 pressure range; they found that $\Delta V^{\neq}$ values were essentially unchanged by substituents (*p*-Cl, MeO, H). This result shoud support the above prediction of the case A.

As has been mentioned above, Ellis' prediction is based on the electrostriction theory; *i.e.*, for example, the $\Delta_2 V^{\neq}$ value for reactions (3) and (4) will be small because the net charge of the system does not change during the activation processes.*1

$$\underset{}{A_1 + B^+ \rightarrow \underset{I}{A_1^{+\delta} \cdots B^{+\delta}} \rightarrow P_1} \quad (3)$$

$$\underset{}{A_2 + B^+ \rightarrow \underset{II}{A_2^{+\delta} \cdots B^{+\delta}} \rightarrow P_2} \quad (4)$$

Hence, the difference in $\Delta V^{\neq}$ between reactions (3) and (4), $\delta\Delta V^{\neq}$,*2 will be negligible. Therefore, it may be concluded that pressure changes have little effect on the value of ρ.*3

However, it should be possible to consider as follows. The solvation in the initial states will be nearly the same in both reactions because of the intervention of the common ion, B^+, as an attacking entity. Consequently, the difference in $\Delta_2 V^{\neq}$ must come from the difference in solvation between the two transition states, I and II. The situation is the same for the dissociation of benzoic acids, (5) and (6):

$$C_6H_5COOH \rightarrow C_6H_5COO^- + H^+ \quad (5)$$

$$XC_6H_4COOH \rightarrow XC_6H_4COO^- + H^+ \quad (6)$$

In this case, the differences in $\Delta\bar{V}^{\circ}$ values are large enough for the ρ value to change with the pressure. Since the two carboxylic acids will be solvated to quite the same extent, the difference in the $\Delta\bar{V}^{\circ}$ values is mainly due to the difference in solvation between the two carboxylate ions. Therefore, if the degrees of charge distribution in the two transition states, I and II, are considerably different, $\delta\Delta V^{\neq}$ will be large enough to be detected experimentally.

The nitration of monosubstituted benzenes by nitric-sulfuric acid in acetic acid seems to be a suitable model reaction for studying the influence of the pressure upon the ρ value for a reaction between an ion and a neutral molecule for the following reasons:

(1) The value of $|\rho|$ for the nitration reaction is large (*ca.* 6.0).[7]

(2) The attacking entity is undoubtedly an ionic species, an incipient nitronium ion.[8]

(3) As the competitive method is applicable, uncertainties arising from imperfect and, consequently, unequal pressure and temperature control are avoided.

In addition, the effect of the pressure on the *ortho* : *para* ratios would give new information about the steric hindrance in ionic reactions. In many instances, it is observed that $\Delta V^{\neq}$ becomes more negative as the reacting center becomes more sterically hindered.[9] The most plausible explanation of such a phenomenon is Gonikberg's[10] suggestion that $\Delta V^{\neq}$ contains a negative term, $\Delta V^{\neq}_{\text{sterle}}$, arising from the overlap of interfering atoms in the transition state.*4 Coillet and Hamann[11] have reported, however, that the *ortho* : *para* ratios in the nitration of toluene and chlorobenzene decrease with an increase in the pressure, but the exact reason for this anomaly could not be ascertained.

This report will describe the studies in the competitive nitration of benzene and six monosubstituted benzenes by nitric-sulfuric acid in acetic

acid at 45°C over the 1—2000 kg/cm² pressure range; we undertook the studies in order to obtain new, detailed information about the solvation and steric hindrance in the transition states for aromatic electrophilic substitution reactions.

Experimental Results

The effects of the pressure on the competitive nitration of benzene and activated monosubstituted benzenes are summarized in Table 1.

While there are only small, but significant, changes in the isomer distribution (position selectivity), one can see rather a large change in the relative reactivity, k_X/k_H (substrate selectivity). As the pressure applied increases, the relative reactivity decreases appreciably. Although the *ortho* : *para* and *meta* : *para* ratios increase with an increase in the pressure in toluene and *t*-butylbenzene, this is not due to the increasing reactivity of the *ortho* and *meta* positions, but to the decreasing reactivity of the *para* position. In the case of biphenyl, the pressure independency of the *ortho* : *para* ratio is observed, while the relative reactivity diminishes more extensively than in alkylbenzenes.

TABLE 2. EFFECT OF PRESSURE ON THE COMPETITIVE NITRATION OF BENZENE AND DEACTIVATED MONOSUBSTITUTED BENZENES IN ACETIC ACID AT 45°C

Fluorobenzene							
P (kg/cm²)	k_F/k_H	*o*- %	*m*- %	*p*- %	f_o^F	$f_m^F \times 10^3$	f_p^F
1	0.142	9.23	0.210	90.6	0.0392	0.89	0.769
1000	0.140	9.32	0.239	90.5	0.0391	1.00	0.758
2000	0.140	9.26	0.268	90.5	0.0390	1.13	0.761
Chlorobenzene							
P (kg/cm²)	k_{Cl}/k_H	*o*- %	*m*- %	*p*- %	f_o^{Cl}	$f_m^{Cl} \times 10^3$	f_p^{Cl}
1	0.0400	23.1	0.669	76.2	0.0277	0.80	0.183
1000	0.0409	23.6	0.768	75.7	0.0290	0.94	0.186

1000	0.0354	27.8	1.03	71.2	0.0295	1.09	0.151
2000	0.0365	28.0	1.12	70.8	0.0306	1.23	0.155

Table 3. Reaction constant ρ and correlation coefficient r for the nitration by mixed acid in acetic acid at 45°C

P (kg/cm²)	1	1000	2000
ρ	−7.22	−7.05	−6.92
r	0.988	0.989	0.986

On the contrary, chlorobenzene and bromobenzene show an increasing relative reactivity with an increase in the pressure. The results are shown in Table 2. In all three cases in Table 2, the increase in f_m is striking; bromobenzene and chlorobenzene reveal an apparent increase in the *ortho* : *para* ratio with the pressure, as is also observed in alkylbenzenes.

The partial rate factors in Tables 1 and 2 are plotted against Brown-Okamoto's σ^+ value to give a straight line. The ρ values calculated by the method of least squares and the correlation coefficients, r, are listed in Table 3. (The values of biphenyl were not included in the calculations. This will be discussed below.) The correlation of these plots is not excellent, but it may be concluded that the ρ value increases appreciably with an increase in the pressure.

Fischer *et al.*[5] have pointed out that the magnitude of $\Delta V^{\neq}$ values could be an indication of anticipating whether or not ρ depends on the pressure. This can be interpreted as follows. Assuming that σ^+ is not a function of the pressure, one can obtain Eq. (9) from Eqs. (7) and (8):

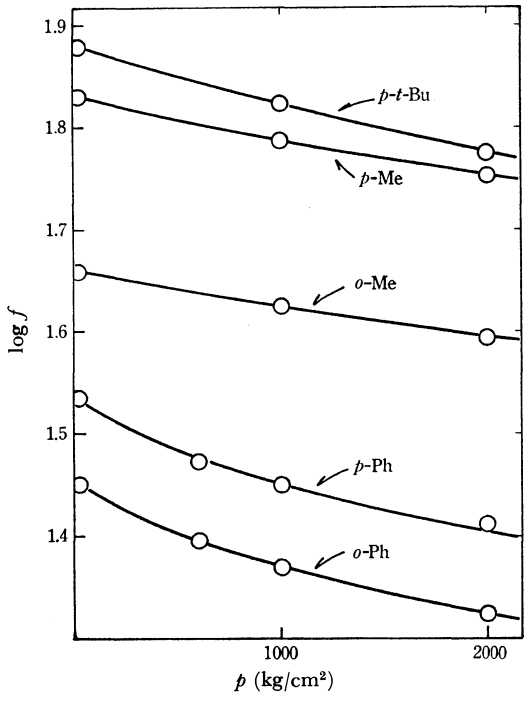

Fig. 1. $\log f$-p curves for the nitration of activated monosubstituted benzenes.

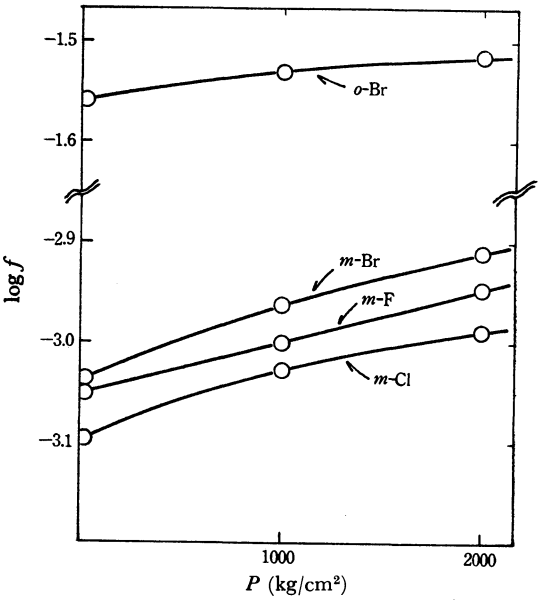

Fig. 2. $\log f$-p curves for the nitration of halobenzenes.

Table 4. $\delta\Delta V_1^{\neq}$ or $\delta\Delta\bar{V}_{1000}^{\neq}$ values for the nitration by mixed acid in acetic acid at 45°C (ml/mol)[a]

Substituent	*o*-	*m*-	*p*-
Methyl	2.1	1.2*	3.2
t-Butyl	0.6*	1.6*	3.5
Fluoro	0.1*	−3.1	0.4*
Chloro	−1.2*	−5.0	−0.5*
Bromo	−2.0	−5.2	−1.1*
Phenyl	6.2		6.6

*: $\delta\Delta\bar{V}_{1000}^{\neq}$ values

a) The error is estimated at most 0.5 ml/mol.

$$\Delta V^{\neq} = -RT(\partial \ln k/\partial P)_T \quad (7)$$

$$\log f = \rho\sigma^+ \quad (8)$$

$$\delta\Delta V^{\neq} = -RT(\partial \ln f/\partial P)_T = -2.3RT\sigma^+(\partial\rho/\partial P)_T \quad (9)$$

Thus, if σ^+ is independent of the pressure and if ρ varies with the pressure, then the plot of $\delta\Delta V^{\neq}$ at a constant pressure and temperature against σ^+ should give a linear line, including the point of origin. Figures 1 and 2 show the dependence of $\log f$ on the pressure. From the slopes of the curves at zero pressure, the $\delta\Delta V^{\neq}{}_1$*5 values were calculated; they are listed in Table 4, together with the values of $\delta\Delta\bar{V}_{1000}^{\neq}$*6 for the other positions.*7

*5 $\delta\Delta V^{\neq}$ values at 1 atm.

*6 $\delta\Delta\bar{V}_{1000}^{\neq} = -RT(\ln f_{1000} - \ln f_1)1/1000$. The numerals indicate the pressure.

*7 The values of $\delta\Delta\bar{V}_{1000}^{\neq}$ are adopted instead of $\delta\Delta V^{\neq}{}_1$ for the *meta* positions of alkylbenzenes and the *para* positions of halobenzenes because the changes in the reactivity of these positions with the pressure are relatively small; hence, $\delta\Delta V^{\neq}$ should change little with the pressure.

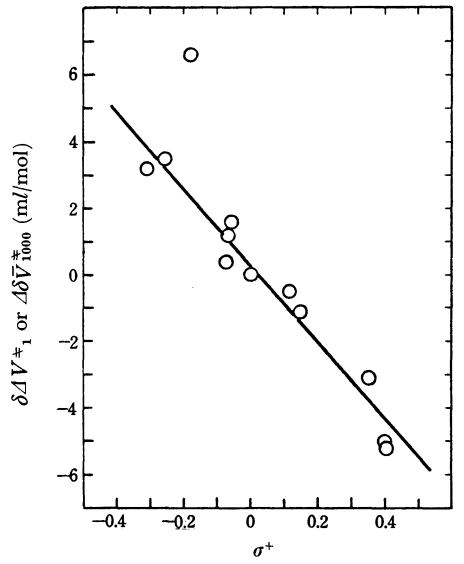

Fig. 3. Plot of $\delta\Delta V^{\neq}_1$ or $\delta\bar{V}^{\neq}_{1000}$ against σ^+.

Those values are plotted in Fig. 3 against σ^+; the line passes through the point of origin. The correlation shown in Fig. 3 reveals this relation:

$$\delta\Delta V^{\neq}_1 = -11.6\sigma^+ + 0.24.$$*8

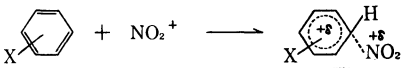
The dependence of the ρ value for nitration by nitric-sulfuric acid in acetic acid on the pressure is evident.

Discussion

Effect of Pressure on f_m and f_p. Since no kinetic isotope effect was observed in the nitration of benzene and a number of its derivatives of widely differing reactivities,[14] the observed $\delta\Delta V^{\neq}$ values represent the difference in $\Delta V^{\neq}$ between the following two processes (in Eqs. (10) and (11), NO_2^+ represents a weaker electrophilic precursor of the nitronium ion):[8]

(10)

III



(11)

IV

According to Evans and Polanyi,[2] $\delta\Delta V^{\neq}$ is separated into two terms, $\delta\Delta_1 V^{\neq}$ and $\delta\Delta_2 V^{\neq}$ (Eq. (12)):

$$\delta\Delta V^{\neq} = \Delta V^{\neq}_X - \Delta V^{\neq}_H = (\Delta_1 V^{\neq}_X - \Delta_1 V^{\neq}_H) + (\Delta_2 V^{\neq}_X - \Delta_2 V^{\neq}_H) = \delta\Delta_1 V^{\neq} + \delta\Delta_2 V^{\neq} \quad (12)$$

When the replacement of a hydrogen atom of benzene molecule with a different substituent, X, occurs at a point sufficiently remote from the reaction site, a condition for the applicability of the $\rho\sigma^+$ equation is fulfilled; the first term, $\delta\Delta_1 V^{\neq}$, is decided by the difference in the C···N bond length in the two transition states, III and IV. The position of the trasition state on the reaction coordinate might change with the reactivity of the substrate; however, it is unlikely that the C···N bond length changes so greatly that $\delta\Delta_1 V^{\neq}$ amounts to several milliliters.*9 The detritiation of methylbenzenes seems a good example indicating that the position of the transition state does not change with the substituents. Ansell and Taylor[15] found that $\log f_o^{Me}$: $\log f_p^{Me}$ ratio for *m*-xylene is 0.885 ± 0.035, exactly the same as in toluene, in spite of the fact that the former is 200 times as reactive as the latter. From this result they concluded that the transition states are not sufficiently different for any effect of the differing stabilizations of the *ortho* and *para* positions to show up. Consequently, if the attack by a nitrating agent occurs at a position *meta* or *para* to the substituent X, the $\delta\Delta_1 V^{\neq}$ should be nearly equal to zero; *i.e.*, $\delta\Delta_2 V^{\neq}$ should be responsible to the observed $\delta\Delta V^{\neq}$. When the substituent X is more electron-donating than the hydrogen atom, the charge on the nitrogen atom disperses more extensively into the benzene ring in IV than in III. Thus, the desolvation attributable to charge dispersion during the activation step should be more extensive in IV. On the other hand, when X is more electron-attracting than the hydrogen atom, the desolvation during the activation step should be less extensive in IV. The $\delta\Delta V^{\neq}$ values listed in Table 4 clearly reveal that this is the case. The anomalous pressure dependence of the reactivity of biphenyl will be discussed later.

Thus, the extent of solvation in the transition state of the nitration of benzene derivatives changes with the substituents. Accordingly, the ρ value increases with an increase in the pressure. The reported independency of the ρ value of the saponification of ethyl benzoates[6] must have its origin in its relatively small ρ value ($\rho \fallingdotseq 2$), which makes the difference in $\Delta V^{\neq}$ small.

Abnormal Deactivation of Biphenyl by Pressure. The *para* and *ortho* positions to phenyl group are anomalously deactivated with an increase in the pressure. From the plot of $\delta\Delta V^{\neq}_1$ against σ^+, $\delta\Delta V_1^{\neq}$ may be expected to be approximately 2.5 ml/mol for the *para* position of biphenyl.

*8 The results for biphenyl were not included in the calculation.

14) Numerous investigations of kinetic isotope effects in nitration have been conducted. See H. Zollinger, Ref. 1, p. 163.

*9 If one arbitrarily assumes that the van der Waals cross-sectional area of the C···N bond is equal to $1.5^2\times3.14=7.07$ Å^2, there must be *ca.* 1 Å difference in the C···N bond length in order for $\delta\Delta_1 V^{\neq}$ to amount to 4.3 ml/mol.

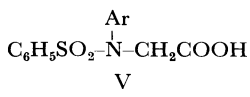
15) H. V. Ansell and R. Taylor, *J. Chem. Soc.*, *B*, **1968**, 526.

The observed value, 6.6 ml/mol, is more than twice that expected. The deviation from the $\delta\Delta V^{\ddagger}_1$-$\sigma^+$ plot implies a pressure dependence of the substituent constant, $\sigma^+_{p\text{-Ph}}$.

Stock and Brown[16] pointed out that the reactivity of the *para* position in biphenyl increases significantly with an increase in the electron demand of the substitution reaction; that is, $\sigma^+_{p\text{-Ph}}$ decreases as the electrophile becomes less reactive. They attributed this anomaly to the variation in the angle between two rings and explained as follows: "..... the full contribution of the substitutent is not achieved because of steric repulsions among the four hydrogens.....As the selectivity of the electrophilic reaction increases, the steric forces are, in part, overcome by the increased energy requirements of the transition state."

As the other substituents do not show any anomaly, the anomalous deactivation of biphenyl by pressure must be due to the change of the angle between two rings. However, the cause of the increased angle should not be the increase in the reactivity of the attacking incipient nitronium ion as a result of the pressure, because an ion should be solvated more strongly at high pressures than at atmospheric pressure. It seems to be rather reasonable to consider that, as the angle between two phenyl groups at the transition (and ground) state becomes greater, the volume of the system decreases.

McCune *et al.*[17] have reported that the racemization of sodium salt of L-6-nitro-2,2'-carboxybiphenyl is retarded by an increase in the pressure to an extent corresponding to $\Delta V^{\ddagger}=2$ ml/mol at 1 atm in a 0.1 N aqueous sodium hydroxide solution. McKelvey and Brower[18] independently studied the effect of the pressure on the rate of the racemization of three compounds with the general strcture V, where Ar denotes an aryl group with hindering *ortho* substituents. In ethanol the rate constant decreased with an increase in the pressure ($\Delta V_1^{\ddagger}\fallingdotseq 2$ ml/mol). Although the exact



V

reason for these activation volumes could not be obtained, it may be quite all right to assume that as the angle between two phenyl groups in the transition (and ground) state decreases, the volume of the system increases. Consequently, under high pressure the angle will increase and the resonance contribution will decrease to some extent. We suggest that the observed $\delta\Delta V^{\ddagger}$ value reflects not only the volume change during the activation step, but also the decreased resonance contribution caused by an external pressure. In other words, the structure of the transition state changes with the pressure.

Table 5. Effect of pressure on the *ortho* : *para* ratios in the nitration of monosubstituted benzenes by mixed acid in acetic acid at 45°C

Substituent	P (kg/cm²)		
	1	1000	2000
Methyl	1.35	1.38	1.39
t-Butyl	0.117	0.127	0.136
Phenyl	1.65	1.66	1.64
Fluoro	0.102	0.103	0.102
Chloro	0.303	0.312	0.312
Bromo	0.380	0.390	0.395

Effect of the Pressure on the *ortho* : *para* Ratio. The *ortho*: *para* ratios at various pressures are shown in Table 5. Except for the cases of biphenyl and fluorobenzene, the *ortho* nitration increases with the pressure, and as substituent becomes larger the tendency becomes even more remarkable. These results show a tendency the reverse of that reported by Coillet and Hamann.[11] They reported the nitration of toluene and chlorobenzene by anhydrous nitric acid in acetic acid at 0°C. Their results are quoted in Table 6.

Table 6. Effect of pressure on the isomer distributions in the nitration of toluene and chlorobenzene by nitric acid in acetic acid at 0°C

P (atm)	Toluene				Chlorobenzene		
	o- %	*m*- %	*p*- %	*o*-/*p*-	*o*- %	*p*- %	*o*-/*p*-
1	56.0	2.0	42.0	1.33	24.7	75.3	0.328
1200	55.0	2.2	42.8	1.29			
2000	54.3	2.4	43.3	1.25	20.4	79.6	0.256

Obviously, the *ortho* : *para* ratios decrease with the pressure and the tendency is more remarkable in chlorobenzene. These two inconsistent results can most plausibly be explained in terms of the difference in solvation in the two systems. The activation volume of the *ortho* nitration can be separated into four terms, as in Eq. (13).

$$\Delta V^{\ddagger}(ortho) = \Delta_1V^{\ddagger}+\Delta_2V^{\ddagger} = (\Delta_1V^{\ddagger}_{bond}+\Delta_1V^{\ddagger}_{steric}) + (\Delta_2V^{\ddagger}_{el}+\Delta_2V^{\ddagger}_{steric}) \quad (13)$$

$\Delta_1V^{\ddagger}_{bond}$: volume change of the reacting molecules due to changes in the bond length during the activation process. In the present case, $\Delta_1V^{\ddagger}_{bond}<0$.

$\Delta_1V^{\ddagger}_{steric}$: volume change of the reacting molecules due to the overlap of interfering atoms in the transition state. $\Delta_1V^{\ddagger}_{steric}<0$.

$\Delta_2V^{\neq}_{el}$: volume change of the solvent due to the changing electrostatic interaction of the reacting molecules with the solvent during the activation process. In the present case, $\Delta_2V^{\neq}_{el}>0$.

$\Delta_2V^{\neq}_{steric}$: volume change of the solvent due to the steric inhibition of solvation in the transition state. $\Delta_2V^{\neq}_{steric}>0$.

In the *para* nitration the $\Delta_1V^{\neq}_{steric}$ and $\Delta_2V^{\neq}_{steric}$ terms are not present; accordingly, $\Delta_1V^{\neq}=\Delta_1V^{\neq}_{bond}$ and $\Delta_2V^{\neq}=\Delta_2V^{\neq}_{el}$. It seems to be plausible to assume $\Delta_1V^{\neq}_{bond}$ (*para*) is equal to $\Delta_1V^{\neq}_{bond}$ (*ortho*). Although it is not obvious whether or not $\Delta_2V^{\neq}_{el}$ (*para*) is larger than $\Delta_2V^{\neq}_{el}$ (*ortho*), the difference, $\Delta_2V^{\neq}_{el}$ (*ortho*) $-\Delta_2V^{\neq}_{el}$ (*para*), will be small compared to the $\Delta_2V^{\neq}_{steric}$ term. In view of the above approximations, the difference in the activation volumes in the *ortho* nitration and *para* nitration may be represented as in Eq. (14). In Eq. (14) $\Delta_1V^{\neq}_{steric}$ is negative and $\Delta_2V^{\neq}_{steric}$ is positive.

$$\Delta V^{\neq}(ortho)-\Delta V^{\neq}(para)\fallingdotseq\Delta_1V^{\neq}_{steric}+\Delta_2V^{\neq}_{steric} \quad (14)$$

Accordingly, it depends on the relative magnitude of the above two terms whether the applied pressure increases the *ortho* : *para* ratio or decreases it. The solvation of an ionic species and a dipolar molecule should be more striking under Coillet and Hamann's conditions (acetic acid solution at 0°C) than in the present case (acetic acid solution at 45°C). Therefore, the volume increase due to the steric inhibition of solvation, $\Delta_2V^{\neq}_{steric}$, should be larger at 0°C than at 45°C and $\Delta_2V^{\neq}_{steric}$ should exceed the volume contraction arising from the overlap of interfering atoms, $\Delta_1V^{\neq}_{steric}$, at 0°C. As a result, the *ortho* : *para* ratios decrease with an increase in the pressure. On the other hand, under the present conditions $\Delta_1V^{\neq}_{steric}$ exceeds $\Delta_2V^{\neq}_{steric}$ and the applied pressure causes the increase in the *ortho* : *para* ratio.

If the above explanation is correct, the *ortho*: *para* ratio in chlorobenzene should decrease more extensively with the pressure than in toluene at 0°C for reasons to be outlined below.

The initial state solvation should be more striking for chlorobenzene because of the larger polarization of the C–Cl bond than of the C–CH_3 bond.*10 In the reaction of allyl chloride with phenoxide ion in water, the product ratio, (*o*-allylphenol)/(*p*-allylphenol), decreases with an increase in the pressure ($\delta\Delta V_1^{\neq}=5.4$ ml/mol at 30°C).[12] The data in Table 6 are in accordance with the above prediction; the fact that the changes in the *ortho*: *para* ratios with the pressure in chlorobezene and in toluene are nearly equal at 45°C indicates that the difference in the initial state solvation is small and does not play a principal role in the effect of the pressure on the *ortho* : *para* ratios. Since the values of $\Delta_1V^{\neq}_{steric}$ are not known, the extent of the volume increase due to the steric inhibition of solvation can not be discussed further on the basis of the data at hand.

*10 The dipole moments of chlorobenzene and toluene are 1.56 and 0.39 respectively.

Experimental

Materials. Unless otherwise stated, the materials used in the present experiment were prepared by standard methods; the purities were inspected by g.l.c. and had the following physical constants (all the melting and boiling points are uncorrected).

t-Butylbenzene, prepared by the method of Norris and Strugis[19]; bp 168.5°C, n_D^{27} 1.4889. Fluorobenzene, prepared by the method of Flood[20]; bp 85.5°C, n_D^{20} 1.4677. Nitrotoluenes, *o*- bp 110—111°C/28 mmHg, n_D^{27} 1.5424; *m*- bp 121°C/32 mmHg, n_D^{27} 1.5431; *p*- mp 51.9—52.1°C. *o*-Nitro-*t*-butylbenzene, prepared by the nitration of *t*-butylbenzene and collected by preparative g.l.c.; n_D^{27} 1.5141. *m*-Nitro-*t*-butylbenzene, prepared from *p*-*t*-butylaniline*11; n_D^{27} 1.5238. *p*-Nitro-*t*-butylbenzene, prepared by the nitration of *t*-butylbenzene and collected by preparative g.l.c.; mp 27°C, n_D^{27} 1.5305. Biphenyl; mp 70.0—70.5°C. *o*- and *p*-Nitrobiphenyls, purified by recrystallization, *o*-; mp 35.4—36.0°C from ethanol. *p*-; mp 114.3—115.0°C from methanol-chloroform. *m*-Nitrobiphenyl, prepared by the method of Elks *et al.*;[22] mp 59.9—60.0°C from ethanol. *o*-Nitrofluorobenzene, bp 95—96°C/15.5mmHg, $n_D^{22.6}$ 1.5292. *m*-Nitrofluorobenzene, kindly supplied by the Hashimoto Kasei Co., Ltd.; bp 82—83°C/19 mmHg, $n_D^{22.6}$ 1.5231. *p*-Nitrofluorobenzene, prepared by the method of Cheek *et al.*[23] from *p*-nitrobenzenediazonium tetrafluoroborate,[24] $n_D^{22.7}$ 1.5293. Nitrochlorobenzenes, *o*- mp 32.5—32.7°C; *m*- mp 44.7—44.9°C; *p*- mp 83.9—84.0°C. Nitrobromobenzenes, prepared by the method of Newman and Fones,[25] *o*- mp 41.6—

All the other materials and solvents were purified by ordinary methods. Guaranteed-reagent-grade nitric acid (d=1.42) and sulfuric acid (d=1.84) were used.

High-pressure Apparatus. The high-pressure apparatus has been described previously.[13]

Nitration and Analytical Procedure. Nitrations were carried out by adding an acetic acid solution of nitric-sulfuric acid to a solution of benzene, substituted benzene, and a suitable internal standard at room temperature. The initial concentrations of acids and water were as follows; for alkyl- and aryl-benzenes, H_2O=1.3M, HNO_3=0.6N, H_2SO_4=2.6N; for halobenzenes, H_2O=2.3M, HNO_3=1.0N, H_2SO_4=4.7N. The substrate concentrations were in the range of 0.15—1.15M.

About 2.5 m*l* of the reaction mixture was transferred to a reaction vessel (sealed tube or glass syringe) and maintained at 45°C at the desired pressure. The reaction was stopped by adding water after a few hours depending on the pressure. The mixture was neutralized with aqueous sodium hydroxide and extracted repeatedly with methylene chloride. The extracts were washed, concentrated carefully, and analyzed by g.l.c. The validity of this procedure was previously proved using synthetic mixtures of nitrobenzenes. Analyses were made for nitro aromatics, and this value was subtracted from the initial concentration of the aromatic to obtain the value of the final concentration.

The relative reactivities were calculated by Eq. (15)[26]:

$$k_X/k_H = [\log [XC_6H_5]_0 - \log [XC_6H_5]_t]/[\log [C_6H_6]_0 - \log [C_6H_6]_t] \quad (15)$$

The *meta*: *ortho* ratios in the nitration of halobenzenes were determined independently in order to obtain the exact concentration of *m*-nitrohalobenzenes.

The kinetic runs were performed at least three times under each set of conditions; the averaged values are shown in Tables 1 and 2. A typical example is shown in Table 7.

Table 7. Competitive nitration of benzene and *t*-butylbenzene at 2000 kg/cm²

k_{Bu}/k_H	*o*- %	*m*- %	*p*- %	f_o^{Bu}	f_m^{Bu}	f_p^{Bu}
12.4	10.9	7.8	81.2	4.1	2.9	60.4
12.6	10.9	7.9	81.2	4.1	3.0	61.4
12.0	11.3	8.4	80.3	4.1	3.0	57.8
12.0	11.1	8.3	80.6	4.0	3.0	58.0
12.5	11.0	7.9	81.1	4.1	3.0	60.8

In the reaction of biphenyl, the remaining biphenyl was determined directly. It was assumed that nitrobiphenyls consist of *o*- and *p*-nitrobiphenyl, for the separation of *m*-nitrobiphenyl from the *para* isomer on g.l.c. was not enough to determine its quantity; however, the quantity is very small and the obtained partial rate factors for the *ortho* and *para* positions should be real ones.

Gas-chromatographic Analysis. All analyses of the nitration mixtures were carried out on a Yanagimoto gas chromatograph Model GCG 5DH. A thermal-conductivity detector was used except for the determination of the *meta*: *ortho* ratio in the case of halobenzenes. For this purpose a flame-ionization detector was used. The analytical conditions and retention times are presented in Table 8.

The author wishes to express his appreciation to Professor Jiro Osugi for his courtesy of providing the high-pressure apparatus used in the present experiment. He is also indebted to Professors Ryozo Goto and Akira Sera for their helpful discussions and encouragement throughout this work.

Ring Expansion of Bicyclic *gem*-Dihalo- and Monohalocyclopropanes

Teiichi ANDO, Hirokazu HOSAKA, Hiroki YAMANAKA and Wataru FUNASAKA

Department of Industrial Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received December 13, 1968)

Some bicyclic *gem*-dichlorocyclopropanes (Ia through Id) and *gem*-chlorofluorocyclopropanes (IIa through IId) were prepared by the addition of dichloro- and chlorofluorocarbene, respectively, to the appropriate cyclic olefins. The reduction of these dihalocyclopropanes with tri-*n*-butyltin hydride gave the corresponding monochloro- (IIIa through IIId) or monofluorocyclopropanes (IVa through IVd) in fairly good yields. When treated with an excess of hot quinoline, the *endo*-chloro isomers of IIa, IIb, IId, IIIa, IIIb, and IIId were converted to their ring expansion products, whereas their *exo*-chloro isomers were recovered unchanged. In contrast, the *exo*-chloro isomers of IIc and IIIc decomposed more readily than their *endo*-chloro isomers under similar conditions. These results were discussed on the concept of a concerted disrotatory process.

The ring opening or ring expansion reactions of *gem*-dihalo- and monohalocyclopropanes have received much attention in recent years, and it has been found that the reaction rate is dependent not only on the kind of halogen[1] but also on the molecular geometry of the substrate.[2-9] Baird and Reese[2] have proved that *endo*-6-chlorobicyclo[3.1.0]hexane is converted to 3-chlorocyclohexene when heated at 120°C. Ghosez *et al.*,[3] have shown that the *endo*-chloro isomer of 3-chloro-8-oxatricyclo[3.2.1.$0^{2,4}$] octane undergoes ring expansion at 80°C, while the *exo*-chloro isomer remains unchanged after being heated at 150°C for 15 hr. Analogous results have been reported with the chlorofluorocarbene adduct to indene,[4] and the chloro-, bromo-, or chlorofluorocarbene adduct to norbornene.[5-7] Schweizer and Parham[8] showed that the *exo*-chloro isomer of 7-chloro-2-oxabicyclo[4.1.0]heptane decomposed at 120°C in quinoline to give 2,3-dihydro-öxepin, while the *endo*-chloro isomer remained unchanged at 176.5°C in quinoline.

This paper describes the synthesis of a series of *n*,*n*-dichloro-, *n*-chloro-*n*-fluoro-, *n*-chloro-, and *n*-fluorobicyclo[$n-3.1.0$]alkanes ($n=6$, 7, and 9) and their 2-oxa analogues ($n=7$) and the stereospecificity observed in some of their ring expansion reactions in quinoline. A part of the present work has already been reported in preliminary communications.[9,10]

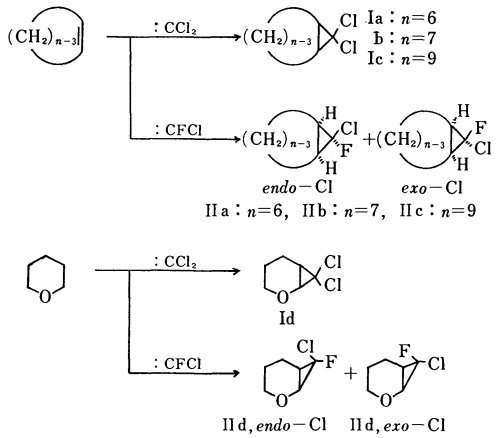
Results and Discussion

Synthesis of *n,n*-Dichloro- and *n*-Chloro-*n*-fluorobicyclo[*n*−3.1.0]alkanes (*n*=6, 7, and 9) and Their 2-Oxa Analogues (*n*=7). 6,6-Dichlorobicyclo[3.1.0]hexane (Ia), 7,7-dichlorobicyclo[4.1.0]heptane (Ib), 9,9-dichlorobicyclo[6.1.0]nonane (Ic), and 7,7-dichloro-2-oxabicyclo[4.1.0]heptane (Id) were prepared by the reaction of dichlorocarbene with cyclopentene, -hexene, -octene, and 2,3-dihydro-4*H*-pyran, respectively. The corresponding chlorofluoro derivatives (IIa, IIb, IIc, and IId) were prepared similarly from chlorofluorocarbene. The dihalocarbenes were generated very conveniently by gradual addition of methanol to a mixture of sodium hydride and methyl trichloro- or dichlorofluoroacetate, which generally gave better yields of the dihalocarbene adducts than the conventional sodium methoxide - trihaloacetate method.[11,12] The yields and the properties of the *gem*-dihalocyclopropanes thus prepared are summarized in Table 1.



As is shown in Table 1, each of the chlorofluoro derivatives obtained was a mixture of the *endo*-chloro and the *exo*-chloro isomers, with the former predominating. Similar results have been reported in the addition of chlorofluorocarbene to other olefins.[13a] Probably, as Moss and Gerstl pointed out,[13] the electronic factor (difference in polarizability of the halogen substituent) plays a more important role than the steric factor in determining the stereoselectivity of the dihalocarbene addition.

The assignments of the configuration were made by NMR spectroscopy, based on the generalization that in fluorocyclopropanes $J_{HF,cis}$ is larger than $J_{HF,trans}$[14] and that cyclopropyl fluorines are shielded by *cis*-, and deshielded by *trans*-, alkyl groups.[9,13] Their NMR data are given in Tables 2 and 3.

Synthesis of *n*-Chloro- and *n*-Fluorobicyclo[*n*−3.1.0]alkanes (*n*=6, 7, and 9) and Their 2-Oxa Analogues (*n*=7). 6-Chlorobicyclo[3.1.0]hexane (IIIa), 7-chlorobicyclo[4.1.0]heptane (IIIb), 9-chlorobicyclo[6.1.0]nonane (IIIc), and 7-chloro-2-oxabicyclo[4.1.0]heptane (IIId) were prepared, as a mixture of the *endo*-chloro and the *exo*-chloro isomers, by partially reducing the corresponding dichloro derivatives (Ia, Ib, Ic, and Id) with an equimolar amount of tri-*n*-butyltin hydride in the

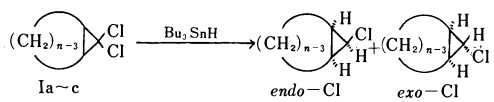
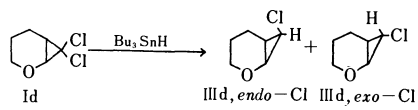
presence of azobisisobutyronitrile.[15] The yields and the properties of the chlorocyclopropanes thus prepared are shown in Table 4, together with the isomer ratios determined by gas chromatography (glpc) before distillation.

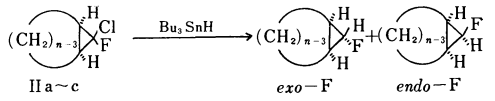


IIIa : *n*=6, IIIb : *n*=7, IIIc : *n*=9

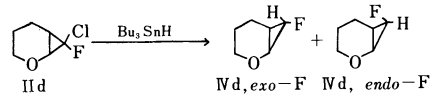


It is to be noted that the *endo*-chloro isomer predominates in IIIb and IIIc, whereas the *exo*-chloro isomer predominates in IIIa.[16]

Under similar conditions, an isomeric mixture of IIa was converted to a mixture of the *endo*-fluoro and the *exo*-fluoro isomers of 6-fluorobicyclo[3.1.0]-hexane (IVa). 7-Fluorobicyclo[4.1.0]heptane (IVb), 9-fluorobicyclo[6.1.0]nonane (IVc), and 7-fluoro-2-oxabicyclo[4.1.0]heptane (IVd) were obtained, as a mixture of isomers, from IIb, IIc, and IId, respectively. The reduction of these chlorofluorocyclopropanes required a longer reaction time than that of the corresponding dichlorocyclopropanes, and there was no sign of the monochloro derivative being formed. The yields and the properties of the products are shown in Table 5, together with the isomer distributions.



IVa : *n*=6, IVb : *n*=7, IVc : *n*=9



A comparison of Tables 1 and 5 reveals that the isomer ratio of the reduction product (IVa, IVb, and IVc) is quite close to that of the starting material (IIa, IIb, and IIc, respectively). This result is best explained by the stereospecific nature of the reduction of *gem*-halofluorocyclopropanes by organotin hydrides, which has already been demonstrated with IIa and IIb by isolating the pure isomers and reducing them separately.[17] In contrast, the reduction of IId did not occur stereospecifically, as is suggested by the disagreement of the isomer ratio of IVd with that of IId. The nonstereospecific nature of the reduction has been demonstrated by reducing the pure *endo*-chloro isomer of IId,[18] and will be discussed in a separate paper.

The configurations of the isomers of the chloro- and fluorocyclopropanes thus prepared were determined by their NMR spectra; in addition to the generalizations quoted above, use was made of the rule that $J_{HH,cis}$ is generally larger than $J_{HH,trans}$ in cyclopropanes.[19] The NMR data are presented in Tables 2 and 3. The NMR spectra of IId, IIId, and IVd were analyzed by the double resonance method.[20]

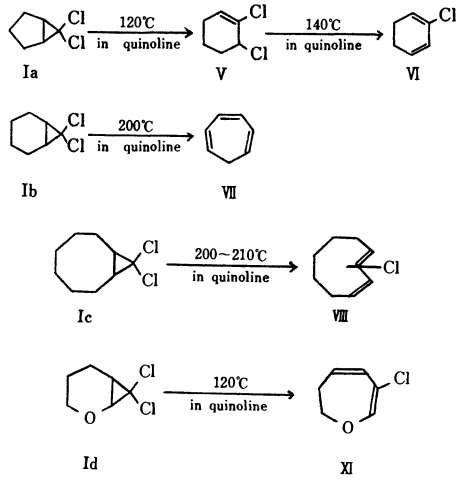
7, and 9) and Their 2-Oxa Analogues ($n=7$). Recently, Lindsay and Reese[21] have found that the treatment of 7,7-dibromobicyclo[4.1.0]heptane with quinoline at 220—238°C gives 1,3,5-cycloheptatriene in 66—68% yield, while at 200°C under reduced pressure it gives a mixture of 1- and 2-bromo-1,3-cycloheptadiene in 38% yield. It has also been reported that 6,6-dibromobicyclo[3.1.0]-hexane or 6,6-dichlorobicyclo[3.1.0]hexane rearranges to the corresponding 2,3-dihalocyclohexene when heated at 150—180°C,[22] and that 7,7-dichlorobicyclo[4.1.0]heptane is converted to 1,3,5-cycloheptatriene when heated at 444—520°C.[23] These experimental results suggest that the thermal rearrangement of *n,n*-dihalobicyclo[$n-3.1.0$]alkanes is often accompanied by dehydrohalogenation, and is assisted by the presence of a base such as quinoline.

In accord with these findings, 6,6-dichlorobicyclo-[3.1.0]hexane (Ia) was converted to 2,3-dichlorocyclohexene (V) when heated at 120°C with an excess of quinoline. Further heating at 140°C resulted in the formation of 2-chloro-1,3-cyclohexadiene (VI). 7,7-Dichlorobicyclo[4.1.0]heptane (Ib) and 9,9-dichlorobicyclo[6.1.0]nonane (Ic) did not react at 120°C, and had to be heated at *ca.* 200°C in order to effect ring expansion. The products formed from Ib and from Ic were 1,3,5-cycloheptatriene (VII) and monochlorocyclononadiene (VIII),[24] respectively. Triene (VII) was probably formed *via* the intermediate chlorocycloheptadiene, which, however, could not be isolated under the reaction conditions. 7,7-Dichloro-2-oxabicyclo[4.1.0]heptane (Id) at 120°C in quinoline was converted to 2,3-dihydro-6-chloroöxepin (IX).

The lower temperature required for effecting the ring expansion of Ia, relative to that of Ib or Ic, may be due to the difference in ring strain between Ia (five-membered) and Ib or Ic (six- or eight-membered).



A similar ring expansion reaction occurred also when an isomeric mixture of 6-chloro-6-fluorobicyclo[3.1.0]hexane (IIa) was treated with quinoline at 110°C or at 140°C; 3-chloro-2-fluorocyclohexene (X) or 2-fluoro-1,3-cyclohexadiene (XI) were obtained, respectively. In these cases, the *exo*-chloro isomer was completely recovered. Similarly, the treatment of an isomeric mixture of 7-chloro-7-fluorobicyclo[4.1.0]heptane (IIb) and 7-chloro-7-fluoro-2-oxabicyclo[4.1.0]heptane (IId) with quinoline at 200°C or 120°C resulted in the formation of 1,3,5-cycloheptatriene (VII) and 2,3-dihydro-6-fluoroöxepin (XII), respectively, with complete recovery of the *exo*-chloro isomer. Fluorocycloheptadiene, the most probable precursor of VII in the ring expansion of IIb, was again not isolated.

These experimental facts indicate a much higher reactivity of the *endo*-chloro than that of the *exo*-chloro isomers. This stereospecificity, *i.e.*, the

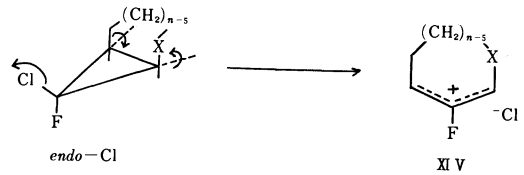
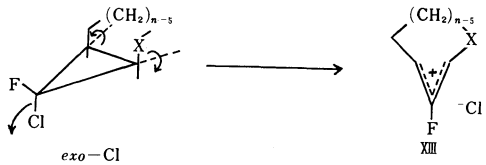
23) a) H. E. Winberg, *ibid.*, **24**, 264 (1959). b) G. C. Robinson, *ibid.*, **29**, 3433 (1964).

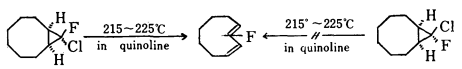
24) The structures of VIII, XV, and XVIII have not yet been fully established, but are only estimated; the results of their elemental analyses and their IR and NMR spectral data are in good agreement with the proposed structure (see Experimental), but the possibility that they might be a *cis*-diene or its derivative is not completely excluded.

strong dependence of the reaction rate upon the molecular geometry of the substrate, can be reasonably explained by assuming the rate-determining step of the ring opening of *gem*-chlorofluorocyclopropanes to be a "concerted disrotatory process,"[25] in which the chlorine is removed in preference to the fluorine, to form the corresponding 2-fluoroallyl cation. The selection rule advanced by DePuy *et al.*,[25] for such a process states that when the ring opening and the removal of the substituent occur simultaneously, the groups *trans* to the leaving group must rotate outward, and those *cis*, inward. If the same mechanism applies to the present reactions, the transition state (XIII) formed from the *exo*-chloro isomer of IIa, IIb, or IId would be sterically too much strained, as is shown below, for the ring expansion to occur. In contrast, the transition state (XIV) formed from the corresponding *endo*-chloro isomer would be much less strained.





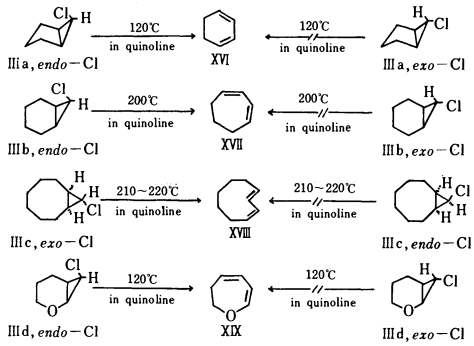
The above arguments predict that if the transition state of type XIII is more stable than that of type XIV, the ring expansion of the *exo*-chloro isomer of *gem*-chlorofluorocyclopropanes must occur faster than that of the *endo*-chloro isomer. This was proved to be the case in the ring expansion of 9-chloro-9-fluorobicyclo[6.1.0]nonane (IIc); the treatment of an isomeric mixture of IIc with quinoline at 215—225°C resulted in the formation of monofluorocyclononadiene (XV)[24] with the *endo*-chloro



IIc, *exo*-Cl XV IIc, *endo*-Cl

isomer recovered. In view of the well-known higher stability of *trans*- than *cis*-cyclononene, and probably of *trans*- than *cis*-2-cyclononenyl cation, this result is by no means "anomalous." Similar apparent anomalies have been reported in the acetolysis of bicyclo[5.1.0]octyl and -[6.1.0]nonyl tosylates[26] as well as in the ring expansion of 9-bromobicyclo-[6.1.0]nonane by aqueous chromous sulfate.[27]

Ring Expansion of *n*-Halobicyclo[*n*−3.1.0]-alkanes (*n*=6, 7, and 9) and Their 2-Oxa Analogues (*n*=7) in Quinoline. As might be expected from the above discussion, the ring expansion of 6-chlorobicyclo[3.1.0]hexane (IIIa), 7-chlorobicyclo-[4.1.0]heptane (IIIb), 9-chlorobicyclo[6.1.0]nonane (IIIc) and 7-chloro-2-oxabicyclo[4.1.0]heptane (IIId) also occurred with distinct stereospecificity; it was only the *endo*-chloro isomers of IIIa, IIIb, and IIId, or the *exo*-chloro isomer of IIIc that underwent the ring expansion when treated with quinoline at 120—220°C.



The more facile conversion of the *endo*-chloro, compared with the *exo*-chloro, isomer of IIId to 2,3-dihydroöxepin, does not agree with the experimental results reported by Schweizer and Parham,[8] who prepared an isomeric mixture of IIId by the addition of chlorocarbene, generated by the method of Closs and Closs,[28] to 2,3-dihydro-4*H*-pyran. They stated that the *exo*-chloro isomer of IIId decomposed more easily than the *endo*-chloro isomer, and attributed the difference in reactivity to an anchimeric assistance exerted by the *trans*-oxygen atom during the loss of the chlorine. Their structural assignment for the isomers of IIId, however, is tentative and lacks decisive evidence: it was based only on the idea that the sterically less hindered *exo*-chloro isomer must be formed in greater predominance than the more hindered *endo*-chloro isomer. In view of the findings by Closs[29] that chlorocarbene reacts with cyclohexene to yield more *endo*- than *exo*-chloronorcarane and with unsymmetrical olefins

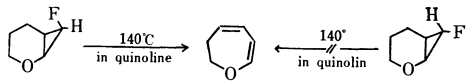
to yield more *syn*-than *anti*-isomers, it is not surprising that the more hindered *endo*-chloro isomer is formed in greater predominance when it reacts with 2,3-dihydro-4H-pyran.

Both the *endo*-fluoro and the *exo*-fluoro isomers of 6-fluorobicyclo[3.1.0]hexane (IVa), 7-fluorobicyclo-[4.1.0]heptane (IVb), and 9-fluorobicyclo[6.1.0]-nonane (IVc) were quite stable under conditions similar to, or severer than, those used for the ring expansion of their chlorofluoro analogues. This is in good agreement with the observed lack of reactivity of the *exo*-chloro isomers of IIa, IIb, and IId or of the *endo*-chloro isomer of IIc, which evidently indicates the stability of the C–F bond, as compared with the C–Cl bond, in the ring expansion of halo- or dihalocyclopropanes.



IVd, *endo*-F XIX IVd, *exo*-F

The *endo*-fluoro isomer of 7-fluoro-2-oxabicyclo-[4.1.0]heptane (IVd), however, was converted to 2,3-dihydroöxepin (XIX) when heated at 140°C for 5 hr with an excess of quinoline. The enhanced reactivity of the *endo*-fluoro isomer of IVd, relative to that of IVa, IVb, and IVc, may be accounted for by the resonance effect of oxygen to stabilize the transition state of type XIV. The *exo*-fluoro isomer of IVd was recovered unchanged under similar conditions.

Experimental

General. The infrared spectra were obtained with a Shimadzu IR 27B Spectrophotometer. The UV spectra were measured with a Beckmann DB Spectrophotometer. The proton NMR spectra were obtained with a Varian Associates A-60, H-100, or a JEOL JNM C-60H Spectrometer in duteriochloroform or carbon tetrachloride with TMS as internal reference. Chemical shift data are given in δ values. The fluorine NMR spectra were obtained with a Hitachi High-Resolution NMR Spectrometer H-60 or a JEOL JNM C-60 (at 56.4 MHz) in carbon tetrachloride with trifluoroacetic acid as external reference. Gas chromotography (glpc) was performed on a Shimadzu GC-2C or a Yanagimoto 5DH Chromatograph. The analytical columns were 3 m×3 mm of 7.5% apiezon grease L, 10% tricresyl phosphate, 5% silicone grease, or 10% polyethylene glycol 6000 on 60/80 mesh or 80/100 mesh celite 550 or chromosorb W; the preparative columns were 2 m×10 mm of either 30% apiezon grease L or 30% tricresyl phosphate on 60/80 mesh celite 550. The percentage composition of isomers was estimated from peak areas of glpc or NMR signals.

General Procedure for Preparation of *n*,*n*-Dichlorobicyclo[*n*−3.1.0]alkanes (*n*=6, 7, and 9) and Their 2-Oxa Analogues (*n*=7). In a 200-m*l* five-necked flask fitted with a reflux condenser, a stirrer, a thermometer, a dropping funnel and an inlet tube for nitrogen, was placed a mixture of 4.9 g (0.2 mol) of sodium hydride (as a 50% dispersion in mineral oil), 0.2 mol of the corresponding olefin, and 20 m*l* of anhydrous ether. To the mixture was added under nitrogen, 35.5 g (0.2 mol) of methyl trichloroacetate and then 7 g (0.22 mol) of methanol, both dropwise at *ca.* 0°C. The addition of methanol required about 2 hr. After the reaction mixture was let to stand overnight, a small amount of methanol, and subsequently 70 m*l* of water, were gradually added. The organic layer was separated, the aqueous layer was extracted with ether, and the combined organic layer was washed with aqueous sodium hydroxide and with water. After being dried over anhydrous calcium chloride, it was distilled in vacuum to give *gem*-dichlorocyclopropanes. In the distillation of Ia, care had to be taken in order to avoid its isomerization to V. The yields and the properties of the products are given in Table 1.

General Procedure for Preparation of *n*-Chloro-*n*-fluorobicyclo[*n*−3.1.0]alkanes (*n*=6,7, and 9) and Their 2-Oxa Analogues (*n*=7). The procedure was essentially the same as above, except that 32.2 g (0.2 mol) of methyl dichlorofluoroacetate was used instead of methyl trichloroacetate, and that methanol was added at *ca.* 25—35°C instead of *ca.* 0°C. The yields and the properties of the products are given in Table 1. The gas chromatograms of IIa and IIb thus prepared had two peaks, the ratio of the areas of which was taken to be equal to the ratio of the weights of the isomers. The isomer distribution of IIc and IId, which showed only a single peak in glpc under various conditions, was determined from the integrated areas of the fluorine NMR peaks.

General Procedure for Reduction of *n*,*n*-Dichloro- and *n*-Chloro-*n*-fluorobicyclo[*n*−3.1.0]alkanes (*n*=6,7, and 9) and Their 2-Oxa Analogues (*n*=7). A mixture of 0.1 mol of *n*,*n*-dichloro- or *n*-chloro-*n*-fluorobicyclo[*n*−3.1.0]alkane, 29.1 g (0.1 mol) of tri-*n*-butyltin hydride, and a small amount of azobisisobutyronitrile or di-*t*-butyl peroxide was heated, with stirring, at the temperature shown in Table 3 until an aliquot from the reaction mixture showed no IR absorption due to Sn–H stretching (near 1820 cm^{-1}). The product was isolated by distillation, and the isomer ratio was determined by glpc.

Ring Expansion of 6,6-Dichlorobicyclo[3.1.0]hexane (Ia). In a flask fitted with a reflux condenser and a thermometer, a mixture of 7.6 g (0.05 mol) of Ia and 18 g (0.15 mol) of quinoline was heated at 120°C for 5 hr. After distillation (85—95°C/20 mmHg), the product was purified by preparative gas chromatography, and identified to be 2,3-dichlorocyclohexene by comparison of its refractive index and IR spectrum with those of an authentic sample;[22b] n_D^{20} 1.5155, $\nu_{C=C}$ 1640 cm^{-1}.

Found: C, 47.80; H, 5.52%. Calcd for $C_6H_8Cl_2$: C, 47.71; H, 5.34%.

Further heating of the above reaction mixture at 140°C for 5 hr gave 82% yield of 2-chloro-1,3-cyclohexadiene, bp 70°C/78 mmHg, n_D^{20} 1.5055, IR (cm^{-1}): 3045 (m), 2940 (s), 2820 (s), 1632 (s), 1590 (w), 1440 (m), 1430 (s), 1390 (s), 1028 (s), 945 (s), 805 (s), and 720 (s).

Found: C, 62.85; H, 6.33%. Calcd for C_6H_7Cl: C, 62.90; H, 6.16%.

Ring Expansion of 7,7-Dichlorobicyclo[4.1.0]heptane (Ib). A mixture of 30 g (0.18 mol) of Ib and 77.4 g (0.6 mol) of quinoline was heated at 200°C in a

200-ml flask fitted with a reflux condenser and a thermometer. After 4 hr, the reflux of the reaction mixture became vigorous and the temperature in the flask lowered to below 180°C. At this temperature the mixture was heated for an additional 6 hr. Distillation of the reaction mixture gave 16 g (61% yield) of 1,3,5-cycloheptatriene which was identified by comparing its IR, UV, and NMR spectra with those of an authentic sample;[21] bp 108—110°C, n_D^{20} 1.5235, λ_{max}^{EtOH} 261 mμ (ε 3700).

Found: C, 91.46; H, 8.54%. Calcd for C_7H_8: C, 91.25; H, 8.75%.

Ib was heated at 200°C for 26 hr without quinoline. Although the generation of hydrogen chloride was noted, the glpc analysis of the reaction mixture showed no definite products. The starting material was almost completely recovered by distillation.

Ring Expansion of 7,7-Dichloro-2-oxabicyclo-[4.1.0]heptane (Id). A mixture of 8.3 g (0.05 mol) of Id and 50 g (0.39 mol) of quinoline was heated at 120°C for 6 hr. Distillation of the reaction mixture gave 5.2 g (80% yield) of 2,3-dihydro-6-chloroöxepin, bp 85—90°C/14 mmHg, n_D^{21} 1.5183.

Found: C, 55.31; H, 5.32%. Calcd for C_6H_7ClO: C, 55.19; H, 5.40%.

Ring Expansion of 6-Chloro-6-fluorobicyclo-[3.1.0]hexane (IIa). A mixture of 6.7 g (0.05 mol) of IIa (isomeric mixture) and 18 g (0.15 mol) of quinoline was heated at 110°C for 5 hr. Distillation of the reaction mixture afforded 70% yield of 2-fluoro-3-chlorocyclohexene (X) and the unchanged *exo*-chloro isomer, which were separated by preparative gas chromatography. IR (cm^{-1}) of X: 2940 (s), 1702 (s), 1380(s), 1150 (s), 975 (s), 885 (s), and 705 (s).

The above reaction mixture was heated at 140°C for an additional 5 hr. 2-Fluoro-1,3-cyclohexadiene was obtained in 49% yield; n_D^{20} 1.4520, IR (cm^{-1}): 3020 (w), 2970 (s), 2850 (m), 1670 (s), 1595 (w), 1410 (s), 1165 (s), 815 (m), 795 (m), and 730 (m).

Found: C, 73.61; H, 7.22%. Calcd for C_6H_7F: C, 73.45, H, 7.19%. The *exo*-chloro isomer was completely recovered.

Ring Expansion of 7-Chloro-7-fluorobicyclo-[4.1.0]heptane (IIb). A mixture of 30 g (0.2 mol) of IIb (isomeric mixture) and 90 g (0.7 mol) of quinoline was heated at 200°C for 10 hr. Distillation of the reaction mixture afforded 5.2 g (50% yield based on the *endo*-chloro isomer) of 1,3,5-cycloheptatriene and 12.5 g of the unchanged *exo*-chloro isomer.

A mixture of IIb (isomeric mixture), ethylbenzene (as internal reference), and quinoline was heated at 200°C. Glpc analysis indicated that the *endo*-chloro isomer was lost completely after 10 hr, while the *exo*-chloro isomer remained unchanged.

Ring Expansion of 7-Chloro-7-fluoro-2-oxabicyclo[4.1.0]heptane (IId). A mixture of 10 g (0.065 mol) of IId (isomeric mixture) and 42 g (0.33 mol) of quinoline was heated at 120°C for 3 hr. Distillation of the reaction mixture gave two fractions, (a) bp 51—57°C/45 mmHg, 3.5 g, and (b) bp 70—80°C/25—30 mmHg, 3.5g. Redistillation of fraction (a) gave 77% yield (based on the *endo*-chloro isomer) of pure 2,3-dihydro-6-fluoroöxepin; bp 58—60°C/65 mmHg, n_D^{21} 1.4706, IR (cm^{-1}): 3024 (m), 2995 (m), 2945 (m), 2913 (m), 1670 (m), 1628 (m), 1420 (s), 1290 (s), 1238 (s), 1126 (vs), 928 (s), and 740 (s).

Found: C, 63.30; H, 6.25%. Calcd for C_6H_7FO: C, 63.15; H, 6.18%. Fraction (b) was the unchanged *exo*-chloro isomer.

Ring Expansion of 6-Chlorobicyclo[3.1.0]hexane (IIIa). A mixture of 5.8 g (0.05 mol) of IIIa (isomeric mixture) and 18 g (0.15 mol) of quinoline was heated at 120°C for 4 hr. Distillation of the reaction mixture gave 80% (based on the *endo*-chloro isomer) of 1,3-cyclohexadiene; bp 78—80°C, n_D^{20} 1.4756, and the unchanged *exo*-chloro isomer which was recovered unchanged even after being heated at 140°C for an additional 10 hr.

Found: C, 89.80; H, 10.20%. Calcd for C_6H_8: C, 89.94; H, 10.06%.

Ring Expansion of 7-Chlorobicyclo[4.1.0]heptane (IIIb). A mixture of 14 g (0.11 mol) of IIIb (isomeric mixture) and 45 g (0.35 mol) of quinoline was heated at 140°C for 5 hr. Glpc analysis of the reaction mixture showed that no reaction had occurred. The mixture was then heated at 200°C for 10 hr. Distillation of the reaction mixture gave 6.2 g (80% yield based on the *endo*-chloro isomer) of 1,3-cycloheptadiene; bp 118—120°C, n_D^{20} 1.4970, λ_{max}^{EtOH} 246 mμ (ε 7500), and 3.0 g of the unchanged *exo*-chloro isomer.

Found: C, 89.15; H, 10.84%. Calcd for C_7H_{10}: C, 89.29; H, 10.71%.

Heating of IIIb (isomeric mixture) without quinoline at 165°C for 19 hr gave a small amount of black, tarry material, but no diene product.

Ring Expansion of 7-Chloro-2-oxabicyclo[4.1.0] heptane (IIId). A mixture of 8.5 g (0.064 mol) of IIId (isomeric mixture) and 20 g (0.16 mol) of quinoline was heated at 120°C for 3 hr. Distillation of the reaction mixture gave 2.0 g (70% yield based on the *endo*-chloro isomer) of 2,3-dihyroöxepin; bp 56°C/10 mmHg, n_D^{22} 1.4958, and 4.2 g of the unchanged *exo*-chloro isomer which was recovered unchanged even after heated in quinoline at 120°C for 10 hr.

Found: C 74.78; H 8.30%. Calcd for C_6H_8O: C, 74.97; H, 8.39%.

Ring Expansion of 6-Fluorobicyclo[3.1.0]hexane (IVa) and 7-fluorobicyclo[4.1.0]heptane (IVb). A mixture of IVa or IVb (isomeric mixture), ethylbenzene (internal reference), and quinoline was heated at 200°C for 10 hr in a sealed tube. Glpc analysis of the reaction mixture proved that neither of the isomers had decomposed under these conditions.

Ring Expansion of 7-Fluoro-2-oxabicyclo[4.1.0] heptane (IVd). An isomeric mixture of IVd did not show any appreciable change when heated in quinoline at 120°C for 10 hr, but prolonged heating at 140°C for an additional 5 hr resulted in the decomposition of the *endo*-fluoro isomer to yield 2,3-dihyroöxepin (in a low yield), with recovery of the *exo*-fluoro isomer.

Ring Expansion of 9,9-Dichloro- (Ic), 9-Chloro-9-fluoro- (IIc), 9-Chloro- (IIIc), and 9-Fluorobicyclo [6.1.0]nonane (IVc). A mixture of Ic, IIc, IIIc, or IVc and quinoline was heated at 200—220°C for 10 hr. After distillation of the reaction mixture, the products were purified by preparative gas chromatography. Chlorocyclononadiene (VIII); bp 94°C/17 mmHg, n_D^{22} 1.5130, IR (cm^{-1}): 3015 (m), 2940 (s), 2860 (s), 1625 (s), 1590 (w), 1460 (s), 1040 (s), 950 (s), and 785 (s), NMR: δ 1.3—2.5 (m) (10H) and δ 5.5—6.0 (m) (3H).

Found: C, 69.12; H, 8.28%. Calcd for $C_9H_{13}Cl$: C, 69.00; H, 8.37%. Fluorocyclononadiene (XV); bp

98°C/70 mmHg, n_D^{21} 1.4783, IR (cm^{-1}): 3015 (m), 2940 (s), 2860 (s), 1690 (s), 1640 (w), 1460 (m), 1450 (m), 1120 (s), 1115 (m), 840 (m), and 750 (m). NMR: δ 1.2—2.6 (m) (10H) and δ 4.8—6.0 (m) (3H).

Found: C, 77.16; H, 9.52%. Calcd for $C_9H_{13}F$: C, 77.10; 9.35%. Cyclononadiene (XVIII); bp 105°C/83 mmHg, n_D^{21} 1.4940, IR (cm^{-1}): 3020 (s), 2940 (s), 2860 (s), 1630 (w), 1458 (s), 770 (s), and 734 (s), NMR: δ 1.2—2.4 (m) (10H) and δ 5.1—5.9 (m) (4H).

Found: C, 88.23; H, 11.77%. Calcd for C_9H_{14}: C, 88.45; H, 11.55%.

The *endo*-chloro isomer of IIc or IIIc and both isomers of IVc remained unchanged after being heated at 220°C for an additional 10 hr.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 2021—2028 (1969)

1,3-*O*-Benzylidene-L-sorbose[1)]

Takashi MAEDA, Mitsuru KIMOTO, Shigeru WAKAHARA and Kanji TOKUYAMA

Shionogi Research Laboratory, Shionogi & Co., Ltd., Fukushima-ku, Osaka

(Received December 17, 1968)

It has been proposed that 1,3-*O*-benzylidene-L-sorbose (III) exists as an equilibrium mixture of a pyranose form (IIIp), a keto-form (IIIk) and a furanose form (IIIf) in solutions. The acetylation of III in pyridine afforded the acetates of IIIf; one of them (IV) is in a keto-form (IVk) in a crystalline state, and at a low temperature, while the acetates of IIIf and IIIp at higher temperatures. When a pyridine solution of III was allowed to stand for some time before acetylation, the yield of the acetate of IIIp increased. The recrystallization of III usually gave crystals of IIIf, however, while the addition of petroleum ether to the concentrated pyridine solution of III afforded a powder which was consisted mainly of IIIp. These results suggest that III exists as IIIf in a crystalline state and as an equilibrium mixture of IIIf, IIIk, and IIIp in solution; the existence of this equilibrium was also confirmed by proton magnetic resonance spectroscopy.

The 1,3-*O*-acetal of L-sorbose (I) is a key intermediate in the acetalation of I, which is an important reaction for L-ascorbic acid production.[2–4)] We have successfully isolated two examples of this kind of acetals, 1,3-*O*-ethylidene-α-L-sorbopyranose (II) from the ethylidenation[3)] and 1,3-*O*-benzylidene-L-sorbose (III) from the benzylidenation.[2)] It is quite natural that the ring structure of II has a pyranose form, for I is stable in an α-L-pyranose form.[5)] On the other hand, much attention should be paid to the surprising fact with III that a β-furanose form (IIIf) of the *cis*-decalin type is more likely than an α-pyranose form (IIIp) of the *trans*-decalin type (see Chart 2). III exists as IIIf in a crystalline state, while IIIp is considered to exist only as an equilibrium mixture with IIIf in solution. This paper will be concerned with the equilibrium of III. For this purpose, further studies of the

acetylation of III and proton magnetic resonance spectroscopic studies were carried out.

The acetylation of III in pyridine with acetic anhydride at −5—6°C has been shown to give 4,6-di-*O*-acetyl- (V) and 2,4,6-tri-*O*-acetyl-1,3-*O*-benzylidene-β-L-sorbofuranose (VI), along with a limited amount of 4,5-di-*O*-acetyl-1,3-*O*-benzylidene-α-L-sorbopyranose (VII).[2] This fact suggests that III usually exists as IIIf in a pyridine solution at a low temperature. The acetylation at about −30°C gave strong support to this suggestion. The examination of the reaction by thin-layer chromatography (TLC) showed that a mono-acetate (IV) initially appeared and that V and VI then appeared at the expense of IV. No formation of detectable amount of VII was observed. The interuption of the reaction after 2 hr gave mainly IV, which was then converted into VI *via* V, by further acetylation, but not into VII.

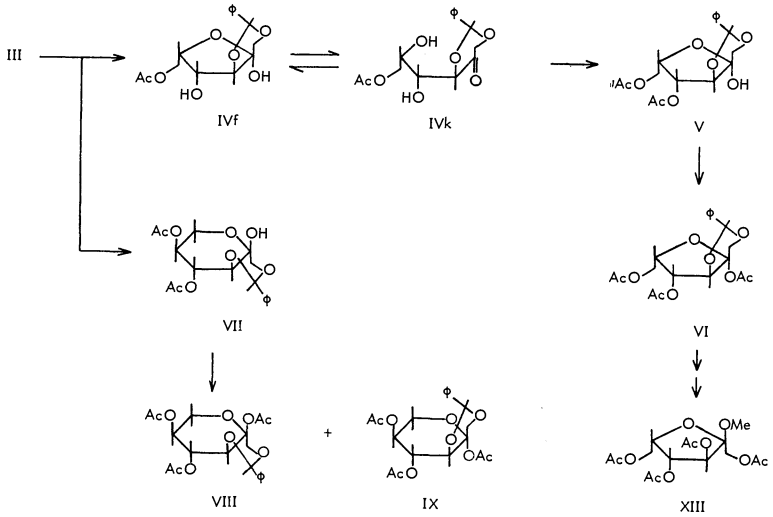

Chart 3

In view of the above facts, possibility of a pyranose structure for IV may be excluded. As the primary hydroxyl group at the C_6 position of IIIf must be more reactive for the acetylation than the secondary one at C_4,[6] the structure of IV is determined to be 6-*O*-acetyl-1,3-*O*-benzylidene-β-L-sorbofuranose. The PMR spectrum of IV in chloroform-d showing the absence of a proton on a tertiary carbon bearing an acetoxyl group (AcO$\underset{|}{\underset{|}{\text{C}}}$H), confirmed this structure (Fig. 1).

The behavior of IV is very interesting. The infrared (IR) spectrum of IV in a KBr disk, showing two strong absorption bands at 1720 and 1740 cm^{-1} due to carbonyl groups (Fig. 2), and the optical rotatory dispersion (ORD), showing no Cotton effect[7] (Fig. 3), made it clear that IV exists as a keto-form (IVk) in a crystalline state to a considerable extent and as a furanose form (IVf) in solution.

The acetylation of III, IV, and V with acetic anhydride in pyridine gave VI as the final product, even though weak conditions were used.[8] This unexpected acetylation of a tertiary hydroxyl group was not observed in the case of VII. For the formation of the 2-*O*-acetyl derivative of VII

7) Acyclic ketoses are known to show a Cotton effect. See T. Sticzay, C. Reciar, K. Babor, M. Fedoroňks and K. Linek, *Carbohyd. Res.*, **6**, 418 (1968).

8) This type of abnormal acetylation has been reported on a Noranisation-derivative by Hirata *et al.*, however, a longer reaction period was required. K. Yamada, S. Takada, S. Nakamura and Y. Hirata, *Tetrahedron*, **24**, 1267 (1968).

H_A shows the signal due to a benzylic proton.

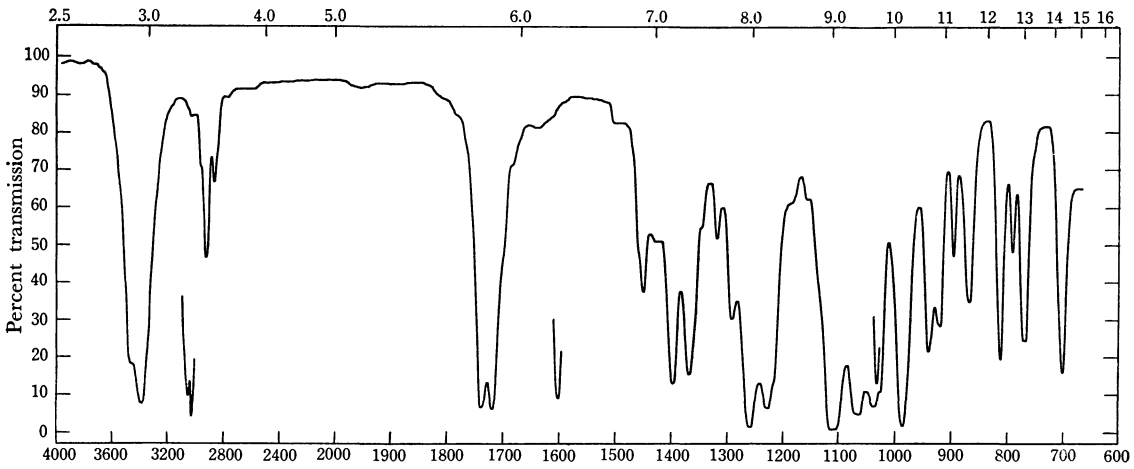

Fig. 2. IR spectrum of IV (KBr disk).

(VIII), ordinary reaction conditions were required, such as heating on a boiling-water bath or using sodium acetate and acetic anhydride under heating. In the case of the acetylation on a boiling-water bath, the β-anomer of VIII (IX) was also isolated.

The structures of VIII and IX were confirmed by the methods described below. The PMR spectrum of VIII in chloroform-d revealed the presence of one axial (τ 7.79) and two equatorial (τ 7.95) acetoxyl groups.[9] Two one-proton signals due to H_4 and H_5 appeared as a quartet (τ 4.41) and a multiplet (τ 4.90) respectively in the AcO-C-H range. The coupling constants ($J_{3,4}\simeq$10 and $J_{4,5}\simeq$9Hz) suggested that the pyranose structures was in the 1C chair form. Thus, the structure

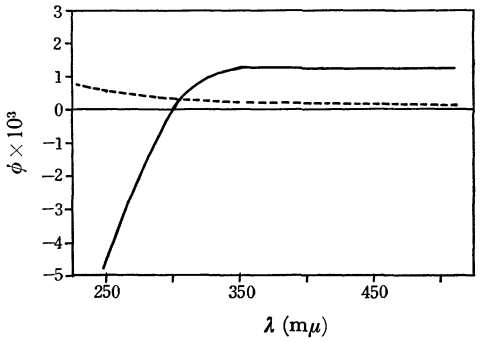

Fig. 3. ORD curves of IV and IX.
—— IV
--- IX

of VIII was determined to be 2,4,5-tri-*O*-acetyl-1,3-*O*-benzylidene-α-L-sorbopyranose.

The structure of IX should be compatible with either 2,4,5-tri-*O*-acetyl-1,3-*O*-benzylidene-β-L-sorbopyranose or 4,5,6-tri-*O*-acetyl-1,3-*O*-benzylidene-L-sorbose. However, the latter structure could de excluded because the ORD curve showed the absence of a carbonyl group[7] (Fig. 3). The positive value of the optical rotation and the fact that the PMR spectrum in chloroform-d was close to that of 1,2,3,4,5-penta-*O*-acetyl-β-L-sorbopyranose (X)[10] supported the former structure. The formation of IX was somewhat curious, for IX has an unstable *cis*-decalin type conformation in which its sugar moiety must also adopt the unlikely Cl chair form;[11] however, IX will be shown below to indeed possess this structure.

The easy acetylation of the tertiary hydroxyl group of V could not be attributed to the presence of the 1,3-*O*-benzylidene group, because the acetylation of the tertiary hydroxyl group of VII did not occur under similar reaction conditions. More especially, no acetylation of 1,3,4,6-di-*O*-benzylidene-β-L-sorbofuranose was obtained even on heating on a boiling-water bath. Therefore, the acetylation of the tertiary hydroxyl group of V must be caused by the closeness of the acetyl group at C_4 to the anomeric hydroxyl group. The closeness made possible the migration of the acetyl group from C_4 to C_2.

The existence of the long range coupling across 4 σ bonds between H_1 and H_3 also supported the structure of IX.[13] The coupling is usually observed in the 1,3-*O*-benzylidene-β-derivatives and suggests that the protons are in a zig-zag or W-letter arrangement (see Chart 2). The possibility of an epimerization on the C_3-configuration during the heating in pyridine was ruled out by the fact that the catalytic hydrogenation of IX in MeOH, followed by acetylation gave 1,3,4,5-tetra-*O*-acetyl-α-L-sorbopyranose (XII).[14]

In the hydrogenation of IX, methyl 1,3,4,5-tetra-*O*-acetyl-α-L-sorbopyranoside (XI)[15] was also isolated. This König-Knorr type glycosidation from IX to XI was also observed in the case of VI, which gave a fairly good yield of methyl 1,3,4,6-tetra-*O*-acetyl-α-L-sorbofuranoside (XIII).[16] However, the treatment of X under the same reaction conditions gave XI to a very limited extent. Accordingly, the existence of 1,3-*O*-benzylidene groups in VI and IX seems to enhance the rate of exchange of the acetoxyl group with the methoxyl group.

The above-described product analyses of the acetylations of III pointed out that IIIf is a predominant form in pyridine at low temperatures and that it transforms to IIIp with a rise in the temperature. The transformation from IIIf to IIIp was confirmed by the following PMR spectroscopic studies.

The PMR spectra of III in pyridine-d_5 are reported in Fig. 4. Two singlet signals (H_A) at τ 4.20 and 4.24, assignable to benzylic protons, appeared when measured at room temperature immediately after the dissolution of III in pyridine-d_5 (Fig. 4a). The third signal (H_B) at τ 4.09 assignable also to a benzylic proton which newly appeared when measured at 70°C (Fig. 4b), and its relative intensity increased synchronically with the decrease in the former two signals when the pyridine solution was heated at 100°C for 1 hr (Fig. 4c). An increase in the third signal was also obtained when the pyridine-d_5 solution was allowed to stand at room temperature for a long time (Fig. 4d).

The relative ratio of the signals (H_A) at τ 4.20 and 4.24 was constantly about 2 : 1 during the measurements. The one can reasonably be assigned to the benzylic proton of IIIf, and the other, to that of the keto-form of III (IIIk). The α-furanose form of III may be excluded, since a 1,3-*O*-acetal ring fused to an α-furanose can be expected to deform the furanose-ring conformation seriously.[16] On the other hand, the existence of IIIk is supported by the fact that IV adopts the keto-form IVk to

10) H. Paulsen, H. Köster and K. Heyns, *Chem. Ber.*, **100**, 2669 (1967).

11) Methyl 1,3,4,5-tetra-*O*-acetyl-β-L-sorbopyranoside was confirmed to exist as a conformer mixture of 1C and Cl chair forms.[12] The comparison of the PMR data of IX with those of the above pyranoside suggested that X may adopt mainly the Cl chair form.

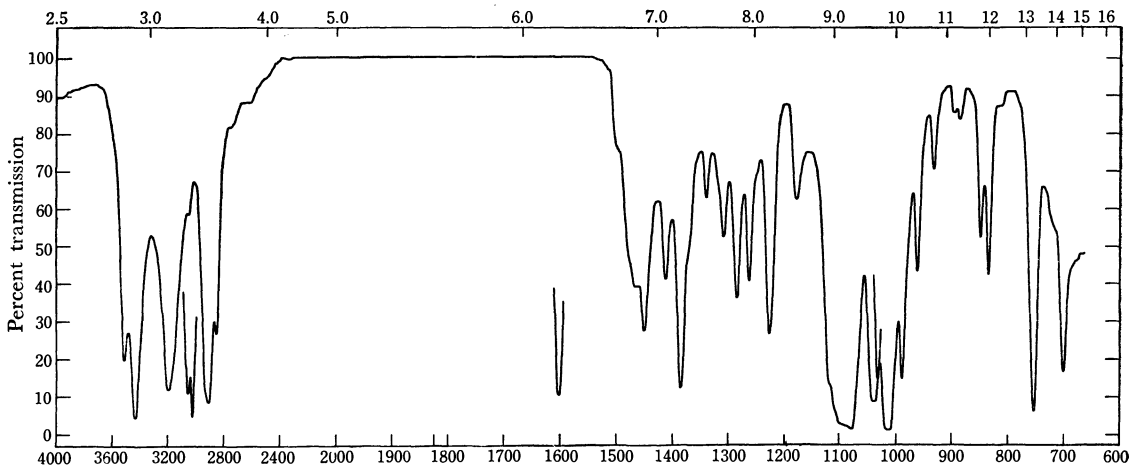

Fig. 5. IR spectrum of III (IIIf) (KBr disk).

some extent. However, as the absorption band due to the carbonyl group was hardly detected in the attenuated total reflection IR (ATR) spectrum of the pyridine solution of III, it was concluded that IIIk was a minor component compared to IIIf. Therefore, we could assign the signal at τ 4.20 to that of IIIf, and the one at τ 4.24, to IIIk. The third signal (H_B) at τ 4.09 was assigned to the benzylic proton of IIIp, since the acetylation of the pyridine solution, which showed a strong intensity of this signal, gave VII as the major product.

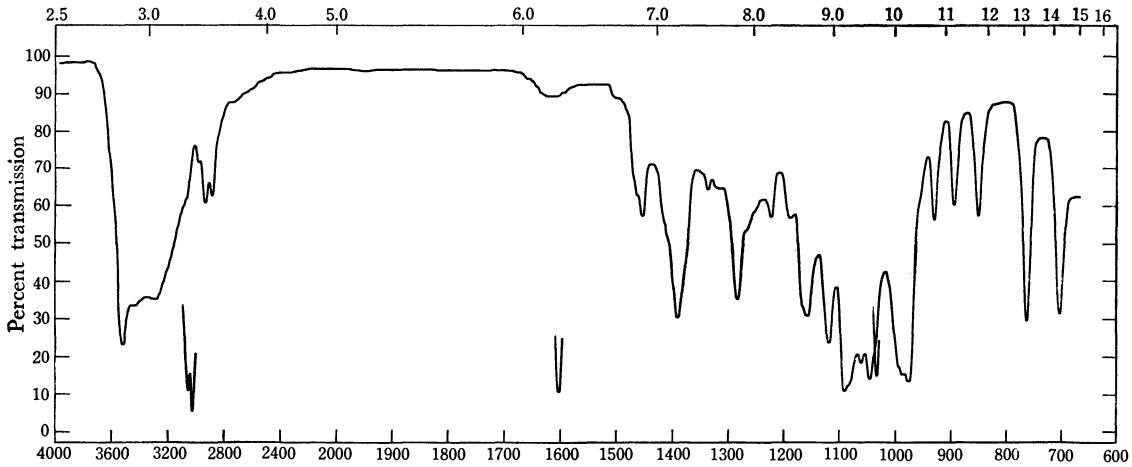

Fig. 6. IR spectrum of III (mainly IIIp) (KBr disk).

As has previously been reported, III adopts IIIf in a crystalline state. Further, the above-mentioned facts establish that III exists in solution as a mixture of IIIf, IIIk, and IIIp. As IIIp is the dominant form in pyridine we attempted to isolate it. Crystals of IIIf usually appeared upon the concentration of the pyridine solution, which showed a high concentration of IIIp. On the other hand, an amorphous powder was obtained on the addition of petroleum ether to the concentrated pyridine solution before any crystals started to appear. This powder had a low melting point, a negative optical rotation (which suggested the presence of IIIp), and it obviously differed from IIIf in its IR spectrum (see Figs. 5 and 6). The recrystallization of this powder from methanol gave IIIf, and the acetylation gave VII as the major product. Therefore, this powder is considered to contain considerable amount of IIIp. These data also supported the idea that IIIf is dominant in a crystalline state.

In conclusion, III usually crystallizes as IIIf and equilibrates among IIIf, IIIk, and IIIp in solution. It is obscure why IIIf of the unstable *cis*-decalin type can exist exceptionally in the case of benzylidene derivatives of L-sorbose (I). The presence of IV of the keto-form in a crystalline state is also surprising. We hope that these interesting fused-ring systems will be elucidated by thermodynamic treatments.

Experimental

All the melting points were recorded on a Kofler microstage apparatus and have been corrected.

The optical rotations were determined in chloroform containing 1% ethanol unless otherwise stated, and the concentrations were recorded in percentages. The ORD curves were obtained on a Nippon-Bunko ORD/UV 5 spectrometer.

The PMR spectra were measured on a Varian A-60A spectrometer equipped with a variable temperature probe using 5% solutions of samples and with TMS as the internal standard. The results obtained from first-order approximation are listed in Table 1.

Thin-layer chromatography (TLC) and preparative TLC (PTC) were carried out on a silica-gel plate in the

same manner as has been previously described.[2] The solvent systems used were chloroform-acetone (9 : 1, v/v, solvent A), ether-petroleum ether (5 : 1, v/v, solvent B; 3 : 1, v/v, solvent C, 2 : 1, v/v; solvent D), and benzene-ether (2 : 1, v/v, solvent E).

General Procedure of Acetylation. A compound (1 part in weight) was treated with a mixture of pyridine and acetic anhydride (1 : 1 v/v; 10 parts in volume) at the cited temperature. The reaction mixture was then poured onto crushed ice, neutralized with sodium hydrogencarbonate, and extracted with chloroform. The chloroform was washed with water, 1N HCl and water, and then dried and evaporated. The acetate thus obtained was purified by recrystallization and/or by PTC.

Acetylation of III. a) III (1.00 g) was acetylated at −30°C for 2 hr. The recrystallization of the product from ethanol gave IV as needles (301 mg). V (60 mg)[2] was separated from the mother liquor (351 mg) by repeated PTC with solvents A and B.

IV: mp 153—155°C, $[\alpha]_D^{25}$ +16.5° (*c* 0.956). Found: C, 58.14; H, 5.86%; mol wt, 314. Calcd for $C_{15}H_{18}O_7$: C, 58.06; H, 5.85%; mol wt, 310. ORD: $[\phi]_{400}$ +172°; $[\phi]_{300}$ +298°; $[\phi]_{232}$ +616.

b) III (500 mg) was acetylated for 5 hr at room temperature and then for 1 hr at around 70°C. VI[2] was mainly obtained, it was purified by recrystallization from ethanol-water. The yield was 536 mg.

c) A solution of III (583 mg) in pyridine (6 m*l*) was heated on a boiling-water bath for 13.5 hr and then kept overnight at room temperature. Acetic anhydride (6 m*l*) was added to the solution. After having been kept at room temperature for 15.5 hr, the solution was worked up by the general procedure. A crystalline syrup (871 mg) was obtained. The recrystallization of the syrup from ether gave VII (126 mg). From the mother liquor, VI (212 mg) and VII (175 mg) were separated by PTC with solvent A. The total yield of VII was 311 mg.

d) III (1.00 g) was preliminarily heated in a way similar to the above and then acetylated at around 0°C for 4 hr. A syrup (1.20 g) was obtained. The recrystallization of the syrup from ether gave VII (697 mg). From the mother liquor, V (140 mg) was separated by PTC with solvent D.

Acetylation of VII. a) VII (600 mg) was acetylated on a boiling-water bath for 3 hr. The products were separated into VIII (131 mg) and IX (200 mg) by PTC with solvent D.

VIII (84 mg) was obtained as needles by further recrystallization from ether. It had mp 203.5—205°C, $[\alpha]_D^{23}$ −38.7° (*c* 0.988). Found: C, 57.58; H, 5.76%; mol wt, 394. Calcd for $C_{19}H_{22}O_9$: C, 57.86; H, 5.62%; mol wt, 394.

IX was a very hygroscopic syrup, $[\alpha]_D^{23}$ +14.7° (*c* 0.911). Found: C, 56.51; H, 5.65%; mol wt, 412. Calcd for $C_{19}H_{22}O_9$: C, 57.86; H, 5.62%; mol wt, 394. ORD: $[\phi]_{400}$ +1273°, $[\phi]_{350}$ +1307°, $[\phi]_{300}$ +89°, $[\phi]_{250}$ −4670°.

b) A solution of VII (30 mg) in acetic anhydride (3.0 m*l*) was heated at 70°C in the presence of sodium acetate (0.30 g). After 4.5 hr, the mixture was cooled to room temperature and kept overnight. Then the solution was worked up by the usual procedure. The recrystallization of crude crystals from ether (34 mg) gave VIII (21 mg). The lack of any formation of IX was confirmed by TLC.

Acetylations of IV, V and VII. These acetylations were carried out a) below 0°C and b) at 100°C for 3 hr. The reactions were checked by TLC with solvents A and D. The results are listed in Table 2.

Table 2. Acetylation products

Starting material	Reaction conditions	
	a)	b)
IV	V, VI	VI
V	VI	VI
VII	recovered	VIII, IX

Formation of XI from IX. A solution of IX (168 mg) in methanol (20 m*l*) was hydrogenated in the presence of 5% Pd-C (840 mg) at atmospheric pressure. After 1 hr, the catalyst was removed by filtration and washed with methanol. The combined solution of the filtrate and the washings were evaporated to give a syrup (77 mg). The syrup was acetylated without further purification. The product was separated into XII (31 mg) and XI (30 mg) by PTC with solvent C. A mixture of XII, methyl iodide (5 m*l*), and silver oxide (0.5 g) was refluxed for 4 hr and then kept overnight at room temperature. The precipitates were removed by filtration. The filtrate was concentrated to give XI (23 mg).

Preparation of X. 1,3,4,5-Tetra-*O*-acetyl-α-L-sorbopyranosyl chloride (3.59 g)[17] was treated with anhydrous acetic acid (100 m*l*) in the presence of mercuric acetate (5 g) at room temperature. After 70 min, the reaction mixture was poured into ice water and extracted with chloroform. The extract was subsequently washed with water, a 5% sodium hydrogencarbonate solution, and water. The solution was dried over $MgSO_4$ and then evaporated to give a syrup (4.6 g). X (0.26 g, R_f 0.38—0.45) was isolated by PTC with solvent E. The recrystallization of crude X from ether gave needles (97 mg); mp 108—109.5°C, $[\alpha]_D^{23}$ +71.6° (*c* 0.705) (lit.[15] mp 113.8°C, $[\alpha]_D$ +74.4°).

Preparation of XIII from VI. VI (767 mg) was hydrogenated by the same procedure as was used for IX. The acetylation of a crude product gave a syrup (432 mg) from which XIII (88 mg) was isolated by repeated PTC with solvents A and D.

Treatment of X under Hydrogenation Conditions. A solution of X (10.5 mg) in methanol was treated in a manner similar to that used for IX. Hardly any hydrogen up-take could be observed. The thin-layer chromatogram showed the existence of a trace of XI along with the unreacted X.

The Equilibrium of III in Pyridine. *a) Isolation of IIIp.* (i) A solution of crystals of IIIf (100 mg) in pyridine (0.2 m*l*) was allowed to stand at room temperature. After 6 days, the solution was poured into petroleum ether (10 m*l*). A precipitated syrup was separated by decantation and washed with petroleum ether. The addition of ether to the syrup gave an amorphous powder (67 mg) which consisted mainly of **IIIp.** It had mp 151—182°C, $[\alpha]_D^{23}$ −26.7°→−24.1°

17) K. Tokuyama and M. Katsuhara, This Bulletin, **39**, 2728 (1966).

(24 hr) (*c* 0.640, methanol). Found: C, 58.41; H, 5.99%. Calcd for $C_{13}H_{16}O_6$: C, 58.20; H, 6.01%. The acetylation of the powder (10 mg) at 0°C for 6 hr gave VII (9.6 mg).

(ii) A solution of crystals of IIIf (1 part) in pyridine (10 parts) was heated at 100°C for 15 hr and then kept at room temperature for 35 hr. The solution was concentrated to a brown syrup containing a small amount of pyridine. The syrup was washed with petroleum ether and then dissolved in methanol. Insoluble crystals of IIIf were removed by filtration. The filtrate was evaporated to give a syrup. Ether was added to the syrup and the powder thus precipitated, which contained IIIf and IIIp, was removed by filtration. The filtrate was evaporated to give a powder. The recrystallization of the powder from ether gave the powder of IIIp of a considerable purity. It had mp 150—158°C.

b) *Transformation of IIIp to IIIf.* (i) A solution of IIIf (21.5 mg) in pyridine (0.4 m*l*) was heated at 100°C for 13.5 hr and then kept at room temperature for 30.5 hr. The solution was evaporated under reduced pressure. Crystals of IIIf (21.4 mg) were thus obtained.

(ii) A solution of IIIp (7 mg), prepared by the above procedure (a-ii), in methanol was allowed to stand overnight at room temperature; then it was concentrated. Crystals of IIIf (6 mg) were obtained.

The authors wish to express their gratitude to Professor Toshihiko Okamoto, The University of Tokyo, and to Dr. Ken'ichi Takeda, Director of this Laboratory, for their encouragement. They are also indebted to Drs. Kaoru Kuriyama, Kazuo Tori and Shiroh Satoh for the ORD and PMR.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 2028—2032 (1969)

The Nucleophilic Substitution Reactions of 2-Aminotropone Derivatives

Takashi TODA, Shôji RYU[1] and Tetsuo NOZOE

Department of Chemistry, Faculty of Science, Tohoku University, Katahira-cho, Sendai

(Received December 31, 1968)

The nucleophilic substitution reactions of 2-aminotropone (I), 2-methylaminotropone (II), 2-dimethylaminotropone (III), and 2-troponyl trimethylammonium iodide (IV), and their alkyl derivatives were investigated. It was found that the properties of I and II are similar to those of tropolones. On the other hand, those of III are analogous to those of tropolone methyl ethers, while those of IV are, rather, comparable to those of 2-halotropones or tropolone tosylates.

2-Aminotropone (I) and its derivatives have been obtained early in the history of troponoid chemistry.[2-4] However, only a few examples of the electrophilic and nucleophilic substitution reactions of these compounds have been investigated[3,4] other than the syntheses of many 1-azaazulan-2-one derivatives from 2-aminotropones by the action of active methylene compounds.[3b,4,5] Recently, the present authors investigated the electrophilic substitution reactions[6] of I and its *N*-alkyl derivatives —2-methylaminotropone (II)[3a] and 2-dimethylaminotropone (III)[3a]— and found that the reaction of III caused the hydrolysis of the dimethylamino group, thus giving tropolone derivatives.[6] The reaction mechanism of the hydrolysis was later clarified.[7] In this paper, the authors wish to report their

findings on the nucleophilic substitution reactions of I, II, III, and 2-troponyl trimethylammonium iodide (IV)[3a] and their alkyl derivatives; especially, the properties of these compounds in relation to nucleophiles will be compared with those of tropolones, tropolone methyl ethers, tropolone tosylates, and 2-halotropones.

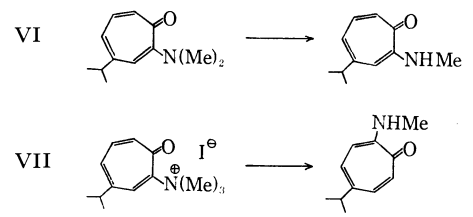
I: R=NH_2 IV: R=$N(Me)_3^{\oplus}\cdot I^{\ominus}$
II: R=NHMe V: R=OH
III: R=$N(Me)_2$

It has been shown that I gives tropolone (V) by the action of aqueous alkali.[3c] II and III afforded V under the same reaction conditions; however, IV gave a rearrangement product, benzoic acid. Although the treatment of III and IV with hydrochloric acid in alcohol gave V in a good yield, the same treatment of I and II resulted in the recovery of the starting substances. The action of hydrogen chloride on I, II, and III in absolute dioxane gave the corresponding hydrochlorides; on the other hand, IV afforded 2-chlorotropone.[3a,8] When III was treated with sodium methoxide in methanol, V and its methyl ether were obtained in 74% and 25% yields respectively. The treatment of IV resulted in 59% methyl benzoate and 26% benzoic acid, but I and II were recovered unchanged under the same reaction conditions. I, II, and III are stable entities on heating. IV is recovered when heated in acetone, methanol, and ethanol for a short period; however, when it is heated in water or directly under reduced pressure, IV gives III, and methyl iodide is liberated. III was a detectable product only by the treatment of IV with silver oxide with heating; however, when IV was treated with silver oxide in ethanol, benzoic acid was obtained in a good yield.

I and II were recovered unchanged when treated with amines at room temperature or even when heated with aniline under reflux. On the other hand, III gave I, II, and 2-hydrazinotropone[3a] in good yields by treatment with ammonia, methylamine, and hydrazine respectively. IV also afforded I and II under the same conditions. The treatment of III with *p*-thiocresol, potassium cyanide, cupric cyanide, or potassium thiocyanate resulted in the recovery of the starting substance, while IV gave 2-(*p*-tolylthio)-tropone[8,9] with *p*-thiocresol and III with inorganic cyano compounds.

Generally, the reaction of tropolone methyl ethers with nucleophilic reagents gives normal substitution products.[4,10] On the other hand, the reaction of 2-halotropones and tropolone tosylates with nucleophiles affords abnormal substitution products.[4,10]

The reaction of 2-dimethylamino-4-isopropyltropone (VI)[11] and its methyl iodide (VII) with methylamine gave a normal substitution product, 2-methylamino-4-isopropyltropone, from the former, and an abnormal substitution product, 2-methylamino-5-isopropyltropone,[11] from the latter. Therefore, the reaction mode of 2-dimethylaminotropones is analogous to that of tropolone methyl ethers, and the reactions of their quaternary bases to nucleophilic reagents take place in abnormal ways, much as with 2-halotropones and tropolone tosylates.[12]



The Grignard reaction of tropolone methyl ethers gave 2-substituted tropone derivatives[13–15]; the reaction mechanism has been proved to proceed by way of 1,8-addition.[16]

The reactions of III with methylmagnesium bromide, phenylmagnesium bromide, and butyllithium afforded 2-methyltropone,[17] 2-phenyltropone,[13a,14] and 2-butyltropone[14] respectively in good yields. In order to clarify the mechanism of the above reaction, the reaction of VI with phenylmagnesium bromide was investigated and found to give 5-isopropyl-2-phenyltropone.[13,17] Therefore, the Grignard reaction of 2-dimethylaminotropone proceeds in the fashion of 1,8-addition, similar to that of tropolone methyl ethers.

As has been shown above, 2-aminotropones and 2-methylaminotropones behave similar to tropolones[4] in both electrophilic[6] and nucleophilic substitution reactions. On the other hand, 2-dimethylaminotropones show different properties toward electrophiles compared with those of tropolone methyl ethers,[6] but they possess properties analogous with those of tropolone methyl ethers toward nucleophilic reagents. The properties of the quaternary bases of 2-dimethylaminotropones are similar to those of 2-halotropones and troplone tosylates.[4] The reason why alkaline hydrolyses are the only exchange reactions of the amino and methylamino groups of I and II with nucleophiles to take place is as follows: a hydrogen atom on the nitrogen in these compounds can be ionized, especially under the basic conditions, and the attack of nucleophiles on the formed aminotroponates is not easy, while the attacks of electrophiles on such entities occur readily.[6] A weak nucleophile such as the chloride anion can not be exchanged with amino groups of I, II, and III, even under acidic conditions. Only IV gives 2-chlorotropone, as has been mentioned above.

Experimental[18]

Base Hydrolyses. a) III (450 mg) was heated under reflux for 4 hr with 5 m*l* of 1.6N ethanolic potassium hydroxide. On the removal of the ethanol, a yellow crystalline mass was obtained; water was then added, and the solution was made slightly acidic (pH 6—6.5) with dilute hydrochloric acid and extracted with chloroform. On the evaporation of the solvent under reduced pressure, the residual oil crystallized in needles; it was recrystallized from petroleum ether - cyclohexane to give light yellow needles, mp 46—47°C (400 mg); undepressed when mixed with an authentic sample of tropolone.

b) From 450 mg of II, 400 mg of V were obtained by the same procedure.

c) VI was hydrolyzed as above to give light yellow plates, mp 49—50°C, which was identical with that of an authentic sample of hinokitiol. Yield, 150 mg from 200 mg of VI.

d) IV (600 mg) was refluxed for 3 hr on a water bath with 5 m*l* of 1.6N ethanolic potassium hydroxide. After the solution had been cooled, water was added; then the solution made weakly acidic with dilute hydrochloric acid and extracted several times with ether. An oily product solidified on the removal of the solvent, and recrystallization from benzene yielded white needles, mp 117—118°C (230 mg), which was undepressed on admixture with benzoic acid.

Acid Hydrolyses. a) I (243 mg) was heated under reflux with a mixture of 10% hydrochloric acid (5 m*l*), water (3 m*l*), and ethanol (5 m*l*) on a water bath for 6 hr. After the reaction mixture had cooled, it was made neutral and extracted with chloroform. The removal of the solvent and the recrystallization of the residue from cyclohexane yielded 220 mg of pale yellow needles, mp 105—106°C, identified as the recovered starting material from its IR and UV and by a mixed-melting-point determination with an authentic sample of I.

b) When the procedure described above was run using 270 mg of II, 250 mg of II, mp 76—77°C, were recovered.

c) When 300 mg of III were treated as above, 200 mg of V were obtained, mp 47—47.5°C. Its mixed melting point with an authentic sample of tropolone was undepressed.

The mother layer, after the separation of the tropolone, was made neutral with sodium bicarbonate, and extracted with chloroform, and the extract was dried over sodium sulfate. On the removal of the solvent, a brownish-yellow oily residue was obtained. Its IR and UV spectra were identical with those of III, and the oil gave a picrate, mp 144—146°C; yield, 75 mg.

d) When IV was treated as above, it gave tropolone; yield, 200 mg from 500 mg of IV.

Reactions with Anhydrous Hydrogen Chloride in Dioxane. a) I (365 mg) was dissolved in 5 m*l* of anhydrous dioxane in an ampoule through which dry hydrogen chloride was passed. The hydrogen chloride-saturated reaction mixture was then heated on a boiling-water bath for 3 hr. After the ampoule had been cooled, it was opened and the contents transferred to a small, round-bottomed flask. The removal of the solvent left white needles, mp 198—200°C; yield, 450 mg. IR: ν_{KBr} 3000—2400 cm^{-1} (broad, $\nu_{NH_3^+}$). This was dissolved in water, neutralized with aqueous sodium bicarbonate, extracted with benzene, and dried over sodium sulfate; the subsequent removal of the solvent gave a pale yellow solid. The recrystallization of the solid from cyclohexane-benzene afforded 320 mg of needles, mp 105—107°C, which had IR and UV spectra identical with those of an authentic specimen of 2-aminotropone.

b) When II (405 mg) was treated at above, a nearly quantitative yield of the hydrochloride (mp 250°C) was obtained as white needles. On the neutralization of the hydrochlorides, 350 mg of the starting substance (mp 74—76°C) were recovered.

c) From 450 mg of III, 530 mg of the hydrochloride (mp *ca.* 250°C) were obtained by the above procedure. On neuntralization with dilute sodium carbonate, followed by the usual working-up and alumina chromatography, 320 mg of III were regenerated.

18) All melting points are uncorrected.

d) IV (500 mg) was heated with 5 m*l* of hydrogen chloride-saturated dioxane in a sealed tube at 40—50°C for 4 hr. By the usual working-up and by purifying the reaction product through alumina chromatography, 200 mg of white needles were obtained, mp 59—60°C. This was found by a mixed-melting-point determination to be identical with and authentic sample of 2-chlorotropone.

Reactions with Sodium Methoxide. a) III (450 mg) was refluxed for 3 hr with a solution of sodium methoxide prepared by dissolving 90 mg of sodium in 5 m*l* of freshly-distilled absolute methanol, while moisture was carefully excluded. When the methanol was evaporated under reduced pressure, the reaction mixture partly solidified; it was washed three times with 2N potassium hydroxide and then extracted with benzene. The benzene layer was dried over sodium sulfate, and evaporated; the residue, on vacuum distillation, afforded a light yellow oil, 300 mg, whose IR spectrum was identical with that of 2-methoxytropone. From the product, a picrate, mp 115—117°C, was prepared in the usual way; its melting point was undepressed on admixture with an authentic sample of 2-methoxytropone picrate.

The water layer obtained in the alkaline washings described above was acidified, extracted with chloroform, dried, and evaporated to dryness. The residue crystallized from cyclohexane-light petroleum gave light yellow needles, mp 48—49°C, identified as tropolone by a mixed-melting-point determination.

b) I and II were treated by the procedure described above. The starting substances were recovered unchanged in nearly quantitative yields in both cases.

c) Metallic sodium (110 mg) was dissolved in 5 m*l* of absolute methanol, and to the resulting solution IV (600 mg) was added. The reaction mixture was allowed to stand at room temperature for 2 hr, and then refluxed on a water bath for one hour. The methanol was removed under reduced pressure, and to the residue water was added; the solution was washed three times with 2N potassium hydroxide to remove free benzoic acid, and it was extracted with benzene. The benzene layer was dried, and evaporated, and the residual oil was purified by vacuum distillation to afford a colorless oil (160 mg) which was found by a comparison of their IR spectra to be identical with an authentic sample of methyl benzoate.

From the water layer, benzoic acid was obtained (65 mg) following the same procedure after acidification with dilute hydrochloric acid and subsequent extraction with ether. The identification was made by a mixed-melting-point determination with an authentic sample.

Reactions with Amines and Hydrazine Hydrate. *2-Aminotropone.* a) III (450 mg) was allowed to react with an excess of liquid ammonia in a sealed tube at room temperature for 6 days. The removal of the excess ammonia and the liberated dimethylamine left a solid residue which was then recrystallized from cyclohexane-benzene to give 350 mg of pale yellow needles, mp 105—106°C; this substance was identified as I by a study of its IR spectrum and by a mixed-melting-point test with an authentic sample.

b) IV was treated as above to give 300 mg of I from 600 mg of IV.

c) II was treated in the same manner, but the starting substance was recovered quantitatively.

2-Methylaminotropone. a) III was allowed to react with a large excess of liquid methylamine in a sealed tube at room temperature for 6 days. The recryltallization of the solid residue obtained after the removal of the amine afforded yellow needles, mp 78—79°C, identified as 2-methylaminotropone; yield, 290 mg from 450 mg of III.

b) The treatment of IV (600 mg) with an excess of liquid methylamine yielded 350 mg of II.

c) I was recovered quantitatively when treated as above,

4-Isopropyl-2-methylaminotropone VI (200 mg) was allowed to react with liquid methylamine in a sealed tube for 4 days at room temperature. On the removal of the excess amine, the reaction mixture solidified; it was recrystallized from petroleum ether to give yellow crystals, mp 83—84°C (180 mg), undepressed on admixture with an authentic sample of 4-isopropyl-2-methylaminotropone.[19]

5-Isopropyl-2-methylaminotropone. VII (350 mg) was treated as above with liquid methylamine. After the excess amine had been removed, the product was dissolved in benzene and chromatographed on alumina. The benzene effluent gave a picrate in the usual way; the mp 208—210°C from ethanol did not show any depression on admixture with the authentic picrate of 5-isopropyl-2-methylaminotropone.

2-Hydrazinotropone. a) III (450 mg) was dissolved in 10 m*l* of ethanol, and to the resulting solution there were added 250 mg of 80% hydrazine hydrate. The reaction mixture was then refluxed on a water bath for 40 min, The evaporation of the solvent left a crystalline residue which was recrystallized from cyclohexane to give 400 mg of 2-hydrazinotropone, mp 94—95°C. The identification was made by study of its IR spectrum and by a mixed-melting-point determination with an authentic sample of 2-hydrazinotropone.

b) IV (600 mg) was treated with 170 mg of 80% of hydrazine hydrate in 10 m*l* of ethanol as above to gave 135 mg of 2-hydrazinotropone.

c) When I and II were treated under the same reaction conditions as above, the starting sudstances were recovered quantitatively.

Attempted Reaction of I and II with Aniline. a) A mixture of 365 mg of I and 5 m*l* of aniline was heated to reflux on an oil bath at 200°C for 3 days. The aniline was then expelled under reduced pressure, and the the black resinous residue was subjected to vacuum (0,1 mmHg) sublimation to give brownish-yellow prisms, mp 103—105°C. The crude crystals were further recrystallized from cyclohexane-benzene to afford 330 mg of recovered I, which was confirmed by a mixed-melting-point determination with an authentic sample of I.

d) The attempted reaction of II with aniline under the conditions described above gave rise to only the recovery of the starting materials unchanged.

Reaction with *p*-Thiocresol. a) IV (600 mg) and *p*-thiocresol (300 mg) were added to an ethanolic solution of sodium ethoxide prepared by dissolving metallic sodium (46 mg) in 10 m*l* of absolute ethanol. The reaction mixture was then refluxed, while all

19) Unpublished, prepared in the authors' laboratory.

moisture was excluded, on a water bath for 2 hr. After the solvent had been removed, the residual solid mass was recrystallized from cyclohexane to afford yellow crystals, mp 144—145°C (450 mg), identified as 2-(*p*-tolylthio)-tropone by a study of the IR spectrum and by a mixed-melting-point determination with an authentic sample.

b) When II was treated with a 1-equivalent mole of *p*-thiocresol and with 2-equivalent moles of sodium ethoxide under the same conditions, the starting substances were recovered in *ca.* a 90% yield.

Reaction with Silver Oxide. Silver nitrate (500 mg) was dissolved in 5 m*l* of water. To the resulting solution there was added a 1N sodium hydroxide solution until no more precipitation occurred. The grayish-brown precipitate was washed thoroughly until neutral to pH test paper and then used directly in the subsequent step.

To a stirred solution of IV (290 mg) in 50% aqueous ethanol, the moist silver oxide prepared above was added, portion by portion, at room temperature. Immediately after the addition of the reagent, a conspicuous evolution of trimethylamine was observed; it was detected from its odor, the alkaline reaction to pH test paper, and a picrate formation; mp 214—216°C.

The reaction mixture exhibited an alkalinity at pH *ca.* 8.5 (pH test paper) because of the dissolved trimethylamine. The reaction mixture, after having been stirred for 15 min at room temperature, was made acidic (pH *ca.* 4) and extracted with ether (20 m*l* ×4). The removal of the solvent and recrystallization from benzene afforded 110 mg of needles, mp 120—121.5°C, undepressed in a mixed-melting-point test with authentic benzoic acid.

b) When IV was reacted with dry silver oxide in xylene at 150°C for 5 hr and then worked-up as usual, *ca.* 90% of III was obtained.

Reaction with Organometallic Compounds. a) To a stirred solution of phenylmagnesium bromide prepared from bromobenzene (3.4 g) and magnesium ribbons (525 mg) in 50 m*l* of anhydrous ether under a nitrogen stream, there was added, drop by drop, a solution of III (1.0 g) in 30 m*l* of anhydrous ether; the reaction mixture was then heated under reflux for one hour. Upon the addition of the reactant, a solid yellowish mass attached to the wall of the vessel gradually turned grey white. After refluxing, 50 m*l* of a 40% ammonium chloride solution was added. The ether layer was separated, and the water layer was extracted several times with ether; then the combined organic layer was washed with water, dried over sodium sulfate, and evaporated under reduced pressure. The residue which solidified on cooling was purified through vacuum sublimation and then recrystallized from cyclohexane to give 1.05 g of needles (mp 84°C, which did not show any depression on admixture with authentic 2-phenyltropone).

b) An ethereal solution of III (1.0 g) was added to a stirred solution of methylmagnesium iodide, and then reacted as above. The residual oil, on vacuum distillation, gave 860 mg of a light yellow oil which was identified as 2-methyl tropone by a comparison of its IR spectrum with that of an authentic specimen.

c) III (500 mg) was dissoved in 100 m*l* of dry ether, and into the resulting solution there was vigorously stirred, drop by drop and in a nitrogen atmoshpere, an ethereal solution containing 7 m*l* of 1.8 mol *n*-butyllithium (supplied by Japan Chem. Industry K. K.). The reaction mixture was subjected to gentle reflux for 1.5 hr and then decomposed with dilute hydrochloric acid; the product was taken up in ether and dried. After the removal of the solvent, the residual oil was purified through vacuum distillation to give 500 mg of oil identified as 2-*n*-butyltropone by a comparison of its IR spectrum with that of an authentic specimen prepared by the reaction of 2-methoxytropone with *n*-butyllithium.[14]

d) VI (500 mg) was allowed to react with phenylmagnesium bromide prepared from magnesium ribbons (250 mg) and bromobenzene (1.57 g) in an ethereal solution with stirring for 2 hr under a nitrogen stream. After the usual working-up, the oily product thus obtained was chromatographed on alumina, and from the cyclohexane effluent, on the removal of the solvent, there were obtained pale yellow plates (mp 86—88°C, undepressed on admixture with an authentic sample of 5-isopropyl-2-phenyltropone).

Reaction with Potassium Thiocyanate. IV was dissolved in dimethylformamide, and to the resulting solution 2 equimoles of potassium thiocyanate were added. The reaction mixture was then refluxed for 3 hr and the excess solvent was removed under reduced pressure. After the usual working up, the residual oil was distilled under reduced pressure to give 89% of III, identified by a comparison of its IR spectrum with that of an authentic sample.

When potassium cyanide or cupric cyanide were used instead of potassium thiocyanate, almost the same results were obtained.

The treatment of III with these cyanides under the same conditions resulted in the recovery of the starting substances.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 2033—2037 (1969)

A Study of Valence Tautomerism of Cycloheptatriene-Norcaradiene

Teruji TSUJI, Shuji TERATAKE and Hiroshi TANIDA

Shionogi Research Laboratory, Shionogi & Co., Ltd., Fukushima-ku, Osaka

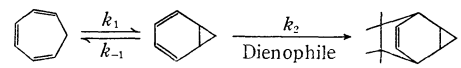
(Received January 22, 1969)

Rates of the Diels-Alder reaction of cycloheptatriene, tricyclo[4.3.1.0]deca-2,4-diene, 1,3-cyclohexadiene, and *cis*-bicyclo[4.3.0]nona-2,4-diene with excess of fumaryl chloride were measured using a dilatometer. Comparison of the rate of cycloheptatriene with that of other olefins raises the question of the free energy difference so far estimated between cycloheptatriene and norcaradiene, which has been proposed to exist in equilibrium. It is suggested that the most preferable mechanism of the Diels-Alder reaction of cycloheptatriene is not through the norcaradiene isomer, but through the transition state of the norcaradiene structure.

The valence tautomerism of unsaturated medium ring systems is of current interest,[1] and recent studies have indicated that cyclooctatetraene,[2] cyclooctatriene[2,3] and oxepine[4] are in equilibrium with their tautomeric isomers, bicyclo[4.2.0]octa-2,4,7-triene, bicyclo[4.2.0]octa-2,4-diene, and benzene oxide, respectively. In this kind of study for cyclooctatriene, the major technique was a kinetic study of the Diels-Alder reaction.[2] Regarding tropilidene, the spectroscopic studies have indicated that the principal species is 1,3,5-cycloheptatriene, whereas the product studies of the chemical reactions have suggested that norcaradiene is the reacting species.[5] The reaction of tropilidene with dienophile yields tricyclic products containing a cyclopropane ring formally derived from norcaradiene,[6] and the thermal isomerization of tropilidene gave toluene formed, presumably, by cleavage of the three-membered ring of norcaradiene.[7] For about twenty years, the chemistry of tropilidene and related compounds has been actively carried out in Japan.

These circumstances prompted us to carry out a kinetic study of the Diels-Alder reaction of tropilidene with fumaryl chloride[6a] in the hope that the norcaradiene isomer hypothetically existing in equilibrium with cycloheptatriene could be demonstrated.[8]

Kinetic Problem.



A B D C

If we assume an equilibrium ($K=k_1/k_{-1}$) between cycloheptatriene (A) and norcaradiene (B), followed by the Diels-Alder addition of B to a dienophile (D), that is a two-step mechanism, the rate of the adduct (C) formation, d[C]/dt, is denoted by k_2-[B][D]. Setting d[B]/dt=0 from steady state approximation, we have

$$d[B]/dt = k_1[A] - k_{-1}[B] - k_2[B][D] = 0$$

$$[B] = k_1[A]/(k_{-1}+k_2[D])$$

$$d[C]/dt = k_2[B][D] = k_1k_2[A][D]/(k_{-1}+k_2[D]) \quad (1)$$

Under the condition that the concentration of D is much larger than that of A, the concentration of D is constant throughout the reaction period.

$$k_1k_2[D]/(k_{-1}+k_2[D]) = k_c \quad (2)$$

k_c is the pseudo-first order rate constant varying with [D], and one can get the following equation.

$$d[C]/dt = k_c[A]$$

8) Interest in the kinetic studies of the Diels-Alder reactions was stimulated by the lecture given by Professor R. Huisgen at the Shionogi Research Laboratory in March 1962, and personal discussions one of the authors had with him later in October 1967. Our thanks are due to Professor Huisgen.

According to the magnitude of k_1,k_{-1} and k_2, the situation is further divided into three cases.

(a) $k_2[D] \ll k_1$ and k_{-1}. The slow combination of B with D compared to the rapid equilibrium is rate-determining. From Eqs. (1) and (2) we have $d[C]/dt = (k_1/k_{-1})k_2[A][D]$ and $k_c = (k_1/k_{-1})k_2[D]$.

(b) $k_2[D] \gg k_1$ and k_{-1}. The first equilibrium step becomes the rate-determining step. $d[C]/dt = k_1[A]$ and $k_c = k_1$.

(c) $k_2[D] \approx k_1$ and k_{-1}. This case corresponds to that between the two limiting cases (a) and(b), and both steps are effective on rate-determination. The relation is represented by Eqs. (1) and (2).

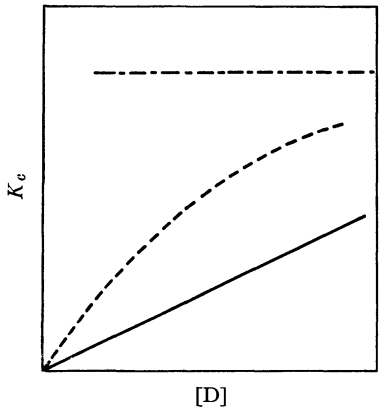

Fig. 1. Correlation of K_c and $[D]$.
—— Case (a) and (d)
---- Case (c)
———— Case (b)

Plotting k_c against the varying amounts of D, as shown in Fig. 1, provides, for the case (a), a straight line through the origin having a slope of $(k_1/k_{-1})k_2$, for (b), a straight line parallel to the abscissa corresponding to $k_c = k_1$, and for (c), a curve through the origin.

The case (d): if the Diels-Alder reaction proceeds without intervention of B and produces C with the second order rate constant of k_2', we have

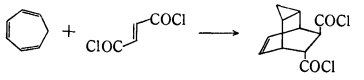
$$d[C]/dt = k_2'[A][D]$$

When the concentration of D is much larger than that of C, we have $d[C]/dt = k_c'[A]$ where $k_c' = k_2'[D]$. This relation should be the same as the case (a).

Results

The kinetic studies were performed under such conditions that the concentration of fumaryl chloride[9] varied from ten to thirty times the concentration of cycloheptatriene. The rate was followed dilatometrically in dioxane by measuring the reduction in the total reaction volume due to the union of the two molecules to one.[10] A decrease of the meniscus height in the graduated capillary against the reaction time satisfied the correlation of the pseudo-first-order up to about three half-lives. As an example, rate constants, k_{obs} at 55.01°C, varying the concentration of fumaryl chloride are shown in Table 1.

Table 1. The Diels-Alder reaction of cycloheptatriene with fumaryl chloride



A D

$[A]\times10^2$ mol/l	[D] mol/l	[D]/[A]	K_{obs}· sec^{-1}
6.01	0.63	10.4	5.54×10^{-5}
6.01	1.20	20.0	1.16×10^{-4}
6.01	1.51	25.0	1.44×10^{-4}
6.01	1.79	29.8	1.84×10^{-4}

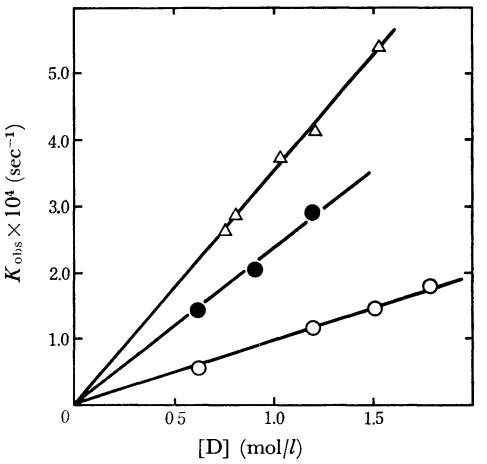


Fig. 2. Correlation of kobs and [D] at three temperatures.
○ 55.01°C ● 72.47°C △ 79.98°C

Plotting k_{obs} against increasing concentrations of fumaryl chloride at 55.01°C, 72.47°C and 79.98°C, yielded straight lines, as shown in Fig. 2. These linearities correspond either to the case (a) $k[D] \ll k_1$ and k_{-1} involving the intermediate (B), or the case (d) which is not through B. Similar lines were also obtained from the reaction with a more reactive dienophile, tetracyanoethylene.

Slopes of the straight lines represent the values of $(k_1/k_{-1})k_2$ or k_2' at the respective temperatures.

9) Fumaryl chloride is a very reactive dienophile. Its addition to cyclopentadiene proceeds (at 20°C in dioxane) 100 times more rapidly than the addition of maleic anhydride to the same diene. J. Sauer, H. Wiest and A. Mielert, *Chem. Ber.*, **97**, 3183 (1964).

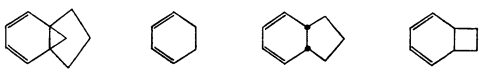
a) Calculated from the observed rates using the least square method.

Table 2 shows their values and the value extrapolated to 15°C by use of the Arrhenius equation.

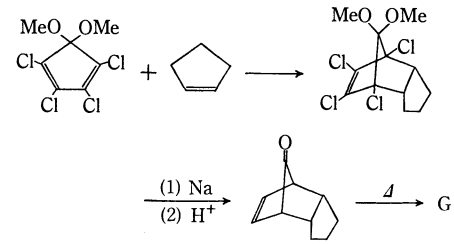
If the Diels-Alder reaction of cycloheptatriene proceeds through an equilibrium with B, since $(k_1/k_{-1})k_2$ is now known, evaluation of k_2 leads to a determination of the equilibrium constant (k_1/k_{-1}). We wanted to evaluate k_2 from the Diels-Alder reactions of some compounds, which are structually related to norcaradiene, with fumaryl chloride. The compounds chosen were tricyclo[4.3.1.0]deca-2,4-diene (E),[11] 1,3-cyclohexadiene (F), *cis*-bicyclo-[4.3.0]nona-2,4-diene (G), and bicyclo[4.2.0]octa-2,4-diene (H), in which E has the norcaradiene structure fixed by an additional five-membered ring.



E F G H

G was prepared by us according to the schema shown below, although it had been synthesized by Alder through a different route.[12]

Under the conditions of the pseudo-first-order with excess of fumaryl chloride, the addition rates of the dienes were determined in the same way as above and summarized in Table 3.



Discussion

If the cycloheptatriene-norcaradiene pre-equilibrium exists, the overall rate of the adduct formation from cycloheptatriene is shown as $(k_1/k_{-1})k_2=9.7\times10^{-6}$ l/mol·sec at 15°C. The second-order rate constants, k_E, k_F, k_G and k_H, obtained from E, F, G and H, respectively, are given in Table 4. Here, k_H was estimated on the fact that the addition of H to maleic anhydride is thirty times faster than that of cycloheptadiene (F) in dioxane at 30°C (by Huisgen[2] and Sauer[13]).

Table 4. Assumed equilibrium between cycloheptatriene and norcaradiene[a]

Compd.	k_2 (l/mol·sec)[b]	k_1/k_{-1}[c]	Norcaradiene at equilibrium (%)
E	1.2×10^{-5}	0.8	45
F	4.7×10^{-4}	2×10^{-2}	2

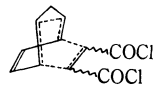
Replacement of k_2 by these second-order constants yields various estimations of k_1/k_{-1}, from which the equilibrium concentrations of norcaradiene are derived as 45, 2, 0.1 and 0.07% (Table 4). However, the former two values could be eliminated, because they are very unreasonable on the basis of the spectral properties of tropilidene reported.[5] Appropriate adoptions of the latter two values lead to the free energy differences of 4.0 and 4.5 kcal/mol respectively, existing between cycloheptatriene and norcaradiene.

On the other hand, the free energy difference of 11 ± 4 kcal has been proposed[14] basically from the table of bond-energy[15] and some discussions using this value have appeared frequently in literatures.[16] The value of 11 ± 4 kcal/mol corresponds to k_1/k_{-1} of 5×10^{-6}—4×10^{-12}. Thus, introduction of this k_1/k_{-1} value into the equation, $(k_1/k_{-1})k_2 = 9.7\times10^{-6}$ l/mol·sec, yields k_2 of 2—2×10^6 l/mol·sec as the addition rate of norcaradiene to fumaryl chloride at 15°C, which turns out to be an astonishingly large value referring to the second-order rate constants of E, F, G and H. Even the lowest value, 2 l/mol·sec, which corresponds to the free energy difference of 7 kcal/mol, is close to the rate of highly reactive cyclopentadiene with fumaryl chloride at 20°C in dioxane.[9] These lead to two alternative views; (i) the rate of the Diels-Alder reaction of norcaradiene is abnormally larger than we would expect on the basis of present organic theories, or (ii) the estimated value of 11 ± 4 kcal/mol is unreasonably large.

By comparison of the rate of G with that of F (Table 3), it might be considered that a fused five-membered ring accelerates the Diels-Alder reaction by a factor of twenty. If view (i) is taken, it is reasonable to regard that Vogel's compound (E) fusing a five-membered ring to the norcaradiene structure has also a great reactivity in the Diels-Alder reaction. However, it is found that E is less reactive by a factor of forty than F. Although there was no evidence that the reactivity of E should be compatible with that of norcaradiene, these discrepancies throw a serious doubt upon the free energy difference of 11 ± 4 kcal/mol.

Consequently, three basic limiting cases are derived for the relationship between cycloheptatriene and norcaradiene. (1) The free energy difference between both structures is much smaller than the previously proposed value of 11 ± 4 kcal/mol. (2) The difference of 11 ± 4 kcal/mol exists and then the addition rate of norcaradiene is abnormally great by presently unknown factors. (3) The Diels-Alder reaction of cycloheptatriene does not proceed through norcaradiene which has been proposed to exist in the ground state, but takes the norcaradiene structure in the transition state, pictured as



Although available data are insufficient to obtain a conclusion on the above alternatives, we prefer the possibility of (3) that transition into norcaradiene takes place only under the influence of the attacking agent.

Experimental

All melting points were corrected. Infrared spectra were recorded on a Nippon Bunko IR-S spectrometer. NMR spectra were determined at 60 Mc with a Varian A-60 Spectrometer using tetramethylsilane as an internal standard.

Materials and Apparatus. The cycloheptatriene used in this work was Shell chemical material which was obtained in a purity better than 95% by distillation (bp 114—115°C). Tricyclo[4.3.1.0]deca-2,4-diene (E), bp 71—73°C/15 mmHg, n_D^{24} 1.5248 (lit.[11] bp 61—62°C/11 mmHg, n_D^{20} 1.5267) was prepared by the procedure of Vogel. 1,3-Cyclohexadiene (F) (bp 79—80°C) was supplied by Dr. T. Nakata.[17] Dioxane was purified by the procedure of Hess and Frahm.[18]

The dilatometer used, whose desigh is explained in Ref. 10, is equipped with a reaction vessel of about 20 cc and a graduated capillary of inner-diameter of 0.5 mm. Thermostat was maintained in a range of ±0.01°C at the indicated temperatures.

Typical Rate Determination. The sample of 1.385 g of cycloheptatriene was weighed in a 20 ml volumetric flask and filled to 20 ml with dioxane. Fumaryl chloride (4.590 g) was accurately weighed in a 25 ml volumetric flask, to which *ca.* 20 ml of dioxane and an aliquot of 2 ml from the dioxane solution of cycloheptatriene previously prepared was added. The mixed solution was kept in thermostat at 55.01°C for a short time and filled to 25 ml with dioxane, so that the concentrations of cycloheptatriene and fumaryl chloride were 0.0601 and 1.200 mol/l. After cooling, the resulting solution was transferred into the dilatometer, whose meniscus in the capillary was adjusted to the desired height when the thermostat attained the reaction temperature. Then reading of the meniscus height was started and continued until ten-half lives. The difference in the meniscus height from start to ten-half lives was 6.67 cm.

Addition of Tetrachlorocyclopentadienone Dimethyl Ketal to Cyclopentene. A mixed solution of 10 g of cyclopentene and 41.7 g of tetrachlorocyclopen-

tadienone dimethyl ketal was sealed in a glass tube and heated to 170°C for 18 hr. After cooling, the solid residue was chromatographed on 100 g of standard Merck alumina with petroleum ether (bp 40—50°C) to exclude dark brown impurity. The eluent was concentrated. The residue solidified was recrystallized from petroleum ether to give 40.1 g (82.3% based on cyclopentene) of *endo*-1,7,8,9-tetrachlorotricyclo[5.2.1.$0^{2,6}$]deca-8-en-10-one dimethyl ketal, mp 83.5—84.5°C. NMR (CCl_4) at τ 6.44 and 6.52 (two methoxyls, 6H, singlet), 7.0 (two methines, 2H, multiplet) and 7.57 (three methylenes, 6H, multiplet). Found: C, 43.69; H, 4.27%. Calcd for $C_{12}H_{14}Cl_4O$: C, 43.41; H, 4.25%.

***endo*-Tricyclo[5.2.1.$0^{2,6}$]deca-8-en-10-one.** A solution of 33.2 g of the above adduct in 600 m*l* of tetrahydrofuran and 96.5 g of *t*-butyl alcohol was efficiently stirred at reflux temperature under nitrogen atmosphere. Sodium chip (57.5 g) was cautiously added for over one hour to the reaction mixture followed by stirring for an additional 5 hr. After cooling, the remaining sodium was decomposed with cold methanol and then with a large amount of cold water. The solution was extracted with ether, dried over sodium sulfate, and evaporated to yield 19.0 g of an oily residue, which was distilled at 98—103°C /8 mmHg to give 14.0 g of the dechlorinated ketal.

The ketal was dissolved in 30 m*l* of methanol and 50 m*l* of 70% aqueous acetic acid, and warmed to 80°C under stirring for 3.5 hr. The reaction mixture was poured into cold water and made alkaline with sodium hydroxide. After extraction with ether, evaporation gave 9.8 g of a solid residue, which was recrystallized from petroleum ether to give 8.5 g (57.5%) of white needles, mp 61.5—63.0°C (in sealed tube). NMR (CCl_4) at τ 3.62 (vinyl, 2H, triplet), 7.1 (two methines, 2H, at carbon 1.7, quintet), 6.58 (two methines at carbon 2.6, multiplet), and 8.0—9.2 (three methylenes, 6H, multiplet). IR $\nu_{max}^{CCl_4}$ 2985, 2940, 2858, 2866, and 1782 cm^{-1}. Found: C, 81.29; H, 8.20%. Calcd for $C_{10}H_{12}O$: C, 81.04; H, 8.16%.

***cis*-Bicyclo[4.3.0]nona-2,4-diene (G).** The ketone was vaporized at 120—130°C and reduced pressure (35 mmHg) in a stream of nitrogen introduced by means of a fine capillary tube. The vapor passed through a 30 cm section of 4 mm (diameter) tubing packed with glass grain of 30—40 mesh and maintained at 250—300°C by means of an externally heated coil of nichrome wire. The products were trapped at dry ice-acetone temperature. The crude pyrolysate was distilled at 101—102°C/123 mmHg to yield 4.5 g (79.2%) of the decarboxylated diene, n_D^{25} 1.5052. NMR (CCl_4) at τ 4.42 (vinyl, 4H, multiplet), 7.4 (two methines, 2H, multiplet) and 8.0—8.8 (three methylenes, 6H, multiplet). Kinetics of the Oxidation of Benzyl Alcohol by Acid Permanganate

K. K. BANERJI and P. NATH

Department of Chemistry, University of Jodhpur, Jodhpur, India

(Received January 29, 1968)

The observed kinetic isotope effect[1] in the oxidation of cyclohexanol by acid permanganate has indicated that probably oxidation involves a hydride ion transfer from alcohol to the oxidant. Recently Barter and Littler[2] suggested that oxidation of alcohols and ethers involves transfer of a hydride ion from the carbon atom carrying the functional group to the oxidant. Littler[1] indicated permanganic acid as the important oxidising species, however, Banerjee and SenGupta[3] have postulated manganese(III) as the active species in the acid permanganate oxidation of methanol and ethanol. No information is available on the acid permanganate oxidation of benzyl alcohol except a preliminary work reported by Cullis and Ladbury.[4] It was, therefore, considered fruitful to investigate the kinetics of the oxidation of benzyl alcohol by acid permanganate.

Experimental

Materials. Perchloric acid (60% E. Merck) was used as a source of hydrogen ions; sodium perchlorate (Reidel) was used to adjust ionic strength; permanganate solutions were prepared by dissolving 'AnalaR' potassium permanganate and acetic acid (99.5% B.D.H.) was used for preparing the solvent mixture. Benzyl alcohol (B.D.H.) was purified by fractionation. All other chemicals used were chemically pure.

Kinetic Measurement. The reactions were studied at constant temperature (±0.02°C). Unless otherwise stated, the solvent was 20% acetic acid. The concentration of benzyl alcohol was kept in excess to that of $KMnO_4$. Reaction mixtures containing requisite amounts of perchloric acid, acetic acid and benzyl alcohol were placed in thermostat for sufficient time. Reactions were started by adding permanganate solution rapidly through a pipette. Aliquots were withdrawn at known intervals of time and concentration of permanganate was estimated iodometrically.

Results

Product Study. Oxidation of benzyl alcohol by acid permanganate gives benzaldehyde as the main product. The amount of benzaldehyde formed was estimated by gravimetric method as 2,4-dinitrophenylhydrazone.[5] The recovery of benzaldehyde is about 85% based on the following reaction:

$$2MnO_4^- + 5C_6H_5CH_2OH + 6H^+ \rightarrow 2Mn^{2+} + 5C_6H_5CHO + 8H_2O$$

This shows that the further oxidation of benzaldehyde is not significant under the conditions

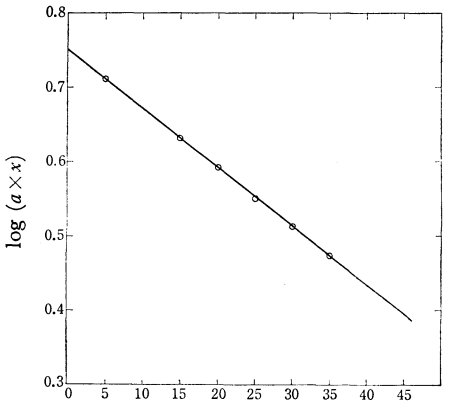

Fig. 1. Typical run.
[$PhCH_2OH$]: 2.0×10^{-3}M, [MnO_4^-]: 4.0×10^{-4}M, [H^+]: 0.61M, Temp. : 35°C, K_1 : $18.4\times10^{-3}min^{-1}$

1) J. S. Littler, *J. Chem. Soc.*, **1962**, 2190.

of the reaction.

Rate Laws. When benzyl alcohol and hydrogen ions are in excess the rate at which permanganate disappears follows the first order rate law. A typical kinetic run is illustrated in Fig. 1. In all cases the values of first order constants were determined graphically, for first 30—40 percent of the reaction.

Further the value of first order rate constant does not vary with the initial concentration of permanganate (Table 1).

Table 1. Variation of rate with concentration of manganese(VII)

$[PhCH_2OH]$: 2.0×10^{-3}M; $[H^+]$: 0.61M; Temp. 35°C					
$[MnO_4^-]\times10^4$ mol l^{-1}	4.0	6.0	8.0	10.0	12.0
$k_1\times10^3$ min^{-1}	18.4	18.4	18.6	17.3	18.0

Thus the order with respect to manganese (VII) is one.

The reaction is also of first order with respect to benzyl alcohol (Table 2).

Table 2. Variation of rate with concentration of benzyl alcohol

$[MnO_4^-]$: 4.0×10^{-4}M; $[H^+]$: 0.61M; Temp. 35°C.					
$[PhCH_2OH]\times10^3$ mol l^{-1}	1.0	2.0	3.0	4.0	5.0
$k_1\times10^3$ min^{-1}	9.1	18.4	27.7	36.8	46.1
$k_1/[PhCH_2OH]$	9.1	9.2	9.2	9.2	9.2

Under the conditions of constant ionic strength the rate varies linearly with concentration of hydrogen ions (Table 3).

Table 3. Variation of rate with concentration of hydrogen ions

$[MnO_4^-]$: 4×10^{-4}M; $[PhCH_2OH]$: 1×10^{-3}M; Temp. 35°C. Ionic strength (μ): 1.92M						
$[H^+]$ mol l^{-1}	0.48	0.72	0.96	1.44	1.68	1.92
$k_1\times10^3$ min^{-1}	10.0	13.8	17.5	26.5	30.9	26.8
$10^2\,k_1/[H^+]$	2.08	1.92	1.82	1.84	1.84	1.92

This indicates that increase in acidity brings about an increase in the rate of the oxidation. This may well be due to protonation of permanganate anion to give permanganic acid, a more powerful oxidant.

$$H^+ + MnO_4^- \rightleftarrows HMnO_4$$

This accords well with the suggestion of Littler[1] that acid catalysed path in the oxidation of cyclohexanol by permanganate involves a protonation in the pre-equilibrium. Stewart and Mocek also observed such an effect in the acid permanganate oxidation of formic acid.[6]

Effect of Manganese(II). Addition of manganous sulphate does not appreciably affect the rate of the oxidation (Table 4).

Table 4. Effect of manganese(II) on the rate of oxidation

$[MnO_4^-]$: 4×10^{-4}M; $[PhCH_2OH]$: 1×10^{-3}; $[H^+]$: 1.23M; Temp. 35°C					
$[Mn(II)]\times10^4$ mol l^{-1}	0.0	4.0	8.0	10.0	12.0
$k_1\times10^3$ min^{-1}	21.0	23.0	22.2	22.7	23.0

These results are contrary to that observed by Banerjee and SenGupta[3] in the acid permanganate oxidation of methanol and ethanol. They observed that the rate of oxidation is decreased by addition of manganese(II). The fact that the rate of the oxidation is unaffected by manganese(II) indicates that intermediate valency states of manganese are not important in this reaction.

Effect of Fluoride Ions. Addition of sodium fluoride also does not cause any change in the first order rate constant.

This also supports the view that intermediate valency states of manganese are not important in this oxidation, as fluoride ions are known to suppress the oxidation by manganese(III) and manganese(IV) by complexation.

Effect of Temperature. Data on the effect of temperature on the rate of oxidation are summarized in Table 5.

Table 5. Variation of rate with temperature

$[PhCH_2OH]$: 2.0×10^{-3}M; $[MnO_4^-]$: 4.0×10^{-4}M; $[H^+]$: 0.61M

Temp. °K	$k_1\times10^2$ min^{-1}	$k\times10^2$ l^2 m^{-2} sec^{-1}	
303	1.38	18.9	$\Delta S^{\neq}$
308	1.84	25.1	-27.2 e.u.
313	2.46	33.6	$\Delta H^{\neq}$
318	3.24	44.3	10.8 kcal mol^{-1}

It is found that a plot of $\log k$ against inverse of temperature is straight line. Arrhenius equation is therefore, valid for this reaction. The specific rate constant, k defined as

$$k = \frac{k_1\ (\text{min}^{-1})}{60\cdot[PhCH_2OH][H^+]}$$

Discussion

Absence of any effect of manganese(II) and

6) R. Stewart and M. M. Mocek, "Oxidation in Organic Chemistry," ed. by K. B. Wiberg, Academic Press, New York (1965), p. 56.

of fluoride ions on the rate of oxidation suggests that benzyl alcohol is mainly oxidzed by manganese-(VII). The linear increase in the rate of oxidation with increase in acidity accords well with the suggestion that probably permanganic acid is the active species.

$$H^+ + MnO_4^- \rightleftarrows HMnO_4$$

The entropy of activation and heat of activation data suggest that a C–H bond is ruptured in the rate-determining step (*cf.* Bakore and Narain[7,8]). The hydrogen may be removed by the oxidant either as a hydrogen atom or a hydride ion. It has been pointed out that known cases of hydride-ion transfer reactions seems to have a low isotope effect.[9] The value of 2.42 for the kinetic isotope effect in the oxidation of cyclohexanol by acid permanganate, observed by Littler,[1] suggests hydride transfer in the oxidation. This is, however, not conclusive and permanganate is known to function as a one-electron oxidant also, abstracting a hydrogen atom. Recently Barter and Littler[2] have shown that acid permanganate oxidation of alcohols involve a two-electron mechanism, with transfer of a hydride-ion from the carbon atom bearing the functional group to the oxidant. The values of heat of activation and entropy of activation for the oxidation of benzyl alcohol are of the same order as those of methanol and ethanol. This indicates that probably same mechanism operates in these oxidations.

If one accepts the hydride-transfer mechanism, the oxidation of benzyl alcohol by acid permanganate may be visualized as

$$HMnO_4 + H\text{–}\overset{\overset{C_6H_5}{|}}{\underset{\underset{H}{|}}{C}}\text{–}OH \xrightarrow{\text{slow}} H_2MnO_4^- + C_6H_5\overset{+}{C}HOH$$

(Mn(V))

$$C_6H_5\overset{+}{C}HOH \xrightarrow{\text{fast}} C_6H_5CHO + H^+$$

$$5Mn(V) \xrightarrow{\text{fast}} 2Mn(II) + 3Mn(VII)$$

The existance of manganese(V) as a reaction intermediate is well established.

Hot-Atom Chemistry of Bromine. III.[1] The Use of Bromides and Bromate in an Attempt at the Recoil-Synthesis of Two Organic Radiobromides in Solid Mixture Systems

Chiro SHINOMIYA, Akira OYOSHI and Toshiaki KISHIKAWA

Department of Industrial Chemistry, Faculty of Engineering, Kumamoto University, Kumamoto

(Received July 10, 1968)

Since the early study of recoil syntheses with organic bromides in organic solutions,[2] many experiments on the recoil syntheses of ^{82}Br-labeled organic bromides have been undertaken in the liquid phase. A few, however, have been done in solid phase It has previously been reported that the radiative neutron capture and the isomeric transition produce bond disruption in irradiated aqueous bromate[3] and that the radiobromine-82 so produced in a pyrenebromanil-molecular compound could combine with the pyrene ring to produce ^{82}Br-labeled pyrene.[1] The present note describes an attempt at the recoil labeling of the ^{82}Br atoms in pyrene or *p*-benzoquinone, with potassium bromate, bromide or ammonium bromide used as the bromine source.

Experimental

The samples were composed of the organic target and the bromine source (in a molar ratio of 1 : 4[4]); the ingredients were mixed by pestling them together

1) Part II: C. Shinomiya *et al.*, This Bulletin, **42** (8), (1969), in press.

2) E. Glückauf and J. W. J. Fay, *J. Chem. Soc.*, **1936**, 390.

4) The equal ratio of the quinone ring: bromine in bromanil reported in the previous paper.[1]

on an agate motar. They were then irradiated at the reactor temperature (*ca.* 40°C) in a pneumatic tube of KUR[5] for 1—80 min. The thermal neutron flux and the accompanying gamma-dose rate at 1 MW operation were 5×10^{12} n/cm²/sec and 2.7×10^{7} R/hr respectively. After standing for more than 2 hr[6] at room temperature, the samples were extracted into a two-phase mixture of a carbon disulfide solution of bromine and an aqueous mixture of potassium bromide and bromate; radioactivity measurements were then made with respect to the ^{82}Br activities. The organic yield was calculated in the manner described in a previous paper.[1]

Results

Table 1 shows the organic yields in the irradiated pyrene or *p*-benzoquinone and bromine compound mixtures at various irradiation times. No definite dependency of the irradiation time on the organic yield was established. In these heterogeneous mixtures a chance for a recoiled atom to escape from the bromide or bromate crystal may be small, and only the atoms recoiled at or near the surface of the crystal may be stabilized in both the organic crystal and the parent one. No dependency of the irradiation time can be supported by this explanation.

Table 1. Organic yields in irradiated mixtures

Bromine source	Irrad time min	Organic yield, % in organic targets	
		Pyrene	*p*-Benzoquinone
NH_4Br	20	4.4	2.1
KBr	1	0.7	1.3
	5	0.4	0.4
	10	2.7	3.3
	20	3.2	1.9
	30	3.6	4.3
$KBrO_3$	1	1.0	3.3
	5	2.4	4.4
	10	1.8	2.0
	30	3.7	2.2
	80	1.6	3.9

Ammonium bromide was considered to be more effective than potassium bromide on the organic yields in both pyrene and *p*-benzoquinone. Bromate was effective for a short period of irradiation, and bromide, for a long period.

The authors wish to express their appreciation to Dr. Shiro Iwata, Dr. Yoshiyuki Kiso, and the personnel of the Research Reactor Institute, Kyoto University, for their assistance in the irradiation.

The Isotope Effect of Hydrogen on the Autoxidation of Benzene and Toluene in Aqueous Solutions*1

Hiroshi HOTTA, Nobutake SUZUKI and Takuji KOMORI

Japan Atomic Energy Research Institute, Takasaki, Gunma

(Received August 2, 1968)

As the result of studies of the autoxidation of benzene[1] and toluene[2] in aqueous solutions catalyzed by metal ions at elevated temperatures, it has been assumed that the main reaction of the propagation process is the abstraction reaction of hydrogen by peroxides:

$$ROO\cdot + RH \rightarrow ROOH + R\cdot \qquad (1)$$

where R represents the phenyl or benzyl radical. As an extension of this work, the autoxidation, initiated by Fenton's reagent, was carried out for an equimolar mixture of C_6H_6 and C_6D_6 and one of $C_6H_5CH_3$ and $C_6D_5CD_3$ in a previous work.[2] The isotope effect of hydrogen or the rate constant ratio of this reaction, k_H/k_D, was then estimated from the isotopic composition of the products at a low reaction conversion by using the equation:

$$\frac{k_H}{k_D} = \frac{(RD)}{(RH)} \times \frac{(Product)}{(d\text{-}Product)} \qquad (2)$$

where (RD)/(RH) is the initial mole ratio of the

*1 The Autoxidation of Aromatic Hydrocarbons in Aqueous Solutions. XII.

1) H. Hotta, N. Suzuki and T. Abe, This Bulletin, **39**, 417 (1966).

2) N. Suzuki and H. Hotta, *ibid.*, **40**, 1361 (1967).

deuterated reactant to the normal reactant, which was unity, while (Product)/(d-Product) is the mole ratio of the normal product to the deuterated product. This method should give the value of k_H/k_D, when the concentration of the reactant (RH or RD) in the aqueous phase is always high in comparison with that of ROO· in reaction (1).[3] For this purpose, acetone was added in the aqueous phase in order to increase the solubility of aromatic hydrocarbons.

The values in the previous work[2] (*i. e.*, *ca.* 1.4), however, seemed to be rather low for the confirmation of reaction (1). Recently, it has been found that direct mass spectrometry is not a good method for measuring the isotopic composition of the products, since the isotope effect of vaporization during sampling sometimes becomes effective for products with such low vapor pressures.[4] Therefore, the isotopic measurements were carried out by an entirely different procedure in the present work. Namely, the products, separated by gas chromatography, were converted to hydrogen and deuterium prior to the mass spectrometry. The present method is definitely a better way for the isotopic measurement, since it avoids the inherent error due to the above isotope effect of vaporization. The values of the present work, estimated by Eq. (2), are listed in Table 1.

Table 1. Isotope effect of hydrogen

Reactant	Product	Temp., °C	k_H/k_D
Benzene	Biphenyl	20	1.9
	Phenol	70	2.4±0.2
Toluene	Benzyl alcohol	70	4.6±0.3
	Dibenzyl	70	4.8

The values (4.5—4.8) obtained for toluene are similar to the values for the propagation process (reaction (1)) of the autoxidation of aromatic hydrocarbons, that is, 5.5 for cumene at 60°C[5] and 5.1 for diphenylmethane at 30°C.[6] Meanwhile, similar values (4.5—5.1) have also been reported for the oxidation of *p*-methoxytoluene by manganic acetate in acetic acid,[7] which involves the detachment of the hydrogen atom by an electron-transfer process.

As for the oxidation of benzene, Smith and Norman suggested, after a qualitative experiment, that there is no kinetic isotope effect on the hydroxylation of benzene to phenol by Fenton's reagent at room temperature.[8] Meanwhile, the addition of the hydroxyl radical to benzene has been confirmed as the primary process in the formation of phenol in the pulse radiolysis of an aqueous solution of benzene at room temperature.[9]

Contrary to the above observations of Smith and Norman, however, the present value for benzene at 70°C (2.4) appears somewhat unexpectedly high. In our previous preliminary study,[3] too, it was a general tendency for the value of k_H/k_D, obtained at 70°C to be relatively larger than that at 20°C. Since the kinetic isotope effect usually decreases with an increase in the temperature, the higher value at 70°C seems to suggest that the process at 70°C includes a different reaction route, which has a higher isotope effect. A few possible pathways have already been proposed as examples in reference (8). However, none of these mechanisms can explain the fact that more than one half of the oxygen in the produced phenol is originated from water.[4] Further investigation is necessary, for the mechanism is rather complicated for the case of benzene.

Experimental

The oxidation procedure was almost the same as an earlier one.[3] That is, 0.4 cc of benzene was dissolved in 75 cc of a 0.4N sulfuric acid solution containing 0.01M ferrous sulfate and 25 cc of acetone at 20°C, while 0.5 cc-portions of benzene and toluene were dissolved in 80 cc of the above ferrous solution and 20 cc of acetone at 70°C. Benzene or toluene was almost an equimolar mixture with the respective deuterated reagent, Benzene-d_6 and toluene-d_8, obtained from Merck, Sharp & Dohme of Canada, Ltd , were proved extremely pure chemically and isotopically by gas chromatography and mass spectrometry, 10 cc of 1.5% hydrogen peroxide were added, drop by drop, over a period of about 90 sec, to the above solutions in a 300 cc flask opened to the air.

After the mixture had been stirred for 10 min and then cooled, the products were separated by gas chromatography (PEG 6000). Then they were converted to water by being passed through cupric oxide pellets at 500°C with dry oxygen. This water was again reduced to hydrogen gas by passing it through zinc pellets at 370°C. The ratio of hydrogen to deuterium in this gas was determined by mass spectrometry.

The Formation of 3-*n*-Butylamino-7-hydroxy-9-*n*-butyl-carbazolquinone(1, 4) in the Reaction of *p*-Benzoquinone with *n*-Butylamine

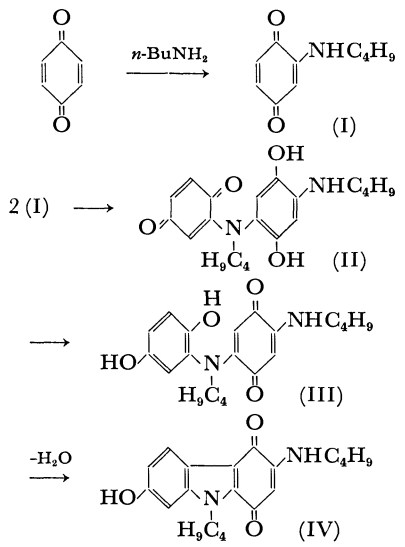
Kazuyuki SUGITA*1 and Ju KUMANOTANI

The Engineering Research Institute, Faculty of Engineering, The University of Tokyo, Yayoi, Bunkyo-ku, Tokyo

(Received September 5, 1968)

The reaction of *p*-benzoquinone with amines has been employed conveniently as a method of preparing 2,5-diamino-*p*-benzoquinoid compounds;[1] however, the details of the reaction remain to be elucidated. For instance, it is found in our laboratory that the reactions generally yield considerable amounts of resinous matter, especially with aliphatic amines.

We will report that, in the reaction of *p*-benzoquinone with alcoholic *n*-butylamine, a new compound, 3-*n*-butylamino-7-hydroxy-9-*n*-butyl-carbazolquinone(1,4) (IV), is formed in appropriate quantity, together with 2,5-bis(*n*-butylamino)-*p*-benzoquinone. The following scheme may be proposed for the formation of the carbazolquinone. I is formed through two steps:[1] (a) the nucleophilic 1,4-addition of the amine to the quinone to give an amino-quinol, and (b) the oxidation of the quinol with *p*-benzoquinone. III is obtained from I *via* a route similar to that described for I: the formation of III through II is due to the reductive potential of the diaminoquinone nucleus being more negative than that of the monoaminoquinone nucleus.



The compound (IV) was separated fractionally by recrystallization, and its molecular weight and formula were determined by the VPO method and by elementary analysis respectively. The structure of IV was confirmed as follows. The polarographic potential, −0.48 V (*vs.* SCE), measured at 25°C in a mixed solvent (1 : 1 v/v) of isopropanol and a phosphate buffer (pH, 6.0), indicates that IV has a diamino-*p*-benzoquinone nucleus.[2] This is supported by the following UV and IR spectral data: $\lambda_{max}^{CHCl_3}$ 354 mμ (ε, 17000), attributable to the π–π* transition band of the quinone nucleus; 3370 (m. ν_{N-H}), 1650 (m. $\nu_{C=C}$), 1590 (s. $\nu_{C=O}$), and 1510 cm^{-1} (s. amido II type band).[2] The intensity of the ν_{N-H} band of IV was found IR spectroscopically to be equivalent to one N–H group per mole unlike that of 2,5-bis(*n*-butylamino)-*p*-benzoquinone. The NMR spectrum in pyridine showed signals at 8.9—9.4 (triplet, 6H, $-CH_2-C\underline{H}_3$), 8.0—9.0 (multiplet, 8H, $>N-CH_2-C\underline{H}_2-C\underline{H}_2-CH_3$), 6.6—7.1 (quartet, 2H, $-NH-C\underline{H}_2-$), and 5.1—5.5 τ (triplet, 2H, $>N-C\underline{H}_2-$); in dimethyl sulfoxide it showed signals at 4.82 (singlet, 1H, quinoid ring proton), 2.4—3.3 (multiplet, 4H, three aromatic and one N–H protons), and 0.55 τ (singlet, 1H, O–H proton). The hydroxy proton was assigned by the deuterium substitution method. Further clear evidence obtained from the NMR spectrum of the *O*-acetate of IV proved the presence of three aromatic protons in the ABC system.

Experimental

Materials. *p*-Benzoquinone (mp 115—116°C) was utilized by submitting a commercially-available chemical to sublimation. *n*-Butylamine, obtained commercially, was of a chemically pure grade and was used without further purification.

Separation by TLC and Instrumental Analyses.

2) J. Kumanotani, F. Kagawa, A. Hikosaka and K. Sugita, This Bulletin, **41**, 2118 (1968).

These proceedings were carried out in the same way as has already been described in a previous paper.[2)]

Purification and Identification of the Products. A solution of *p*-benzoquinone (25 g, 0.232M) in 250 m*l* of 98% ethanol was stirred into a solution of *n*-butylamine (9.73 g, 0.133M) in 50 m*l* of ethanol at room temperature for 25 min. Then the solution was refluxed for 1 hr and subsequently cooled to room temperature for 1 hr under stirring. The red crystals thus precipitated were filtered off, washed with a small amount of ethanol, and dried *in vacuo*; they amounted to 5.1 g (27% of the theoretical yield). Recrystallization from dioxane gave red rod crystals, mp 163.5—164.5°C (Found: N, 11.19%). This compound was identified with an authentic sample of 2,5-bis(*n*-butylamino)-*p*-benzoquinone prepared in our laboratory.[2)] When the mother liquor was evaporated to dryness at 30°C under reduced pressure, a black material was given as a residue. The light brown substance (10.7 g) obtained as an insoluble part after the black material had been washed several times with 100 m*l* of chloroform was recrystallized from water and submitted to sublimation to give white needles, mp 169.5—170.8°C. The needles were identified by comparing their IR spectrum and they showed no depression in a mixed-melting-point determination with an authentic sample of hydroquinone The solid material obtained by the removal of the chloroform from the solution under reduced pressure with an aspirator was dissolved in 60 m*l* of methanol and refrigerated for 12 hr. The crystals that precipitated were filtered off and dried *in vacuo* to yield 3.4 g (8.6%). Recrystallization from methanol and then from chloroform gave yellowish brown powders; mp 184.9—185.7°C (corr).

Found: C, 70.31; H, 7.20; N, 7.97%; mol wt, 345. Calcd for $C_{20}H_{24}O_3N_2$: C, 70.56; H, 7.11; N, 8.23%; mol wt, 340.

Derivation of the O-Acetyl Carbazolquinone. The carbazolquinone (300 mg) was dissolved in 30 m*l* of acetic anhydride, and then the solution was refluxed for 4 hr. The resulting solution was cooled and treated twice with 10 times as much as warm water (at *ca.* 50°C) to give precipitates. The crude acetate obtained by extraction with ether was dissolved in a small amount of chloroform, applied in lines on the silica-gel layers (thickness, 0 5 mm), anddeveloped with chloroform. A broad and dark brown zone at R_f 0.15—0.25 was scraped off and eluted with 30 m*l* of chloroform The elute was evaporated to dryness at room temperature under reduced pressure with an aspirator to give dark brown powders (145 mg). The powders were recrystallized from methanol; mp 147.5—149.0°C. Found: N, 7.11%; mol wt, 389. Calcd for $C_{22}H_{26}O_4N_2$: N, 7.34%; mol wt, 382. The saponification value was found to be 148.9 (*theor.* 147.4) by titrating the residual alkaline after refluxing a solution of the acetate (40 mg) dissolved in 20 m*l* of 0.05N aqueous sodium carbonate methanol (2 : 3 v/v) for 1 hr. The spectral data, *i.e.*, $\nu_{C=O}$ at 1760 cm^{-1} and the signal at 7.70 τ (3H, $-CO-C\underline{H}_3$), are in agreement with thoes of the acetate. In comparison with the NMR spectra between the acetate and its parent quinone, the three aromatic proton signals of the ABC-system are clearly seen in the range between 2 τ and 4 τ, and the proton signal of N-H is at 3.9 τ.

Synthesis and Spectrophotometric Observations of Ethyl *p*-(Acetylsalicylylamino)-benzoate*1

Yukinao NODA

Division of Chemistry, Osaka City University Medical Shool, Osaka

(Received September 10, 1968)

Ethyl *p*-(acetylsalicylylamino)-benzoate (AB) has been synthesized in a water medium.[1] This paper will describe a new simple method of synthesizing AB and will present its ultraviolet, infrared, fluorometric, and phosphorometric spectra.

Acetylsalicylic acid (1 g) and ethyl *p*-aminobenzoate (1 g) were dissolved in 40 m*l* of ethyl acetate, and then dicyclohexylcarbodiimide (1 g) in 5 m*l* of ethyl acetate was gradually stirred into the mixed solution at room temperature. As the reaction proceed, dicyclohexylurea was obtained as the precipitate. The reaction mixture was then allowed to stand at room temperature for 16 hr. The precipitated dicyclohexylurea was filtered off, and the filtrate was evaporated to dryness *in vacuo* below 40°C. The oily residue was dissolved in 5 m*l* of methanol, and 5 m*l* of ether and 100 m*l* of petroleum ether were added to the solution. Crystals were obtained after the solution had been kept in a refrigerator. This crystalline material was recrystallized from methanol, ether, and then petroleum ether; fine needles were thus obtained. The yield was 900 mg. Melting point: 140°C (uncorrected, this is identical with that in Reference 1).

Found: C, 66.03; H, 5.40; N, 4.45%. Calcd

*1 This is an anaesthetica.

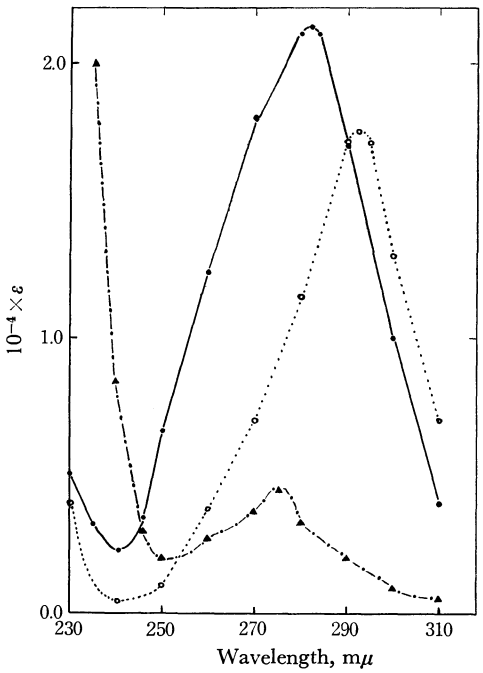

Fig. 1a. Ultraviolet spectra of AB, ethyl *p*-aminobenzoate and acetylsalicylic acid.
●——● AB
○·····○ Ethyl *p*-aminobenzoate
▲—·—·▲ Acetylsalicylic acid
Each concentration in methanol was 5×10^{-5}M.

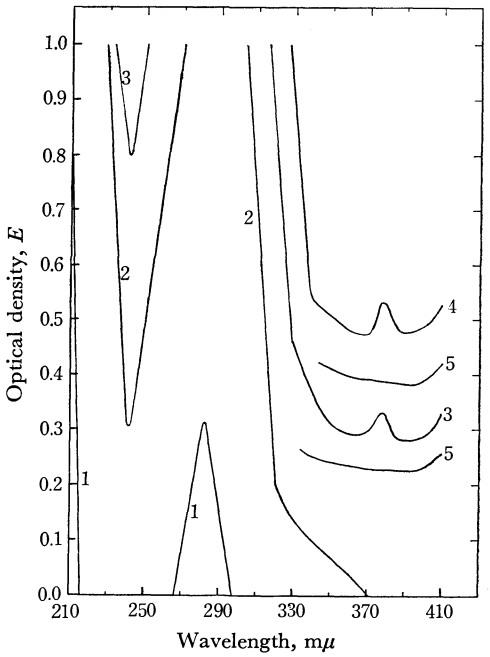

Fig. 1b. Ultraviolet spectrum of AB.
The concentration of AB in methanol was 5×10^{-5}M.
Curves 1, 2, 3 and 4 were determined at different sensitivities of spectrophotometer.
Curve 5 is methanol.

for $C_{18}H_{17}O_5N$: C, 66.06; H, 5.20; N, 4.28%.

One mg of AB is soluble in 5 m*l* of water at 100°C and in methanol, ethanol, and ether, and insoluble in petroleum ether. The ferric chloride reaction[2] was negative with this compound.

The ultraviolet spectrum of AB was determined in methanol using Beckman DU and Shimadzu MPS-50L spectrophotometers; the results are shown in Figs. 1a and 1b.

From the results, the λ_{max} of AB was located at 282.5 mμ (ε, 21400) and the λ_{min} at 241 mμ in methanol. AB may exist in the two forms of keto and enol isomers, shown below;

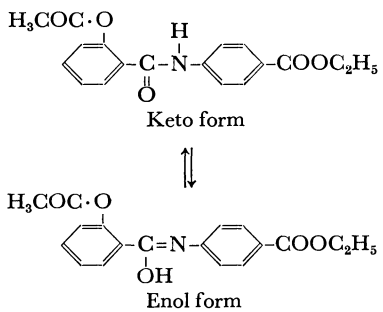

Figure 1b shows the presence of a band at 377.5 mμ, and the infrared spectrum of AB, as measured with a Hitachi infrared spectrophotometer, EPI-G type, showed characteristic absorption bands at 3320 cm^{-1} and 3070 cm^{-1} attributable to the *trans* form of the amide group,[3] as is shown in Fig. 2.

Consequently, it is probable that the steric structure of AB is mainly the keto form. If the band at 377.5 mμ is the enol form as shown in Fig. 1b, it is in a negligibly low concentration.

When AB was excited at 280 mμ or at 300 mμ

The Effect of Impurities on the Whiteness of Lanthanum Oxide

Kazuhide MIYAZAKI

Central Research Laboratories, Mitsui Mining and Smelting Co., Mitaka-shi, Tokyo

(Received September 18, 1968)

The present paper will investigate how the whiteness of lanthanum oxide is affected by the presence of minor amounts of three common impurities, praseodymium, neodymium and calcium; the influence is expressed in terms of the Munsell Value scale.

Lanthanum oxide, La_2O_3, is a white, amorphous powder which has increasingly been used in many fields of industries; for instance, using it the glass industry has produced a silica-free optical glass with a high refractive index. The purity of the commercially available material is usually 99.5% or more.

However, it has been accepted that, from an industrial point of view, one of the most important factors in evaluating a white powdery product on the market is its appearance of whiteness. The case of lanthanum oxide is no exception; a visual comparison is one of the usual practices in judging the quality or marketability of the white product.

The element has been separated from a rare earth mixture, itself derived from monazite sand and consisting of the rare earth elements from La through Lu, by basicity separations[1,2] or by fractional crystallization.[3] Praseodymium and neodymium are frequent contaminants in the lanthanum due to the fact that these two elements are the closest neighbors of the lanthanum in the La-Lu series and so are the most difficult to separate.

1) E. V. Klever and B. Love, "The Technology of Scandium, Yttrium and the Rare Earth Metals," Pergamon Press, London and New York (1963), p. 19.
2) C. A. Hampel, *Glass Ind.*, **41**, No. 1, 15 (1960).
3) F. H. Spedding and A. H. Daane, "The Rare Earths," John Wiley and Sons, New York and London (1961), p. 137.

While the oxides of La, Ce^{3+}, Tb, and Lu are colorless, the coloring is most distinct in the case of Pr_6O_{11} and Nd_2O_3; Pr_6O_{11} is black, and Nd_2O_3 is lavender blue.[4] Therefore, the presence of these two elements in the La_2O_3, even in small quantities, will appreciably degrade the whiteness of the product; such presence usually gives a grayish shade to the product, which would otherwise be pure white.

Still another impurity which commonly accompanies this element is calcium coming from the monazite sand and the processing water used in the manufacturing plant. Calcium is also close to lanthanum in many characteristics, such as its basicity, its separability with ion exchange resins, and the solubility product of oxalate. Although the removal of calcium from the lanthanum is of prime importance for the manufacturer, the influence of this element on the coloring of La_2O_3 has previously been frequently overlooked, for the calcium oxide is also white in itself.

This paper will present the results of a study whereby a color difference meter was used to characterize the interdependence of the influence of three common impurities, Pr, Nd, and Ca, on the coloring of highly pure lanthanum oxide in an attempt to provide a convenient criterion in terms of the value scale in the Munsell color system. The purpose here is to establish a practical measure for judging which one of these three elements is the major source of the coloring and to help to improve the quality of the La_2O_3 product in terms of its whiteness as well as of its chemical purity.

Experimental

Materials. Spectrographic-grade highly pure oxides of lanthanum, neodymium, and praseodymium were commercially available from the Lindsay Chemical Division, American Potash and Chemical Corp., and from Johnson, Matthey & Co. Lanthanum oxide was graded as 99.997% La_2O_3, while praseodymium oxide and neodymium oxide were 99.9% Pr_6O_{11} and 99.9% Nd_2O_3 respectively. As for the calcium component, reagent-grade calcium oxide was used. Spectrographic examinations showed no evidence of unnecessary elements in this material.

Procedures. The component oxides are weighed into a beaker, dissolved with dilute hydrochloric acid, and stirred. An oxalic acid solution was then added, and a mixed oxalate precipitate was obtained and ignited at about 1000°C to give several samples of lanthanum oxides contaminated, to several degrees, with small amounts of neodymium, praseodymium, and calcium oxides. Contaminations with Pr_6O_{11} to the extent of 0.15%, Nd_2O_3 0.35%, and CaO 1.0% of the lanthanum oxide produced a dark-colored sample which no longer bore a commercial value in its appearance. The degradation of the lanthanum oxide due to the artificially incorporated impurities was measured with a Color Difference Meter using the Munsell value scale, and the values *versus* the impurity contents were plotted. However, no appreciable differences in the Chroma and Hue scales were observed because the produced colors were solely gray or dark, well fitting into the value scale from about 6.5 to 9.5, the latter of which was the reading for the lanthanum oxide as received.

4) *E.g.*, Catalogue for Products of The Rare Earth Group, Johnson, Matthey & Co., London.

Results and Discussion

Figure 1 shows the value of the lanthanum oxide against the CaO content in the presence of Nd_2O_3 and/or Pr_6O_{11}. It may be observed from curve (1) that the presence of 0.5% Nd_2O_3 exhibits no appreciable effect on the appearance of La_2O_3, even with an increase in the CaO content up to 1.0%. Therefore, a rather low-purity lanthanum oixde (about 98.5% La_2O_3) can retain its white appearance, with a value of about 9.0, if the La_2O_3 contains no impurities other than Nd_2O_3 and CaO.

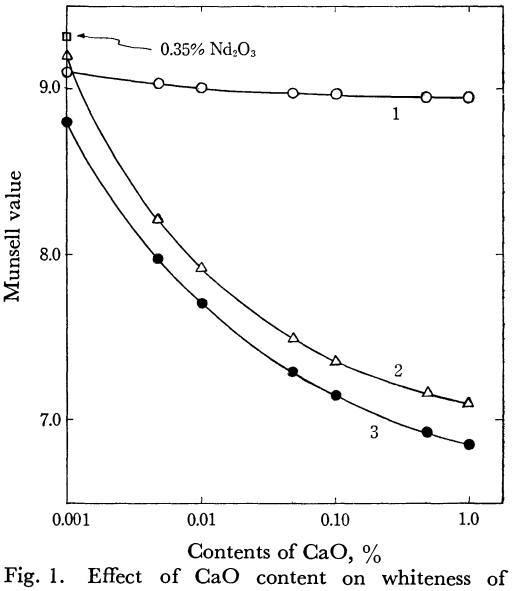

Fig. 1. Effect of CaO content on whiteness of La_2O_3 contaminated with Pr_6O_{11} and/or Nd_2O_3 expressed in terms of the Munsell Value scale.
(1): La_2O_3-0.5% Nd_2O_3 system, (2): La_2O_3-0.15% Pr_6O_{11} system, and (3): La_2O_3-0.15% Pr_6O_{11}-0.35% Nd_2O_3 system.

On the other hand, the situation is quite different in the case of Pr_6O_{11} as may be observed from curve (2). A contamination of La_2O_3 with only 0.15% Pr_6O_{11} and 0.01% CaO has much degraded the white appearance down to the value of 7.9, although the net La_2O_3 content is still higher (being 99.8% La_2O_3). It may also be seen from curve (2) that the presence of CaO to the extent of 1.0% together with the Pr_6O_{11}, gives the low value of 7.1, with which the product may no longer be marketable. It is to be noted from curves (1) and

(2), however, that the presence of 0.15% Pr_6O_{11} is less detrimental than that of 0.5% Nd_2O_3 if the CaO is not present at all or if only a trace is present.

From the initial position of curve (3) on the ordinate of Fig. 1 it may be seen that the combination of 0.15% Pr_6O_{11} and 0.35% Nd_2O_3 is more detrimental than 0.5% Nd_2O_3 alone. It can be naturally expected that the individual effect of 0.35% Nd_2O_3 will be less harmful than that of 0.5% Nd_2O_3, which gives a value reading of 9.3. 0.15% Pr_6O_{11} without calcium also does practically no harm, giving 9.2 However, the starting point of curve (3), positioned on the ordinate at a value less by about 0.3 than curves (1) and (2), indicates that the interaction of 0.35% Nd_2O_3 and 0.15% Pr_6O_{11} exists in spite of the fact that these elements individually behave much less harmfully. The additions of CaO to the La_2O_3-Pr_6O_{11}-Nd_2O_3 system remarkably decrease the value of the whiteness, and the curve (3) parallels the curve (2) down to about 6.9 with 1% CaO.

Most commercial rare-earth salts contain individual elements in about the same ratio as the ore treated.[5] After cerium has been removed by oxidation and hydrolysis, therefore, praseodymium and neodymium are the major impurities of lanthanum remaining until the last stages of the purification process, because these two elements are close to lanthanum in chemical and physical characteristics except in color. Moreover, they are present in the raw materials in amounts next to that of lanthanum. On the other hand, the rest of the impurities, from Sm through Sc, are relatively easier to separate because of their considerable difference in characteristics and their small amounts. Although it has been conventionally thought that the best way to obtain a pure white lanthanum oxide is simply to make the net La_2O_3 content as free as possible from these rare earth impurities, the results of Fig. 1 show that there is a possibility of a sample with 99.8% La_2O_3 (0.15% Pr_6O_{11}+ 0.01% CaO) being worse in color than one with 98.5% La_2O_3 (0.5% Nd_2O_3 + 1.0% CaO). It follows, accordingly, that emphasis should be placed on the removal of calcium in many cases in order to obtain a La_2O_3 product of high quality in both whiteness and chemical purity.

5) J. G Parker, "Mineral Facts and Problems, Rare Earths," Bull. 630, Bureau of Mines, 1965 ed., p. 753.

Summary

The detrimental effects of three common impurities, praseodymium, neodymium, and calcium, on the coloring of lanthanum oxide were investigated in terms of the Munsell value scale, using a color difference meter. The co-existence of praseodymium and calcium was most distinct in degrading the white color of lanthanum oxide, while neodymium was a minor coloring source even when combined with calcium. The effect of praseodymium present in a minor amount was not very pronounced without the simultaneous presence of calcium. The combination of praseodymium and neodymium did the most harm in the presence of calcium.

Triplet-Singlet Emission Spectrum of Acenaphthenequinone Vapour

S. Nath SINGH, M. G. JAYSWAL and R. S. SINGH

Department of Spectroscopy, Banaras Hindu University, Varanasi-5, India

(Received September 11, 1968)

The phosphorescence spectrum of acenaphthenequinone has been reported by Kuboyama and Yabe[1] at 77°K in various solvents and in the crystalline state. These authors have identified it as due to n–π^* (Triplet-Singlet) transition from the position of bands, solvent effect and life-time considerations. Recently, we have reported infrared and Raman spectra[2] of the molecule and the observed bands were assigned to different modes of vibrations. In the present work, the emission spectrum of the molecule in the vapour phase has been reported and discussed.

Experimental

The Eastman L. R. grade sample of acenaphthene-

1) A. Kuboyama and S. Yabe, This Bulletin, **40**, 2475 (1967).

2) S. Nath Singh and R. S. Singh, *Current Sci.*, **36**, 624 (1967).

quinone was sublimed before use and yellow needles were obtained. The emission was excited by using an uncondensed transformer discharge in the presence of flowing vapour of benzene, employing the conventional π-type of discharge tube. The yellowish emission glow was photographed by Fuess glass spectrograph with 60 μ slit width in 10 hr using Kodak I-F plates. Two different plates were measured on Hilger L-76 comparator and the average values of the measurements have been reported.

Results and Discussion

The emission spectrum of acenaphthenequinone lies in the region 5700—6900 Å and consists of thirteen diffuse but intense bands (Fig. 1). The intensity distribution of bands is unusual similar to those observed in various *p*-quinones[3] where the bands in the middle of the spectrum are more intense compared to those on the either sides. The wave numbers, visually estimated intensities and analysis of bands are given in Table 1.

The moderately strong band at 17552 cm^{-1} has been taken as the (0,0) band of the system. From the gross structure of bands, it is evident that the

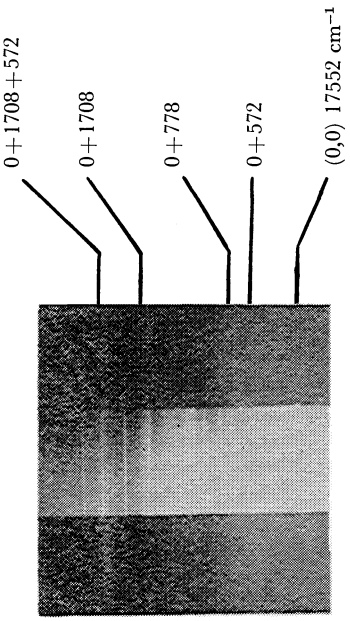

Fig. 1. Emission Spectrum of Acenaphthenequinone.

system is due to an allowed transition, as most of the totally symmetric fundamental frequencies are found to be superposed on this (0,0) band. Assuming C_{2v} symmetry for the molecule both in the ground as well as in the excited state, the spectrum has been analysed in terms of three totally symmetric vibrations: 572 (ring deformation), 778 (ring breathing) and 1708 cm^{-1} (C=O stretching) for which the corresponding Raman frequencies[2] have been reported at 575, 790 and 1723 cm^{-1}. The weak band at 17271 cm^{-1}, which is 281 cm^{-1} apart from the (0,0) band, may in all probability be due to excitation of a nontotally symmetric skeletal deformation type of vibration, the corresponding Raman value of which is 276 cm^{-1}. It is found that the ring breathing and C=O stretching mode of vibrations are predominent in the spectrum and most of the bands may be explained in terms of these two frequencies. The magnitude 1708 cm^{-1} for C=O stretching mode of vibration which has a higher value as compared to *p*-quinones[4] shows aliphatic character of the substituent group and molecule has been characterised not as a "true quinone.[5]"

Table 1. Emission bands of acenaphthenequinone

Wave number (cm^{-1})	Intensity	Difference from (0,0) band	Assignment
17552	(5)	0	(0,0)
17271	(1)	281	0+281
16980	(6)	572	0+572
16774	(6)	778	0+778
16493	(2)	1059	0+778+281
16194	(4)	1358	0+778+572
16009	(4)	1543	0+2×778
15844	(10)	1708	0+1708
15574	(5)	1978	0+1708+281
15264	(10)	2288	0+1708+572
15082	(2)	2470	0+1708+778
14793	(1)	2759	0+1708+778+281
14481	(1)	3071	0+1708+778+572

In the phosphorescence study[1] an intense band has been reported at 5990 Å (16690 cm^{-1}) in the crystalline state at 77°K and may be the electronic origin of the system. The (0,0) band identified at 5696 Å (17552 cm^{-1}) in the present vapour emission spectrum is at a higher energy value by 862 cm^{-1} as compared to the electronic origin in the phosphorescence spectrum in the crystalline state. This value is in conformity with the common observation that the electronic origin of the same system lies at a higher energy in the vapour phase as compared to the crystalline state. The two spectra seem to correspond to each other and the present vapour emission may be assigned as due

to n–π^* (Triplet-Singlet) electronic transition. The life-time of the phosphorescence emission at low temperature[1] has been reported of the order of 10^{-2} sec which is a favourable value for observing a triplet-singlet emission even in the vapour state and such type of observation has been made in several *p*-quinones.[3] Moreover, the presence of benzene vapours seems to be quite important which possibly transfer its energy to excite the quinone molecule.[6]

The authors are thankful to Professor N. L. Singh for his keen interest in the work. One of them S. N. S. is grateful to N. B. S. (PL-480), U. S. A. for financial assistance.

Nuclear Quadrupole Resonance of α-Dimethyltellurium Dichloride

Seiichi KONDO, Emiko KAKIUCHI and Tsuyoshi SHIMIZU

Laboratory of Physical Chemistry, Osaka University of Education, Tennoji-ku, Osaka

(Received October 7, 1968)

Chlorine nuclear quadrupole resonance has been reported on several tellurium compounds such as tellurium tetrachloride[1] and complex salts[2]. The ionicity of Te–Cl bonds in these compounds differs from each other considerably. It is of interest to compare the ionicity of these compounds with that of an organotellurium compound, α-dimethyltellurium dichloride. It is also interesting to study the Zeeman effect of the single crystal whose structure has been determined by X-ray analysis by Christofferson, Sparks and McCullough.[3]

Experimental

The material was synthesized by the method of Vernon[4] from metallic tellurium and methyl iodide as raw material and was recrystallized twice from ethanol solution. Mp 96.6°C (lit.[4] 92°C). Found: Cl 31.85%. Calcd for $C_2H_6TeCl_2$: Cl 31.57%. X-Ray powder diffraction lines of this sample by X-ray diffractometer were in good agreement with those of literature.[3]

A single crystal was grown from the melt by slow cooling in the vacuum-sealed cylindrical ampoule and used for the Zeeman measurement. Since this material decomposes gradually by heating, the crystal thus obtained was slightly colored and opaque. The *b*-axis of this monoclinic crystal was found by Laue photographs to lie about 30° from the axis of the ampoule.

Resonance signals were recorded with the usual self-quenching superregenerative oscillator detector.[5] The Zeeman field was generated by a Helmholtz coil with an intensity of about 20 gauss.

Results and Discussion

Two resonance absorptions were recorded with approximately the same signal to noise ratio, *S/N*, within the searching range of 40 to 12 MHz, as shown in Table 1.

TABLE 1. THE NQR FREQUENCIES OF α-DIMETHYLTELLURIUM DICHLORIDE AT VARIOUS TEMPERATURES

Temp. °K	Freq., MHz Cl_1	*S/N*	Freq., MHz Cl_2	*S/N*
77	18.124	4	15.685	2
205	18.028	4	15.463	2
298.3	17.855	4	15.323	3
340.0	17.752	4	15.268	3

Single crystal Zeeman effect study showed two different orientations for each of the two resonance lines. These two sets of orientations seem to arise from two molecules in the unit cell being related to each other by the operation of two-fold axial symmetry as seen from the crystal stucture. The valence angles of Cl–Te–Cl bonds of these molecules observed were 176±3° and are almost equal to 172±0.3° determined by crystal structure analysis.[3] The loci of angles of Zero-splitting, θ_0, were searched to find the assymmetry parame-

ter, but it was difficult to obtain a more accurate value of θ_0 than $55\pm1°$ owing to an experimental error. The Zeeman effect study has guided us to the assignment of two resonances to each of the two chlorine nuclei in the molecule as shown in Table 2.

Table 2. The NQR frequencies of Cl atoms, the covalency $(1-i)$ of Te–Cl bonds, the effective charge ρ of Te atoms and the bond lengths of several Te compounds

	Freq. MHz	$(1-i)$	ρ	Te–Cl Å
α-$(CH_3)_2TeCl_2$	18.124	0.44	1.18	2.48[c]
	15.685	0.38		2.54[c]
$TeCl_4$[a]	28.166	0.68	1.30	2.27
	27.382	0.40		2.40
$(NH_4)_2TeCl_6$[b]	15.137	0.32	2.08	2.54

a) Ref. 1. b) Ref. 2. c) Ref. 3.

This conclusion is also supported by the fact that each chlorine atom in the molecule has only one equivalent position in the unit cell and that the frequency difference of the two resonance lines is much larger than that usually expected from the effect of crystalline field.

Table 2 shows (1) the NQR frequencies of Cl atoms of several Te compounds, (2) the respective covalency $(1-i)$ of Te–Cl bonds in which i is the ionicity, using Townes and Dailey relation[6] with s-hybridization character assumed as 0.15, and (3) the effective charge ρ of Te atom and their bond lengths. The ionicity of Te–Cl bond of α-dimethyltellurium dichloride is larger than that of tellurium tetrachloride by the influence of methyl groups.

This research was partly supported by a grant from the Ministry of Education.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 2051—2054 (1969)

The Spectrophotometric Determination of Scandium with Chromal Blue G

Katsuya UESUGI

Laboratory of Chemistry, Himeji Institute of Technology, Himeji

(Received October 8, 1968)

For the spectrophotometric determination of scandium, various workers have proposed many organic reagents including alizarin red S,[1,2] oxine,[3] tiron,[4] morin,[5] naphthyl azoxine S,[6] arsenazo,[7] sulfonazo,[8] pontachrome azure blue B, [9] eriochrome cyanine R,[10] xylenol orange,[11] pontacyl violet 4BSN,[12] and chromazurol S.[13]

In this paper, a new method for the spectrophotometric determination of scandium using chromal blue G (sodium-2″-chloro-4″-nitro-4′-hydroxy-3,3′-dimethylfuchsone-5,5′-dicarboxylate, color index 43835), similar in structure to pontachrome azure blue B, eriochrome cyanine R, and chromazurol S, will be described. The method is based on the highly-sensitive colored reaction of chromal blue G with scandium in an acetate

buffer solution. It will be found that chromal blue G is a more sensitive reagent for scandium than eriochrome cyanine R[10] or chromazurol S,[13] and that the proposed method is comparable in sensitivity to the method using pontachrome azure blue B.[9]

Experimental

Reagents. *Standard Scandium Solution.* The standard solution of scandium was prepared by dissolving 153 mg of scandium oxide (Mitsuwa Chemicals) in 50 m*l* of concentrated hydrochloric acid and then by diluting the solution to 1 *l*. This solution contained 100 μg of scandium per m*l*. This stock solution was then diluted to the concentration required for each experiment.

Chromal Blue G Solution. The chromal blue G (Geigy Company, Inc., New York, U.S.A.) was purified by recrystallization from ethanol before use, and 0.1 g of it was dissolved in 100 m*l* of 95% ethanol. This solution was stable for at least a month.

Buffer Solution (*pH* 6.0). A buffer solution of pH 6.0 was prepared by mixing a 0.2 M acetic acid solution and a 0.2 M sodium acetate solution.

All other reagents were analytical grade in quality and were used without further purification.

Apparatus. Absorbance measurements were made with a Hitachi spectrophotometer, model 139, using 1.00-cm matched quartz cells. The pH measurements were carried out with a Hitachi-Horiba glass electrode pH meter, model M-4.

The Standard Procedure for the Determination of Scandium. Transfer the sample solution containing 3—30 μg of scandium to a 25 m*l* volumetric flask and add 2 m*l* of the 0.1% chromal blue G solution. Then add 10 m*l* of the buffer solution (pH 6.0), shake well, and make up to the mark with distilled water. After 20 min, measure the absorbance at 590 mμ, using a reagent blank solution treated in a similar manner as a reference.

Results and Discussion

Absorption Curves. The absorption curves of the reagent solution at various pH values are shown in Fig. 1. The maximum absorption of the reagent solution are found at 480 mμ below pH 4.0, at 430 mμ over the pH range from 5.5 to 10.0, and at 590 mμ above pH 10.5. The absorption curves of the scandium complex at different pH are shown in Fig. 2. The curves in Fig. 2 were obtained by measuring the absorbance of colored solutions containing 0.6 ppm of scandium against a reagent blank containing the same amount of the reagent. The maximum absorption of the complex is found at 590 mμ in acidic media, above pH 7.0, the position of the maximum absorption shifts toward a longer wavelength.

Effect of the pH on Color Development. The effect of the pH on the color development of the scandium complex was examined by measuring the absorbance of a colored solution at 590 mμ. The results are shown in Fig. 3, from which it can be seen that the maximum intensity can be obtained in the pH range from 5.8 to 6.5. An acetic acid-acetate buffer solution, pH 6.0, was found to be satisfactory for this purpose.

Rate of the Color Development. The color of the scandium complex gradually develops at room temperature; the full color is obtained 15 minutes after preparation and then remains almost constant for at least an hour.

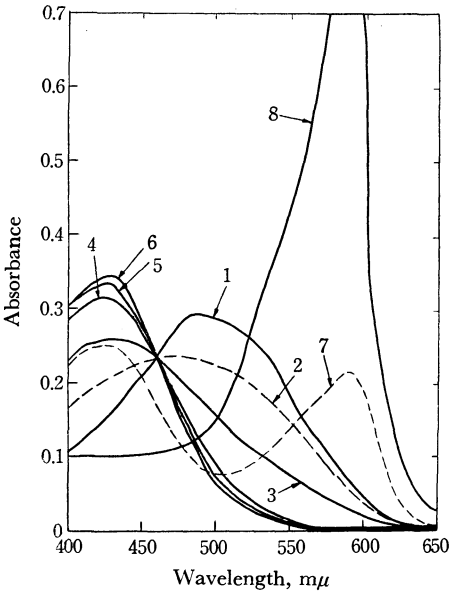

Fig. 1. Absorption spectra of reagent at various pH.
Reagent 20 ppm
pH 1: 4.0, 2: 4.5, 3: 5.0, 4: 5.5, 5: 6.0—6.5, 6: 7.5, 7: 11.5, 8: 12.5

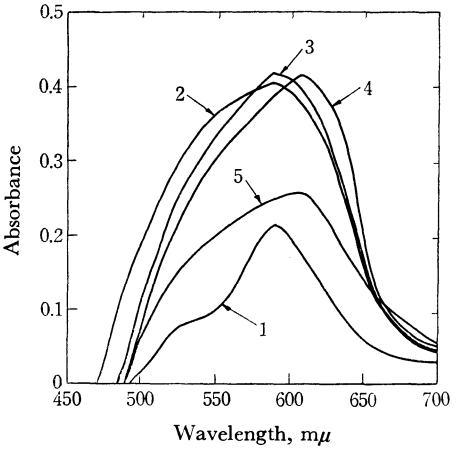

Fig. 2. Absorption spectra of scandium complex at various pH.
Sc 0.6 ppm, Reagent 80 ppm
Reference: Reagent blank
pH 1: 4.0, 2: 5.5, 3: 6.0—6.5, 4 :7.0, 5: 8.0

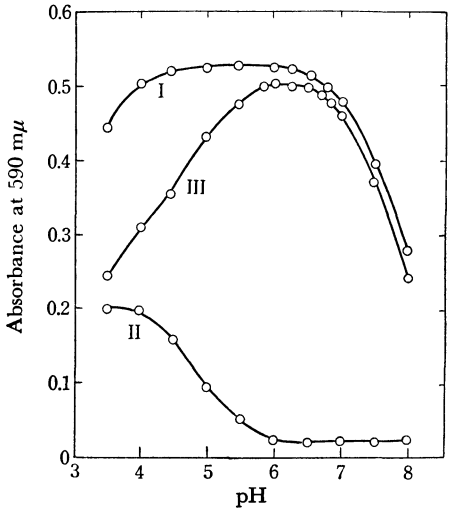

Fig. 3. Effect of pH on color intensity.
I: Reagent 80 ppm+Sc 0.72 ppm (Reference: water)
II: Reagent 80 ppm (Reference : water)
III: Reagent 80 ppm+Sc 0.72 ppm (Reference: Reagent blank)

Effect of Amount of the Reagent on Color Intensity. The effect of variable amounts of the reagent on the color development was examined for a definite concentration of scandium. The absorbance of the scandium complex at 590 mμ gradually increases at higher reagent concentrations. Therefore, it is necessary to keep constant the amount of the reagent added. Two milliliters of a 0.1% solution of the reagent were found to be sufficient for less than 1.2 ppm of scandium.

Effect of Temperature on the Color Development. There was no variation in the absorbance of the color system over the temperature range from 10 to 30°C.

Beer's Law. The scandium complex is found, using the standard procedure, to follow Beer's law up to 1.2 ppm of scandium. The molar extinction coefficient is 3.14×10^4 at 590 mμ. The spectrophotometric sensitivity of the reaction is 1.4×10^{-3} μg Sc/cm², corresponding to $\log I_0/I = 0.001$.

Effect of Diverse Ions. The effect of 28 cations and some anions on the determination of scandium were examined. Copper(II), cobalt(II), beryllium, iron(III), chromium(III), yttrium, and rare earth elements interfere. These cations give a positive error in the determination of scandium, as these also form colored complexes with the reagent in a slightly acidic medium. Chloride, nitrate, sulfate, and acetate do not interfere, even at a high concentration.

Complex Formation. The method of continuous variations was applied for the determination of the component of the proposed scandium complex with chromal blue G. The results are

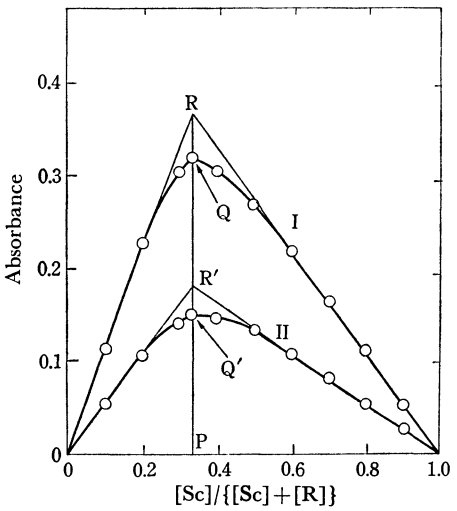

Fig. 4. Continuous variation method.
pH 6.0, 25°C
I: $[Sc]+[R]=7.0\times10^{-5}$M
II: $[Sc]+[R]=3.5\times10^{-5}$M

shown in Fig. 4, which indicates that a 1-to-2 complex is formed between scandium and chromal blue G. These results were confirmed by the mole-ratio method.

The formation constant was calculated from the curves obtained by the continuous-variation method. As the mole ratio of the scandium-chromal blue G complex is 1 : 2, the reaction can be expressed as:

$Sc + 2R \rightleftarrows ScR_2$			
0	0	C	initial concentration
αC	$2\alpha C$	$C(1-\alpha)$	equilibrium concentration

where C is the total concentration of the complex in moles per liter assuming no dissociation and where α is the degree of dissociation. The formation constant, K, was estimated from the curves shown in Fig. 4 on the basis of the following relationships:[14]

$$K = C(1-\alpha)/(\alpha C)(2\alpha C)^2$$

$$\alpha = (E_m - E_s)/E_m$$

where E_m is the maximum extinction of the complex when all the scandium is present in the form of the complex, and where E_s is the actual absorbance of the complex. The value of E_m and E_s correspond to PR or PR′ and PQ or PQ′ respectively. The formation constant at pH 6.0 and 25°C was estimated to be 2.8×10^{10}.

The proposed method using chromal blue G has several advantages as a reagent for scandium: the maximum absorbance can be obtained rapidly; no extraction of the complex is required, since the scandium complex is water-soluble; it is also comparable with the method using pontachrome

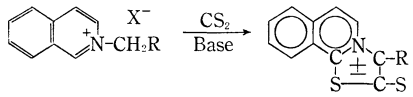
The Reaction of *N*-Acylmethylisoquinolinium Betain with Heterocumulens*1

Shigeru SATO and Masaki OHTA

Laboratory of Organic Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received October 9, 1968)

Among the various methods of formation of mesoionic compounds, the 1,3-dipolar cycloaddition method has been widely investigated by Huisgen *et al.*[1,2] In an earlier paper,[3] we reported the preparation of mesoionic triazolone by means of the 1,3-dipolar addition between 3-phenylsydnone and phenyl isocyanate. Kroehnke and his coworkers prepared the mesoionic thiazolo[2,3-*a*]isoquinolinium ring system by treatment of *N*-arylmethyl- and *N*-acylmethylisoquinolinium salts with carbon disulfide and alkali, in which 1,3-dipolar cycloaddition followed by dehydrogenation occurred as shown below.[4,5]

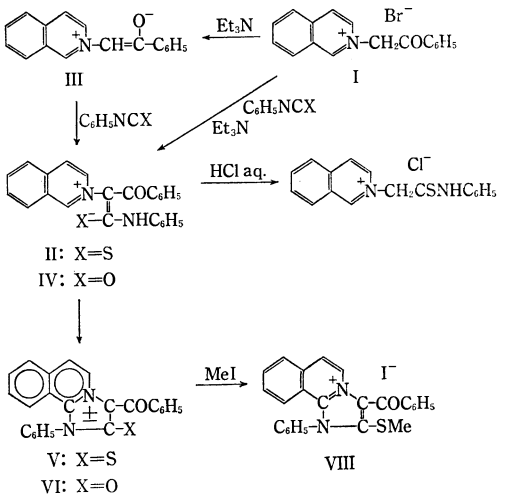


In this paper we wish to report the results of reactions of pyridinium and isoquinolinium betain with heterocumulens.

When triethylamine was added into the solution of *N*-phenacylisoquinolinium bromide (I) and an equimolar amount of phenyl isothiocyanate in dimethylformamide, the yellow precipitates were separated out immediately. The structure of this compound was assinged to be 2-(α-phenylthiocarbamoylphenacyl)isoquinolinium enol betain (II) based on the elementary and spectral analyses. II was obtained directly by the treatment of *N*-phenacyl-isoquinolinium enol betain (III) with phenyl isothiocyanate in quantitative yield. Similarly 2-(α-phenylcarbamoylphenacyl)isoquinolinium enol betain (IV) was obtained by the treatment of III with phenyl isocyanate. However, dicyclohexylcarbodiimide did not react with III.

The hydrolysis of II with hydrochloric acid gave 2-(phenylthiocarbamoyl) isoquinolinium chloride, while II was stable towards the hydrolysis with sodium hydroxide.

The oxidative ring closure of II by air did not occur by passing of air into the solution of II in ethanol for a day. However, II underwent cyclization and dehydrogenation on being heated in toluene for two hours to give anhydro-2-mercapto-3-benzoyl-imidazolo[2,3-*a*]isoquinolinium hydroxide (V) in 40% yield. Furthermore V was obtained by the oxidation of II with potassium ferricyanide



*1 This paper was presented at the 20th Annual Meeting of the Chemical Society of Japan, Tokyo, April, 1967.

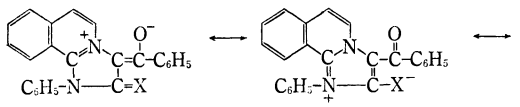
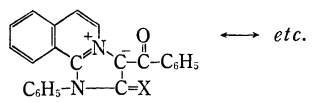
in 50% yield. A similar treatment of IV with potassium ferricyanide gave anhydro-2-hydroxy-3-benzoyl-imidazolo[2,3-*a*]isoquinolinium hydroxide (VI).

The significant differences of the IR spectra between V and VI were as follows: V has strong absorptions at 1550 cm^{-1} and 1350 cm^{-1}. VI has strong absorptions at 1650 cm^{-1} and 1550 cm^{-1}, but no absorption at 1350 cm^{-1}. These absorptions are attributed as follows: the absorption at 1650 cm^{-1} is due to the ring-carbonyl group, 1350 cm^{-1} to the ring-thiocarbonyl group and 1550 cm^{-1} to the carbonyl group of the benzoyl group. These facts suggest that the carbonyl group of the benzoyl group is fairly polarized, and among the many canonical forms such as VIIa—c which are considered to contribute to the resonance of V and VI, VIIa may be the most important contributor.



VIIa VIIb

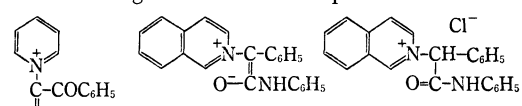


VIIc

V and VI did not melt at 300°C and did not undergo hydrolysis with hydrochloric acid or sodium hydroxide. V was converted to *S*-methyl derivative (VIII) by treatment with methyl iodide in an almost quantitative yield.

An unidentified resinous oil was obtained by oxidation of 2-(α-phenylcarbamoylphenacyl)- and 2-(α-phenylthiocarbamoylphenacyl)pyridinium enol betain[6] (IX) with potassium ferricyanide in boiling DMF. It may be produced by the decomposition of the corresponding mesoionic compounds or the starting material under oxidative reaction conditions.

In order to obtain 2-(α-phenylcarbamoylmethyl)-isoquinolinium enol betain (X), 2-benzylisoquinolinium chloride was reacted with phenyl isocyanate in the presence of triethylamine. However, the trimer of phenyl isocyanate was obtained instead of X. The hydrochloride (XI) of X was obtained by the treatment of isoquinoline and phenylchloroacetanilide. However, the treatment of XI with triethylamine gave the tarry substances from which nothing was obtained in pure state.



XI X XI

6) These compounds were prepared by Kroehnke's method: F. Kroehnke and H. Koebler, *Ber.*, **70**, 538 (1937).

When the benzylpyridinium chloride was reacted with phenyl isothiocyanate or phenyl isocyanate, *N*,*N'*-diphenylthiourea and carbanilide were obtained respectively.

Experimental[7]

Preparation of 2-(α-Phenylthiocarbamoylphenacyl)isoquinolinium Enol Betain (II). (A) Into a solution of 3.1 g of I and 1.3 g of phenyl isothiocyanate in 10 m*l* of water and 50 m*l* of dimethylformamide (DMF), 1.5 g of triethylamine was added dropwise with stirring. Immediately orange precipitates were separated out. After stirring for half an hour, 50 m*l* of water was added and the precipitates were collected by filtration and recrystallized from ethanol to give 3.5 g of II, yellow needles; mp 175—177°C. Found: C, 75.57; H, 4.34; N, 7.37%. Cacld for $C_{24}H_{18}N_2SO$: C, 75.39; H, 4.71; N, 7.33%.

(B) 0.3 g of phenyl isothiocyanate was added into a suspension of 0.5 g of III in 50 m*l* of DMF, which was stirred for half an hour. After removal of the solvent under reduced pressure, oily residue was crystallized by adding ether. After collecting by filtration, the precipitates were recrystallized from ethanol to give 0.65 g of II; mp 175—176°C.

The Hydrolysis of II with Hydrochloric Acid. A solution of 1 g of II in 80 m*l* of ethanol and 4 m*l* of concentrated hydrochloric acid was refluxed for 2 hr. After removal of the solvent under reduced pressure, the residual precipitates were recrystallized from ethanol to give 0.5 g of 2-(α-phenylthiocarbamoylmethyl)isoquinolinium chloride, pale yellow prisms; mp 230—232°C. Found: C, 64.73; H, 4.52; N, 8.82%. Calcd for $C_{17}H_{15}N_2SCl$: C, 64.86; H, 4.78; N, 8.96%.

Preparation of 2-(α-Phenylcarbamoylphenacyl)-isoquinolinium Enol Betain (IV). Into a suspension of 3.3 g of I and phenyl isocyanate in 50 m*l* of dry DMF, 2.5 g of triethylamine was added dropwise with stirring. After stirring for 5 hr, the solvent was removed under reduced pressure. The residual precipitate were collected and recrystallized from ethanol to give 4 g of IV; yellow needles, mp 190—192°C. Found: C, 78.28; H, 5.33; N, 7.66%. Calcd for $C_{24}H_{18}N_2O_2$: C, 78.67; H, 4.95; N, 7.65%.

The Oxidative Ring-closure of II and IV. (A) A suspension of 1 g of II and 1 g of potassium ferricyanide in 50 m*l* of DMF and 50 m*l* of water was refluxed for half an hour. After cooling, a large amount of water was added and separated precipitates were collected by filtration. Recrystallization from dimethyl sulfoxide (DMSO) gave 0.5 g of V, pale yellow needles; mp over 300°C. V was insoluble in ethanol, benzene and ether, and soluble in hot DMSO. Found: C, 75.27; H, 4.45; N, 7.51%. Calcd for $C_{24}H_{16}N_2OS$: C, 75.79; H, 4.21; N, 7.38%.

The same treatment of IV with potassium ferricyanide as mentioned above gave VI, pale yellow needles. VI did not melt at 300°C. Found: C, 78.24; H, 4.41; N, 7.89%. Calcd for $C_{24}H_{16}N_2O_2$: C, 79.12; H, 4.39; N, 7.69%.

(B) A suspension of 1.2 g of II in 100 m*l* of toluene

7) All melting points were determined on a hot plate and were not corrected.

was refluxed for 2 hr. After removal of the solvent, the residual crystals were recrystallized from DMSO to give 0.3 g of V; mp over 300°C.

The Methyl Derivative of V (VIII). A suspension of 0.5 g of V in 30 m*l* of acetic acid and 0.5 m*l* of methyl iodide was refluxed for a few minutes. After cooling, ether was added into the solution, and the separated precipitates were collected by filtration. The recrystallization from ethanol gave VIII. Yield was almost quantitative. VIII did not melt at 300°C. Found: N, 5.58%. Calcd for $C_{25}H_{19}IN_2OS$: N, 5.47%.

Preparation of 2-(α-Phenylcarbamoylbenzyl)-isoquinolinium Chloride (XI). A mixture of 0.6 g of isoquinoline and 1.2 g of phenylchloroacetanilide was heated at 120—125°C in an oil bath for 5 min. After cooling, the oily reaction mixture was crystallized by the addition of acetone, and was collected by filtration. The recrystallization from ethanol gave 1.4 g of XI, colorless silky needles; mp 245°C. Found: C, 73.33; H, 5.34; N, 7.53%. Calcd for $C_{23}H_{19}ClN_2O$: C, 73.80; H, 5.08; N, 7.49%.

Reaction of *N*-Benzylisoquinolinium Chloride with Phenyl Isocyanate in the Presence of Triethylamine. Into a solution of 5.2 g of *N*-benzylisoquinolinium chloride and 1.5 g of phenyl isocyanate in 100 m*l* of dry DMF, 2.5 m*l* of triethylamine was added dropwise with stirring. The solution was stirred for 5 hr. After removal of the solvent under reduced pressure, 50 m*l* of water and 20 m*l* of alcohol were added into the oily residue, and the separated precipitates were collected by filtration. The recrystallization from ethanol gave 1.2 g of the trimer of phenyl isocyanate; mp 288—289°C.

Reaction of *N*-Benzylpyridinium Chloride with Phenyl Isothiocyanate. Into a solution of 3 g of *N*-benzylpyridinium chloride and 3.7 g of phenyl isothiocyanate in 50 m*l* of acetonitrile, 3.7 g of triethylamine was added dropwise with stirring. After stirring for one hour, the reaction mixture was evaporated to dryness under reduced pressure. Into the residual mixture of triethylamine hydrochloride and oily product, 50 m*l* of water added. The separated precipitates were collected by filtration and recrystallized from ethanol to give 2 g of pale yellow needles; mp 157—158°C. No depression of the melting point on admixture with *N,N'*-diphenylthiourea was observed.

Similarly, by the treatment of *N*-benzylpyridinium chloride with phenyl isocyanate, carbanilide was obtained.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 2056—2058 (1969)

Selenium Dioxide Oxidation of Styrene and Norbornene

Khan A. JAVAID, Noboru SONODA and Shigeru TSUTSUMI

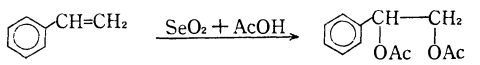
Department of Chemical Technology, Faculty of Engineering, Osaka University, Yamadakami, Suita, Osaka

(Received October 12, 1968)

Oxidation of olefins by selenium dioxide generally produces allylic derivatives resulting from the oxidation at α-methyl or α-methylenic carbon atom.[1-6] So it was interesting to study the behavior of the olefins like styrene and norbornene where such carbon atom is not present. Norbornene was selected also for studying the ionic nature of the reaction. Styrene reportedly did not react with selenium dioxide in a sealed tube.[7] Here we report the oxidation of these olefins using glacial acetic acid and some other solvents.

Results and Discussion

Oxidation of styrene with selenium dioxide in glacial acetic acid at 150—160°C in an autoclave produced styrene glycol diacetate in a good yield. The other products were phenylglyoxal and styrene glycol monoacetate.



The identification of the products was carried out by IR and glc analyses by comparison with authentic samples. No organoselenium compound could be characterized. An almost stoichiometric amount of metallic selenium was deposited under suitably controlled experimental conditions. Base-catalyzed hydrolysis of the products gave styrene glycol.

When dioxane was used as the solvent phenyl-

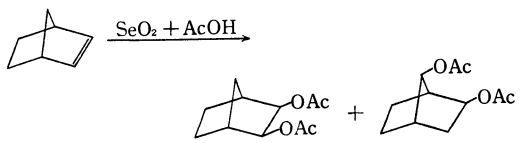
glyoxal was obtained in an 11% yield with a trace of benzaldehyde. To examine the possibility of styrene glycol formation, water was added to the dioxane, but styrene glycol could be obtained in trace only. Some other solvents like methyl alcohol, *t*-butyl alcohol and DMSO were also tried. The results are summarized in Table 2. Polymerization of styrene was observed in all cases except when the acetic acid was used as the solvent.

Oxidation of norbornene with selenium dioxide in glacial acetic acid under the similar conditions as employed for the oxidation of styrene produced 2,3-*exo-cis*-norbornane diacetate and 2,7-*exo-syn*-norbornane diacetate in the ratio of 2 to 1. Appreciable amounts of monoacetates could not be detected as the qualitative glc analysis remained almost the same after treatment of the reaction products with acetic anhydride. The base-catalyzed hydrolysis of the reaction products gave a mixture of 2,7-*exo-syn*-norbornane diol and 2,3-*exo-cis*-norbornanediol which showed a positive test for vicinal alcohols by periodic acid.

Our results are in good agreement with the mechanism postulated by Schaefer[3,4] which suggests the electrophilic attack of selenium dioxide itself or conjugate acid of selenium dioxide on the double bond of the olefin. Again, in the oxidation of norbornene the formation of rearranged product 2,7-*exo-syn*-norbornane diacetate apart from the 2,3-*exo-cis*-norbornane diacetate, indicates that oxidation is passing through a carbonium ion.

Strained olefins such as bicycloheptene or bicyclooctene usually add electrophiles with rearrangement,[8b] or with trans stereochemistry,[8a] but many reagents as mercuric acetate,[9] nitrosyl chloride[10] and hydrogen halides,[8b] *etc.* have been observed to add in cis fashion. In our experiments, both cis addition and rearrangement occurred with preference to cis addition.



The formation of cis product can be attributed to the torsional and windshield wiper effects.[9] From the experimental data it can be further noted that the yields are very low in the solvents other than

Table 1. Oxidation of styrene and norbornene with selenium dioxide in glacial acetic acid

acetic acid. This catalytic effect of acetic acid has been well explained by Olson.[11]

Experimental

Oxidation of Styrene in Acetic Acid. In a 30 m*l* of glacial acetic acid 5 g of anhydrous selenium dioxide was dissolved and 5 g of freshly distilled styrene was added. The solution was put in a 50-m*l* autoclave and volume made up to 40 m*l* with acetic acid. Heating was continued at 150—160°C for 10 hr. The temperature was raised to 180°C for the last two hours. The metallic selenium was filtered off. Acetic acid was removed by distillation under reduced pressure. The fraction boiling at 118—125°C/2mmHg was identified to be a mixture of phenylglyoxal[12] (3%) bp 95—97°C/25mmHg, styrene glycol monoacetate[13] (7%) and styrene glycol diacetate[14] (52%) bp 159.5°C/18mmHg by comparison of their glc and IR with authentic samples. Base-catalyzed hydrolysis gave white needles after recrystallization from *n*-hexane. Its IR and mixture melting point were in complete agreement with that of authentic styrene glycol.[15]

Oxidation of Styrene in Different Solvents. The same procedure as mentioned above was repeated using dioxane, dioxane - water, dioxane - water - sulfuric acid, dioxane - methyl alcohol and *t*-butyl alcohol respectively. The experimental conditions are given in Table 2. Qualitative and quantitative analyses of the products were carried out by IR and glc.

Oxidation of Notbornene in Acetic Acid. Five grams of selenium dioxide was dissolved in 30 m*l* of acetic acid and 5 g of norbornene was added. The reactants were heated for 10 hr at 140—150°C in the 50-m*l* autoclave. After filtering off the metallic selenium and removing the acetic acid by distillation under vacuum, the distillate boiling at 70—99°C/2mmHg was collected. Product identification was carried mainly by glc techniques. S. E. 30 column was found suitable for separating the isomers of norbornane diacetate. 2,3-*exo-cis*-Norbornane diacetate (25%) and 2,7-*exo-syn*-norbornane diacetate (15%)[16] were found as main products by comparison with authentic samples. Authentic 2,3-*exo-cis*-norbornane diacetate was prepared by esterification of 2,3-*exo-cis*-norbornanediol.[17] Four grams of 2,3-diol was treated with 40 m*l* of acetic anhydride in 100 m*l* of pyridine for 4 hr under reflux.

Base-Catalyzed Hydrolysis of the Products. To 1 g of reaction products were added 50 m*l* of methyl alcohol, 5 g of sodium hydroxide and 5 m*l* of water. The mixture was refluxed for 4 hr. After filtration and adjusting the pH to 6, methyl alcohol was distilled off and the remaining liquid was extracted with hot *t*-butyl alcohol, dark sticky crystals were obtained which were dissolved in a small amount of ethyl alcohol and the solution was put in the sublimation tube. Ethyl alcohol was evaporated at 100°C and then sublimation was carried out at 120—130°C/20mmHg. White crystals melting near 165°C were obtained. The IR was analogous to a mixture of 2,3-*exo-cis*-norbornane diol and 2,7-*exo-syn*-norbornanediol and their presence was confirmed by glc analysis. The crystals also gave a positive periodic acid test for vicinal alcohols due to the presence of 2,3-exo-*cis*-norbornanediol.

On the Erlenmeyer Reaction. II. Mechanism of DL-*threo*-*N*-Benzal-diphenylhydroxyethylamine Formation[1]

Kaoru HARADA

Institute of Molecular Evolution and Department of Chemistry, University of Miami Coral Gables, Florida 33134 U.S.A.

(Received October 11, 1968)

Erlenmeyer reported that glycine condensed easily with benzaldehyde in strongly alkaline aqueous ethanol.[2,3] The rapid condensation reaction at room temperature resulted in the formation of sodium salt of *threo*-*N*-benzalphenylserine.[4] The mechanism of the *threo*-phenylserine formation was explained in the earlier report[5] by a second order asymmetric transformation.

From the reaction mixture of the Erlenmeyer phenylserine formation, *N*-benzalisodiphenylhydroxyethylamine (*threo*-isomer) was isolated. The *threo*-diphenylhydroxyethylamine (*threo*-DHEA) was found to be the main product when three moles (instead of two moles) of benzaldehyde were used.[6] The presence of the more soluble *erythro*-*N*-benzal-DHEA isomer in the reaction mixture was identified.[6] It was found in the previous study[5] that the amount of DHEA in the Erlenmeyer reaction increased steadily with time. It was also found that with long reaction time, the final product was crystalline *threo*-*N*-benzal-DHEA. From these results, it may be inferred that *erythro*-DHEA is converted into the *threo*-DHEA during the reaction.

In order to elucidate the stereochemical course of Erlenmeyer's DHEA formation, several sets of synthetic and conversion reactions were carried out. These reactions are: 1) glycine, benzaldehyde and alkali; 2) DL-*threo*-phenylserine, benzaldehyde and alkali; 3) DL-*erythro*-phenylserine, benzaldehyde and alkali; 4) DL-*erythro*-DHEA, benzaldehyde and alkali; 5) L-(+)-*erythro*-DHEA, benzaldehyde and alkali; 6) D-(+)-*erythro*-*N*-benzal-DHEA and alkali. These reactions were carried out in alcoholic aqueous solution at room temperature in a manner similar to that of the Erlenmeyer reaction. It was found that final products of reactions 1)—6) were all DL-*threo*-*N*-benzal-DHEA. Melting points, elemental analyses, and infrared absorption spectra all agreed with the authentic DL-*threo*-*N*-benzal-DHEA. Results are

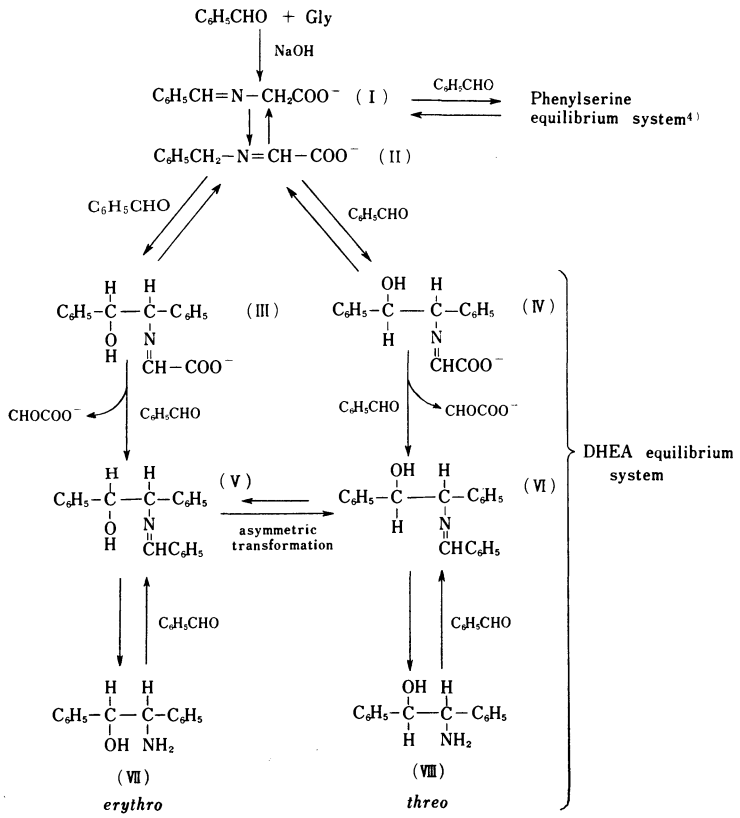

Fig. 1. Postulated mechanism of DL-*threo*-diphenylhydroxyethylamine formation in the Erlenmeyer reaction.

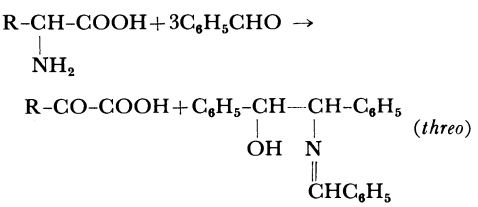
summarized in Table 1. These results suggest a possible mechanism for the formation of DL-*threo*-DHEA in the Erlenmeyer reaction. The postulated pathway of the reactions is shown in Fig. 1.

As described in the earlier study,[5] *N*-benzalglycine (I) was the starting material to form *threo*-phenylserine. The I could be tautomerized under strongly alkaline conditions into structure II, which was proven by isolation of benzylamine from a reaction mixture of the Erlenmeyer reaction.[6,7] The II reacts with benzaldehyde forming two racemic isomers, *erythro* (III) and *threo* (IV) isomers. These III and IV could be converted to *N*-benzal isomers V and VI in the presence of benzaldehyde. The solubility of V in the reaction mixture (alkaline aqueous ethanol) was found to be very large and it does not crystallize. However, the solubility of the corresponding diastereomeric isomer (VI) is small and it crystallized easily from the reaction solvent. Therefore, if there is an equilibrium between V and VI under the reaction conditions, the *erythro* isomer V could be converted into *threo* isomer VI by crystallization (second order asymmetric transformation). It has been reported that the reaction of benzaldehyde with phenylalanine, tyrosine, leucine, and aspartic acid resulted in the formation of corresponding α-keto acids and DL-*threo*-DHEA with no isolable phenylserine analogs.[6,8]

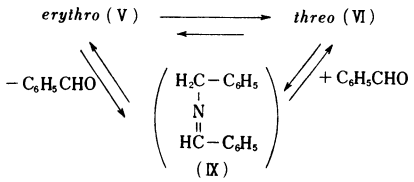


This finding also supports the inference that the DHEA formation is not dependent on the amino acid used but on the intermediate (II) which is tautomerized from the *N*-benzal-amino acid. Under conditions which were employed in this study, optically active *erythro*-DHEA was converted to racemic *threo*-DHEA. Solubility of the optically active *erythro*-*N*-benzal-DHEA was found to be much smaller than that of the racemic *N*-benzal-

7) Benzylamine was also isolated from the reaction mixture of glycine and benzaldehyde by heating at 130°C; T. Curtius and G. Lederer, *Ber.*, **19**, 2462 (1886).

8) E. Erlenmeyer, Jr., *Ann.*, **337**, 205 (1904); *Ber.*, **30**, 2896 (1897).

DHEA in the reaction solvent. Therefore, the reaction mixture was kept at 60—65°C for 10 min at the beginning of the reaction. This might be a reason for the racemization of both asymmetric carbons of optically active *erythro*-DHEA. However, another explanation of the racemization is possible, *i. e.*, a cleavage of α-β carbon linkage. Such a mechanism is conceivable since the α,β-linkage is rather weak.[9] However, at the present time it is difficult to decide whether the conversion pathway is a) direct (V→VI) or b) indirect (V→IX→VI).



The results obtained in this study and also in the previous study[5] show that there are two large equilibrium systems in the Erlenmeyer reaction (Fig. 1). The one is the phenylserine equilibrium system[5] and the other is the DHEA equilibrium system. These two systems are connected to each other at structure I in Fig. 1. In a short reaction time, the Erlenmeyer reaction resulted in the formation of crystalline sodium salt of DL-*threo*-phenylserine from glycine and benzaldehyde by the second order asymmetric transformation. However, in a prolonged reaction, *threo*-*N*-benzal-DHEA was crystallized out from the reaction mixture by the second order asymmetric transformation.

Experimental

Reaction (1): Formation of DL-*threo*-*N*-benzal-DHEA from Glycine. Glycine, 1.50 g (0.02 mol), was dissolved in a solution of 3.50 g of potassium hydroxide in 20 m*l* of water. The solution was mixed with a solution of 4.75 m*l* of benzaldehyde and 10 m*l* of ethanol under cooling. Nitrogen gas was introduced in the reaction flask and the mixture was shaken until it became clear. Crystallization of *N*-benzal-*threo*-phenylserine sodium salt began after 30 min. The mixture was kept at room temperature. After two days, the crystals of *threo*-phenylserine sodium salt decreased in amount. It seems that the conversion reaction of phenylserine to DHEA took place during this time. In order to complete the conversion reaction, the reaction mixture was kept at room temperature for two more weeks. After the reaction was over, the crystals were filtered and washed with a small amount of cold ethanol, yield 2.70 g, mp 132—133°C. This was recrystallized from 24 m*l* of ethanol, yield 2.33 g, mp 132—133°C. Nitrogen analysis, found: 4.57%. Infrared absorption spectrum: 3480, OH; 2700—3000 monosubstituted benzene; 1650, C=N; 1605, 1590, benzene CH; 754, 700, monosubstituted benzene. The infrared absorption spectrum was found to be identical with that of authentic DL-*threo*-*N*-benzal-DHEA.

Reactions (2) and (3) were carried out in the same way as Reaction (1). In both reactions, DL-*threo*-*N*-benzal-DHEA was isolated after 16 days of reaction.

Reaction (4): Conversion of DL-*erythro*-DHEA to DL-*threo*-DHEA. A mixture of DL-*erythro*-DHEA, 4.26 g (0.02 mol), and 3.20 m*l* of benzaldehyde in 35 m*l* of ethanol was mixed with a solution of 3.5 g of potassium hydroxide and 5.0 m*l* of water. Nitrogen gas was introduced in the reaction flask and the mixture was heated in a water bath at 65°C to dissolve the DHEA under shaking. After the reaction mixture became clear, the solution was cooled by water and was kept at room temperature for 16 days. Crystallization began after 3 hr. Crystals were separated by filtration and were washed with a small amount of cold ethanol. Yield, 2.58 g, mp 130—131°C. This was recrystallized once from ethanol, mp 132—133°C. Infrared absorption spectrum was found to be identical to the authentic DL-*threo*-*N*-benzal-DHEA. Nitrogen analysis, found: 4.84%.

Reaction (5): Conversion of L-(+)-*erythro*-DHEA to DL-*threo*-DHEA. D-(−)- and L-(+)-*erythro*-DHEA was resolved by the use of L- and D-glutamic acid.[10] D-(−)-*erythro*-DHEA, mp 142.5—143°C, $[\alpha]_D^{25}$ −6.0° in absolute ethanol; D-*erythro*-DHEA hydrochloride, mp 213—214°C, $[\alpha]_D^{25}$ −62.8° in H_2O; D-*erythro*-*N*-benzal-DHEA, mp 109°C, $[\alpha]_D^{25}$ +76.9° in absolute EtOH. L-(+)-*erythro*-DHEA, mp 142.5—143°C, $[\alpha]_D^{25}$ +6.3° in absolute ethanol; L-*erythro*-DHEA hydrochloride, mp 213—214°C, $[\alpha]_D^{25}$ +64.2° in H_2O; L-*erythro*-*N*-benzal-DHEA, mp 109°C, $[\alpha]_D^{25}$ −77.3° in absolute EtOH. Reaction (5) was carried out in the same way as reaction (4). Starting from 2.13 g of L-*erythro*-DHEA, 1.78 g of DL-*threo*-*N*-benzal-DHEA was obtained after 6 days of reaction, mp 130—132°C. After one recrystallization, the melting point rose to 131—132°C. No optical rotation was observed. Infrared absorption spectrum was identical to that of the authentic DL-*threo*-*N*-benzal-DHEA. Nitrogen analysis, found: 4.67%.

This work was supported by Grant NGR 10-007-052 of the National Aeronautics and Space Administration, U. S. A., to which the author expresses gratitude. The author wishes to express his thanks to Dr. Takeo Kaneko for his discussion and encouragement.

9) DL-*threo*-DHEA resulted in benzylamine by heating at 130°C.

10) J. Weiland, K. Pfister, III, E. F. Swanezy, C. A. Robinson and M. Tishler, *J. Am. Chem. Soc.*, **73**, 1217 (1951). The literature reported that the specific rotation of D- and L-*erythro*-DHEA were −10.1° and +10.2° respectively. Attempts to obtain D- and L-*erythro*-DHEA which have the specific rotations of −10.1° and +10.2° were unsuccessful. Recent literature [M. Nakazaki, This Bulletin, **36**, 1204 (1963)] reported that the specific rotation of D-(−)-*erythro*-DHEA was −6.4°. However, other physical properties were found to be the same as in the literature by Weiland *et al.*

Fluorination of Inorganic Sulfur Compounds*1

Shunji NAGASE, Takashi ABE and Hajime BABA

Government Industrial Research Institute, Nagoya, Kita-ku, Nagoya

(Received October 22, 1968)

Sulfuryl fluoride has been prepared by a number of methods, including the fluorination of sulfur dioxide,[1-7] sulfur trioxide,[8,9] sulfuryl chloride,[2-4,10,11] and sodium sulfate or sodium sulfite[12] by the use of various inorganic fluorinating agents. The thermal decompostion of barium fluorosulfonate has been known to yield sulfuryl fluoride.[13] The formation of sulfuryl fluoride has also been observed in the electrochemical fluorination of fluorosulfonic acid[14] and in that of several inorganic sulfur compounds.[15] In the electrolysis of a liquid mixture of sulfur dioxide and hydrogen fluoride at a low temperature,[16] and in that of inorganic sulfur compounds in fused potassium-dihydrofluoride,[15] sulfuryl fluoride was found among the products.

Sulfuryl fluoride is a useful commercial fluorochemical; it is, for example, a good insecticidal fumigant.[17] In the course of our studies of the electrochemical fluorination of gaseous compounds,[18] we have now found that sulfuryl fluoride can be readily produced in a good yield directly from gaseous sulfur dioxide. This electrochemical process involves the bubbling of the starting material into anhydrous liquid hydrogen fluoride. In the present paper, emphasis will be placed on the application of this recently-developed electrochemical method of the fluorination of gaseous compounds for the production of sulfuryl fluoride.

The electrochemical fluorination of related sulfur compounds, such as thionyl fluoride, thionyl chloride, sulfuryl chloride, sulfur mono-, and dichlorides, was also carried out in order to clarify their behavior in the fluorination.

Experimental

Materials. Sulfur dioxide (99.9%) was obtained from the Takachiho Chemical Industrial Co. Thionyl fluoride was prepared by the procedure given in the literature.[19] Thionyl chloride, sulfuryl chloride, sulfur mono-, and dichlorides were redistilled under atmospheric pressure or at reduced pressure before use. Anhydrous hydrogen fluoride (99%) was used after preliminary electrolysis.

Fluorination of Sulfur Dioxide. The apparatus and procedures for the fluorination have previously been described.[20] The electrolysis was carried out without using a conductivity additive. The exit gases from the sodium fluoride tube were regularly monitored by gas chromatography by taking the sample through a sampling valve placed immediately after the tube. Chromatographic analyses were carried out with a Shimadzu GC-2C model chromatograph, using a 0.3 cm i.d. × 6 m column packed with 60% (by wt) perfluoro-tri-*n*-butylamine*2 on 60/80 mesh Celite 545 SK.*3 (Column temperature: 0°C; carrier gas: helium).

The products formed (in the order of their peak appearance in the chromatogram) were as follows:

*3 Gaschro-Kogyo Co., Ltd.,

oxygen difluoride, a mixture of sulfuryl fluoride and sulfur hexafluoride,*4 and thionyl tetrafluoride. When the feed rate was high, unchanged sulfur dioxide appeared after oxygen difluoride. The gases from the sodium fluoride tube were led to and bubbled through an aqueous solution of sodium sulfite containing a small amount of potassium iodide, by which means the products other than sulfuryl fluoride and sulfur hexafluoride were removed.*5 These two products were guided to cold traps and then subjected to low-temperature distillation.

Fluorination of Thionyl Fluoride. An electrolytic cell with a capacity of 300 ml[18] was used. Among the several runs made, the best reaction conditions were as follows: thionyl fluoride (36 ml/min) and helium (15 ml/min) were led through the bubbler into anhydrous hydrogen fluoride containing sodium fluoride (5 g). The electrolysis was then conducted at −30°C with an anodic current density of 1.6 A/dm² and at a cell voltage of 6—7 V. However, even under these conditions, explosions in the reaction system frequently occurred and quantitative analyses of the products were not possible. The products consisted of a considerable amount of thionyl tetrafluoride and traces of sulfur hexafluoride and oxygen difluoride.

Fluorination of Thionyl Chloride, Sulfuryl Chloride, Sulfur Mono-, and Dichlorides. For these liquid samples, the fluorination was conducted in batches by the use of the electrolytic cell with a capacity of 1 *l*.[20] A conductivity additive, sodium fluoride (10 g), was necessary for the fluorination of sulfur mono-, and dichlorides. The products obtained from these materials were treated similarly to those obtained from the fluorination of sulfur dioxide. Thionyl tetrafluoride produced from thionyl chloride was yielded as sulfuryl fluoride by hydrolysis.

Results and Discussion

The reaction conditions for the electrochemical fluorination of sulfur dioxide and the results obtained are shown in Table 1. The reaction can be carried out easily; sulfuryl fluoride is produced as the principal product, along with cleaved by-products.

$$SO_2 \xrightarrow{[F]} SO_2F_2,\ SOF_4,\ SF_6,\ OF_2$$

The sulfur in the products is in the hexavalent state, as is usual in the electrochemical fluorination of sulfur-containing compounds. The composition of the products was not changed practically by the reaction time. A representative example of the composition*6 (Run 1) was sulfuryl fluoride, 62%; thionyl tetrafluoride, 23%; sulfur hexafluoride, 1%; and oxygen difluoride, 14%.

Table 1. Fluorination of sulfur dioxide

Run No.	SO_2 feed[a] rate ml/min	Total amount of SO_2 fed, mol	Electricity[b] passed A. hr	Cell temp. °C	SO_2F_2[c] Yield %
1	32	0.201	60	6—7	70.0
2	47	0.312	65	6—7	49.5
3	36	0.239	65	16	90.4
4	30	0.204	50	16—17	64.8

a) He flow rate: 15 ml/min.
b) Anodic current density: 2.8 A/dm², Cell voltage: 6—8 V
c) Calculated on the basis of the amount of SO_2 fed.

Generally, a lower feed rate with a higher cell temperature gave sulfuryl fluoride in a better yield. Under the conditions used, the highest yield of sulfuryl fluoride was given at a feed rate of 36 ml/min and at a cell temperature of 16°C. At this temperature, however, the reaction with the smaller feed rate did not proceed smoothly due to explosions in the apparatus, thus giving a lower yield of sulfuryl fluoride. The cause of the explosions may be the generation of free fluorine because of the insufficient concentration of sulfur dioxide in anhydrous hydrogen fluoride.

The sulfur-oxygen bond in the oxygen-containing sulfur compounds is relatively stable to fluorination, as may be seen in the poor yields (<1%) of sulfur hexafluoride. The sulfur-oxygen bond in sulfuryl fluoride is particularly inert; the thionyl tetrafluoride and sulfur hexafluoride formed from sulfur dioxide are not produced through the exhaustive fluorination of sulfuryl fluoride, which is found not to be fluorinated by the electrochemical fluorination,*7 just as it has been shown not to be fluorinated by the catalytic fluorination.[21]

The electrochemical fluorination of thionyl fluoride resulted in the formation of thionyl tetrafluoride, together with traces of sulfur hexafluoride and oxygen difluoride. However, more highly-fluorinated products such as pentafluorosulfur hypofluorite,[21,22] were not detected.

$$SOF_2 \xrightarrow{[F]} SOF_4,\ (SF_6,\ OF_2)^{*8}$$

The reaction conditions and the yields of the principal products obtained in the electrochemical fluorination of sulfur oxychlorides and sulfur chlorides are shown in Table 2. The several compounds were produced as follows:

*4 Can be separated by gas chromatography over silica gel.

*5 Thionyl tetrafluoride was converted into sulfuryl fluoride by hydrolysis [H. Jonas, *Z. anorg. allgem. Chem.*, **265**, 273 (1951)].

*6 The ratio of the peak areas in the chromatogram.

*7 The electrochemical fluorination of sulfuryl fluoride was examined by procedures similar to those used for thionyl fluoride. Sulfuryl fluoride was recovered, unchanged.

22) J. K. Ruff and M. Lustig, *Inorg. Chem.*, **3**, 1422 (1964).

*8 The amounts of the compounds listed in parentheses in this and in the following equations were small.

Table 2. Fluorination of sulfur compounds

Run No.	Sample[a] mol	Electricity[b] passed A. hr	Main product Yield[c] %
5	$SOCl_2$ (0.25)	69	SOF_4 (31.7), SOF_2
6	SO_2Cl_2 (0.25)	97	SO_2F_2 (65.7)
7	S_2Cl_2 (0.125)	155	SF_6 (78.2)[d]
8	SCl_2 (0.25)	113	SF_6 (63.7)

a) He flow rate: 60 ml/min.
b) Anodic current density: 2.8 A/dm^2, Cell voltage: 5.5—7 V, Cell temperature: 5—6°C.
c) Calculated on the basis of the amount of the starting material charged.
d) A 100% yiled represents the formation of 2 mol of SF_6 from 1 mol of the starting material.

$$SOCl_2 \xrightarrow{[F]} SOF_2, SOF_4, (SF_6, OF_2, HCl)$$

$$SO_2Cl_2 \xrightarrow{[F]} SO_2F_2, Cl_2, (SO_2ClF, SF_6, OF_2)$$

$$S_2Cl_2 \xrightarrow{[F]} SF_6, Cl_2, (SOF_2, SOF_4)$$

$$SCl_2 \xrightarrow{[F]} SF_6, Cl_2, (SF_5Cl, SOF_2, SOF_4)$$

The compositions of the products varied with the reaction time. The amount of sulfur hexafluoride produced from thionyl chloride and sulfuryl chloride was small (1—2% yield). Chlorine in thionyl chloride appeared to be removed mostly as hydrogen chloride,*9 while in sulfuryl chloride most of the chlorine was removed as chlorine gas.

The electrochemical fluorination of sulfur monochloride which has been briefly described in a patent,[23] and that of sulfur dichloride afforded sulfur hexafluoride in substantial yields. Traces of thionyl fluoride and thionyl tetrafluoride might be produced from impurities in the sulfur chlorides.

*9 These oxychlorides are known to react with anhydrous hydrogen fluoride to yield the corresponding oxyfluorides and hydrogen chloride (Ref. 10). This fact was examined under the modified reaction conditions used for the present work; without passing the current through the anhydrous hydrogen fluoride solution in the cell, but with bubbling helium into it, the oxychlorides were subjected to fluorination at 6°C. Thionyl chloride gave thionyl fluoride, while sulfuryl chloride yielded sulfuryl chlorofluoride.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 2064—2066 (1969)

The Influence of Lanthanide Ions on the Polarographic Minima of Peroxodisulfate Ions

Akio IWASE and Tsuguo ITO

Department of Chemistry, Faculty of Science, Yamagata University, Koshirakawa-cho, Yamagata

(Received November 1, 1968)

It is generally known, from a report by Frumkin[1] on the effect of cations on the minimum wave of peroxodisulfate ions, that when the cationic charge is constant, the effect is more pronounced for larger ionic radii (r_c). This seems to demonstrate that the mutual electrostatic interaction between depolarizer and electrode depends on the size of the hydrated cations adsorbed on the electrode. The aim of the present study is to examine the behavior of this minimum wave of the $S_2O_8^{2-}$ anion in the presence of the lanthanide cations, which have similar ionic radii, in order to obtain some information about the hydration structure of these cations as they are adsorbed on the electrode surface. For comparison, the aluminum ion was also investigated.

Experimental

D. c. polarograms were recorded using a Yanagimoto Polarograph PB, Type 4. The capillary constants used were: $m=1.432$ mg/sec, $t=5.1$ sec/drop, $m^{2/3}t^{1/6}=1.667$ $mg^{2/3}\,sec^{-1/2}$ in a 0.1N KCl solution with a mercury column height of 58.4 cm at -1.15 V *vs.* SCE. The temperature was 25 ± 0.1°C in all cases. The dissolved oxygen was removed by passing through nitrogen gas.

To prepare the 0.01M $K_2S_2O_8$ solution, $K_2S_2O_8$ of an analytical grade was dissolved in distilled water without further purification; the concentration was determined by indirect titration using a $KMnO_4$ standard solution. 0.01M lanthanide ion solutions and an aluminum ion solution were prepared by dissolving in 0.001N HCl the corresponding amounts of their chloride compounds, which had been prepared from the oxides (99.9% pure) by treatment with HCl. The concentrations were determined by chelatometric titration using an EDTA

standard solution. Each solution described above was diluted to the required concentration before use. All the other reagents used were reagent-grade.

Results and Discussion

D. C. Polarogram of Peroxodisulfate in the Presence of the Lanthanide Ion or the Aluminum Ion. In order to obtain a proper minimum wave of $S_2O_8^{2-}$, 0.01 M LiCl was chosen as the supporting electrolyte. D. c. polarograms of solutions containing 4.2×10^{-4}M $S_2O_8^{2-}$, 1×10^{-4}M HCl, and 1×10^{-5}M of Al, La, and Yb ions respectively are shown in Fig. 1. The current-voltage

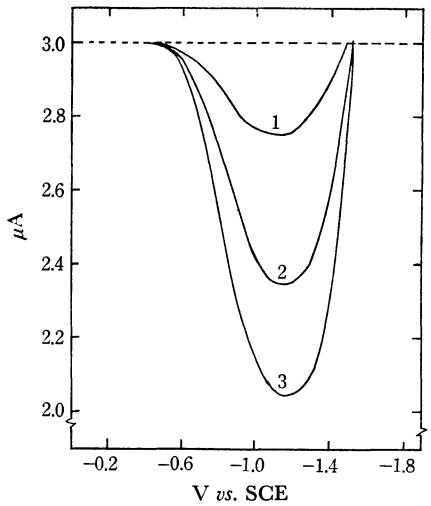

Fig. 1. D.c. polarograms of 0.42 mM $K_2S_2O_8$ in 0.01 M lithium chloride and 0.1 M hydrochloric acid, in the presence of 0.01 mM of (1) Al, (2) La, and (3) Yb.

curves were recorded by sweeping the voltage in the negative direction from −0.45 V, since the maxima appeared at *ca.* −0.3 V. In this case the plateau of the limiting current lay within a very small region, −0.45——0.50 V. The minimum current, i_{dep}, was obtained by measuring the current corresponding to the depth from the limiting current at −0.45 V to the minimum point. The voltage corresponding to the minimum was approximately −1.15 V. As is obvious from Fig. 1, i_{dep} increases in the order: $Al^{3+}<La^{3+}<Yb^{3+}$. The effect of cations on the minimum phenomena (for $S_2O_8^{2-}$) is due to their adsorption, as was noted by Frumkin. Also, the effect of the concentrations of La or Tb ions (Fig. 2) obviously shows that the relation between the persulfate current at the minimum and their concentration gives a saturated curve and that the adsorption equilibrium is of a Langmuir type. The temperature coefficient of i_{dep} was also examined between 30°C and 50°C in the presence of lanthanide ions, but no well-

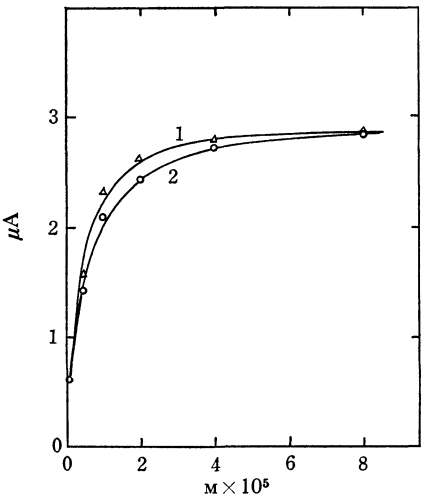

Fig. 2. Effects of (1) lanthanum and (2) terbium concentrations on persulfate current at the minimum in solutions containing 0.42 mM $K_2S_2O_8$ plus 10 mM LiCl and 0.1 mM HCl.

defined wave was observed.

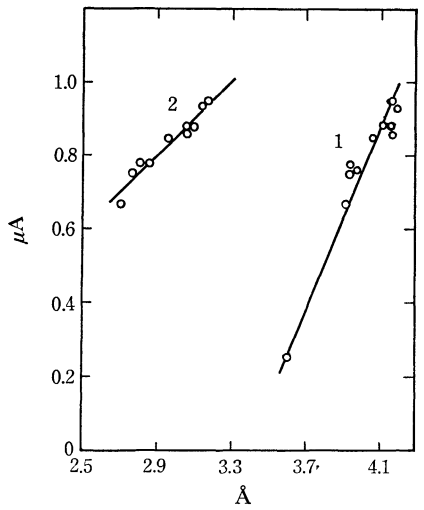

Fig. 3. Relation between i_{dep} and ionic radius : (1), r_s; (2), $r_s - r_c$.

calculating μ were obtained from the literature.[3] In Table 1, r_c are the ionic radii reported by Goldschmidt.[4] The value of r_s for the aluminum ion was calculated as follows. First, the value of the equivalent conductivity[5] of $AlCl_3$ at an infinite dilution was obtained by extrapolation. Second, the value of the Cl^- mobility, 76.3, was subtracted from the value obtained above. The value of the Al^{3+} mobility was then found to be 75.5 (at 25°C). Figure 3 shows the relation between i_{dep} and r_s. All the points on curve 1 in Fig. 3 apparently lie on an approximately straight line drawn from Al to La. However, the values of r_s in Table 1 are almost unchanged for La, Pr, and Nd, although there is a clear difference between the i_{dep} values of La and Pr. The same phenomenon is recognized in Dy, Ho, Er, Tm, and Yb. Curve 2 in Fig. 3 is a plot of the radius difference ($r_s - r_c$) *vs.* i_{dep}; this shows a better linear relation than does 1 (except for Al). Consequently, among the lanthanide ions with the same r_s values, it seems probable that the charge-transfer process of $S_2O_8^{2-}$ is more suppressed by thicker hydration layers. The increase in i_{dep}value in the presence of the Eu(III) ion can be interpreted as follows: the Eu(III) ion is reduced immediately to the Eu(II) ion at -1.15 V and is adsorbed as a bivalent hydrated cation, so it gives a relatively large value of i_{dep}.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 2066—2068 (1969)

The Rearrangement of 2-Aminobenzophenones

Kakuzo ISAGAWA, Takumi ISHIWAKA, (the late) Masamichi KAWAI and Yasaburo FUSHIZAKI

Department of Applied Chemistry, Faculty of Engineering, University of Osaka Prefecture, Sakai, Osaka

(Received November 6, 1968)

A previous paper[1] described how 2-amino-5-chlorobenzophenone (Ib) afforded the intermolecular condensation product, 2,8-dichloro-6,12-diphenyldibenzo[*b*,*f*]-1,5-diazocine (IIb), under the several sets of conditions.[2]

This report will deal with the rearrangement of aminobenzophenones (I) to benzanilides (III) by treating them with zinc chloride.

It has been reported that the migration of acetyl, propionyl, and benzoyl groups occurred when the *N*-monoacyl- or *N*,*N*-diacylaniline was heated for a long time with anhydrous aluminum chloride or zinc chloride, and that the migration groups entered into the *o*-position or, preferably, the *p*-position.[3-5] On the other hand, 9-acridone was prepared from 2-aminobenzophenone in the presence of lead

monoxide,[6] and a series of 2-amino-2′-fluorobenzophenones, upon treatment with potassium carbonate in *N,N*-dimethylformamide, underwent internal nucleophilic exchange to give the corresponding 9-acridones.[7]

We have now found that the treatment of I with zinc chloride gave benzanilides (III) and 9-acridones (IV), together with dibenzodiazocines (II). In this reaction, the rearrangement of I to III was brought about, and the benzoyl group migrated from the carbon of the aromatic nucleus to the nitrogen of the amino group. At the same time, I underwent dehydrocyclization to IV.

a) Theoretical yield, based on aminobenzophenones.

Table 1 presents the results obtained under suitable conditions.

As may be seen in Table 1, Ib scarcely rearranged to IIIb at all in the presence of aluminum chloride. However, the rearrangement proceeded well when zinc chloride was used as the catalyst. When the mixture was heated at 200°C or 220°C, the yields of anilides increased in the following order: R= CH_3<H<Cl, where R is as shown in the synthetic scheme. As for the reverse reaction, Dippy and Moss reported that the percentage conversion into 2-aminobenzophenones was 15% for IIIb and 5% for IIIc.[4] Furthermore, these authors described how a monoacyl and a *N,N*-diacylaniline rearranged by an intermolecular mechanism, since the acyl group could be removed in the form of acyl chloride. In our experiment, a small amount of benzoic acid was produced upon the treatment of Ia with zinc chloride.

Experimental

Treatment of 2-Aminobenzophenones with $ZnCl_2$ or $AlCl_3$. Only a typical reaction will be described here. All of these reactions were carried out by a method similar to that described below.

To 4.63 g (0.02 mol) of Ib heated to 120°C there were added 2.6 g of zinc chloride. The mixture was then heated to the temperature shown in Table 1 for ten hours. After cooling to room temperature, 100 m*l* of warm water and 200 m*l* of chloroform were added to the reaction mixture; brownish, insoluble solids were filtered off. The aqueous layer was separated and discarded. The organic layer was dried over anhydrous potassium carbonate, filtered, and concentrated to dryness *in vacuo*. The residue was dissolved in a mixture of chloroform and carbon tetrachloride (1 : 1) and chromatographed on a column of silica gel. The residue remaining after the evaporation of the first eluate was added to 20 m*l* of methanol. The insoluble material, diazocine IIb, was recrystallized from a mixture of methanol and methylene chloride to give yellow prisms; mp 219—220°C (lit[1,2] mp 219—220°C). IR:*1 1615, 890, 854 cm^{-1}. (Found: C, 72.92; H, 3.60; N, 6.34; Cl, 16.59%).

The mother liquors were concentrated to dryness *in vacuo*, and the residue was added to carbon tetrachloride and filtered. The insoluble material, 4′-chloroben zanilide IIIb, was recrystallized from methylene chloride to give colorless needles; mp 190—192°C (lit[8] mp 192—193°C). IR: 3300, 1650 cm^{-1}. NMR:*2 δ 10.06 (broad singlet, 1H, NH), δ 8.06—7.27 (multiplet, 9H, aromatic protons). (Found: C, 67.59; H, 4.40; N, 6.33%).

2-Chloro-9-acridone (IVb) was afforded from an eluate of the second band (blue-violet fluorescence). The second eluate was concentrated to dryness *in vacuo*, and the residue was recrystallized from *N,N*-dimethylformamide to give bright yellow prisms; mp>320°C (lit[9] mp>360°C). IR: 1635, 1600, 1560 cm^{-1}. (Found: C, 67.78; H, 3.49; N, 6.23%).

Identification of the Other Products. The diazocines, anilides, and acridones were identified by

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 2068—2069 (1969)

Preparation of Epicamphor

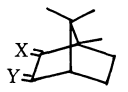
Hitoshi TAKESHITA, Takeo MUROI and Shô ITÔ*1

Department of Chemistry, Tohoku University, Sendai

(Received November 18, 1968)

Although the stepwise reduction of camphorquinone (I) by aluminum and sodium amalgam is reported[1,2] to be the most convenient method for the preparation of epicamphor (II), we have found it to prove inadequate for large scale preparations, affording a mixture of *exo*-3-hydroxycamphor (III) and *exo*-2-hydroxyepicamphor (IV) in varying amounts.[3] In view of the extreme sensitivity of IV toward alkali, as was demonstrated by its conversion to III,[4] IV could not be expected to survive under the conditions used for the reduction even if the reaction first produced IV preferentially. In order to utilize II for other purposes, we have been trying to develop its convenient large-scale synthesis. The preparation and structure elucidation of exo-2-hydroxyepicamphor have recently been described by Fleming and Woodward.[5] Though the first step of our method is essentially the same as theirs, we wish to record in detail our synthesis of epicamphor II.

When I was heated with ethylene glycol and benzene in the presence of *p*-toluenesulfonic acid, monoketal (V) was obtained as the major product



I: X = Y = O
II: X = H_2, Y = O
III: X = O, Y =
IV: X = , Y = O
V: X = O, Y = VI: X = Y =
VII: X =  , Y =
VIII: X = , Y = O

together with a small amount of diketal (VI). These products were separated efficiently by crystallization and alumina column chromatography. V was subsequently reduced stereospecifically with lithium aluminum hydride[5] to yield *exo*-2-hydroxyepicamphor ketal (VII) which was then hydrolysed to IV by 12N sulfuric acid in five minutes with no indication of the presence of the product formed by acyloin rearrangement. Although direct reduction of IV by sodium amalgam afforded a mixture of II and camphor, the same reduction (pH adjusted to 6—8) of the corresponding acetate (VIII), which was obtained quantitatively by mild acetylation of IV, afforded II with a purity of more than 95%. The reaction sequence appears to be the most convenient way of preparing *l*-epicamphor from *d*-camphor.

Experimental*2

Reaction of Camphorquinone (I) and Ethylene Glycol. I (prepared from *d*-camphor) (17 g), *p*-toluenesulfonic acid (0.5 g) and ethylene glycol (22 g) were dissolved in benzene (200 m*l*) and heated under reflux with azeotropic removal of water. The mixture was poured into water and extracted with benzene. Evaporation of the solvent gave a crystalline solid which was recrystallized from cyclohexane to give pure V (14 g) as colorless needles, mp 88—89.5°C, Found: C, 68.36; H, 8.69%. Calcd for $C_{12}H_{18}O_3$: C, 68.54; H, 8.68%. IR (KBr): 1752, 1399, 1375, 1041, 1024, 984, 974, 955, 938, 908, 780 cm^{-1}. NMR: 0.85 (3H, singlet), 0.99 (6H, singlet), 3.75—4.35 (4H, multiplet).

Alumina chromatography of the recrystallization mother liquor eluting with benzene - ethyl acetate mixture (3.0 g) gave additional V (4.4 g) and diketal VII (3.0 g) which after recrystallization from cyclohexane formed colorless needles, mp 63—63.5°C. Found: C, 65.97; H, 8.71%. Calcd for $C_{14}H_{22}O_4$: C, 66.11; H, 8.72%. IR (KBr): 1386, 1364, 1206, 1020, 996, 973, 953, 900, 820 cm^{-1}. NMR: 0.72 (3H, singlet), 0.83 (3H, singlet), 1.27 (3H, singlet), 3.47—4.10 (8H, multiplets).

Lithium Aluminum Hydride Reduction of Camphorquinone Monoketal (V). V (13.7 g) was dissolved in anhydrous ether (50 m*l*) and lithium aluminum hydride (1.5 g) in ether (15 m*l*) were added dropwise at 0°C. After excess of the reagent was decomposed in the usual manner, the reaction mixture was extracted with ether. Removal of the solvent and distillation of the residual oil yielded the hydroxyketal (VII) as a colorless oil, (13.1 g). Found: C, 67.91; H, 9.56%. Calcd for $C_{12}H_{20}O_3$: C, 67.89; H, 9.50%. IR (CCl_4): 3520, 1392, 1372, 1094, 1029, 1009, 990, 982, 950, 918, 811 cm^{-1}. NMR: 0.80 (3H, singlet), 0.84 (3H, singlet), 1.05 (3H, singlet), 2.07 (OH), 3.13 (1H, *sharp* singlet), 3.70—4.10 (4H, multiplet).

***exo*-2-Hydroxyepicamphor (IV).** VII (13.2 g) was shaken with aqueous 12N sulfuric acid for five minutes at room temperature and then extracted with ether. After removal of the solvent, the residue was recrystallized from ligroin to yield IV (8.3 g) as colorless prisms, mp 229—230°C. IR (KBr): 3395, 1745, 1395, 1375, 1096, 980, 809 cm^{-1}. NMR: 0.92 (3H, singlet), 1.00 (6H, singlet), 3.42 (1H, *sharp* singlet).

***exo*-2-Acetoxyepicamphor (VIII).** IV (4.0 g) was heated in acetic anhydride (15 m*l*) at 140°C for 4 hr. After removal of the excess reagent *in vacuo* the residual oil was distilled to give VIII (4.7 g), as a colorless liquid. (Found: C, 67.96; H, 8.53%. Calcd for $C_{12}H_{18}O_3$: C, 68.54; H, 8.68%. IR (CCl_4): 1758, 1748, 1397, 1376, 1230, 1070 cm^{-1}. NMR: 0.89 (3H, singlet), 0.93 (3H, singlet), 0.99 (3H, singlet), 2.06 (3H, singlet), 4.74 (1H, *sharp* singlet).

Sodium Amalgam Reduction of *exo*-2-Hydroxyepicamphor (IV). *a*) IV (500 mg) in methanol (100 m*l*) was reduced with 1.2% sodium amalgam (5 g) at room temperature. After dilution with water, the reaction mixture was extracted with ether to yield colorless crystals (300 mg), GLC of which showed the presence of more than 95% of epicamphor (II).

b) IV (30 g) in 25% methanol (2 *l*) was reduced with 1.5% sodium amalgam (220 g) at room temperature. The reaction was followed by GLC which indicated the formation of camphor even at an early stage. After completion of the reduction the colorless product isolated was composed of 59% of II and 41% of camphor.

Epicamphor (II). VIII (10 g) in 30% aqueous methanol (300 m*l*) was reduced with sodium amalgam (prepared from 19.2 g of sodium and 1500 g of mercury) the pH of the solution being maintained between 6 and 8 by addition of glacial acetic acid. The reaction was followed by GLC during the reaction period. After the reaction was completed, the reaction mixture was diluted with water and the aqueous layer was extracted with ether. Removal of the solvent yielded colorless crystals, which after sublimation *in vacuo* afforded colorless scales (II), mp 186°C. $[\alpha]_D$ −58.0° (5.1 g) (Found: C, 78.19; H, 10.47%). IR (KBr): 1744, 1415, 1388, 1373, 1200, 1005 cm^{-1}. NMR: 0.94 (6H, singlet), 1.01 (3H, singlet). 2,4-DNP, mp 190.5—191.5°C. (lit[2] mp 189—190°C).

*2 All NMR spectra were measured using a Varian A-60 spectrometer for carbon tetrachloride solutions. Chemical shifts are expressed in ppm from internal tetramethylsilane. Optical rotation was measured for 2.8% methanol solution.

H. T. and S. I. are indebted to the Matsunaga Science Foundation and Takeda Science Foundation, respectively, for their generous grants.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 2070—2071 (1969)

A Study of the Mechanism of the Carboxylation of Potassium Phenoxide by Means of the Carbon-14 Tracer Technique[1)]

Yutaka YASUHARA,* Tatsuo NOGI* and Hideo SAISHŌ**

* *Mishima Laboratory, Toyo Rayon Company, Ltd., Mishima, Shizuoka*

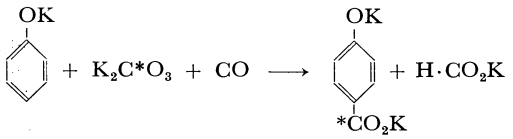
** *Central Research Laboratories, Toyo Rayon Company, Ltd., Otsu, Shiga*

(Received November 19, 1968)

A novel synthesis of *p*-hydroxybenzoic acid from potassium phenoxide, potassium carbonate, and carbon monoxide has previously been reported.[2)] The reaction mechanism has, however, not yet been established, it has not been made clear whether the carboxyl group of *p*-hydroxybenzoic acid is derived from either potassium carbonate or carbon monoxide. In the present study, potassium carbonate ^{14}C is used to throw light on the mechanism.

Results and Discussion

The radioactivities of the two products, *p*-hydroxybenzoic acid and formic acid, are listed in Table 1. The results lead to the conclusion that the carbon atom of potassium carbonate attacks the phenoxide nucleus and that carbon monoxide is converted into potassium formate:

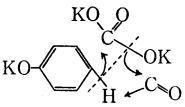


Since this reaction proceeds almost quantitatively, and since most of the carboxyl group seems to be introduced directly into the position *para* to the hydroxyl group,[2,3)] a possible mechanism of the reaction is:

TABLE 1. RADIOACTIVITIES OF *p*-HYDROXYBENZOIC ACID AND FORMIC ACID PRODUCED FROM POTASSIUM CARBONATE-^{14}C

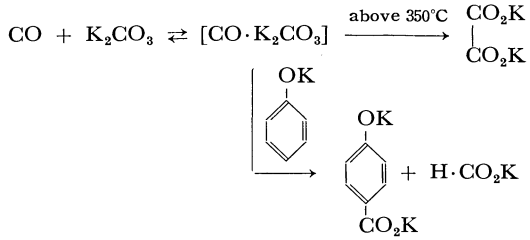
Sample* mg	Radioactivity dpm	Specific activity μCi/mg
p-HBA: 2.92	50.17×10^{4}	7.8×10^{-2}
0.50	8.71×10^{4}	7.9×10^{-2}
FA: 56	9.13×10^{4}	7.4×10^{-4}

* *p*-HBA: *p*-hydroxybenzoic acid
FA: formic acid



It is rather difficult to postulate that the termolecular complex is directly formed in such a smooth reaction. To study the mechanism of this reaction in detail, the reaction of potassium carbonate with carbon monoxide,[4)] that of potassium phenoxide with carbon monoxide, and that of potassium phenoxide with potassium carbonate were each examined at 250 and 350°C. Among these six cases, only in the case of potassium carbonate with carbon monoxide at 350°C was a chemical change observed. Oxalic acid (1.2 g, 11%) was obtained from 13.8 g of potassium carbonate under an initial carbon monoxide pressure of 90 kg/cm^2 (at room temperature) after 6 hr. By analogy with the Kolbe-Schmitt reaction,[5)] the formation of a complex of potassium phenoxide and carbon monoxide might be suggested. However, in view of the facts described above, together with the fact that phenol itself can also be carboxylated with potassium carbonate under a carbon monoxide atmosphere,[6)] such a possibility may be ruled out in this case.

Thus, the following assumption is the most probable. First, potassium carbonate and carbon monoxide form a complex, which may be a precursor of dipotassium oxalate. Secondly, the complex reacts with potassium phenoxide, and dipotassium *p*-hydroxybenzoate and potassium formate are formed:



1) Carboxylation by Alkali Salts and Carbon Monoxide. IV. Paper III: Y. Yasuhara and T. Nogi, *Chem. & Ind. (London)*, **1969**, 77.

2) Y. Yasuhara and T. Nogi, *Chem. & Ind. (London)*, **1967**, 229.

3) Y. Yasuhara and T. Nogi, *J. Org. Chem.*, **33**, 4512 (1968).

4) C. Matignon and C. Faurholt, *Compt. Rend.*, **179**, 273 (1923).

5) J. L. Hales, J. I. Jones and A. S. Lindsey, *J. Chem. Soc.*, **1954**, 3145.

6) T. Nogi and Y. Yasuhara, in preparation.

The results shown in Table 1 indicate also that the exchange of the carboxyl group between dipotassium *p*-hydroxybenzoate and potassium formate is very slow. This is in contrast to the Kolbe-Schmitt reaction,[7] in which an appreciable exchange of the carboxyl group between dipotassium salicylate and potassium carbonate accompanies the rearrangement, and to the Henkel process,[8] in which the exchange between dipotassium phthalate and potassium carbonate takes place through carbon dioxide in the gas phase. However, it is not obvious whether such different results come from differences, alone or in combination, in the temperatures, in the atmospheres (CO and CO_2), or in the reagents (the formate and the carbonate).

Experimental

Materials. The potassium phenoxide was prepared by neutralizing phenol with potassium hydroxide in *n*-propanol. After filtration the crystals were dried at 130°C *in vacuo* (N_2, 20 mmHg). Potassium carbonate-^{14}C was prepared by heating a mixture of 6.9 g of potassium carbonate and 9.0 m*l* of an aqueous solution containing *ca.* 1 mCi of sodium carbonate-^{14}C (the Radiochemical Centre, England) to dryness.

Procedure. A glass vessel containing potassium phenoxide (6.6 g) and potassium carbonate-^{14}C (6.9 g) was placed in a stainless-steel autoclave (*ca.* 100 m*l*) and then dried *in vacuo* (N_2, 10 mmHg) at 220°C for 5.5 hr. The autoclave was then filled with carbon monoxide at a pressure of 85 kg/cm^2 (initial, at room temp.) and heated at 240—250°C for 6.0 hr (20 min preheating). The product was dissolved into 50 m*l* of water, and then the solution was acidified to pH 9.0 with 6N sulfuric acid. The regenerated phenol was extracted with ether. After further acidification with 12N sulfuric acid to pH 1.0, the aqueous solution was extracted again with ether. From the ether extract *p*-hydroxybenzoic acid was obtained, and, after treatment with activated charcoal, recrystallization from water, and drying, 3.0 g of purified *p*-hydroxybenzoic acid (mp 211—213°C) was recovered. Formic acid (bp 100—101°C) was obtained from the aqueous solution by exhaustive extraction with ether and fractional distillation. The reactions of three pairs, potassium carbonate and carbon monoxide, potassium phenoxide and potassium carbonate, and potassium phenoxide and carbon monoxide, were carried out analogously to that described above.

The radioactivities of *p*-hydroxybenzoic acid (in dioxane) and formic acid (in toluene) were measured on a Tracerlab LSC-20A liquid scintillation counter.

The authors wish to express their deep thanks to Mr. Hiroyuki Nagao of the Nippon Atomic Industry Group Co., Ltd., for his measurement of the radioactivities. Thanks are also due to Mr. Tadao Katō of the Toyo Rayon Co., Ltd., for his helpful suggestions and to Mr. Ikuzō Takahashi of the Toyo Rayon Co., Ltd., for his assistance in the experimental work.

A Complex Formed by the Reaction of Ruthenium Tetroxide with 1,10-Phenanthroline in Carbon Tetrachloride

Toshio ISHIYAMA

Radiation Center of Osaka Prefecture, Shinke-cho, Sakai, Osaka

(Received November 29, 1968)

The synthesis and identification of the organic chelate compound of ruthenium in its higher oxidation states, for instance, Ru(IV), Ru(VI), Ru(VII), and Ru(VIII), are quite difficult since most organic compounds are oxidized by ruthenium tetroxide in the reaction mixture. Martin[1] obtained an interesting complex as an orange-brown precipitate by the reaction of ruthenium tetroxide with nitric oxide in carbon tetrachloride according to the following equation:

$$2RuO_4 + 8NO = Ru_2N_6O_{15} + N_2O$$

He suggested that it might be a nitrato complex containing two bis(nitrosyl)ruthenium groups linked by an oxo-bridge $[RuO_2(NO)_2NO_3]_2O$. Koda[2] reported obtaining an addition compound of ruthenium tetroxide with pyridine, $RuO_4 \cdot 2C_5H_5N$, as greenish-black crystals in carbon tetrachloride.

1) F. S. Martin, J. M. Fletcher, P. G. M. Brown and B. M. Gattehouse, *J. Chem. Soc.*, **1959**, 76.

2) Y. Koda, *Inorg. Chem.*, **2**, 1306 (1963).

A previous paper[3] reported obtaining a ruthenium tetroxide complex with 2,2′-bipyridine by the reaction of ruthenium tetroxide with 2,2′-bipyridine in carbon tetrachloride. In the present paper a binuclear complex of ruthenium(VII) will be reported, together with the electronic spectra of the previous complex, [RuO_4 bipy].

Experimental

Materials. Ruthenium(III) chloride monohydrate (extra pure grade) supplied by Mitsuwa Chemicals & Co. was used without further treatment, while commercial 1,10-phenanthroline was dried by heating it at 115°C for 3 hr and was then recrystallized from ethanol. The carbon tetrachloride was washed with a 1.5 per cent alcoholic solution of potassium hydroxide more than three times and repeatedly with pure water, and then distilled.

Preparation. *Ruthenium(VII) Oxide Complex with 1,10-Phenanthroline*, [Ru_2O_7 $phen_2$]. Ruthenium tetroxide in a nitric acid solution was prepared according to the method reported in a previous paper.[3] Ruthenium tetroxide in a nitric acid solution was extracted with carbon tetrachloride. To the organic solution, cooled in an ice bath, there was added a carbon tetrachloride solution of 1,10-phenanthroline. A dark green precipitate of the ruthenium(VII) oxide complex with 1,10-phenanthroline was separated immediately. After 20 hr, the precipitate was filtered, washed with carbon tetrachloride, and dried *in vacuo*. The mole ratio of 1,10-phenanthroline to ruthenium tetroxide employed in the reaction varied from 1:1 to 1:4, but the product obtained was the same in any case. The dried precipitate was dissolved in pure water, and an insoluble product was filtered off. After concentration on a hot water bath, the crystals formed were separated, recrystallized once again from water, and dried *in vacuo*. Yield: 10.2% on the basis of the ruthenium tetroxide. The complex is insoluble in carbon tetrachloride, chloroform, benzene, acetone, ether, ethanol, and acetic acid, but soluble in water and methanol.

The ruthenium content and the molecular weight of the complex were measured by a method reported previously.[3]

Found: Ru, 29.36; C, 42.60; H, 2.69; N, 8.41%; mol wt, 680. Calcd for [$Ru_2O_7(C_{12}H_8N_2)_2$]: Ru, 30.12; C, 42.62; H, 2.41; N, 8.21%; mol wt, 675.

Ruthenium(VIII) Oxide Complex with 2,2′-Bipyridine, [RuO_4 bipy]·$3H_2O$. This was synthesized according to the method reported in a previous paper.[3]

Found: Ru, 26.33; C, 31.07; H, 3.79; N, 7.80; H_2O, 15.00%; mol wt, 330. Calcd, for [$RuO_4(C_{10}H_8N_2)$]·$3H_2O$; Ru, 27.06; C, 31.81; H, 3.70; N, 7.46; H_2O, 14.70%; mol wt, 321 (anhydride).

Absorption Spectra. The infrared absorption spectra were obtained by the KBr disk method on a infrared spectrophotometer, Model IR-S, of the Japan Spectroscopic Co. The visible and ultraviolet absorption spectra were measured with a Beckmann Model DU spectrophotometer.

Magnetic Measurement. The mangetic susceptibility was measured at 27°C with a Gouy balance. The complex was found to be diamagnetic.

Results and Discussion

Composition of the Complex. From the results of the elemental analysis, the mole ratio of ruthenium to 1,10-phenanthroline was found to be 1:1. The observed molecular weight indicates that the complex is binuclear, [Ru_2O_7 $phen_2$].

Infrared Absorption Spectra. The main infrared absorption bands of the ruthenium(VII) oxide complex with 1,10-phenanthroline are shown in Table 1, together with those of the pure ligand. The C=N stretching peak is shifted to the higher frequency side by the ligation. This behavior is interpreted as an indication that the bond order of the carbon-nitrogen link is increased. The bands attributable to the C=C and C–H bonds are also shifted to the higher frequencies. Similar observations have also been reported for [Fe $phen_3$]Cl_2 and other phenanthroline complexes by Schilt and Taylor,[4] Inskeep,[5] and Busch and Bailor.[6]

Table 1. The characteristic infrared absorption bands of ruthenium(VII) oxide complex with 1,10-phenanthroline (cm^{-1})

Assignment	phen	[Ru_2O_7 $phen_2$]

Electronic Absorption Spectra. The visible and ultraviolet absorption spectra of ruthenium-(VIII) and (VII) oxide complexes with 2,2′-bipyridine and 1,10-phenanthroline respectively were measured in water and methanol. They are shown in Figs. 1 and 2, together with those of pure ligands and ruthenium tetroxide in water.

The ruthenium(VIII) oxide complex with 2,2′-bipyridine has four absorption bands, at 740, 440, 292, and 245 mμ. A similar spectrum has also been reported by Koda[2] for bis(pyridine)ruthenium-(VIII) oxide. The two peaks of a higher intensity observed in the visible region may both be assigned to the charge transfer from ligand to metal. The two absorption bands observed for ruthenium tetroxide have also been attributed to the charge transfer from oxygen to ruthenium.[7] The two peaks at 292 and 245 mμ can be assigned to the π_1 and π_2-bands respectively, corresponding to the 279 and 233 mμ bands in the 2,2′-bipyridine. The red-shifts of the π_1 and π_2-bands by ligation to ruthenium(VIII) can be explained as follows. The molecule of 2,2′-bipyridine has been proved by Fielding and LeFèvre,[8] and by Krumholz[9] to assume the *trans*-form in a neutral or basic aqueous solution and also in organic solutions. The facts that *trans*-bipyridine was changed to the *cis*-form, and that the π_1 and π_2-bands were shifted to a longer wavelength by coordination to a metal atom, were confirmed by Nakamoto[10] in the case of the tris-(2,2′-bipyridine)nickel(II) complex. The same effect must be felt in the present case of the ruthenium(VIII)-2,2′-bipyridine chelate.

In an aqueous solution of the ruthenium(VII) oxide complex with 1,10-phenanthroline, three absorption bands and a shoulder are observed at 685, 450, 264, and 315 mμ respectively. The two peaks of a higher intensity observed in the visible region may both be assigned to the charge transfer from ligand to metal. The first charge-transfer bands of [RuO_4 bipy] and [Ru_2O_7 $phen_2$] are observed in a region of wavelength longer than those of [Ru $bipy_3$]Cl_2 and [Ru $phen_3$]Cl_2 which were reported by Crosby *et al.*[11] These facts show that the charge-transfer transitions in Ru-(VIII)-2,2′-bipyridine and Ru(VII)-1,10-phenanthroline chelates occur with a lower energy because the t_{2g} orbitals are not filled. A shoulder and a peak, observed at 315 and 264 mμ respectively, nearly coincide with the two absorption bands, at 320 and 265 mμ, of 1,10-phenanthroline. It should be noticed that the influence of ruthenium bonding on the spectrum of 1,10-phenanthroline is much less than in the case of 2,2′-bipyridine. The same situation was also observed in the case of mono-2,2′-bipyridine and mono-1,10-phenanthroline complexes of cobalt(II) and nickel(II) by Sone *et al.*[12]

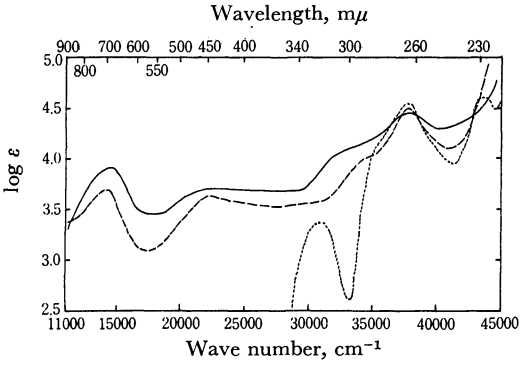

Fig. 2. Electronic absorption spectra of [Ru_2O_7-$phen_2$] and 1,10-phenanthroline.
—— [Ru_2O_7 $phen_2$] in H_2O
—— [Ru_2O_7 $phen_2$] in CH_3OH
------ phen in H_2O

Magnetic Property. The measured molecular weight suggests that the ruthenium(VII) oxide complex with 1,10-phenanthroline is binuclear. The observed diamagnetism of the binuclear complex, [Ru_2O_7 $phen_2$], may be explained as follows. When the Ru(VII) ions, each containing one unpaired d electron, form the binuclear complex with an oxygen-bridge between ruthenium atoms (presumably linear), one electron from each Ru-(VII) and two from the oxygen atom will be form two electron pairs occupying the lower two of the three center MO's. The molecular orbital treatments of $K_4Ru_2OCl_{10}$ and $[RuO_2(NO)_2NO_3]_2O$ which have been reported by Dunitz and Orgel[13] and by Martin *et al.*[1] can be applied to [Ru_2O_7-

The Separation Factor for Alkali Metals in Solvent Extraction with Hexyl

Shoji MOTOMIZU,* Tadashi IWACHIDO** and Kyoji TÔEI*

* *Department of Chemistry, Faculty of Science, Okayama University, Tsushima, Okayama*
** *College of Liberal Arts and Sciences, Okayama University, Tsushima, Okayama*

(Received December 16, 1968)

The extractions of alkali metals reported to date have almost all been based upon the ion-association principle. For example, polyiodide,[1] tetraphenylborate,[2,3] hexafluorophosphate,[4] and phenols[5,6] have been investigated. The extraction of alkali metals into nitrobenzene using Hexyl[7,8] is also related to the ion association. However, the mechanism for the extraction with Hexyl has not yet been extensively studied. In our previous paper,[9] the mechanism for the extraction of alkali metals using Hexyl was discussed, and the association constants of Hexyl salts in an aqueous solution and in a nitrobenzene solution, the partition coefficients of ion-pairs, and the extraction constants were reported.

In this paper, the separation factor of two alkali metals will be discussed and an equation for the extraction separation of alkali metals with Hexyl will be given theoretically and examined in the cases of sodium and potassium.

Calculations

The Separation Factor of Two Alkali Metals. The general equation for the separation factor, α, is given hereafter by using the extraction and the association constants.

The separation factors for alkali metals, M_1 and M_2, are written as:

$$\alpha_{M_2}^{M_1} = \frac{q_{M_1}}{q_{M_2}} = \left(\frac{[M_1R]_o+[M_1^+]_o}{[M_1R]_a+[M_1^+]_a}\right)\left(\frac{[M_2R]_o+[M_2^+]_o}{[M_2R]_a+[M_2^+]_a}\right)^{-1} \quad (1)$$

where q_{M1} and q_{M2} are the distribution ratios of M_1 and M_2 respectively, and where the subscripts o and a refer to the organic and aqueous phases respectively. [MR], [M^+], and [R^-] are the concentrations of the ion-pair, the metal ion, and the Hexyl anion respectively. $[M_1R]_o$ and $[M_2R]_o$ can be neglected compared with $[M_1^+]_o$ and $[M_2^+]_o$ respectively, because the association constants for M_1R and M_2R are very small. When $[R^-]_a$ is relatively small compared with the concentration of the alkali metal in the aqueous phase, $[M_1R]_a$ and $[M_2R]_a$ can also be neglected compared with $[M_1^+]_a$ and $[M_2^+]_a$ respectively. Therefore, Eq. (1) can be rearranged to Eq. (2):

$$\alpha_{M_2}^{M_1} = \frac{[M_1^+]_o}{[M_2^+]_o} \times \frac{[M_2^+]_a}{[M_1^+]_a} \quad (2)$$

The combination of the two association constants, $K_o^{M_1R}$ and $K_o^{M_2R}$, leads to Eq. (3):

$$\frac{[M_1^+]_o}{[M_2^+]_o} = \frac{K_o^{M_1R}}{K_o^{M_1R}} \times \frac{[M_1R]_o}{[M_2R]_o} \quad (3)$$

The combination of Eqs. (2) and (3) leads to Eq. (4):

9) K. Tôei, T. Iwachido and S. Motomizu, *ibid.*, **42**, 1006 (1969).

$$\alpha_{M_2}^{M_1} = \frac{K_o^{M_1R}}{K_o^{M_2R}} \times \frac{[M_1R]_o[M_2^+]_a}{[M_2R]_o[M_1^+]_a} = \frac{K_o^{M_1R} \cdot E_{M_1R}}{K_o^{M_2R} \cdot E_{M_2R}} \quad (4)$$

where E_{M_1R} and E_{M_2R} are the extraction constants of M_1R and M_2R respectively and are defined as:

$$E_{M_1R} = \frac{[M_1R]_o}{[M_1^+]_a[R^-]_a f_a^2} \quad (5)$$

$$E_{M_2R} = \frac{[M_2R]_o}{[M_2^+]_a[R^-]_a f_a^2} \quad (6)$$

where f_a indicates the activity coefficient.

Equation (4) is rearranged to Eq. (7):

$$[M_1^+]_a = \frac{1}{1+(q_{M_2} \cdot \alpha_{M_2}^{M_1})} \times T_{M_1} \quad (7)$$

where T_{M1} is the total concentration of metal, M_1.

Experimental

Reagents. The Hexyl sodium salt was prepared and purified by the method reported in the previous paper.[9] The Hexyl-Na nitrobenzene solution was prepared by dissolving the Hexyl-Na in nitrobenzene to give 1.0×10^{-3}M. All the other chemicals used were of a guaranteed reagent grade. Aqueous solutions were prepared by dissolving the sodium hydroxyde, the sodium, and the potassium chloride to give 0.001M, 0.1M, and 2×10^{-5}—1×10^{-3}M respectively.

Apparatus. The concentration of potassium in the aqueous phase after the extraction was determined flame-photometrically by using a Hitachi Flamephotometer, FPF-2.

Extraction Procedures. The extractions were all carried out at 25°C. Twenty milliliters of an aqueous solution containing sodium and potassium were placed into a 50-m*l* separatory funnel and shaken moderately for about thirty minutes with an equal volume of a nitrobenzene solution of Hexyl-Na (1.0×10^{-3}M) so as not to form an emulsion. The final equilibrated pH of the aqueous phase was 10—11. The potassium and Hexyl in the aqueous phase separated from the organic phase were determined flamephotometrically and spectrophotometrically respectively.

Table 1. The constants for hexyl salts

MR	K_o^{MR} *1	K_a^{MR} *2	D_{MR} *3	E_{MR}
Hexyl-Li	3.3	8.9	0.5	4.5
Hexyl-Na	4.0	9.4	3.4	3.2×10
Hexyl-K	4.6	174	20.4	3.5×10^3
Hexyl-Rb	4.7	365	22.2	8.1×10^3
Hexyl-Cs	2.3			

*1 The association constant in nitrobenzene saturated with water:

$$K_o^{MR} = [MR]_o/[M^+]_o[R^-]_o f_a^2$$

*2 The association constant in the aqueous solution:

$$K_a^{MR} = [MR]_a/[M^+]_a[R^-]_a f_a^2$$

*3 The partition coefficient:

$$D_{MR} = [MR]_o/[MR]_a$$

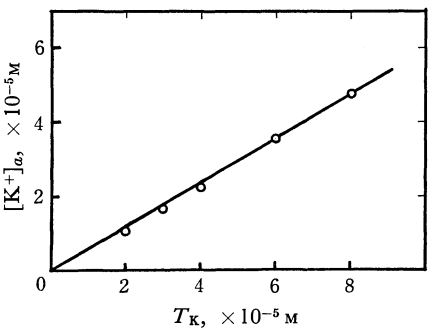

Fig. 1. The plot of $[K^+]_a$ *vs.* T_K.
Original concentration of sodium chloride in the aqueous phase: 1.0×10^{-1}M.
Original concentration of Hexyl-Na in the organic phase: 1.0×10^{-3}M.
In all extractions, the concentration of Hexyl salt in the aqueous phase was less than about 10^{-5}M.

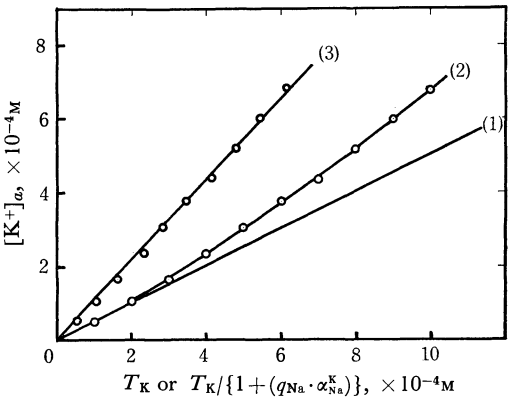

Fig. 2. The plot of $[K^+]_a$ *vs.* T_K or $T_K/\{1+(q_{Na}\cdot\alpha_{Na}^K)\}$.
(1): the line with a slope of 0.5.
(2): the plot of $[K^+]_a$ *vs.* T_K.
(3): the plot of $[K^+]_a$ *vs.* $T_K/\{1+(q_{Na}\cdot\alpha_{Na}^K)\}$.

Results and Discussion

As is shown in Table 1, which is reprinted from our previous report,[9] the association constants of Hexyl alkali metal salts in an organic phase are very small, so the theoretical equation (4) is useful. For example, if M_1 and M_2 are potassium and sodium respectively, the value of α_{Na}^K is calculated from the extraction constants and the association constants to be 9.5×10.

Figures 1 and 2 show the plot of $[K^+]_a$ against T_K. In the region where the concentration of potassium can be neglected in the organic phase, compared with the concentration of sodium, q_{Na} is thought to be kept at 0.01 and α_{Na}^K is 9.5×10, as has been mentioned above, so the slope may be expected to be about 0.5 $(1/(1+0.95))$. In Fig. 1 the slope is about 0.5, as expected. When q_{Na} seems to vary, the plot of $[K^+]_a$ against T_K gradually

deviates from the line of the 0.5 slope (Fig. 2). Figure 2 also shows the plot of $[K^+]_a$ against $T_K/\{1+(q_{Na}\cdot\alpha^K_{Na})\}$. This plot shows a good linearity, and the slope is 1.1.

Equation (7) has thus been found to be in good agreement with the experimental data. Therefore, Eq. (4) will be very useful in estimating the separation of alkali metals.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 2076—2077 (1969)

Proof of the Configuration at C_4 of Guaioxide

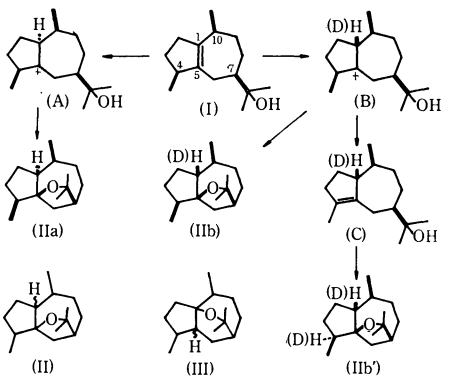
Yoshiaki TANAHASHI, Shûji TOMODA and Takeyoshi TAKAHASHI

Department of Chemistry, Faculty of Science, The University of Tokyo, Bunkyo-ku, Tokyo

(Received December 18, 1968)

Recent communications[1,2] on the structure of guaioxide have prompted us to report our results on this problem. Our attention to the structure of this compound has been drawn by isolation of two new sesquiterpene oxides ($C_{15}H_{26}O$) from "San-shion" of *Ligularia* genus (probably *L. sibirica*).[3] These oxides which we conventionally called LB and LC are both isomeric to guaioxide. One (LC) of these recently turned out to be identical with liguloxide.[4]

Guaioxide has been isolated from guaiac wood oil by Bates and Slagel.[5] They reported that acid treatment of guaiol (I) gave guaioxide for which the structure II or III was suggested. Later Ledoux *et al.*[6] assigned the structure IIa to guaioxide, provided that the hydroxyl group adds to the double bond at C_1—C_5 in *trans* manner, and that no isomerization occurs at the other centers (I→A→IIa). Ishii *et al.*[1] recently deduced the structure IIb for guaioxide in which the hydrogen at C_1 and the ether bridge are both β-oriented. One of the most probable courses of formation of guaioxide might be a migration of the double bond at C_1—C_5 to the position C_4—C_5 with addition of proton at C_1 from β-side followed by *srans* addition of the hydroxyl group (I→B→C→IIb′). Hence use of deuteriated acid in cyclization of guaiol (I) is expected to give information on the mechanism of formation of guaioxide and on the stereochemistry at C_4.



Guaiol (I) gave guaioxide-d_1 when treated with sulfuric acid-d_2 in acetic acid-d_1. The mass spectrum of deuteriated guaioxide shows a molecular ion peak at *m/e* 223, and the NMR spectrum is essentially the same with that of non-deuteriated guaioxide, showing no change in the region of methyl signals. One deuterium atom introduced is, therefore, located at C_1.

This result eliminates the possibility of any acid-catalyzed isomerizations of the double bond (*e.g.* I→B→C→IIb′) during the formation of guaioxide, and establishes that guaioxide has the same configurations at C_4, C_7 and C_{10} as those of guaiol, although no evidence is given as to the ring junction. The above result firmly confirms the 4β-methyl configuration which was previously given for guaioxide by Ishii *et al.*[1] on the basis of generally accepted considerations for microbial hydroxylation.

With Ishii's conclusion[1] admitted, guaioxide should be formed by the route I→B→IIb. *Cis* addition of hydroxyl group would be due to the

conformational stability of an intermediate cation B in comparison with cation A. This evidence is important in view of the structural studies of the remaining oxide (LB) which are in progress in our laboratory and in the Shionogi Research Laboratory.[7]

Experimental

Treatment of Guaiol with Sulfuric Acid-d_2 in Acetic Acid-d_1. Guaiol (957 mg) was dissolved in 99% acetic acid-d_1 (CIBA Ltd. ; 19 g) containing sulfuric acid-d_2 (13 μl). The solution was left at room temperature (13—15°C) for 72 hr. Repeated chromatographies (eluted with petroleum ether) of the crude reaction product (763 mg) over silica gel, then over alumina, gave a hydrocarbon mixture (437 mg) and a colorless oil (41 mg). The latter, having the same retention time in VPC with that of guaioxide, showed essentially the same IR and NMR spectra with those of guaioxide respectively, and gave rise to a molecular ion peak at m/e 223 on its mass spectrum (measured using the Hitachi Mass Spectrometer, RMU-6D Type).

We thank Dr. H. Ishii of Shionogi Research Laboratory, Shionogi and Co., for his valuable discussion and for the identification of LC with liguloxide.

Reactions of Isocyanides with Carbon Tetrahalogenides in the Presence of Dicobalt Octacarbonyl

Yasuhiro YAMAMOTO*1 and Nobue HAGIHARA

The Institute of Scientific and Industrial Research, Osaka University, Suita-shi, Osaka

(Received December 19, 1968)

It is well established that isocyanides, analogous to carbon monoxide, coordinate to transition metals to give the complexes of isocyanides. In previous papers we have reported on the catalytic polymerization of isocyanides by $BF_3O(C_2H_5)_2$ or transition metal complexes,[1] and on the reactions of isocyanides with various transition metal complexes.[2]

Bamford and Maltman reported some of the characteristic properties of metal carbonyl-organic halide systems as free radical initiators.[3] In the course of our studies on the polymerization of isocyanides with metal carbonyl-carbon tetrahalogenide systems, we found that isocyanides readily reacted with carbon tetrahalogenides in the presence of $Co_2(CO)_8$ to yield *N*-substituted dihaloacetamides and cobalt(II) complexes of isocyanides, suggesting the formation of carbene as intermediates.

Carbon tetrachloride containing a small amount of water was added to a mixture of cyclohexyl isocyanide and $Co_2(CO)_8$ in benzene at room temperature. The subsequent reaction was initiated with evolution of carbon monoxide and gave *N*-cyclohexyldichloroacetamide and dichlorotetrakis(cyclohexyl isocyanide)cobalt(II).

A similar reaction in methanol gave *N*-cyclohexyldichloroacetimidate and dichlorotetrakis(cyclohexyl isocyanide)cobalt(II). The use of other metal carbonyls or metal carbonyl derivatives, such as $Fe(CO)_5$, $Cr(CO)_6$, $Mo(CO)_6$, $[Co(PPh_3)_2(CO)_3]BPh_4$ and [Fe(morphorine)][$Fe(CO)_4$] did not promote the reactions. The use of $[Co(PPh_3)_2(CO)_3][Co(CO)_4]$ promoted the reaction to give *N*-cyclohexyldichloroacetamide, $Co(C_6H_{11}NC)_4Cl_2$ and $Co(PPh_3)_2(CO)_2Cl_2$. The results of the reaction are listed in Table 1.

It has been reported by Halleux that *N*-cyclohexyldichloroacetimidate was obtained from the reaction of cyclohexyl isocyanide with dichlorocarbene, prepared from potassium methoxide and chloroform, and it decomposed spontaneously to produce *N*-cyclohexyldichloroacetamide.[4]

a) Based on $Co_2(CO)_8$ employed. b) All complexes, $Co(CNR)_4X_2$, decomposed.
c) KBr method, N≡C band.

The fact that *N*-substituted dihaloacetamides or *N*-cyclohexyldichloroacetimidate was obtained in our reaction suggested the existence of dihaloketenimine as the intermediates of the reactions. In order to confirm the formation of carbenes, the reaction of $[Co(CO)_3(PPh_3)_2][Co(CO)_4]$ with carbon tetrachloride or carbon tetrabromide was carried out in cyclohexene. The reaction gave 7,7-dichloronorcarane and $Co(CO)_2(PPh_3)_2Cl_2$, or 7,7-dibromonorcarane and $Co(CO)_2(PPh_3)_2Br_2$. These results suggest the formation of the carbene intermediates.

The possible pathway for the reaction may be sketched in the following manner:

$$5R\text{-}N{\equiv}C + Co_2(CO)_8 \rightarrow Co(CNR)_5Co(CO)_4 + 4CO \quad (1)$$
$$(I)$$

$$I + 2CX_4 + 5RNC \rightarrow 2Co(CNR)_4X_2 + 4CO + 2RN{=}C{=}CX_2 \quad (2)$$

$$RN{=}C{=}CX_2 + H_2O \rightarrow RNHCOCHX_2$$
$$RN{=}C{=}CX_2 + CH_3OH \rightarrow RNC{=}C(OCH_3)CHX_2 \quad (3)$$

When $Co_2(CO)_8$ was added to excess isocyanide, it reacted with isocyanide, as was reported by Sacco,[5] to yield $Co(CNR)_5Co(CO)_4$ by the evolution of 4 mol of carbon monoxide, according to Eq. (1). In addition, the evolution of 4 mol more of carbon monoxide was observed, when carbon tetrahalogenide was added to the reaction mixture. This fact showed that *N*-substituted dihalokenimine and $Co(CNR)_4X_2$ were formed, according to Eq. (2). *N*-Substituted dihaloketenimine rapidly reacted with water or methanol to produce the corresponding amide or imidate.

Experimental

Materials. Various isocyanides[6] and transition metal complexes[7] were prepared according to the prescription given in literature.

The Reaction of Cyclohexyl Isocyanide with Carbon Tetrachloride in the Presence of $Co_2(CO)_8$. To a solution of 1.0 g of $Co_2(CO)_8$ in 25 ml of *n*-hexane was added 2.3 g of cyclohexyl isocyanide. After 20 min, into this was added 5.0 g of aqueous carbon tetrachloride (*ca.* 5% H_2O) with constant stirring at room temperature. The reaction was completed within 2 hr to give dark green solution, with the precipitaiton of a green solid. Precipitate was filtered and washed by *n*-hexane. It was found to be $Co(CNC_6H_{11})_4Cl_2$ and was soluble in acetone and chloroform, but was insoluble in petroleum ether. The evaporation of the filtrate gave raw products of *N*-cyclohexyl dichloroacetamide, which was recrystallizad by benzene-acetone mixture. The infrared spectrum and the melting point of this

product were identical with those of authentic *N*-cyclohexyldichloroacetamide.

By analogous procedure, other *N*-substituted dihaloacetamides and dihalotetrakis(isocyanide)cobalt(II) were obtained. Their melting points, analyses and infrared spectra are summarized in Table 1.

The Reaction of Carbon Tetrachloride with $[Co(CO)_3(PPh_3)_2][Co(CO)_4]$ in the Presence of Cyclohexene. Carbon tetrachloride (5.4 g) was added to a mixture of $[Co(CO)_3(PPh_3)_2][Co(CO)_4]$ (4.5 g) and cyclohexene (20 m*l*) at room temperature. After the reaction mixture had been kept for 2.5 hr with constant stirring, a pale green precipitate was filtered, and found to be $Co(CO)_2(PPh_3)_2Cl_2$(3.65 g, mp 82—83°C). Glpc analysis of the distillate of the filtrate showed the presence of 7,7-dichloronorcarane, which was identified by comparison of its glpc retention time with that of an authentic sample.

Found: C, 64.52; H, 4.39; Cl, 10.15%. Calcd for $Co(CO)_2(PPh_3)_2Cl_2$: C, 64.24; H, 4.26; Cl, 9.98%.

The Structure Theory of Water. II. The Thermodynamic Properties of Liquid Deuterium Oxide

Kiyoshi ARAKAWA, Katsutaka SASAKI and Yuko ENDO

Research Institute of Applied Electricity, Hokkaido University, Sapporo

(Received December 20, 1968)

In the preceding paper[1] (Part I), a statistical thermodynamic theory was successfuly applied to liquid water, based on a two state model which consists of an ice-like structure (class I) and unbonded monomers (class II). The same treatment has been applied to liquid deuterium oxide, with the intention to explain the thermodynamic properties of the liquid and to test the applicability of the two state model.

In the calculation of the partition function (Part I), the two quantities, *viz.*, the energy difference between class I and class II, ε, and the free volume for the molecule in class II, v_f, were used as adjustable parameters. The values of the parameters were estimated to be 3 kcal/mol and 4.0×10^{-25} cm^3 respectively. They are in line with the thermodynamic properties of the liquid water. In the present calculation the same value for v_f has been used, since the dimension of the molecule and the dipolar interactions *etc.* of D_2O are practically the same as those of H_2O.[2]

For the magnitude of ε for D_2O a higher value is required than for H_2O, since the energy of sublimation for the former ($\Delta E_{\text{subl}}^{D_2O}$: 12.08 kcal/mol) is larger than that of the latter ($\Delta E_{\text{subl}}^{H_2O}$: 11.65 kcal/mol).[2] Considering that the van der Waals interactions between D_2O molecules may be nearly the same as those between H_2O molecules, the magnitude of ε for D_2O is estimated to be 3.4 kcal/mol.

$$\varepsilon_{D_2O} - \varepsilon_{H_2O} \fallingdotseq \Delta E_{\text{subl}}^{D_2O} - \Delta E_{\text{subl}}^{H_2O} \tag{1}$$

Concerning the frequencies which have been attributed to intermolecular vibrations of the molecules in class I, a tentative assignment has been made with reference to the data from the infrared and Raman spectroscopy[3,4] and also by taking into account the difference in the mass and the principal moments of inertia between D_2O and H_2O molecules.[5] The ratio of librational frequencies, and that of the principal moments of inertia between D_2O and H_2O are estimated to be 1.38, and 1.91 respectively, according to Swain and Bader.[5] The values for ν_i and A, B, C are given in Table 1.

TABLE 1. INTERMOLECULAR VIBRATIONAL FREQUENCIES AND PRINCIPAL MOMENTS OF INERTIA FOR D_2O

Calculation of Thermodynamic Variables.

According to the statistical mechanical theory reported in Part I, calculations of thermodynamic variables for liquid D_2O have been made over the temperature range from 4—60°C, using the values of parameters described above. The calculated values of the Helmholtz energy, A, the internal energy, E, the entropy, S, and the specific heat at constant volume, C_v, are given in Table 2. The results calculated are compared with the experimental data for liquid D_2O and also with the results calculated by Némethy and Scheraga.[2] They are plotted against temperature in Figs. 1—4. The mole fraction x of hydrogen bonded portion is calculated and given in Table 3, together with the ratio, x_{D_2O}/x_{H_2O}.

TABLE 3. FRACTION OF HYDROGEN BONDED PORTION, x

Temp. (°C)	x_{D_2O}	x_{D_2O}/x_{H_2O}*
4	0.514	1.03
10	0.479	1.03
20	0.427	1.03
30	0.378	1.03
40	0.336	1.03
50	0.298	1.02
60	0.268	1.02

* The values of x_{H_2O} are those calculated in Part I.

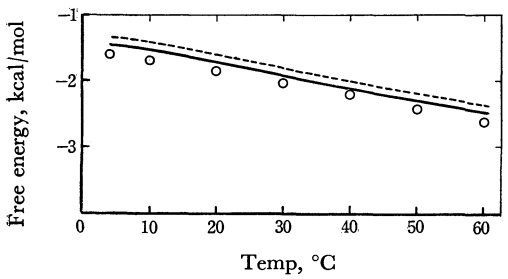

Fig. 1. Helmholtz energy, A, for liquid D_2O. Circle, observed: Solid ine, calculated; Dotted line, Némethy and Scherage[2]

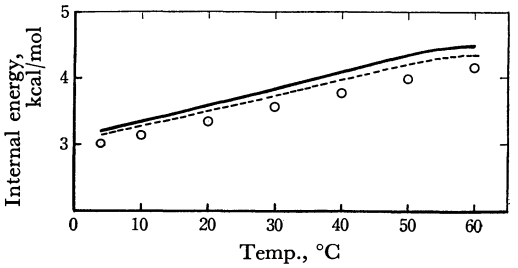

Fig. 2. Internal energy, E, for liquid D_2O. Circle, observed; Solid line, calculated; Dotted line, Némethy and Scheraga[2]

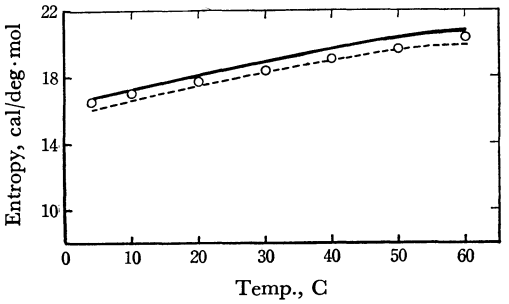

Fig. 3. Entropy, S, for liquid D_2O. Circle, observed; Solid line, calculated; Dotted line, Némethy and Scheraga[2]

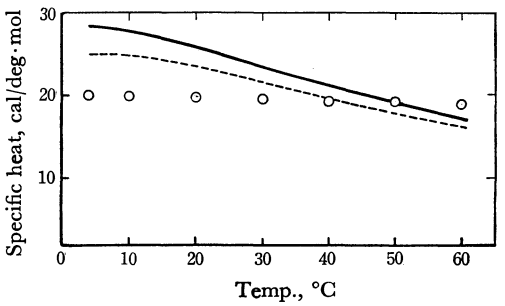

Fig. 4. Specific heat, C, for liquid D_2O. Circle, observed; Solid line, calculated; Dotted line, Némethy and Scheraga[2]

As seen in Figs. 1—4, the agreement between calculated and observed values for D_2O is fairly good, except that deviations are seen in the values of C_v. In the present calculation for D_2O, the parameters, ε, v_f, and v_t have been fixed theoretically as compared with those for H_2O. Thus we might say that agreement is satisfactory.[2,6]

It seems reasonable from observed data[2] that in liquid D_2O the degree of hydrogen bonding is higher than for liquid H_2O. The ratio, x_{D_2O}/x_{H_2O} given in Table 3 is in line with this view.

We see that the thermodynamical behavior of liquid D_2O is described adequately by using the value of ε_{D_2O} which is larger than ε_{H_2O}. The results support the idea that the bond strength of O—D···O is stronger than that of O—H···O.

It is concluded that the two state theory for liquid water (Part I) gives an adequate representation of thermodynamical behaviors of liquid D_2O.

(Received December 24, 1968)

The preparation of a large number of pentammine and tetrammine cobalt(III) complexes containing L-amino acids as unidentate ligands were given in previous papers,[1,2] and the studies on the so-called vicinal effect due to the coordinated L-amino acids by means of rotatory dispersion (RD) and circular dichroism (CD) were reported.

From these studies, it was shown that the magnitude of inversive dispersion of RD and the intensity of CD in the d→d transition band region are enhanced by the sterical restriction of the conformational mobility of the coordinated L-amino acid. As a supplement to these studies, some new tetramminebis(amino-acid)cobalt(III) complexes are described in the present paper. The following abbreviations are used for the amino acid ligands: glyH = $CH_2(COO^-)NH_3^+$, alaH = $CH_3CH(COO^-)NH_3^+$, β-alaH = $CH_2(COO^-)CH_2NH_3^+$, sarH = $CH_2(COO^-)(NH_2CH_3)^+$, and proH = $CH(COO^-)CH_2CH_2CH_2NH_2^+$.

Experimental

cis-Tetrammine(β-alanine)(L-alanine)cobalt(III) Perchlorate and cis-Tetrammine(sarcosine)(L-alanine)cobalt(III) Perchlorate: cis-$[Co(NH_3)_4(\beta\text{-alaH})(L\text{-alaH})](ClO_4)_3$ and cis-$[Co(NH_3)_4(sarH)(L\text{-alaH})](ClO_4)_3$. The crude complexes were obtained by a method similar to that employed in the preparation of cis-$[Co(NH_3)_4(glyH)(L\text{-alaH})](ClO_4)_3\cdot 2H_2O$.[2] Purification was carried out by reprecipitation from their methanol solutions with dropwise addition of ether. These purple complexes are readily soluble in water and acetone, but insoluble in ether. The elemental analyses were made after dehydrating them on phosphorus pentoxide in a vacuum desiccator.

Found: C, 11.78; H, 4.37; N, 13.64%. Calcd for $C_6H_{26}N_6O_{16}Cl_3Co$: C, 11.94; H, 4.35; N, 13.93%.

Found: C, 12.02; H, 4.30; N, 13.67%. Calcd for $C_6H_{26}N_6O_{16}Cl_3Co$: C, 11.94; H, 4.35; N, 13.93%.

cis-Tetramminebis(L-proline)cobalt(III) Perchlorate: cis-$[Co(NH_3)_4(L\text{-proH})_2](ClO_4)_3$. A solution of cis-$[Co(NH_3)_4(OH_2)_2](ClO_4)_3$[3] and the calculated amount of L-proline in a small amount of water was warmed on a water-bath at 65°C for about seven hours. After the resulting solution had been kept for two days at room temperature, a large amount of methanol-ether mixture (2 : 1) was added to it. Purification of the crude product obtained was made from the methanol solution by the addition of ethanol-ether mixture (2 : 1). This was dehydrated on phosphorus pentoxide in a vacuum desiccator.

Found: C, 18.05; H, 4.54; N, 12.81%. Calcd for $C_{10}H_{30}N_6O_{16}Cl_3Co$: C, 18.32; H, 4.62; N, 12.82%.

The preparation of the other complexes studied has

already been reported.[2] The CD curves were obtained by a Model ORD/UV-5 spectrophotometer of Japan Spectroscopic Co. and the absorption spectra by a Shimadzu QR-50 spectrophotometer; the measurements were made in aqueous solutions at room temperature. The CD curves are shown in Fig. 1 and their extremum data are listed in Table 1.

Discussion

The analytical results and the absorption spectra of the complexes obtained obviously indicate that the amino acid ligands are coordinated to the cobalt(III) ion with the oxygen atom of the carboxyl group, and that the two oxygen donor atoms are situated at the *cis* positions of an octahedron. Therefore all of the complexes studied here have a general type of coordination, namely *cis*-[$Co(N)_4(O)_2$] structure.

In the first absorption band region, the CD bands of the *cis*-[$Co(OH_2)(NH_3)_4$(L-alaH)]$^{3+}$ complex are very weak in contrast to those of the other complexes (Fig. 1). The CD bands of the [$Co(NH_3)_5$(L-alaH)]$^{3+}$ complex, which contains only one L-alanine ligand, is also very weak.[1] If the aquo ligand in the (aquo)(L-alanine) complex is replaced by another amino acid ligand, the CD bands are considerably intensified (Fig. 1). In these complexes, the two amino acids in *cis* positions should take conformations somewhat restricted by the mutual interaction between them. The interaction between the L-alanine and the aquo ligands in the (aquo)(L-alanine) complex will be less than that between the two amino acid ligands in a bis(amino-acid)tetrammine complex. Thus the enhancement of the CD intensity may be attributed to the sterical restriction of the conformational mobility of the L-alanine ligand.

The *cis*-[$Co(N)_4(O)_2$] structure has a symmetry of C_{2v}, and two CD components are expected in the region of the first absorption band of these complexes. Indeed they show the two CD bands; the longer wavelength bands of all the complexes are positive in their signs. A positive CD band is also commonly observed in the second absorption band region for each L-amino acid complex. These CD bands of the bis(amino-acid) complexes will

be useful in determining the absolute configurations of amino acids. It has already been reported that the complexes of *trans*-$[Co(en)_2(L\text{-amino-acid})_2]^{3+}$ type have positive CD signs in the longer wavelength component of the first absorption band, and also in the second absorption band. Dunlop and Gillard[4] proposed the use of the complexes of $[Co(NH_3)_5(OCOR)]^{n+}$ type for the determination of absolute configuration of the $RCOO^-$, and this was criticized by Hawkins and Lawson.[5] The latter authors stated that the pentammine type complexes with the L-ligands impose a positive sign to the $^1A_1 \rightarrow {}^1E$ and a negative sign to the $^1A_1 \rightarrow {}^1A_2$ transition in the first absorption band region. Almost all of the pentammine type complexes, however, show only one component in the first absorption band region.[1,5] It seems that the bis(amino-acid) type complexes are more suitable for the determination of the absolute configurations of amino acids.

SHORT COMMUNICATIONS

The Structure of a New Flavone, "Arthraxin"

Makoto KANETA and Noboru SUGIYAMA

Fukushima Technical College, Fukushima, and Department of Chemistry, Tokyo Kyoiku University, Otsuka, Tokyo

(Received April 7, 1969)

We have isolated from *Arthraxon hispidus* Makino, commonly called "Kobunagusa," a new flavonoid (I, mp 336°C, empirical formula $C_{21}H_{16}O_9$), which we wish to call "arthraxin." Kobunagusa has been used as a source of natural dyestuff for "Kihachijo," which is a traditionally well-known brilliant yellow silk cloth produced on Hachijo island. The only report on a chemical study of the dyestuff has been made by Hayashi *et al.*,[1] and they did not succeed in obtaining a pure substance because of the difficulty of purification.

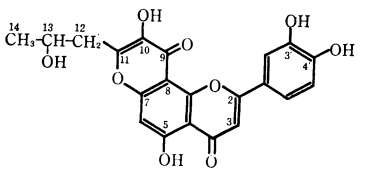
Compound I has neither methoxyl nor methylenedioxy groups, and it forms a penta methyl ether (II), $C_{21}H_{11}O_4(OCH_3)_5$ and a penta acetate (III), $C_{21}H_{11}O_4(OCOCH_3)_5$. The ultraviolet absorption spectrum of I in ethanol showed characteristic absorption bands at 256, and 340 mμ and a pronounced inflection at 273 mμ. The λ_{max} of the band at 256 mμ did not shift with the addition of anhydrous sodium acetate. This fact indicated the absence of the hydroxyl group or the presence of the protected hydroxyl group at C^7.[2] The infrared absorption spectrum of I demonstrated the presence of the >CO of γ-pyrone by the band at 1645 cm^{-1} and the absence of a furan ring or a lactone grouping in the molecule. On fusion with caustic potash, I yielded protocatechuic acid and pholoroglucinol.

The NMR spectrum of I in deuterated DMSO indicated the presence of 1H at C^6 (τ 3.70, s), C^3 (τ 3.35, s),[3] C$^{5'}$ (τ 3.10—3.20,m), C$^{2'}$, and C^6 (τ 2.60—2.75, m).[4] The spectrum also suggested the presence of the CH_3–$\underset{\underset{OH}{|}}{CH}$–$CH_2$– grouping by the signals at τ 8.50 (d, 3H of –CH_3), τ 7.20—7.40 (m, 2H of –CH_2–), and τ 5.30 (m, 1H of –CH–). The NMR spectrum of II in $CDCl_3$ showed the presence of five OCH_3 groups by the signals at τ 6.50 (s, 3H), τ 6.15 (s, 3H), τ 6.10 (s, 3H), τ 6.05 (s, 3H), and τ 5.95 (s, 3H).[5] The mass spectra further showed the presence of five OH groups in I by the difference in the molecular weights of II (482) and I (412).[6]

On the basis of these results, it can be considered that I is a luteolin derivative with a $C_6H_8O_4$ residue attached at C^7 and C^8. As three OH groups are present in the benzene rings, the remaining two OH groups must be present in this $C_6H_8O_4$ residue. The mass spectrum of I gave the fragments of *m/e* 397 and 379, which were interpreted by the general pattern of fragmentation:

$$\underset{(412)}{R\text{-}\underset{\underset{OH}{|}}{CH}\text{-}CH_3} \xrightarrow[-CH_3]{} \underset{(397)}{[R\text{-}\underset{\underset{OH}{|}}{CH}]^+} \xrightarrow[-H_2O]{} \underset{(379)}{[R\text{-}CH{=}CH]^+}$$

From these data and the fragmentations of the mass spectra of I and II, the following structure was deduced to be the most probable one for arthraxin.



The structure of flavone, in which a side-chain, CH_3–$\underset{\underset{OH}{|}}{CH}$–$CH_2$– or a γ-pyrone ring is attached to the benzene ring, has not yet been established.

An ESR Study of the Copper(II) Complexes of DL-α-Alanine and L-α-Alanine

Hiroshi Yokoi and Taro Isobe

Chemical Research Institute of Non-aqueous Solutions, Tohoku University, Katahira-cho, Sendai

(Received May 6, 1969)

The copper(II) complexes of α-amino acids contain almost planar chelate rings; therefore, no stereospecificity is expected.[1,2] An investigation of the properties of the copper(II) complexes of α-alanines, both in solution and in the solid state, has shown that there are almost no differences in properties between the copper(II) complexes of racemic- and *laevo*-α-alanines, except in some specific points.[1]

The purpose of this communication is to report the ESR results for the copper(II) complexes of racemic- and *laevo*-α-alanines, both in solution and in the solid state. Figure 1 shows the K-band ESR

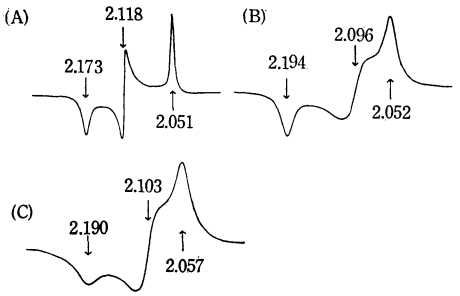

Fig. 1. The powder ESR spectra (K-band, 22°C). The numbers in this figure indicate *g* values.
(A) [Cu(DL-α-alanine)$_2$]·H_2O
(B) [Cu(DL-α-alanine)$_2$]
(C) [Cu(L-α-alanine)$_2$]

spectra of the powdered samples at room temperature. This figure indicates that the water of crystallization of [Cu(DL-α-alanine)$_2$]·H_2O, I, plays the very important role in determining the properties of the complex in a crystal, and that there is a clear difference in the absorption line shape between

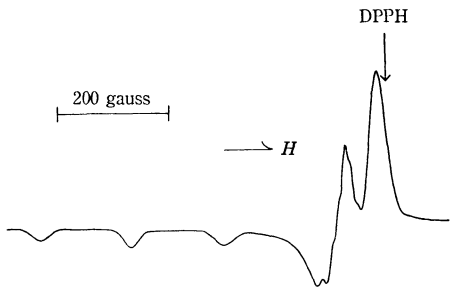

Fig. 2. The X-band ESR spectrum of [Cu(DL-α-alanine)$_2$] in aqueous-methanolic solution at 77°K.

[Cu(DL-α-alanine)$_2$], II, and [Cu(L-α-alanine)$_2$], III, the former bing prepared by the elimination of the water of crystallization of I at 165°C *in vacuo*.

Figure 2 shows the X-band ESR spectrum of I in an equivolume mixture of water and methanol at the temperture of liquid nitrogen. The results determined for the complexes in the solution are as follows:

I: $g_{//}=2.264$, $A_{//}=178\times10^{-4}\text{cm}^{-1}$,
$A_N^{\perp}=11.7\times10^{-4}\text{ cm}^{-1}$

III: $g_{//}=2.264$, $A_{//}=175\times10^{-4}\text{cm}^{-1}$
$A_N^{\perp}=11.1\times10^{-4}\text{ cm}^{-1}$

$A_N^{\perp}$ was determined from the super-hyperfine structure observed on the $g_{\perp}$ component by the second-derivative X-band ESR measurements. These results show that there is a significant difference in the values of $A_{//}$ and $A_N^{\perp}$ between I and III in solution.

In conclusion, all the ESR results obtained here indicate that there is some stereospecific difference in electronic structure between the copper(II) complexes of racemic- and *laevo*-α-alanines, both in solution and in the solid state. The details will be published elsewhere.

Effect of Phase on the Trapped Radical in the Radiolysis of Solid Isobutane as Studied by ESR Spectroscopy

Tetsuo MIYAZAKI, Terunobu WAKAYAMA, Kenji FUEKI and Zen-ichiro KURI

Department of Synthetic Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya

(Received May 8, 1969)

The solvent radicals observed in the radiolysis of solid hydrocarbons are mostly formed by the C–H bond rupture. Since the yields of the radicals are generally not affected by the addition of electron scavengers[1] or by the photobleaching of trapped electrons,[1] the mechanism of their formation cannot be explained simply in terms of charge neutralization reactions. Recently the present authors reported that the addition of carbon tetrachloride to solid isobutane suppresses the production of the solvent radicals.[2,3]

In this work we have observed that quite different radicals are trapped in the radiolysis of isobutane depending on whether it is in the glassy or the crystalline state. The ESR spectrum of γ-irradiated pure isobutane, which is polycrystalline at 77°K, is shown in Fig. 1a. The spectrum can be assigned to the isobutyl radical.[4] An isobutane (92 mol%)—3-methylpentane (8 mol%) mixture can be frozen to a clear glass by rapid cooling or to a polycrystal by slow cooling at 77°K. Upon the γ-irradiation of the mixture in the polycrystalline state, the ESR spectrum shown in Fig. 1b was obtained; it is the same as the spectrum obtained in the radiolysis of pure isobutane at 77°K. A quite different ESR spectrum, however, was obtained by the γ-irradiation of the mixture in the glassy state (Fig. 1c). The spectrum consists of ten equally-spaced lines with a coupling constant of 22.3G; the value is consistent with the value of 22.5G for the t-C_4H_9 radical.[5] The spectrum coincides with the spectrum of t-C_4H_9 radicals produced by dissociative-electron attachment to t-C_4H_9Br in the radiolysis of 3-methylpentane containing 5 mol% t-C_4H_9Br at 77°K.

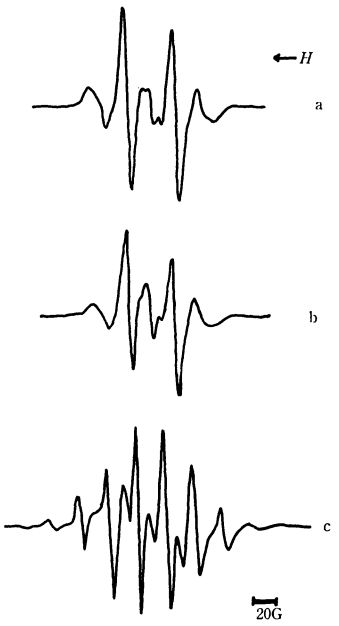

Fig. 1. (a) ESR spectrum of γ-irradiated isobutane at 77°K.
(b) ESR spectrum of γ-irradiated isobutane (92 mol%)–3-methylpentane (8 mol%) mixture in the polycrystalline state at 77°K.
(c) ESR Spectrum of γ-irradiated isobutane (92 mol%)–3-methylpentane (8 mol%) mixture in the glassy state at 77°K.
Irradiation dose: 3.7×10^5 rad, Spectrometer gain setting of figures a, b and c were 67 db.

Such a phase effect in the radiolysis of solid hydrocarbons has not been reported previously. Further studies of this phenomenon are now in progress.

The Spectral Blue Shift of Li(TCNQ) at High Pressures

Ichimin SHIROTANI, Nobuko SAKAI, Hiroo INOKUCHI and Shigeru MINOMURA

The Institute for Solid State Physics, The University of Tokyo, Roppongi, Tokyo

(Received May 19, 1969)

The energies of the electronic transitions of most organic crystals are shifted toward the lower side with an increase in the pressure.[1-3] However, the absorption band at 540 mμ of quaterrylene ($C_{40}H_{20}$) evaporated film is less affected by the pressure,[4] and in the cases of azulene and ferrocene a small blue shift is observed at high pressures.[5]

The activation energy of Li(TCNQ) decreases from 0.32 eV at 1 bar to 0.07 eV at 169 kbar.[6] However, a large blue shift was observed with a change in the pressure on the absorption spectra of Li(TCNQ).

A hydrostatic pressure was applied to the optical cell by means of a pressure-transmitting medium, kerosene, up to 7 kbar at room temperature.

Figure 1 shows the absorption spectra of crystalline Li(TCNQ) at 1 bar and 5.4 kbar. Two bands situated in the visible region showed a large blue shift with an increase in the pressure. The rates of pressure shift are listed in Table 1. Since the crystalline absorption spectrum is similar to that of the dimer $(TCNQ^-)_2$ in an aqueous Li(TCNQ) solution,[7] the large blue shift may be explained by assuming a bimolecular association of $(TCNQ^-)$ ion radicals in the solid.

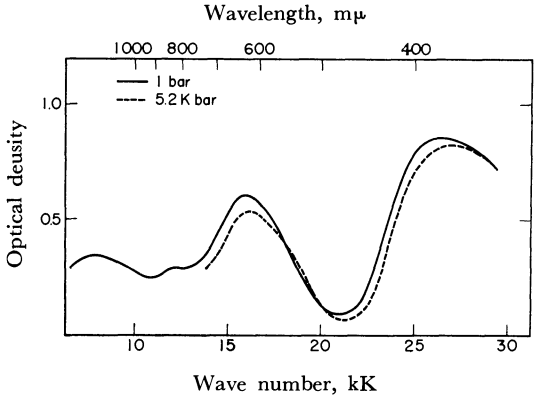

Fig. 1. The pressure dependece of the absorption spectra of Li(TCNQ).

Table 1. Pressure shift of the optical absorption peak for several anion radical salts

Compound	Absorption peak (kK)	Pressure shift (cm^{-1}/kbar)
Li(TCNQ)	26.5	+86
	16.0	+51
	7.7	—
K(TCNQ)	27.5	+58
	16.1	+45
	8.3	—
DAD(TCNQ)	25.8	+52
	11.6	—
Na(chloranil)	26.2	+62
	11.8	−58
Azulene	14.4	+ 6[a]
Ferrocene	23.3	+20[a]

a) Ref. 5

However, the absorption band of the salt in a PVA solid solution was insensitive to the applied pressure. Therefore, it is assumed that the major contribution to the blue shift does not arise from the bimolecular association in the crystalline state, but from the crystal field of metal-positive ions.

The near-infrared band at 7.7 kK observed in the solid Li(TCNQ) can be assigned to an inter-radical charge-transfer band.[8] The pressure effect on this peak could not be observed because of interference by the transmitting fluid. Generally, the charge-transfer bands of molecular complexes show a red shift at high pressures.[2] The low-energy band at 7.7 kK may be expected to be shifted to the red with a change in the pressure.

Similar results for K(TCNQ), diaminodurene (DAD) (TCNQ), and Na(chloranil) are listed in Table 1. The 11.8 kK band of Na(chloranil), which did not appear in solution spectra, showed a red shift at high pressures. This may be ascribed to the inter-radical charge-transfer band in the solid.

Natural Occurrence of Humuladienone, Humulenone-II, and α-Corocalene; New Constituents of Hop Oil

Yoko NAYA and Munio KOTAKE

The Institute of Food Chemistry, Dojimanaka, Kita-ku, Osaka

(Received May 23, 1969)

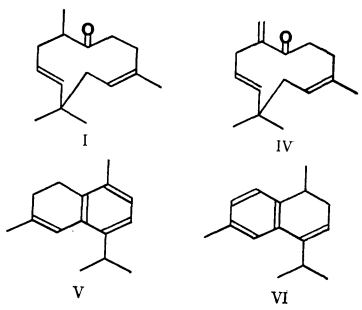
By a combination of fractionation, column chromatography over silica gel and neutral alumina-silver nitrate, and preparative GLC, it has now been possible to isolate the titled sesquiterpenes, (I), (IV), and (V), from the Japanese hop (*Humulus lupulus* L.).

Compound (I), $C_{15}H_{24}O$, $[\alpha]_D^{24}$ +5.0° (c=0.68, $CHCl_3$) is a colorless oil which exhibited carbonyl absorption (1705 cm^{-1}) in the infrared spectrum. Other peaks of diagnostic value were at 1380, 1363 (gem-dimethyl), and 975 and 840 cm^{-1} (C=C *trans*). Its NMR spectrum*1 showed a singlet at 1.01 (6H, tertiary methyl) and a doublet at 1.04 (3H, J=6.8 cps, secondary methyl); the doublet (3H, J=1 cps) at 1.59 is assignable to a methyl on a trisubstituted olefinic linkage; complex multiplets located between 4.80 and 5.25 accounted for three vinyl protons (HC=CH and CH_3C=CH–). Its MS spectrum exhibits the molecular ion peak at *m/e* 220 and the base peak at *m/e* 96, together with quite an abundant peak at *m/e* 138.

On catalytic hydrogenation over PtO_2 in ethanol, I took up one mole of hydrogen to yield (II), $C_{15}H_{26}O$ (M^+, *m/e* 222). Examination of its IR and NMR spectra revealed that the *trans* C=C bond has been reduced and that CH_3C=CH is still present. On the other hand, the hydrogenation of I by the same catalyst in acetic acid gave the saturated compound (III), $C_{15}H_{28}O$, (M^+, *m/e* 224).

All the above data are compatible with the structure (I) for humuladienone. Such a formulation was also supported by the co-occurrence of humulenone-II (IV), which is identical (IR, NMR) with the ketone derived from humulenol-II by Damodaran and Dev.[1] The final conclusion was obtained by the partial hydrogenation of IV over PtO_2 in ethanol-ether, where two products were provided. The main product of the hydrogenation had an IR spectrum completely superimposable on that of I, while the other was found to be identical with that of II.

In addition, it may be noted from the solvent effect on the NMR spectra that the methyl group adjacent (α) to a carbonyl function of humuladienone (I) seems to exist in a pseudo-axial nature: ($\Delta=\delta^{obs.}_{CCl_4}-\delta_{C_6H_6}$=0.1 ppm). A similar range of up-field shift is also observed for the hydrogenated derivatives, II and III.



For compound (V), $C_{15}H_{20}$ (M^+, *m/e* 200), we propose the name α-corocalene. The other ingredient of the same fraction was γ-calacorene (VI), which afforded calamenene on catalytic hydrogenation and which was identical with the compound isolated from *Juniperus rigida* (IR, NMR, MS, UV).[2] The infrared spectrum of V showed a characteristic absorption for an aromatic compound (3050, 1875, 1650, 1595, 1480, 860, 815 cm^{-1}). Moreover, the NMR spectrum exhibited a doublet at 1.22 (6H, J=7.5 cps) and a singlet at 2.19 (3H) which are assignable to an isopropyl and a methyl on an aromatic ring respectively; a doublet (3H, J=1 cps) at 1.94 and a broad singlet at 6.48 (1H) accounting for the group, CH_3C=CH, conjugated to an aromatic ring, and a singlet at 6.86 (2H) and a complex signal located between 2.57 and 3.50 (4H) which are attributable to two aromatic protons and two allylic methylenes respectively. The catalytic hydrogenation of V resulted in the uptake of one mole of hydrogen to give a dihydro-α-corocalene (VII), $C_{15}H_{22}$ (M^+, *m/e* 202). The characteristics mentioned above support the structure of 1,6-dimethyl-4-isopropyl-7,8-dihydronaphthalene for α-corocalene. The IR spectra of V and VII were identical with those of authentic compounds, which were synthesized by Šorm *et al.*[3]

*1 All the NMR spectra were taken in CCl_4 on a JEOL C-60 spectrometer, with TMS as the internal reference. The values are reported in ppm.

Preparation and Optical Resolution of μ-Amido-μ-superoxo and μ-Amido-μ-peroxo Tetrakis(α-di-imine) Dicobalt(III) Ions

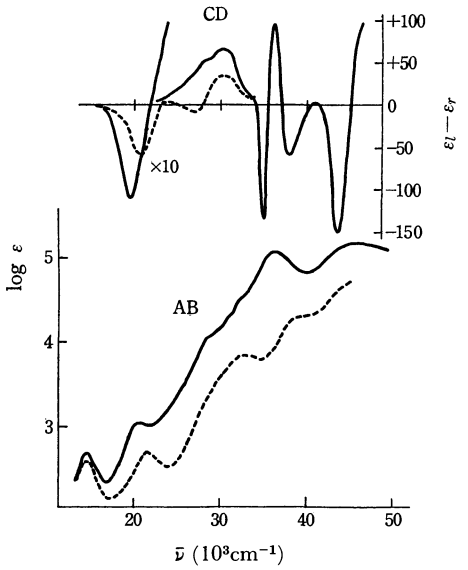
Yoichi SASAKI and Junnosuke FUJITA

Department of Chemistry, Faculty of Science, Tohoku University, Katahita-cho, Sendai

(Received May 26, 1969)

New binuclear cobalt(III) complexes of the type, $[L_2Co(\mu\text{-}NH_2,O_2)CoL_2](ClO_4)_n$, where L is 1,10-phenanthroline (phen) or 2,2′-bipyridyl (bip), and $n=3$ and $n=4$ correspond to the so-called μ-peroxo and μ-superoxo form, respectively, were prepared and resolved into their optical isomers. These are first examples of binuclear cobalt(III) complexes involving conjugated aromatic ligands, and their circular dichroism (CD) spectra will provide useful information in elucidating the electronic state of binuclear complexes. The μ-peroxo complexes were precipitated by warming a mixture of $[(NH_3)_4Co(\mu\text{-}NH_2,O_2)Co(NH_3)_4](ClO_4)_4$ and phen or bip (molar ratio 1 : 4) in methanol at 60°C for 10 hr, and recrystallized from hot water. The μ-superoxo complexes were obtained by adding solid sodium perchlorate to 7N nitric acid solutions of the corresponding μ-peroxo complexes. Found: C, 47.75; H, 2.72; N, 10.29%. Calcd for $C_{48}H_{36}N_9O_{15}Co_2Cl_3=[(phen)_2Co(\mu\text{-}NH_2,O_2)Co(phen)_2](ClO_4)_3\cdot H_2O$: C, 47.76; H, 3.01; N, 10.44%. Found: C, 43.60; H, 2.94; N, 9.34%. Calcd for $C_{48}H_{38}N_9O_{20}Co_2Cl_4=[(phen)_2Co(\mu\text{-}NH_2,O_2)Co(phen)_2](ClO_4)_4\cdot 2H_2O$: C, 43.66; H, 2.90; N, 9.55%. Found: C, 42.99; H, 3.31; N, 11.45%. Calcd for $C_{40}H_{38}N_9O_{16}Co_2Cl_3=[(bip)_2Co(\mu\text{-}NH_2,O_2)Co(bip)_2](ClO_4)_3\cdot 2H_2O$: C, 42.71; H, 3.41; N, 11.21%. Found: C, 39.69; H, 3.11; N, 10.50%. Calcd for $C_{40}H_{36}N_9O_{19}Co_2Cl_4=[(bip)_2Co(\mu\text{-}NH_2,O_2)Co(bip)_2](ClO_4)_4\cdot H_2O$: C, 39.82; H, 3.01; N, 10.45%. The racemic μ-peroxo complexes were converted into chloride and treated with silver *d*-antimonyltartrate to be resolved into optical isomers. The optically active μ-superoxo complexes were prepared from the corresponding active μ-peroxo complexes.

As the figure shows, the CD spectrum of $(+)_D$-μ-superoxo-phen complex is similar to that of $(-)_D$-$\Lambda\Lambda$-$[(en)_2Co(\mu\text{-}NH_2,O_2)Co(en)_2]^{4+}$ (en= ethylenediamine)[1] in the visible region. Furthermore, the phen complex gives a strong negative and a positive CD component from longer to shorter wavelength corresponding to the π–π^* transition of chelated phen (34000—37000 cm^{-1}). These results lead to the conclusion that the $(+)_D$-μ-superoxo-phen complex has $\Lambda\Lambda$ absolute configuration.[2,3] The enantiomers, $(+)_D$-μ-peroxo-phen, $(+)_D$-μ-superoxo-bip and $(+)_D$-μ-peroxo-bip have also $\Lambda\Lambda$ configuration.



Fig, 1. The absorption (AB) and CD spectra of $(+)_D$-$[(phen)_2Co(\mu\text{-}NH_2,O_2)Co(phen)_2](ClO_4)_4$ in 60% perchloric acid (——) and $\Lambda\Lambda$-$[(en)_2Co(\mu\text{-}NH_2,O_2)Co(en)_2](NO_3)_4$ in water (------).

Luminol Amidine

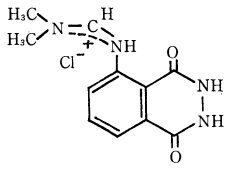
Yoshimori OMOTE, Hiroshi YAMAMOTO, Shoji TOMIOKA and Noboru SUGIYAMA

Department of Chemistry, Tokyo Kyoiku University, Otsuka, Tokyo

(Received May 30, 1969)

Luminol, one of the most popular chemiluminescent compounds, has been used as an indicator in titration analysis.[1] Recently luminol was shown to be a mixture and not a pure compound, as had usually been believed.[2] It is very difficult to purify commercial luminol by recrystallization because it is sparingly soluble in most solvents.

During the course of synthetic studies of luminol derivatives we found that luminol reacts with the Vilsmeier reagent from dimethylformamide (DMF) and thionyl chloride to afford luminol amidine (I), which is moderately soluble in water and which is easily purified by recrystallization from water.



The luminol amidine (*N,N*-dimethyl-*N'*-diketophthalazine-5-yl-formamidine) was prepared as follows: 1.77 g of luminol was dissolved in 20 m*l* of DMF, into which the Vilsmeier reagent from 2.19 g of DMF and 3.57 g of thionyl chloride was stirred. The precipitates which appeared were recrystallized from water to give colorless needles, mp 271—272°C (dec).

Found: C, 49.15; H, 4.94; N, 20.93%. Calcd for $C_{11}H_{13}O_2N_4Cl$: C, 49.16; H, 4.87; N, 20.85%. UV: $\lambda_{max}^{H_2O}$ nm (log ε), 228 (4.53), 283 (4.17) and 318 (4.17). IR: ν_{max}^{KBr} cm^{-1} 1705, 1645. NMR δ^{D_2O} 3.35 (3H, s), 3.55 (3H, s), 7.7—7.9 (3H, m) and 8.87 (1H, s).

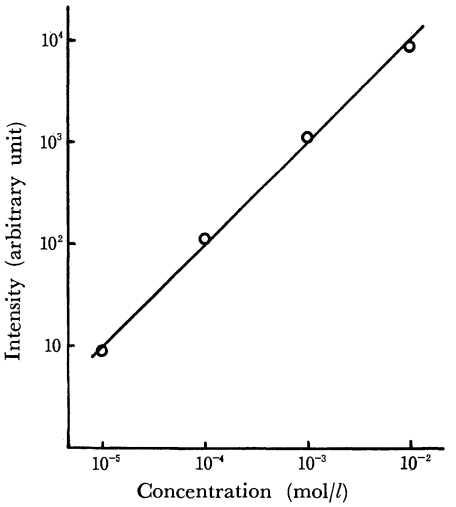


Fig. 1. The chemiluminescence intensity of luminol amidine (I) against molar concentration when the mixture of 0.3% aqueous hydrogen peroxide (0.5 m*l*) and 0.3% potassium ferricyanide aqueous solution (0.5 m*l*) was added to the solution of I in 0.1 N sodium hydroxide aqueous solution.

The chemiluminescence of luminol amidine was measured by Hitachi Photomultiplier. The relative intensity of light emission of luminol amidine is about one twenty-fifth that of luminol itself, the maximum of the chemiluminescence spectrum is 452 nm. The plot of the chemiluminescence intensity with the variation in concentration between 10^{-2} and 10^{-5} mol/*l* shows a straight line (Fig. 1). This suggests that luminol amidine will be useful as a standard compound for the chemiluminescence measurement.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 2091—2098 (1969)

Infrared Study of the Conformational Equilibria of *meso*- and *racemic*-2,3-Dichlorobutanes

Kazuyoshi IIMURA, Naoto KAWAKAMI and Masatami TAKEDA

Department of Chemistry, Faculty of Science, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo

(Received July 17, 1968)

The conformational equilibria of rotational isomers of *meso*- and *racemic*-2,3-dichlorobutanes were investigated in various solvents by an infrared method. The coexistence of three rotational isomers was found for each of the *meso* and *racemic*-2,3-dichlorobutanes. However, the equilibrium concentrations changed depending on the solvent dielectric constant. The equilibrium concentration of the less polar form of a rotational isomer, in which the conformation is extended *trans* with respect to the Cl–C–C–Cl linkage, decreased as the solvent dielectric constant increased. The energy differences between the rotational isomers in the gaseous state and in acetonitrile solvent were also discussed.

One of the present authors has examined the solvent effect on the unperturbed molecular dimensions of chlorinated *trans*- and *cis*-1,4-polybutadienes, and has found that those of chlorinated *trans*-1,4-polybutadiene changed depending on the solvent dielectric constant.[1] For chlorinated *cis*-1,4-polybutadiene the situation was obscure. These experimental findings, however, can be correlated with the solvent effect on the conformational changes of the polymer chain.

The chemical structure of chlorinated 1,4-polybutadiene manifests a head-to-head linkage of polyvinyl chloride and has adjacent CHCl groups in the polymer chain. If the *trans* chlorination takes place to the unsaturated double bond of 1,4-polybutadiene, the chemical structures of the chlorinated parts of *trans*- and *cis*-1,4-polybutadienes become the *meso* and *racemic* structures respectively. In solution, the conformation of the chlorinated part having adjacent polar C–Cl bonds would vary under the influence of an electrostatic interaction by the surrounding solvent molecules. However, the conformation of the ethylenic linkage of chlorinated 1,4-polybutadiene may not strongly depend on the solvents. The conformational structure of chlorinated 1,4-polybutadiene in solution may, therefore, be mainly subjected to the local conformations of the chlorinated parts.

An infrared study of the conformations of *meso*- and *racemic*-2,3-dichlorobutanes (hereafter abbreviated as *meso*-DCB and *racemic*-DCB respectively) should give basic information on the stable local conformations of chlorinated *trans*- and *cis*-1,4-polybutadienes respectively. Although quantitative investigations of the equilibrium concentrations of rotational isomers of *meso*- and *racemic*-DCB have been reported by Bothner-By and Naar-Colin[2] and by Anet[3] using NMR method, no detailed studies of the equilibrium concentrations in solvents with different dielectric constants have been reported. Taufen *et al.*[4] have reported on the Raman spectra of *meso*- and *racemic*-DCB and discussed the qualitative equilibrium concentrations of the rotational isomers in pure liquids only.

In the present study the infrared spectra of *meso*- and *racemic*-DCB are examined in different solvents and are discussed in terms of the solvent effect on the equilibrium concentrations of rotational isomers. In addition, the energy difference between the rotational isomers is also discussed.

Experimental

Preparations of *meso*- and *racemic*-DCB. Dried chlorine gas was reacted with *trans*- and *cis*-2-butenes (Matheson Co.; purity, 99.8%) at −20°C for 3 hr in order to prepare *meso*- and *racemic*-DCB respectively. The products were washed with water and then with a 10% sodium carbonate solution, and were dried over anhydrous calcium chloride. The *meso*- and *racemic*-DCB were distilled under atmospheric pressure, whereupon fractions with boiling points of 113—114°C and 116—118°C respectively were collected.[5] A gas-chromatographic analysis (stationary phase, Carbowax 20 M; column temperature, 117.5°C; column length, 1 m; carrier gas, helium with a speed of 40 ml/min) indicated that the amount of impurity due to

trichlorobutane is less than 1% for both isomers. The NMR spectra of the samples were completely identical with those observed by Bothner-By and Naar-Colin.[2]

Measurements of Infrared Spectra. The infrared spectra were recorded mainly for the region of 400—800 cm^{-1} using a Hitachi EPI-2 double-beam spectrophotometer with a KBr prism. Spectral observation was also made in the region of the NaCl prism for reference. In measuring the solution spectra, the absorption due to the solvent was compensated for by a variable-thickness cell filled with the solvent.

Results and Discussion

Spectra of Liquid State and the Existence of Rotational Isomers. The possible rotational isomers of *meso*- and *racemic*-DCB are shown in Fig. 1, and are designated by T, G or G'; in them the two terminal C–CH_3 bonds are located *trans* and *gauche* to each other. The *meso* and *racemic* isomers are identified by prefixing M and R respectively. In the case of the *meso* isomers, MG is a mirror image of MG'. Hence, both MG and MG' should give the same spectrum.

In general, the frequencies of C–Cl stretching vibrations, which will hereafter be abbreviated as ν(C–Cl), appearing in the region of 760—550 cm^{-1} are characteristic of the geometrical arrangments near the C–Cl bond of chlorohydrocarbons.[6-8] The number of absorption bands and their relative intensities in this region should, therefore, give information on the existence of rotational isomers of DCB. Actually, as Fig. 2 shows, two bands, at 695 and 650 cm^{-1} for *meso*-DCB, and four bands, at 703, 692, 652, and 596 cm^{-1}, for *recemic*-DCB are observed in the ν(C–Cl) region. No absorption band attributable to the ν(C–Cl) is observed in the range from *ca.* 700 cm^{-1} up to 850 cm^{-1} for either *meso*- or *racemic*-DCB. All the absorption bands appearing at frequencies higher than 850 cm^{-1} can be assigned to the C–H stretching and deformation, and C–C stretching, vibrations. The bands at 535 and 420 cm^{-1} of *meso*-DCB, like those at 559 and 522 cm^{-1} of *racemic*-DCB, can be assigned to the skeletal bending vibrations, because the frequencies of these bands are too low to be assigned to the ν(C–Cl) vibrations.

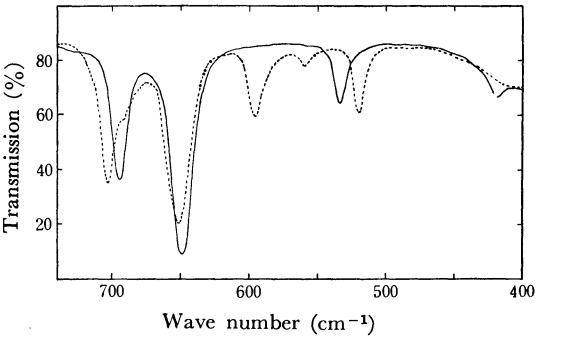

Fig. 2. The infrared spectra of liquid state.
Full line: *meso*, broken line: *racemic*

In the case of *meso*-DCB, MT should give only one infrared active ν(C–Cl) because of its C_t symmetry. The relative intensities of the two absorption bands observed in the ν(C–Cl) region would not depend on the solvents if these bands arose merely from MG and MG'. The relative intensities of these two bands, however, strongly depend on the solvents, as will be described below. This experimental finding suggests that these two bands are caused by two different components, namely, MT and MG or MG'.

As for the liquid *racemic*-DCB, two absorption bands due to the ν(C–Cl) may be expected for each of the rotational isomers. The four absorption bands observed in the ν(C–Cl) region indicate the existence of more than one rotational isomer.

Solvent Effect on the Spectra and Assignment of the ν(C–Cl) Bands. Using the method proposed by Miyagawa,[9] we have calculated the dipole moments of the rotational isomers of *meso*- and *racemic*-DCB. The calculated values are listed in Table 1. In accounting for the difference in dipole moments, it can be said that the equilibrium concentrations of rotational isomers in solution vary because they are affected by a reaction field induced from the solvent molecules;[10] the polar forms of rotational isomers are stabilized in the solvent with a larger dielectric constant.

It follows that the ν(C–Cl) bands can be assigned to a definite rotational isomer by observing the intensity change in the ν(C–Cl) bands in solvents with different dielectric constants. Indeed, the changes in the spectra of *meso*- and *racemic*-DCB with the solvents are remarkable as is shown in Fig. 3.

Table 1. Calculated dipole moments (in D.U.) for *meso*- and *racemic*-2,3-dichlorobutanes

Isomer	Chain conformation	Dipole moment
meso-DCB	MT	0
	MG	3.08
	MG′	3.08
racemic-DCB	RG	0.66
	RT	2.64
	RG′	3.33

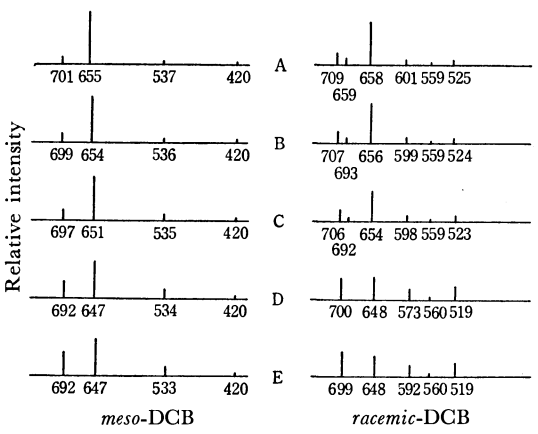

Fig. 3. The relative intensities of absorption bands in the various solvents (concentration: 0.8—0.5 mol/*l*, cell thickness: 0.047—0.055 mm).
A: *n*-Hexane, B: Cyclohexane,
C: Carbon disulfide, D: Cyclohexanone,
E: Acetonitrile

In the spectra of *meso*-DCB, the intensities of the bands at 695, 535, and 420 cm^{-1} increase, and that of the bands at 650 cm^{-1} decreases, as the dielectric constant of the solvent increases from 1.89 (*n*-hexane) to 37.5 (acetonitrile). At the same time, a downward shift of the absorption frequency is noted in the polar solvents.*1 In the light of the notations proposed by Shimanouchi *et al.*,[6] the types of ν(C–Cl) bands for DCB may be classified as S_C, S_{Cl} and S_H, where the subscripts represent the *trans* substituents on the C–C bond adjacent to a C–Cl bond. According to this classification, the types of ν(C–Cl) bands arising from the individual rotational isomers are denoted as S_{Cl} for MT and RG, as S_C for RG′, as S_H for RT, and as S_C and S_H for both MG and MG′.

In the spectrum of *meso*-DCB, the intense bands at 650 cm^{-1}, the intensity of which decreases in the solvent with the larger dielectric constant, is ascribed mainly to the antisymmetric S_{Cl}-type vibration of the nonpolar MT. The 695 cm^{-1} band is assigned to the S_C-type vibration of the polar MG and MG′ by taking account of the increase in its intensity in the solvent with the larger dielectric constant. A remaining band, due to the S_H-type vibration of MG and MG′, may be expected in the range around 640—600 cm^{-1}. In the Raman spectrum[4] of liquid *meso*-DCB, an intense band at 703 cm^{-1} and a somewhat weak band at 652 cm^{-1} are found in the ν(C–Cl) region. The antisymmetric S_{Cl}-type vibration of MT is a Raman inactive vibration and, hence, should not be observable in the Raman spectrum. The weak Raman band at 652 cm^{-1} must, therfore, be assigned to the infrared and Raman-active S_H-type vibrations of MG and MG′. The intense Raman band at 703 cm^{-1} probably involves the symmetric S_{Cl}-type vibration of MT and the infrared and Raman-active S_C-type vibrations of MG and MG′. The Raman-active symmetric S_{Cl}-type vibration should not give any infrared absorption because of the C_i symmetry of MT. Consequently, the infrared band at 695 cm^{-1} may be attributed to the S_C-type vibration of MG and MG′, while that at 650 cm^{-1} may be said to consist of two components of ν(C–Cl) bands; one arises from the S_{Cl}-type vibration of MT, and the other, from the S_H-type vibrations of MG and MG′.

The above assignments agree almost entirely with an empirical rule established by Shimanouchi

9) I. Miyagawa, *Nippon Kagaku Zasshi (J. Chem. Soc. Japan, Pure Chem. Sect.)*, **75**, 1061 (1954).
10) I. Watanabe, S. Mizushima and Y. Mashiko, *Nippon Kwagaku Kwaishi (J. Chem. Soc. Japan)*, **64**, 962 (1943).

*1 Hereafter, for convenience, the frequencies of absorption bands given are those observed in the liquid spectra.

et al.[6] and by Shipman *et al.*[8] According to this rule, the ν(C–Cl) *trans* to a C–Cl or C–C bond and that *trans* to a C–H bond usually appear in the frequency regions of 700—655 cm^{-1} and 640—600 cm^{-1} respectively. With respect to *racemic*-DCB, therefore, two ν(C–Cl) bands arising from each of RG and RG′ may be observed nearly in the former frequency region, and those arising from RT, in the latter one. The 692 and 652 cm^{-1} bands, the intensities of which decrease with an increase in the solvent dielectric constant, can be assigned to the S_{Cl}-type vibrations of the less polar RG. The 703 and 596 cm^{-1} bands can be assigned to the S_C and S_H-type vibrations of polar RG′ and RT respectively, since their intensities increase with an increase in the solvent dielectric constant. Although two S_C bands and two S_H bands must be expected for RG′ and RT respectively, in this case no bands except the 703 and 596 cm^{-1} bands are found in the ν(C–Cl) region. This absence of bands cannot be explained at present.

For liquid *racemic*-DCB, Taufen *et al.*[4] have observed the three Raman bands at 695, 653, and 599 cm^{-1} and have assigned them to RG, RG′, and RT respectively. The assignment for the former two bands is the reverse of our interpretation. However, the Raman band at 695 cm^{-1} is believed to be related not only to RG but also to RG′, for the more intense band at 703 cm^{-1} of RG′ and the weaker band at 692 cm^{-1} of RG in the infrared spectrum of the liquid state are so close in their frequencies (see Fig. 2) that the Raman bands corresponding to them could not be separately observed in the Raman spectrum. As is evident from the behavior of the infrared band at 652 cm^{-1} for the solvents, the Raman band at 653 cm^{-1} can be assigned to the S_{Cl}-type vibration of RG.

The empirically-established correlations between the infrared absorption bands and the structures of rotational isomers are summarized in Table 2.

TABLE 2. ASSIGNMENTS OF ABSORPTION FREQUENCY

Isomer	Frequency	Assignment[a]	Rotational isomer
meso-DCB	695	S_C	MG, MG′
	650	S_{Cl}	MT
		S_H	MG, MG′
	535	δ	
	420	δ	
racemic-DCB	703	S_C	RG′
	692	S_{Cl}	RG
	652	S_{Cl}	RG
	596	S_H	RT
	559	δ	
	522	δ	

a) S and δ denote C–Cl stretching and skeletal bending vibrations respectively.

Equilibrium Concentrations of Rotational Isomers in Various Solvents. We can determine the change in the equilibrium concentrations of rotational isomers in solution from the change in the intensity ratio of the ν(C–Cl) bands belonging to each of the rotational isomers.

In the case of *meso*-DCB, the optical densities of the 695 cm^{-1} and 650 cm^{-1} bands, D_{695} and D_{650}, can be represented with reference to the concentrations of rotational isomers as follows:

$$D_{695} = K_G C_G l \quad (1)$$

$$D_{650} = K_G' C_G l + K_{MT} C_{MT} l \quad (2)$$

where C_{MT} is the concentration of MT; C_G, the sum of the concentrations of MG and MG′, which are equal in population, and l, the optical pathlength of the cell. K_G is the absorption coefficient of the 695 cm^{-1} band, which arises from MG and MG′. Equation (2) is introduced by considering the 650 cm^{-1} band to be composed of two types of ν(C–Cl) bands belonging to MT and to MG and MG′; hence, K_{MT} and K_G' are the absorption coefficients arising from the component of MT and from that of MG and MG′ respectively. Dividing Eq. (2) by Eq. (1), we obtain:

$$C_{MT}/C_G = (K_G/K_{MT})(D_{650}/D_{695}) - (K_G'/K_{MT}) \quad (3)$$

We have at present no available information for determining the ratios of the absorption coefficients in Eq. (3). However, in the case of liquid *meso*-2,3-dibromobutane the values of K_G/K_{MT} and K_G'/K_{MT} are determined to be 0.534 and 0.223 respectively.*2 Taking into account the similarity in the molecular structures, the ratios of absorption coefficient which are experimentally determined for *meso*-2,3-dibromobutane can be transferred to those for *meso*-DCB; we thus obtain:

$$C_{MT}/C_G = 0.534(D_{650}/D_{695}) - 0.223 \quad (4)$$

Putting 2.27, the observed value of D_{650}/D_{695} for the liquid state, into Eq. (4), we obtain the equilibrium concentrations of the rotational isomers of liquid *meso*-DCB at 28°C as $C_{MT}=0.50$ and $C_G=0.50$. Further, it is also possible to determine the value of the equilibrium concentration by an independent method; *e. g.*, the mean dipole moment of the liquid state, which can be calculated from the dielectric constant of the liquid through

*2 Unlike the results obtained for *meso*-DCB, in the spectrum of liquid *meso*-2,3-dibromobutane the three ν(C–Br) bands are separately observed at 552 cm^{-1} for MT, and at 636 and 600 cm^{-1} for MG and MG′. Therefore, the determination of the values of K_G/K_{MT} and K_G'/K_{MT} becomes possible on the basis of the ratios of the observed optical densities, D_{636}/D_{552} and D_{600}/D_{552}, and the equilibrium concentrations of each rotational isomer, which are calculated from the dielectric constant (6.245) of the liquid.[11]

11) K. Iimura, to be published.

TABLE 3. EQUILIBRIUM CONCENTRATIONS OF THE ROTATIONAL ISOMERS IN THE VARIOUS SOLVENTS

Solvent	MT	MG	MG'	RT	RG	RG'	Method
n-Hexane (1.89)	0.74	0.13	0.13	0.24	0.58	0.18	IR study (at 28°C)
Cyclohexane (2.02)	0.71	0.14_5	0.14_5	0.24	0.58	0.18	present investigation
Carbon disulfide (2.64)	0.70	0.15	0.15	0.26	0.52	0.22	
Liquid sample*	0.50	0.25	0.25	0.34	0.39	0.27	
Cyclohexanone (18.3)	0.49	0.25_5	0.25_5	0.42	0.27	0.31	
Acetonitrile (37.5)	0.30	0.35	0.35	0.43	0.25	0.32	
Carbon disulfide	0.58	0.21	0.21			0.14	NMR study (at 29°C) by
Acetonitrile	0.33	0.33	0.33				Kondo *et al.*[17]
Carbon disulfide	0.64	0.18	0.18				NMR study by Bothner-By
Liquid sample	0.52	0.24	0.24	0.33	0.33	0.33	and Naar-Colin[2]

The numerals in parentheses indicate the dielectric constant of solvent.
* Dielectric constants of pure liquids are 8.823 and 9.761 for *meso*- and *racemic*-DCB, respectively.[5]

Onsager equation.*3 The equilibrium concentration at 25°C thus determined is $C_{MT}=0.49$ and $C_G=0.51$. It will be seen that the agreement with the equilibrium concentration observed by the infrared method is very satisfactory.

In estimating the equilibrium concentration in solution, it is necessary to examine the applicability of Eq. (4) since, in general, the value of the absorption coefficient of an infrared band changes depending upon the nature of the solvent.[13] According to the study by Hirota, however, the ratio of the absorption coefficients of an infrared band in two solutions is kept constant, is determined by the solvents, and is common to the absorption bands of any molecules.[14] The ratio of the absorption coefficient of the ν(C–Cl) bands of DCB in a solvent may, therefore, change little; hence, no serious error will be introduced into the values of the equilibrium concentrations in the various solvents obtained through Eq. (4). The equilibrium concentrations thus obtained for *meso*-DCB are listed in Table 3.

With respect to *racemic*-DCB, the values of the absorption coefficients can not be determined by the above-described method, for all three rotational isomers have different dipole moments. The ratios of absorption coefficients were, therefore, obtained from the equilibrium concentrations, which were themselves estimated by means of the energy difference between the rotational isomers in the gaseous state. Let D be the optical density; k, the absrption coefficient; C, the concentration or the number of molecules of the rotational isomer, and f, the partition function. We then have:

$$D_I/D_{II} = (k_I/k_{II})(C_I/C_{II}) = (k_I/k_{II})(f_I/f_{II})\exp(-\Delta E/\boldsymbol{R}T) \quad (5)$$

where ΔE is the energy difference between the two rotational isomers, which are discriminated by the subscripts I and II. The ratio of the partition function can be assumed to be approximately unity.[15] For the case of 1,2-dichloroethane, Watanabe *et al.*[16] have calculated the ratio of the partition function of the *gauche*-form to that of the *trans*-form, and they have determined the value to be 0.95 at 25°C. From the assumption above mentioned, the value of C_I/C_{II} can be estimated from ΔE, and then the ratio of the absorption coefficient, k_I/k_{II}, can be determined by means of the observed ratio of optical densities in Eq. (5).

The energy differences between RG' and RG and between RT and RG are found to be 1.1 kcal/mol and 1.0 kcal/mol respectively by measuring the temperature change in the absorption intensities, as will be described below. From these data, the values of $C_{RG'}/C_{RG}$ and C_{RT}/C_{RG} at 28°C are calculated as 0.159 and 0.188 respectively. The ratios of the absorption coefficients, $k_{RG'}/k_{RG}$ and k_{RT}/k_{RG}, are then determined to be

*3 The equilibrium concentration in the liquid stated is calculated from the following relation:

$$m^2 = (\mu^2_{MT}N_{MT} + \mu^2_G N_G)/(N_{MT} + N_G)$$

where, m is the mean dipole moment of the liquid; μ, the dipole moment, and N, the number of molecules which are discriminated by the subscripts (G shows two *gauche*-forms). The calculated dipole moments listed in Table 1 are used for μ_{MT} and μ_G. The value of m^2 was calculated by the Onsager equation:[12]

$$m^2 = (9\boldsymbol{k}T/4\pi\boldsymbol{N})(M/d)[(\varepsilon-n^2)(2\varepsilon+n^2)/\varepsilon(n^2+2)^2]$$

where $\boldsymbol{k}$ is the Boltzman constant; $\boldsymbol{N}$, the Avogadro number, and M, the molecular weight. The values of the dielectric constant (ε=8.823), the density (d=1.1023), and the refractive index (n=1.4386) at 25°C were taken from the paper of Lucas and Gould.[5]

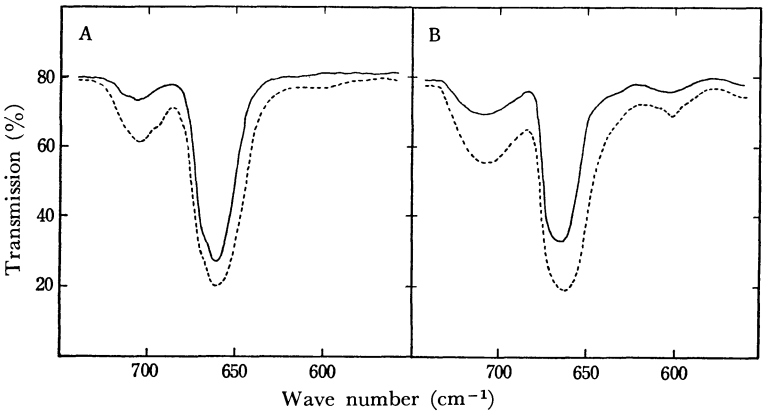

Fig. 4. The infrared spectra of gaseous state at the different temperatures.
A: *meso* (full line: 29°C, broken line: 146°C),
B: *racemic* (full line: 28°C, broken line: 151°C)

0.987 and 0.292 respectively from the observed ratios of the optical densities, $D_{RG'}/D_{RG}=0.157$ and $D_{RT}/D_{RG}=0.055$, at 28°C. The equilibrium concentrations of *racemic*-DCB in various solvents are obtained using these ratios of absorption coefficients; they are listed in Table 3, together with those obtained for *meso*- and *racemic*-DCB by the NMR investigations.[2,17]

Although there are only few solvents available to be compared commonly for both infrared and NMR method, a fair agreement between the data obtained by the two independent methods is noted for the liquid state and the acetonitile solution of *meso*-DCB. For the carbon disulfide solution, however, the data for MT obtained by the infrared method are slightly larger than those obtained by the NMR methods. With respect to liquid *racemic*-DCB, the data obtained by the infrared method agree almost entirely with those obtained by the NMR method. In our previous NMR investigation it was noted that the vicinal coupling constants of *racemic*-DCB depends little upon the solvents.[17] In contrast to the infrared results shown in Table 3, this experimental finding leads to the conclusion that the equilibrium concentrations of *racemic*-DCB does not remarkably change under the influence of solvents. However, as is shown in Fig. 3, the considerable changes in the intensity of the ν(C–Cl) bands in the different solvents suggest that the equilibrium concentrations change depending upon the solvents.

Spectra of the Gaseous State and the Energy Difference of Rotational Isomer. The spectra of gaseous *meso*- and *racemic*-DCB at different temperatures are shown in Fig. 4. The bands appearing at 706 and 661 cm^{-1} of *meso*-DCB correspond to those at 695 and 650 cm^{-1} respectively in the liquid state. For the gaseous *racemic*-DCB the bands corresponding to those at 703, 652, and 596 cm^{-1} of the liquid state are observed at 710, 665, and 603 cm^{-1} respectively. In general, from the temperature-dependence of the band intensities, the energy difference, ΔE, between the rotational isomers can be calculated by Eq. (5). Since, for *racemic*-DCB in the liquid state, the very weak 692 cm^{-1} band appears as a shoulder band on the more intense 703 cm^{-1} band, we have assumed that the broad band at 710 cm^{-1} in the geseous state arises mainly from the RG'.

In the case of *meso*-DCB the ratio of the intensity of the 661 cm^{-1} band to that of the 706 cm^{-1} band does not directly represent the abundance ratio of

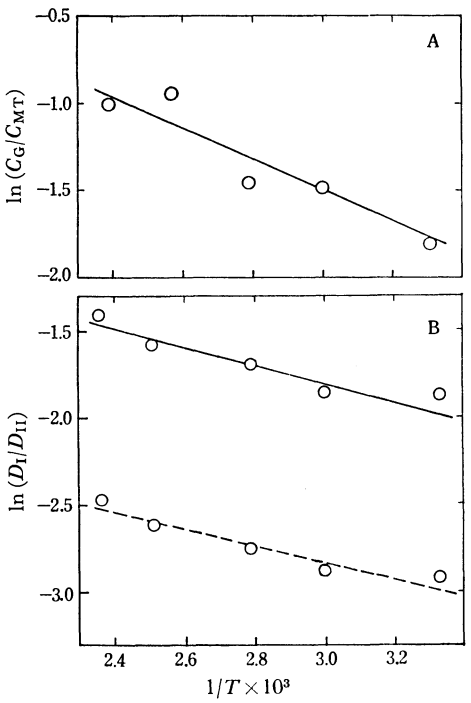

Fig. 5. The temperature dependences of abundance ratio and of intensity ratio in gaseous state.
A: *meso*, B: *racemic* (full line: $D_I/D_{II}=D_{710}/D_{665}$, broken line: $D_I/D_{II}=D_{603}/D_{665}$)

the two isomers. The abundance ratio, C_{MT}/C_G, was, therefore, estimated through Eq. (3), and then ΔE was obtained by means of Eq. (5).

As Fig. 5 shows, relations of the logarithmic values of the intensity ratios or the abundance ratio against $1/T$ were found to be linear. From the slope of the straight lines, the energy differences in the gaseous state are estimated; they are listed in Table 4.

Table 4. Energy differences between the rotational isomers in gaseous state
(kcal/mol)

Energy difference*	Observed value	Calculated value[17]
ΔE^{gas}_{MG-MT}	1.7	1.45
$\Delta E^{gas}_{RG'-RG}$	1.1	0.85
ΔE^{gas}_{RT-RG}	1.0	0.75

* The energy difference between two rotational isomers of which are shown by the subscripts.

The observed values of ΔE are of the same order as the calculated results of our previous report.[17] The value of ΔE^{gas}_{MG-MT} for *meso*-DCB is larger than the ΔE between *gauche* and *trans* forms of 1,2-dichloroethane (1.2 kcal/mol).[18] This is understandable, for the steric repuslion between the two methyl groups is somewhat larger than that between the chlorine atom and the methyl group,*4 and therefore the difference in steric potential between the MG of *meso*-DCB and the corresponding *gauche* form of 1,2-dichloroethane is to be larger than that between the *trans* forms of these two substances. In the case of *racemic*-DCB, the potential energies of RG' and RT are almost the same in magnitude, both higher than that of RG by approximately 1.0 kcal/mol. These results suggest that the energy difference between the rotational isomers of 2,3-dichlorobutane is mainly affected, just as in the case of 1,2-dichloroethane, by the skeletal conformations of the Cl–C–C–Cl linkage and an electrostatic interaction induced by the two C–Cl bonds.

Temperature Change in Spectra in the Acetonitrile Solution. Figure 6 shows the temperature dependence of the abundance ratio, C_G/C_{MT}, for *meso*-DCB, and the intensity ratio of the infrared band for *racemic*-DCB in the acetonitrile solvent. In contrast with the same relation for the gaseous state (see Fig. 5), in this case positive slopes are obtained against $1/T$. The results can be explained in terms of change in energy difference between the rotational isomers, a change which is caused by an interaction between the molecular dipole and its induced moment in the surrounding solvent medium. By taking Onsager's field[12] as the reaction field,[10] when a molecule of dipole moment, μ, in the gaseous state is transferred from the vacuum into the solvent medium of the dielectric constant, ε, the potential energy is lowered by:

$$E_r = (\varepsilon-1)\mu^2/(2\varepsilon+1)a^3 \qquad (6)$$

where a is the radius of the solute molecule.

Putting the dipole moments listed in Table 1 and the dielectric constant of acetonitrile (37.5) into Eq. (6), the energy differences between the rotational isomers in the solution can be calculated as $\Delta E^{sol}_{MG-MT} = 0.02$ kcal/mol, $\Delta E^{sol}_{RG'-RG} = -0.73$ kcal/mol, and $\Delta E^{sol}_{RT-RG} = -0.24$ kcal/mol.*5 The observed energy differences in the solution, which are determined from the linear relations shown

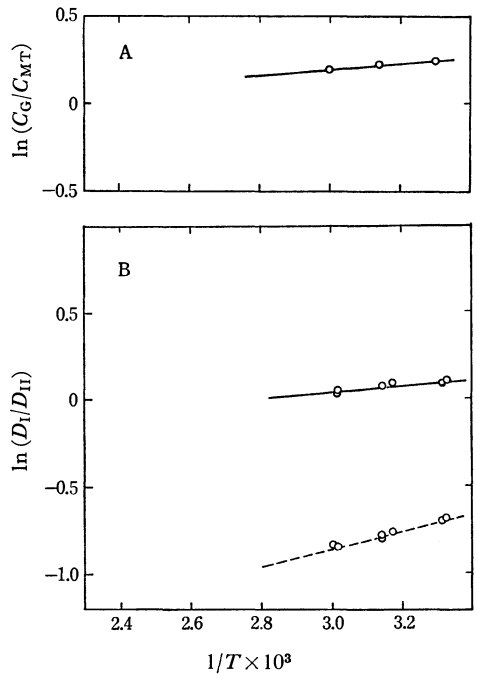

Fig. 6. The temperature dependences of abundance ratio and of intensity ratio in acetonitrile solution.
A: *meso*, B: *racemic* (full line: $D_I/D_{II}=D_{699}/D_{648}$, broken line: $D_I/D_{II}=D_{592}/D_{648}$)

18) T. Shimanouchi, H. Tsuruta and S. Mizushima, *Sc. Pap. Inst. Phys. Chem. Res. Tokyo*, **42**, 165 (1945).

*4 The van der Waals radii of the chlorine atom and the methyl group are 1.8 and 2.0 Å respectively (L. Pauling, "The Nature of the Chemical Bond," Cornell Univ. Press, Ithaca, New York (1940)).

*5 In calculating E_r, a is roughly estimated by the equation; $M/d=(4\pi a^3/3)N$, where M and d are the molecular weight and the density of the solute molecule, and N, the Avogadro number. As the values of the densities, 1.1023 and 1.1063 were used for *meso*- and *racemic*-DCB respectively.[5] To estimate the energy difference in the solution, ΔE^{sol}, the calculated ΔE^{gas} values listed in Table 4 were used.

in Fig. 6, are $\Delta E^{sol}_{MG\text{-}MT} = -0.3$ kcal/mol, $\Delta E^{sol}_{RG'\text{-}RG} = -0.3$ kcal/mol, and $\Delta E^{sol}_{RT\text{-}RG} = -1.0$ kcal/mol.

Although some discrepancies between the calculated and observed energy differences in the solution are noted, the decreases in the potential energy of the polar MG, RG' and RT conformations in the acetonitrile solvent can be explained qualitatively by appling Onsager's reaction field.

The authors are grateful to Professor T. Shimanouchi for his guidance and to Dr. S. Kondo and Mr. S. Shimogawara for their kind discussions and assistance.

Raman and Infrared Spectra of β-Alanine

R. S. KRISHNAN and R. S. KATIYAR

Department of Physics, Indian Institute of Science, Bangalore 12, India

(Received March 8, 1968)

The Raman spectrum of β-alanine has been recorded in the single crystal form employing λ 2537 technique. The infrared spectra in Nujol mull and KBr pellet have been taken for the range 400—4000 cm^{-1}. The spectra exhibit the characteristic lines of the zwitter ion and also hydrogen bond vibrations in the region 2400—3000 cm^{-1}. The tentative assignments of the observed lines are given and compared with those of other amino acids.

The study of the vibration spectra of amino acids by Raman and infrared spectroscopy is useful for getting information about their molecular configurations and the nature of hydrogen bonding in these substances. A systematic study of the Raman spectra of glycine and its addition compounds from this laboratory has been reported by Krishnan and Narayanan.[1] The infrared spectra of crystalline amino acids have been studied by Klotz and Green[2] and Thompson *et al.*[3] Edsall and his coworkers[4] have made extensive spectral measurements on a large number of amino acids in aqueous solution. Attempts have also been made to assign the vibrational frequencies of glycine molecule on the basis of the normal coordinate analysis.[5-7] The Raman and infrared spectra of β-alanine (β-amino propionic acid, $H_2N{\cdot}CH_2{\cdot}CH_2{\cdot}COOH$) in the crystalline state have, however, not been studied. The authors have recorded the Raman spectrum of β-alanine in the single crystal form and the infrared absorption spectrum in the powder form at the room temperature and the results are presented in this paper. A comparative study of the vibration spectra of α-glycine, γ-glycine, α-alanine and β-alanine has also been made.

Experimental

Single crystals of β-alanine were grown from aqueous solution of the pure substance. The biggest crystal grown had roughly the size, 6 mm^3. Using mercury λ 2537 excitation and a Hilger medium quartz spectrograph the Raman spectrum of the crystal was recorded on Ilford Zenith Astronomical plates with exposures of one day. The infrared absorption spectrum of the substance was recorded in the spectral region 4000—400 cm^{-1} in the form of the potassium bromide disc, using a Carl Zeiss UR-10 Infrared spectrometer.

Results

An enlarged photograph of the Raman spectrum of β-alanine is reproduced in Fig. 1, along with its microphotometer record. The positions and frequency shifts of the Raman lines are marked on the microphotometer tracing. The frequency shifts are also listed in Table 1. The figures in brackets represent the relative intensities of the Raman lines estimated visually. Thirty nine Raman lines have been recorded. Some of these lines fall very near some mercury lines and are therefore not clearly separated. However, their

presence can be predicted from the infrared spectrum of the substance. The infrared absorption curve obtained for β-alanine is reproduced in Fig. 2. The observed infrared absorption frequencies are listed in Table 1. Forty nine absorption maxima have been identified.

Discussion

β-Alanine crystallises in the orthorhombic system (Jose and Pant[8]) with the space group D_{2h}^{15}-*Pbca*. The unit cell (a=9.865, b=13.8 and c=6.07 Å), has eight molecules occupying general positions. The molecule as such does not have any symmetry and therefore all the internal vibrations of the molecule should be both Raman and infrared active. Exclusive of the long wavelength acoustic modes, there are a total of 309 factor group fundamentals. Each molecule of β-alanine has 33 internal vibrations. Since there are eight molecules in the unit cell, each internal vibration will be further split. Since the intermolecular forces in the crystal are relatively weak, the splitting of the degeneracies would be small and difficult to be experimentally observed. One can expect to observe at least 33 vibrations in Raman effect and in infrared absorption. This is actually the case. The remaining 45 fundamentals are known as the external vibrations and can further be divided into 24 rotatory type and 21 translatory type of oscilations. Since the crystal has got the centre of symmetry, only 12 translatory type and 12 rotatory type of oscillations will be Raman active.

	3300(w), 3400(w)	Combination frequencies

The thirty three internal vibrations of the molecule can be classified as due to the vibrations of the various groups in the molecule. The assignments of the observed Raman and infrared frequencies are given in column 3 of Table 1. Theoretically the group $-CH_2-CH_2-$ should have two symmetric and two asymmetric CH_2 stretching vibrations. However, as one CH_2 group stretches in and out of phase, it disturbs the carbon atom of the next CH_2 group very little because of the insulating effect of the low frequency C–C vibration. Therefore the coupling between the two CH_2 groups is very weak. As a result, the two symmetric CH_2 stretching vibrations will have almost the same frequency and the two asymmetric stretching modes will also have nearly the same frequency which is somewhat higher than the symmetric stretching frequency. In the case of CH_2 bending vibrations such as wag and rock, the angle H–C–H does not change appreciably and the motions of the hydrogen atoms must be directly opposed by the motion of the carbon of the next CH_2 group which indicates a strong coupling between the two CH_2 groups and therefore they may be expected to have different rocking and wagging frequencies.

The absence of the C–O and NH_2 group frequencies and the presence of COO^- and NH_3^+ frequencies clearly indicate that the molecules exist in the zwitter ion form ($NH_3^+ \cdot CH_2 \cdot CH_2 \cdot COO^-$) in the crystal. Further, since the N–H stretching frequencies of NH_3^+ group are considerably lowered and are broad, the molecules are held together by strong hydrogen bonds of N^+–H···O type. According to Parimala Jose and Pant[8] the N···O distances are 2.76, 2.78 and 2.78 Å and three strong hydrogen bonds should therefore be present around the nitrogen atom. This view is confirmed in the present analysis. From the correlation curve of N^+–H···O stretching frequencies *versus* the H-bond lengths given by Krishnan and Krishnan,[9] the N^+–H···O stretching frequencies can be identified at 2651 and 2731 cm^{-1} in Raman spectrum corresponding to the N···O distances of 2.76 and 2.78 Å. The large number of subbands in this region quite possibly arises from an anharmonic interaction o the allowed overtone and summation frequencies. The presence of the hydrogen bonds must be accompanied by some low frequency N+H···O stretching oscillations. These low frequency stretching oscillations are calculated using the formula given by Pimentel and Sederholm.[10] The results of the calculation show that the frequency shifts 221 and 242 cm^{-1} may be attributed to the motions of the hydrogen bonds N+H···O. Similar low

frequency shifts due to hydrogen bond oscillations have been observed by Gross,[11] Balasubramanian, Krishanan and Iitaka[12] and Krishnan and Krishnan[13] in hydrogen bonded crystals.

The tentative assignments of the other Raman frequencies have been made by comparing the vibration spectra of β-alanine with that of glycine. A comparative study of the vibration spectra of α-glycine,[1] γ-glycine,[12] α-alanine[14] and β-alanine has been made in the Table 2. It is to be noted that the group frequencies do not vary much in these crystals except some frequencies in the case of β-alanine. All these crystals exist as dipolar (zwitter) ions in the crystalline state. There are some weak bands observed in the infrared spectrum in the region from 1800 to 2500 cm^{-1}. These can be explained as the overtones and combinations of some of the fundamental vibration frequencies.

The low frequency Raman lines are due to the external oscillations of the molecules in the crystal.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 2102—2106 (1969)

Optical Spectra of Transition Metals in Na_2O-P_2O_5 Glasses

Takashi MAEKAWA, Toshio YOKOKAWA and Kichizo NIWA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo

(Received November 18, 1968)

The optical spectra and the magnetic susceptibilities were obtained in sodium phosphate glasses containing transition metal ions. It was shown that the content of the transition metal ions of higher valency states increases with an increase in that of Na_2O whenever an oxidation equilibrium occurs between two or more valency states. By combining the visible spectra analyzed from the viewpoint of the ligand field theory with the results of the magnetic susceptibility measurement, it was shown that most transition metals coordinate six oxygen atoms in the phosphates.

The studies of the coloration of the transition metal ions in fused salts have, so far, greatly progressed with regard to the halide and nitrate systems especially. Bates applied the ligand-field theory to the analysis of the spectra of the colored glass.[1] In a sodium silicate and a sodium borate, the variation of the visible spectra with the sodium concentration was observed by Bamford.[2] Recently, the concept of the formation of non-bridging oxygen ions in a borate was used in explaining the fact that the intensity of absorption rapidly changed at a definite alkali concentration.[3] In contrast with the borates and the silicates, however, those have been few experimental measurements of the phosphates. The ligand-field absorption of the manganous ion in $3K_2O{\cdot}7P_2O_5$ and $3Na_2O{\cdot}7P_2O_5$ glass was obtained by Bingham and Parke.[4] Recently, the optical spectra and the magnetic susceptibility of cobalt(II) ion in Na_2O-P_2O_5 glass at various sodium oxide concentrations were measured.[5]

In this experiment the variation in the intensity and position of the visible absorption spectra were examined in sodium phosphate glasses with various compositions of Na_2O in order to investigate the structure of the phosphate network as well as their relation to the transition metal ions. The magnetic susceptibilities of this glass were also measured, since those quantities provide important information on the valency states of transition metal ions as well as their coordination numbers.

Experimental

Materials. The sample glass was prepared by melting $NaPO_3$, P_2O_5, and H_3PO_4 of a guaranteed reagent grade. The transition metals which were added as oxides were V_2O_5, Cr_2O_3, MnO_2, Co_2O_3, Fe_2O_3, NiO, and CuO. These were added, in amounts up to about 0.5 wt per cent, to the sodium phosphate, melted in a platinum crucible, and kept in the liquid state for 10 hr in order to get uniform mixtures.

Measurement of Optical Absorption Spectra. The melt in a crucible was cast into a mould of brass. The thickness of the sample plate was 0.5 cm. To avoid the moisture and the scattering caused by the rough surface, the sample was immersed in a benzene-chlorobenzene solution in an absorption cell.

Measurement of Magnetic Susceptibility. Use was made of a Gouy balance. The strength of the magnetic field was 15000 gauss. The net susceptibility due to the transition metal ions was obtained after the correction for the blank from the solvent glass was applied.

Determination of the Composition of the Glass Solvent. The sample was dissolved in an aqueous solution of nitric acid, and all the phosphates were converted to orthophosphate. From the quantity of NaOH required to neutralize the solution from the first to the second neutralization point, the quantity of P_2O_5 was determined. The Na_2O content was determined by the difference from the total weight.

Water Content in Glass. In the phosphate glass it is important to consider the presence of water. It is quite difficult to remove the water completely by the ordinary procedure. A considerable amount of water will still be present, especially when the sodium oxide concentration is low. This water was, however, ignored because water dissolves in glass not as H_2O molecules by as a network modifier, like sodium oxide. Although the presence of water alters the so-called basicity of the glasses, this doesn't have as much effect on transition metal ions as free H_2O molecules.

Results

Visible Absorption Spectra. *1) Vanadium.* The glasses containing vanadium were yellow when

the Na_2O content was high, but they turned green as the Na_2O content decreased. The extinction curves of the glasses are given in Fig. 1. The small absorption around 700 mμ increased in intensity as the Na_2O content decreased. Vanadium is able to have three valency states, V(III), V(IV), and V(V), in the glasses. V(V) has a $3d^0$ electronic configuration, so it has no absorption bands caused by the crystal field of oxygen ligands. V(IV) ($3d^1$) has a single spin-allowed band which occurs in the infrared region,[6] so it could not be detected in this experiment either. Therefore, it is considered that the small absorption is due to the V(III) ion in the glass and that the proportion of the V(III) decreases as the Na_2O

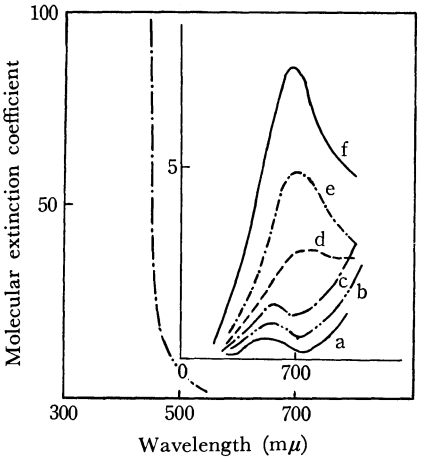

Fig. 1. The optical absorption of vanadium in sodium phosphate glasses with various sodium oxide concentration.

a 53.6 mol% Na_2O, b 52.5, c 50.3, d 27.7, e 17.4, f 0

content increases. The proportion of the higher valency state usually increases with the Na_2O content in glasses containing transition metals,[7] as may also be seen below.

2) Chromium. The glass containing chromium was green, and the color did not change with the composition. The extinction curves of the glasses are shown in Fig. 2. This glass has three prominent peaks, around 450, 635 and 600 mμ; they are considered to be three spin-allowed transitions in an octahedral crystal field of Cr(III). The assignment of these bands will be discussed later.

3) Manganese. The glasses changed from pale brown to pale purple with an increase in the Na_2O content. The extinction curves are shown in Fig. 3; they consist of a single band at 500 mμ. This band increases in intensity with an increase in the Na_2O

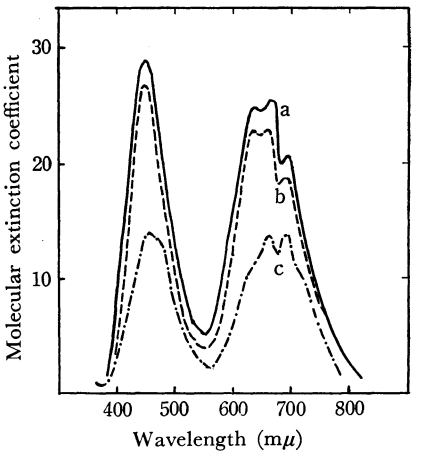

Fig. 2. The optical absorption of chromium in sodium phosphate glasses with various sodium oxide concentrations.

a 55.4 mol% Na_2O, b 50.8, c 0

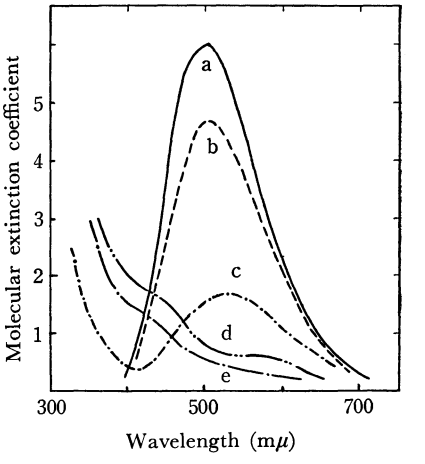

Fig. 3. The optical absorpion of manganese in sodium phosphate glasses with various sodium oxide concentrations.

a 56.1 mol% Na_2O, b 51.4, c 44.6, d 22.1, e 0

content. Manganese is present in glasses as divalent or trivalent ions. The absorption at 500 mμ is considered to be the spin-allowed transition of Mn(III), whose content increases with an increase in the Na_2O content. Mn(II) has a $3d^5$ electronic configuration and has no spin-allowed crystal-field bands.

4) Iron. The glasses were yellowish brown. The extinction curves are shown in Fig. 4. Iron is present in glasses as divalent or trivalent ions. Fe(II) ($3d^6$) has a single spin-allowed absorption band in the infrared region, but the band could not be detected in this experiment. Fe(III)($3d^5$) has an *iso*-electronic configuration with Mn(II) and has no spin-allowed crystal-field band. The weak absorption is due to the spin-forbidden crystal-field

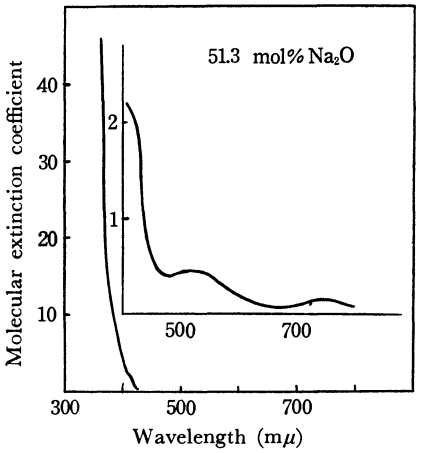

Fig. 4. The optical absorption of iron in sodium phosphate glass.

band. Chemical analysis showed that most of the iron ions are present as trivalent (about 95%) in the sodium metaphosphate glass.

5) Cobalt. The glasses change from pink to blue with an increase in the Na_2O content. The extinction curves are shown in Fig. 5. Cobalt is divalent in the glass. When the Na_2O content is low, Co(II) is surrounded by six oxygen atoms, but as the Na_2O content increases the proportion of the tetrahedrally-coordinated cobalt ion increases. The variation in color is consistent with this change. The change from octahedral to tetrahedral coordination occurs in other glasses.[3]

6) Nickel. The glasses were yellow but became greenish with an increase in the Na_2O content. The extinction curves are shown in Fig. 6. The nickel in the glasses is in the form of the divalent ion, which has a $3d^8$ electronic configuration. In the octahedral field, the nickel(II) ion has three spin-allowed bands.

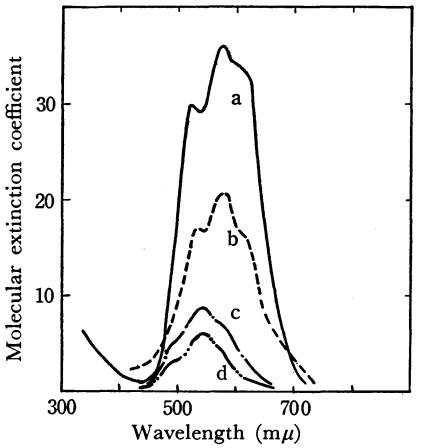

Fig. 5. The optical absorption of cobalt in sodium phosphate glasses with various sodium oxide concentrations.

a 57.4 mol% Na_2O, b 50.6, c 44.0, d 0

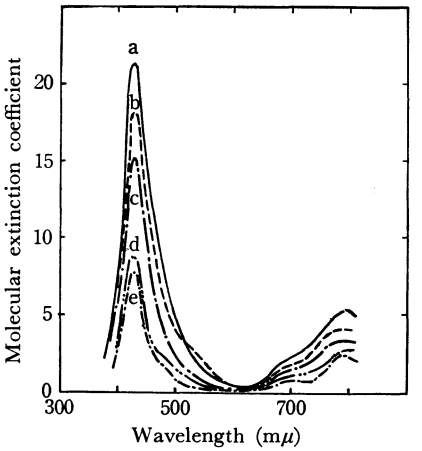

Fig. 6. The optical absorption of nickel in sodium phosphate glasses with various sodium oxide concentrations.

a 59.0 mol% Na_2O, b 55.5, c 51.4, d 36.6, e 0

The absorptions around 425 and 780 mμ correspond to these bands, and the other band appears in the infrared region. It was shown in the sodium borate glasses that the tetrahedrally-coordinated nickel ion is present in the higher-alkali-content glasses.[8] In the phosphate glasses this is shown by the variation in the intensity of the absorption, which will be discussed later.

7) Copper. All the sodium glasses containing copper were pale blue. The extinction curves of the glasses are shown in Fig. 7. The main absorp-

Table 1. Assignment of the absorption band of transition metals in sodium phosphate glasses

Ion	Band assignment	$-6H_2O$ (mμ)	Na-Glass (mμ)
V +3	$^3T_1 \rightarrow {}^3T_2$	562	665
Cr +3	$^4A_2 \rightarrow {}^4T_1$	410	450
	$^2T_1$		634
	$^4T_2$		658
	^2E	671	690
Mn +3	$^5E \rightarrow {}^5T_2$	476	500
Fe +3	$^6A_1 \rightarrow {}^4E, {}^4A_1$	406	410
	$^4T_2$	540	520
	$^4T_1$	793	740
Co +2	$^4T_1 \rightarrow {}^4T_1$	465	490
		515	530
	$^4A_2 \rightarrow {}^4T_1$ (Tetrahedral)	600	620
Ni +2	$^3A_2 \rightarrow {}^3T_1$	395	425
	^1E	649	700
	$^3T_1$	741	782
Cu +2	$^2E \rightarrow {}^2T_2$	796	760

tion band appeared at 760 mμ, its intensity increasing with the Na_2O content. The copper in the glasses is in the divalent state with a $3d^9$ electronic configuration. This absorption band is due to the transition in an octahedral field. The apparent ligand field strength is 13000 cm^{-1}.

Discussion

The observed bands are summarized in Table 1. The corresponding values in octahedrally-coordinated aquo-complex are also included. A comparison of the two sets of data shows that the bands may be identified as transitions in the octahedral-ligand field. In Co and Ni, however, the tetrahedral-ligand field must be taken into consideration.

In general the field strength of the phosphate glass is smaller than tnat of the corresponding aquo-complex by about 10%. This fact is also seen in other glasses.[1] In copper, on the other hand, the splitting of *d* levels due to the ligand field is greater than that of the copper(II) aquo-complex. This result may be explained by considering that there occurs a large tetragonal distortion.[1]

Figure 8 shows the relation between the intensity of the absorption and the Na_2O content in nickel(II), copper(II), and chromium(III) glasses. The increase in intensity is probably caused by the following two effects:

(1) the increase in the portion of ions which occupy the sites under the octahedral and/or tetrahedral crystal field and cause the optical absorption. This increase is closely related to the structure of the glasses, and

(2) the increase in the number of the ions in the relevant valency state, which is related to redox equilibrium of the transition metal ions.

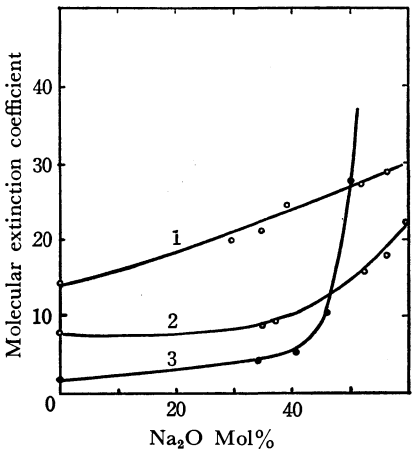

Fig. 8. The variation of the intensity with sodium oxide concentration.
1 Cr ~450 mμ, 2 Ni ~420 mμ, 3 Cu ~760 mμ

In chromium, the intensity increases moderately with the Na_2O content. This suggests that the proportion of Cr(III) increases with an increase in the Na_2O content, although no divalent chromium ions were detected. In copper, on the other hand, the intensity changes abruptly at an Na_2O content of 40 mol%. This shows that, in addition to a possible increase in the proportion of Cu(II), the structure of the glasses changes at this composition; that is, the glass network disintegrates into discrete ions so that the probability of occupying the octahedral site increases at this composition.

In nickel, an abrupt change in intensity occurs at the composition of 40 mol% Na_2O. As in the borate glasses, it is considered that the proportion of tetrahedral Ni(II) coordination increases from this point.

Magnetic Susceptibilities. From the magnetic susceptibilities, the effective magnetic moments of

Table 2. Effective magnetic moment of transition metal ions in sodium metaphosphate glasses

		$-6H_2O$ μ_{eff} (B.M.)	Sodium metaphosphate μ_{eff} (B.M.)	Ion
V	+4	1.70	1.10	V^{3+}, V^{4+}, V^{5+}
	+3	2.61		
	+2	3.80		
Cr	+3	3.80	3.77	Cr^{2+}, Cr^{3+}
	+2	4.80		
Mn	+3	4.80	5.62	Mn^{2+}, Mn^{3+}
	+2	5.83		
Co	+2	4.90	4.70	Co^{2+}
Ni	+2	3.12	3.21	Ni^{2+}
Cu	+2	1.83	2.02	Cu^{2+}

transition metal ions in sodium metaphosphate glasses were derived from the relation:

$$\mu_{eff} = 2.84\sqrt{\chi_M \cdot T}$$

where χ_M is the molar susceptibility, and T, the absolute temperature. These results are summarized in Table 2. The corresponding values in octahedral aquo-complex are included. In general, the effective magnetic moment of the transition metal ions in a crystal field can be represented by the following relation:

$$\mu_{eff} = \mu_0\left(1 - \alpha\frac{\lambda}{\Delta}\right)$$

where Δ is the strength of the crystal field, λ is a parameter of spin-orbit interaction, μ_0 is a spin-only magnetic moment, and α is a positive constant. λ is positive when there are fewer than five 3d electrons and is negative when there are more.

Therefore, if it is assumed that the transition metal ions in the glasses coordinate six oxygen atoms and that λ does not differ much between the glasses and aquo-complexes, the μ_{eff}'s of V, Cr, and Mn become smaller, and those of Co, Ni, and Cu become larger than those of the corresponding aquo-complex. Table 2 shows that this relation holds except in the case of Co. It is known that the magnetic moment in the tetrahedral field is smaller than that in the octahedral field.[9] Therefore, in cobalt this result can be explained by the existence of the tetrahedrally-coordinated cobalt ions, which is consistent with spectra results.

As to vanadium, the values suggest that the V(IV) and V(V) are predominant, as has also been implied from the spectral measurements. The μ_{eff} of Mn shows that there are a considerable number of Mn(II) ions which can not be detected spectroscopically. It may be concluded from the table that nickel and copper are predominant in the divalent state in the phosphate glasses.

In conclusion, the coordination of oxygen atoms on the transition metal ion is closely related to the structure of the glass. Thus, when the Na_2O content is low, most of the transition metal oxides act as network modifiers and the coordination number is 6, while some of them (Ni, Co) act as network formers at a high Na_2O content when the coordination number becomes 4. This is also reflected in the fact that, at a high basicity, transition metal ions of high valency state form stable coordination complexes.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 2106—2111 (1969)

Ignition Delay Time Studies of Hydrogen and Oxygen Reactions through Silent Electric Discharge

Kihei MORINAGA

Department of Chemistry, Defense Academy, Hashirimizu, Yokosuka

(Received November 25, 1968)

The ignition of hydrogen and oxygen could be induced by the so-called silent electric discharge, and the ignition delay time after the termination of the discharge was found to be proportional to a logarithm of the discharge intensity (pulse current). The proportionality constants in different diluents, argon and helium, were analyzed to yield the net effect of chain breaking in the reaction:

$$H + O_2 + M \xrightarrow{k_4} HO_2 + M$$

and the rate coefficient, k_1, for the reaction:

$$H + O_2 \xrightarrow{k_1} OH + O$$

assuming a third-body efficiency of the diluent gases. It was inferred from the results that the radical reproducing from HO_2 significantly lessened the effect of the above chain breaking reaction, the accumulation of radicals seemed to be persistent even in the low-temperature region, where the k_1 value was observed not to be above the assumed value of $k_1[M]/2$.

The ignition of hydrogen and oxygen by silent electric discharge was reported previously[1] regarding the effects of the gas composition and the pressure on the threshold of the ignition.

The present paper will attempt to estimate the net effect of the chain breaking reaction by com-

1) K. Morinaga, This Bulletin, **35**, 627 (1962).

paring the experimental results on the ignition delay time in an argon diluent and in a helium diluent, assuming a third-body efficiency of the diluent gases.

Unlike spark discharge, silent discharge can be characterized by numerous small discharges which continue for a certain period of time. These small discharge can be represented on the Lichtenberg figure[2] as numerous spots[3] sporadically distributed all over the electrode (which is a dielectric substance) surface and on the current diagram as numerous fringe-like pulses the summation of which can lead to pulse current.[3,4] These are essential features of the silent electric discharge.

The linear relationship between the pulse current and the extent of chemical reaction in silent discharge was confirmed in previous papers.[5,6]

In the present paper, the pulse current was adopted in order to show the extent of the discharge which brings about the silent-discharge ignition of hydrogen and oxygen.

Experimental

Hydrogen, oxygen, and inert gases over three-nine pure were dried over silica gel and were then manometrically mixed to the desired composition in a conventional vacuum system without further treatment. The mixture was left to stand for more than 48 hr ($p=1$ atm) in a glass vessel before use. The composition of the inert gas *i. e.*, argon or helium, ranged from 5 to 55%, while the hydrogen and oxygen remained stoichiometric. The initial pressure of the gas mixture for runs was kept at 250 mmHg in all cases.

The electric circuit system which actuated the one-shot silent electric discharge and the device for the observation of the current diagram of the discharge were similar to those in previous experiments.[1,7] Under the present experimental conditions, the pulses on the current diagram appeared satisfactorily separated for convenient pulse-height measurements.

The cylindrical test bomb of the preceding work[1] was replaced by a cubic bomb with a 3 cm×8 cm×8 cm interior. It was provided with a quartz window for observing the emission from the ignited gas. The former conventional spark plugs[1] through which a high voltage was applied to the inside electrodes were replaced by Teflon plugs for better insulation from surface leakage. A safety diaphragm and needle valves were attached to the bomb just as in the previous work. The leak rate of the bomb system was less than 2 mmHg per hour in any case, and the bomb was filled with the test gas after repeated washing operations which took less than 3 min.

The silent discharge electrodes were composed of two polished Toshiba Terex glass plates (hard glass of the boric oxide type) 5 cm×6 cm×1 mm. The discharge gap distance of the electrodes was maintained by means of cementing an appropriate glass piece in each corner of the plate, and the discharge gap width was within the limit of 2.05—2.12 mm. Tin foil (7.5 cm^2) was stuck on the outside of the glass electrodes. The entire set-up of the electrodes was sustained by two springs which acted as electric leads insulated from the test bomb by the Teflon plugs.

The pick-up system for the emission from the ignited gas between two electrodes consisted of two slits, an interference filter,*1 and a photomultiplier tube (RCA 1P-28). The slits were designed so as not to transmit any light from the electrode surface. The interference filter separated the band system of $OH(^2\Sigma-^2\Pi)_{v=0,0}$ from the other emission of the ignited gas. The signal from the photomultiplier tube and the current diagram of the discharge were recorded simultaneously on a dual-beam oscilloscope.

To avoid unnecessary disturbance of the light-emission trace due to the discharge noise, much care was taken and all the ground points were coordinated at a unified earth point while the test bomb was floating, entirely from the ground.

A primary DC current was applied to the primary coil of a transformer through a switch, the ON and OFF operation of which produced secondary high tension in the secondary circuit. The discharge intensity or the pulse current in the secondary circuit could be regulated by changing the primary DC current, while the discharge period was less affected. In the present experiment, the high tension in the secondary coil which accompanied the ON stage of the switch was used exclusively.

Results

Typical oscillographic patterns of the pulse current and of the signal from the photomultiplier tube are shown in Fig. 1, where t and τ_i denote the discharge period and the ignition delay time

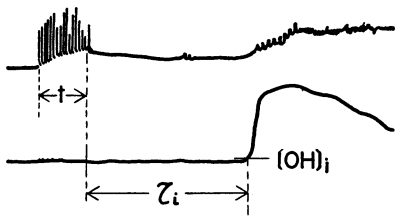

Fig. 1. Oscillographic pattern of current diagram (upper trace) and OH emission profile (lower trace).

respectively. The ignition delay time is determined by two cut-off points, one of which is the termination of the silent electric discharge and the other, the rise of the light emission to a definite value. In the figure, the ordinate of the upper trace can be represented by Coulomb units; the sum of the pulse heights divided by t gives the pulse current, I_p.

With an increasing in the pulse current, the ignition delay time decreased. Figures 2 and 3 show the relation between the ignition delay time and the logarithm of the pulse current in the argon diluent and the helium diluent respectively. The solid lines in the figures represent the least-square

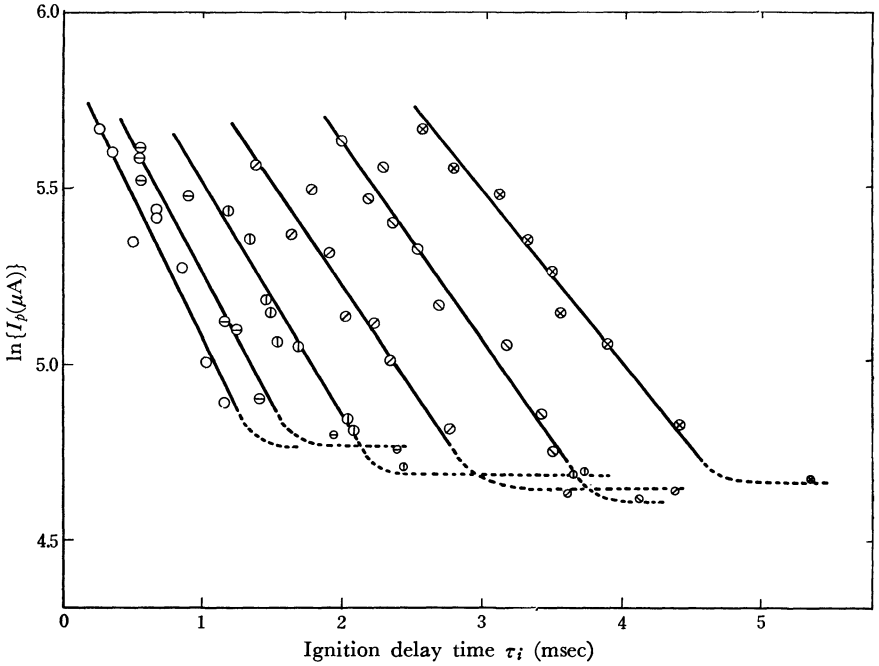

Fig. 2. Relation between ignition delay time and pulse current in argon diluent mixtures. Diluent composition is; ○, 5%; ⊖, 15%; ⓘ, 25%; ⊘, 35%; ⊘ 45%; ⊗, 55%.

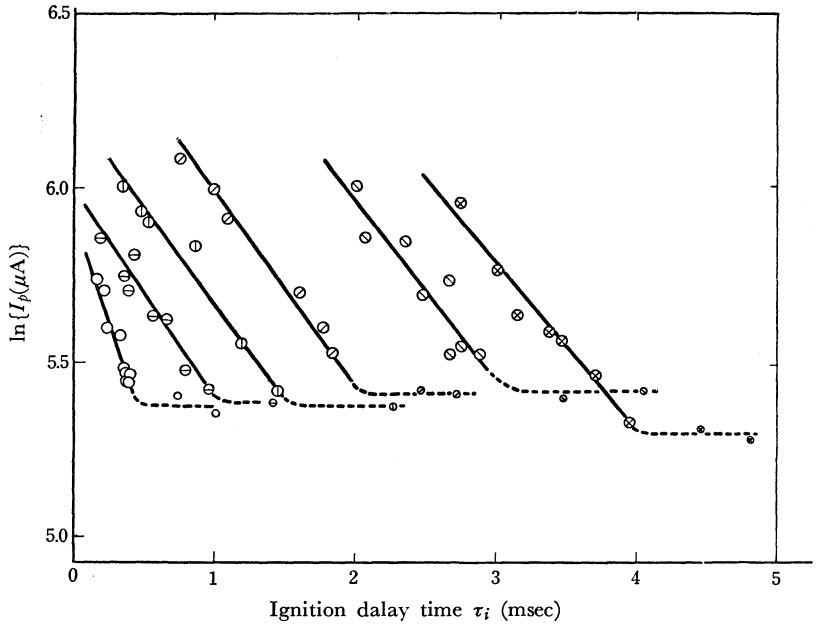

Fig. 3. Relation between ignition delay time and pulse current in helium diluent mixtures. Data points as in Fig. 2.

lines of the experimental results which are shown by the larger circles. The ignition delay time shows a linear relationship against the logarithm of the pulse current well above the threshold of the ignition, though the results most contiguous to the threshold manifest themselves in the longer delay time region, as are shown by the smaller circles.

The threshold pulse current value of the ignition in the helium diluent is of an order of magnitude higher than that in the argon diluent, while the threshold value in argon tends to decrease with an increase in the argon fraction; however, only the difference in the slopes of the solid lines in the argon diluent and the helium diluent will be discussed in the present paper.

To check indirectly whether or not any unexpected corona discharge occurred, electrodes, the outer surfaces and corners of which had been covered by paraffin wax, were tested. However, there was no significant difference in the experimental results between paraffin-coated and non-coated electrodes.

Two photomultiplier experiments, in which one of the photomultipliers was used for the observation of the outer side of the electrodes, and the other, for the inside, were conducted. It was confirmed that the ignition always started from the midst of the electrodes.

Discussion

In the course of the pre-induction period, where the silent electric discharge takes place, the chain-carrier radicals H, O, and OH, will be produced:

$$0)\quad H_2,\ O_2 \text{ and } M \xrightarrow{R_0} H,\ OH \text{ and } O$$

where R_0 denotes the rate of the formation of any specific chain-carrier radicals.

As far as the radical concentration at the termination of the discharge is concerned, the following two cases can be presumed as an approximation. If the discharge period, t, is long enough for the radicals to attain a saturated concentration through the discharge on condition that the forward rate is proportional to the pulse current[6,7] and that the decay of radicals is proportional to the concentration, then the radical concentration at the end of the discharge will be proportional to the pulse current. On the other hand, if the back reaction of decay of radicals can be ignored, then the radicals will accumulate through the discharge period, t, and the radical concentration at the end of the discharge will be proportional to $(R_0 \times t)$ or to the pulse current multiplied by t. However, under the present experimental conditions, the discharge period, t, was independent of the pulse current, as was stated formerly; therefore, the radical concentration at the end of the discharge will again be proportional to the pulse current.

Accordingly, we can estimate that the radical concentration at the end of the discharge is proportional to the pulse current, or:

$$[H]_0 \propto [O]_0 \propto [OH]_0 \propto I_p \qquad (1)$$

After the termination of the discharge, the reaction profile will be analogous to the shock-initiated induction-period reaction starting from the above radical concentration.

The elementary reaction in the hydrogen and oxygen system which should govern the induction period would appear to be the bimolecular reaction among H, O, OH, H_2 and O_2 and the three-body radical recombination reaction. However, in the present case we disregard the mutual reaction among H, O and OH because the concentrations of such species will be very low compared to those of hydrogen and oxygen during the induction period. Accordingly, we assume the following reaction scheme[8,9]:

$$1)\quad H + O_2 \xrightarrow{k_1} OH + O$$

$$2)\quad O + H_2 \xrightarrow{k_2} OH + H$$

$$3)\quad OH + H_2 \xrightarrow{k_3} H_2O + H$$

$$4)\quad H + O_2 + M \xrightarrow{k_4} HO_2 + M$$

Miyama and Takeyama[9] found that the gas-phase reaction of HO_2 came to play an important role in a low-temperature and high-pressure regime shock wave experiment. The fate of HO_2, which should be taken into consideration in the present experimental environment, will be:

$$5)\quad HO_2 + H_2 \xrightarrow{k_5} H_2O_2 + H$$

$$6)\quad HO_2 \xrightarrow[\text{wall}]{K_6} \text{destruction}$$

where K_6 is a function of the electrode dimensions, the diffusion coefficient, and the chain-breaking efficiency.

The steady-state assumptions for the O, OH, and HO_2 radicals will lead to the equation:

$$[H] = [H]_0 \exp[\{2k_1 - k_4[M]K_6/(K_6 + k_5[H_2])\}[O_2]\tau] \qquad (2)$$

and finally to:

$$[OH] = [OH]_0 \exp[\{2k_1 - k_4[M]K_6/(K_6 + k_5[H_2])\}[O_2]\tau] \qquad (3)$$

where the origin of time, τ, should coincide with the termination of the discharge and where $[H]_0$ and $[OH]_0$ are the concentrations of H and OH at $\tau = 0$. We had adopted the rise of OH emission to a definite value as to be used for a cut off point of the ignition delay time, τ_i.

8) G. L. Schott and J. L. Kinsey, *J. Chem. Phys.*, **29**, 1177 (1958).

9) H. Miyama and T. Takeyama, *ibid.*, **41**, 2287 (1964).

Belles and Lauver[10] referred to the possibility of using the emitted light as an indication of the progress of the main reaction to allow quantitative comparisons to be made between the induction times measured by following the concentration of the ground state OH(Π) with absorption spectroscopy and those measured by the easier method of observing the emitted light, regarding OH(Σ) as having been formed in the monoradical reaction: $H+O_2+H_2 \rightarrow H_2O+OH(\Sigma)$. Accordingly, we assumed that the ignition delay time, τ_i, was approximately the time interval between two cuts, namely, the termination of the discharge and the rise of OH(Π) radicals to a certain definite value of $[OH]_i$, though our recent shock-wave studies of the emission of OH($\Sigma-\Pi$)[11] ascribed the chemical excitation of OH(Σ) to the biradical reaction of $H+O+M \rightarrow OH(\Sigma)+M$.

Then:

$$[OH]_i = [OH]_0 \exp[\{2k_1-k_4[M]K_6/(K_6+k_5[H_2])\}[O_2]\tau_i] \quad (4)$$

Equations (1) and (4) lead to:

$$-\log(I_p) = \{2k_1-k_4[M]K_6/(K_6+k_5[H_2])\}[O_2]\tau_i+C \quad (5)$$

provided $[OH]_i$ is a certain definite value. The above relation can represent the experimental results of linear relationship between $\log(I_p)$ *vs.* τ_i.

The values of $2k_1-k_4[M]\times F$ which were obtained from the slopes of the least-square lines in Figs. 2 and 3 are listed on Table 1, where F is the abbreviation of the factor $K_6/(K_6+k_5[H_2])$. The difference between columns 2 and 3 on the same line of Table 1 can be expressed by: $([M]^{Ar}_{He}-[M]^{Ar}_{Ar})k^{Ar}_4\times F$, where $[M]^{Ar}_{Ar}$ and $[M]^{Ar}_{He}$ denote the third-body concentration of the two mixtures. The coefficients of the third-body ability of gas molecules on the reaction 4) had been established through experiments on the second explosion limit of hydrogen and oxygen. The coefficients of argon, helium, and oxygen, in comparison with that of hydrogen, are 0.20, 0.36 and 0.35 respectively.[12] If the coefficient of argon is taken to be unity, the coefficients of helium, hydrogen, and oxygen are 1.80, 5.00, and 1.75. The superscript Ar in the above expression denotes that the coefficient for the third-body ability of argon is taken to be unity.

Table 1. The values for $2k_1-k_4[M]\times F$ obtained from the slopes of the least square lines in Figs. 2 and 3

Diluent composition %	$2k_1-k_4^{Ar}[M]^{Ar}_{Ar}\times F$ (Ar diluent) ($sec^{-1}\,mol^{-1}\,l$)	$2k_1-k_4^{Ar}[M]^{Ar}_{He}\times F$ (He diluent) ($sec^{-1}\,mol^{-1}\,l$)
5	1.84×10^5	2.60×10^5
15	1.86×10^5	1.47×10^5
25	1.90×10^5	1.58×10^5
35	1.91×10^5	1.63×10^5
45	2.15×10^5	1.96×10^5
55	2.51×10^5	2.30×10^5

$F = K_6/(K_6+k_5[H_2])$

Reactant in the mixture is stoichiometric mixture of hydrogen and oxygen.

$[M]^{Ar}_{Ar}$, $[M]^{Ar}_{He}$: Third body concentration for reaction 4), of the mixtures with argon diluent and helium diluent. Superscript Ar denotes the third body ability of argon being stood for standard to express the third body concentration and the rate for reaction 4).

The test gas of a definite diluent composition contained a definite amount of a stoichiometric mixture of hydrogen and oxygen, and the features of the reaction may be expected to be essentially the same in both the argon-diluent and helium-diluent mixtures, and so $[M]^{Ar}_{He}-[M]^{Ar}_{Ar}$ can be attributed solely to the difference in the third-body efficiency of the diluent gases, argon and helium, or:

$$[M]^{Ar}_{He} - [M]^{Ar}_{Ar} = (1.8-1.0)[M]_0 f_{diluent}$$

where $f_{diluent}$ denotes the mole fraction of the diluent gas. The ignition took place in a constant volume system, and $[M]_0$ is obtainable assuming a negligible depletion of the reactant during the induction period. Thus, the values for $k^{Ar}_4\times F$ were derived from a comparison of the experimental results in columns 2 and 3 in Table 1 without any further assumptions.

The values for k_1 could also be derived from the values of column 2 and/or column 3 in Table 1 and the known $k^{Ar}_4\times F$ values, assuming the value for the third-body concentration $[M]^{Ar}_{Ar}$ and/or the concentration $[M]^{Ar}_{He}$, of the mixtures. In the course of the induction period the contribution of water to the reaction 4) is of no consequence, though its third-body ability is quite large.[12] The contribution of other intermediate species can reasonably be ignored. The third-body concentration for the mixture with the argon diluent will then be:

$$[M]^{Ar}_{Ar} = [M]_0(f_{Ar} + 5.00f_{H_2} + 1.75f_{O_2})$$

while for the mixture with the helium diluent it will be:

$$[M]^{Ar}_{He} = [M]_0(1.80f_{He} + 5.00f_{H_2} + 1.75f_{O_2})$$

where f_{Ar}, f_{He}, f_{H_2}, and f_{O_2} are the mole fractions of the subscribed gases. The values for k_1 thus derived from the experimental results are listed on

Diluent composition, %	k_1 ($sec^{-1} mol^{-1} l$)	F	k_5/K_6 ($mol^{-1} l$)
5	—	—	—
15	6.60×10^5	1.39×10^{-2}	0.89×10^4
25	3.50×10^5	0.68×10^{-2}	2.08×10^4
35	2.41×10^5	0.42×10^{-2}	3.85×10^4
45	1.76×10^5	0.22×10^{-2}	8.70×10^4
55	1.81×10^5	0.20×10^{-2}	10.65×10^4

Table 2.

The factor F represents the fraction of atoms H which are destroyed by reacting through the reaction 4); concurrently it will show the net effect of the chain breaking in the reaction 4). The estimation of F was made by assuming the value of k_4^{Ar} in the induction period. The activation energy for the reaction 4) is a small, negative value, and the k_4^{Ar} value in the induction period can be reasonably assumed from a literature expression available elsewhere[13] if we know the approximate temperature during the induction period. An attempt was made to assume the value for k_4^{Ar} with regard to the threshold temperature. The expressions[14] for k_1 and k_4^{Ar} which were used for the estimation of the threshold temperature were $k_1=10^{11.313}\exp(-16490/\boldsymbol{R}T)$ and $k_4^{Ar}=8.6\times10^8\exp(+1280/\boldsymbol{R}T)$, while the threshold expression used was $2k_1=k_4^{Ar}[M]^{Ar}$.

The values for F thus estimated and the values for k_5/K_6 reduced from F are listed on Table 2. The values for F which appear in the table are considerably smaller than unity, signifying that the reaction 5) is predominant over the reaction 6). Miyama and Takeyama[9] have shown that the reaction 5) became significant in reproducing chain carrier radicals in low-temperature, high-pressure regime shock wave experiments. These results as well as ours possibly suggest that chain-carrier reproduction from HO_2 is predominant over the surface destruction of HO_2 under our experimental conditions.

The values for k_1 in Table 2 obtained from the experimental results resembled the literature value[14] in the temperature range between the initial temperature and the second explosion-limit temperature. Due to the small value of F, the net effect of the chain-breaking reaction 4) becomes insignificant; the accumulation of radicals might be persistent resulting in the actuation of ignition even in the temperature range where the k_1 value was observed not to be above the value of $k_4^{Ar}[M]^{Ar}/2$. Fujimoto[15] had provided experimental evidence that in his reflected shock wave ignition, the ignition took place under the threshold temperature.

The variation in values for k_1 and k_5/K_6 in Table 2 is difficult to elucidate quantitatively because of a lack of experimental evidence about the induction-period temperature, which requires a more detailed investigation.

Summary

The induction-period reaction of silent discharge ignition in a hydrogen and oxygen system appears to be analogous to the shock-initiated reaction in a low-temperature high-pressure regime. The reaction in the discharge period may be likened to the 0th. reaction of shock-wave ignition. By comparing the argon diluent and the helium diluent systems, the net effect of chain breaking through the reaction 4) was estimated.

Theory of the Gel-forming Polymerization of Polyepoxy and Related Compounds

Tokio YAMABE and Kenichi FUKUI

Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received November 29, 1968)

A theory of the molecular-size distribution of cross-linked polymers to be formed from a mixture of polyfunctional monomers and mono-functional monomers through step-by-step polymerizations by certain initiators is presented on the assumption that all unconverted functional groups are equireactive for both initiations and propagations, which proceed without termination, transfer, or cyclization. The distribution is obtained by applying the statistical theory of gel formation with multifunctional interunit junctions, which are, in this case, equivalent to cross-linking chains. Some noticeable theoretical results are obtained: (1) the distribution obtained is quite different from that obtained for branched-chain polymers by condensation polymerization; (2) the fraction of converted functional groups at the gel point is independent of the initial concentration of the monofunctional monomer, while it is in proportion to the ratio of the initial concentration of the initiator to that of polyfunctional monomers; (3) there is a certain condition under which the gelation will never take place, even at complete conversion, and (4) the state to be reached after the gel point is quite different from the results obtained previously. The case of a mixture of monomers with any distribution of functionalities is also briefly presented. An explanation of the validity of the distribution beyond the gel point is discussed in the Appendix.

It happens that, in certain step-by-step polymerizations, the chain-initiation and the subsequent addition proceed with comparable velocities, without either termination or transfer. Such is the case in some ring-opening polymerizations of cyclic compounds, such as epoxy, cyclic imino, amide, or anhydride compounds, or in some anionic polymerizations of vinyl compounds.*1

The molecular-size distribution of linear polymers obtained from a monofunctional monomer such as ethylene oxide through the step-by-step polymerization was first given by Flory,[1] while the distribution of cross-linked polymers formed from f-functional monomers ($f \geqq 1$) was reported in our own previous paper.[2] Both were obtained by solving kinetic equations describing the polymerization processes.

In the present paper, a theory of the molecular-size distribution of cross-linked polymers to be formed from a mixture of polyfunctional and monofunctional monomers is presented. By this theory, one can sufficiently explain the characteristic features of such a polymerization process without any loss of generality. The condition for the gelation and the property of the sol fraction after the gel point are also investigated. In the last portion of this text, the case of a mixture of polyfunctional monomers with any distribution of their functionality is treated.

The distribution was obtained, not by solving the kinetic equations as in the previous paper, but by applying the statistical theory of polymerization with multifunctional interunit junctions.[3] A chain to be cross-linked may reasonably be regarded as a kind of interunit junction, as was treated previously.[3] With this idea, which is the essential point of the present paper, we are able to obtain the exact product distribution for the step-by-step polymerization process.

Let us treat first a mixture of f-functional monomers and monofunctional monomers, and then a mixture of monomers of various functionalities. The former and the latter are referred to as Case I and Case II respectively.

Case I. A System Composed of f-Functional and Monofunctional Monomers

Molecular-size Distribution. It should be remarked at the outset that the treatment presented below is applicable to all polymerization processes of this kind which fulfill the following assumptions, already set up in the previous paper:[2] (1) Each polyfunctional monomer possesses f identical

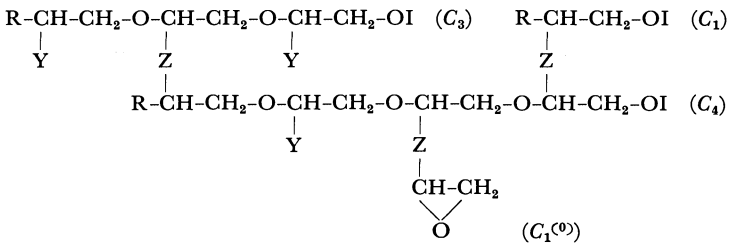
functional groups, and all unconverted functional groups on the monomers or polymers are equivalent and of the same reactivity. (2) Any unconverted functional group can react with the initiator to be changed into a growing chain, and the rate of the initiating step is equal to that of the subsequent addition step. (3) Moreover, reactions proceed without either termination or transfer. Therefore, the number of growing chains is equal to the number of initiators consumed. (4) No formation of rings, not even of the small ones formed by intra-inter polymerization, occurs through the process of polymerization.

Suitable examples may be supplied from the polymerizations of polyepoxides initiated by some hydroxy compounds or secondary amines, or catalyzed by some tertiary amines or boron trifluoride complexes.[4,5] Another ideal case may be realized in the anionic polymerization of some polyvinyl compounds by sodium.[6]

Under these assumptions, a polymeric molecule is composed of various lengths of growing chains. This may be visualized by the following scheme, in which the example taken is the ring-opening copolymerization of monoepoxide, Y–CH(–O–)–CH_2, and diepoxide, CH_2(–O–)–CH–Z–CH(–O–)–CH_2, where RI is the initiator and where Y and Z designate the residues of monoepoxide and diepoxide respectively:



In this schematic presentation, C_k and $C_1^{(0)}$ stand for a growing chain containing k functional groups and an unconverted functional group respectively. The polymeric molecule can be described, therefore, by specifying the length of each growing chain, that is, the number of functional groups involved in it, if any further difference in the structure of the polymeric molecule is disregarded.

On the other hand, a previous paper[3] has treated, in general, the case where the polymerization proceeds with various kinds of interunit junctions being concurrently formed in a system. Here the term "interunit junction" indicates a junction connecting several functional groups, each in different monomeric units, irrespective of the order of combination. According to the number of functional groups involved in one interunit junction formed, they are named as mono-, bi-, ter-, ..., and, more generally, multifunctional interunit junctions. Following this definition, a growing chain composed of k functional units is a k-functional interunit junction.

Moreover, it should be noted here that there are two kinds of monofunctional interunit junctions. The one is apparently a growing chain produced from a functional group indicated by C_1, and the other is that of an unconverted functional group indicated by $C_1^{(0)}$ in the sense of the scheme mentioned above. In this fashion the molecular-size distribution of the polymerization of polyfunctional epoxy or vinyl compounds can be obtained exactly, as long as the polymerization satisfies the conditions already assumed.

Now, let I_0, N_1, and N_f be the numbers of initially-existing initiators, monofunctional monomers, and f-functional monomers respectively, in a system and let $M(n_1, n_f; \nu)$ be the number of polymeric molecules containing ν growing chains, n_1 monofunctional monomers, and n_f f-functional monomers.

Then, as the polymeric molecule has ν growing chains, it contains $(n_1+n_f+\nu-1)$ units of converted functional groups and, hence, $\{(f-1)n_f-\nu+1\}$ unconverted functional groups, since intramolecular reactions are excluded. According to this definition, $M(0, 0; 1)$, $M(1, 0; 0)$, and $M(0, 1; 0)$ represent the instantaneous values of the numbers of initiators, monofunctional monomers, and f-functional monomers respectively.

From the above definitions, we obtain:

$$I_0 = \sum M(n_1, n_f; \nu) \quad (1)$$

$$N_1 = \sum n_1 M(n_1, n_f; \nu) \quad (2)$$

$$N_f = \sum n_f M(n_1, n_f; \nu) \quad (3)$$

where the summation should cover all the integers of n_1, n_f, and ν satisfying $(f-1)n_f+1 \geqq \nu \geqq 0$.

Moreover, if we denote the total number of molecules at the initial state and at a given instant by M_0 and M, respectively, these can be obtained

as follows:

$$M = \sum M(n_1, n_f; \nu) \tag{4}$$

$$M_0 = I_0 + N_1 + N_f = \sum (\nu + n_1 + n_f) M(n_1, n_f; \nu) \tag{5}$$

In order to formulate the molecular-size distribution, it is convenient to introduce two variables, α and ρ, in such a way as:

$$\alpha = F/I_0 \tag{6}$$

$$\rho = (1/F)\sum (n_1 + n_f + \nu - 1) M(n_1, n_f; \nu) = (M_0 - M)/F \tag{7}$$

where α stands for the initial number of functional groups per initiator, where ρ is the fraction of converted functional groups, and where $F = N_1 + fN_f$ is the total number of functional groups in the system.

Now let us attempt to obtain the distribution by the use of the statistical theory of polymerization with multifunctional interunit junctions previously proposed by the present authors.[3]

Let $m(n_1, n_f; \{j_k\})$ be the number of polymeric molecules which are composed of n_1 monofunctional monomeric units and n_f f-functional monomereric units and are also constructed by j_1 monofunctional, j_2 bifunctional, $\cdots$, j_k k-functional chains. The set of these numbers is designated as $\{j_k\}$. In particular, the number of unconverted functional groups is written as $j_1^{(0)}$. Also, we designate the probabilities that a functional group is involved in the growing chain composed of k functional chains ($k \geqq 1$) and in that of unconverted ones as P_k and $P_1^{(0)}$ respectively. It obviously follows that:

$$P_1^{(0)} + \sum_{k=1} P_k = 1 \tag{8}$$

According to Eq. (48) in Ref. 3, the most probable distribution of $m(n_1, n_f; \{j_k\})$ in equilibrium is given by:

$$m(n_1, n_f; \{j_k\}) = (N_1 + fN_f)((f-1)n_f)!(n_1 + n_f - 1)! \frac{w_1^{n_1}}{n_1!} \cdot \frac{w_f^{n_f}}{n_f!} \cdot \frac{P^{j_1^{(0)}}}{j_1^{(0)}} \cdot \prod_{k \geqq 1} \frac{P_k^{j_k}}{j_k!} \tag{9}$$

with these conditions:

$$j_1^{(0)} + \sum_k j_k - 1 = (f-1)n_f \tag{10}$$

and:

$$n_1 + n_f - 1 = \sum_k (k-1) j_k \tag{11}$$

where w_1 and $w_f (= 1 - w_1)$ are the weight fractions of monofunctional monomers and f-functional monomers respectively; namely,

$$w_1 = N_1/(N_1 + fN_f), \qquad w_f = fN_f/(N_1 + fN_f) \tag{12}$$

In the step-by-step polymerization, the number of growing chains composed of k functional groups, which is denoted hereafter by J_k, was given by Flory[7] as follows:

$$J_k = \frac{\lambda^k e^{-\lambda}}{k!} I_0 \qquad (k \geqq 1) \tag{13}$$

$$J_1^{(0)} = I_0 e^{-\lambda}$$

The probability of the formation of a k-functional interunit junction, P_k, is then given, according to the definition, by:

$$P_k = \frac{kJ_k}{F} = \frac{I_0}{F} \cdot \frac{\lambda^{k-1} e^{-\lambda}}{(k-1)!} \tag{14}$$

Therefore, the fraction of converted functional groups, ρ, is represented by the following relation:

$$\rho = \sum_{k \geqq 1} P_k = \frac{\lambda I_0}{F} \sum_{k \geqq 1} \frac{\lambda^{k-1} e^{-\lambda}}{(k-1)!} = \frac{\lambda I_0}{F} = \frac{\lambda}{\alpha}$$

which endows the $\lambda (= \alpha\rho)$ of Eq. (13) with the physical meaning as the mean length of a growing chain (see Eq. (25)). Then, the fraction of unconverted functional groups, $P_1^{(0)}$, is given by:

$$P_1^{(0)} = 1 - \sum_{k \geqq 1} P_k = 1 - \rho \tag{16}$$

By the use of these equations, the distribution, $m(n_1, n_f; \{j_k\})$, may be rewritten as follows:

$$m(n_1, n_f; \{j_k\}) = F \cdot \frac{(fn_f - n_f)!(n_1 + n_f - 1)!}{(fn_f - n_f + 1 - \sum_{k \geqq 1} j_k)!} \cdot \frac{w_1^{n_1}}{n_1!} \cdot \frac{w_f^{n_f}}{n_f!} \cdot \prod_k \frac{1}{j_k!((k-1)!)^{j_k}}$$

$$\times (1-\rho)^{fn_f - n_f + 1 - \sum_k j_k} \cdot \rho^{\sum_k j_k + n_1 + n_f - 1} \cdot e^{-(\sum_k j_k)\alpha\rho} \tag{9'}$$

According to the definition of $M(n_1, n_f; \nu)$ it is obvious that;

$$M(n_1, n_f; \nu) = \sum_{\sum_k j_k = \nu} m(n_1, n_f; \{j_k\}) \tag{17}$$

7) P. J. Flory, *J. Am. Chem. Soc.*, **62**, 1561 (1940).

where summation should cover all sets of positive integers (zero included), j_k, which satisfy the condition: $\sum_k j_k = \nu$.

On the other hand, the following mathematical relation is necessary in calculating the summation in Eq. (17):

$$\sum_{\sum_k j_k=\nu} \frac{(\sum j_k)!}{\prod_k j_k![(k-1)!]^{j_k}} = \left[\text{the coefficient of } Z^{\sum_k (k-1)j_k} \text{ in the expantion of } \left(\sum_{k\geqq 1}^{\infty} \frac{Z^{k-1}}{(k-1)!}\right)^{\sum_k j_k}\right]$$

$$= \frac{\nu^{\sum_k (k-1)j_k}}{(\sum_k (k-1)j_k)!} = \frac{\nu^{n_1+n_f-1}}{(n_1+n_f-1)!} \tag{18}$$

Using this relation, we finally obtain the size distribution as follows:

$$M(n_1,\ n_f;\ \nu) = (N_1+fN_f)\frac{(fn_f-n_f)!\,\nu^{n_1+n_f-1}}{(fn_f-n_f+1-\nu)!\,\nu!} \cdot \frac{{w_1}^{n_1}}{n_1!} \cdot \frac{{w_f}^{n_f}}{n_f!} \rho^{\nu}(1-\rho)^{(f-1)n_f+1-\nu}(\alpha\rho)^{n_1+n_f-1} \cdot e^{-\nu\alpha\rho} \tag{17'}$$

The resulting distribution is, however, by no means restricted to the case of equilibrium system; it should be equally applicable to unidirectionally changing systems, as long as the assumptions mentioned above are fulfilled. This point is supported by the fact that the distribution given by Eq. (17') can equally be derived from differential equations describing the polymerization kinetics, although they are too complex. Also, the following fact helps the present discussion. The distribution for the special case in which only f-functional monomers are contained is reduced to the equation:

$$M(0,\ n_f;\ \nu) = \frac{(fN_f)(fn_f-n_f)!\,\nu^{n_f-1}}{\nu!\,(fn_f-n_f+1-\nu)!\,n_f!} \rho^{\nu}(1-\rho)^{(f-1)n_f+1-\nu}(\alpha\rho)^{n_f-1}e^{-\nu\alpha\rho}$$

which agrees with the distribution function of our previous paper[2] derived from the kinetic method.

The instantaneous values of the initiators, the monofunctional monomers, and the f-functional monomers may be presented, respectively, as:

$$M(0,\ 0;\ 1) = I = I_0e^{-\alpha} \tag{19}$$

$$M(1,\ 0;\ 0) = N_1(1-\rho) \tag{20}$$

$$M(0,\ 1;\ 0) = N_f(1-\rho)^f \tag{21}$$

The number and weight-average molecular sizes can readily be obtained as:

$$\langle P_n\rangle = 1 + \frac{f\rho}{1-f\rho-(1-\rho)^f+f/\alpha} \tag{22}$$

$$\langle P_w\rangle = 1 + \frac{(f/\alpha)[(\alpha\rho)^2+2\alpha\rho+(f-1)\alpha\rho^2]}{[1-(1-\rho)^f+f/\alpha][1-(f-1)\alpha\rho^2]} \tag{23}$$

Both the unconverted monomers and the initiators are excluded in these averages.

The number- and the weight-average chain lengths, $\langle k_n\rangle$, $\langle k_w\rangle$, of cross-linked polymers are easily obtained from Eq. (14) as:

$$\langle k_n\rangle = \sum_{k=1}^{\infty} P_k / \sum_{k=1}^{\infty} (P_k/k) = \lambda/(1-e^{-\lambda}) \tag{24}$$

$$\langle k_w\rangle = \sum_{k=1}^{\infty} kP_k / \sum_{k=1}^{\infty} P_k = 1+\lambda \tag{25}$$

where the unconverted functional groups and the initiators are not taken into account.

The Condition for Gelation. The critical condition determining the gel point can be characterized by the following equation, derived from Eqs. (6) and (23):

$$\rho_c = \left[\frac{I_0}{f(f-1)N_f}\right]^{1/2} \tag{26}$$

where ρ_c is the extent of reaction at the gel point. It is remarkable that ρ_c is dependent on the amount of initiators as well as on that of f-functional monomers, while it is independent of the amount of monofunctional monomers.

It should be noted here, however, that there exists a restriction for the attainment of the gel point. This comes from the condition $\rho \leqq 1$, which implies that the fraction of converted functional groups should be less than unity. Therefore, it is necessary, on the basis of Eq. (26), that:

$$f(f-1)N_f \geqq I_0 \tag{27}$$

for the attainment of the gel point. If the system is initially prepared, irrespective of the amount of the monofunctional monomer, in such a way that

$$I_0 > f(f-1)N_f \geqq 0 \tag{28}$$

the critical conversion, ρ_c, can never be reached at any extent of reaction. Such an amount of f-functional monomers compared with that of initiators is too small for the gelation to occur, so such a system will remain as a sol phase. The circumstance mentioned above may be clarified by information as to the number and the weight averages of chains in a mixture of polymeric molecules. Using Eq. (17'), we obtain the number-average number of chains, $\langle \nu_n\rangle$, which is usually called by the crosslinking index, γ:

$$\langle \nu_n\rangle = \frac{\sum \nu M(n_1, n_f; \nu)}{\sum M(n_1, n_f; \nu)} = \left[1 - \frac{N_f}{I_0}\left(\frac{(1-\rho)^f-(1-f\rho)}{1-e^{-\alpha\rho}}\right)\right]^{-1} \tag{29}$$

while the weight-average number of chains, $\langle \nu_w\rangle$, is written:

$$\langle \nu_w \rangle = \frac{\sum \nu(n_1+fn_f)M(n_1, n_f; \nu)}{\sum (n_1+fn_f)M(n_1, n_f; \nu)} = \frac{1+(f-1)w_f}{(1-w_f(f-1)\alpha\rho^2)(1-w_f(1-\rho)-w_f(1-\rho)^f)} \tag{30}$$

Therefore, the number-average number of chains at the gel point, $\langle \nu_n \rangle_c$, can be represented by:

$$\langle \nu_n \rangle_c \cong \left[\frac{1}{2}+\frac{(f-2)}{3!}\rho_c-\frac{(f-2)(f-3)}{4!}\rho_c^2+\cdots\right]^{-1} \tag{31}$$

where the term of $e^{-\alpha\rho}$ is neglected.

If the initial condition, namely, the N_f/I_0, ratio is varied within the range indicated by Eq. (27) within which the gelation occurs, ρ_c will change from zero to unity. Then we have:

$$2 \geqq \langle \nu_n \rangle \geqq \frac{f}{f-1} \tag{32}$$

which shows that in the N_1 - N_f system the cross-linking index at the gel point keeps the value between two and $f/(f-1)$ as long as the gelation takes place. On the other hand, $\langle \nu_w \rangle$ tends to become infinite as ρ nears ρ_c, irrespective of the functionality, f, of the polyfunctional monomer.

At complete conversion ($\rho=1$) without gelation, which is attained by means of Eq. (28), the number-average number of branches is:

$$\langle \nu_n \rangle_{\rho=1} = \frac{I_0}{I_0-N_f(f-1)} \tag{33}$$

while the weight-average number is:

$$\langle \nu_w \rangle_{\rho=1} = \frac{N_1+f^2N_f}{N_1+fN_f} \cdot \frac{I_0}{I_0-f(f-1)N_f} \tag{34}$$

The weight-average molecular size is a finite value, as is given by:

$$\langle P_w \rangle_{\rho=1} = \frac{N_1+f^2N_f}{N_1+fN_f} \cdot \frac{I_0+N_1+fN_f}{I_0-f(f-1)N_f} \tag{35}$$

Likewise, according to the variation in the initial ratio, N_f/I_0, in the range of Eq. (28), $\langle \nu_n \rangle_{\rho=1}$ and $\langle \nu_w \rangle_{\rho=1}$ vary in the ranges:

$$\frac{f}{f-1} > \langle \nu_n \rangle_{\rho=1} \geqq 1 \tag{36}$$

and

$$\infty > \langle \nu_w \rangle_{\rho=1} \geqq 1 \tag{37}$$

respectively.

The small average number of branches indicated by Eq. (36) implies that a small amount of the functional groups of the f-functional monomers specified by the condition of Eq. (28) is consumed by the reaction with the initiator, thus preventing the branching. The chains in polymeric monomers can grow longer and longer by means of the reaction with monofunctional monomers, without any branching in the polymeric molecules. In this way, the average length of a chain, given by Eq. (24), in polymeric molecules finally reaches $\alpha=F/I_0$ at complete conversion.

Furthermore, at a given value of F for a fixed value of I_0, the range of N_1, where the gelation does not occur at any extent of reaction, can be rewritten from Eq. (28) as:

$$F \geqq N_1 \geqq F - \frac{I_0}{f-1} \tag{28'}$$

This equation presents the amount of monofunctional monomers which may be present without causing gelation; it may have practical significance since this equation gives the experimental condition under which the polymerization of polyfunctional monomers might be carried out without gelation. The equation determining the gel point reported in a previous paper[2] is completely consistent with Eq. (26).

The situation is different in the corresponding case of the selfcondensation between f-functional and bi-functional monomers. The fraction of converted functional groups at the gel point, ρ_c in our notation, expressed by Flory[7] and Stockmayer[8] as:

$$\rho_c = \frac{1}{1+(f-2)w_f}$$

can never exceed unity, so the gelation always takes place at a certain conversion. Compared with this result, one can recognize that the present treatment indicates the importance of the amount of initiator for the condition of gelation.

Relationships after the Gel Point. This section will be devoted to a discussion of the sol fraction after the gel point has been reached. Our general theory, presented previously,[3] will be used here.

In the present case, the generating function, $f(x)$, defined by Eq. (15) in Ref. 3 is expressed as follows:

$$f(x) = w_1 + w_f u^{f-1} \tag{38}$$

where:

$$u(x) = P_1^{(0)} + \sum_{k=1} P_k x^{k-1} \tag{39}$$

or, by the use of Eq. (14):

$$u(x) = 1 - \rho + \rho e^{-(1-x)\lambda} \tag{39'}$$

The characteristic equation defined by Eq. (26) in Ref. 3 can be readily obtained from Eqs. (38) and (39') as:

$$x = f(x) = w_1 + w_f\{1-\rho+\rho e^{-(1-x)\lambda}\}^{f-1} \tag{40}$$

It was proved also in Ref. 3 that, besides the trivial solution $x=1$, there exists another real positive root, $x_1<1$, of Eq. (38) beyond the gel point ($(f-1)\alpha^2>1$). In general, the root is obtained only by numerical methods except in a few special cases.

With this root, x_1, the sol fractions of the mono- and the f-functional monomers, $w_1^{(s)}$ and $w_f^{(s)}$,

8) W. H. Stockmayer, *J. Chem. Phys.*, **11**, 45 (1943).

are obtained as, respectively (see Eq. (25) in Ref. 3):

$$w_1^{(s)} = w_1 u_1 \tag{41}$$

$$w_f^{(s)} = w_f u_1^f \tag{42}$$

where $u_1 = u(x_1)$.

The total sol fraction, W_{sol}, is then given by:

$$W_{sol} = w_1^{(s)} + w_f^{(s)} = x_1\{1 - \rho + \rho e^{-(1-x_1)\lambda}\} \tag{43}$$

The soluble part, $P_k^{(s)}$, of the weight fraction of C_k-chains is given by:

$$P_k^{(s)} = P_k x_1^k \tag{44}$$

$${}^{(s)}P_1^{(0)} = P_1^{(0)} x_1 \tag{45}$$ *2

By the use of Eqs. (42) and (43), the probability, $P_k'^{(s)}$, of forming a C_k-chain in the sol phase is obtained as:

$$P_k'^{(s)} = P_k^{(s)}/W_{sol} = P_k x_1^k / W_{sol} \tag{46}$$

The number- and the weight-average lengths of the chains in the sol phase are expressed as follows:

$$\langle k_n \rangle^{(sol)} = \sum_{k=1}^{\infty} P_k'^{(s)} / \sum_{k=1}^{\infty} (P_k'^{(s)}/k) = \frac{x_1\lambda}{e^{-\lambda}(e^{x_1\lambda} - 1)} \tag{47}$$

$$\langle k_w \rangle^{(sol)} = \sum_{k=1}^{\infty} k P_k'^{(s)} / \sum_{k=1}^{\infty} P_k'^{(s)} = (1+\lambda x_1) e^{-(1-x_1)\lambda} \tag{48}$$

Equations (47) and (48) show that the average chain length varies with the progress of the reaction after the gel point.

Likewise, the fraction, ρ', of converted functional groups in the sol phase is:

$$\rho' = \sum_{k=1}^{\infty} P_k'^{(s)} = \frac{\rho e^{-(1-x_1)\lambda}}{1 - \rho + \rho e^{-(1-x_1)\lambda}} \tag{49}$$

The quantities of the gel phase are then obtained by their differences from the totals, namely:

$$\left.\begin{aligned} w_f^{(g)} &= w_f - w_f^{(s)} = w_f(1 - u_1^f) \\ w_1^{(g)} &= w_1 - w_1^{(s)} = w_1(1 - u_1) \\ W_{gel} &= 1 - W_{sol} = w_1^{(g)} + w_f^{(g)} \end{aligned}\right\} \tag{50}$$

Similarly, we get:

$$\left.\begin{aligned} P_k^{(g)} &= P_k - P_k^{(s)} = P_k(1 - x_1^k) \\ {}^{(g)}P_1^{(0)} &= P_1^{(0)} - {}^{(s)}P_1^{(0)} = P_1^{(0)}(1 - x_1) \end{aligned}\right\} \tag{51}$$

and, hence:

$$\left.\begin{aligned} P_k'^{(g)} &= P_k^{(g)}/W_{gel} \\ {}^{(g)}P_1'^{(0)} &= {}^{(g)}P_1^{(0)}/W_{gel} \end{aligned}\right\} \tag{52}$$

The fraction, ρ'', of converted functional groups in the gel phase is obtained from Eq. (52) as follows:

$$\rho'' = \sum_{k=1}^{\infty} P_k'^{(g)} = \frac{\rho(1 - x_1 e^{-(1-x_1)\lambda})}{(1-x_1) + \rho x_1(1 - e^{-(1-x_1)\lambda})} \tag{53}$$

The weight-average chain length $\langle k_w \rangle^{(gel)}$ forming the gel phase is presented from Eq. (52):

$$\langle k_w \rangle^{(gel)} = \frac{\sum_{k=1}^{\infty} k P_k^{(g)}}{\sum_{k=1}^{\infty} P_k^{(g)}} = \frac{(1+\lambda) - x_1(1+x_1\lambda)e^{-(1-x_1)\lambda}}{1 - x_1 e} \tag{54}$$

Especially, at the instant immediately after the gel point, *i. e.*, at the point where:

$$\rho = \rho_c + \Delta\rho \tag{55}$$

x_1 and u_1 are approximated to the first order of $\Delta\rho$ as follows:

$$x_1 \cong 1 - \frac{4(f-1)w_f}{1 + (f-2)\rho_c}\Delta\rho \tag{56}$$

$$u_1 \cong 1 - \frac{4}{1 + (f-2)\rho_c}\Delta\rho \tag{57}$$

With these values of x_1 and u_1, all the quantities expressed in Eqs. (41) to (54) may be approximated in explicit forms as functions of $\Delta\rho$. For example,

$$W_{gel} \cong \frac{4(w_1 + f w_f)}{1 + (f-2)\rho_c}\Delta\rho \tag{50'}$$

$$\rho'' \cong \frac{1 + (f-1)w_f\rho_c}{1 + (f-1)w_f} + \frac{(f-1)w_f\{2 - (2f-5)\rho_c + (f-6)\rho_c^2\}}{(1 - (f-1)w_f)(1 + (f-2)\rho_c)}\Delta\rho \tag{53'}$$

$$\langle k_w \rangle^{(gel)} \cong 1 + \alpha\rho_c + \frac{\alpha\rho_c}{1 + \alpha\rho_c} - \frac{\alpha}{2}(\alpha\rho_c + 2)(\alpha\rho_c - 1)\Delta\rho \tag{54'}$$

At the gel point, $\Delta\rho \to 0$, both ρ'' and $\langle k_w \rangle^{(gel)}$ have finite values, indicated by the first terms of Eqs (53') and (54').

Case II. A Mixture of Monomers of Various Functionalities

Molecular-size Distribution. Here let us consider briefly the system of a mixture of polyfunctional monomers with different numbers of equivalent functional groups; say, N_1 monofunctional, N_2 bifunctional, $\cdots$, and N_s s-functional monomers.

With the same treatment as in Case I, we can obtain the molecular size distribution of the copolymers formed under the same assumptions:

$$M(n_1, n_2, \cdots, n_s; \nu) = \frac{(\sum_s (s-1)n_s)!\, \nu^{\sum_s n_s - 1}}{(\sum_s s N_s)\, \nu!\, (\sum_s (s-1)n_s + 1 - \nu)!} \cdot \Pi \frac{w_s^{n_s}}{n_s!} \times \rho^{\nu}(1-\rho)^{\sum_s (s-1)n_s + 1 - \nu} \cdot (\alpha\rho)^{\sum_s n_s - 1} \cdot e^{-\nu\alpha\rho} \tag{58}$$

where:

*2 Only for $P_1^{(0)}$, the suffixes (s) and (g), indicating the soluble part and the gel respectively, are hereafter replaced by ${}^{(s)}P_1^{(0)}$ to avoid confusion.

$$w_s = \frac{sN_s}{\sum_s sN_s}, \quad \text{and} \quad \alpha = \frac{\sum_s sN_s}{I_0}$$

The fraction of converted functional groups at the gel point, ρ_c, is given by:

$$\rho_c = \sqrt{\frac{I_0}{\sum_s s(s-1)N_s}} \tag{59}$$

The sol fraction, W_{sol}, is represented by:

$$W_{sol} = \sum_{f=1}^{s} w_f u_1^f \tag{60}$$

where x_1 in Eq (39') defining u_1 is, instead, the lowest positive root of the following equation:

$$x = \sum_{f=1}^{s} w_f x^{f-1} \tag{61}$$

The other relationships after the gel point may be obtained in a similar fashion.

Discussion

First let us discuss the noticeable theoretical finding of Eq. (26), the finding that the fraction of converted functional groups at the gel point depends on the concentration of the initiator or the catalyst.

In the case of the polycondensation of polyfunctional monomers (and, hence, in the case of the radical polymerization of divinyl compounds, which has been considered by Flory and Stockmayer to be equivalent to the case of the self-condensation of tetrafunctional monomers), such a dependency on the initiator has been out of question from the theoretical point of view. Some experimental results show, however, in a few polymerizations of divinyl compounds[9] or diepoxy compounds,[10] a dependency of ρ_c on the initiator concentration which has been confirmed by a careful reinvestigation. For example, Kakurai and Noguchi[10] reported on the curing process of diepoxide (Epon 828) with tertiary amine, where the assumptions set up in the present theoretical treatment seemed to be roughly fulfilled. In their case, they found that $\rho_c=0.5$, independent of the amount of the catalyst employed, using a complicated treatment based on Flory's expectation method; they concluded, from Fig. 1, that this value agreed with the actual observations. Figure 1 seems to show, however, that in fact ρ_c depends upon the amount of the catalyst. If so, it may be of interest to reanalyze these results by means of the present theory, which requires that $\rho_c=1/\sqrt{\alpha}$. The theoretical gel points indicated in Fig. 1 appear to explain

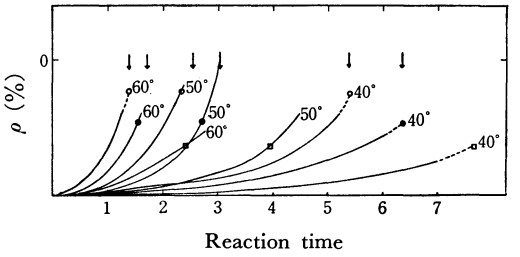

Fig. 1. The comparison between the total gel point (ρ_c) and the experimental ones obtained by Kakurai and Noguchi (from Fig. 4 in Ref. 10).
Theoretical gel points: ○ ($\alpha=7$, $\rho_c=0.37$), ● ($\alpha=14$, $\rho_c=0.28$), □ ($\alpha=28$, $\rho_c=0.18$)

the observed gel point satisfactorily.

The same paper also reports some experimental information on the sol fraction after the gel point, as is shown in Fig. 2. The theoretical value for the sol fraction of this case ($f=2$, $w_1=0$, $w_f=1$) given by Eq. (42) is presented in the same figure. The relationship between ρ and the reaction time, t, was obtained from Eq. (7a) of Ref. 2, *i. e.*, $\rho=1-\exp(-2kN_2t/\alpha)$ with $2kN_2=2.3$ 1/hr.*3 The agreement of the theory with the experimental results is satisfactory.

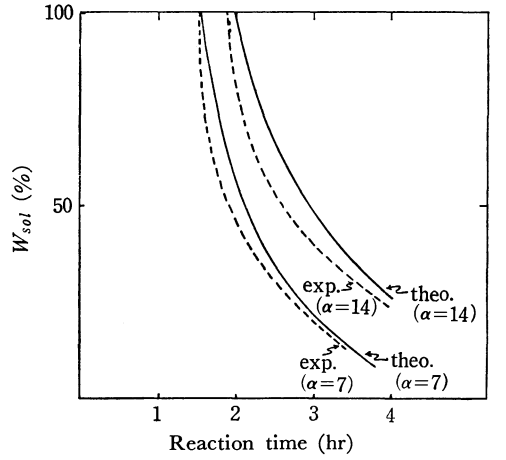

Fig. 2. The comparison between the theoretical sol fraction and the experimental ones obtained by Kakurai and Noguchi (Fig. 5 in Ref. 10).

Usually, the amount of catalysts directly affects the physical properties of the cured epoxy resins. For various kinds of catalysts, the favorable ratio of $\alpha=F/I_0$, *i. e.*, the number of epoxy groups per initiator, is determined through experiments; for instance, Bruin[11] observed that one amine

nitrogen atom in the catalyst is sufficient for from six to eight epoxide groups (namely, $\alpha=6$—8). It may be reasonable to attribute some physical properties of the gel to the average chain length (Eq. (54)) and the average number of active network chains, which can be calculated by the present theory.

In commercial practice, the epoxy resins are usually modified by reactive diluents, which are usually monoepoxides,[4] such as allylglycidyl ether and phenylglycidyl ether. To the extent that these diluents are incorporated, they lower the epoxide functionality of the resin, *i. e.*, the average number of epoxides per monomeric molecule. Since it is only the excess over one epoxide per molecule that can result in cross-linking, too large an amount of a reactive diluent ruins some physical properties of the cured resin.[12] In fact, it has been demonstrated that, in concentrations above 15 per cent, they much reduce the strength and solvent resistance of the cured resin.[5] The present theory can provide a basis for a quantitative discussion of this important diluent effect; such a detailed discussion will be undertaken elsewhere.

Appendix

It is well known that, in commenting on the earlier theory of Flory regarding gel formation, Stockmayer, in 1943,[8] threw doubt upon the validity of the application of the distribution equation beyond the gel point. Stockmayer pointed out the contradiction that the fraction of converted functional groups in the gel phase exceeds a limit which could not be surpassed if intramolecular reaction were forbidden (for instance, in the case of the self-condensation of f-functional monomers, the value of this limit is $2/f$). Notwithstanding Flory's protest,[1,13] it seems that no unequivocal explanation of this problem has yet been given. Therefore, we will present here a simple explanation of Stockmayer's paradox. For the convenience of explanation, let us consider the following "hypothetical" gel to be formed by the self-condensation of f-functional monomers ($f\geqq3$). All the functional groups are converted to form a single gel molecule in which *any* functional group is converted and is connected to paths to infinity without cyclization. Such a gel would have a structure of an infinite number of monomeric units with an infinite number of branches without end. In this gel, ρ'' is considered to be unity.

Therefore, according to our opinion, it may be considered that, from a purely theoretical point of view, there is no such limit of ρ''. However, physically, it is quite imperfect, since the number of units and the number of branches of the "physical" gel are finite after all. In conclusion, the validity of the distribution beyond the gel point in the present theory may have been verified only from a theoretical point of view. In this way, the Stockmayer paradox may be attributed to the fact that the "facsimile" of nature treated in physical theory is not nature itself.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 2120—2122 (1969)

The Mechanism of ESR Relaxation in Peroxylamine Disulfonate Ion $\cdot ON(SO_3)_2^{2-}$

Shizuo FUJIWARA and Kayoko SAKIOKA*1

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo

(Received December 4, 1968)

The mechanism of ESR relaxation in $\cdot ON(SO_3)_2^{2-}$ is discussed. As the line width in an aqueous solution is plotted against the concentration, it is almost concentration independent in the range lower than 7×10^{-3} mol/*l*, but the dependence increases in the higher range. Powles and Moseley showed that the anisotropy of the *g*-value contributes to the line width in the lower concentration range, but the line width in the higher-concentration range, which is investigated in the present investigation, can not be accounted for by the *g*-tensor anisotropy. Hence, it is supposed that electron spin exchange or nuclear quadrupole interaction contributes in the higher-concentration range. The latter can, however, be eliminated by the line width measurement in a deuterium measurement in a deuterium oxide solution, and so it may be concluded that electron spin exchange is the main contribution to the line width in the higher-concentration range. This is in accordance with the proposal of Jones. Furthermore, we could show that, by calculation of the line shape for Bloch's equation, including exchange interactions, the exchange frequency of 5.4×10^{7} sec^{-1} can give a line fitting the observed line shape for the 7.8×10^{-2} mol/*l* solution. This result can be taken as another evidence showing that the electron spin exchange is the main source of the line width in the higher-concentration range.

The widths of ESR hyperfine lines, ΔH, have attracted the interest of many investigators. For example, a very careful examination of ΔH in organic radicals has proven useful for the elucidation of molecular motion of free radicals.[1] Rogers and Pake[2] observed the dependence of ΔH on the nuclear quantum number, m_I; McConell interpreted this phenomena in terms of a model where the electron spin which carries anisotropy relaxes with the hyperfine field.[3] This model worked nicely and excited more detailed investigations.[4] For example, Powles and Moseley,[4a] working on the peroxylamine disulfonate ion ($\cdot ON(SO_3)_2^{2-}$) in mixed solvents of glycerine and water, noted viscosity dependence of the each hyperfine line width. Although this study presented several interesting features, they are not suitable for the general discussion of relaxation mechanisms, for the chemical surroundings of the paramagnetic ion change with the change in the concentration of glycerine. Kivelson classified the mechanisms of the spin relaxation in detail, and one of the present authors applied his results to the case of an aqueous solution of cupric ions. In the latter investigation, the relaxation of cupric ions in a dilute aqueous solution was found to be determined mainly by the perturbation of the spin-orbit interaction of isotropically-hydrated $[Cu(H_2O)_6]^{2+}$ ions and, in higher-concentration regions, by anisotropies of the *g*-values and by electron spin exchange.[5] A similar conclusion has also been obtained experimentally with respect to the Ti(III) ion.[6] Jones has studied an aqueous solution of $\cdot ON(SO_3)_2^{2-}$ and analyzed the line width, assuming that electron spin exchange is the main effect of the relaxation.[7]

Besides the electron spin exchange and the spin-orbit interaction, the nuclear quadrupole effect is a possible source of relaxation. Kubo presented a theoretical treatment of the contribution of the quadrupole effect to the nuclear spin relaxation, and much experimental evidence has been put forward with regard to this mechanism.[8,9] As this evidence

is related to NMR, we have become interested in investigating to what extent, if any, this effect is related to the relaxation of the electron system which couples with a nucleus carrying quadrupole moment. We chose peroxylamine disulfonate ion $\cdot ON(SO_3)_2^{2-}$ as the sample, because it reveals a well-resolved hyperfine interaction with nitrogen,[10] and we can find pertinent results on such related compounds as di-tertiary butyl nitroxide (DTBN).[11] This paper will show that the contribution of the quadrupole interaction is small and that the line width is, as has been noted by Jones, dominated by the electron spin exchange.

Experimental

Spectra were measured on a Japan Electron Optics X-band ESR spectrometer, Model JES-3BS-X, with 100 kHz/sec field modulation. The modulation amplitude is 30 mgauss, and the microwave power is kept low so as not to saturate the signal. All measurements were carried out at room temperature (20°C).

Solutions of the peroxylamine disulfonate ion $\cdot ON(SO_3)_2^{2-}$ were made by dissolving Fremy's salt in a 0.1 N aqueous solution of sodium carbonate. The concentration of the sample was determined by optical method, taking the molar extinction coefficient of this compound as $\varepsilon=20.8$ (at 545 mμ).[12] Water and deuterium oxide were used as solvents. The ESR intensities of the sample solutions were found constant over several hours, hence, we assume that they are stable over the period of measurement. The concentration of the sample solutions varied from 5×10^{-4} to 8×10^{-2} mol/l. No degassing procedure was carried out.

For the calculation of the line shapes, the RA-5 electronic digital computer made by Japan Electron Optics Company was used.

Results and Discussion

The width was measured as the separation of the maximum slope points of the derivatives of the absorption spectrum, which can be shown as a function of the concentration shown in Fig. 1. The results in Fig. 1 suggest that, the lower concentration range, the width is almost independent of the concentration, having a value of 0.24 gauss. It is also found that the width is the same in both H_2O and D_2O, which have different viscosities 1.0 and 1.2 cps respectively. These findings eliminate the spin-spin dipole interaction, the quadrupole interaction, and the anisotrpy due to the nuclear quantum number as the dominant sources of the electron spin relaxation, because if the spin-spin interaction is working as the dominant factor, the line width should be concentration dependent, while if the quadrupolar interaction or the anisotropy due to the nuclear quantum number works, then the width should be viscosity dependent. Using the B. P. P.[13] model, the dipolar line width is evaluated as 0.18 gauss for the solution of 0.01 mol/l. This is about two-thirds of the observed line width of 0.3 gauss. Hence, we assume that complexity exists in the system; *i. e.*, the spin-orbit interaction or the electron spin exchange interaction contributes to the relaxation as well as the dipolar interactions, and also that the apparent features of the concentration dependence can not be simply interpreted. This can be presented in a different way by manipulating the line shape. We construct an absorption line of three hyperfine components, each of a Lorentzian shape and of a definite width, the hyperfine components being separated from each other by 13 gauss. The calculated line is as shown in Fig. 2, where the line width of the hyperfine component is given two values, 2.9 gauss and 4 gauss. It may be seen in the figure that the outer peak is higher than the central peak; moreover, the line width is broader than the latter, contrary to the experimental observations. In the latter, the

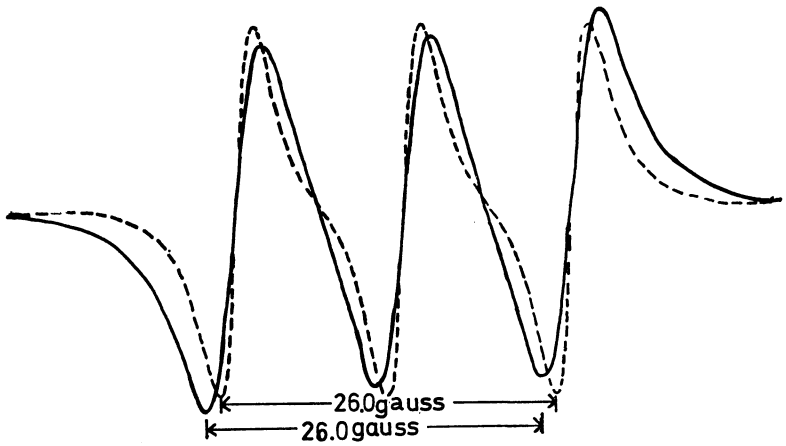

Fig. 2. Calculated line shape with the assumption of equal line width of each hyperfine component separated by 13 gauss from each other. Dotted curve refers to the line of 2.9 gauss of ΔH_{pp}, the peak to peak line width of the hyperfine component, and the full line to that of 4.0 gauss of ΔH_{pp}.

central line width is slightly narrower in the range of about 6×10^{-2} mol/l, and then it becomes broader in the higher concentration range ($\sim1\times10^{-1}$ mol/l). This suggests that the line shape could not be analyzed simply by the overlap of Lorentzian hyperfine lines of the same line width. This investigation supports that of Kivelson.[11] As to the nonequivalence of the hyperfine component, the line width in this system can be produced by the spin exchange mechanism. We manipulate the line shape on the basis of a modification of Bloch's equation which carries an exchange interaction term by which we can evaluate the magnitude of this interaction roughly. We write first modifications of the Bloch equation for three sites,[14] assuming that the fraction of each spin state is equal and that the spin state are mixed through electron exchange. The imaginary part, v, of the total magnetization, M, is given below;

$$v = \frac{M(PZ+RM)}{P^2+R^2}$$

where;

$$P = 3(\Delta\nu + 4\tau\Delta\nu/T_2 + 3\tau^2\Delta\nu/T_2^2 - \tau^2\Delta\nu^3 + \Delta\nu\tau^2\delta\nu^2)$$

$$R = 3/T_2 + 6\tau/T_2^2 - 6\Delta\nu^2\tau + 2\tau\delta\nu^2 + 3\tau^2/T_2^3 - 9\Delta\nu^2\tau^2/T_2 + 3\tau^2\delta\nu^2/T_2$$

$$W = 3 + 6\tau/T_2 + 3\tau^2/T_2^2 - 3\Delta\nu^2\tau^2 + \delta\nu^2\tau^2$$

$$Z = 6(\tau\Delta\nu + \Delta\nu\tau^2/T_2)$$

where T_2 refers to the spin-spin relaxation time in the absence of electron spin exchange, and where $1/\tau$ is the exchange frequency, $\delta\nu$, the coupling constant, and $\Delta\nu$, the frequency from the center.

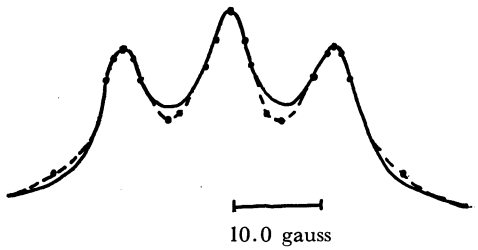

Fig. 3. —— The integrated line shape for a solution of 7.8×10^{-2} mol/l of $\cdot ON(SO_3)_2^{2-}$. -●- The calculated line shape for the modified Bloch's equation.

As the exchange frequency is taken as 5.4×10^7 sec^{-1}, $1/T_2$, as 0.36×10^7 sec^{-1}, and $\delta\nu$, as 3.6×10^7 sec^{-1}, the line shape is calculated to be as shown by the dotted curve in Fig. 3. It agrees fairly well with the curve observed with the solution of 7.8×10^{-2} mol/l, which is shown in Fig. 3 by the straight curve. Jones investigated the electron spin exchange in his study of the line width. However, the present analysis of the total line shape should be more efficient.

*** *Department of Chemistry, Faculty of Science, Kyushu University, Hakozaki, Fukuoka*

(Received December 5, 1968)

Solubilities and critical micelle concentrations (CMC) of potassium dodecyl sulfate (KDS) and hexadecyl sulfate (KHS) were measured in aqueous solutions to which dioxane, acetone, urea, or dimethyl sulfoxide had been added over the temperature range of 5—40°C. It was found that all additives mentioned above raised solubility and CMC with an exception for dioxane which showed a slight minimum on a CMC-additive concentration curve. Solvent effects on the alkyl and ionic groups of a surfactant molecule were separated by considering the difference of the standard free energy change for the solution process of KHS and that of KDS. It was deduced that a primary effect on the alkyl group is the one that a strongly cohesive solvent, water, is replaced by a less cohesive organic solvent and other mechamisms, such as an effect on the water structure, follow as the secondary. In terms of the above considerations, effects on the Krafft point were also referred to.

In Part I of this series, the solvent effects on potassium alkyl sulfates of such compounds as lower alcohols and glycols were reported.[1] The present paper will describe solvent effects, on the same surfactants, of dioxane, acetone, urea and dimethyl sulfoxide which are characterized by the name, nonhydroxy compounds. The effects on CMC caused by these additives have been reported by many authors,[2-6] but the nature of the effects has not been elucidated. We believe that the phenomena should be understood in terms of solvent effects on single-ion dispersion as well as on micelle dipersion, as these two are equilibriated with each other. Then it was attempted to measure solubilities and CMC's of KDS and KHS (solubility only) in various mixed solvents of aqueous organic compounds mentioned above. Dioxane was employed because of the diverse dielectric constants of its aqueous solution, and other three are interesting for their related chemical structures.

Experimental

Materials. Potassium alkyl sulfates are the same samples as used in the previous work.[1] Dioxane was refluxed on metallic sodium for hours and distilled. Acetone was purified by distillation, after treated with a small amount of potassium permanganate. Urea was recrystallized twice from ethanol-water (2 : 1 in volume) mixture and dried in vacuum. Dimethyl sulfoxide was shaken and distilled in the presence of alumina under reduced pressure.

Procedures. Solubility and CMC measurements were performed by the same methods as in Part I. Urea solutions were kept in refrigerator and used within 10 days so as to avoid any error that may come from the hydrolysis of urea.

Results and Discussion

Solubilities and CMC's of KDS are plotted against temperature in Figs. 1—4.*1 It is evident from the figures that the increase in concentration of the additive results in increases both in solubility and in CMC except for the dioxane-water mixed solvent in which a slight CMC-decreasing effect was observed. These results are in contrast with the effects caused by hydroxy compounds,[1] where the solubility curve crosses that for pure water. Thus, the hydroxy additives caused increase in

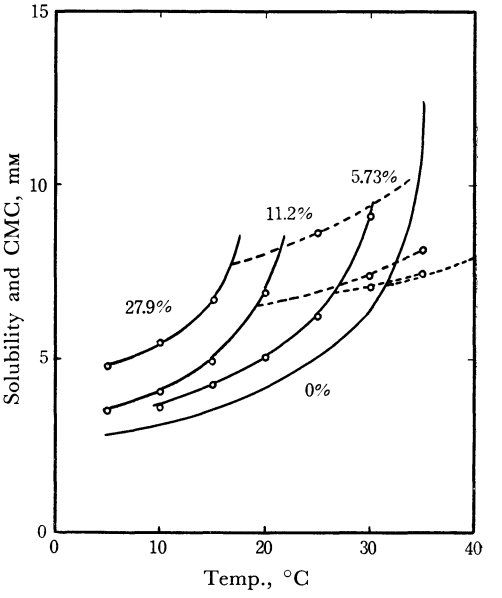

Fig. 4. Solubilities and CMC's of KDS in urea-water mixed solvents.

solubility at higher temperature ranges, but at lower temperature ranges they caused decrease in solubility, as compared with solubilities in pure water. On the other hand, the additives used in the present work enhance solubilities at all experimental temperatures, although for acetone-, and dimethyl sulfoxide - water systems, the solubility curves crossed at the lowest experimental temperature (near 5°C), and for dioxane- and urea - water mixed solvents, it may be expected that solubility curves will intersect each other at temperatures lower than 0°C. This enhanced solubility is a marked difference from the solubility of a simple electrolyte, for which electrostatic theory predicts reduced solubility in most organic solvent-water mixtures.[7] The organic additives in the

7) H. S. Harned and B. B. Owen, "The Physical Chemistry of Electrolyte Solutions," Reinhold Publ. Corp., New York (1958), p. 81.

present work, *i. e.*, nonhydroxy compounds would form hydrogen bond with water just as hydroxy compounds do and strengthen the net-work structure which limits the dissolution of hydrophobic solutes. But this effect is well compensated by the fact that the structuredness of liquid water, or clusters, are "molten" by the presence of the additives, just as by the thermal agitation, and bulky closed space is liberated for the dissolved solute.[8]

To be more quantitative, the standard free energy change for the solution process, and the corresponding enthalpy and entropy changes defined as

$$\Delta F^\circ = -2RT \ln X_s, \quad (1)$$

$$\Delta H^\circ = \frac{\partial \Delta F^\circ}{\partial (1/T)} \quad (2)$$

and

$$\Delta S^\circ = \frac{\Delta H^\circ - \Delta F^\circ}{T} \quad (3)$$

may be considered. Here X_s is a solubility in mole fraction, and other notations are usual ones. The values of ΔH° and $T\Delta S^\circ$ are shown as a function of weight percentage of the additives in Fig. 5, where the values in ethanol-water mixed solvents are also added for comparison. Both enthalpy and entropy changes are rather small as compared with those in alcohols-water mixed solvents. It is especially noted that the effect by urea is very small. This fact might suggest some different mechanism with this compound which is well-known for its protein denaturating ability, often discussed in connection with the structure of liquid water.[9] Another example of this difference

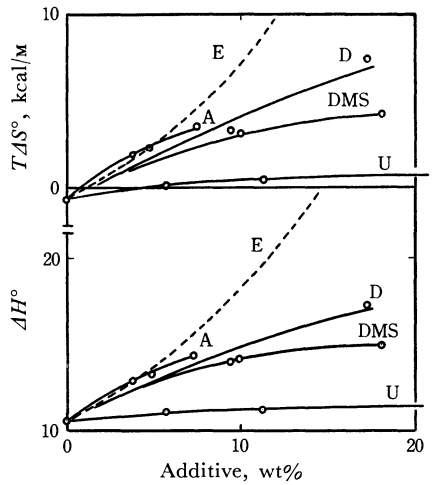

Fig. 5. The values of ΔH°'s and $T\Delta S^\circ$'s in mixed solvents.

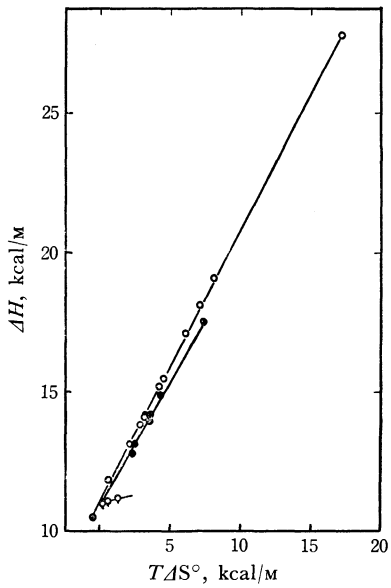

Fig. 6. ΔH°'s *vs.* $T\Delta S^\circ$'s plot.
○: hydroxy compound, ●: nonhydroxy compound, ○: urea, ⊙: water

would be seen in Fig. 6, where ΔH°'s are plotted against $T\Delta S^\circ$'s for the mixed solvents studied in both Parts I and II. Figure 6 represents that effects of hydroxy, nonhydroxy and urea fall on different lines, respectively. This fact may suggest that these additives would have some diverse roles in the solution process.

At the same enthalpy change, the entropy change is in order of urea, nonhydroxy and hydroxy compounds. These differences may arise from the difference in the net-work structure formation effect and the space-releasing effect of these compounds. It was reported by Nakanishi[10] that an effect on the partial molar volume of water by the addition of the compounds can be classified by the two categories of hydroxy and nonhydroxy compounds.

Solvent Effect on CMC. In view of the above explanations, the changes in CMC's given in Fig. 7 are understood: in a monomer-micelle equilibrium, if monomer becomes more stable but micelle does not by an additive, the equilibrium should displace to the monomer side, thus CMC is raised. This is clearly seen in Fig. 8, where a relative solubility (r_s) is plotted against a relative CMC (r_m). The relative solubility here means a ratio of a solubility of single-ion dispersion extrapolated to 35°C in a mixed solvent to that in pure water. The extrapolated values obtained by the logarithm of solubility *vs.* the reciprocal of temperature plot, and the ones by the graphical extrapolation tracing the smooth curve agreed each other. The relative CMC also has a similar meaning. An approximate

⊙: water, ○: dioxane, ●: urea, ○: acetone, ●: dimethyl sulfoxide.

pararellism between the two ratios supports this idea. A less or non CMC-decreasing ability of dimethyl sulfoxide might be attributed to its highly hydrophilic nature as compared with others. The CMC-decreasing power of dioxane is, although slight, explicit in Fig. 7. Urea is also believed to be effective in breaking micelles because of high dielectric constant of its aqueous solutions.[3] The CMC-decreasing power of acetone might not be negligible, judging from its both hydrophilic and hydrophobic nature, but it would be overcome by a marked CMC-increasing effect. A shallow minimum of the CMC *vs.* additive concentration curve in dioxane-water mixed solvent was found for sodium dodecyl sulfates too,[2] and explained in term of solubilization of dioxane molecules into micelles just as seen in the cases of alcohols-water mixtures.[11,12]

Separation of Solvent Effects. As was done in Part I, solvent effects can be divided into two portions: a solvent effect on the nonpolar group and one on the ionic group of a surfactant molecule. In order to do so, solubilities of KHS in respective mixed solvents were measured (shown

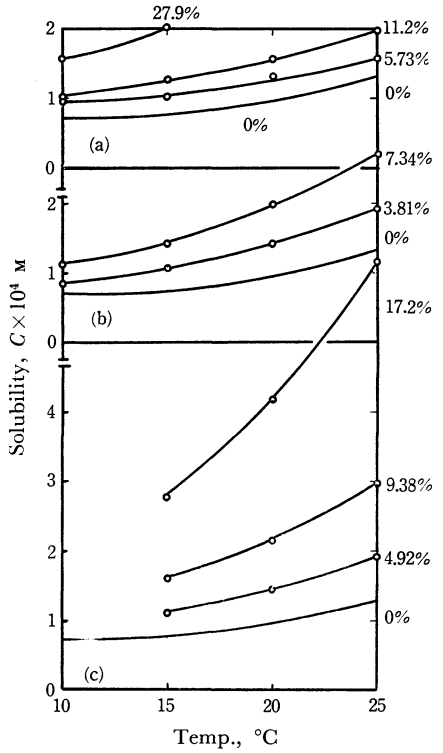

Fig. 9. Solubilities of KHS in mixed solvents.

in Fig. 9, and for aqueous dimethyl sulfoxide, 0.110, 0.129 mM in 9.91 and 18.0 DMS wt% respectively, at 15°C only) and then the solvent effect on the nonpolar group $\Delta\Delta F^\circ$ was calculated by applying the following equation,

$$\Delta\Delta F^\circ = \Delta F^\circ_{KHS} - \Delta F^\circ_{KDS} = -2RT\ln\frac{C_{KHS}}{C_{KDS}}, \quad (4)$$

where subscripts refer to the respective surfactants, C's are solubilities of surfactant in a solvent, and other notations are usual ones. The values of $\Delta\Delta F^\circ$ are presented as a function of weight percentage of additives in Fig. 10, where a hypothetical solvent effect is drawn as before.[1] The hypothetical solvent effect is simply expressed as

$$\Delta\Delta F^\circ_{hypo} = \Delta F^\circ_w(1-\phi_H), \quad (5)$$

where ΔF°_w is the standard free energy change of the nonpolar group for the solution process in pure water, *i. e.*, a solvent effect of water, ϕ_H is a volume fraction of hexane which was taken as a hypothetical additive. Here is again a positive deviation from the hypothetical behavior. This deviation is relatively small for acetone and dioxane which enhance the solubilities of the surfactants, probably due to their space-releasing effect. Another useful indication is a $\Delta\Delta F^\circ$ *vs.* CED plot in Fig. 11, where CED's (cohesive energy density) are calculated from the pressure-temperature, and density data from various sources of the corresponding binary systems.[13]

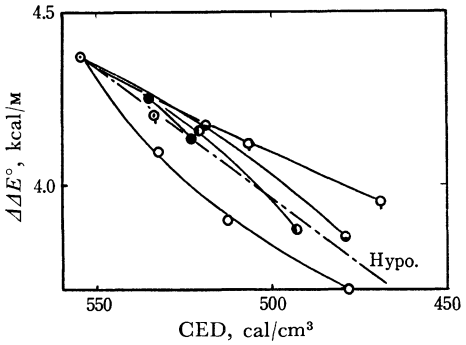

Fig. 11. $\Delta\Delta F^\circ$ *vs.* CED plot.
⊙: water, ○: dioxane, ○: acetone, ●: urea, ●: DMS, ◐: methanol, ◒: ethanol, ⊙: 1-propanol.

The CED of the hypothetical mixture was calculated by the equation,[14]

$$(CED)_{hypo} = (\phi_w\delta_w + \phi_H\delta_H)^2, \quad (6)$$

where subscripts w and H refer to water and a hypothetical solvent, respectively, and ϕ's and δ's are volume fractions and solubility parameters, respectively. Here hexane was taken as a hypothetical additive, for which the density and the solubility parameter are available. In Fig. 11, points are scattered around the hypothetical effect. This may indicate a primary solvent effect that the strongly cohesive liquid, water, becomes energetically loosened by adding any less cohesive compound. Both the net-work formation and the space-releasing effect would follow this primary effect and work against, or sometimes, for it. Urea which is solid and therefore the most cohesive shows a remarkable solvent effect and thus should hold a special position in affecting the structure of liquid water.

The solvent effect in the ionic group ΔF°_{ion} was calculated from the equation,

$$\Delta F^\circ_{ion} = \Delta F^\circ_{KDS} - \Delta\Delta F^\circ \times 3. \quad (7)$$

In Fig. 12, ΔF°_{ion}'s are plotted against the reciprocals of dielectric constants of the mixed solvents. A line was determined by the least square method. The slope gives the Born radius 0.5 Å.

Solvent Effects on the Krafft Point. The Krafft point is defined as the intersection of solubility curve and CMC curve. Thus detailed knowledge on the two curves might be required to predict the solvent effect on the Krafft point, but here, as in Part I, two simplified extremes are considered: (a) CMC curve changes (increase or decrease) with solubility curve fixed, (b) solubility curve changes with CMC curve fixed. These two extreme cases are schematically shown in Fig. 13. In Fig. 14, the observed Krafft points are plotted against the weight percentage of additives. It is noted that dimethyl sulfoxide affects only a little on the Krafft point probably due to a cancellation of the (a) and (b) effects.

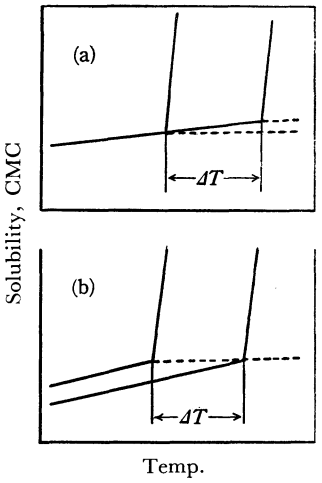

Fig. 13. The two extreme cases of the effects on the Krafft point.
solid line: solubility curve
dotted line: CMC curve
ΔT: change in the Krafft point.

On the other hand, dioxane, acetone and urea show the effects of the same magnitude. The lowering of the Krafft point might be brought about by the (b) mechanism exceeding the (a). This is also clear from Fig. 8 which shows a marked increase in solubility as compared with the CMC increase.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 2128—2131 (1969)

Reactions of Ions in the Radiolysis of Liquid Propane

Kuniyasu TANNO and Shoji SHIDA

Laboratory of Physical Chemistry, Tokyo Institute of Technology, Meguro-ku, Tokyo

(Received December 6, 1968)

The reactions of ions, especially fragmentation of excited ions and the subsequent reactions of fragment ions in the radiolysis of liquid propane have been investigated by the use of charge scavengers such as sulfur hexafluoride (SF_6) and ammonia (NH_3). It has been confirmed that the fragment ions are produced by the dissociation of the excited parent ion prior to the parent ion-electron recombination. The yields of $C_2H_5^+$ and $C_3H_7^+$ have been measured by the use of the reaction, $RH^+ + NH_3 \rightarrow R + NH_4^+$, with the results $G \geq 0.28$ and ~ 1.1 respectively. These ions neutralize with electrons to form ethylene or propylene. The hydride ion transfer reaction between $C_2H_5^+$ and propane may be competing with the neutralization of $C_2H_5^+$ by electron in the absence of an additive. The yields of fragment ions are compared in the radiolysis of several saturated hydrocarbons.

Studies of ionic reactions in the liquid-phase radiolysis of some branched saturated hydrocarbons using charge scavengers such as SF_6 and NH_3 were reported previously.[1,2] Some of the significant results found were (1) the fragmentation of excited molecular ions still occurs in the liquid phase, (2) the fragment ion (such as t-$C_4H_9^+$ and s-$C_3H_7^+$) neutralizes with an electron to form an olefin molecule, and (3) the hydride ion transfer reaction may not be so fast as in the gas phase. The present report of the radiolysis of liquid propane shows a similar pattern of ionic reactions. Koob and Kevan[3,4] studied extensively the liquid-phase

radiolysis of propane by the use of deutrated propane and a radical scavenger (oxygen). However, we have employed a different technique to detect the ionic species, that is, proper use of charge scavengers.

Experimental

The propane supplied by Takachiho Shoji Co. was purified by gas chromatography and trap-to-trap distillations to reduce hydrocarbon impurities less than 10 ppm. SF_6 (>98%) (Matheson Co.) and NH_3 Takachiho Shoji Co.) of high purity were used without further purification. Propane was irradiated in Pyrex glass ampoules 5 mm in diameter fitted with break seals. Mole fraction of the gas-phase propane was less than 5% of the total in the ampoule. Samples were kept at 4°±1°C during irradiation in an ice-water mixture. Irradiations were carried out by ^{60}Co γ-rays, at a dose rate of 7.1×10^{19} eV/g hr. The total doses were 3.55×10^{20} eV/g. Other experimental details were described previously.[2] G Values reported here are based on the energy absorbed by propane only.

Results and Discussion

In Fig. 1 is shown the effect of SF_6 on the yield of ethane, ethylene and propylene. Other radiolytic yields are $G(H_2)=4.8$ and $G(CH_4)=0.68$ without SF_6, and $G(H_2)=2.5$ and $G(CH_4)=0.56$ with 4 mol% SF_6. The G values of fragment products obtained in the present work without an additive are somewhat smaller than those obtained by Koob and Kevan.[4]

An appreciable increase in the ethane yield is observed upon the addition of SF_6, while the yields of ethylene and propylene decrease rapidly. This

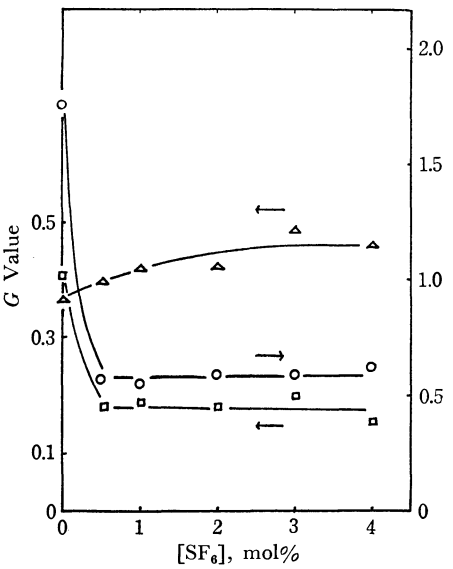

Fig. 1. Effect of SF_6 in the radiolysis of liquid propane.
△ C_2H_6, □ C_2H_4, ○ C_3H_6

phenomenon suggests the definite contribution of ionic reactions to the formation of these products. A similar increase in an alkane and the decrease in an olefin product yield upon the addition of an electron scavenger has also been observed in the radiolysis of liquid isobutane and isopentane where $G(C_3H_8)$ or $G(C_4H_{10})$ increases upon the addition of SF_6[2] or CCl_4.[5]

A possible mechanism of the ionic reactions for the formation of ethylene is

$$C_3H_8 \sim\!\!\!\rightarrow C_2H_5^+ + CH_3 \quad (1)$$

$$C_2H_5^+ + e^- \rightarrow C_2H_4 + H \quad (2)$$

$$C_3H_8^+ + e^- \rightarrow C_2H_4 + CH_4 \quad (3)$$

Ethylene is formed by neutralization with an electron of $C_2H_5^+$ as well as the parent ion such as reaction (3). We reported the formation of an olefin molecule by neutralization of a fragment carbonium ion in the radiolysis of several liquid hydrocarbons.[1,2] A part of $C_2H_5^+$ may form ethane by the hydride ion transfer reaction with propane, competing with the neutralization reaction (2).

$$C_2H_5^+ + C_3H_8 \rightarrow C_2H_6 + C_3H_7^+ \quad (4)$$

The decrease in ethylene yield caused by SF_6 is due to the capture of electrons by SF_6.

$$e^- + SF_6 \rightarrow SF_6^- \quad (5)$$

The increased yield of ethane upon the addition of SF_6 may be explained by the fact that the neutralization of $C_2H_5^+$ is delayed and that the hydride ion transfer reaction (reaction (4)) becomes predominant in place of the neutralization of $C_2H_5^+$. The decrement of ethylene exceeds the increment of ethane, because the ethylene formation by both reactions (2) and (3) is prevented by SF_6, while ethane formation is promoted only by reaction (4).

Although the possibility that SF_6 promotes the H_2^- transfer reaction could not be denied,

$$C_2H_4^+ + C_3H_8 \rightarrow C_2H_6 + C_3H_6^+ \quad (6)$$

the extent of reaction (6), if any, is estimated to be smaller than that of reaction (4), if one considers the result of gas-phase radiolysis of propane[6] or the mass spectral data,[7] where the relative abundance of $C_2H_5^+$ greatly exceeds that of $C_2H_4^+$. Actually Koob and Kevan[3] infrerred that the degree of reaction (6) is about half as much smaller than that of reaction (4) in the liquid-phase radiolysis of propane at 35°C. However, the following explanation for the increased yield of ethane could not be entirely excluded.

5) A. A. Scala and P. Ausloos, *J. Chem. Phys.*, **47**, 5129 (1967).
6) L. I. Bone, L. W. Sieck and J. H. Futrell, "The Chemistry of Ionization and Excitation," ed. by G. R. A. Johnson and G. Scholes, Taylor and Francis, Ltd., London (1967), pp. 223—235.
7) American Petroleum Institute Research Project 44

$$C_2H_5^+ + SF_6^- \rightarrow C_2H_5 + SF_6 \quad (7)$$

$$C_2H_5 + C_3H_8 \rightarrow C_2H_6 + C_3H_7 \quad (8)$$

Thus, following reaction (5), SF_6^- neutralizes with $C_2H_5^+$ to lead to the formation of ethyl radicals which then abstract hydrogen atom of propane to form ethane. Detailed discussion on this point was given in a previous paper.[2] We tentatively prefer reaction (4) for the increase in the ethane yield upon the addition of SF_6.

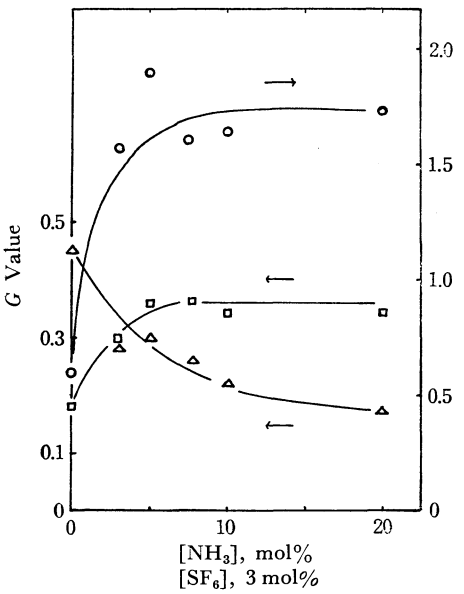

Fig. 2. Effect of NH_3 in the presence of SF_6 in the radiolysis of liquid propane.
△ C_2H_6, □ C_2H_4, ○ C_3H_6

The increased yield of ethylene and the decreased yield of ethane caused by NH_3 added together with SF_6 (Fig. 2) is undoubtedly attributed to the proton transfer from $C_2H_5^+$ to NH_3.

$$C_2H_5^+ + NH_3 \rightarrow C_2H_4 + NH_4^+ \quad (9)$$

Proton transfer reactions between several carbonium ions and NH_3 have been reported.[8,9] The G increment of ethylene at higher concentrations of NH_3 is 0.17, while the G decrement of ethane is 0.28. A plausible explanation for the difference is that the condensation reaction occurs between $C_2H_5^+$ and NH_3 which does not lead to the formation of ethylene.

$$C_2H_5^+ + NH_3 \rightarrow C_2H_5NH_3^+ \quad (10)$$

Ward and Hamill[10] reported the similar condensation reactions between several carbonium ions and methyl alcohol. If reaction (10) is assumed, $G(C_2H_5^+) \geqq 0.28$ may be estimated from the decrement of ethane at 20 mol%NH_3 allowing for the possibility that $C_2H_5^+$ cannot be captured completely even at 20 mol% NH_3.

Propylene is formed in the absence of an additive as

$$C_3H_7^+ + e^- \rightarrow C_3H_6 + H \quad (11)$$

The occurrence of the reaction may be supported by the fact that the yield of propylene increases with the addition of NH_3 in the presence of SF_6 (Fig. 2). The increase is due to the proton transfer from $C_3H_7^+$ to NH_3.

$$C_3H_7^+ + NH_3 \rightarrow C_3H_6 + NH_4^+ \quad (12)$$

Reaction (12) seems to be very efficient, because 5 mol% NH_3 is sufficient enough to capture almost all of $C_3H_7^+$ as seen in Fig. 2. The G increment of propylene is 1.12, and $G(C_3H_7^+) \approx 1.1$ is estimated.

$C_3H_7^+$ can be formed from the decomposition of the excited parent ion as well as the secondary reaction such as reaction (4). In the xenon-sensitized radiolysis of propane in the gas phase,[6] $C_3H_7^+$ produced by the secondary reaction (hydride ion transfer reactions of fragment ions with propane) was estimated as much as 0.91 in M/N yield. However, in the liquid phase, the yield of the fragment ions which undergo the secondary reaction to produce $C_3H_7^+$ is estimated not to greatly exceed $G(C_2H_5^+) \approx 0.28$, so $C_3H_7^+$ may be formed directly from the decomposition of the parent ion in the liquid phase.

We have so far investigated the ionic reactions in the radiolysis of several staurated hydrocarbons and were able to measure the approximate yields of the fragement carbonium ions. The results is summarized in Table 1. The yield of fragment ions differs from one hydrocarbon to another. A simplified theoretical treatment has been proposed by Miyazaki *et al.*[11] to explain the difference and they obtained the qualitative agreement with the experiment. In any case, there seem to be two factors governing the fragment ion formation prior to the parent ion-electron recombination in the radiolysis of liquid saturated hydrocarbons. The two factors are (1) the heat of formation of a carbonium ion from the parent ion and (2) the number of atoms in the hydrocarbon, that is, the number of degrees of vibrational freedom.

The internal energy distribution functions of excited parent ions were determined experimentally for only propane and *n*-butane.[12] However, if one assumes that the amount of the internal energy and its distribution of the excited parent ions do not differ greatly from one hydrocarbon to another,

In the parentheses are shown the heat of formation of the fragment ion formed from the parent molecular ion in kcal/mol, taken from Ref. 13 or F. H. Field and J. L. Franklin, "Electron Impact Phenomena," Academic Press, Inc., New York (1957)

the smaller the number of bonds in a hydrocarbon, the greater the energy partitioned per one bond. If these two conditions are favorably satisfied, relatively high values of fragment ions may be obtained, for example, such as $G(C_3H_7^+)=1.1$ and 1.15 for propane and isobutane, and $G(C_4H_9^+)=1.0$ for neopentane.

The $C_4H_9^+$ is formed in the radiolysis of neopentane as well as isopentane, but in different yields. Both hydrocarbons have the same number of degrees of vibrational freedom. However, the heat of formation by reaction (13) is 20 kcal/mol,[13] while only 8 kcal/mol[13] is required for reaction (14).

$$iso\text{-}C_5H_{12}^+ \rightarrow C_4H_9^+ + CH_3 \qquad (13)$$
$$\Delta H = 20 \text{ kcal/mol}$$

$$neo\text{-}C_5H_{12}^+ \rightarrow t\text{-}C_4H_9^+ + CH_3 \qquad (14)$$
$$\Delta H = 8 \text{ kcal/mol}$$

Naturally the latter case gives the larger yield of $C_4H_9^+$. The C–C bond energy of a parent ion of a branched hydrocarbon is generally greatly weaker than that of a straight-chain alkane. Although we have not measured, except propane, the yield of fragment ions produced by the C–C bond rupture in the radiolysis of straight-chain alkanes, the yield of fragment ions may be expected smaller, if present, in the radiolysis of straight-chain alkanes such as *n*-pentane and *n*-hexane.

Reactions (15) and (16) require almost the same heat of formation.[13]

$$iso\text{-}C_4H_{10}^+ \rightarrow sec\text{-}C_3H_7^+ + CH_3 \qquad (15)$$
$$\Delta H = 14 \text{ kcal/mol}$$

$$iso\text{-}C_8H_{18}^+ \rightarrow t\text{-}C_4H_9^+ + C_4H_9 \qquad (16)$$
$$\Delta H = 13 \text{ kcal/mol}$$

However, if one compares the values in Table 1, $G(sec\text{-}C_3H_7^+)$ exceeds $G(t\text{-}C_4H_9^+)$. This may be because that the number of degrees of the vibrational freedom of C_4H_{10} is much smaller than that of C_8H_{18}, and that the energy partitioned per C–C bond is larger in the case of isobutane.

The authors wish to thank Dr. T. Miyazaki of Nagoya University for valuable suggestions.

ESR Studies of Carboxylic Acid- and Ester-Radical Anions Produced by γ-Irradiation at 77°K

Yukihiko NAKAJIMA, Shin SATO and Shoji SHIDA

Department of Applied Physics, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received December 10, 1968)

A series of monocarboxylic acids and esters have been γ-irradiated at 77°K, either pure or in the rigid matrix of 2-methyltetrahydrofuran, and the products have been examined by ESR spectroscopy. The spectra obtained in the pure state showed that the primary paramagnetic species in each case is the corresponding radical anion, $R-\dot{C}\begin{smallmatrix}O^-\\O-R'\end{smallmatrix}$. In the rigid matrix, these characteristic spectra have been obtained after illuminating the γ-irradiated sample with visible light at the expense of the spectra of trapped electrons. When ultraviolet light was used for the illumination, the spectra of the radical anions disappeared, but instead appeared the spectra of the radicals produced by the decomposition of the radical anions. The latter spectra were almost the same as those obtained by the direct photolyses of acids and esters.

Many radicals and ions in rigid matrices at low temperatures have been characterized by their optical and ESR spectra.[1-4] These unstable intermediates are usually produced by the irradiation of ultraviolet light or γ-rays. As the rigid matrix, 2-methyltetrahydrofuran (MTHF) has often been used; in it trapped electrons are easily formed by γ-irradiation. When electrophilic molecules are present in the matrix, electrons released from the traps by the illumination of visible light are captured by the solute molecules. In the present paper, a series of monocarboxylic acids and esters are used as the solutes.

In 1959, Alger, Anderson and Webb[5] examined X-irradiated formic and acetic acids and several esters of these acids by ESR spectroscopy; they observed doublet spectra in every case, but they did not assign the spectra. Miyagawa and Gordy[6] also studied X-irradiated acetic acid and discussed the paramagnetic species responsible for the doublet spectrum.

In connection with a study of the behavior of electrons in rigid matrices, we reinvestigated the radiolyses and the photolyses of carboxylic acids and esters, both pure and in the matrix of MTHF, by means of ESR spectroscopy. While the present research was being undertaken, a study[7] appeared on a series of carboxylic acid radical anions, where the anions were prepared by the reaction with alkali metals. Our results on the acids are almost entirely consistent with theirs, but quantitatively a few variances are observed.

Experimental

Commercially-available carboxylic esters, methyl formate, methyl acetate, ethyl acetate, propyl acetate, methyl propionate, ethyl propionate, methyl *n*-butyrate, and methyl pivalate were purified by trap-to-trap distillations. Formic acid, acetic acid, propionic acid, and fully-deuterated acetic acid commercially obtained were used without purification. MTHF was stored in a sodium mirror for more than a day before use. For irradiating samples, carboxylic acids, esters, and MTHF containing small amounts of esters were frozen in Spectrosil tubes at the temperature of liquid nitrogen. These tubes were irradiated at 77°K with ^{60}Co γ-rays for half an hour at the dose rate of 2.2×10^5 R/hr. After the irradiation, samples were examined in the dark by means of a JEP-1 X-band ESR spectrometer with a field modulation of 100 kc/sec. After the initial measurement, bleaching experiments were performed with visible light from a tungsten lamp, and then with ultraviolet light from a Toshiba SHL-100 UV-2 mercury lamp. On the other hand, direct photolyses of several esters with ultraviolet light were also performed. As the standard for determining the hyperfine splitting constants and the line widths observed, Mn^{2+} in MgO was applied to the cavity.

Results

γ-Radiolyses of Pure Carboxylic Esters. An ESR spectrum of γ-irradiated ethyl acetate is shown in Fig. 1. The spectrum A was obtained immediately after γ-irradiation. This spectrum was little affected by the illumination of visible light, while 2 min illumination with ultraviolet light was enough to eliminate this characteristic spectrum of the doublet and produce instead a quartet due to methyl radicals, as is shown in the spectrum B of Fig. 1. The underlying weak spectra in the A and B consist of five lines which are probably due to the radical, $CH_3\dot{C}OOCHCH_3$.[8,9] Characteristic doublet spectra obtained with γ-irradiated ethyl acetate were also observed with other esters, such as methyl acetate, propyl acetate, methyl propionate, ethyl propionate, and methyl *n*-butyrate. As an example, the ESR spectrum of γ-irradiated propyl acetate is

shown in Fig. 2. All these doublet spectra were little affected by the visible light-illumination, but were converted to the spectra due to such radicals as methyl and formyl by the ultraviolet light-illumination. The underlying spectra for each ester were well explained as being due to the following radicals: $CH_3COO\dot{C}H_2$ or $\dot{C}H_2COOCH_3$ for methyl acetate, $CH_3COOCH_2\dot{C}HCH_3$ for propyl acetate, CH_3-$\dot{C}HCOOCH_3$ for methyl propionate, and CH_3-$\dot{C}HCH_2COOCH_3$ for methyl butyrate. Table 1 summarizes the hyperfine splitting constants and the line-widths of the doublets, including the results obtained with methyl formate, methyl pivalate, and several carboxylic acids. The ESR spectrum of γ-irradiated methyl formate is shown in Fig. 3. A strong singlet spectrum is seen at the center. This singlet was not affected by the visible light-illumination, but upon ultraviolet illumination for 2 min it changed to the spectra mainly due to methyl radicals. The underlying spectra in the A of Fig. 3 are probably due to $HCOO\dot{C}H_2$ and $\dot{C}HO$. These spectra became stronger after the ultraviolet illumination. Figure 4 shows the ESR spectrum of γ-irradiated methyl pivalate. The underlying spectra are probably due to the radicals, $\dot{C}H_3$ and $(CH_3)_2\dot{C}H_2CCOOCH_3$ or $(CH_3)_3CCOO\dot{C}H_2$. The singlet spectrum at the center decayed a little upon the visible light-illumination. Upon the ultraviolet illumination, however, it immediately changed to the spectra due to methyl and formyl radicals, as is shown in Fig. 4.

We also made observations with monocarboxylic acids under the same condition as for their esters. The results are included in Table 1. These characteristic spectra were almost the same as those already reported by Bennett and Gale using alkali metal-deposition on the acids in preparing the paramagnetic species.[7] The coincidence in the splitting constants and in the line-widths of the spectra is satisfactory.

Ultraviolet Photolyses of Esters. Most of the esters, when frozen at 77°K, become polycrystalline; this is not desirable for the photolyses. Therefore, the experiments were performed with only the five esters which become glassy or nearly glassy at 77°K. These samples were irradiated for about half an hour with a high-pressure mercury lamp. In the case of methyl formate, the spectra due to three radicals, $\dot{C}H_3$, $\dot{C}HO$, and $HCOO\dot{C}H_2$, were observed. Similar spectra were obtained with methyl acetate, and it was noticed that the spectrum due to methyl radicals decayed more rapidly in methyl formate than in methyl acetate at the temperature of liquid nitrogen. Figure 5 shows the ESR spectrum of UV-irradiated ethyl acetate. The spectrum may be identified as being due to the two radicals, $\dot{C}H_3$ and $\dot{C}H_3COO$-

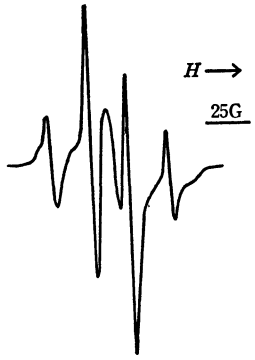

Fig. 5. ESR spectrum of UV-irradiated ethyl acetate.

$\dot{C}HCH_3$. The spectra obtained with other esters, methyl acetate, ethyl propionate, and methyl pivalate, were also well explained by the combination of those due to $\dot{C}H_3$ and $\dot{C}HO$ radicals and the radicals produced by the cleavage at the weakest C–H bond of esters. With ethyl propionate, the contribution of the formyl radical was extremely small and the spectrum due to ethyl radicals was observed instead of that due to methyl radicals.

As has been stated above, ultraviolet irradiation does not give the characteristic spectra obtained by γ-irradiation, such as the doublet with methyl acetate and the singlet with methyl pivalate.

γ-Radiolyses of Esters in the Rigid Matrix of MTHF. The ESR spectrum observed immediately after the γ-irradiation of pure MTHF consisted of a large singlet and a small seven-line spectrum. The singlet may be due to trapped electrons, while the underlying spectrum is probably due to MTHF radicals.[10] When a small quantity of a solute such as a carboxylic ester or sulfur hexafluoride was added to the matrix, the singlet spectrum was reduced. In Fig. 6, the peak height of the singlet

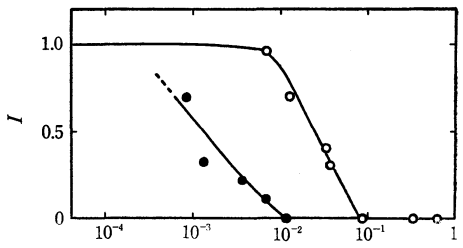

Fig. 6. Relative peak heights (I) of the spectra due to trapped electrons in γ-irradiated MTHF as a function of the mole fractions of additives.
○: ethyl acetate
●: sulfur hexafluoride

10) D. R. Smith and J. J. Pieroni, *Can. J. Chem.*, **43**, 876 (1965).

is plotted as a function of the concentrations of sulfur hexafluoride and ethyl acetate. In the present experiment, the concentration of esters in the matrix was always kept within the range of 1 to 2 mol%, so that the peak height of the singlet obtained immediately after γ-irradiation was almost the same as that obtained with pure MTHF. After the illumination with visible light, however, spectra characteristic of γ-irradiated pure esters appeared at the expense of this singlet spectrum. Figure 7 shows the spectra obtained with γ-irradiated

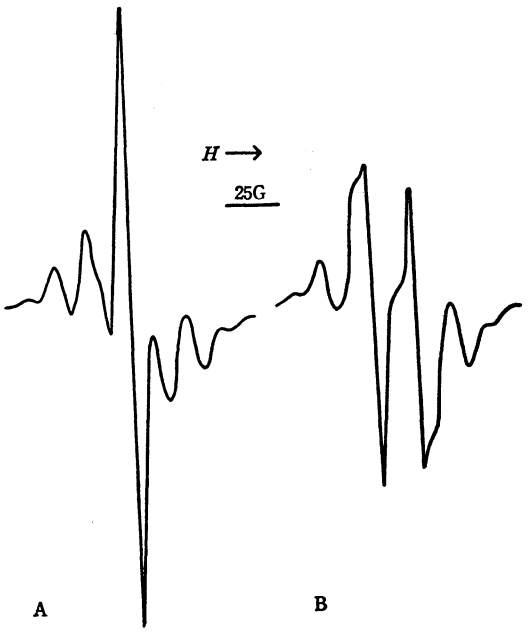

Fig. 7. ESR spectra of γ-irradiated MTHF containing 1 mol% ethyl acetate.
A: immediately after γ-irradiation
B: after bleaching by visible light

MTHF containing 1 mol% ethyl acetate before and after the illumination with visible light. Solute molecules with which the characteristic doublet was observed were methyl, ethyl and propyl acetate, ethyl and methyl propionate, and methyl butyrate. When ultraviolet light was used for the illumination, all the doublets disappeared and the spectra of such radicals as methyl and formyl appeared. These changes correspond exactly to those observed in the pure states previously described. The hyperfine splitting constants and the line-widths of the doublets are summarized in Table 2.

Acetic acid and propionic acid were also used for the solute molecules in the γ-irradiated MTHF glasses. The observed spectra correspond well to those obtained in the pure states. Fully-deuterated acetic acid was also examined. Judging from the spectrum obtained with the pure acid, the expected spectrum was a triplet with a hyperfine splitting constant of 5 G. However, the spectrum actually obtained was a broad singlet. This may be due to the overlap of the spectra due to various radicals produced by γ-irradiation. A similar result was obtained with formic acid; in the pure state a doublet

Table 2. Main ESR spectrum of γ-irradiated MTHF containing monocaboxylic esters or acids after bleaching by visible lights

Compound	No. of line	Hfs const. (oe)	Line widths (oe)
$HCOOCH_3$	1	—	6.7

A: immediately after γ-irradiation
B: after 1-min illumination of visible light
C: after 3-min illumination of visible light

was obtained, but in the matrix a broad singlet was obtained. The spectra A and B in Fig. 8 show the ESR spectra obtained with γ-irradiated methyl pivalate-MTHF glass after the illumination with visible and ultraviolet light. The change from the spectrum A to B exactly corresponds to that observed in the pure state. Figure 9 shows the change in the spectrum obtained with a MTHF glass containing methyl formate during the illumination with visible light. At the beginning of the illumination, the singlet at the center decayed and a doublet appeared, but upon the continuous illumination the doublet diminished and the singlet increased again. The decreased singlet may be attributed to trapped electrons, but the cause of the increased one cannot be specified. This singlet may be the spectrum observed in the pure state. After the ultraviolet illumination, the singlet disappeared, leaving the spectra mainly due to methyl and formyl radicals.

Discussion

As may be seen in Tables 1 and 2, the spectra obtained with γ-irradiated pure carboxylic esters and acids are in good agreement with those obtained with γ-irradiated MTHF containing the corresponding esters and acids after the illumination with visible light. It is now well known that the singlet spectrum observed immediately after the γ-irradiation of a MTHF rigid glass is due to electrons trapped in the solvent and that this singlet is easily quenched by the illumination with visible light. Therefore, the spectra obtained with MTHF glass solutions after illumination with visible light are probably due to the paramagnetic species formed in the reaction of electrons with solute molecules.[3,4] Since carboxylic compounds have large electron affinities, the paramagnetic species above stated might be the corresponding radical anions. Bennett and Gale, using the technique of alkali metal deposition on the carboxylic acids at the temperature of liquid nitrogen, observed the spectra due to the products. The spectra they observed with acids are very similar to those we obtained with acids and esters. They assigned these spectra to the corresponding radical anions, $R-\dot{C}\begin{smallmatrix}O^-\\ O-R'\end{smallmatrix}$. This assignment exactly fits the present results, except for the case of methyl formate.

If radical anions, $R-\dot{C}\begin{smallmatrix}O^-\\ O-R'\end{smallmatrix}$, are responsible for the characteristic spectra obtained with γ-irradiated esters, the doublets observed with esters having β-protons in the substitute, R, suggest that the bond R–Ċ does not rotate freely at the temperature of liquid nitrogen. This has already been substantiated in the case of acetic acid by Bennett and Gale; when the sample was warmed up from the temperature of liquid nitrogen, the doublet observed at 77°K was converted to a quartet typical of that observed in a freely-rotating methyl group, while the reverse process occurred when it was cooled again at 77°K. In the case of methyl pivalate, the corresponding characteristic spectrum observed was a singlet. This is consistent with the above assignment, because this ester has no β-protons.

If the foregoing discussion is applicable to every acid and ester, formic acid and its esters should give a doublet spectrum because of the interaction of an α-proton. Bennett and Gale reported that they observed a doublet with methyl formate, although the details were not presented. As has been stated in the Results section, we observed a singlet with γ-irradiated methyl formate and a peculiar change in the spectrum with the MTHF rigid solution during the illumination with visible light, as is shown in Fig. 9. This change can tentatively be explained as follows; the decrease in the singlet by the illumination is due to the quenching of trapped electrons, while the increase in the doublet may be due to the formation of the radical anions, $H-\dot{C}\begin{smallmatrix}O^-\\ O-CH_3\end{smallmatrix}$. However, if this radical anion is unstable when illuminated with visible light, the following reaction may occur:

$$H-\dot{C}\begin{smallmatrix}O^-\\ O-CH_3\end{smallmatrix} \rightarrow CO_2^- + \text{residue} \qquad (1)$$

In the present interpretation, this reaction corresponds to the change from the spectra B to the C in Fig. 9. Carbon dioxide anions are known to show a singlet and to be stable in visible light.[11] Accordingly, the singlet observed with γ-irradiated methyl formate may be explained in terms of the reaction (1) under γ-irradiation.

In the experiments of Bennett and Gale, carboxylic acids were examined mainly. Therefore, the paramagnetic species they obtained were perhaps dimer anions but were not the monomer radical anions:

$$R-\dot{C}\begin{smallmatrix}O-H-O\\ O-H-O\end{smallmatrix}C-R^-$$

This consideration can also be applied to the present results obtained with acids. In the case of esters, however, the hydrogen bonding is not expected to be so strong that the characteristic spectra observed may be attributed to the monomer radical anions. This may explain the differences in the hyperfine splitting constants of acids and the corresponding esters.

The authors are indebted to Dr. K. Shimokoshi of this Institute for his valuable suggestion.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 2137—2140 (1969)

Activity Coefficients of Aqueous Xylose and Maltose Solutions

Hatsuho UEDAIRA and Hisashi UEDAIRA

The Textile Research Institute of Japanese Government, Sawatari, Kanagawa-ku, Yokohama

(Received December 16, 1968)

Osmotic and activity coefficients of aqueous xylose and maltose solutions at 25°C are measured by the isopiestic vapor pressure method. Densities of these solutions are also determined at 25°C. The activity coefficients of water in these solutions show that both xylose and maltose solutions do not behave as regular solutions. Second virial coefficients for xylose and maltose are calculated from partial molar volumes of the solute and the solvent at infinite dilution and empirical equations of water activity coefficient. The coefficients calculated for xylose and maltose are 111 and 248 cc/mol, respectively. Second virial coefficients for these sugars and a few other sugars are approximately proportional to the molecular weight. This relation is explained by the van der Waals model.

The tendency of nonpolar solute to adhere to one another in aqueous environment is affected by the addition of sugars to the system. The protective action of sugars, including xylose, glucose and sucrose, in the coagulation of plasma proteins has been found by Hardt *et al.*[1] They showed that the degree of the action varied with sugars. In a previous paper,[2] we have reported that sucrose affected the hydrophobic bonding between dye ions and decreased the self-association of dyes.

The influence of the addition of sugars on the aqueous solutions of protein and nonpolar solute can be explained by the thermodynamic properties of aqueous sugar solutions. Activity coefficient has been obtained, however, so far only for glucose,[3] sucrose[4] and raffinose.[5] Stigter[6] and Kozak *et al.*[7] calculated the second virial coefficients for these three sugars from the activity and density data.

In the present work, osmotic and activity coefficients of maltose and xylose solutions were determined by the isopiestic vapor pressure method. Density was measured for these two systems. The second virial coefficients of these sugars were calculated by the method of Kozak *et al.*[8]

Experimental

Materials. Maltose (G. R.) and xylose (G. R.) were purified by crystallization repeated two or three times from water-ethanol solutions. Potassium chloride of analytical grade (Merck Co.) was used without further purification. These samples were dried *in vacuo* over phosphorus pentoxide at 100°C. Solutions were made up in conductance water which was air-freed by boiling before use.

Isopiestic Vapor Pressure Method. Osmotic and activity coefficients were determined with an apparatus similar to that employed by Robinson and Stokes.[4] About 2 m*l* of the sample solution was placed in each of two or three cylindrical silver dishes with lids. The reference potassium chloride solution was also placed in another set of silver dishes. These dishes were placed on a flat copper block contained in a vacuum desiccator, which was set in a thermostat bath at 25°C, controlled to ±0.01°C. At the start of the run, the hinged lids of the dishes were held open by a similar device as described by Robinson and Stokes.[4] The desiccator was evacuated to about 20 mmHg. In order to stir the solution the desiccator was rocked once every four or five seconds. Stirring was made by 3 mm pyrex glass spheres rolling across the bottom of the dishes. At the end of the run, after each dish was closed the vacuum was broken. Equilibrium concentration was measured by weighing the dishes. All the weights were corrected to vacuum. The time required for the equilibrium to be attained was 48 to 90 hr.

Calculation of the Osmotic and the Activity Coefficients. The osmotic coefficient of sugar, ϕ, is given by

$$\phi = 2m_R\phi_R/m, \quad (1)$$

where m_R and m are the molal concentrations of reference solute potassium chloride and sugar in isopiestic equilibrium, respectively. ϕ_R is the osmotic coefficient of potassium chloride at the concentration m_R. The values of the osmotic coefficient for potassium chloride solutions were tabulated by Robinson and Stokes.[8] The osmotic coefficients for each system were represented by the equations of the form

$$\phi = 1 + am + bm^2 + cm^3 . \quad (2)$$

The coefficients a, b and c were obtained by the method of least squares.

From the Gibbs-Duhem relation and the definition of ϕ, the activity coefficient of solute, γ, is shown by

$$\ln \gamma = (\phi - 1) + \int_0^m (\phi - 1) \mathrm{d} \ln m$$

$$= 2am + \frac{3}{2} bm^2 + \frac{4}{3} \mathrm{cm}^3 . \quad (3)$$

The activity coefficient of solvent water, γ_w, was expressed as a power series in the mole fraction of the solute, x. For solutions of nonelectrolytes we have

$$\ln \gamma_w = Bx^2 + Cx^3 + Dx^4 . \quad (4)$$

The coefficients B, C and D have the form[7],*1

$$B = -\left[\frac{1}{2} + a\frac{10^3}{W}\right], \quad (5)$$

$$C = -\left[\frac{2}{3} + 2a\frac{10^3}{W} + b\left(\frac{10^3}{W}\right)^2\right], \quad (6)$$

$$D = -\left[\frac{3}{4} + 3a\frac{10^3}{W} + 2b\left(\frac{10^3}{W}\right)^2 + c\left(\frac{10^3}{W}\right)^3\right], \quad (7)$$

where W is the molecular weight of water.

Density Measurements and the Calculation of Partial Molar Volumes. Density measurements were performed at 25±0.01°C with springel pycnometers of 30 m*l* capacity. At higher concentration of maltose solutions, that of 10 m*l* capacity was used. The density values for each system were fitted to the equations of the form

$$d = d_0 + A_1 m + A_2 m^2 + A_3 m^3 . \quad (8)$$

From Eq. (8), specific volume V is obtained.

$$V = \frac{1}{d_0} - \frac{A_1}{d_0} m + \left(\frac{A_1^2}{d_0^3} - \frac{A_2}{d_0^2}\right) m^2 + \left(-\frac{A_1^3}{d_0^4} + \frac{2A_1A_2}{d_0^3} - \frac{A_3}{d_0^2}\right) m^3 + \left(\frac{A_1^4}{d_0^5} - \frac{3A_1^2A_2}{d_0^4} + \frac{A_2^2 + 2A_1A_3}{d_0^3}\right) m^4 + \cdots . \quad (9)$$

Partial molar volumes of water, $\bar{v}_1$, and of solute, $\bar{v}_2$, can be calculated by the equations

$$\bar{v}_1 = W \cdot V - [(1000 + mM)mW/1000](\partial V/\partial m) , \quad (10)$$

$$\bar{v}_2 = M \cdot V + (1000 + mM)(\partial V/\partial m) , \quad (11)$$

where M is the molecular weight of the solute.

Results

The experimental values of the equilibrium molalities of xylose and maltose, and the molalities of the corresponding potassium chloride solutions are given in Table 1. The osmotic coefficients calculated by Eq. (1) are also given. These coefficients of xylose and maltose solutions are represented by the following equations.*2

$$\phi_{xy} = 1 + 0.01407m + 0.002288m^2 - 0.000482m^3 \quad (12)$$

$$\phi_{mal} = 1 + 0.03635m + 0.001818m^2 - 0.002405m^3 \quad (13)$$

The slope of the osmotic coefficient-concentration curves increases in the order

xylose < glucose < maltose < sucrose < raffinose.

From Eqs. (3), (4), (12) and (13), the expressions of activity coefficients of the solute and the solvent were obtained. They are for xylose solution,

$$\ln \gamma_{xy} = 0.02814m + 0.003432m^2 - 0.0006427m^3 , \quad (14)$$

$$\ln \gamma_{w,xy} = -1.281x^2 - 9.093x^3 + 65.61x^4 , \quad (15)$$

and for maltose solution

$$\ln \gamma_{mal} = 0.007270m + 0.02727m^2 - 0.003207m^3 , \quad (16)$$

$$\ln \gamma_{w,mal} = -2.518x^2 - 60.71x^3 + 302.5x^4 . \quad (17)$$

In contrast to glucose solutions,[3] none of xylose, maltose and sucrose[4] solutions behave as regular solutions.

0.99162	1.1049
1.4480	1.1421
2.3365	1.1996
2.8692	1.2275

Densities of xylose and maltose solutions are shown in Table 2, and are represented by the equations

$$d_{xy} = 0.99707 + 0.05505m - 0.00572m^2 + 0.000426m^3, \quad (18)$$

$$d_{mal} = 0.99707 + 0.13122m - 0.02505m^2 + 0.002551m^3. \quad (19)$$

From Eqs. (8), (9), (10), (11), (18) and (19), partial molar volumes of water and xylose in aqueous xylose solution are

$$\bar{v}_1 = 18.069 + 0.009003m^2 - 0.003251m^3 + 0.002313m^4, \quad (20)$$

$$\bar{v}_2 = 95.20 + 0.9994m + 0.2707m^2 - 0.1712m^3 + 0.01356m^4. \quad (21)$$

and those of water and maltose in maltose solution are

$$\bar{v}_1 = 18.069 + 0.9551m^2 + 0.03240m^3 - 0.01557m^4, \quad (22)$$

$$\bar{v}_2 = 211.3 - 106.0m + 8.025m^2 + 1.167m^3 - 0.8652m^4. \quad (23)$$

Discussion

Activity coefficients of xylose and maltose in aqueous solutions show deviations from ideality. The behavior of these aqueous solutions can be discussed more definitely by the second virial coefficient in the osmotic virial equations.

Recently Kozak *et al.*[7] proposed the method of calculation of the second virial coefficient from water activity coefficient and partial molar volume. If compressibility effects can be neglected, and concentrarions in the osmotic virial equation expressed in molecules per unit volume, then the second virial coefficient B_2^* can be calculated by

$$B_2^* = (v_2^* - v_1^0) + v_1^0\left(\frac{1}{2} - B\right)/N_A, \quad (24)$$

where N_A is the Avogadoro number, v_1^0 and v_2^* the partial molar volumes of solvent and solute at infinite dilution, and B the coefficient in Eq. (4). The values of v_1^0 and v_2^* are unchanged whether $\bar{v}_1$ and $\bar{v}_2$ are expressed as a power series in the molal concentration or molar concentration, so B_2^* be calculated from Eqs. (15), (17), (20), (21), (22), and (23). The values are

$$B_2^* \cdot N_A = 111 \text{ cc/mol for xylose in water},$$

$$B_2^* \cdot N_A = 248 \text{ cc/mol for maltose in water}.$$

The values of B_2^* for glucose and sucrose were calculated by Stigter,[6] and that for raffinose by Kozak *et al.*[7]

If we take the sugars as rigid spheres with attractive tails, the second virial coefficient $B_2^*(T)$ for such a van der Waals model is[9]

$$B_2^* = \left(4 - \frac{3}{64}\frac{h\nu_0}{kT}\frac{\alpha^2}{a^6}\right)\frac{4}{3}\pi a^3, \quad (25)$$

where a is the radius of a molecule, α the polarizability, other symbols have their usual meanings. As α and a^3 are proportional to the molecular weight, the quantity in the parenthesis of Eq. (25) is approximately independent of the molecular weight. Therefore, B_2^* will be proportional to

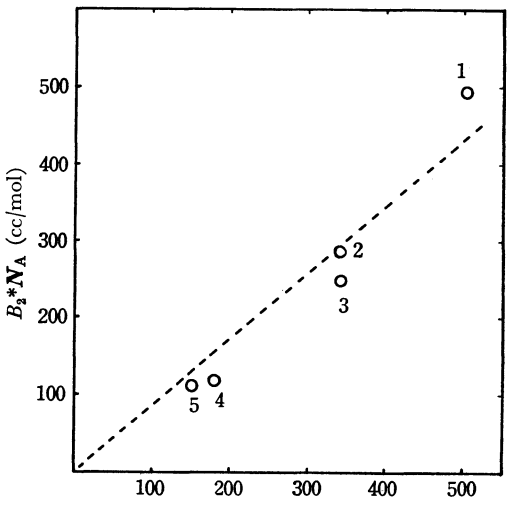

Fig. 1. The relation between second virial coefficient and molecular weight.
1: raffinose 2: sucrose 3: maltose 4: glucose 5: xylose

9) B. Chu, "Molecular Forces," Chap. 3, John Wiley & Sons, New York, London (1967).

the molecular weight. In Fig. 1, the plots of the second virial coefficients *versus* molecular weights are shown. The figure shows that the relation (25) holds approximately. While maltose and sucrose have the same molecular weight, B_2^* of maltose is smaller than that of sucrose. This may be caused by the larger attractive force between maltose molecules.

Diffusion Coefficients of Xylose and Maltose in Aqueous Solution

Hisashi UEADAIRA and Hatsuho UEDAIRA

The Textile Research Institute of Japanease Government, Sawatari, Kanagawa-ku, Yokohama

(Received December 16, 1968)

Diffusion coefficients for the systems aqueous xylose solution and aqueous malotse solution at 25°C were measured by the Rayleigh interference method. Viscosities of these systems were also determined. The concentration dependence of diffusion coefficient for maltose solution is well described by the Gordon relation. For xylose solution, however, a small deviation from this relation is observed. The translational frictional coefficient of maltose was calculated by the shell model of Bloomfield *et al.* If the effect of the local viscosity around a molecule of the solute is corrected, the agreement between the calculated and the observed values is satifsactory.

Only a small amount of data on diffusion of sugars in aqueous solution can be found in literature. Studies on such sugars are limited to the application of the Stockes-Einstein relation and the Gordon empirical relation. For example, the limiting diffusion coefficient of sucrose in aqueous solution is compared with the value calculated by the Stokes-Einstein relation,[1] though the molecule of sucrose has a non-spherical shape.

We present here the viscosity data and the diffusion coefficients for xylose and maltose in the aqueous solution at 25°C. Activity coefficients and densities for these systems have been presented previously.[2] The Gordon relation is tested by these data, and the translational frictional coefficient of maltose in the solution is calculated by the shell model of Bloomfield *et al.*,[3] a comparison being made between the observed and the calculated frictional coefficient.

Experimental

Materials. Xylose and maltose were purified as before.[2]

Viscosity Measurements. An Ubbelohde viscometer was used, the flow time for water at 25°C being 373.6 sec. The correction of the kinetic energy was not made. Viscosity measurement was made at 25.00±0.01°C.

Diffusion Measurements. The diffusion experiment was performed at 25.00±0.01°C using a Spinco Model H diffusion apparatus with a Rayleigh interferometer. For typical run, eight or nine photographic exposures were made at intervals ranging from 15 min to 4 hr; 4 inch by 5 inch Kodack type M glass photographic plates were used. The concentration difference of the solution on both sides of the diffusion boundary was adjusted so that the total number of Rayleigh fringes became 50 or 60. The plates were measured with a Shimadzu type SR-2 comparator. The zero time correction was the order of several seconds. The computation of diffusion coefficients was made by the method suggested by Creeth.[4]

Deionized water was employed as the solvent for these systems. All solutions were prepared by weight, and the weighing was corrected to vaccum. The molar concentrations of solutions were calculated from the density.

Results and Discussion

Reciprocals of relative viscosities of xylose and maltose solutions are represented by the following experimental equations.

$$\eta_0/\eta = 1 - 0.337c \quad (c<0.5) \tag{1}$$

for xylose solution, and

$$\eta_0/\eta = 1 - 0.851c \quad (c<0.3) \tag{2}$$

for maltose solution, where c is the molarity of solute.

In Table 1, the mean concentration of each diffusion experiment and the corresponding observed

value of diffusion coefficient for the xylose solutions are given in the first two columns. The corresponding data for maltose solution are given in Table 2. Diffusion coefficients for the two systems decrease linearly with the increase of concentrations. Extrapolated diffusion coefficients are also given in these Tables. The concentration dependence of the diffusion coefficients is larger for maltose than for xylose solution.

Gosting and Morris[5] demonstrated that the observed diffusion coefficients of sucrose in dilute aqueous solutions agreed with diffusion coefficients calculated from the Gordon relation[6]

$$D = D_0\left(1 + c\frac{d \ln y}{dc}\right)\frac{\eta_0}{\eta}, \qquad (3)$$

where y was the molar activity coefficient of solute, η_0 and η the viscosities of water and the solution, and D_0 the limiting value of D as $c \to 0$.

In a previous paper,[2] we obtained the activity coefficients of xylose and maltose in aqueous solution at 25°C. Using the available density data,[2] we obtain the following experimental equations of the molar activity coefficients y

$$\ln y = 0.1237c + 0.01195c^2 \quad (c<3.0) \qquad (4)$$

for xylose solution, and

$$\ln y = 0.2856c + 0.05475c^2 + 0.02720c^3 \quad (c<2.0) \qquad (5)$$

for maltose solution.

It is of interest whether Eq. (3) may describe the dependence which we have observed in the diffusion coefficients upon the concentration for xylose and maltose solutions. In Table 1 for the xylose solution, the third column contains the values of $[1+c(d \ln y/dc)]$ computed by Eq. (4). The values of η_0/η, column 4, were calculated from Eq. (1). Substitution of these values of D_0, $[1+c(d \ln y/dc)]$ and η_0/η into Eq. (3) then gives the values of D_{calc}, column 5. The ratio D_{exp}/D_{calc} is given in the last column in Table 1. The arrangement of Table 2 for the maltose solution is similar to that of Table 1.

As seen from Table 2, Eq. (3) holds for the maltose solution. For the xylose solution, however, the value of D_{exp} is larger than that of D_{calc} (Table 1), and its deviation, though small, increases with the increase of concentration. It is thought that the effect of the kinetic correction term of Eq. (3) is overestimated.

Longsworth[7] suggested that the value of D_0 of different solution could be expressed by the Stokes-Einstein relation in the form

$$D_0 = \frac{kT}{6\pi\eta_0}\left(\frac{4\pi N_A}{3V}\right)^{1/3} \qquad (6)$$

where V is the apparent molar volume of solute, N_A the Avogadro number, and the other symbols have their usual meanings. The apparent molar volumes at the infinite dilution for the xylose and the maltose in the solutions are 95.2 and 211.3

5) L. J. Gosting and M. Morris, *ibid.*, **71**, 1998 (1949).

6) A. R. Gordon, *J. Chem. Phys.*, **5**, 522 (1937).

7) L. G. Longsworth, *J. Am. Chem. Soc.*, **74**, 4155 (1952).

cc/mol, respectively.[2] Using Eq. (6) to calculate the diffusion coefficients of xylose and maltose at infinite dilution we obtained 7.311 and 5.607×10^{-6} cm²/sec, respectively, whereas the values extrapolated from the observed data are 7.495 and 5.201 $10^{-6}\times$ cm²/sec (Tables 1 and 2). The differences between the calculated and the observed values amount to 2.5 and 7.8%. Gladden and Dole[1] found that the differences between the calculated and the observed diffusion coefficients of glucose and sucrose amounted to 2.3 and 7.8%. The differences between the calculated and the observed values for xylose and glucose are small in comparison with the differences between the corresponding values for maltose and sucrose, because the molecules of xylose and glucose are nearly spherical. From this result, even for a small molecule such as maltose and sucrose, the deviation from the spherical shape has a large effect on the application of Eq. (6).

The assumption of the solvent as a continuum in the derivation of the Stokes relation implies that the dimensions of the diffusing particles are large in comparison with those of the solvent molecules. This assumption does not hold in the case of the small molecule, and its frictional coefficient is affected by the structure of solvent. In the aqueous solution, the water structure in the immediate vicinity of the solute is different from that of bulk water. Therefore, the value of η_0 of Eq. (6) must be different from that of bulk water. The translational frictional coefficient for a small molecule with any structure is not given yet. Therefore, when the equation of the frictional coefficient for a large particle is applied to the small molecule, the effect of the local viscosity must be suitably corrected.

Recently, Bloomfield, Dalton and Van Holde,[3] using the shell model, proposed the following expression for the translational frictional coefficient of the macromolecule with a structure which can be visualized as composed of n spherical subunits.

$$f=\frac{6\pi\eta_0\left(\sum_{l=1}^{n}r_l^2\right)^2}{\sum_{l=1}^{n}r_l^3+\sum_{l=1}^{n}\sum_{s=1}^{n}{}'\,r_l^2r_s^2\langle R_{ls}^{-1}\rangle} \qquad (7)$$

where R_{ls} is the distance between centers of two spherical shells of radius r_l and r_s

As the molecule of maltose consists of two identical spherical shells (glucose), the translational frictional coefficient f_M of maltose can be calculated by Eq. (7). Thus we have the expression

$$f_M=1.3(6\pi\eta_0r_G), \qquad (8)$$

where r_G is the radius of glucose. Water structure around the glucose and the maltose in the aqueous solution is regarded as identical. Therefore, the ratio of the frictional coefficient of maltose and glucose is independent of the water structure around the solute. The frictional coefficient f_G of glucose is equal to $6\pi\eta_0r_G$, and so $f_M/f_G=1.3$. On the other hand, the diffusion coefficient is in inverse proportion to the frictional coefficient. The limiting diffusion coefficient of glucose in the aqueous solution at 25°C obtained by Gladden and Dole[1] is 6.75×10^{-6} cm²/sec. Thus the ratio of experimental frictional coefficient of maltose to that of glucose is

$$\frac{f_M}{f_G}=\frac{D_{0G}}{D_{0M}}=\frac{6.75\times10^{-6}}{5.201\times10^{-6}}=1.29_7.$$

Agreement between the calculated and the observed ratio is very good, and is not accidental. Recently, we obtained a good agreement between the calculated and the observed ratio for the β-cyclodextrin in aqueous solution.[8] Generally, the frictional coefficient of the small molecule with complex shape is calculated by expression (7), if the effect of the local viscosity around the solute is corrected.

The authors thank Dr. K. Tsuda in our Institute for helpful discussions, and Mr. S. Tomita (Government Chemical Industrial Research Institute) for the use of a Spinco Model H.

BULLETIN OF THE CHEMICAL SOCEITY OF JAPAN VOL. 42 2143—2148 (1969)

Studies of the Estimation of the Interfacial Energy of Embryo in Solid-Liquid Systems

Tasuku NAKAI

Department of Chemical Engineering, Faculty of Engineering, Hiroshima University, Senda-machi, Hiroshima

(Received December 18, 1968)

A novel method for the estimation of the interfacial energy of an embryo from the solubility data in solid-liquid systems has been proposed. The distribution function of embryos in solutions derived thermodynamically has been used as the base for the present treatment. The interfacial energies were calculated numerically for three different combinations of solute and solvent, namely, water-inorganic salt, water-organic compound, and organic solvent-organic compound. A fairly good linear relationship was observed between the interfacial energies calculated and the temperatures over the whole temperature range of solubility data. The semiempirical equation describing the relationship between the interfacial energy of the embryo and the temperature in the solid-liquid system was found to be exactly the same as that between the surface energy of the liquid in contact with gas through a free surface and the temperature. The size dependence of the interfacial energy has also been briefly described.

With regard to the nucleation phenomena in both gas and liquid phases, it has been concluded theoretically that the interfacial energy is an important physical property directly affecting the nucleation rate. In spite of the importance of the interfacial energy of embryo in solid liquid systems, however, few reports have been published so far. Accordingly, the determination of the interfacial energy of the embryo seems to be indispensable to developing the nucleation study in solid-liquid systems.

The interfacial energies of the embryo in solid-liquid systems have been sporadically determined from the measurements of the excess solubility of finely-divided crystals,[1-4] the waiting time in the critical nucleus formation,[5-7] and the nucleation rate.[8-10] Because of many theoretical and experimantal difficulties, the numerical values of the interfacial energy reported so far differ from one another depending on the method of measurement and the investigator, and the values are considered to be unreliable. Moreover, the temperature dependence of the interfacial energy in solid-liquid systems has not been studied at all. In this paper, a method of estimating the interfacial energy of the embryo from the solubility data is proposed, and its numerical values over the entire temperature ranges of the solubility data are calculated for a large number of solid-liquid systems. In addition, both the temperature- and the size-dependences of the interfacial energy are described.

Theoretical

It is generally recognized that a great number of embryos of various sizes are present in a supersaturated solution.*1 According to this concept, it is possible to derive a distribution function of the embryos in a supersaturated solution.

Let X_{nj} be the number fraction of embryos composed of j molecules of solute, and assume that the interfacial energy is independent of both the embryo size and the solution composition. For an ideal solution, the change in the Gibbs free energy due to the coagulation of j molecules is given by:[11,12]

10) H. Naono, *ibid.*, **40**, 1104 (1967).

*1 An embryo is defined as a molecular aggregate the aggregation number of which ranges from two to a number less than that in a critical nucleus.

11) H. Reiss, *Ind. Eng. Chem.*, **44**, 1284 (1952).
12) A. E. Nielsen, "Kinetics of Precipitation," Pergamon Press, Oxford, London (1964), p. 7.

$$\Delta g = -j\phi + \beta\sigma j^{2/3} + \boldsymbol{k}T \ln Xn_j \quad (1)^{*2}$$

where Δg is the Gibbs free energy change per j molecules; ϕ, the Gibbs free-energy change per molecule; β, the geometric factor of the embryo; σ, the interfacial energy; $\boldsymbol{k}$, the Boltzmann constant, and T, the absolute temperature. The number fraction of embryos composed of j molecules of the solute, X_{nj}, is defined by:

$$Xn_j = \frac{n_j}{\sum_{j=2}^{j} n_j + n_1 + n_s} \quad (2)$$

where n_j is the number of embryos composed of j molecules of the solute; $\sum_{j=2}^{j} n_j$, the number of embryos of various sizes; n_1 the number of monomolecules of the solute, and n_s, the number of solvent molecules.

When the equilibrium of the embryo distribution in a supersaturated solution is accomplished, Δg becomes zero and Eq. (1) reduces to:

$$Xn_j = \frac{n_j}{\sum_{j=2}^{j} n_j + n_1 + n_s} = \exp\left(-\frac{\beta\sigma j^{2/3} - j\phi}{\boldsymbol{k}T}\right) \quad (3)$$

and

$$n_j = \left(\sum_{j=2}^{j} n_j + n_1 + n_s\right) \exp\left(-\frac{\beta\sigma j^{2/3} - j\phi}{\boldsymbol{k}T}\right) \quad (4)$$

If it is possible to extend this distrubition function to the saturated state, ϕ should become zero; Eq. (4) can then be rewritten as:

$$n_j = \left(\sum_{j=2}^{\infty} n_j + n_1 + n_s\right) \exp\left(-\frac{\beta\sigma j^{2/3}}{\boldsymbol{k}T}\right) \quad (5)$$

where the upper limit of the summation is taken to infinity, since the number of solute molecules in the critical nucleus is considered to be infinite in a saturated solution.

If the number of the monomolecules of the solute is also assumed to be expressed by Eq. (5), the total number of embryos of various sizes and monomolecules is given by:

$$\sum_{j=2}^{\infty} n_j + n_1 = \sum_{j=1}^{\infty} n_j = \left(\sum_{j=1}^{\infty} n_j + n_s\right)\left\{\sum_{j=1}^{\infty} \exp\left(-\frac{\beta\sigma j^{2/3}}{\boldsymbol{k}T}\right)\right\} \quad (6)$$

Accordingly, the number of solvent molecules is given by:

$$n_s = \left(\sum_{j=1}^{\infty} n_j + n_s\right) - \sum_{j=1}^{\infty} n_j = \left(\sum_{j=1}^{\infty} n_j + n_s\right)\left\{1 - \sum_{j=1}^{\infty} \exp\left(-\frac{\beta\sigma j^{2/3}}{\boldsymbol{k}T}\right)\right\} \quad (7)$$

When all the embryos of various sizes dissociate to monomolecular solutes, the total number of monomolecular solutes is given by:

$$\sum_{j=1}^{\infty} jn_j = \left(\sum_{j=1}^{\infty} n_j + n_s\right)\left\{\sum_{j=1}^{\infty} j \exp\left(-\frac{\beta\sigma j^{2/3}}{\boldsymbol{k}T}\right)\right\} \quad (8)$$

Finally, the so-called "*solubility*" in the mole fraction can be expressed as follows:*3

$$solubility = \frac{\sum_{j=1}^{\infty} jn_j}{\sum_{j=1}^{\infty} j \cdot n_j + n_s} = \frac{\sum_{j=1}^{\infty} j \exp\left(-\frac{\beta\sigma j^{2/3}}{\boldsymbol{k}T}\right)}{\sum_{j=1}^{\infty} j \exp\left(-\frac{\beta\sigma j^{2/3}}{\boldsymbol{k}T}\right) + 1 - \sum_{j=1}^{\infty} \exp\left(-\frac{\beta\sigma j^{2/3}}{\boldsymbol{k}T}\right)} \quad (9)$$

The average number of solute molecules per embryo in a saturated solution, j_{av}, may be estimated in the following manner:

$$j_{av} = \frac{\sum_{j=2}^{\infty} jn_j}{\sum_{j=2}^{\infty} n_j} = \frac{\sum_{j=2}^{\infty} j \exp\left(-\frac{\beta\sigma j^{2/3}}{\boldsymbol{k}T}\right)}{\sum_{j=2}^{\infty} \exp\left(-\frac{\beta\sigma j^{2/3}}{\boldsymbol{k}T}\right)} \quad (10)$$

where the lower limit of the summation is taken as two, since the aggregate composed of two or more molecules is defined as an embryo.

The dimensionless quantity included in the above equations is then replaced by:

$$\frac{\beta\sigma}{\boldsymbol{k}T} \equiv K \quad (11)$$

By substituting Eq. (11) into Eqs. (9) and (10), one obtains:

$$solubility = \frac{\sum_{j=1}^{\infty} j \exp(-Kj^{2/3})}{\sum_{j=1}^{\infty} j \exp(-Kj^{2/3}) + 1 - \sum_{j=1}^{\infty} \exp(-Kj^{2/3})} \quad (12)$$

$$j_{av} = \frac{\sum_{j=1}^{\infty} j \exp(-Kj^{2/3})}{\sum_{j=2}^{\infty} \exp(-Kj^{2/3})} \quad (13)$$

The relationship between the *solubility* or j_{av} and the K value can be determined by the numerical calculation using Eqs. (12) and (13), since the *solubility* and j_{av} are the functions of only K. If the embryo is assumed to be a sphere, β should be expressed as:

$$\beta = (4\pi)^{1/3}(3v)^{2/3} \quad (14)$$

*2 The present author is aware that the use of the term "interfacial energy" is not always appropriate, since the idea of an "interface" between a solution and an embryo composed of only a few solute molecules is purely formal. In such a case the term should simply be understood as a word meaning the excess energy which is inherent in the embryo formation.

*3 The solubility in the mole fraction is usually defined as the ratio of the number of monomolecular solutes to the number of both monomolecular solutes and solvents. In the present paper, however, the number fraction defined by Eq. (2) is used as the concentration. In order to avoid confusion, italic type is used for the former quantity.

where v is the molecular volume of the solute.

The results of the numerical calculation for the *solubility* and j_{av} as a function of K are shown in Figs. 1 and 2 respectively.

The interfacial energy and the average number of solute molecules per embryo in a saturated solution can be obtained through the following procedures: 1) the calculation of the *solubility* at an arbitrary temperature from the solubility data; 2) the determination of K corresponding to the *solubility* from Fig. 1; 3) the calculation of β by Eq. (14); 4) the calculation of σ corresponding to the K obtained by means of Eq. (11), and 5) the determination of j_{av} corresponding to K from Fig. 2.

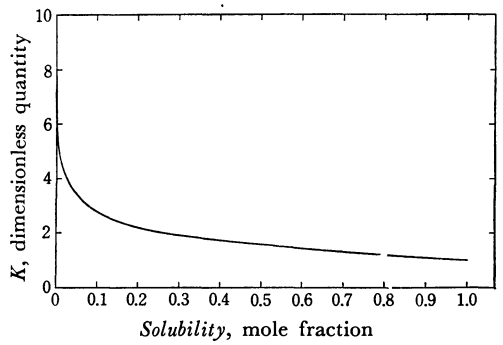

Fig. 1. Relationship between K and *solubilty*.

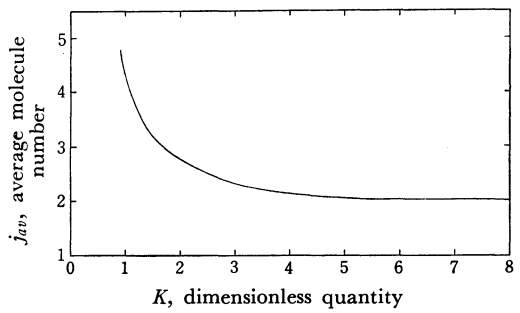

Fig. 2. Relationship between j_{av} and K.

Results

The present calculation was applied to the solid-liquid systems for which the solubility data were known over a wide temperature range. The systems were selected from "Kagaku Binran."[13] Since Eqs. (12) and (13) should hold for any combination of solute and solvent, the calculation was carried out for three different systems: 1) fifty inorganic salts in water, 2) fifteen organic compounds in water, and 3) fifteen organic compounds in organic solvents.

The interfacial energies for three sorts of inorganic salts, *i. e.*, easily-soluble anhydrides, easily-soluble hydrates, and sparingly-soluble anhydrates, were calculated. Some of the results are shown in Figs. 3, 4 and 5, where the interfacial energy is plotted against the centigrade temperature. As these figures show, a fairly good linearity in the plot of σ values against the centigrade temperatures was obtained for all fifty systems calculated.

Similar calculations were also carried out for both water-organic compound and organic solvent-organic compound systems. Some of the results are shown in Figs. 6 and 7. In these instances linearity was also obtained for all thirty systems.

Discussion

Temperature Dependence. The temperature dependence of the surface energy in the gas-liquid system has been studied theoretically by several authors[14,15] and a linear relationship has been concluded to hold. The temperature dependence of the surface energy of liquids which come in contact with gases through a free surface has been experimentally ascertained, and the following empirical equation has been proposed;[16,17]

$$\sigma\left(\frac{M}{\rho_l}\right)^{2/3} = \alpha(T_c - T - 6) \tag{15}$$

where M is the molecular weight; ρ_l, the density of the liquid; α, a constant; T_c, the critical absolute temperature of the liquid, and T, the absolute temperature corresponding to σ,

On the other hand, a linear relationship between the interfacial energy of embryo and the temperature was also obtained from the present study for solid-liquid systems. Since v in Eq. (14) is expressed by:

$$v = \frac{M}{N\rho_s} \tag{16}$$

one obtains, by substituting Eq. (16) into Eq. (14):

$$\beta = (4\pi)^{1/3}\left(\frac{3}{N}\right)^{2/3}\left(\frac{M}{\rho_s}\right)^{2/3} \tag{17}$$

⊖: K_2SO_4 ◑: ZnI_2 ◐: K_2CrO_4 ⓘ: KCl
◒: NH_4Cl ◓: NH_4Br ○: NaCl

where ρ_s is the density of the solute at the solid state and N, the Avogadro number.

The K values lie on a straight line in the plot against the reciprocal of the absolute temperature, as is shown in Fig. 8, in which the same systems as those in Fig. 3 are selected. Therefore, the relationship between K and the absolute temperature is given as:

$$K = A + \frac{B}{T} \tag{18}$$

where both A and B are constants characteristic of their solid-liquid systems.

By substituting Eqs. (17) and (18) into Eq. (11), one can derive the following semi-empirical equation for solid-liquid systems;

$$\sigma\left(\frac{M}{\rho_s}\right)^{2/3} = \frac{Ak}{(4\pi)^{1/3}\left(\frac{3}{N}\right)^{2/3}}\left(T + \frac{B}{A}\right) \tag{19}$$

By comparing Eq. (15) with Eq. (19), one can conclude that the temperature dependence of the interfacial energy can be expressed by similar equations for both cases, *i. e.*, liquids coming into contact with gases through a free surface and solid embryos in saturated solutions.

Size Dependence. The size dependence of the surface energy of a small droplet in a gas-liquid system has been thermodynamically studied by Tolman,[18] and the following theoretical equation has been derived:

$$\frac{\sigma_r}{\sigma_\infty} = \frac{1}{1 + \frac{2\delta}{r}} \tag{20}$$

where σ_r is the surface energy of the droplet with the radius r; σ_∞, that of the liquid with a free surface, and δ, a constant. Although he suggested that δ should be of the same order as the molecular diameter of liquid species, he did not make any numerical examination, presumably because of the lack of the surface energy data on small droplets in gas-liquid systems.

Since the *solubilities* don't change greatly with the temperature in the systems calculated in the present study, the variation in j_{av} was not appreciable over the whole temperature range. For instance, when the *solubility* of potassium chloride varies from 0.0694 to 0.120, corresponding to the temperature elevation from 0°C to 100°C, the K value changes from 3.06 to 2.50. Accordingly, the J_{av} value obtained from Fig. 2 varies from 2.32 to 2.44 corresponding to the variation of K. Since the variations in j_{av} were unappreciable for all solid-liquid systems studied, it may be reasonable to say that the size effect of the interfacial energy of embryo does not appear in the σ values calculated by the present method.

Comparison with the Published Data. Although the interfacial energies of the finely-divided crystals in solid-liquid systems have been investigated by several authors[1-4,19] on the basis of measuring the excess solubility, the results seem questionable. This is an indication of the number of theoretical and experimental difficulties unavoidable in treating fine particles, as was pointed out by Harbury.[19] The interfacial energies calculated by the present method will be compared below with recently-published data.

Recently, the interfacial energy of strontium sulfate has been estimated by Enüstün and Turkevich[4] utilizing the dependence of the solubility on the particle size. They have given 84 ± 8 erg/cm² as the interfacial energy of the finely-divided crystals (radius, 9 Å) at 25°C. On the other hand, by means of the present method σ and j_{av} are determined to be 53.9 erg/cm² and 2.0 respectively in the saturated solution at 25°C. Assuming that the difference in σ values depends only on the difference in the number of molecules in the two embryos, one can determine δ in Eq. (20). If the embryo is spherical, the radius of the embryo composed of two molecules becomes 3.33 Å. By substituting the σ and r of both embryos into Eq. (20) and by then dividing the former by the latter, one can obtain;

$$\frac{84}{53.9} = \frac{1 + \frac{2\delta}{3.33}}{1 + \frac{2\delta}{9}} \tag{21}$$

From Eq. (21) δ is calculated to be 2.20 Å. As a result of the above examination, δ seems to be roughly equated to the molecular radius (2.64 Å) of strontium sulfate, where the molecular radius is calculated on the assumption of a spherical molecule.

18) R. C. Tolman, *J. Chem. Phys.*, **16**, 758 (1948). **17**, 333 (1949).

19) L. Harbury, *J. Phys. Chem.*, **50**, 190 (1946).

Van Zeggeren and Benson[3] have investigated, by means of the electric-conductivity method, the solubilities of sodium chloride specimens varying in specific surface in ethanol at 25°C. They have given 171 erg/cm^2 as the interfacial energy of the fine crystal with a radius of 325 Å. In the present study the value is 50.9 erg/cm^2 for the embryo with a radius of 2.78 Å. In this system the δ in Eq. (20) becomes 3.37 Å (molecular radius: 2.20 Å)

Fisher *et al.*[8] have shown that the interfacial energy for the critical nucleus in a water-sucrose system is about 6 erg/cm^2. In the present study the value is 4.6 erg/cm^2 for the sucrose embryo composed of solute molecules of 2.4 at 25°C.

As a whole, the present calculation of the interfacial energies gives somewhat smaller values than those previously reported. This is probably due to the fact that smaller values of the embryo size were here calculated. Since our knowledge of the size dependence of the interfacial energy is insufficient at the present stage, it is difficult to predict in detail the interfacial energies of the fine crystals of various sizes in solid-liquid systems.

The conclusions are that it is possible to estimate the interfacial energy of embryos from the solubility data for all solid-liquid systems and that the interfacial energies calculated are linear in the plot against the temperature, as has been ascertained in gas-liquid systems with a free surface.

The author wishes to thank Professor Shigefumi Fujita, Faculty of Engineering, Tokyo Institute of Technology, for his many helpful discussions and suggestions during this study. Thanks are also due to Professor Masaji Miura, Faculty of Science, Hiroshima University, for his continuing interest and encouragement.

Electron Diffraction Studies of Formaldehyde, Acetaldehyde and Acetone

Chuichi KATO,*1 Shigehiro KONAKA, Takao IIJIMA and Masao KIMURA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo

(Received December 18, 1968)

The molecular structures of formaldehyde, acetaldehyde, and acetone have been investigated by the sector-microphotometer method of electron diffraction. Certain of the bonded interatomic distances, r_g, were determined to be as follows: for formaldehyde, $r(C-O)=1.209_3\pm0.003_3$ Å and $r(C-H)=1.096_7\pm0.053_5$ Å; for acetaldehyde, $r(C=O)=1.208_5\pm0.003_3$ Å and $r(C-C)=1.514_2\pm0.005_1$ Å; for acetone, $r(C=O)=1.211_0\pm0.004_1$ Å and $r(C-C)=1.516_7\pm0.004_8$ Å. The value of $r_g(C=O)$ for formaldehyde was perfectly consistent wth the zero-point average distance, $r_z(C=O)$, determined by microwave spectroscopy.

The structures of formaldehyde, acetaldehyde, and acetone have been the subject of a large number of structural investigations, for these compounds are the simple and elementary units of organic molecules containing carbonyl groups. Several structure determinations by microwave spectra have been published in the past decade.[1-3] In contrast to these studies by microwave spectra, however, studies by electron diffraction have so far been carried out[4-6] by the visual method and, necessarily, their results have included large uncertainties.

It is well known that bond lengths originally determined by microwave spectroscopy and by electron diffraction are not of the same physical siginificance, but can be related to each other by

taking into account the effect of thermal motions.[7] Since structure determinations for relatively complicated molecules must be performed on several assumptions when either method is used, microwave spectroscopy and electron diffraction may be considered to complement each other in determinations of molecular configurations.[8] Thus, the most reliable structures of formaldehyde, acetaldehyde, and acetone will be determined by combining information from electron diffraction with that from spectroscopy. The purpose of the present paper is to present the accurate molecular structures of these compounds as determined by the sector-microphotometer method of electron diffraction.

studies was newly designed and constructed. The camera lengths, the distance from the nozzle center to a plate, was perfectly fixed at 10.930 cm. Details about the unit will be reported elsewhere.[9] Diffraction photographs were taken with an r^3-sector at room temperature, 21.5°C. An accelerating voltage (~46 kV) was stabilized to within 0.1 percent throughout the sequence of exposures, which included a few pictures of the reference molecule and several pictures of sample molecules.

For the determinations of accelerating voltages, carbon disulfide was used as the reference material, for it has a suitable vapor pressure at room temperature and its distance parameters have been determined very accurately from spectroscopic data and confirmed by electron diffraction.[10] The use of a gaseous reference eliminates any systematic error due to the probable discrepancy between the nozzle and the actual diffraction centers and also some other systematic errors in the course of the experiment and analysis, for such errors are probably compensated for by employing the same procedure for both sample and reference gases.

The samples of carbon disulfide and acetone were special-grade reagents obtained from commercial sources. The sample of formaldehyde was prepared by the thermal depolymerization of commercial paraformaldehyde at 110°C according to the method of Spence and Wild.[11] Similarly, a sample of acetaldehyde was prepared by fractional distillation after depolymerizing commercial paraldehyde. The gases of carbon disulfide, formaldehyde, acetaldehyde, and acetone were stored in 1.5 *l* flasks at pressures of about 80 mmHg 120 mmHg, 135 mmHg, and 125 mmHg respectively, and then led into the diffraction chamber through a nozzle with an orifice 0.2 mm in diameter.

The photographic densities were measured by two different method: (1) with a double-beam microphotometer, model NLM-III, of the Narumi Co., Ltd, in our laboratory; this microphotometer was equipped with a cam converting transmission into optical density and a pen-recorder (pen-recording method), and (2) with a single-beam microphotometer, model MP-3, of the Rigaku Denki Co., Ltd., to which an integrating digital voltmeter was connected (digital method).[12],*2 Measurements were made by scanning across the full diameters of the diffraction patterns while the photographic plates were being rotated about the diffraction centers. The diffraction intensities were determined by averaging the corresponding points on both sides of the center; they covered the range $q=25$—150 at intervals of $\Delta q=1.0$.

Analysis and Results

After correction for the deviation of the sector shape from an ideal r^3-curve, the measured total intensities were leveled by dividing by the smooth theoretical backgrounds. Examples of the leveled experimental intensities are shown in Fig. 1a—d. The backgrounds on these intensity curves (solid lines in Fig. 1) were not in perfect agreement with the theoretical values. Since photographs taken without the injection of gases were perfectly transparent, the turned-up backgrounds at larger scattering angles may be due mainly to the reflection of scattered electrons from the inside wall of the sector mount.[9] The final leveled intensities, I_T, were obtained by subtracting these extraneous backgrounds, which were assumed to be given by the deviations of the experimental backgrounds from the theoretical values normalized to the experimental values at $q=65$.

By drawing smooth backgrounds, I_B, through

the leveled intensity curves, I_T, the molecular intensities, $qM(q)^{obs}$, were obtained according to the equation:

$$qM(q)^{obs} = q(I_T/I_B - 1) \quad (1)$$

The final smooth backgrounds and the corresponding molecular intensity curves were determined after Karle's criterion[13] by the Fourier inverse transformation of the radial distribution curves.[14] The molecular intensity curves and the radial distribution curves thus obtained are shown in Fig. 2a—d and Fig. 3a—d respectively.

The structure determinations were carried out by the method of least-squares applied to the molecular intensities, $qM(q)^{obs}$, with a conventional weight function, as is shown in Fig. 4. The theoretical expression corresponding to the observed $qM(q)^{obs}$ value is:

$$qM(q)^{calc} = \kappa \sum_i \sum_j{}' A_{ij}\mu_{ij} \cos \Delta\eta_{ij} \times \exp\left[-\frac{1}{2}\left(\frac{\pi}{10}q\right)^2 l^2_{ij}\right] \sin\left[\frac{\pi}{10}q\left\{r_{aij} - \left(\frac{\pi}{10}q\right)^2 \kappa_{ij}\right\}\right], \quad (2)$$

$$A_{ij} = \left(\frac{10}{\pi}\right)\frac{1}{r_{aij}} \cdot \frac{Z_iZ_j}{\sum_k Z_k(Z_k+1)},$$

$$\mu_{ij} = \frac{|F_i||F_j|}{\sum_k |F_k|^2 + \sum_k S_k} \cdot \frac{\sum_k Z_k(Z_k+1)}{Z_iZ_j}, \quad (3)$$

$$|F| = (h^2s^2/8\pi^2 me^2)|f|, \; s = \frac{\pi}{10} \cdot q,$$

where all the notations have their usual significances. The atomic scattering factors for electrons, $|f|$, and the phase shifts, $\Delta\eta_{ij}$, were those calculated by Kimura *et al.*,[15] while the inelastic scattering factors, S_k, were taken from the table given by Tavard *et al.*[16],*3 The starting models for the least-squares fittings are given in Table 1. Simultaneous least-squares refinements were not successful for all parameters because the low-weight

structure parameters are very insensitive to refinement and, also, certain parameters are strongly correlated with one another. Assuming equal interatomic distances and mean amplitudes for the equivalent pairs of atoms, the parameters refined by the present least-squares treatments were as follows: for CS_2, k, r_a(C–S), r_a(S–S) and their associated mean amplitudes; for formaldehyde, k, r_a(C=O), r_a(O···H), r_a(C–H) and their associated mean amplitudes; for acetaldehyde, k, r_a(C=O), r_a(C–C), r_a(C···O), r_a(C–H methyl) and their associated mean amplitudes; and for acetone, k, r_a(C=O), r_a(C–C), r_a(C···O), r_a(C···C) and their associated mean amplitudes. The other parameters were all fixed at the assumed values indicated in parentheses in Table 1. The interatomic distances and mean amplitudes in Table 1 were selected from those given in previous structural studies of these molecules[1-6,10] and other related compounds. The anharmonicity constants, κ_{ij}, for carbon disulfide were given by Kuchitsu.[17] The values for bonded atom pairs of the other molecules were estimated from the following approximate equation:[18]

$$\kappa_{ij} \approx (1/9)l^2_{ij}\langle \Delta z_{ij} \rangle \approx (1/6)al^4_{ij} \quad (4)$$

assuming the Morse potentials with the asymmetry constant, a, of $2\,\text{Å}^{-1}$.[19] Although no proper method of estimating κ's is available for non-bonded atom pairs, it was suggested by Kuchitsu[17] that they appear several-fold smaller than the diatomic estimates given by Eq. (4). Therefore, the κ_{ij}'s for non-bonded atom pairs were assumed to be one-third of the values estimated from Eq.

(4). At any rate, ambiguities in κ's have no substantial influence on the final results in the present studies.

The optical densities for each plate were measured by the two different methods described in the Experimental section. The least-squares refinements were applied to the individual molecular intensity curves. The results agreed with each other within their associated standard deviations, the interatomic distances especially being in perfect agreement. However, the standard deviations were smaller for the results obtained from optical densities by the digital method than for those obtained by the pen-recording method, for the former method gave the smoother intensity curves than the latter. Therefore, for the determinations of r_a and l_a we adopted only the results of the least-squares refinements applied to the whole range of observations by the digital method. The center of gravity of the probability function, r_g, can be obtained by the relation:

$$r_g = r_a + l_a^2/r_a. \quad (5)$$

The scale factors for each sequence of exposures were determined by the use of the diffraction patterns of carbon disufide. Examples are shown in Table 2. Since the scale factors were very close to unity, no correction was made of parameters

other than interatomic distances. The final values of r_g are given as averages of the r_g values determined separately for two selected plates. Tables 3, 4, and 5 show the results for formaldehyde, acetaldehyde, and acetone respectively.

The σ_1 and σ_2 values were estimated according to these two formulae: $\sigma_1^2=\langle\sigma^2\rangle/2$ and $\sigma_2^2=\sum v_i^2/n(n-1)$ respectively. Here, $\langle\sigma^2\rangle$ is the average of the square standard deviations for two plates, and v_i the residuals of the results of the ith plate subtracted from the average value. For most structure parameters, σ_2's were smaller than σ_1's. Taking the greater of σ_1 and σ_2 as a standard deviation, σ, for each parameter, random errors were given by 2.5 σ, representing 99% confidence intervals.

Five plates, one for each compound and two for carbon disulfide, were taken in a sequence of exposures; they are designated as plate 1 in the tables. Plate 2 for each compound was obtained in a separate sequence of exposures, one which included a plate for carbon disufide. The overall consistency in the results between plates 1 and 2 shows that the same experimental conditions were reproduced in the repeated exposures and that various systematic errors, such as errors originating from the drift of voltage, the uncertainty of the effective camera distance, *etc.*, may be regarded as being reflected in the error of the scale factor to be estimated below. Although a rigorous statistical meaning cannot be imposed on σ_2, which was estimated from only two plates in the present studies, σ_2 would coincide with σ_1 if a sufficiently large number of observations were made.

Since ach scale factor for plate 2 was determined by the analysis of only one plate of carbon disulfide, the largest standard deviation for individual scale factors may safely be taken as a standard deviation for all the scale factors used in the present studies. Thus, the error in the scale factor was given by 2.5 $\sigma=0.00207$, and $\sigma=0.00083$ for the C–S distance of plate 1 (II), corresponding to an error of 0.208 percent in interatomic distances. The total error for each parameter was considered to consist of two independent errors, the random error obtained in the least-squares fitting and the error in the scale factor. The final values of interatomic distances and their estimated total errors are given in Fig. 5. The interatomic distances obtained for acetone explain the planar frame of CCCO, as may clearly be seen by comparing them with the calculated values for a planar model shown in parentheses in Fig. 5.

The mean amplitudes, l_a, experimentally determined were not corrected for the effects of the sample size,[20] for the magnitudes of the corrections are much less than the total experimental errors. In Table 6 the final values of the mean amplitudes, l^{ED}, and their associated errors are summarized.

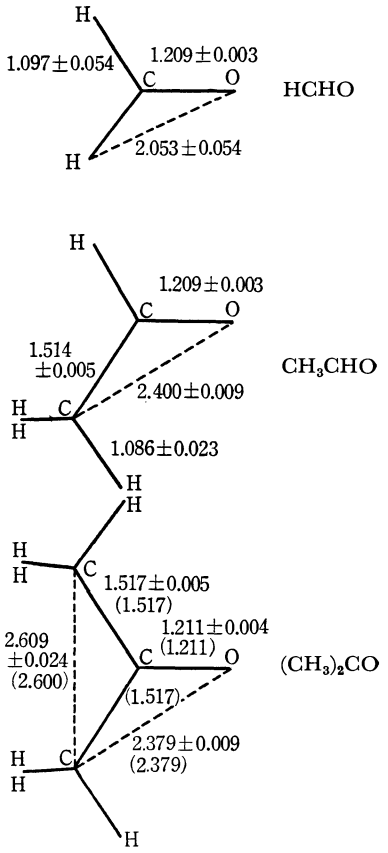

Fig. 5. The interatomic distances r_g in Å unit. The values in parentheses for acetone are interatomic distances calculated for a rigid model with the C_{2v} symmetry.

Discussion

The results of the present studies show there is no significant difference in the carbon-oxygen bond lengths of formaldehyde, acetaldehyde, and acetone in spite of their different environments. In other words, the difference between H and CH_3 as substituents does not affect the carbon-oxygen bond lengths. The carbon-carbon bond lengths in acetaldehyde and acetone were almost the same, their values being intermediate between about 1.54 Å for single bonds and about 1.47 Å for central C–C single bonds in conjugated systems.

The mean amplitude, l_a, is approximately equal to the value of l_g, which refers to r_g, and also to l_α, which refers to the harmonic oscillators.[17] Therefore, the observed values, l^{ED}, are in Table 6 compared with the values, l^{spectr}, calculated from the spectroscopic data, values which are equivalent to l_α. The l^{spectr} values were calculated by a usual method[21] by the use of the fundamental frequencies and the force constants of the valence force field (the VF3 set) reported by Cossee and Schachtschneider.[22] The agreements between l^{ED} and l^{spectr} are quite satisfactory.

Table 7 compares the bond lengths determined in the present study with those obtained from the rotational constants by microwave spectroscopy. For acetaldehyde and acetone, it is at this moment a question whether the bond lengths as determined by two different methods can be regarded as consistent with each other, for r_g, r_0, and r_s represent bond lengths with different physical significances.

Fortunately, the zero-point structure, r_z, for formaldehyde was given by Takagi and Oka.[1b] Since the conversion of r_z into r_g can be made rather straightforwardly, r_g was estimated from the r_z for the C=O bond of formaldehyde. To a good approximation, r_z can be related to r_g by the equation:[17,23]

$$r_g = r_z + \delta r + \frac{3}{2}a(l_T^2 - l_0^2) + [\langle \Delta x^2 \rangle_0 + \langle \Delta y^2 \rangle_0]/2r_a \quad (6)$$

Here, δr is the correction for the centrifugal distortion, $\langle \Delta x^2 \rangle_0$ and $\langle \Delta y^2 \rangle_0$ are the perpendicular mean amplitudes at 0°K, and l_T and l_0 are the parallel mean amplitudes at T °K and 0°K respectively. The values of $\langle \Delta x^2 \rangle$, $\langle \Delta y^2 \rangle$, and l_0 were calculated simultaneously in the calculations of l^{spectr}.[21,24] The estimation of δr was based upon a model in which the CH_2 group and the oxygen atom were bound with a force constant of 11 md/Å (K(C=O) in Ref. 22) at a distance of 1.2078 Å (r_z in Ref. 1b). The numerical values thus calculated were 0.00062 Å for δr, 0.00000 Å for $(3/2)a(l_T^2 - l_0^2)$ and 0.00004 Å for $[\langle \Delta x^2 \rangle_0 + \langle \Delta y^2 \rangle_0]/2r_a$. The value of r_g estimated from r_z then becomes 1.2085 Å, which agrees almost perfectly with the r_g value obtained by electron diffraction.

It has recently been shown that a cooperative use of diffraction and spectroscopic data is most useful in obtaining accurate structures of medium-sized molecules.[8] The present results for acetaldehyde and acetone must, therefore, be effectively combined with available spectroscopic informations. The application of this procedure to the structural studies of these molecules will be reported in separate papers.

The calculations of the least-squares analysis were carried out on the electronic computer, HITAC 5020 E, in the computing center of the University of Tokyo, to which the present authors' thanks are due.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 2159—2164 (1969)

Zero-point Average Structure of Acetaldehyde

Takao IIJIMA and Masao KIMURA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo

(Received December 18, 1968)

The zero-point average structure of acetaldehyde has been determined by the use of the moments of inertia and the average distances, obtained by microwave spectroscopy and electron diffraction respectively. The following r_z parameters have been determined: 1.515±0.005 Å for C–C, 1.207±0.004 Å for C=O, 1.073±0.002 Å for C–H(methyl), 123°48′±9′ for ∠CCO, and 108°52′±17′ for ∠HCH of the methyl top.

The molecular structure of acetaldehyde was studied by Kilb, Lin, and Wilson[1] by means of microwave spectroscopy. They determined the structure parameters (the so-called r_0 structure) from the moments of inertia for normal acetaldehyde and its six isotopically-substituted molecules, assuming that the bond distances and angles, except for those of the methyl group, were the same for all isotopic species.

Recently the present authors and their collaborators made an electron diffraction study of the structure of this molecule.[2] The results were not in close agreement with those from the microwave study, as may be seen by comparing the C–C and C=O distances in Table 1. However, this does not necessarily mean that the results are inconsistent with each other, for the distance parameters reported do not have exactly the same physical significance.

TABLE 1. PREVIOUS RESULTS FOR r(C–C) AND r(C=O) OF ACETALDEHYDE (IN Å)

	r(C–C)	r(C=O)
r_0(MW)[a]	1.501±0.005	1.216±0.002
r_g(ED)[b]	1.514±0.005	1.209±0.003

a) Microwave spectroscopy. Ref. 1.
b) Electron diffraction. Ref. 2.

Recent theoretical studies[3-5] have provided methods of converting the original spectroscopic and diffraction results into common physical quantities in order to facilitate their comparison. One practical way is to reduce the structure parameters determined experimentally to those of the zero-point average structure. Furthermore, several investigations[6-10] have shown that the cooperative use of spectroscopic and diffraction results is successful in the determination of the accurate structures of gas molecules. In the present study, the zero-point average structure of acetaldehyde has been determined by a cooperative use of microwave and electron diffraction data.

Zero-point Moments of Inertia

The moments of inertia obtained by microwave spectroscopy are effective moments of inertia for the ground vibrational state. They are converted to zero-point moments of inertia by correcting for apparent variations due to intramolecular harmonic vibrations. The relations between the effective moments $(I_{\alpha\alpha})_{eff}$ and the moments of inertia of a non-vibrating rigid molecule, $I^0{}_{\alpha\alpha}$, are given by the following equations:[3,4],*1

$$\frac{1}{(I_{\alpha\alpha})_{eff}} = \frac{1}{I^0{}_{\alpha\alpha}} + \frac{1}{(I^0{}_{\alpha\alpha})^2}\sum_s \frac{h}{8\pi^2 c\omega_s} \times \left[\sum_{s'}{}' \frac{4\omega_{s'}{}^2}{\omega_s{}^2-\omega_{s'}{}^2}(\zeta_{ss'}{}^{(\alpha)})^2 + 3A_{ss}{}^{(\alpha\alpha)}\right] + \frac{h^3}{8\pi^2}(3\tau_{\beta\gamma\beta\gamma} - 2\tau_{\alpha\beta\alpha\beta} - 2\tau_{\alpha\gamma\alpha\gamma}) \quad (1a)$$

and:

$$\frac{1}{(I_{\alpha\beta})_{eff}} = \frac{1}{I^0{}_{\alpha\alpha} I^0{}_{\beta\beta}}\sum_s \frac{h}{8\pi^2 c\omega_s}$$

a) Effective moments of inertia for the ground vibrational state observed by microwave spectroscopy (Ref. 1).
b) Zero-point moments of inertia reduced from I_{eff} by Eq. (3).

$$\times\left[\sum_{s'}{}'\frac{4\omega_{s'}{}^2}{\omega_s{}^2-\omega_{s'}{}^2}\zeta_{ss'}{}^{(\alpha)}\zeta_{ss'}{}^{(\beta)}+3A_{ss'}{}^{(\alpha\beta)}\right]. \quad (1b)$$

The last term of Eq. (1a) comes from the quadratic term of centrifugal distortion, where $\tau_{\alpha\beta\gamma\delta}$ is given by:[11]

$$\tau_{\alpha\beta\gamma\delta}=-\sum_s\frac{1}{I^0{}_{\alpha\alpha}I^0{}_{\beta\beta}I^0{}_{\gamma\gamma}I^0{}_{\delta\delta}}\cdot\frac{a_s{}^{(\alpha\beta)}a_s{}^{(\gamma\delta)}}{8\pi^2\boldsymbol{hc}^2\omega_s{}^2}. \quad (2)$$

All the notations are the same as in Ref. 4. The non-vanishing off-diagonal elements, $1/(I_{\alpha\beta})_{eff}$, indicate that the principal axes in a vibrating molecule deviate slightly from those in equilibrium. However, numerical calculations have shown that these terms are negligibly small for acetaldehyde and its isotopic species.

When the $(I_{\alpha\alpha})_{eff}$ represents the observed principal moments of inertia for the ground vibrational state, the $I^0{}_{\alpha\alpha}$ is the zero-point moment of inertia according to Oka[3] and Laurie and Herschbach.[12,13] In other words, $I^0{}_{\alpha\alpha}$ is the moment of inertia of such a rigid molecule that each atom is fixed at an average position which may be slightly different from an equilibrium position because of the first-order effect of anharmonicity. By using the observed moments of inertia, I_α(obs), of Table 2, the zero-point moments of inertia, $I_\alpha^{(z)}$(obs), were obtained by:

$$I_\alpha^{(z)}(\text{obs})=I_\alpha(\text{obs})-[(I_{\alpha\alpha})_{eff}-I^0{}_{\alpha\alpha}]_{calc}, \quad (3)$$

where $(I_{\alpha\alpha})_{eff}$ was calculated from Eq. (1a). The structure parameters determined by microwave spectroscopy[1] and the force constants determined by Cossee and Schachtschneider, the VF3 set,[14] were used in this calculation. The same force constants were assumed for all the isotopic species. Although there are, for some reason, slight discrepancies between the vibrational frequencies calculated in the present study and those reported

orignally by Cossee and Schachtschneider, as is shown in Table 3, no further refinement of the force constants was made. The mean-square amplitudes of vibration calculated by use of the force constants were in good agreement with those observed by electron diffraction (*cf.* Table 4 in Ref. 2).

The effects of the slipping rotation of the π-electrons of a C=O bond and the lone-pair electrons of the oxygen atom were corrected for in the case of formaldehyde by Oka.[3] His corrections were -0.003 amu.Å^2 at most. Although the effects are expected to be of a similar magnitude for acetaldehyde, the corrections are only a few in ten thousand or less since the moments of inertia of acetaldehyde are much greater than those of formaldehyde. Therefore, the corrections for these effects were ignored in the present study.

Isotope Effect on Zero-point Structure

In order to determine the r_z-structures from the moments of inertia, $I_\alpha^{(z)}$, of several isotopic species, the primary and secondary isotope effects*2 on r_z distances should be estimated. By defining the local Cartesian coordinates, x, y, and z, for a particular pair of atoms with a z axis taken in the direction of their equilibrium positions, r_z is expressed as:

$$r_z = r_e + \langle \Delta z \rangle_0 \tag{4}$$

in terms of the equilibrium distance, r_e, and the average increment of the distance along the z-axis, $\langle \Delta z \rangle_0$. The average is taken at 0°K, or for the ground vibrational state. By the diatomic approximation[8,15] $\langle \Delta z \rangle_0$ is given by:

$$\langle \Delta z \rangle_0 = (3/2)a_3 l_0^2 - K_0 \tag{5}$$

and:

$$K_0 = [\langle \Delta x^2 \rangle_0 + \langle \Delta y^2 \rangle_0]/2r_e\,, \tag{6}$$

where a_3 is the Morse anharmonicity parameter of the bond-stretching; l_0^2, the mean-square amplitude of vibration at 0°K, and $\langle \Delta x^2 \rangle_0$ and $\langle \Delta y^2 \rangle_0$, the perpendicular mean-square amplitudes of vibration at 0°K.

The anharmonicity parameters for C-H, C-C, and C=O bonds were assumed to be 1.98 Å^{-1}, 2.1 Å^{-1}, and 2.4 Å^{-1}, respectively.[15] The mean-square amplitudes and the perpendicular amplitudes needed for the estimation of K_0 were calculated by the use of l-matrix elements, which were obtained simultaneously with a computing program for the calculation of the I_{eff} values. The numerical values of $\langle \Delta z \rangle_0$ calculated for the bonded distances of several isotopic species are tabulated in Table 4.

Table 4. Isotope effects on r_z parameters. Calculated values of $\langle \Delta z \rangle_0$ (in Å units)

	C-H_{Me}	C-H_{Ald}	C-C	C=O
CH_3CHO	−0.005	0.001	0.0059	0.0026

$CH_3CH^{18}O$	a	a	a	0.0025

a) Not calculated. This does not necessarily mean that the values are negligibly small.

The relatively large negative values of $\langle \Delta z \rangle_0$ for the methyl C–H distances are caused by the large perpendicular amplitudes due to the torsional motion of the methyl top. For the C–C and C=O distances, the differences in $\langle \Delta z \rangle_0$ for different isotopic species are negligibly small, as had been expected.

The values of $\langle \Delta z \rangle_0$ in the table might include large systematic errors, caused mainly by assuming the values of a_3.[9,16,17] Kuchitsu estimated an uncertainty of +0.002 Å for the difference between the $\langle \Delta z \rangle_0$ values of the C–C bonds in C_2H_6 and C_2D_6.[9] This amount of uncertainty in the isotope effect sometimes leads to large errors in the structure parameters determined by the least-squares adjustment, especially when the adjustment is made under the circumstances that a strong correlation exists among some of the parameters.[7] In the present study, the correlation between r_{C-C} and $r_{C=O}$ was very strong when only spectroscopic data were used, as will be shown in the following section. Therefore, the uncertainties in the parameters are expected to be yet larger than those listed in Table 6, column I, which appears later. When diffraction data are used cooperatively, however, the influence of the possible systematic errors in $\langle \Delta z \rangle_0$ would be unimportant. The isotope effect for bond angles was ignored in the present study.

Zero-point Structure from $I_\alpha^{(z)}$

The seven parameters shown in Fig. 1 determine the structure of acetaldehyde when C_{3v} symmetry is assumed for the methyl top. In the final results, the parameters h and x shown in the figure are converted into r_{C-H} and ∠HCH respectively. It was confirmed by Kilb, Lin, and Wilson[1] that one of the three hydrogen atoms of the methyl top is opposed by the oxygen atom.

By a simple geometrical consideration, the following equation is obtained:

$$I_a^{(z)} + I_b^{(z)} - I_c^{(z)} = 3m_H h_z^2\,, \tag{7}$$

where:

$$h_z = (2/\sqrt{3})r_z \sin(\alpha_z/2)\,, \tag{8}$$

*2 Primary and secondary isotope effects have the meaning defined in Ref. 17.

and where r_z and α_z designate r_z(C–H) and ∠HCH respectively. From the observed $I_\alpha^{(z)}$ values of CH_3CHO, CD_3CDO, and CD_3CHO, the best-fit value of h_z, or the product of the parameters r_z and $\sin(\alpha_z/2)$, was determined, where slight differences in the h_z values of the three isotopic species were taken into consideration. The right-hand side of Eq. (7), calculated from the determined value of h_z, is compared with the observed value

of the left-hand side for each isotopic species in Table 5. As may be seen in the table, the agreement is quite satisfactory. This is one of the cases in which an isotope effect of r_z estimated on the basis of the mass difference accounts for the observed results. In this stage, r_z(C–H) and α_z were not determined separately.

The Jacobian matrix elements of twelve moments of inertia (two from each of the six isotopic species)*3 with regard to six in-plane parameters were calculated. The Jacobian matrix showed that $I_\alpha^{(z)}$'s were quite insensitive to ∠CCH(ald); hence, this angle was fixed at the value reported by Kilb, Lin, and Wilson,[1] and five parameters, r_{C-C}, $r_{C=O}$, ∠CCO, x, and $r_{C-H(ald)}$, were adjusted by the standard least-squares procedure. The parameters derived are listed in the column I of Table 6, along with their limits of error. The twelve

*3 The moments of inertia of $CH_3{}^{13}CHO$ were not included, because they probably depend more strongly on those of the other isotope species.

observed $I_\alpha^{(z)}$'s are not independent enough to alleviate the strong correlation between the increase in r_{C-C} and the decrease in $r_{C=O}$; the correlation factor estimated from the elements of the error matrix*4 amounted to 100 percent. This is more

*4 A matrix $\boldsymbol{B}$ is defined in terms of the Jacobian matrix $\boldsymbol{J}$ and a diagonal weight matrix $\boldsymbol{W}$ as $\boldsymbol{B}=\boldsymbol{J}\boldsymbol{W}\tilde{\boldsymbol{J}}$. The inverse of B is called an error matrix. According to the theory of errors, a correlation factor between the ith and jth parameters which have been adjusted by the least-squares method is given by
correlation factor$=(B^{-1})_{ij}/[(B^{-1})_{ii}(B^{-1})_{jj}]^{1/2}$.

easily seen in Fig. 2, where the process of solving the normal equation in the least-squares adjustment is reduced to the determination of the cross point of two straight lines drawn on the r_{C-C} *versus* $r_{C=O}$ plane. However, because of the strong correlation between r_{C-C} and $r_{C=O}$ the two lines are almost identical. Large standard errors result from this correlation making the error matrix nearly singular.

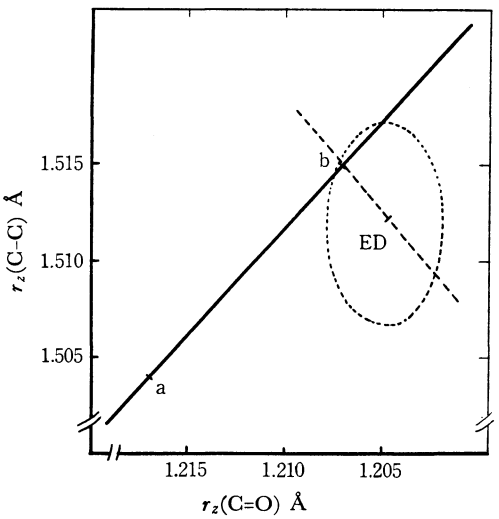

Fig. 2. Relation between r_z(C-C) and r_z(C=O). The cross point a of the two straight lines, indistinguishable in this figure, indicates the most probable values of r_z(C-C) and r_z(C=O) determined for spectroscopic moments of inertia. The point b indicates the most probable values determined by using electron diffraction data in addition to the spectroscopic data. The point ED indicates the results of electron diffraction for r_z(C-C) and r_z(C=O). The contour shows the limits of error of the diffraction data. The dashed line shows possible variation of r_z(C-C) and r_z(C=O) when a systematic error is allowed for in the scale factor of the diffraction data.

The moments of inertia, $I_\alpha^{(z)}$, calculated from the most probable values of the parameters are listed in Table 7, together with deviations from the observed moments of inertia. A deviation as large as 0.03 amu.Å^2 can originate from possible systematic errors in the isotope effects estimated for $\langle \Delta z \rangle_0$ and from the ignorance of anharmonicity in the deformation of bond angles, as has been mentioned in the preceding sections. Fractional deviations, however, are as small as a few parts per thousand or less. Therefore, uncertainties in the structure parameters due to these origins may also be expected to be a few parts per thousand unless correlations between parameters are as strong as in this case.

Zero-point Average Distance from Electron Diffraction

The distances, r_g(C–C) and r_g(C=O), determined by electron diffraction at room temperature were converted to r_z distances by the following equation;[9,10]

$$r_z = \lim_{T\to 0°K} r_g^T - K_0$$
$$\cong r_g^T - (3/2)a_3(l_T^2 - l_0^2) - \delta r_{cent} - K_0 \qquad (9)$$

where l_T^2 is the mean-square amplitudes and δr_{cent} the centrifugal stretching, both at room temperature, and where the other notations are as specified in Eqs. (5) and (6). This process is based on the assumption that a potential function associated with a bonded distance is well approximated by the Morse-type potential if the net distance between the two atoms, not the distance projected onto the equilibrium direction, is taken as a parameter of the potential function.[15] The non-bonded distances were not converted, for the uncertainties in their values are larger and, also, the anharmonicities for non-bonded atom pairs are not well known. The C–H distances were not determined with sufficient accuracy by electron diffraction.

The centrifugal stretching corrections were roughly estimated to be 0.000_4 Å for C–C and 0.000_2 Å for C=O by referring to the C=O bond of CO_2 calculated rigorously at room temperature, 0.0003 Å.[18] The numerical values for this conversion are summarized in Table 8. A comparison of the r_z-values in Table 8 with those in Table 6 reveals no inconsistency between the spectroscopic and diffraction r_z values; any inconsistency would be obscured by the large limits of error in the spectroscopic values.

Table 8. Conversion from r_g to r_z

	r_g^T (Å)	l_T^2 (Å^2)	l_0^2 (Å^2)	a_3 (Å^{-1})

Zero-point Structure with Additional r_2's Observed by Electron Diffraction

The strong correlation between the r_{C-C} and $r_{C=O}$ values was dissolved by a cooperative use of the r_z distances observed by electron diffraction

18) Y. Murata, K. Kuchitsu and M. Tanimoto, This Bulletin, to be published.

and the moments of inertia observed by microwave spectroscopy. The least-squares procedure was straightforward, and the two observed quantities, r_z^{ED}(C–C) and r_z^{ED}(C=O), were added to the twelve $I_\alpha^{(z)}$'s. Thus, five parameters were adjusted to fourteen observations. Obviously, the additional part of the Jacobian matrix had only two non-vanishing elements, one between the parameter r_{C-C} and the observed r_z^{ED}(C–C), and the other between r_{C-O} and r_z^{ED}(C=O). The relative weighting factors for observed quantities were identified as being inversely proportional to the square of the error of each observed value. The limits of error (99% confidence interval) in electron diffraction were reported to be ± 0.005 Å for r_z^{ED}(C–C) and ± 0.003 Å for r_z^{ED}(C=O). The errors arising from the conversion from r_g to r_z were ignored because they were considered to be less important. For the $I_\alpha^{(z)}$'s determined by microwave spectroscopy, the errors from which the weighting factors should be estimated are not only the original experimental errors in the moments of inertia, but also those including uncertainties in the conversion from I_{eff} to $I_\alpha^{(z)}$. However, most of the errors may be considered to arise from the conversion process. Therefore, these uncertainties are represented by the deviations of $I_\alpha^{(z)}$(obs) from $I_\alpha^{(z)}$(calc) calculated by use of the most probable values of the parameters. Corresponding to the 99% confidence interval in electron diffraction, the maximum deviation of $I_\alpha^{(z)}$(calc), ± 0.03 amu.Å^2, was taken as an error for $I_\alpha^{(z)}$.

The results of the least-squares adjustment are summarized in the second column of Tables 6 and 7. The adjusted values of r_{C-C} and $r_{C=O}$ are also indicated in Fig. 2 by the b point. Although there might be additional systematic errors which do not appear as a mutual inconsistency between the $I_\alpha^{(z)}$'s of several isotopically-substituted species, they were not taken into consideration, for their amounts are not well known. In the present case, however, even if the weighting factor for $I_\alpha^{(z)}$ were reduced to a quarter of the values used in view of the possible systematic error, the final set of parameters would remain almost unchanged, for the b point in Fig. 2 is the nearest point to the ED point on the solid line. The authors' view is that better estimates of errors for $I_\alpha^{(z)}$ will be established gradually through the further application to other molecules of the method of the cooperative use of diffraction and spectroscopic data.

Another method of this cooperative use is to eliminate a systematic error in the scale factor for diffraction results by the use of the spectroscopic moments of inertia, as was applied to the cyanogen molecule by Morino *et al.*[7] and to ethane by Kuchitsu.[9] In the present study this corresponds to finding a cross point of the two lines in Fig. 2: a dashed line passing the ED point so as to represent a proportional variation in r_{C-C} and $r_{C=O}$ according to a small deviation in the scale factor, and a solid line which represents the values of r_{C-C} and $r_{C=O}$ satsifying the least-squares condition for $I_\alpha^{(z)}$. Fortuitously, the cross point was very close to the b point, so the parameter values were identical with those obtained by the least-squares adjustment. Thus, the structure parameters listed in column II of Table 6 are considered to give the most reliable average structure of acetaldehyde.

From the values of $\langle \Delta z \rangle_0$ shown in Table 4 and the r_2 values determined in the present study, an approximate value of r_e was estimated by the use of Eq. (4), although it might include a large systematic error. The value of r_e obtained for the C–H bond of the methyl group was 1.078 Å, showing fair agreement with the 1.085 Å of CH_4[19] and the 1.080 Å of CH_3X.[20] When the r_z-value of the C–H(Me) of acetaldehyde, 1.073 Å, is compared with the r_2-value of the C–H in CH_4, 1.100 Å, one might erroneously conclude that there is a remarkable difference in the nature of the C–H bonds in acetaldehyde and methane. However, it must be noted that the r_z value depends not only on the nature of the bond but also on the environment of the bond in a molecule and the isotope effect. Judging from the agreement of the approximate r_e-values, it is probable that the C–H bonds in these molecules are similar in nature and that the difference between r_z-values arises mainly from the environment effect, *e. g.*, the torsional motion of the methyl top in acetaldehyde.

The authors wish to thank Mr. Chuichi Kato for his help in the early stage of this study. The numerical calculations were performed on a HITAC 5020E of the Computing Center of the University of Tokyo and on a FACOM 270-20 in the laboratory of Professor Kimio Ohno, Hokkaido University, to whom the authors' thanks are also due.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 2165—2169 (1969)

Temperature-jump Studies of the Kinetics of the Formation of the Monochloro and Monobromo Complexes of Iron(III)

Tatsuya YASUNAGA and Shoji HARADA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashi-sendamachi, Hiroshima

(Received December 21, 1968)

The temperature-jump method was used to study the kinetics of $FeCl^{2+}$ and $FeBr^{2+}$ complex formations in aqueous solutions. Complex formation is composed of two paths. In the acid-independent path, the rate-determining step of complex formation may be the reaction between $Fe(H_2O)_5^{3+}$ and X^- ($X^- = Cl^-$, Br^-). The other path is that *via* the hydrolysis of ferric ions, and the rate-determining step is the loss of a water molecule from the inner coordination sphere of the metal ion. The kinetic values obtained are in good agreement with the results obtained by the flow method.

Many of the fast metal complex formation reactions in solution have been studied with the help of the relaxation methods developed mainly by Eigen and Mayer,[1] and a step-by-step association picture has been presented to explain their relaxation phenomena.

Some of the complex formation reactions of Fe(III) have also been studied by the flow method,[2-6] the pressure-jump method,[7] and, most recently, the temperature-jump method.[8,9] By the temperature-jump method Cavasino[8,9] has reexamined a few of the Fe(III) complex formation reactions previously studied by the flow method and has given the kinetic values and interpreted the reactions.

The present study was undertaken in order to obtain kinetic information on the $FeCl^{2+}$ complex formation reaction over a wide range of acidity and temperature by the temperature-jump method. Moreover, since there has been very little information on the kinetics of the $FeBr^{2+}$ complex formation reaction,[3] we aimed to establish the mechanisms in more detail and to obtain the kinetic values of the reaction. Another purpose was to test the operation of a newly-built device at the beginning of the temperature-jump study.

Experimental

All the inorganic chemicals were of a reagent grade. Stock solutions of $Fe(NO_3)_3$ and NaCl were prepared. The concentration of ferric ion was determined photometrically. The chloride concentration was checked by titration with a standard silver nitrate solution. The hydrogen ion concentration was changed by the addition of $HClO_4$. The ionic strength was adjusted to $\mu = 1.0$ by the addition of $NaClO_4$. The temperature-jump apparatus used was a modification of that described by Hammes and Fasella.[10] A schematic diagram of our apparatus is shown in Fig. 1. The 0.1 μF condenser was charged to 18000 V and discharged

through the air gap. The observation cell was connected in parallel with the condenser *via* two gold-plated electrodes. The concentration changes were observed by single-beam-designed optical techniques. The temperature jump of the solution between the two electrodes was 5±1°C. The magnitude of the temperature jump was calibrated by comparing the change in the absorbance value of a test sample induced by discharge with the values previously measured at various temperatures. The test sample was a 0.02 M glycine solution (μ=1.0) at pH 9 containing phenolphthalein; it was followed at 550 mμ.

In all the ferric chloride solutions, the relaxation spectrum was characterised by a single relaxation time. A representative relaxation effect is shown in Fig. 2. Blank solutions containing only $Fe(NO_3)_3$ or NaCl with $NaClO_4$ gave no relaxation phenomena in the same range of time. The reciprocal relaxation time was calculated from a plot of $-\log \Delta C$ *vs.* the time, where ΔC is the deviation of the concentration from its equilibrium value. The wavelength of observation was 390 mμ. The quoted relaxation times and rate constants are the mean values of several runs.

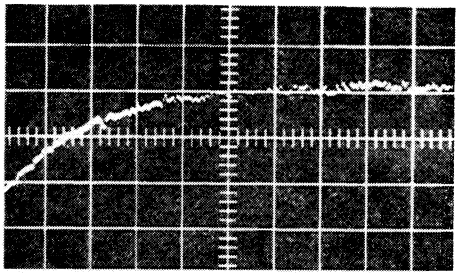

Fig. 2. Experimental relaxation curve at 27°C and μ=1.0.
$\sum$[Fe]=5×10^{-2} M; $\sum$[Cl]=5×10^{-} M; [H$^+$]= 0.10 M. The sweep rate is 5 msec per devision.

In the case of $FeBr^{2+}$ complex formation studies, $Fe(NO_3)_3$ and NaBr were used. Experiments were performed over the range of acidity of 0.1 M≤[H$^+$]≤ 0.8 M and at temperatures between 20°C and 40°C at μ=1.2.

Results

In the present studies, the following equilibria are assumed to be present and are attributed to the relaxation:

$$Fe^{3+} + X^- \rightleftarrows FeX^{2+} \qquad K_X = \frac{(FeX^{2+})}{(Fe^{3+})(X^-)} \qquad (1)$$

$$Fe^{3+} + H_2O \rightleftarrows FeOH^{2+} + H^+ \qquad K_{OH} = \frac{(FeOH^{2+})(H^+)}{(Fe^{3+})} \qquad (2)$$

Taking into account the low concentrations of Fe^{3+} and X^- and the high acidities, the following equilibria may be neglected:

$$FeX^{2+} + X^- \rightleftarrows FeX_2^+ \qquad (3)$$

$$FeOH^{2+} + H_2O \rightleftarrows Fe(OH)_2^+ + H^+ \qquad (4)$$

$$2FeOH^{2+} \rightleftarrows Fe_2(OH)_2^{4+} \qquad (5)$$

With these hypotheses, the overall mechanism for the complex formation of FeX^{2+} may be expressed as follows:

$$\begin{array}{ccc} H_2O + Fe^{3+} + X^- & \underset{k_{21}}{\overset{k_{12}}{\rightleftarrows}} & FeX^{2+} + H_2O \\ k_{13}\downarrow\uparrow k_{31} & & k_{42}\uparrow\downarrow k_{24} \\ Fe(OH)^{2+} + X^- + H^+ & \underset{k_{43}}{\overset{k_{34}}{\rightleftarrows}} & Fe(OH)X^+ + H^+ \end{array} \qquad (6)\ (7)$$

The protolytic reactions (vertical steps) will be very fast, and the other two processes may correspond to the rate-determining steps of complex formation.

Assuming that $Fe(OH)X^+$ is in a steady state, the rate of FeX^{2+} formation is given by:

$$\frac{d(FeX^{2+})}{dt} = k_{12}(Fe^{3+})(X^-) + k_{34}(FeOH^{2+})(X^-) - k_{21}(FeX^{2+}) - k_{43}(Fe(OH)X^+) \qquad (8)$$

and

$$\frac{d\Delta[FeX^{2+}]}{dt} = -\Delta[FeX^{2+}]([Fe^{3+}] + [X^-] + 1/K_X)(k_{12} + k_{34}\cdot K_{OH}/[H^+]) \qquad (9)$$

The reciprocal relaxation time is, then, related to the rate constants and the concentrations as follows:

$$\begin{aligned} 1/\tau &= (k_{12} + k_{34}\cdot K_{OH}/[H^+])([Fe^{3+}] + [X^-] + 1/K_X) \\ &= (k_f^\circ + k_f'/[H^+])([Fe^{3+}] + [X^-] + 1/K_X) \\ &= k_f([Fe^{3+}] + [X^-] + 1/K_X) \end{aligned} \qquad (10)$$

with $k_f^\circ = k_{12}$; $k_f' = k_{34}\cdot K_{OH}$; $k_f = k_f^\circ + k_f'/[H^+]$. The concentrations of Fe^{3+} and X^- are obtained from the total iron and halide concentrations and the corrected equilibrium constants, K_X and K_{OH}.

0.80		295	290	310	280

a) Unit, sec^{-1}

The relaxation times were affected only very slightly by the ferric and halide concentrations, as is shown in Tables 1 and 2. This can easily be foreseen from the fact that the quantity of the concentration part, $([Fe^{3+}]+[X^-])$, is smaller than $1/K_X$ (maxima: 30% in the case of $FeCl^{2+}$ but only 3% in the case of $FeBr^{2+}$); therefore, it is not necessary to know the concentrations with any great accuracy.

A) $FeCl^{2+}$ Complex Formation Reaction. The formation rate constants were calculated by Eq. (10) with $1/\tau$ values in Table 1, the equilibrium concentrations of the ions, and the dissociation constant. As may be seen in Fig. 3, the observed rate constant depends greatly on the hydrogen ion concentration. The points are linear, with a finite intercept at $1/[H^+]=0$. The intercept and slope of Fig. 3 give values of $k_f^\circ=20\pm10$ $M^{-1}sec^{-1}$ and $k_f'=26\pm3$ sec^{-1} at 27°C.

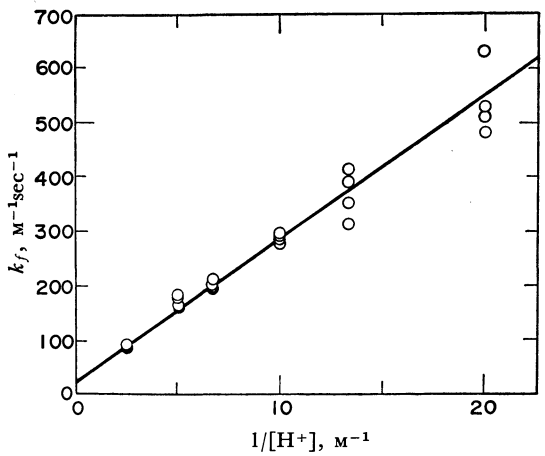

Fig. 3. The acid dependence of the formation rate constant of $FeCl^{2+}$ at 27°C and $\mu=1.0$.

In order to determine the enthalpies and entropies of activation, a series of experiments was run covering the temperature range from 20°C to 40°C. The equilibrium constants for ferric chloride at various temperatures have been estimated by the van't Hoff equation using the value at 25°C of 4.03 M^{-1} and $\Delta H=6.0$ kcal mol^{-1}.[2] K_{OH} has been estimated in the same way with the values of $\Delta H=10.2$ kcal mol^{-1} and $K_{OH}=1.60\times10^{-3}$ M^{-1} at 25°C.[11] The rate constants were calculated by means of Eq. (10), with the concentrations corrected for the temperatures; the results are shown in Fig. 4.

a) Calculated from $\Delta H^\ddagger_{f'}$ and the enthalpy change of reaction (12).

11) R. M. Milburn, *J. Am. Chem. Soc.*, **79**, 537 (1957).

Figure 5 shows a plot of log $k_f°/T$ °K *vs.* $1000/T$ °K, and similarly for k_f'. From the slopes of these lines, $\Delta H^{\ddagger}_{f°}=16\pm5$ kcal mol and $\Delta H^{\ddagger}_{f'}=21\pm2$ kcal mol^{-1} were calculated using the Eyring equation. $k_f°$ and k_f' at 25°C were taken to be $k_f°=19\pm10$ M^{-1} sec^{-1} and $k_f'=18.5\pm3$ sec^{-1} (*cf.* Fig. 5). These values are in good agreement with Connick's values,[2] $\Delta H^{\ddagger}_{f°}=16.6$ kcal mol^{-1}, $\Delta H^{\ddagger}_{f'}=23.3$ kcal mol^{-1}, $k_f°=9.5$ M^{-1} sec^{-1}, and $k_f'=18.0$ sec^{-1} at 25°C. The other kinetic values for $FeCl^{2+}$ formation and dissociation reactions are also listed in Table 3.

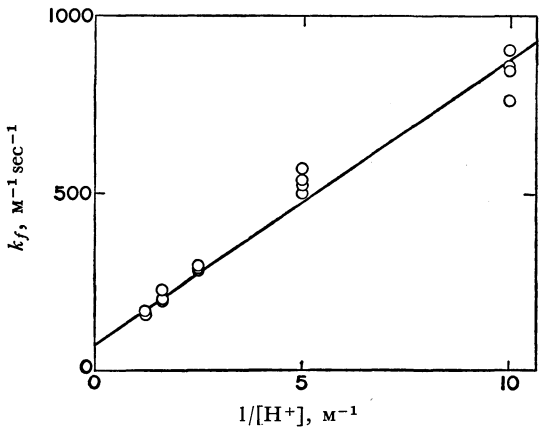

Fig. 6. The acid dependence of the formation rate constant of $FeBr^{2+}$ at 27°C and $\mu=1.2$.

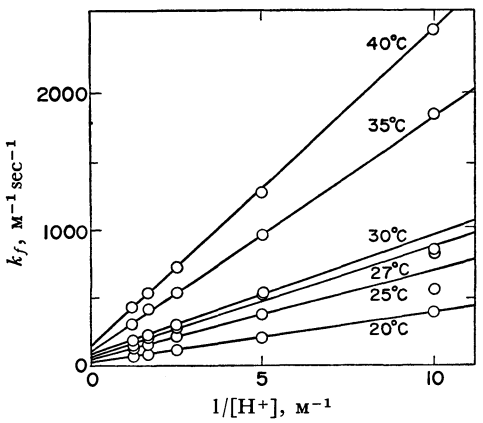

Fig. 7. k_f of $FeBr^{2+}$ *vs.* 1/[H$^+$] plot at various temperatures and $\mu=1.2$.

B) $FeBr^{2+}$ Complex Formation Reaction. The formation rate constants were calculated from the data in Table 2 and the equilibrium constants, $K_{Br}=0.56$ M^{-1} and $K_{OH}=1.78$ M^{-1} at $\mu=1.2$ and 27°C. Plots of the rate constants against 1/[H$^+$] in Fig. 6 gave values of $k_f°=73\pm20$ M^{-1} sec^{-1} and $k_f'=80\pm5$ sec^{-1} at 27°C. The enthalpies and entropies of activation were calculated from the data in Fig. 7. The kinetic values for the $FeBr^{2+}$ formation and for the dissociation reactions are listed in Table 4.

Discussion

Taking into account the fact that the rate constant of the complex formation is composed of two terms, one independent of hydrogen ion concentration and the other dependent on it, the complex formation reaction *via* rapid ion-pair formation, followed by the rate-determining loss of a water molecule in the inner coordination sphere of the metal ion, may be proposed as this reaction mechanism:

$$Fe(H_2O)_6^{3+} + X^- \overset{K°_{Fe}}{\rightleftharpoons} (H_2O)_5Fe^{3+}(H_2O)X^- \overset{k^*_{Fe}}{\rightleftharpoons} (H_2O)_5FeX^{2+} + H_2O \quad (11)$$

$$Fe(H_2O)_6^{3+} \overset{K_{OH}}{\rightleftharpoons} (H_2O)_5Fe(OH)^{2+} + H^+ \quad (12)$$

$$(H_2O)_5Fe(OH)^{2+} + X^- \overset{K°_{FeOH}}{\rightleftharpoons} (H_2O)_4Fe(OH)^{2+}(H_2O)X^- \overset{k^*_{FeOH}}{\rightleftharpoons} (H_2O)_4Fe(OH)X^+ + H_2O \quad (13)$$

$$(H_2O)_4Fe(OH)X^+ + H^+ \overset{\text{fast}}{\rightleftharpoons} (H_2O)_5FeX^{2+} + H_2O \quad (14)$$

where $K°$ is the ion-pair equilibrium constant and k^* is the rate constant for the rate-determining step of the inner coordinated water substitution. The two rate constants obtained above, k_{12} and k_{34}, have the following relationships:

$$k_{12} = K°_{Fe} \cdot k^*_{Fe} \quad (15)$$

b) k'_{12} corresponds to $Fe^{3+}+HX \xrightarrow{k'_{12}} FeX^{2+}+H^+$

c) k'_{34} corresponds to $FeOH^{2+}+HX \xrightarrow{k'_{34}} Fe(OH)X^{+}+H^+$

d) $t=22$°C

$$k_{34} = K^{\circ}_{FeOH}\cdot k^{*}_{FeOH} \qquad (16)$$

Unfortunately, K° cannot be determined experimentally; therefore, it has become customary to estimate K° from the Fuoss equation.[12,13] Assuming that the distance of the closest approach of the ion-pair partners is about 5 Å, K°_{Fe} and K°_{FeOH} can be calculated to be about 5 and 1 respectively at $\mu=0.5$—1.0, for the corresponding type of ion pairs. The value of K° in this calculation is uncertain because of the large ionic strength correction made in the calculation. The value of k^* for some of the Fe(III) complex formation reactions can be estimated from K° and the rate constants in Table 5.

The rate constants for the rate-determining process of reaction (13), k^{*}_{FeOH}, lie approximately in the same order, $(1-4)\times10^4$, irrespective of the nature of the entering ligand. According to Connick and Genser,[15] the rate constant for the water exchange on $(H_2O)_5FeOH^{2+}$ is estimated to be of the same order as these values ($\sim10^4\,sec^{-1}$). These facts indicate that the substitution of a water molecule in the inner coordination sphere of the metal ion is the rate-determining process of the complex formation reaction.

On the other hand, we must admit that the k_{12} and k_{12}' values also fall in nearly the same order. With $K^{\circ}_{Fe}=5$, k^{*}_{Fe} can be calculated to be 1—25 sec^{-1} by Eq. (15). Comparing k^{*}_{Fe} with the rate constant for water exchange on $Fe(H_2O)_6^{3+}$, $2.8\times10^2\,M^{-1}\,sec^{-1}$,[15] these values are a little too small. This shows that Eq. (11) is not the best possibility for the mechanism of reaction (6). An alternate mechanism consistent with the data may be proposed:

$$Fe(H_2O)_6^{3+} \overset{fast}{\rightleftarrows} Fe(H_2O)_5^{3+} + H_2O \qquad (17)$$

$$Fe(H_2O)_5^{3+} + X^- \rightleftarrows Fe(H_2O)_5X^{2+} \qquad (18)$$

where the reaction (17) is fast and where the rate-determining step is the reaction (18). This mechanism seems reasonable in view of two facts: the water exchange reaction rate is faster than the complex formation rate, and the complex formation rate of Fe(III) depends on the nature of the entering ligand.

Among the activation parameters for the complex formations of Fe(III), Cavasino[9] indicated some discrepancy in the reaction with Cl^- and attributed it to the high ionic strength at which the kinetic studies were carried out. In this work, however, we could not observe any such discrepancy in either $FeCl^{2+}$ or $FeBr^{2+}$ formation reactions; this fact also suggests that the rates of Fe(III) complex formation reactions are controlled by the rate of loss of a coordinated water molecule from the cation.

Further studies with other complexes of Fe(III) are in progress and will be reported on in due course.

Orbital Electronegativities in Molecules and Ionic Character in Molecular Complexes

Yoshio MATSUNAGA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo

(Received December 21, 1968)

The orbital electronegativities in the nine aromatic hydrocarbons were estimated on the basis of the ionization potentials and the appearance potentials of the doubly-charged ions. Then, by applying the principle of electronegativity equalization to molecular complexes, the orbital electronegativities in typical electron acceptors were evaluated. The ionic character in single and crystal complexes were discussed in terms of the electronegativities of the component molecules. Consideration of neither the ionization potential of the donor molecule, the electron affinity of the acceptor molecule, nor the orbital electronegativities appeared to be enough to define the ionic character in a complex.

The formation of molecular complexes by aromatic compounds has been interpreted in terms of weak covalent interaction between the π-electrons of the donor and acceptor.[1] The donor is a molecule with a relatively low ionization potential and the acceptor is a molecule with a relatively high electron affinity. The transfer of a negative charge from the donor to the acceptor takes place by the interaction. As the orbital electronegativity, defined as the derivative of the energy with respect to the charge, has been known to be a measure of the power of atoms and groups to attract an electron,[2,3] the extension of this concept to molecules might be useful in systematizing the experimental data and in gaining an understanding of the ionic character in molecular complexes.

The molecular electronegativity introduced by Becker and Wentworth is constant for aromatic hydrocarbons, 4.07 ± 0.05 eV,[4] and so is apparently different from the quantities considered in this paper.

Orbital Electronegativities in Molecules

We assume that the form:

$$\varepsilon(\rho) = a\rho + b\rho^2 \qquad (1)$$

is a good approximation of the true equation for representing the energies of molecules in various states of ionization. ε represents the total energy of all the electrons in a molecule, taking the energy of the neutral molecule to be zero. ρ is the charge on the molecule at a particular state of ionization. The differentiation of Eq. (1) with respect to ρ gives the electronegativity:

$$\chi(\rho) = a + 2b\rho \qquad (2)$$

Specifically for the neutral molecule:

$$\chi(0) = a \qquad (3)$$

As the compounds under consideration are neutral, closed-shell entities, the ε *vs.* ρ curve has a discontinuity in the slope at $\rho=0$. The electronegativity evaluated with $\varepsilon(1)$ and $\varepsilon(2)$ is for the highest occupied orbital and is different from that evaluated with $\varepsilon^*(-1)$ and $\varepsilon^*(-2)$. The latter is the electronegativity of the lowest vacant orbital. (Hereafter the quantities involving the lowest vacant orbital are indicated by asterisks.) Becker and Wentworth have defined their molecular electronegativity by an average of the ionization potential, $\varepsilon(1)$, and the electron affinity, $-\varepsilon^*(-1)$. Thus, theirs is not the property of a single orbital but concerns both the highest occupied and the lowest vacant orbitals.

The ionic character in donor-acceptor complexes may be defined by the following equation, which is based on the principle of electronegativity equalization or on the concept of bond electronegativity:[3]

$$\rho = \frac{a_A^* - a_D}{2(b_D + b_A^*)} \qquad (4)$$

where the subscripts D and A refer to the donor and the acceptor respectively. This approximation may not be poor provided that the ionic character is low. Equation (4) corresponds to the condition for minimizing the energy of the complex by charge transfer:

1) G. Briegleb and J. Czekalla, *Angew. Chem.*, **72** 401 (1960).

2) R. P. Iczkowski and J. L. Margrave, *J. Am. Chem. Soc.*, **83**, 3547 (1961).

3) J. Hinze, M. A. Whitehead and H. H. Jaffé, *ibid.*, **85**, 148 (1963).

4) R. S. Becker and W. E. Wentworth, *ibid.*, **85**, 2210 (1963).

$$\varepsilon_C(\rho) = a_D\rho + b_D\rho^2 - a_A^*\rho + b_A^*\rho^2 \quad (5)$$

By eliminating ρ from Eq. (5) using Eq. (4), we obtain the contribution of the charge transfer to the binding energy:

$$\varepsilon_C = -\frac{(a_A^*-a_D)^2}{4(b_D+b_A^*)} \quad (6)$$

Thus, the stabilization energy may be anticipated to be nearly proportional to the square of the difference in orbital electronegativity.

Once the parameters, a and b, for a typical donor (or acceptor) molecule are known, those in the acceptor (or donor) molecule may be estimated on the basis of the magnitude of the ionic character or the charge transfer, ρ, in the complex. Of course, the value of $\varepsilon^*(-1)$ for the acceptor (or $\varepsilon(1)$ for the donor) must be available, but generally it can be easily measured or estimated.

Aromatic Hydrocarbons. There are, at present, very few compounds for which both $\varepsilon(1)$ and $\varepsilon(2)$ or $\varepsilon^*(-1)$ and $\varepsilon^*(-2)$ are known. For several aromatic hydrocarbons the ionization potentials, $\varepsilon(1)$, and the appearance potentials of doubly-charged ions, $\varepsilon(2)$, have been measured by Wacks and Dibeler.[5,6] The electronegativities of the highest occupied orbitals can be evaluated by means of Eq. (1). The results are presented in Table 1 with the values of $\varepsilon(1)$ and $\varepsilon(2)$. The appearance potentials of doubly-charged ions have been reported to have an estimated probable error of ± 0.5 eV; therefore, the estimation of a_D and b_D cannot be very accurate. It must be noted that the electronegativity, a_D, is more variable than the ionization potential. Moreover, the changes in these two quantities are not quite parallel. The values of the b_D parameters are scattered in the range from 3 to 4 eV, and no correlation with the ionization potential is noted.

Table 1. Ionization potentials $\varepsilon(1)$, appearance potentials of doubly charged ions $\varepsilon(2)$ and electronegativities of the highest occupied orbitals in some aromatic hydrocarbons

Hydrocarbon	$\varepsilon(1)$ (eV)	$\varepsilon(2)$ (eV)	a_D (eV)	b_D (eV)

Acceptors. Electron affinities have been estimated for a number of acceptors by Briegleb.[7] Recent measurements of the affinity of *p*-benzoquinone by the magnetron technique have suggested that Briegleb's value is too low, probably by 0.8 eV.[8] We assume that this difference can be used in estimating the acceptors now under consideration.

If the wave function of the ground state of a single 1 : 1 complex is approximated by:

$$a\psi_0(D, A) + b\psi_1(D^+\text{-}A^-) \quad (7)$$

where $\psi_0(D, A)$ is the wave function for a no-bond structure and $\psi_1(D^+\text{-}A^-)$ is that for a dative structure formed by the transfer of one electron from the donor (D) to the acceptor (A) molecule, while the ionic character is given by b^2. Briegleb *et al.* have measured the dipole moments of the three naphthalene complexes in solution and estimated the coefficients, a and b, in Eq. (7).[9] The parameters, a_A^* and b_A^*, may then be calculated using Eq. (4), with the values of $b^2(=\rho)$ and the electron affinities, $-\varepsilon_A^*(-1)$, estimated separately. The results are summarized in Table 2. Contrary to the case of the electron donors, the electronegativity, a_A^*, is relatively constant in these three acceptors. The change in the electron affinity arises mostly from the change in the b_A^* parameter.

Table 2. Electron affinities of acceptors $-\varepsilon_A^*(-1)$, ionic character ρ estimated for the naphthalene complexes and electronegativities of the lowest vacant orbitals of acceptors

Acceptor	$-\varepsilon_A^*(-1)$ (eV)	ρ	a_A^* (eV)	b_A^* (eV)
s-Trinitrobenzene	1.5	0.028	5.57	4.07
p-Chloranil	2.2	0.041	5.71	3.51
TCNE	2.6	0.063	5.99	3.39

Ionic Character in Donor-Acceptor Complexes

Single Complexes. With the parameters listed in Tables 1 and 2, the ionic character in the tetracyanoethylene (TCNE) complexes can be estimated by means of Eq. (4), they are presented in Table 3. The values for the complexes of large hydrocarbons seem to be too high. For example, Kuroda *et al.* have reported that the dipole moment of the pyrene

7) G. Briegleb, *Angew. Chem.*, **76**, 326 (1964).

complex is 2.0 debye.[10] By adopting Eq. (7), an ionic character about a half of the present estimation is obtained. This disagreement is rather serious. It has also been pointed out that Eq. (7) is too simple to represent the true wave function of the donor-acceptor complex.[10,11] The

TABLE 3. IONIC CHARACTERS AND STABILIZATION ENERGIES ESTIMATED FOR THE TETRACYANOETHYLENE COMPLEXES

Hydrocarbon	ρ by Eq. (4)	$-\varepsilon_C$ (eV) by Eq. (6)
Benzene	0.030	0.006
Naphthalene	(0.063)	0.026
Anthracene	0.113	0.081
Phenanthrene	0.107	0.079
Pyrene	0.166	0.212
Tetracene	0.210	0.332
Tetraphene	0.142	0.149
Chrysene	0.116	0.095
Triphenylene	0.114	0.095

significance of higher-energy charge-transfer configurations, including back charge-transfer configurations, has been emphasized. Therefore, the a_A^* and b_A^* parameters should be accepted only with some reservations. The disagreement in the pyrene complex may be regarded as an indication that the contributions from back charge-transfer configurations, D^--A^+, involving higher-energy orbitals, to the ground state of the pyrene complex are more appreciable than those to the ground state of the naphtalene complex. Table 3 includes the stabilization energies calculated by Eq. (6). These energies differ from the resonance energies given by the quantum mechanical treatment. Nevertheless, the calculated energies are mostly in the right order of magnitude, suggesting that the classical charge-transfer stabilization may be of some importance in the formation of molecular complexes.

Crystal Complexes. McConnell *et al.* have elaborated a Hartree-Fock molecular-field approximation to the energy of a 1 : 1 crystal complex and have proposed the following equation:[12]

$$E(\rho) = N(\varepsilon_0\rho - \varepsilon_1\rho^2) \tag{8}$$

Here $N\varepsilon_0$ is the energy required to charge the lattice so that there is a unit positive charge on each donor molecule and a unit negative charge on each acceptor molecule, while $-N\varepsilon_1\rho^2$ indicates the total attractive energy in the lattice. ε_0 is related to the ionization potential of the donor, $\varepsilon_D(1)$, and the electron affinity of the acceptor, $-\varepsilon_A^*(-1)$, by:

$$\varepsilon_0 = \frac{1}{2}[\varepsilon_D(1) + \varepsilon_A^*(-1)] \tag{9}$$

Assuming that ρ has to be in the range of 0 to 1, the energy is found by Eq. (8) to be at its minimum at $\rho=0$ when $\varepsilon_1<\varepsilon_0$ and at $\rho=1$ when $\varepsilon_1>\varepsilon_0$. Accordingly, they have concluded that 1 : 1 crystal complexes must divide quite sharply into two classes, namely, $\rho=0$ and 1.

Using the present approach, however, we reach conclusions very different from these. Within the framework of the electronegativity equalization, the energy of a crystal complex consisting of $N/2$ molecules of the donor and $N/2$ molecules of the acceptor is simply Eq. (5) multiplied by $N/2$, namely:

$$E(\rho) = \frac{N}{2}[(a_D - a_A^*)\rho + (b_D + b_A^*)\rho^2] \tag{10}$$

As $(a_D - a_A^*)$ is small in the complexes to which this approximation is good, the second term dominates in this equation. Therefore, the general features of the E *vs.* ρ curve given by Eq. (10) bear no resemblance to those suggested by McConnell *et al.* In Fig. 1 the energy of the naphthalene-TCNE complex is plotted against the charge using the parameters listed in Tables 1 and 2. The curve given by Eq. (8) is also illustrated for the sake of comparison.

If the ionic character in a crystal complex is high, the electrostatic ion-ion interaction becomes of major importance, just like the energy required to charge the lattice. Then:

$$E(\rho) = \frac{N}{2}[(a_D - a_A^*)\rho + (b_D + b_A^*)\rho^2 - 2\varepsilon_i\rho^2] \tag{11}$$

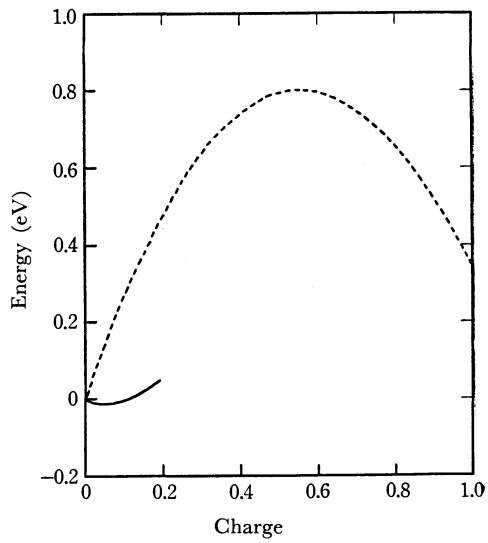

Fig. 1. Energy *vs.* charge as given by Eq. (10) (——) and by Eq. (8) (- - -) for naphthalene-TCNE complex.

11) R. S. Mulliken, *J. Chim. Phys.*, **61**, 20 (1963).
12) H. M. McConnell, B. M. Hoffman and R. M. Metzger, *Proc. Natl. Acad. Sci.*, **53**, 46 (1965).

where the ε_i has the same meaning as the ε_1 in Eq. (8). The amount of charge transfer in equilibrium is given by:

$$\rho = \frac{a_A^* - a_D}{2(b_D + b_A^* - 2\varepsilon_i)} \tag{12}$$

The condition $\varepsilon_i > [\varepsilon_D(1) + \varepsilon_A^*(-1)]/2$ leads to $\rho > 1/2$. As ε_i seems to be of the order of the magnitude of 2 eV,[13] among the donors and acceptors in Tables 1 and 2 the $\rho > 1/2$ condition is likely to be fulfilled when tetracene is combined with TCNE. Figure 2 presents the E *vs.* ρ curves given by Eqs. (8) and (11) with the parameters for this combination and with $\varepsilon_i = 2.5$ eV. If we employ Eq. (8), the assumption that $0 \leqq \rho \leqq 1$ is important. However, this does not seem very reasonable because each orbital may accommodate two electrons. It must be added that the presence of this particular complex is unlikely because of the chemical reaction between component compounds. Furthermore, as has been discussed in the preceding section, the ionic character defined by the parameters in Tables 1 and 2 may be too large and the $\rho > 1/2$ condition is not necessarily attained by the whole complex even if this complex could be prepared. Nevertheless, it should be emphasized that the presence of a number of crystal complexes in which $\varepsilon_i > [\varepsilon_D(1) + \varepsilon_A^*(-1)]/2$ is fulfilled has been indicated by the electronic and vibrational spectra.[14,15] The curves in Fig. 2 may be considered to present the general features of the ionic character in such complexes.

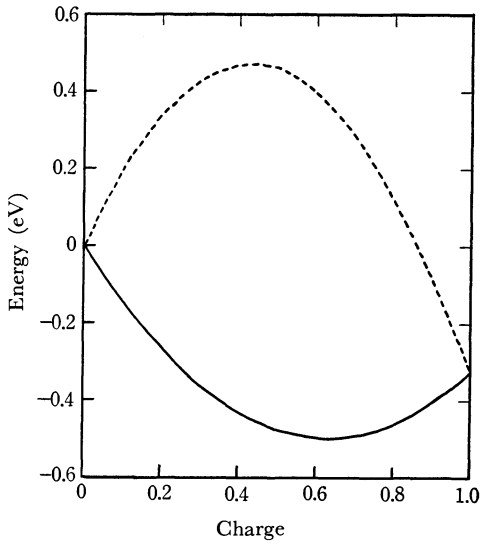

Fig. 2. Energy *vs.* charge as given by Eq. (11) (——) and by Eq. (8) (- - -) for tetracene-TCNE complex.

In conclusion, we wish to remark that consideration of neither the ionization potential of a donor, the electron affinity of an acceptor, nor the electronegativities represented by the a_D and a_A^* parameters is enough to define the ionic character in a complex. Let us therefore suppose the presence of some donors which have the same ionization potential as tetracene but which have a_D and b_D parameters different from those of the hydrocarbon, say, $a_D = 3.50$ and $b_D = 3.45$, and $a_D = 4.00$ and $b_D = 2.95$, respectively. Such donors may be considered to be more electronegative than tetracene; however, the ionic character in the TCNE complexes indicated by Eq. (12) may be anticipated to be higher than that in the tetracene complex, namely, 0.677 and 0.743 compared to 0.630.

The Crystal and Molecular Structure of Carbazole

Masayasu KURAHASHI,*1 Makoto FUKUYO and Akira SHIMADA

Department of Chemistry, Faculty of Science, Osaka City University, Sumiyoshi-ku, Osaka

and Akio FURUSAKI and Isamu NITTA

Faculty of Science, Kwansei Gakuin University, Nishinomiya

(Received December 27, 1968)

The crystal structure of carbazole has been refined with three-dimensional X-ray data. Single crystals obtained from the melt are orthorhombic with four molecules in a unit cell of the dimensions $a=7.77_2$, $b=19.18_2$ and $c=5.72_5$ Å; space group is *Pnma*. Positional and thermal parameters were obtained by the least-squares method. The final discrepancy index R is 10.9% excluding zero intensity data. The e.s.d.'s in bond lengths not involving hydrogen atoms are 0.006—0.010 Å, and the corresponding errors in bond angles are about 0.5°. The molecule is planar within the deviation of 0.03 Å. A crystallographic mirror plane normal to the b-axis passes through the nitrogen atom and is perpendicular to the molecular plane. Comparison of the observed and theoretical bond lengths is made with discussion thereof. Some physical properties related to the crystal structure are also discussed by comparing its structure with that of fluorene. With the help of thermodynamical data, it has been argued that the hydrogen bond of N-H···N between molecules is not formed not only in the crystalline state but also in the liquid state.

A preliminary note on the crystal structure analysis of carbazole[1] was reported in 1966 by the authors. However, as the analysis was not sufficiently precise, a three-dimensional refinement has been undertaken. The main purpose of this investigation is to elucidate the molecular structure in detail, so as to obtain some information about the behavior of the hydrogen atom attached to the nitrogen. It will also be of significance to compare the experimental result with the theoretical one calculated by the MO method. It is further hoped that discussions may be given on some physical properties such as sublimation, cleavage, density and melting point in relation to the crystal structure.

Experimental

The crystals in colorless plates obtained from the melt belong to the orthorhombic system. The cell dimensions were determined from $hk0$ and $0kl$ Weissenberg photographs calibrated with silicon powder lines. The crystal data are summarized in Table 1. From systematic absences ($0kl$ with $k+l$ odd and $hk0$ with h odd) and intensity statistics, the space group of this crystal is determined to be *Pnma*. There are four molecules in the unit cell, and the molecule should have a mirror in it. The integrated intensities of 698 reflections were estimated visually from multiple-film equi-inclination Weissenberg photographs of the layers $hk0$ to $hk5$ and $0kl$ to $4kl$. Lorentz and polarization corrections were applied together with a spot-shape correction for upper layers, and all the intensities were placed on a common scale. Since the cross section of the crystals used was small enough(0.2×0.5 mm² for the a- and 0.3×0.5 mm² for the c-axis), no correction was made for the absorption effect.

Determination and Refinement of the Structure

The approximate coordinates of nitrogen and carbon atoms had already been found in the preliminary investigation. A least-squares refinement was started with the final parameters in that study. At first, hydrogen atoms were omitted from the calculations. After

four cycles of the refinement, R dropped from the initial value 22.0 to 17.6%. The positional parameters were further refined by the block-diagonal matrix least-squares method with the anisotropic temperature factors of the form $\exp\{-(B_{11}h^2+B_{22}k^2+B_{33}l^2+B_{12}hk+B_{23}kl+B_{31}lh)\}$, and R fell to 13.6% after four cycles. At this stage of refinement a three dimensional difference synthesis shown in Fig. 1 was calculated. In the map, the five of the eight highest peaks between 0.3 and 0.5 e.Å^{-3} corresponded to the hydrogen atoms. Including these, further four cycles of the refinement reduced R to 10.9%. Individual isotoropic temperature factors of 5.0 Å^2 had been assigned to these hydrogen atoms, and after the refinement those of the four hydrogen atoms attached to the benzene ring turned into 4.0—6.0 Å^2 and that of the hydrogen atom attached to the nitrogen increased to 7.3 Å^2.

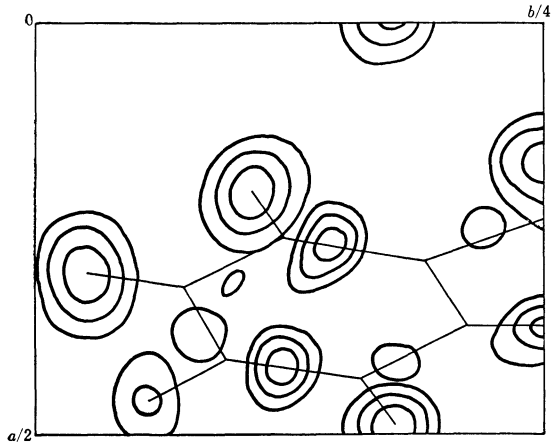

Fig. 1. Composite difference synthesis showing the hydrogen atoms. Contours at 0.1 e.Å^{-3} beginning at 0.2 e.A^{-3}.

Results and Discussion

Table 2 gives the final positional parameters of all the atoms with their e.s.d.'s evaluated in the least-squares calculations. The final temperature factors are listed in Table 3. The direction cosines and distances from the origin of the best planes through various sets of atoms in the molecule are presented in Table 4, together with the angles between these planes. The displacements of atoms from the various planes of Table 4 are given in Table 5. The electron density and difference syntheses in the molecular plane are shown in Fig. 2. The final calculated structure factors are compared in Table 6* with the observed values.

A crystallographic mirror plane normal to the b-axis passes through the nitrogen atom and is perpendicular to the molecular plane. Putting aside the positions of the hydrogen atoms, benzene rings and pyrrole ring in the carbazole molecule are respectively planar within the experimental error, less than 0.01 Å. Carbazole molecule itself is approximately planar within the deviations of 0.03 Å, though, strictly speaking, the two benzene rings in the molecule make an angle of 1.63°. The slightly bent structure might be due to the intermolecular interactions in the crystal field.

Least-squares plane is determined by the atoms with *.

Figure 3 shows the projection of the molecule upon its mirror plane. There the nitrogen atom and the hydrogen attached to it are given by the electron density contours, of which those for the hydrogen are drawn on the basis of a difference synthesis. As seen in the figure, electron density contours of the hydrogen atom are elongated in the direction normal to the molecular plane, where the peak is located. In view of the contour lines and anisotropic thermal parameters for the nitrogen clearly showing its oscillation in the direction normal to the molecular plane, the elongation mentioned above will imply that the hydrogen oscillates apparently more intensely than the nitrogen in the same direction.

It may be noted that such elongation can be interpreted as one of the two following possibilities. The first is to assume that the valence state of the nitrogen atom is mainly the sp^2 state and the equilibrium position of the hydrogen atom lies in the molecular plane, its out-of-plane oscillation being quite violent. The second is that the state is more or less sp^3 and the equilibrium position of

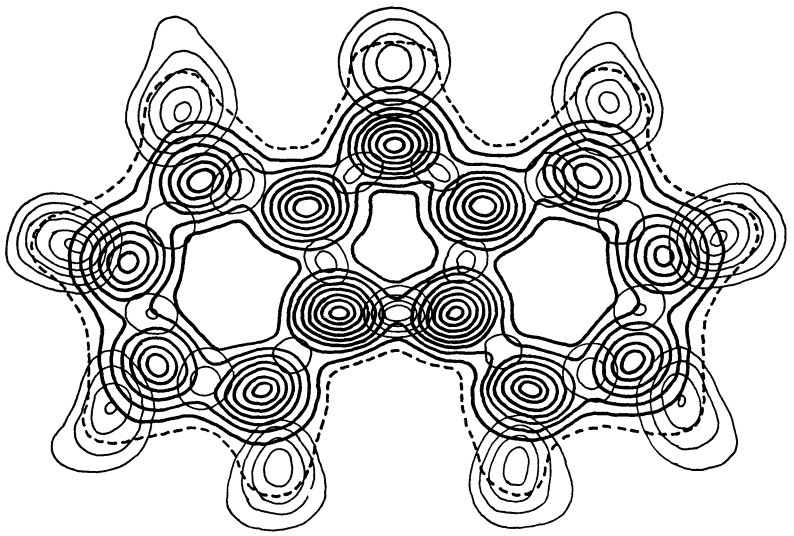

Fig. 2. Electron density and difference syntheses on the molecular plane. The contour lines, starting from 1.0 e.Å^{-3} are at intervals of 1.0 e.Å^{-3}. The broken line is 0.5 e.Å^{-3}. The fine lines, starting from 0.1 e.Å^{-3} are at intervals of 0.1 e.Å^{-3}.

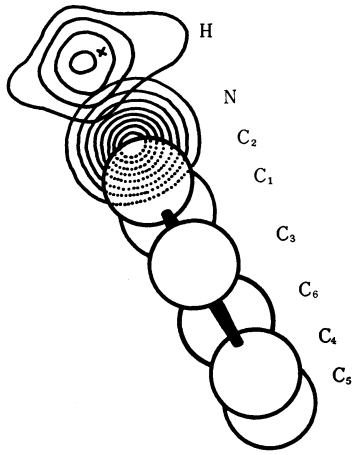

Fig. 3. Electron density for the nitrogen and difference synthesis for the attached hydrogen atom. The contour lines for the nitrogen, starting from 1.0 e.Å^{-3} are at intervals of 1.0 e.Å^{-3}, and for the hydrogen starting from 0.15 e.Å^{-3} at intervals of 0.1 e.Å^{-3}. The cross shows the position of the hydrogen atom determined by the least-squares method. The circles show the carbon atoms.

the hydrogen atom is on either side of the molecular plane and moves back and forth between these two positions somewhat like the umbrella inversion of ammonia molecule.

The cross in Fig. 3 indicates the position of the hydrogen determined by the least-squares method. It is deviated by 0.22 Å from the mean molecular plane (Table 5, 1), the e.s.d.'s of its positional parameters being of the order of 0.10 Å (Table 2). The temperature factor obtained by the least-squares method for this hydrogen atom is 7.33 Å^2, which is the largest of the hydrogen atoms in the molecule. Although it is not certain that the N–H bond is bent as the cross shows, there remains a possibility that this bending might be really due to the crystal field or some other reason. Anyhow, evidence that the hybridization state of the nitrogen is purely sp^3, can be excluded, for in such a case the deviation of the hydrogen from the molecular plane should be as large as 0.6 Å.

Bond lengths and angles are shown in Fig. 4. The e.s.d.'s of the bond distances are about 0.007 Å, except for 0.010 Å for the central C–C bond related to the mirror symmetry. The average C–C bond distance in the six-membered ring is 1.39_4 Å which is very close to the value found in crystalline benzene. Several theoretical treatments[2-4] have been made on carbazole. The observed bond lengths are compared with theoretical values

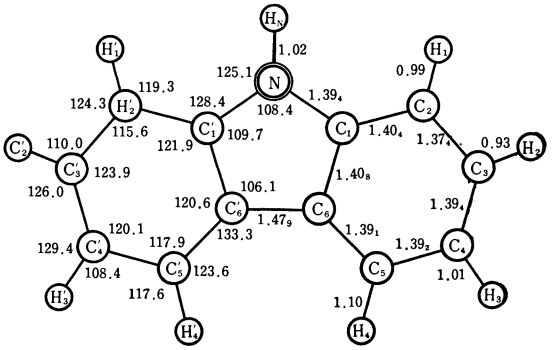

Fig. 4. Bond lengths and angles of carbazole.

Table 7. Comparison with theoretical investigation

	Bond order	Bond length		
		Theoretical*1	Observed*2	(e.s.d.)

C_6–C_6'	0.404	1.444	1.479 (1.484)	0.010

*1 Theoretical bond lengths were calculated by
r(C-C) = 1.517 − 0.18p
r(C-N) = 1.451 − 0.18p
r: bond length p: bond order

*2 Bond lengths corrected for thermal motion are in parentheses. The thermal parameters of the molecule were reasonably well explained on the basis of rigid-body motion.

calculated by SCFMO,[4] which is shown in Table 7. Observed C_5–C_6 is shorter by 0.02_1 Å, and C_6–C_6' and N–C_1 are longer by 0.03_5 and 0.01_9 Å respectively than theoretical values. It is suggestive that these are related to either C_6 or N, of which the hybridization state may be somewhat deviated from the standard sp^2 as seen in the bond angle distribution.

The bond angles in the five-membered ring ranges from 106.1° to 109.7° and that in the phenyl ring ranges from 115.6° to 123.8°. The e.s.d.'s are about 0.5°. Using the observed bond lengths and sp^2 orbital skeletons for nitrogen and carbon atoms, the observed distribution of the bond angles may be qualitatively explained by the molecular model based on the assumption that all the bonds

in the molecule share the strain force uniformly.

The crystal structure is shown in Fig. 5. The nearest approach between two nitrogen atoms of the neighboring molecules is 3.89 Å, and this shows that the hydrogen bond such as N-H···N is not formed in the crystal. This supports Aihara's conclusion from the measurement of the vapor pressure.[5] The position of the hydrogen atom attached to the nitrogen also shows this fact. In addition, it is sterically impossible to form hydrogen bond if the nitrogen is trigonally hybridized. Molecular packing seems to be uniform in *a*- and *c*-directions, and close contacts of 3.42—3.68 Å between molecules are found for any pair of neighboring molecules. On the other side there is considerably large space around $y=0$ and $y=1/2$, and the nearest approach between carbon atoms C_3 and C_4' of the neighboring molecules in the *b*-direction is as large as 3.87 Å. This is the reason why the crystal cannot elongate along the *b*-axis and shows excellent cleavage parallel to the (010) plane.

replaced by $C\langle^{H}_{H}$, and it resembles considerably that of fluorene in both cell dimensions and atomic parameters. Comparison of the crystal data, atomic parameters and thermodynamical data is shown in Table 8. Figure 6 shows the (010) projections of the crystal structure of both compounds. The plane of the fluorene molecules makes an angle of 55.2° to the *a*-axis, while the corresponding angle is 61.0° in carbazole. Intermolecular distances shown in Fig. 6 are generally shorter in carbazole than in fluorene.

As is easily expected from the crystal structure, subliming tendency of these compounds is related to the fact that strong intermolecular forces such as hydrogen bonds do not exist. However, effective partial volume around N-H will be smaller than that around $C\langle^{H}_{H}$, and carbazole, containing a nitrogen in a molecule, shows a dipole moment of 2.09 D.[7] Therefore the molecular arrangement would be influenced to some extent by such effects. Figure 6 shows such influence. In the crystal of carbazole, the dimension of *a*-axis is thus smaller, and this, in addition to the greater molecular weight by 1 than that of fluorene, leads to greater density.

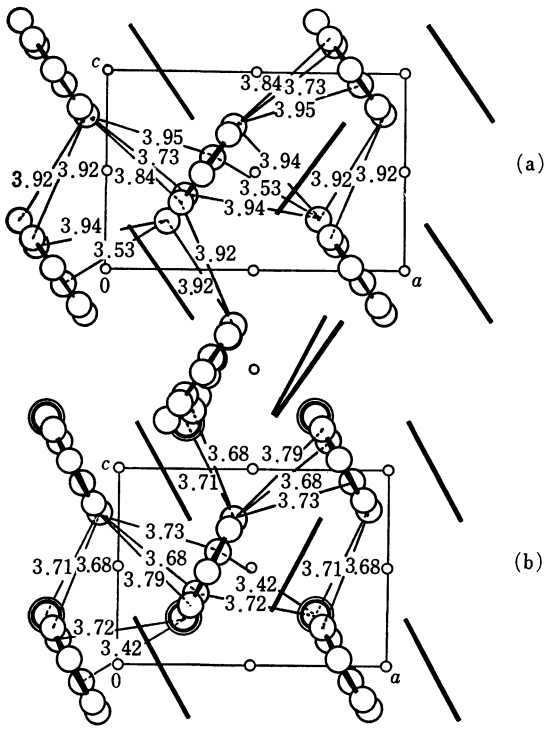

Fig. 6. Comparison of the crystal structure between fluorene (a) and carbazole (b).

The fact that the intermolecular distances are generally shorter in carbazole than in fluorene will imply stronger cohesive forces. In connection with this discussion, it is of interest to make comparison of thermodynamical data for these compounds. The lattice energy is directly related to ΔH_s (heat of sublimation). However, for lack of the datum on fluorene the sum of ΔH_m (heat of fusion) and ΔH_v (heat of vaporization) may be taken instead of ΔH_s and it comes out to be smaller by a few kcal/mol than the ΔH_s of carbazole.

Melting points of cabazole and fluorene are 245 and 115°C respectively. The large difference in melting points must depend on the difference either in ΔH_m or in ΔS_m (entropy change by fusion) because T_m (melting point) is given by $T_m = \Delta H_m / \Delta S_m$. ΔH_m's of carbazole and fluorene are reported to be 7.04 and 4.80 kcal/mol, so that ΔS_m's are calculated to be 13.6 and 12.4 e.u. respectively. It may be concluded that considerable difference in melting points is fairly due to the difference in ΔH_m connected to intermolecular interaction energy. On the other hand, comparison of the ΔS_m's will suggest that in the liquid state of carbazole there exists no perceptible hydrogen bond formation because in the latter case there would be some kind of ordering.

Mössbauer Spectral Observation of α-Fe_2O_3 Supported on Silica Gel during Activation

Taro TACHIBANA and Toshie OHYA

Department of Chemistry, Ochanomizu University, Otsuka, Bunkyo-ku, Tokyo

and Tohru YOSHIOKA, Junji KOEZUKA and Hiroko IKOMA

Central Research Laboratory, Tokyo Shibaura Electric Co., Ltd., Komukai Toshiba-cho, Kawasaki

(Received December 28, 1968)

Mössbauer spectral studies were made of samples of α-Fe_2O_3 highly dispersed on silica gel before and after activation, which consisted of evacuated heating at 475°C. The spectra gave evidence that Fe^{2+} ions were produced from α-Fe_2O_3 during the activation process. Reduction was impossible after the activation and oxidation had been repeated three times. However, the inactivated sample came to be again reduced by activation after having been exposed to water vapor at room temperature. In order to explain these facts, a working hypothesis was advanced that the hydroxyl groups near the surface of the particles play a principal role in reacting with organic contamination from the vacuum system, as a result bringing about the partial reduction of α-Fe_2O_3.

Some metal oxide powders acquire adsorptive or catalytic activity by the activation process consisting of heating *in vacuo* at a high temperature. It is also known that some metal oxides produce non-stoichiometric oxide by the activation, thus changing their color. Very little work has, however, been done on these states of metal oxide. Blyholder and Richardson[1] reported, in their infrared spectral studies of the surface of α-Fe_2O_3, that the presence of Fe^{2+} ions near the surface might be expected as a results of a prolonged heating process at an evacuated atmosphere.

This report will describe some results of the Mössbauer spectral observation of supported α-Fe_2O_3 particles during activation.

Experimental

Two samples, A and B, of α-Fe_2O_3 supported on silica gel were prepared by impregnating silica gel with ferric nitrate solutions (enriched in Fe-57 for sample A), drying it at 120°C, and calcining it at 250°C for 16 hr in air. The Fe_2O_3 content was 2 wt% for sample A and 20 wt% for sample B. Both samples showed the spectrum[2] characteristic of α-Fe_2O_3. The average particle size was roughly estimated to be less than 130Å for sample A, and above 300Å for sample B, by comparing our spectra with the results of Shinjo *et al.*[3] and Kündig and Bömmel.[4] The broadening analysis of the X-ray diffraction patterns gave similar results.

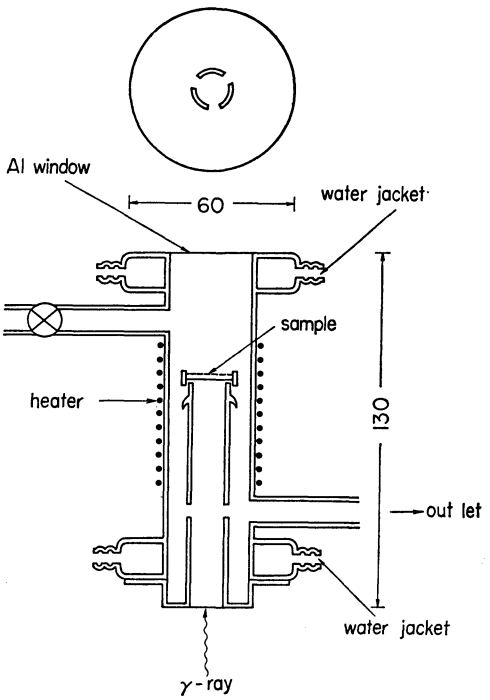

Fig. 1. A cross section of quartz-made cell.

In order to observe the effect of the activation, the sample was put into a small quartz-made supporter, which was mounted in a quartz cell equipped with windows of aluminum foil 100 μ thick as shown in Fig. 1. The activation was carried out by degassing the sample at room temperature for 3 hr, then heating it at 375°C in

an atmosphere of oxygen for one hour, and finally maintaining it at 475°C and under a pressure of 10^{-5} Torr for 8 hr. The spectra were measured after the sample had then been allowed to cool to room temperature. A time-mode Mössbaure spectrometer was used in this experiment.

Results

Figure 2 shows the Mössbauer spectra of sample A before and after the activation. The base lines of the spectral curves are all normalized to one. Curve (a) of the figure is the spectrum of normal sample A. It consists of only a quadrupole-split center line, indicating that the α-Fe_2O_3 is superparamagnetic. Curve (b), the spectrum of activated sample A, is a complex spectrum quite different from that of the original sample. This indicates that Fe atoms of α-Fe_2O_3 particles in the bulk as well as on the surface were changed into a state different from the original one by the activation.

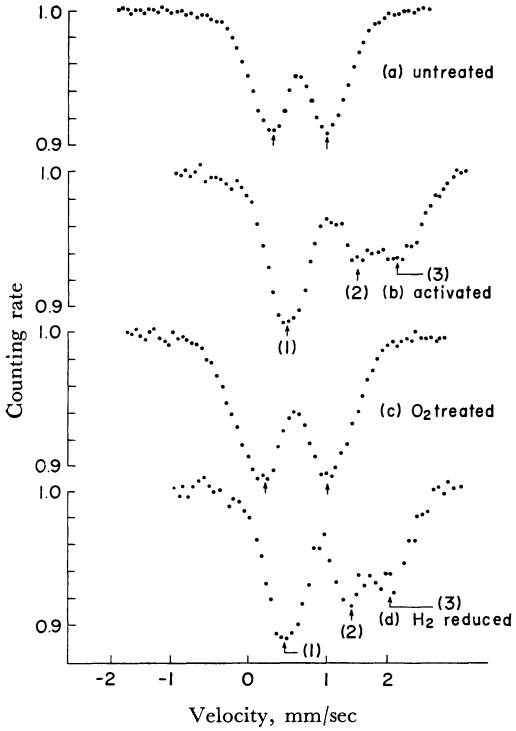

Fig. 2. Mössbauer spectra of a 2wt% α-Fe_2O_3-on-silica gel sample undergoing several treatments.

Figure 3 shows the spectra of sample B. Before the activation, sample B gave a spectrum of six hyperfine-split line, indicating antiferromagnetic characteristics, as is seen with α-Fe_2O_3 in bulk. Only the innermost doublet of the six lines appears in curve (a) of Fig. 3. This spectrum was replaced by curve (b) of the figure after the activation. However, the change was much smaller than that in the sample A. From this result, it follows

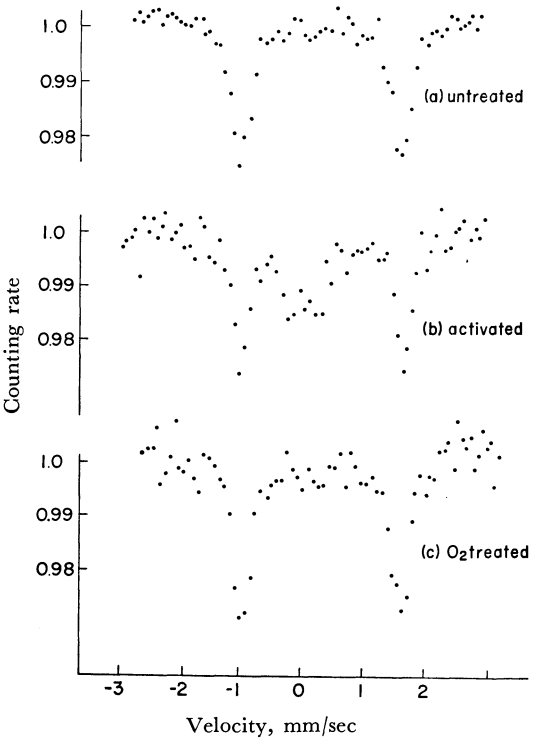

Fig. 3. Mössbauer spectra of a 20 wt%-α-Fe_2O_3-on-silica gel sample undergoing the activation and oxidation.

that, in observing the spectral change upon activation, it is more profitable to experiment with sample A. The following investigation was, therefore, completely conducted with sample A.

The spectrum was observed again after the activated α-Fe_2O_3 had been exposed to thoroughly-dried oxygen gas at 1 atm and at 200°C for about one hour. The resulting spectrum is curve (c) of Fig. 2, which is almost identical with curve (a) of the figure, though the parameters are somewhat larger than those of curve (a). This is shown in Table 1. Similar result was, though ample time is required, obtained also by the experiment at room temperature.

As the cycle of the oxygen treatment and the degassing was repeated, it was found to become

Table 1. Differential chemical shift* (δ), quadrupole splitting (Δ), and full width at half maximum (Γ) for curve (a) and (c) in Fig. 1

gradually more difficult to obtain a sample which showed the activated-state spectrum. After the third cycle, the sample obtained no longer exhibited the activated-state spectrum. However, when this sample was placed in oxygen gas at 200°C and then exposed to water vapor at its saturation pressure at room temperature, it came to reproduce the activated-state spectrum (curve (b) of Fig. 2) upon evacuated heating.

Next, sample A was reduced by heating it in a hydrogen gas stream at 450°C for 8 hr. The resulting spectrum is curve (d) of Fig. 2, which is approximately the same as curve (b) of the figure, *i. e.*, the activated-state spectrum. This result gives evidence that some Fe ions of the activated sample were in a reduced state.

Discussion

The activated state spectrum (curve (b) of Fig. 2) was almost the same as the hydrogen-reduced spectrum which had previously been obtained by Hobson and Cambell.[5] The spectrum is apparently different from that of metallic iron. The spectra, (b) and (d), of Fig. 2 have three peaks, 1, 2, and 3, numbering from left to right. As with Hobson and Cambell, these spectra are resolved into two doublets, consisting of 1-3 and 1-2 peaks. The differential chemical shift, δ, and the quadrupole splitting, Δ, for the superposed doublets are given in Table 2. When we compare these data with the spectral data*1,[6] of many iron compounds, it is not unreasonable to conclude that the doublet 1-3 ($\delta = +1.37$ mm/sec, $\Delta = 1.77$ mm/sec) may be ascribed to a Fe^{2+} ion. The chemical shift of the 1-2 doublet ($\delta = +1.05$ mm/sec, $\Delta = 1.14$ mm/sec) has a value between the typical Fe^{2+} and Fe^{3+} states, with a rather large quadrupole splitting.

Δ	1.14	1.77	1.01	1.65

Unite: (mm/sec) Error: $< \pm 0.02$ (mm/sec)

* Values relative to sodium nitropruside

The nature of this state was not yet been elucidated, but it is evident that two electronic states of the Fe ion, one of which is a typical Fe^{2+} state, exist in the activated α-Fe_2O_3. This activated state is recovered into the original α-Fe_2O_3 when it comes in contact with oxygen gas, so it is probably an unstable and non-stoichiometric iron oxide.

It should be interesting to consider the mechanism by which the Fe^{2+} state is produced from α-Fe_2O_3 by the evacuated heating. Some articles[7,8] show that powders of such metal oxides as TiO_2, MoO_3, are partially reduced by the evacuated heating into a lower oxidized state and that the reduction results from some organic contamination from the vacuum system or from an impurity carbon in the original sample. In our experiment, it is unreasonable to take the latter into consideration, since a considerable amount of carbon must be assumed to explain the complet change in the spectrum of the sample upon activation. Since our experiment was done in a conventional vacuum system equipped with a greased stopcock and an oil-diffusion pump, doubtless our sample was also exposed to an organic contamination. Nevertheless, in this atmosphere it was impossible to activate a sample which had been subjected to repeated degassing and oxidation. This fact suggests that some change was brought about on the surface of α-Fe_2O_3 particles by the repeated activation procedures. Here it is noticeable that such an inactivated sample has its reactivity restored upon exposure to water vapor at room temperature.

Evidence[9] has been given that the chemisorbed water is present in the form of the OH group on the surface of ferric oxide and that it provides the active site for a surface chemical reaction on ferric oxide. This leads us to assume that the OH group on the Fe atom of α-Fe_2O_3 particle surface might act as active sites in reacting with an organic contamination during the activation.

The surfaces of most oxide adsorbents have been found to be composed of hydroxyl groups which are removed during the activation and again formed immediately on exposure to water vapor at room temperature.[10] It is probable that an α-Fe_2O_3 sample which has lost its surface hydroxyl groups by means of the repeated activation procedure can no longer be activated by being in contact with organic contamination. Consequenly, it seems reasonable to assume that the hydroxyl groups on the surface of α-Fe_2O_3 particles play a principal role for reacting with organic contamination and that, as a result, the partial reduction of α-Fe_2O_3 occurs.

In order to draw a decisive conclusion, however,

much remains to be done with the Mössbauer spectral measurements. However, since the application of the Mössbauer spectroscopy to surface work is at present yet in its infancy, it seems valuable to make this report as a preliminary step.

We wish to thank Dr. Kin-ichi Nohga of the Toshiba Central Research Laboratory for his continuous encouragement during this work. We are very grateful to Professor Tetsuo Takaishi of Saint Paul's University for his helpful discussions. The expenses of this work have been supported in part by a Scientific Research Grant from the Ministry of Education.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 2183—2186 (1969)

Microwave Spectrum, Barrier to Internal Rotation, and Dipole Moment of *trans*-Crotonaldehyde

Masao SUZUKI and Kunio KOZIMA

Laboratory of Molecular Spectroscopy, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received December 28, 1968)

The microwave spectrum of *trans*-crotonaldehyde has been measured in the frequency region from 8.2 to 36 kMc/sec. The R-branches for the a-type and the R- and Q-branches for the b-type have been assigned. The low J transitions of the a-type and all of the b-type transitions are split into the A-level and the E-level by the internal rotation of the methyl group. The apparent rotational constants for the A- and E-levels have been obtained from the pseudo-rigid rotor approximation as $A_A=32636.58$ Mc/sec, $A_E=32627.57$ Mc/sec, $B=2183.30$ Mc/sec, and $C=2073.32$ Mc/sec. From these values it can be concluded that this molecule is of the *s-trans* form. The barrier height of the hindering rotation of the methyl group is 1730 ± 10 cal/mol. The value of the total dipole moment is 3.72 ± 0.28 D.

As a result of studies of the microwave or the infrared spectra it has been reported that the conjugated molecules with the structure of $\rangle C{=}\overset{|}{C}{-}\overset{|}{C}{=}$, such as acrolein,[1] butadiene[2] and fluoroprene[3] are planar in form. Of the two planar forms, *i. e.*, the *s-cis* and the *s-trans* form, only the *s-trans* form exists in the vapor with these molecules. However, it has been found that both forms exist in the vapor with acrylic acid,[4] acryloyl fluoride[5] and acryloyl chloride.[6]

It seems that it would be interesting to ascertain the stable conformation of such conjugated molecules with the methyl group and to determine the height of the potential barrier to internal rotation. For these purposes this research was carried out.

Experimental

The spectrum was measured over the frequency range from 8.2 to 36.0 kMc/sec with a conventional Stark-modulation microwave spectrometer. The frequencies were measured by the method reported in previous papers.[7,8] For the frequency range from 32.0 to 36.0 kMc/sec, the klystron 35V11 (Oki) was employed. The measurements were made at the temperature of dry ice by using a 3-m absorption cell.

Commercial crotonaldehyde was dried over magnesium sulfate and distilled *in vacuo*. The purity of the sample was ascertained with a vapor-phase chromatograph.

Results and Discussion

Microwave Spectrum. It was found that the rotational spectrum of *trans*-crotonaldehyde is composed of both the a-type and the b-type, as in the cases of such similar molecules as acrolein[1] and methyl vinyl ketone.[9] The a-type spectrum is much more intense than the b-type spectrum.

* A, B and C were obtained from these transitions.

The assignments of the a-type transitions of the low rotational quantum numbers were determined by their Stark effect. The assignment and the splittings caused by the internal rotation of the methyl group are shown in Tables 1 and 2 respectively. The rotational constants of B and C for the A-levels were obtained from the $1_{10}\rightarrow 2_{11}$ and $1_{11}\rightarrow 2_{12}$ transitions, which occur at frequencies of $(3B+C)$ and $(B+3C)$ respectively. Because the a-type spectrum is characteristic of a near-prolate symmetric rotor, the rotational constant of A cannot be determined accurately by means of this spectrum.

For the a-type transitions, $J_{K,K'}\rightarrow J+1_{K,K'+1}$, the lines in which the value of K is equal to 2 or higher than 2 overlap closely. Therefore, this spectrum was not used to determine the rotational constants and has been omitted from the table.

Table 2. A-E splittings in *trans*-$CH_3CH{=}CHCHO$

Transition	$(\nu_A-\nu_E)_{obs.}$
a-type	
1_{10}–2_{11}	4.02 Mc/sec
1_{11}–2_{12}	−3.80
2_{11}–3_{12}	0.77
2_{12}–3_{13}	−0.85
3_{12}–4_{13}	0.35
3_{13}–4_{14}	−0.28
b-type

5_{05}–4_{14}	9.67
8_{18}–9_{09}	−9.07*
9_{19}–10_{010}	−8.93
7_{07}–7_{16}	8.95*
8_{08}–8_{17}	8.99*
9_{09}–9_{18}	8.84*
10_{010}–10_{19}	8.20
11_{011}–11_{110}	9.28
12_{012}–12_{111}	9.35

* The difference of the rotational constants of A was determined from these transitions.

The splittings caused by the internal rotation of the methyl group could also be observed in the b-type spectrum. These splittings are much larger in the b-type spectrum. As was expected in view of similar molecules, it seems very probable that the framework of the molecule has the planar configuration. Therefore, in order to facilitate the assignments of the b-type spectrum, the rotational constant, A, was estimated from the relation:

$$I_c - I_a - I_b = \delta' - I_\alpha$$

where I_a, I_b, and I_c are the principal moments of inertia, I_α is the moment of inertia of the methyl group about its symmetry axis, and δ' is a pseudo-inertial defect. The $(I_\alpha-\delta')$ value was assumed tentatively to be 3.16 amu·Å^2 which is the same as that reported for propylene.[10] By using the A value thus estimated, the frequencies of the b-type lines of the $J_{0J}\rightarrow J_{1J-1}$ series were calculated and measured. The frequencies of the seven lines which show the Stark patterns of Q-branches and which split into the A- and the E-levels were found to be higher than 32 kMc/sec. By the aid of the Q-branch plot, these lines were identified as those of $J\geq 7$. By the plot, the values of $(A-C)/2$ and of Ray's κ were obtained as 15281 Mc/sec and -0.99279_5 for the A-levels and 15276 Mc/sec and -0.99279 for the E-levels. From this it is clear that the pseudo-rigid rotor approximation holds for the high J and low K transitions of both the E- and A-levels.

10) E. Hirota, *J. Chem. Phys.*, **45**, 1984 (1966).

By using the rotational constants of A estimated from these values, the low J R-branch transitions of the b-type were calculated and measured. The assignments of these transitions are shown in Table 1. From the low J transitions which are marked by a star in Table 1, the accurate pseudo-rigid rotational constants of A_A, B, and C were determined by the least-squares method. The results are listed in Table 3. The values of B and C agreed with those obtained above within the limits of experimental error. The frequencies calculated by the rotational constants thus determined are shown in Table 1 for the A-levels. From this table it can be seen that the effect due to the centrifugal distortion cannot be disregarded, especially for the b-type spectrum. However, the terms for these distortions were not determined, for only the $K=0\rightarrow1$ and $K=1\rightarrow1$ transitions were measured.

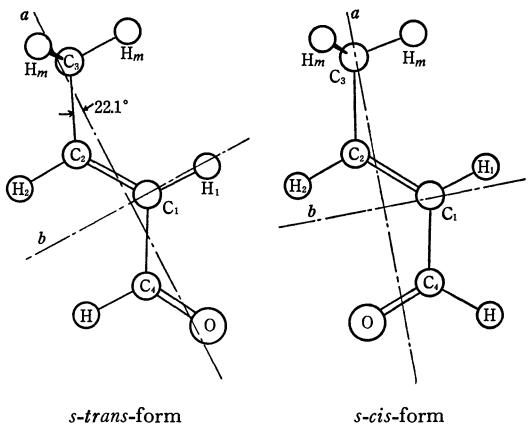
TABLE 3. ROTATIONAL CONSTANTS AND MOMENTS OF INERTIA OF *trans*-$CH_3CH{=}CHCHO$

Rotational constants	Moments of inertia*
$A_A=32636.58\pm0.2$ Mc/sec	$I_a^A=15.485$ amu·Å^2
$A_E=32627.57\pm0.2$	
$B=2183.30\pm0.06$	$I_b=231.474$
$C=2073.32\pm0.04$	$I_c=243.753$
$\kappa_A=-0.992803\pm0.000001$	
$(I_a^A+I_b)-I_c=3.206$ amu·Å^2	

* Conversion factor: 5.05377×10^5, corresponding to $^{12}C=12$ atomic scale.

By the use of the least-squares methods, the difference between the pseudo-rigid rotational constants of A could be determined from the splittings of the transitions marked by a star in Table 2, because it was shown by the Q-branch plot that the pseudo-rigid rotor approximation nearly holds for these transitions. The value of the rotational constant of A_E for the E-level was, then, estimated to be 32627.57 Mc/sec. The difference between the rotational constants of B for both levels is negligible, because the frequencies of the high J and low K lines of the R-branches do not split for the a-type transitions. The calculation mentioned below supports this. In view of the molecular structure, it can be easily seen that the rotational constants of C do not differ in the two levels.

Molecular Structure and Internal Rotation. Because the observed pseudoinertial defect, δ', is nearly zero, it is safe to consider that the molecular framework is planar. However, there are two possible planar forms, *i. e.*, the *s-cis* and the *s-trans* form, as is shown in Fig. 1. When the values of the r_s-structure of acrolein[10] were assumed for this molecule, with the additional assumptions that the CH_3–C bond length and $\angle CH_3$-C=C were 1.501 Å and 123.3° respectively by the use of the values of propylene[11] and that all the valency angles of the methyl group and all the C–H bond lengths were 109.47° and 1.090 Å, the calculated rotational constants of the *s-cis* form were as follows; $A=18580$ Mc/sec, $B=2677$ Mc/sec, and $C=2375$ Mc/sec. As these values are quite different from the observed values, the possibility of the *s-cis* form can be disregarded. However, for the *s-trans* form calculated under the same assumptions the rotational constants were very close to the observed values.



s-trans-form *s-cis*-form

Fig. 1. Two forms of *trans*-$CH_3CH{=}CHCHO$.

In order to ascertain whether or not the *s-cis* form exists in the vapor, the measurements were carefully made near the frequencies of the $J_{0J}\rightarrow J_{1J-1}$ transitions, which were calculated for the *s-cis* form by the use of the rotational constants described above. However, we could not observe any lines which might be assigned to the *s-cis* form. It was concluded that the stable form of *trans*-crotonaldehyde is the *s-trans* form.

To get the best fit between the observed and the calculated values for the rotational constants of B and C, the valency angles, $\angle CH_3$–C=C and $\angle CH_3$–C–H, of the carbon atom to which the methyl group attaches were determined by making the assumptions mentioned above except for these two angles. The probable structural parameters obtained are shown in Table 4. The table also shows that the calculated value for the rotational constant of A agrees with the unperturbed value to be estimated below.

Since the internal top has a threefold axis, the hindering potential, V, may be expanded in the Fourier series:

$$V=\frac{V_3}{2}(1-\cos3\alpha)+\frac{V_6}{2}(1-\cos6\alpha)+\cdots$$

In this paper only the V_3 term is considered, for

Table 4. Molecular structure of *trans*-$CH_3CH{=}CHCHO$

Assumed structural parameters			
$r(C_1-C_4)$	1.470 Å	$\angle C_2{=}C_1-C_4$	119.83°
$r(C_1{=}C_2)$	1.345	$\angle C_1-C_4{=}O$	123.28
$r(C_2-C_3)$	1.501	$\angle C_1-C_4-H$	115.10
$r(C_4{=}O)$	1.219	$\angle H_m-C_3-H_m$	109.47
$r(C_4-H)$	1.108	$\angle C_2-C_3-H_m$	109.47
$r(C_2-H_2)$	1.086	$\angle C_2{=}C_1-H_1$	122.83
$r(C_1-H_1)$	1.084		
$r(C_3-H_m)$	1.090		
Fitted structural parameters			
$\angle C_3-C_2{=}C_1$	125.64°	$\angle H_2-C_2-C_3$	116.09°
Calculated rotational constants			
$A=32630.46$ Mc/sec			
$B=2183.84$			
$C=2073.67$			

the V_6 term would introduce only a minor correction in the value of V_3.

The Hamiltonian can be written in the following manner:

$$H_A{}^0 = A_A P_z{}^2 + B_A P_y{}^2 + C P_x{}^2$$

and

$$H_E{}^0 = A_E P_z{}^2 + B_E P_y{}^2 + C P_x{}^2 + F W_{0E}{}^{(1)} \mathfrak{P}$$

where

$$F = \hbar^2/2rI_\alpha,\ r = 1 - \sum_{g=a,b} \lambda_g{}^2 I_\alpha / I_g$$

$$\alpha = \lambda_a I_\alpha / I_a,\ \beta = \lambda_b I_\alpha / I_b$$

$$\mathfrak{P} = \alpha P_z + \beta P_y$$

$$A_\sigma = A_0 + F\alpha^2 W_{0\sigma}{}^{(2)},\ B_\sigma = B_0 + F\beta^2 W_{0\sigma}{}^{(2)}$$

(σ=A or E)

The notations have the meanings given by Herschbach.[12] The values of the parameters described above are given in Table 5. By use of these values and Herschbach's Table (Appendix C),[12] the values of s, a parameter of the Mathieu equation, and the barrier height can be calculated from the frequency splittings of the $1_{10}\rightarrow 2_{11}$ and the $1_{11}\rightarrow 2_{12}$ transitions, by assuming that $I_\alpha = 3.160$ amu·Å^2. The value of V_3 is 1730±10 cal/mol, lower than that obtained for propylene.[13] The barrier height calculated from the difference, $A_A - A_E$, under the same assumptions is 1720±10 cal/mol. This value agrees with that determined above. The frequency splittings of the other transitions are not used for this calculation, for the contributions of the $FW_{0E}{}^{(1)}\mathfrak{P}$ term to the splittings are equal to or less than about 1 Mc/sec. By using the value of s, the unperturbed value, A_0, was calculated to be 32630.54 Mc/sec and the difference between B_A and B_E was found to be 0.002 Mc/sec in support of the experimental result.

For near-prolate symmetric top molecules like this, the contribution of the $F\alpha W_{0E}{}^{(1)} P_z$ term to the rotational energy ($K_{-1}=1$) of the E-level can be represented approximately as $2(F\alpha W_{0E}{}^{(1)})^2/\{J(J+1)(B-C)\}$. Small deviations from the rigid-rotor approximation for the low J transitions of the E-levels are due to this term. However, because for the high J transitions ($J \geq 7$), the correction due to this term is smaller than 0.2 Mc/sec, therefore, the pseudo-rigid rotor approximation holds.

Dipole Moment. The Stark displacements of the $M=0$ component of seven transitions, shown in Table 6, were measured in order to determine the a and b components, μ_a and μ_b, of the electric dipole moment. These lines fit the quadratic Stark displacements nicely. The absoption cell was calibrated using the $J=0\rightarrow1$ transition of OCS, taking the dipole moment of OCS as 0.7152 D.[14] The observed and calculated Stark coefficients are given in Table 6. The value of the dipole moment obtained is 3.72±0.28 D. This value is in agreement with that of 3.67 D obtained by Debye's method.[15]

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 2187—2193 (1969)

ESR and Optical Absorption Studies of the Copper(II) Complexes of Ethylenediamine and Its Alkyl Derivatives

Hiroshi Yokoi and Taro Isobe

Chemical Research Institute of Non-Aqueous Solutions, Tohoku University, Katahira-cho, Sendai

(Received January 7, 1969)

The ESR and the optical absorption of the copper(II) complexes of ethylenediamine and a series of alkylated ethylenediamines have been investigated in order to estimate the character of the chemical bonding in the copper(II) complex. The covalency of the bonding of the copper atom to the ligand nitrogen atoms in the complexes has been discussed in connection with the chemical and physical properties of the complexes or of their ligand molecules themselves. The ESR results indicate that the σ bonding of the complexes becomes more covalent as the number of alkyl groups in their ligand molecules increases; furthermore, the tendency toward the σ bonding becomes more pronounced when the alkyl groups are ethyl rather than methyl and when they are *N*-substituted alkyl groups rather than *C*-substituted ones. It is also indicated that there is a linear relationship between the energies of the ultraviolet absorption band for the complexes and the relative ionization potentials estimated for their ligand molecules, and that absorption band can be assigned to an electron transfer from a ligand σ orbital to an antibonding orbital associated with the copper atom. From these results, it may be concluded that, as the σ bonding becomes more covalent, this charge transfer band shifts to a longer wavelength.

The ESR spectra of a variety of copper(II) complexes have been measured in order to investigate the bonding character of copper-ligand bonds in the complexes. The bonding parameters showing the degree of covalency for the bonds have been estimated from the magnetic parameters, namely, the g and A values, determined from their ESR spectra.[1-4] Little attention has been paid to the interesting and important problem of finding some correlation between the degree of covalency thus obtained and the chemical and physical properties of the complexes or their ligand molecules themselves. However, it is not easy to do this because of the fact that the ESR of the complexes is substantially concerned with only the antibonding orbitals associated with the copper atom.

In the present work the copper(II) complexes of ethylenediamine and a series of alkylated ethylenediamines were examined systematically by the usual methods of ESR and optical absorption, and an attempt was made to find the above-mentioned correlation. Since only a few papers have been published on the behavior of the optical absorption bands of the complexes, the assignment of the bands in the ultraviolet region was also discussed.

Experimental

The copper(II) complexes employed in this study were: [I] $[Cu(en)_2](ClO_4)_2$, [II] $[Cu(pn)_2](ClO_4)_2$, [III] $[Cu(m\text{-bn})_2](ClO_4)_2$, [IV] $[Cu(d'men)_2](ClO_4)_2$, [V] $[Cu(eten)_2](ClO_4)_2$, [VI] $[Cu(d'een)_2](ClO_4)_2$, [VII] $[Cu(dmen)_2](ClO_4)_2$, and [VIII] $[Cu(deen)_2](ClO_4)_2$, where en, pn, *m*-bn, d'men, eten, d'een, dmen, and deen are ethylenediamine, 1,2-diaminopropane, *meso*-2, 3-diaminobutane, *N,N'*-dimethylethylenediamine, *N*-ethylethylenediamine, *N,N'*-diethylethylenediamine, *N,N*-dimethylethylenediamine, and *N,N*-diethylethylenediamine respectively. The first three copper(II) complexes had already been dealt with in our previous paper.[4] The ligand molecules were commercially available except for *m*-bn, eten, and d'een, which were prepared and purified according to the methods of the literature.[5]

The ESR spectra of the complexes were measured in solutions at room temperature and on frozen solutions at the temperature of liquid nitrogen with a Hitachi X-band and K-band ESR spectrometer, model MES-4001,

equipped with a 100 kc field modulation unit. The solvents were methanol and a 50% water - 50% methanol mixture (volume %). The field was calibrated with an NMR probe and then with a benzene solution of vanadyl acetylacetonate or with Mn(II) ions in MgO powder. Some of the ESR spectra observed are shown in Figs. 1—3. The optical absorption spectra of the complexes in an aqueous solution were measured with a Cary model 14 spectrometer; some of them are shown in Figs. 4 and 5.

Results and Discussion

Magnetic Parameters. The spin Hamiltonian and the methods of determining the magnetic parameters, the g and A values, had already been described in one of our previous papers.[4] It

a) The data for the complexes [I], [II] and [III] were quoted from our previous paper.[4]
b) M: methanol, MH: 50% water, 50% methanol (volume %).
c) $g'_{\perp}$ was calculated using the following equation, $g_0=(1/3)(g_{//}+2g'_{\perp})$. $A_{\perp}$ was also calculated in the same way.
d) $g''_{\perp}$ was directly obtained from the ESR spectrum measured in rigid solution at K-band.
e) Measured at room temperature.

seems that the ligand field can not always be of an axial symmetry for the complexes [V], [VII], and [VIII], because, in their ligand molecules, alkyl groups are not substituted symmetrically on the two nitrogen atoms; this fact is certainly reflected in their ultraviolet absorption spectra, which will be discussed below. However, judging from the line shapes of such K-band ESR spectra as are shown in Fig. 2, it may well be said that the ligand field for the complexes does not deviate greatly from axial symmetry. Therefore, the average value, expressed as $g_{\perp}$, for two slightly different perpendicular g values was adopted for use in the following discussions. The $g_{\perp}$ value was determined according to the following two methods. One is the method of using the parameters, g_0 and A_0, obtained from the ESR spectra of a solution at room temperature, and the equation $g_0=(1/3)(g_{//}+2g_{\perp})$, where the $g_{\perp}$ value thus obtained is expressed as $g'_{\perp}$ in Table 1. The other is the method of determining the $g_{\perp}$ value directly from the K-band ESR spectra in the way shown by the arrow in Fig. 2. The $g_{\perp}$ value thus obtained is expressed as $g''_{\perp}$ in Table 1. All the magnetic parameters obtained in this work are listed in Table 1.

Bonding Parameters. The experimentally-determined magnetic parameters listed in Table 1 can be used for estimating the nature of the chemical bonding between the copper atom and the ligand nitrogen atoms in the complexes by means of the molecular orbital theory. This method had already been outlined in our previous paper on the copper(II) complexes of amines whose ligand field is of axial symmetry.[4] On the other hand, it is convenient to know that almost the same method for obtaining the bonding parameters is substantially applicable to the copper(II) complexes in which ligand field deviates to some extent from axial symmetry. The following wave functions can generally be written for the antibonding molecular orbitals associated with the copper atom;

$$\psi(x^2-y^2) = \alpha d_{x^2-y^2} - \alpha'\phi_L(x^2-y^2)$$
$$\psi(xy) = \beta_1 d_{xy} - \beta_1'\phi_L(xy)$$
$$\psi(z^2) = \alpha_1 d_{z^2} - \alpha_1'\phi_L(z^2)$$
$$\psi(xz) = \beta_x d_{xz} - \beta'_x\phi_L(xz)$$
$$\psi(yz) = \beta_y d_{yz} - \beta_y'\phi_L(yz)$$

The expressions which relate the experimental ESR data to the covalency parameters, α, β_1, β_x, and β_y, are:

$$g_z = 2 - \frac{8\lambda}{\Delta E_{xy}}(\alpha^2\beta_1^2 - f_1) \quad (1)$$

$$g_x = 2 - \frac{2\lambda}{\Delta E_{xz}}(\alpha^2\beta_x^2 - f_2) \quad (2)$$

$$g_y = 2 - \frac{2\lambda}{\Delta E_{yz}}(\alpha^2\beta_y^2 - f_3) \quad (3)$$

$$A_z = P\left\{-\frac{4}{7}\alpha^2 - \kappa + (g_z - 2) + \frac{3}{14}[(g_x - 2) + (g_y - 2)] + f_4\right\} \quad (4)$$

$$A_x = P\left\{\frac{2}{7}\alpha^2 - \kappa + (g_x - 2) - \frac{3}{14}(g_y - 2) + f_5\right\} \quad (5)$$

$$A_y = P\left\{\frac{2}{7}\alpha^2 - \kappa + (g_y - 2) - \frac{3}{14}(g_x - 2) + f_6\right\} \quad (6)$$

where κ is the Fermi contact term, $P=0.036\ cm^{-1}$, $\lambda=-828\ cm^{-1}$, f's are small constants (f_1, f_2, $f_3 \leqq 0.04$, $f_4 \leqq 0.03$, f_5, $f_6 \leqq 0.005$), and $\Delta E_s = E_{x^2-y^2} - E_s$ ($s=xy$, xz, yz). From the above equations, it can be understood that the values of α^2 and κ ($\kappa=\alpha^2\kappa_0{}^2$) can be calculated by the same method as we used previously if we can experimentally obtain the average values of g_x and g_y, and of A_x and A_y, expressed here as $g_\perp$ and $A_\perp$ respectively.[4] Furthermore, the average value of $\beta_x{}^2$ and $\beta_y{}^2$, expressed as β^2, can also be estimated by the above procedure. The approximate ligand field energies of the complexes under discussion were determined by the procedure in our previous paper,[4] assuming that the ligand field for the complexes is of axial symmetry; they are listed in Table 4. The bonding parameters thus calculated are listed in Table 2.

Table 2. Bonding parameters[a]

Copper(II) complex[b]	α^2	$\beta_1{}^2$	β^2	κ_0
[I]	0.83	0.58	0.72	0.42
[II]	0.84	0.58	0.70	0.42
[III]	0.82	0.58	0.72	0.43
[IV]	0.82	0.61	0.71	0.42
[V]	0.82	0.60	0.66	0.42
[VI]	0.81	0.58	0.70	0.42
[VII]	0.81	0.59	0.70	0.41
[VIII]	0.77	0.60	0.68	0.41

a) The parameters were calculated using the experimental data measured in the solvent MH. The mean of $g'_\perp$ and $g''_\perp$ listed in Table 1 were used for convenience as the essential $g_\perp$ value for calculation of the parameters.

b) The listed values for the complexes [I], [II] and [III] were quoted from our previous paper.

The results in Table 2 indicate that there is a clear correlation between the value of α^2 (the covalency parameter of σ bonding) and the structure of the ligand molecule. The more alkyl groups (methyl or ethyl groups) a ligand contains, the smaller the value of α^2 for its complex becomes. Especially, the *N*-substituted alkyl group shows a stronger tendency to make the value of α^2 decrease than the *C*-substituted alkyl group; furthermore, the tendency is more pronounced in the ethyl group than in the methyl group. This tendency

Table 3. Acid dissociation constants pK_{BH^+} of ethylenediamine and its alkyl derivatives and stability constants β_2 of the copper(II) complexes of these ligand molecules[a]

a) These data were cited from the literatures.[6] The measurements were carried out at 25°C in aqueous 0.5 N KNO_3 medium by the method of glass electrode. The values in parentheses are the data measured in aqueous 0.1 N KCl medium.

can be simply explained in terms of the inductive effect of alkyl groups, which increases the electron-donating power of the ligand nitrogen σ orbitals and, consequently, makes the σ orbitals interact more strongly with the $d_{x^2-y^2}$ orbital of the copper atom. The acid dissociation constants of the ligand molecules and the stability constants of their copper(II) complexes are cited in Table 3 from the literature.[6] From a comparison between the results of Tables 2 and 3, it follows that there seems to be little correlation between the acid dissociation constants of the ligand molecules and the values of α^2 for their complexes, but the stability constant decreases as the value of α^2 decreases, that is, as the σ bonding becomes more covalent. However, since the stability constant must be substantially related to the total energy of stabilization for complex formation, it is suggested that more important factors than the σ bonding contribute to the stability of the complex.

The values of $\beta_1{}^2$ and β^2 for all the complexes listed in Table 2 are much smaller than unity. This implies, as has been indicated previously,[2] that in-plane and out-of-plane π bondings must play an important role in determining the properties of the copper(II) complexes of amines.

Optical Absorption Spectra. The spectral data obtained for the complexes employed in this work are listed in Table 4. There have been fewer reports about the spectroscopy of copper(II) complexes than on other metal complexes, and

a) The measurement was carried out in aqueous solution at room temperature.
b) The method for estimating these energy values had been described in our previous paper.[4]
c) Ultraviolet absorption bands were determined by approximate Gaussian analysis.

only a few papers on the ultraviolet spectroscopy for the copper(II) complexes of ethylenediamine and its analogues have been published so far. Basu and Basu reported that the intense absorption bands of the copper(II) complexes of amines in the 200—250 mμ region are the charge-transfer bands between the copper ion and the amines.[7] On the other hand, the single broad band generally observed in the visible region for copper(II) complexes in solution has been ascertained to be due to *d–d* absorption bands and to consist of three or four components.[8] The visible spectral bands of the copper(II) complexes of ethylenediamine and its analogues have already been discussed in our previous paper.[4]

The ultraviolet absorption spectrum of the complex [VII] in an aqueous solution, as is shown in Fig. 5, clearly consists of two absorption bands. For the complexes [V], [VIII], and also [VI] the observed ultraviolet absorption spectra may reasonably be considered to consist of two bands. The data listed in Table 3 for these complexes were obtained from their spectra by approximate Gaussian analysis. Since the structures of these complexes are considered to be lower in symmetry than those of the complexes [I], [II], and [III], the above-mentioned spectral fact seems to result from this decrease in symmetry; the ligand field for the complexes [V], [VI], [VII], and [VIII] deviates to some extent from axial symmetry.

The energy of the ultraviolet absorption band decreases in going from [I] to [VIII] in Table 3 when the lower energy band of the two ultraviolet bands is chosen in [V], [VI], [VII], and [VIII]. This tendency suggests that there is a correlation between the energies of the ultraviolet absorption band for the complexes and the structure of their ligand molecules; furthermore, the value of α^2 also decreases in the same order, as has been indicated above.

Molecular Orbitals and Chemical Bondings. The ESR results obtained for the copper(II) complexes of ethylenediamine and a series of alkylated ethylenediamines revealed that there is a clear correlation between the covalency of σ bonding for the complexes and the structure of their ligand molecules. However, the ESR method can not explain why there is such a correlation, because only antibonding molecular orbitals associated with the copper atom are treated in obtaining bonding parameters from the ESR data, whereas bonding and other antibonding orbitals are not entirely necessary in doing so. Ligand field energies themselves also reflect various aspects of the electronic structure of complexes. However, some of the ligand field energies determined experimentally from optical absorption are used for calculating bonding parameters using Eqs. (1)—(6) without deeply considering the original meanings of the ligand field energies themselves.

The molecular orbitals of the copper(II) complexes are built up by linear combinations of the 3*d*, 4*s*, and 4*p* atomic orbitals or the copper atom and the hybrid orbitals of the ligand atoms directly coordinated to the copper atom. It has generally been accepted that the ligand nitrogen atoms of amines have sp^3 hybrid orbitals or orbitals near to sp^3 hybrid orbitals.

The amount of mixing of atomic orbitals in the molecular orbitals, which shows the degree of covalency directly, is proportional to the atomic orbital overlap and inversely proportional to their Coulomb-energy difference.[9,10] Now, it was assumed that for all the complexes under considera-

tion the values of the overlap integral, S, for the σ bonding are almost equal and that the Coulomb energies of copper atomic orbitals with which ligand orbitals mix to from molecular orbitals are not very different form each other; thus, we do not introduce such a complicated and refined concept as valence-state ionization energy.[10)] On the above assumption, the degree of covalency of the σ bonding for the complexes depends only upon the Coulomb energies of their ligand σ orbitals. As has already been mentioned in the foregoing paragraph, there is a clear correlation between the energies of the ultraviolet absorption band for the complexes and the structure of their ligand molecules. It can, therefore, be expected from this fact that all the ultraviolet absorption bands are of the same type, and that the Coulomb energies of the ligand orbital concerned with the ultraviolet absorption band undergo regular change in the order given in Table 3. Watanabe measured the ionization potentials of various small and simple molecules.[11)] We selected the ionization potentials of various amines from his data; they are listed in Table 5. It is clearly indicated in this table that the ionization potential of alkyl amine becomes smaller as the alkyl group changes from methyl to butyl and as the number of alkyl groups in the amine increases. The ionization potentials of the amines may be considered, on a first approximation, to correspond to the Coulomb energies of the nitrogen lone-pair electron orbital which is used as the ligand σ orbital in their complexes. It is reasonable to expect that the ionization potentials of ethylenediamine and its alkyl derivatives, which have not yet been measured, vary in just the same way as those of alkyl amines. As a trial, the relative values of the ionization potentials for ethylenediamine and its alkyl derivatives were estimated by the following procedure. The ionization potentials of ethylenediamine, 1,2-diaminopropane, *N*-ethylethylenediamine, and *N*,*N*-diethylethylenediamine were assumed to be equal to those of ethylamine, isopropylamine, diethylamine, and triethylamine respectively. The ionization potentials of other alkylated ethylenediamines were also estimated from the corresponding two alkyl amines, with a proportional allotment. The relative values of the ionization potentials thus estimated are listed in Table 6.

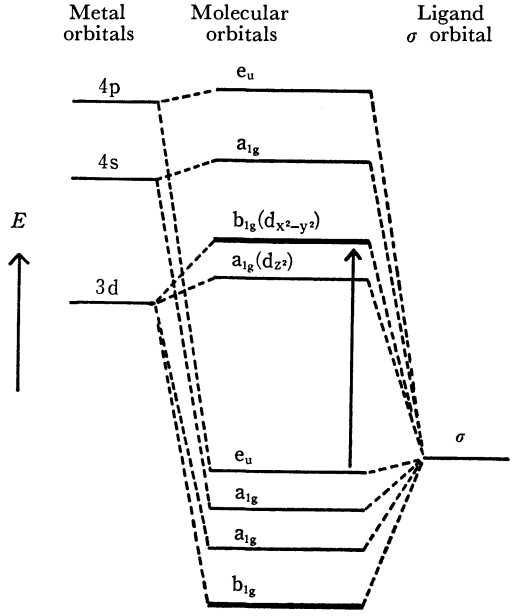

Fig. 6. Molecular orbital energy level scheme for square planar copper(II) complex (D_{4h} symmetry) in which ligand has a σ orbital system.

The energy-level scheme of the molecular orbitals concerned with ligand σ orbitals for the copper(II) complex whose ligand field has a D_{4h} symmetry is shown in Fig. 6. The ground state of the complex is, then, B_{1g}. From symmetry arguments, two allowed charge-transfer transitions may be anticipated for the complex, corresponding to the one-electron transitions:

$e_u \leftarrow b_{1g}$ ($B_{1g} \rightarrow E_u$) and $b_{2u} \leftarrow b_{1g}$ ($B_{1g} \rightarrow B_{2u}$)

11) K. Watanabe, *J. Chem. Phys.*, **26**, 1773 (1957).

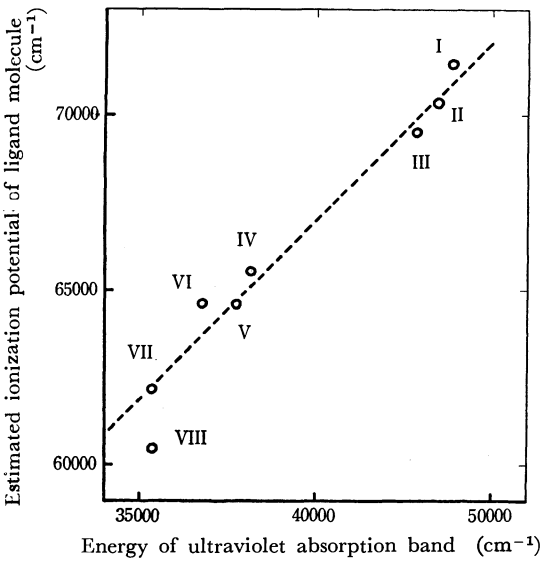

Fig. 7. Shifts in energies of ultraviolet absorption bands with changes in the estimated ionization potentials of ligand molecules.

These are transitions from molecular orbitals essentially localized on the ligands to molecular orbitals essentially localized on the metal atom. In order to ascertain whether or not the ultraviolet absorption band corresponds to the former charge-transfer band, the energies of the band were plotted against the ionization potentials estimated above, where the lower energy band of the two ultraviolet absorption bands was chosen for the complexes [V]—[VIII]; this is shown in Fig. 7. It is obvious in this figure that there is a linear relationship between the energies of the band and the ionization potentials with a slope of about 45°. This relationship is a characteristic feature of the charge-transfer band; it suggests that a dominant factor in determining the energy of the charge-transfer band is the energy difference between the Coulomb energies of copper 3*d* orbitals and ligand σ orbitals. Therefore, the band is assigned to the $B_{1g} \rightarrow E_u$ charge-transfer transition.

As has already been mentioned, the charge transfer bands of the complexes in Table 3 appear at lower energies as the number of alkyl groups in their ligand molecules increases; furthremore, the tendency of the band becomes more pronounced when the alkyl groups are ethyl rather than methyl and when they are *N*-substituted alkyl groups rather than *C*-substituted ones. The fact that the charge-transfer band shifts to a longer wavelength indicates that the energy difference between the levels of the copper 3*d* orbital and the ligand σ orbital becomes smaller and that, accordingly, the σ bonding becomes more covalent. This tendency toward covalency is perfectly consistent with the one derived from the ESR results. Therefore, it may be concluded that, for the metal complexes of ethylenediamine and its analogues, the σ bonding becomes more covalent as the charge-transfer bands appear at longer wavelengths.

Thermodynamic and X-Ray Studies of Solid Solutions of Silver Bromide and Sodium Bromide

Toshihide TSUJI, Kazuo FUEKI and Takashi MUKAIBO

Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Tokyo

(Received January 14, 1969)

Activity, and partial molal free energy, enthalpy and entropy of AgBr in AgBr-NaBr solid solutions have been obtained at 350 and 400°C from the e.m.f. data of galvanic cells of the type Ag/AgBr-NaBr/Br_2. It has been found that the solid solution forms a regular solution defined by Hildebrand. A miscibility gap has been found by the study of galvanic cells and confirmed by high temperature X-ray diffraction. A new phase diagram of the AgBr-NaBr system is presented.

Kiukkola and Wagner[1] showed new potentialities and inherent limitations of e.m.f. measurements on galvanic cells with solid electrolytes for the determination of standard molal free energies of formation of halides, oxides, sulfides and other compounds at elevated temperatures. Although many e.m.f. studies were made for simple oxides, halides and sulfides, only a few studies have been carried out for the solid solutions consisting of

1) K. Kiukkola and C. Wagner, *J. Electrochem. Soc.*, **104**, 308, 379 (1957).

these simple salts.

Wachter,[2] and Panish and his co-workers[3] have reported the e.m.f. of the cell with solid electrolyte AgCl-NaCl and Pal'guev *et al.*[4] have measured the e.m.f. of electrochemical cells of a different type

$$Ag/AgBr//AgBr\text{-}NaBr/Br_2,$$
$$Ag/AgBr//AgBr\text{-}NaBr/Ag,$$
$$Br_2/AgBr//AgBr\text{-}NaBr/Br_2.$$

In the present paper, the result of studies on the activity, and partial molal quantities of AgBr in AgBr-NaBr solid solutions and miscibility gap by means of the galvanic cell $Ag/AgBr\text{-}NaBr/Br_2$ are given. For the determination of miscibility gap, high temperature X-ray diffraction study was also carried out.

Experimental

Samples. Sodium bromide and silver bromide of high purity were supplied from Junsei Pure Chemicals & Co., Ltd. and Kojima Chemical Co., Ltd., respectively. Silver bromide was prepared from pure silver nitrate and sodium bromide. No difference in e.m.f. due to the source of silver bromide was found in the experiment.

Silver bromide and sodium bromide were mixed in a desired proportion and ground together in an agate mortar. The mixture was melted in a quartz tube in bromine atmosphere, heated until the solution became clear, kept at about 400°C for several hours and then quenched. After cooling the sample was taken out from the quartz tube and ground again.

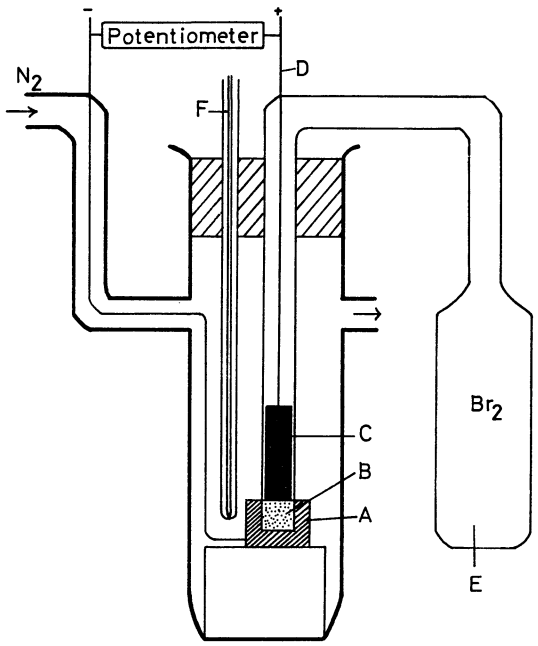

Fig. 1. Cell for the e.m.f. measurement.
A: silver crucible, B: AgBr-NaBr solid solution.
C: graphite, D: platinum wire,
E: bromine reservoir, F: thermocouple

E. M. F. Measurement. The apparatus used for the e.m.f. measurement of galvanic cells is shown in Fig. 1. Powder of solid solution was put into a silver crucible, A, which serves as the anode of the cell. This crucible also serves to keep the temperature of the electrolyte uniform. A quartz tube of 10 mm in diameter was inserted into the crucible. After the powder was melted, a graphite electrode of high purity, C, connected with platinum wire, D, was put into the fused solution. The salt was slowly solidified and kept at 400°C, and then the quartz tube was evacuated. After checking airtightness, bromine which had been purified by vacuum-distillation and dried with a magnesium perchlorate column, was introduced into the quartz tube and purified nitrogen stream was kept flowing along outside the tube.

The thermoelectric potential was measured on a cell which was constructed by replacing of the solid electrolyte with a silver block. It was found that the thermoelectric potential ranged from 1.4 to 4.1 mV depending on the temperature and was quite reproducible. Correction of the thermoelectric potential was made for all e.m.f. data.

The temperature of the furnace was maintained constant within ±0.5°C by means of an electronic controller. The e.m.f. of the thermocouple was measured with a P-42 type pyrometer of Murayama Denki Ltd. The temperature of the reservoir of bromine was controlled within ±0.05°C so that the fluctuation of the vapor pressure of bromine was less than 0.2% of the total pressure. The vapor pressure of bromine at each temperature was calculated from the temperature of the reservoir and the vapor pressure data in the Nesmeyanov table.[5] At a temperature range of 200 to 400°C the e.m.f. was measured by means of a potentiometer of Yokogawa Electric Works Ltd. in conjunction with a G-52 type galvanometer of Murayama Denki Ltd. When a new graphite electrode was employed, it took about 20 hr to attain a constant potential. When the vapor pressure of bromine was changed, the equilibrium was attained in two hours. The e.m.f. was reversible with regard to temperatures and the vapor pressure of bromine, but at low concentrations of silver bromide the conductivity of solid solutions was too small to measure the e.m.f.

High Temperature X-Ray Diffraction. In order to determine the exact solubility limit the powdered sample prepared in the same method as described above was mounted on a platinum sample holder and the lattice constant was measured by means of a high temperature X-ray diffractometer, type D-8C of Rigaku Denki Co., Ltd.

Results and Discussion

Figure 2 shows the plot of E *vs.* $\log P_{Br_2}$ for AgBr-NaBr solid solutions with various compositions at 400°C. A good linear relationship is seen between the vapor pressure of bromine and the e.m.f. within a pressure range 0.0864 and 0.650 Torr. A similar linear relationship was obtained at temperatures from 200 to 400°C.

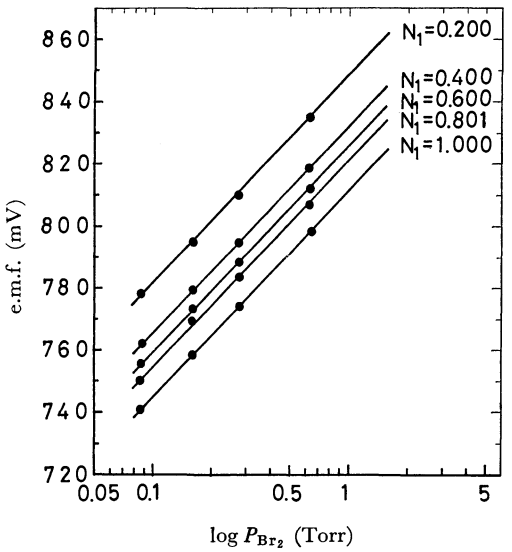

Fig. 2. Plot of E *vs.* $\log P_{Br_2}$ at 400°C.

TABLE 1. VALUES OF E_0 (mV)

N_1	°C				
	400	350	300	250	200
0.100	870.1	(885.2)	(898.2)		
0.200	849.1	865.8	(885.1)	(903.6)	
0.300	836.0	854.1	873.4	892.5	
0.400	832.4	851.4	870.9	886.5	906.9
0.500	826.5	846.9	867.6	889.1	910.8
0.600	826.6	847.4	869.4	885.9	904.0
0.700	823.5	845.3	869.5	890.2	914.0
0.801	821.7	844.8	870.5	888.5	906.5
0.901	818.5	841.4	864.6	885.1	907.6
1.000	811.9	835.3	858.9	878.2	895.3

Table 1 shows E_0, the e.m.f. at a bromine pressure of 1 Torr, which was obtained by extrapolating the plot of E *vs.* $\log P_{Br_2}$. The data with parentheses are those less reproducible.

According to Wagner[6] the open circuit potential, E, for an electrochemical cell, Ag/AgBr-NaBr/Br_2, is given by the equation

$$E = \frac{1}{F}\int_{\mu'_{Br_2}}^{\mu''_{Br_2}} (1-t_e)\mathrm{d}\mu_{Br_2}, \qquad (1)$$

where t_e is the transference number of electrons, μ'_{Br_2} and μ''_{Br_2} the chemical potentials of bromine at the metal-solid solution interface and at the gas-solid solution interface, respectively, and F the Faraday constant.

Using the free energy change ΔG_1 of the reaction $Ag+1/2Br_2=(AgBr)$ in solid solution, Eq. (1) is rewritten as

$$E = \frac{-\Delta G_1}{F} - \frac{1}{F}\int_{\mu'_{Br_2}}^{\mu''_{Br_2}} t_e\mathrm{d}\mu_{Br_2}. \qquad (2)$$

Wagner[7] has reported that the second term in Eq. (2) resulting from electronic conduction in pure silver bromide is 3.8 mV for $P_{Br_2}=0.23$ Torr at 277°C.

Tubandt and Reinhold[8] have shown that pure solid silver bromide is an entirely ionic conductor at temperatures from 200 to 300°C and Pal'guev *et al.*[9] have mentioned that according to the e.m.f. measurements of the electrochemical cell, Ag/AgBr/Br_2, the conductivity of the solid electrolyte were entirely ionic over a temperature range of 100 to 434°C.

In our experiment above 300°C the slope of the plots between E and $\log P_{Br_2}$ of pure silver bromide is close to the theoretical value, $2.303\,RT/2F$, where R is the gas constant and T the absolute temperature. Our experimental values of e.m.f. for pure silver bromide at 300°C is 1.1 mV lower than those calculated by Hamer *et al.*[10] From these results, it is concluded that pure silver bromide is a purely ionic conductor above 300°C. At lower temperatures our experimental data tend to deviate and are about 10 mV lower than those of Hamer *et al.*[10] because of the contribution of electronic conduction.

As shown in Fig. 2 the slope of the plot between E and $\log P_{Br_2}$ of AgBr-NaBr solid solutions with various compositions is the same as that of pure silver bromide. A similar relationship is found at 300 and 350°C. Since pure silver bromide is entirely ionic at the temperatures mentioned above, the solid AgBr-NaBr system is supposed to be also an ionic conductor above 300°C. Therefore, the second term in Eq. (2) can be eliminated for AgBr-NaBr solid solutions as well as pure silver bromide, and ΔG_1 is obtained from the e.m.f. data. If $\Delta G°$ denotes the free energy of formation of pure silver bromide, the partial molal free energy of silver bromide in solid solutions,

$\bar{G}_1$, is obtained by the equation

$$\bar{G}_1 = \Delta G_1 - \Delta G^\circ. \quad (3)$$

From the temperature dependence of $\bar{G}_1$, the partial molal entropy and enthalpy of silver bromide in solid solutions are calculated. If pure silver bromide is chosen as the standard state, the activity of silver bromide in its solution is calculated by the relation

$$\bar{G}_1 = 2.303\,\boldsymbol{R}T \log a_1. \quad (4)$$

The activity of sodium bromide, a_2, is obtained by means of the Gibbs-Duhem equation in the integrated form

$$\log \frac{a_2}{N_2} = -\int_0^{N_1} \frac{N_1}{N_2} \mathrm{d} \log \frac{a_1}{N_1}. \quad (5)$$

Thermodynamic data of the AgBr-NaBr system at 350 and 400°C are shown in Table 2.

Kleppa and Meschel[11] have determined the heat of solution of AgBr-NaBr by high temperature solution calorimetry at 350°C using pure liquid silver nitrate as the solvent. Table 3 gives the data by Kleppa and Meschel together with those obtained by the present study. Agreement is fairly good except for the data at N_1=0.801.

The deviation from Raoult's law is illustrated in Figs. 3 and 4. As can be seen from the figures, the system shows positive deviations from Raoult's law. Figures 3 and 4 also show that the solid solution is completely miscible at 400°C, but partially miscible at 300°C.

Zemczuzny[12] has reported that the AgBr-NaBr system forms a complete solid solution. A recent work by Stokes and Li[13] have indicated the existence of a miscibility gap with a critical temperature near 175°C for the AgCl-NaCl system. In view of the similarity of the AgCl-NaCl and AgBr-NaBr system, a miscibility gap can be expected.

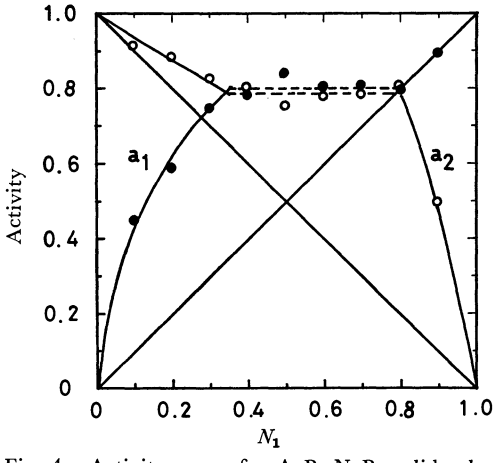

Fig. 4. Activity curves for AgBr-NaBr solid solutions at 300°C.

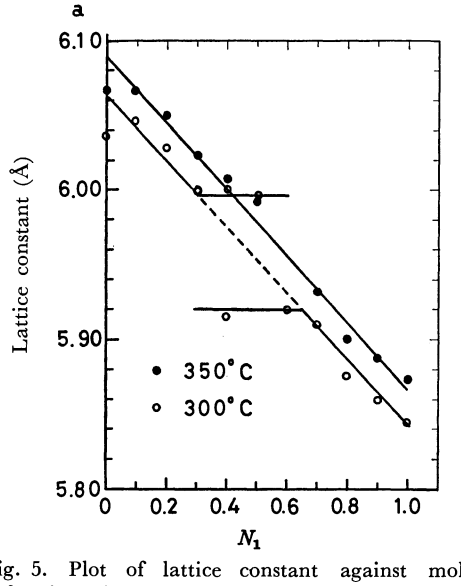

Fig. 5. Plot of lattice constant against mole fraction of AgBr.

In order to determine the exact solubility limit, a high temperature X-ray diffraction was carried out. Figure 5 shows lattice constants, a, plotted against mole fraction of silver bromide, N_1. As can be seen in Fig. 5, the lattice constant at 350°C decreases linearly with the increase in mole fraction of silver bromide (Vegard's law), but at lower temperatures such as 300°C the discontinuity in lattice parameter was found. The solubility limit

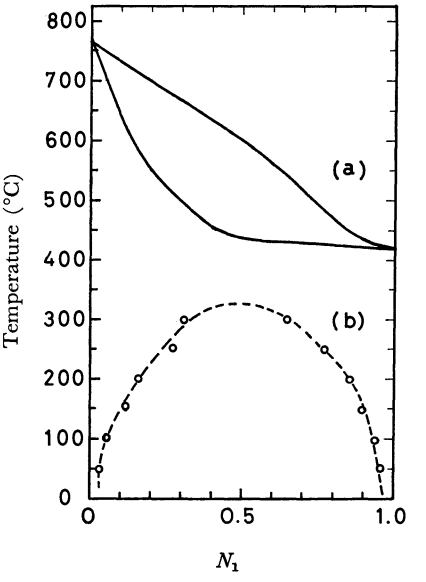

Fig. 6. Phase diagram of the AgBr-NaBr system. (a): Zemczuzny, (b): this work

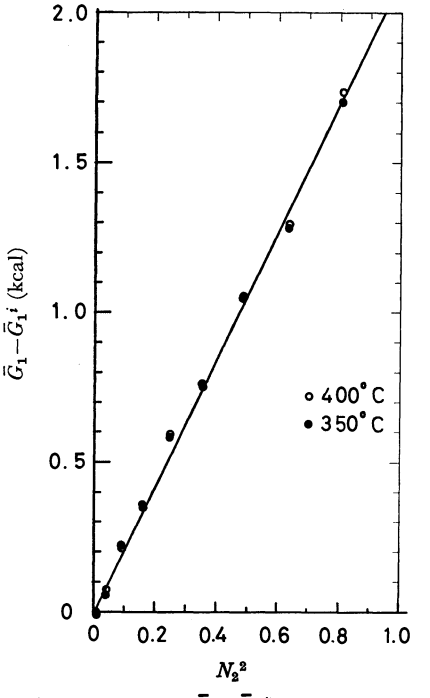

Fig. 7. Plot of $(\bar{G}_1-\bar{G}_1^i)$ against N_2^2.

was measured at an interval of 50°C from 50 to 350°C.

Figure 6 shows the phase diagram of the AgBr-NaBr system. The dotted line is the result of the present work and the liquidus and solidus lines are obtained from the data of Zemczuzny.[12]

Figure 7 gives the plot of $(\overline{G}_1-\overline{G}_1^i)$ *vs.* N_2^2, where $\overline{G}_1^i$ is the partial molal free energy of component 1 in the ideal solution. A good linear relationship exists between $(\overline{G}_1-\overline{G}_1^i)$ and N_2^2 and two sets of points for 350 and 400°C fall on a single straight line. This result clearly shows that the AgBr-NaBr system forms a regular solution which was defined by Hildebrand[14] above the critical temperature. It is concluded from this result that the partial molal entropy is the same as it would be in the ideal solution, *i. e.*, $\overline{S}_1=\overline{S}_1^i=R \ln N_1$, and that two kinds of positive ions are distributed at random in the solid solution.

Summary

(1) The partial molal free energy of AgBr in the solid AgBr-NaBr system was determined by the e.m.f. measurement for the cell, Ag/AgBr-NaBr/Br_2, at 350 and 400°C.

(2) The partial molal entropy and the partial molal enthalpy of AgBr in the solid AgBr-NaBr system were calculated.

(3) From the e.m.f. measurement, a miscibility gap was found in the AgBr-NaBr system. The exact solubility limit was determined by high temperature X-ray diffraction.

(4) A new phase diagram of the AgBr-NaBr system was presented.

(5) The system was found to form a regular solution defined by Hildebrand.

Heat of Immersion of Titanium Dioxide in Water. II. The Effect of the Crystallinity of Anatase

Teiji OMORI, Junichiro IMAI, Mahiko NAGAO and Tetsuo MORIMOTO

Department of Chemistry, Faculty of Science, Okayama University, Tsushima, Okayama

(Received January 16, 1969)

Two kinds of anatase samples which have very large specific surface areas and low crystallinities were prepared, and the interaction between the solid surface and the water molecule was investigated by measuring the water content, the heat of immersion in water, and the infrared spectrum of each sample. Two characteristic features were found in these samples: first, the plot of the heat of immersion *vs.* the pretreatment temperature did not reveal such a maximum as had been found previously with the crystalline anatase, and second, the heat of surface hydration as calculated from the plot of the heat of immersion *vs.* the water content was found to be remarkably smaller than with the crystalline anatase. These facts have led us to conclude that, with the anatase samples of a low crystallinity, not only does the rehydration reaction of a surface oxide structure produced at an elevated temperature proceed more easily on immersion in water, but also the heat of rehydration is smaller, than in a sample of a high crystallinity. Moreover, it was found from an infrared spectroscopic investigation that the water molecules physisorbed on the surfaces of large-area samples could be desorbed more gradually than those on small-area samples and remained small in quantity up to near 300°C *in vacuo*.

Titanium dioxide is one of the most important white pigments produced on an industrial scale; it has been studied by many investigators from the surface-chemical point of view. Nevertheless, it seems that many problems remain to be worked out with this material. Recently, the investigations have been carried out on the vapor adsorption,[1-3] the heat of immersion,[4] the surface

charge,[5,6] and the catalytic activity[7,8] of titanium dioxide; consequently, it has become clear that the surface hydroxyl groups play an important role in these phenomena. The plot of the heat of immersion of most metal oxides in water against the pretreatment temperature reveals a maximum, this phenomenon being also closely related to the presence of surface hydroxyl groups. Since, by analysing the plot, we can estimate the heat of formation of a surface hydroxyl group (the heat of surface hydration), the measurement of the heat of immersion of metal oxides in water makes it possible to make an energetic interpretation of the chemisorption of water on the solid surfaces. Recently, we have discovered two types of heat-of-immersion curves on α-Fe_2O_3; one shows a maximum, while the other does not.[9]

In the present work, anatase samples with large surface areas have been prepared in order to clarify the conditions of the appearance of a non-maximum curve in the plot of the heat of immersion *vs.* the pretreatment temperature. Then the interaction between the solid surface and the water molecule has been investigated by measuring the surface water content, the heat of immersion in water, and the infrared spectroscopy and by comparing the results with those obtained previously for the crystalline anatase.[10] As a result, two typical non-maximum curves have been observed in the plot of the heat of immersion *vs.* the pretreatment temperature; one shows an almost straight line, while the other shows an intermediate type between a maximum curve and a straight line.

Experimental

Materials. Two kinds of anatase were prepared in this study. The first sample was made by repeatedly treating the precipitate of anatase made through the hydrolysis of titanium sulfate with 1 N ammonia water in order to remove a large quantity of contaminated sulfate ions. It was then washed thoroughly with distilled water, and finally treated by means of electrodialysis (sample FA). The second sample was produced by calcining titanium peroxide for 4 hr at 400°C in air; the titanium peroxide had been prepared by the oxidation of metallic titanium with hydrogen peroxide. This sample was washed with distilled water, and finally the contaminating trace of electrolytes was removed by means of electrodialysis (sample SA). These two samples were dried at 110°C for 10 hr. For the sake of comparison, the data on the sample AI obtained in the previous work[10] are also cited, and also some new data were taken on this sample.

Surface-area Measurements. The specific surface areas of the anatase samples were determined by applying the BET theory to the nitrogen adsorption data obtained at the temperature of liquid nitrogen, assuming the molecular area of nitrogen to be 16.2 Å^2.

Heat-of-immersion Measurements. A sample of *ca.* 10 m^2 was used for every immersion measurement. Prior to the calorimetric measurement, the sample was treated in an ampoule at a desired temperature for 4 hr in a vacuum of 10^{-5} Torr, and then the ampoule was sealed off. The calorimeter and the technique of the heat-of-immersion measurements have been reported previously.[11] The measurements were carried out at 25°C. The heat of the breaking of the vacant ampoule was found to be 0.28 J; this was calibrated for the heat-of-immersion data.

Water-content Measurements. The water content of the anatase samples was measured by the successive ignition-loss method reported previously.[11] When the samples of anatase were treated at elevated temperatures *in vacuo*, small amounts of gases other than water vapor were found to be evolved. The amounts of these gases were measured volumetrically by a method described previously;[10] these data were then calibrated for the water content data. For instance, the gases other than water vapor which were evolved at 300, 400, and 600°C for the samples FA and SA were 0.02, 0.10, and 0.16, and 0.39, 0.94, and 1.67 molecules/100 Å^2 respectively.

Infrared Spectroscopy. The apparatus used for the infrared spectroscopic study was one made by the Japan Spectroscopic Co. (IR-G), to which a cell for the powdered sample was attached. The cell was essentially the same as that utilized by Yates.[12] The disk was prepared by pressing the powdered sample under a pressure of *ca.* 300 kg/cm^2. The sample disk set in the cell was first treated at an elevated temperature in a vacuum of 10^{-5} Torr for 4 hr and cooled to room temperature; then an infrared absorption spectrograph was taken. The measurements were repeated successively on one and the same sample after heat treatment at increasing temperatures.

Results and Discussion

The specific surface area of anatase is plotted against the pretreatment temperature in Fig. 1. For the sake of comparison, the surface area of the sample AI in a preceding paper[10] is cited in Fig. 1. The surface area of the sample FA is extremely large at room temperature, but it decreases remarkably with a rise in the temperature of heat treatment, indicating a great sintering. In the case of the sample SA also, a considerable sintering occurs. As a whole, we may conclude about the relation illustrated in Fig. 1 as follows:

the larger the specific surface area, the lower the temperature at which the sintering starts.

Figure 2 gives the relation between the water content and the temperature of pretreatment. The water-content value of the samples decreases in the order: SA>FA>AI.

The heat of immersion of anatase in water is plotted as a function of the temperature of pretreatment in Fig. 3. In spite of the large differences

between the particle sizes of the three kinds of anatase samples, the particle-size rule investigated in detail by Wade and Hackerman,[4] which states the increase in the heat of immersion with the increase in the particle size, does not hold in the present case. However, it should be noted that the samples FA and SA do not reveal any maximum in the heat-of-immersion curve, in contrast with the case of the sample AI. Most plots of the heat of immersion of metal oxides in water *vs.* the pretreatment temperature have revealed a maximum. For instance, in the cases of SiO_2,[13,14] TiO_2,[4,10] ZnO,[15] Al_2O_3,[11] and Fe_2O_3[9] all the heat-of-immersion curves showed a maximum, although the maximum value and the temperature at which the maximum appears vary with the nature of the metal oxides. Only in the case of Fe_2O_3, have samples showing no maximum in the heat-of-immersion curve been discovered besides samples showing a maximum. In the present case of anatase, two samples having large surface areas show no maximum in the heat-of-immersion curve, while the sample AI, which has a small surface area, shows a maximum. Moreover, a new type of characteristic feature can be seen from Fig. 3 — the heat of immersion of one sample (FA) increases sharply and almost linearly even after 400°C, whereas that of the other sample (SA) increases sharply at first, but slowly later. The

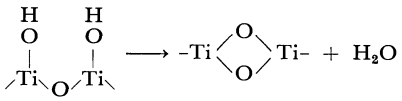
shape of the non-maximum curve observed on α-Fe_2O_3 rather resembles the case of anatase (the sample SA).

The appearance of the maximum in the heat-of-immersion curve has been elucidated as follows: the surface hydroxyl groups can be removed by pretreatment at elevated temperatures, and the resulting activated sites can easily be rehydrated to form hydroxyl groups on immersion in water. This additional heat evolution due to the rehydration reaction of the activated sites reaches a maximum value with the rise in the pretreatment temperature, since the number of the activated sites increases upon this pretreatment. Over a certain degree of pretreatment temperature, however, the activated surface oxide structure formed is stabilized, making it possible to retard the rehydration reaction on immersion in water. Thus the heat-of-immersion value decreases in the range of higher pretreatment temperatures. This heat of chemisorption of water which varies largely with the pretreatment temperature can be superimposed upon the wetting heat due to the physisorption of water.

When we reported, in a previous paper,[9] the first instance where two groups of samples showing both maximum curves and non-maximum curves in the plot of the heat of immersion were discovered in the same substance (α-Fe_2O_3), this phenomenon was not resolved satisfactorily. However, we suggested that the stabilization of the surface oxide structure formed by treatment at elevated temperatures is insufficient on the samples which give a non-maximum curve in the plot of the heat of immersion. With the sample FA in the present work the heat of immersion increases linearly over the range of pretreatment temperatures from 200 to 600°C; this suggests that little stabilization occurs on the surface oxide structure up to this, the highest temperature of treatment studied. With the sample SA, on the other hand, the heat of immersion increases sharply up to 300°C and then slowly, indicating that only weak stabilization takes place upon pretreatment at elevated temperatures.

The anatase samples were submitted to X-ray diffraction measurements. From these data the crystallite size of the samples can be estimated according to Scherrer's equation;[16] it amounts to 114, 258, and 2260< Å for the samples FA, SA, and AI respectively, with reference to the peak of the (101) plane of anatase. These values are those calibrated by using the data on a well-defined quartz crystal taken under the same conditions. It can be seen from these data that the sample with a larger surface area is of a lower crystallinity, as is to be expected. Thus, we may conclude that the stabilization of the surface oxide structure made by heat treatment occurs with more difficulty on the surface of the sample with a lower crystallinity. In other words, the stabilization of the $-Ti\langle^{O}_{O}\rangle Ti-$ structure on the surface of anatase which is produced by the reaction:



occurs with more difficulty; accordingly, the reverse reaction of this equation proceeds more easily on a surface with an ill-defined crystal structure than on a surface with a well-defined one. This phenomenon can probably be considered to be caused by the irregular bond length and the strained bond angle of the $-Ti\langle^{O}_{O}\rangle Ti-$ structure on the surface, both of which features arise from the lower crystallinity of the sample. The sample SA has the intermediate crystallinity among the three, produces a moderate stabilization of the surface oxide structure, and has a break in the heat-of-immersion curve at a temperature of about 300°C.

In Fig. 4 the heat of immersion of anatase is plotted against the water content in the treatment range up to 400°C. All the plots represent a linear relationship, the slope giving the heat of formation of a surface hydroxyl group, that is, the heat of surface hydration. The value of the heat of surface hydration can be read from Fig. 4 as 11.8 and 14.9 kcal/mol water for the samples FA and SA respectively, whereas the value is 26.4 kcal/mol water for the sample AI. The former two values are quite a bit smaller than the latter, which is the value of a representative crystalline anatase sample. This indicates that the heat of surface hydration is smaller on the surface with a lower crystallinity. Thus, we can conclude that the surface of the sample FA, whose crystallinity is the lowest, can be rehydrated most easily even

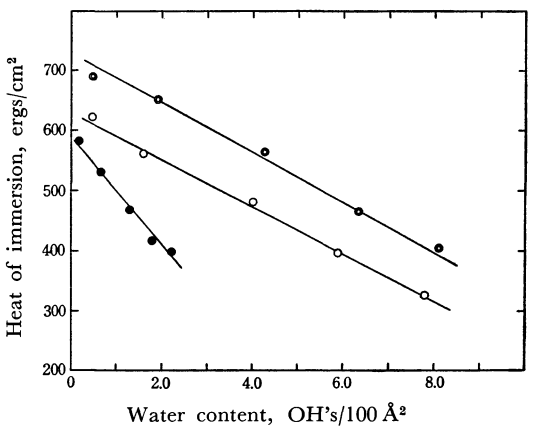


Fig. 4. Relation between heat of immersion and water content on anatase.
○, sample FA; ◎, sample SA; ●, sample AI

16) P. Scherrer, *Göttinger Nachrichten.*, **2**, 98 (1918).

after treatment at higher temperatures; moreover, its heat of surface hydration is the smallest. Since, when the activation energy of a reaction is small, the reaction proceeds rapidly, Fig. 3 suggests that the activation energy of the surface hydration reaction on the sample FA is the smallest, while that on the sample AI is the largest. It is known that, as for reactions with the same reaction mechanism, the activation energy of a reaction is larger on the reaction giving the larger reaction heat.[17] In the present examples it seems that this relation holds also in the case of the surface hydration reaction.

Figure 5a illustrates the infrared absorption spectra of the sample FA. After the sample has been degassed at 10^{-5} Torr for 4 hr at room temperature, the spectrum shows a broad absorption band in the range of 3700—2000 cm^{-1} and a shoulder near 3630 cm^{-1}. The former can be assigned to the stretching vibration of hydrogen-bonded hydroxyl groups, and the latter, to the stretching vibration of the isolated surface hydroxyl groups.[18] Another absorption band, near 1620 cm^{-1}, is considered to be due to the bending of hydroxyl groups, indicating the existence of physisorbed water.[12,18] After treatment at 110°C *in vacuo* the intensity of the spectrum generally decreases and the stretching vibration band of hydroxyl groups comes to separate into two parts, indicating a relative increase in the number of free hydroxyl groups. Even after treatment at 200°C there remains a slight bending vibration of hydroxyl groups, but it is extinguished completely after treatment at 300°C. This may be caused by the difficulty of the desorption of the capillary condensed water molecules. The reason why the heat of surface hydration of the sample FA is the least among these three samples may be partially that the desorption of the physisorbed water is most difficult from the sample FA because of the intensive capillary condensation; this results in an apparent increase in the water content at relatively low temperatures and in an apparent decrease in the heat of surface hydration calculated therefrom.

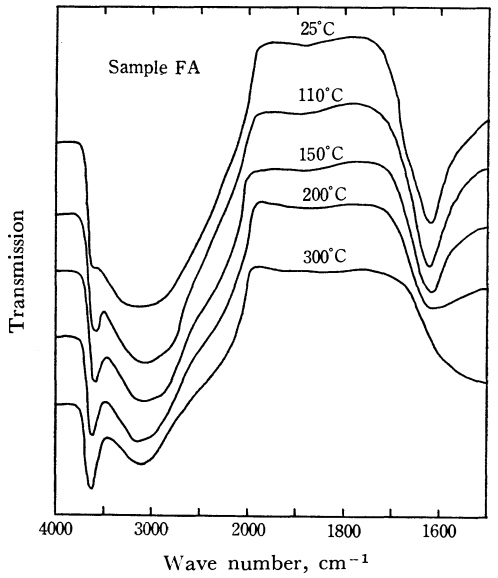

Fig. 5a. Infrared absorption spectra of sample FA under various conditions of treatment.

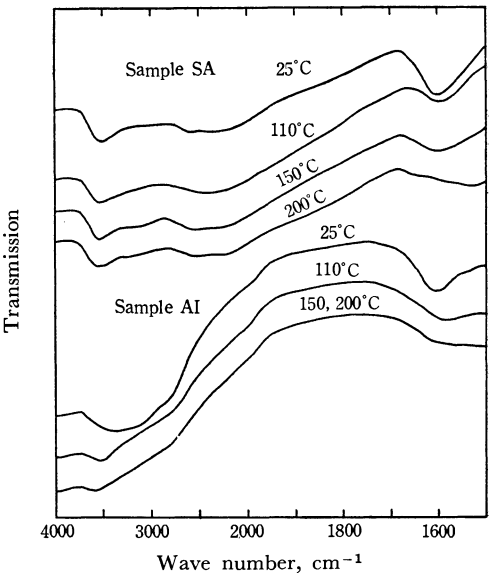

Fig. 5b. Infrared absorption spectra of samples SA and AI under various conditions of treatment.

Figure 5b shows that the water molecules physisorbed on the sample AI can be desorbed by heat treatment up to 150°C in a vacuum of 10^{-5} Torr, while those on the sample SA can be desorbed by heat treatment at a temperature higher than 200°C. Also, the large water content of the sample SA probably comes from the difficult desorbability of the physisorbed water, which may result in the small heat of surface hydration, as in the case of the sample FA.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 2203—2208 (1969)

Theory of Photoselection for Zeeman Split Phosphorescence

Tohru AZUMI and Saburo NAGAKURA

The Institute for Solid State Physics, The University of Tokyo, Roppongi, Minato-ku, Tokyo

(Received January 23, 1969)

General equations applicable to photoselection experiments for Zeeman split phosphorescence are derived. The general equations are also extended to the cases where excitation and observation are effected with unpolarized light, and expressions for the ratio of phosphorescence intensities of the three split subcomponents are obtained. Some comments on experimentation are made.

As reported previously,[1,2] we have succeeded in observing the Zeeman splitting of the phosphorescence of pyrazine. By measuring the phosphorescence intensities of the three Zeeman split components, one is able to obtain matrix elements connecting the ground state and all of the three triplet subcomponents. An example of such treatment has been given in a previous paper for the pyrazine phosphorescence.[2] For more detailed analyses, an experiment under polarized light is necessary. Such polarization measurements, conjoined with the Zeeman effect, will provide us with invaluable information on the nature of spin subcomponents, the manner in which the triplet state acquires the singlet character, effect of coupled vibrations, and so on.

The methods for polarization measurements are divided into two major classes. In one method one uses an oriented sample such as single crystal. In the other, called the method of photoselection, samples of random orientation are used. The former method is usually considered superior in a sense that it provides the polarization nature uniquely. However, the use of single crystals, the very necessary condition for this method, limits the actual application for the following reasons: First, the crystal structure, especially the arrangement of molecules in a unit cell, is not known for a majority of organic molecular crystals. Second, it is extremely difficult to retain a relatively large single crystal uncracked at liquid helium temperature. Finally, most important and crucial of all, many organic molecules do not exhibit phosphorescence in pure crystalline states. This is especially relevant for molecules whose lowest triplet state is of π, π^* nature.[3] Any molecular phosphorescence for molecules of this class should therefore be investigated in solutions or in mixed crystals. Because of the three difficulties associated with the single crystal experiments the method of photoselection acquires greater importance. The general equations which have been used for photoselection work are, however, not valid when external magnetic field is applied. It is consequently required that the theory of photoselection be extended to include the effect of magnetic field. In this paper, general equations applicable to photoselection experiments for the Zeemen split phosphorescence are derived. The general equations and the manner of their derivation are of importance not only for the polarization work but also for ordinary Zeeman effect experiments with unpolarized light because the latter should be treated as a special case of the former.

Theoretical

1) Effect of Magnetic Field on the Phosphorescence Intensities. The effect of magnetic field on the triplet state of organic molecules was treated in a previous paper;[2] consequently, only the essence is outlined here.

Let the lowest triplet state be produced by an excitation of an electron from a molecular orbital ϕ_a to a molecular orbital ϕ_b. We choose the following zeroth order triplet eigenfunctions.

$$\left.\begin{aligned} |T_x> &= 2^{-1/2}(|\bar{\phi}_a\bar{\phi}_b| - |\phi_a\phi_b|) \\ |T_y> &= 2^{-1/2}(|\bar{\phi}_a\bar{\phi}_b| + |\phi_a\phi_b|) \\ |T_z> &= 2^{-1/2}(|\phi_a\bar{\phi}_b| + |\bar{\phi}_a\phi_b|) \end{aligned}\right\} \quad (1)$$

The Hamiltonian for Zeeman effect is represented by

$$\mathscr{H} = g\beta H(lS_x + mS_y + nS_z) \quad (2)$$

where l, m, and n are direction cosines of molecular axes, x, y and z, respectively, with the field direction. Further, the zero field splitting parameters D and E are neglected. This assumption

2) T. Azumi, M. Ito and S. Nagakura, This Bulletin, **42**, 685 (1969).

3) H. Sternlicht, G. C. Nieman and G. W. Robinson, *J. Chem. Phys.*, **38**, 1326 (1963).

may roughly be justified for many organic molecules when magnetic field is larger than, say, 15 kG. (See a previous paper[2]) When magnetic field is applied, triplet wave functions $|T_1>$, $|T_0>$ and $|T_{-1}>$ are now represented in terms of (1) as

$$\begin{pmatrix} |T_1> \\ |T_0> \\ |T_{-1}> \end{pmatrix} = \begin{pmatrix} \sqrt{\frac{1-l^2}{2}} & \frac{n+ilm}{\sqrt{2(1-l^2)}} & \frac{-(nl+im)}{\sqrt{2(1-l^2)}} \\ l & im & n \\ \sqrt{\frac{1-l^2}{2}} & \frac{n-ilm}{\sqrt{2(1-l^2)}} & \frac{-(nl-im)}{\sqrt{2(1-l^2)}} \end{pmatrix} \begin{pmatrix} |T_x> \\ |T_y> \\ |T_z> \end{pmatrix} \tag{3}$$

The spin-orbit interaction which allows spin-forbidden triplet-singlet transitions is approximated as

$$\mathscr{H}_{so} = \sum_i \xi_i l_i S_i \tag{4}$$

where two electron operators are neglected. Then, the singlet state which may mix with the triplet state is only of the type

$$|S> = 2^{-1/2}(|\phi_a\bar{\phi}_c| + |\phi_c\bar{\phi}_a|) \tag{5}$$

The matrix elements for the spin-orbit interaction betwen the singlet and the triplet states are now obtained as follows:

$$\begin{pmatrix} <S|\mathscr{H}_{so}|T_1> \\ <S|\mathscr{H}_{so}|T_0> \\ <S|\mathscr{H}_{so}|T_{-1}> \end{pmatrix} = \frac{\hbar}{2}\xi \begin{pmatrix} -\sqrt{\frac{1-l^2}{2}} & i\frac{n+ilm}{\sqrt{2(1-l^2)}} & \frac{nl+im}{\sqrt{2(1-l^2)}} \\ -l & -m & -n \\ -\sqrt{\frac{1-l^2}{2}} & i\frac{n-ilm}{\sqrt{2(1-l^2)}} & \frac{nl-im}{\sqrt{2(1-l^2)}} \end{pmatrix} \begin{pmatrix} <\phi_c|l_x|\phi_b> \\ <\phi_c|l_y|\phi_b> \\ <\phi_c|l_z|\phi_b> \end{pmatrix} \tag{6}$$

Let the phosphorescence intensities from the three subcomponents, $|T_1>$, $|T_0>$ and $|T_{-1}>$ be denoted by I_1 I_0, and I_{-1}. Then from (6)

$$\begin{pmatrix} I_1/g_1 \\ I_0/g_0 \\ I_{-1}/g_{-1} \end{pmatrix} = c \begin{pmatrix} \frac{1-l^2}{2} & \frac{1-m^2}{2} & \frac{1-n^2}{2} \\ l^2 & m^2 & n^2 \\ \frac{1-l^2}{2} & \frac{1-m^2}{2} & \frac{1-n^2}{2} \end{pmatrix} \begin{pmatrix} u_x \\ u_y \\ u_z \end{pmatrix} \tag{7}$$

where c is a proportionality constant, g's represent the Boltzmann populations of the respective components, and further, u_x, u_y and u_z represent the contribution to intensity from l_x, l_y and l_z in spin-orbit coupling (4).

2) Theory of Photoselection: Incorporation of the Effect of Magnetic Field. Theory of photoselection was presented in an elegant manner by Albrecht.[4] We shall closely follow his presentation, and here merely incorporate the effect of magnetic field.

We choose the two coordinate sets, the molecule-fixed set (x, y, z) and the laboratory-fixed set (a, b, c). Assigning these a common origin we then specify the orientation of a molecule in laboratory using Eulerian angles, θ, ϕ and ψ. The cosines of the angles between the axes of the two coordinates are

	x	y	z
a	$\cos\theta$	$\sin\theta\sin\psi$	$\sin\theta\cos\psi$
b	$\sin\theta\sin\phi$	$\cos\phi\cos\psi-\cos\theta\sin\phi\sin\psi$	$-\cos\phi\sin\psi-\cos\theta\sin\phi\cos\psi$
c	$-\sin\theta\cos\phi$	$\sin\phi\cos\psi+\cos\theta\cos\phi\sin\psi$	$-\sin\phi\sin\psi+\cos\theta\cos\phi\cos\psi$

These nine direction cosines are abbreviated as, for example, t_{ax}.

The experimental arrangement is shown schematically in Fig. 1. Namely, excitation is effected with the light incident along b axis onto ac face, polarized along a axis by an amount p and along c axis 1-p. The magnetic field is applied along c axis. The emitted phosphorescence may be viewed along a axis or along c axis. In the latter case, the Faraday rotarion may affect the polarization values. Hence, we had better avoid observation from c axis when magnetic field is large enough to cause the Faraday rotation.

We assume that at a given wavelength absorption takes place in x, y and z axes of the molecule

4) A. C. Albrecht, *J. Mol. Spectroscopy*, **6**, 84 (1961).

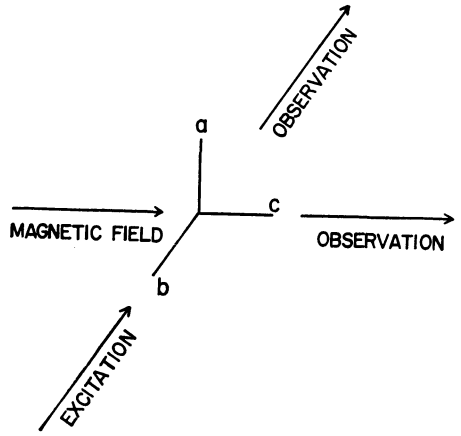

Fig. 1. Experimental arrangement.

with the fraction of r_x, r_y and r_z, respectively. Similarly, we assume that at a given wavelength the phosphorescence is polarized along x, y, and z axes with the fraction of q_x, q_y and q_z, respectively.

Now, the probability that a molecule at θ, ϕ and ψ is photoexcited is given by

$$p[r_x t_{ax}^2 + r_y t_{ay}^2 + r_z t_{az}^2] + (1-p)[r_x t_{cx}^2 + r_y t_{cy}^2 + r_z t_{cz}^2]$$

and the probability for viewing with light polarized, say, along a is

$$q_x t_{ax}^2 + q_y t_{ay}^2 + q_z t_{az}^2$$

with analogous expressions for viewing along b and c axes. Unsplit phosphorescence intensities are proportional to the product of these two expressions. In the presence of magnetic field, these quantities are split up according to (7). Namely, for I_1 and I_{-1} the above product is further multiplied by

$$g_{\pm 1}\left[\frac{1-l^2}{2}u_x + \frac{1-m^2}{2}u_y + \frac{1-n^2}{2}u_z\right]$$

and for I_0

$$g_0[l^2 u_x + m^2 u_y + n^2 u_z]$$

where $l=t_{cx}$, $m=t_{cy}$ and $n=t_{cz}$. In the sample of random orientation we integrate the product of the three expressions over Eulerian angles:

$$\int_0^{2\pi} \mathrm{d}\psi \int_0^{2\pi} \mathrm{d}\phi \int_0^{\pi} \sin\theta \, \mathrm{d}\theta$$

3) Results. Integration of the expressions described above yields the following results. Here, A, B, and C denote the phosphorescence intensities polarized along a, b and c axes, respectively. The subscript $+1$, 0 and -1 indicate the phosphorescence subcomponents.

$$
\begin{aligned}
A_0 &= g_0 r\left[u_x\left\{p\begin{bmatrix}6&4&4\\4&18&6\\4&6&18\end{bmatrix}+(1-p)\begin{bmatrix}4&20&18\\6&2&6\\4&6&4\end{bmatrix}\right\}+u_y\left\{p\begin{bmatrix}18&4&6\\4&6&4\\6&4&18\end{bmatrix}\right.\right.\\
&\quad\left.+(1-p)\begin{bmatrix}6&2&6\\16&8&18\\6&4&4\end{bmatrix}\right\}+u_z\left\{p\begin{bmatrix}18&6&4\\6&18&4\\4&4&6\end{bmatrix}+(1-p)\begin{bmatrix}4&6&4\\6&4&4\\18&18&6\end{bmatrix}\right\}\left.\right]q\\
B_0 &= g_0 r\left[u_x\left\{p\begin{bmatrix}4&4&6\\4&8&16\\6&16&6\end{bmatrix}+(1-p)\begin{bmatrix}4&20&18\\6&2&6\\4&6&4\end{bmatrix}\right\}+u_y\left\{p\begin{bmatrix}4&8&16\\8&0&6\\16&6&6\end{bmatrix}\right.\right.\\
&\quad\left.+(1-p)\begin{bmatrix}6&2&6\\16&8&18\\6&4&4\end{bmatrix}\right\}+u_z\left\{p\begin{bmatrix}6&16&6\\16&6&6\\6&6&2\end{bmatrix}+(1-p)\begin{bmatrix}4&6&4\\6&4&4\\18&18&6\end{bmatrix}\right\}\left.\right]q\\
C_0 &= g_0 r\left[u_x\left\{p\begin{bmatrix}4&6&4\\20&2&6\\18&6&4\end{bmatrix}+(1-p)\begin{bmatrix}34&2&6\\2&10&2\\6&2&6\end{bmatrix}\right\}+u_y\left\{p\begin{bmatrix}6&16&6\\2&8&4\\6&18&4\end{bmatrix}\right.\right.\\
&\quad\left.+(1-p)\begin{bmatrix}2&10&2\\10&26&6\\2&6&6\end{bmatrix}\right\}+u_z\left\{p\begin{bmatrix}4&6&18\\6&4&18\\4&4&6\end{bmatrix}+(1-p)\begin{bmatrix}6&2&6\\2&6&6\\6&6&30\end{bmatrix}\right\}\left.\right]q\\
A_{\pm 1} &= g_{\pm 1} r\left[u_x\left\{p\begin{bmatrix}18&5&5\\5&12&4\\5&4&12\end{bmatrix}+(1-p)\begin{bmatrix}5&4&5\\11&6&11\\12&11&5\end{bmatrix}\right\}+u_y\left\{p\begin{bmatrix}12&5&4\\5&18&5\\4&5&12\end{bmatrix}\right.\right.\\
&\quad\left.+(1-p)\begin{bmatrix}4&13&11\\6&3&5\\11&12&5\end{bmatrix}\right\}+u_z\left\{p\begin{bmatrix}12&4&5\\4&12&5\\5&5&18\end{bmatrix}+(1-p)\begin{bmatrix}5&11&12\\11&5&12\\5&5&4\end{bmatrix}\right\}\left.\right]q\\
B_{\pm 1} &= g_{\pm 1} r\left[u_x\left\{p\begin{bmatrix}5&12&11\\12&3&6\\11&6&4\end{bmatrix}+(1-p)\begin{bmatrix}5&4&5\\11&6&11\\12&11&5\end{bmatrix}\right\}+u_y\left\{p\begin{bmatrix}5&10&6\\10&7&11\\6&11&4\end{bmatrix}\right.\right.\\
&\quad\left.+(1-p)\begin{bmatrix}4&13&11\\6&3&5\\11&12&5\end{bmatrix}\right\}+u_z\left\{p\begin{bmatrix}4&6&11\\6&4&11\\11&11&6\end{bmatrix}+(1-p)\begin{bmatrix}5&11&12\\11&5&12\\5&5&4\end{bmatrix}\right\}\left.\right]q\\
C_{\pm 1} &= g_{\pm 1} r\left[u_x\left\{p\begin{bmatrix}5&11&12\\4&6&11\\5&11&5\end{bmatrix}+(1-p)\begin{bmatrix}4&6&4\\6&16&6\\4&6&18\end{bmatrix}\right\}+u_y\left\{p\begin{bmatrix}4&6&11\\13&3&12\\11&5&5\end{bmatrix}\right.\right.\\
&\quad\left.+(1-p)\begin{bmatrix}20&2&6\\2&8&4\\6&4&18\end{bmatrix}\right\}+u_z\left\{p\begin{bmatrix}5&11&5\\11&5&5\\12&12&4\end{bmatrix}+(1-p)\begin{bmatrix}18&6&4\\6&18&4\\4&4&6\end{bmatrix}\right\}\left.\right]q
\end{aligned}
\qquad (8)
$$

where

$$\boldsymbol{r} = [r_x \; r_y \; r_z]$$

and

$$\boldsymbol{q} = \begin{bmatrix} q_x \\ q_y \\ q_z \end{bmatrix}$$

Hence of cource

$$\boldsymbol{r}\begin{bmatrix} c_{11} & c_{12} & c_{13} \\ c_{21} & c_{22} & c_{23} \\ c_{31} & c_{32} & c_{33} \end{bmatrix}\boldsymbol{q} = \begin{matrix} c_{11}r_xq_x + c_{12}r_xq_y + c_{13}r_xq_z \\ +c_{21}r_yq_x + c_{22}r_yq_y + c_{23}r_yq_z \\ +c_{31}r_zq_x + c_{32}r_zq_y + c_{33}r_zq_z \end{matrix}$$

Extension to Unpolarized Work

The general equations derived above may readily be extended to the cases where both excitation and observation are made with unpolarized light. The results for two different observations are as follows.

(1) Straight view (observation along b axis)

$$\left.\begin{aligned} I_0 &= g_0\boldsymbol{r}\left\{u_x\begin{bmatrix}24 & 16 & 16\\ 16 & 16 & 10\\ 16 & 10 & 16\end{bmatrix} + u_y\begin{bmatrix}16 & 16 & 10\\ 16 & 24 & 16\\ 10 & 16 & 16\end{bmatrix} + u_z\begin{bmatrix}16 & 10 & 16\\ 10 & 16 & 16\\ 16 & 16 & 24\end{bmatrix}\right\}\boldsymbol{q} \\ I_{\pm1} &= g_{\pm1}\boldsymbol{r}\left\{u_x\begin{bmatrix}16 & 13 & 13\\ 13 & 20 & 16\\ 13 & 16 & 20\end{bmatrix} + u_y\begin{bmatrix}20 & 13 & 16\\ 13 & 16 & 13\\ 16 & 13 & 20\end{bmatrix} + u_z\begin{bmatrix}20 & 16 & 13\\ 16 & 20 & 13\\ 13 & 13 & 16\end{bmatrix}\right\}\boldsymbol{q} \end{aligned}\right\} \quad (9)$$

(2) Side view (observation along c axis)

$$\left.\begin{aligned} I_0 &= g_0\boldsymbol{r}\left\{u_x\begin{bmatrix}9 & 24 & 23\\ 10 & 15 & 17\\ 9 & 17 & 16\end{bmatrix} + u_y\begin{bmatrix}17 & 8 & 17\\ 22 & 11 & 23\\ 17 & 9 & 16\end{bmatrix} + u_z\begin{bmatrix}16 & 17 & 9\\ 17 & 16 & 9\\ 23 & 23 & 10\end{bmatrix}\right\}\boldsymbol{q} \\ I_{\pm1} &= g_{\pm1}\boldsymbol{r}\left\{u_x\begin{bmatrix}16.5 & 12.5 & 13\\ 19.5 & 13.5 & 16\\ 20 & 16 & 13\end{bmatrix} + u_y\begin{bmatrix}12.5 & 20.5 & 16\\ 13.5 & 15.5 & 13\\ 16 & 20 & 13\end{bmatrix} + u_z\begin{bmatrix}13 & 16 & 20\\ 16 & 13 & 20\\ 13 & 13 & 16\end{bmatrix}\right\}\boldsymbol{q} \end{aligned}\right\} \quad (10)$$

The above equations determine the ratio of the three split phosphorescence subcomponents when neither polarizer nor analyser is used. It is to be noted that the ratio is not simply a ratio of the Boltzmann populations.

An Example: Predictions for Pyrazine Phosphorescence

Because of the complexity of the general equations it may not be very clear as to how the polarization is affected by magnetic field. From this viewpoint, we shall take pyrazine phosphorescence as an example and illustrate how the phosphorescence intensities are divided among the three subcomponents and how the polarization values are affected by magnetic field.

Group theoretical consideration[2] predicts $u_y=1$ and $q_z=1$ for 0, 0 band of the pyrazine phosphorescence. (For details see a previous paper.[2]) Polarization observed by Krishna and Goodman[5] is in agreement with this prediction. The molecular axes are defined as recommended by Mulliken.[6] Namely, z axis lies in the molecular plane on the N-N axis and x axis is normal to the molecular plane. We consider two different wavelength regions of excitation, one for $^1B_{2u}$ (π, π^*) state (at 37839 cm^{-1}) and the other for $^1B_{3u}$ (n, π^*) state (at 30776 cm^{-1}). Further, we consider the case in which the exciting light is polarized either along a axis (vartical excitation) or along c axis (horizontal excitation).

In Fig. 2 are shown predicted phosphorescence intensities polarized either along a, b, or c axis under the four different modes of excitation. The length of the vertical lines and the numbers specified indicate the phosphorescence intensities divided by the population of the upper level. It is immediately seen how zero field intensities are split up into three subcomponents under the presence of magnetic field. Shown also in Fig. 2 are the values of polarization for straight view and for

Table 1. Predicted intensity ratio of the thrle phosphorescence subcomponents for pyrazine

	$I_1 : I_0 : I_{-1}$	
Excitation	Straight view	Side view
$^1B_{3u}(n, \pi^*)$	$16g_1 : 10g_0 : 16g_{-1}$	$16g_1 : 17g_0 : 16g_{-1}$
$^1B_{2u}(\pi, \pi^*)$	$13g_1 : 16g_0 : 13g_{-1}$	$13g_1 : 23g_0 : 13g_{-1}$
$^1B_{1u}(\pi, \pi^*)$	$20g_1 : 16g_0 : 20g_{-1}$	$13g_1 : 16g_0 : 13g_{-1}$

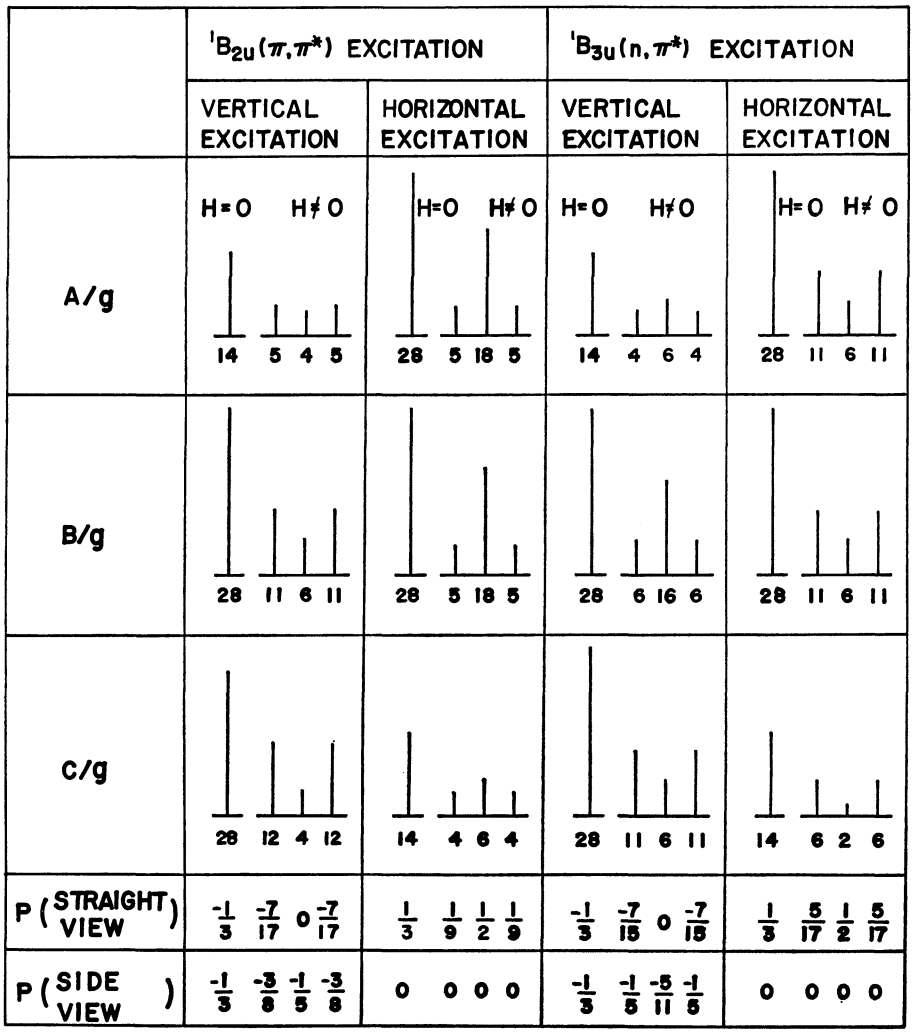

Fig. 2. Predicted phosphorescence intensities and polarizations for pyrazine phosphorescence under different modes of excitation (see the text).

side view. It is amazing to see how fertile informations are obtained by applying magnetic field. It is exactly for this reason that the polarization measurements under magnetic field are recommended. The predicted ratio of the phosphorescence intensities for unpolarized work is summarized in Table 1. A part of this result has been already presented in a previous paper.

Some Comments on Experimentation

The present paper aims only at presenting general equations which may be of use in ideal photoselection experiments. Whether or not ideal conditions for photoselection experiments are satisfied in reality and how to solve any difficulties that might occur is another question. We have not made any considerable effort in this regard so far; however, in the following, we point out our views on experimentation.

One of the difficulties inherent to polarization experiments is due to improper polarization caused by the apparatus. This difficulty is readily overcome in a similar manner to Azumi and McGlynn,[7] and Russel and Albrecht[8] calibrated their apparatus for improper polarization effect in ordinary (*i. e.*, without magnetic field) photoselection experiments. The correction involves a repetition of the experiment keeping everything unchanged except for the excitation which is effected horizontally and emission is observed from the side. Theoretically, the emission should in this case be unpolarized. This is easily seen

7) T. Azumi and S. P. McGlynn, *J. Chem. Phys.*, **37**, 2413 (1962).

8) P. G. Russell and A. C. Albrecht, *ibid.*, **41**, 2536 (1964).

from the fact that in the general equations (8) equating p to zero necessarily yields $A=B$ for all three phosphorescence subcomponents. Any observed polarization should, consequently, be regarded as due to instrumentation, and is served for the correction factor. Further, by observing this correction factor by varying the strength of magnetic field, one may be able to see, though indirectly, the effect of Faraday rotation.

Another difficulty in photoselection experiment is that one has to work with samples of random orientation. Further, the sample should be strain-free. In this connection, it is noted that in the Zeeman effect experiment, one has to lower the temperature to liquid helium temperature to narrow the bandwidth, since the Zeeman splitting at 50 kG may only amount to 5—6 cm^{-1}. Rigid glass solvents which may be used at liquid helium temperature are shown in Table 2. These media have been reported to form transparent glass at 4.2°K, but it is uncertain whether or not they are strain-free. Furthermore, it is doubtful if bandwidth becomes sufficiently narrow in these media. In fact, according to Armstrong,[9] in the isopentane-3-methylpentane mixed solvent no significant band narrowing has been attained by lowering temperature down to 4.2°K. In this regard, one may also try some rare gas matrices such as neon and xenon[10] and also so called "Shpolskii's solvents" such as cyclohexane and carbon tetrachloride[11] even though they are best considered polycrystalline.

Table 2. Rigid glass solvents at 4.2°K

Solvent	Reference
Isopentane + 3-Methylpentane (6 : 1 in volume)	9
Silicone (Dow-Corning 200 with 10^6 cs viscosity)	9
Trifluorobromomethane	12

Test of various solvents for use of photoselection experiments at liquid helium temperature is being attempted and will be reported in future publications.

We wish to express our appreciation to Professor Mitsuo Ito for constant encouragement and invaluable discussions.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 2208—2211 (1969)

ESR Studies on the Reaction of an OH Radical in α,β-Unsaturated Aldehyde*[1]

Takahisa ICHIKAWA*[2] and Keiji KUWATA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka

(Received January 27, 1968)

ESR studies on the UV irradiated α,β-unsaturated aldehyde - hydrogen peroxide mixtures have been done at low temperature in order to examine the reactions of an OH radical with aldehyde: formyl hydrogen-abstraction, methyl hydrogen-abstraction, and addition to an olefinic bond. It has been shown that abstraction of a methyl hydrogen by an OH radical occurs in crotonaldehyde, whereas β-addition of an OH radical to an olefinic bond takes place in methacrolein and acrolein. A formyl hydrogen is unreactive with an OH radical in any case. The distribution of unpaired electron in the radicals was also discussed.

Several ESR studies were carried out in this laboratory concerning the reaction of an OH radical at low temperature with an organic compound having hydroxyl groups.[1] It was found that the OH radical abstracts mainly an α-hydrogen. In some cases the possibility of hydrogen-abstraction from

a hydroxyl group was discussed. In derivatives of glycol, successive reactions, RCHOH–RCHOH $\xrightarrow{\dot{O}H}$ RCHOH–$\dot{R}$COH $\xrightarrow{h\nu}$ $\dot{R}$COH–RCO, were considered on the basis of ESR spectral changes and analysis of evolved gas. In connection with these results, it is interesting to examine the reaction of an OH radical in α,β-unsaturated aldehyde systems, because the aldehyde has a formyl hydrogen, methyl hydrogens, and an olefinic bond, which is expected to bring about a competition among formyl hydrogen-abstraction, methyl hydrogen-abstraction, and addition to an olefinic bond.

Experimental

Materials. Hydrogen peroxide (30 wt%) was concentrated under reduced pressure to 95 wt%, and the antioxidant was removed by distillation before use. Reagent-grade crotonaldehyde, methacrolein, and acrolein were purified by fractional distillation under reduced pressure.

Procedure. The aldehyde containing 10 mol% hydrogen peroxide was introduced into a quartz sample tube and deaerated by freezing and thawing under vacuum. The sample in a clear glassy state was illuminated in a quartz Dewar vessel at 77°K with the light from a low pressure mercury lamp. After illumination for 3hr the sample was transferred quickly into a cavity which was immersed in liquid nitrogen. Warming of the sample was carried out inside the cavity in the range 77—300°K. Details of the cavity have already been shown.[2] Measurements were done at X-band with a homemade spectrometer using 450kc/sec field modulation.

Results and Discussion

Crotonaldehyde. Figure 1a shows the ESR spectrum of an illuminated glass of a crotonaldehyde-hydrogen peroxide mixture at 80°K. On warming the sample to 160°K the spectrum changed as shown in Fig. 1b. The intensity of the signal was not reduced lower than 50% of the initial state. The spectrum consists of equally spaced four lines with the separation of 12.9 G, the intensity ratios of the lines being 1.2 : 2.8 : 2.8 : 1.0. Since the ratios are closer to 1 : 3 : 3 : 1, the radical should have equally interacting three protons.

The four line spectrum can be interpreted by the radical formed by abstraction of a methyl hydrogen; $\dot{C}H_2$–CH=CH–CHO↔CH_2=CH–$\dot{C}$H–CHO↔CH_2=CH–CH=CH–$\dot{O}$. The identification is based upon the following arguments. The molecular orbital calculation of pi-electron spin densities using McLachlan procedure[3] gave the values as follows;

	C_1	C_2	C_3	C_4	O_5
ρ=	0.6456	−0.1704	0.5051	−0.0324	0.0521
a(G)=	14.6	3.9	11.4	0.7	

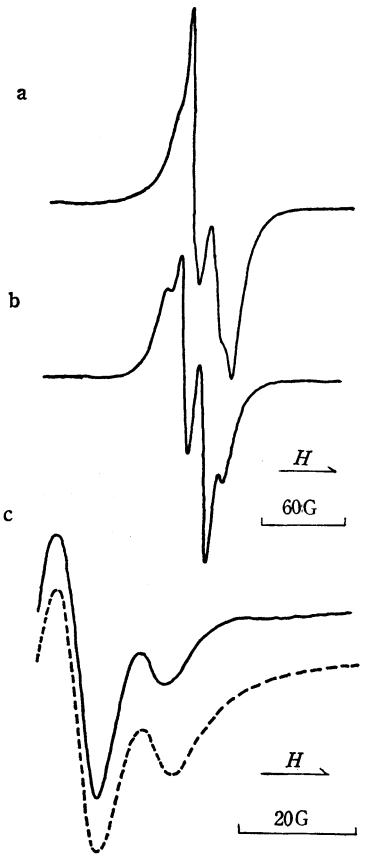

Fig. 1. ESR spectra of an illuminated glass of crotonaldehyde containing 10 mol% hydrogen peroxide.
a) Spectrum measured at 80°K
b) Spectrum measured at 160°K
c) Computed curve (dotted lines)

Hfs constants were estimated by taking into account McConnell's relation[4]

$$a = Q \cdot \rho \qquad (1)$$

where Q is a constant (23 G) and ρ is the spin density on the carbon. The results indicate that the C_2 and C_4 protons do not contribute strongly to the hfs and the difference between C_1 and C_3 proton hfs constants is not larger than the observed line width (5 G). Thus it seems probable that the postulated radical gives the four line spectrum due to the predominant interaction with two C_1

3) A. D. McLachlan, *Mol. phys.*, **3**, 233 (1960). The parameter λ in the procedure was given $\lambda=1.2\beta$. The coulomb integrals and the resonance integrals were assumed to be $\alpha_O=\alpha_C+1.5\beta$, $\alpha_C=\alpha_{C'}-0.15\beta$, $\beta_{CO}=1.6\beta$, and $\beta_{CC'}=\beta$, which were used in the calculation on the anion radicals of aromatic carbonyl compounds (P. H. Rieger and G. K. Fraenkel, *J. Chem. Phys.*, **37**, 2811 (1962)).

4) H. M. McConnell and D. B. Chesnut, *J. Chem. Phys.*, **28**, 107 (1958).

and one C_3 protons. The computed curve with Lorentzian line shapes in consideration of these results is shown in Fig. 1c.

It is apparent that another possible radical such as CH_3-CH=CH-$\dot{C}$=O (hydrogen-abstraction from a formyl group) and CH_3-CHOH-$\dot{C}$H-CHO (OH-addition to an olefinic bond) can not give the four line spectrum. The reason for this is that the former is a sigma radical in which an unpaired electron is localized on a sigma orbital of a carbon atom[5] and has only one interacting proton, and the latter has unequally interacting three protons, *i. e.*, α-, β-, and formyl protons.

Although the spectrum before warming of the sample exhibits asymmetric line shapes, it apparently already contains the characteristic features of the four lines in the spectrum, which suggests that the initial spectrum consists of the four lines and some additional lines. The spectral change, therefore, is likely due to the disappearance of more unstable radicals.

An ESR spectrum of illuminated crotonaldehyde without hydrogen peroxide was also examined, the results showing a relatively small radical yield, *i. e.*, one twentieth in the case containing hydrogen peroxide.

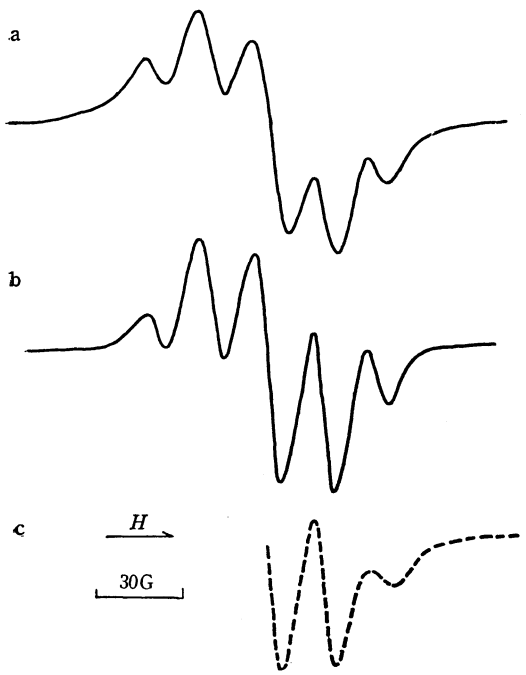

Fig. 2. ESR spectra of an illuminated glass of methacrolein containing 10 mol% hydrogen peroxide.
a) Spectrum measured at 80°K
b) Spectrum measured at 180°K
c) Computed curve

Methacrolein. An illuminated glass of methacrolein-hydrogen peroxide mixture gave the spectrum as shown in Fig. 2a. On warming the sample to 180°K, the spectrum became well resolved five lines with separations of 19.5 G whose intensity ratios were 1.1 : 3.7 : 5.5 : 3.4 : 1.0. The radical should have equally interacting four protons because the theoretical intensity ratios are 1 : 4 : 6 : 4 : 1.

If a methyl hydrogen is abstracted by an OH radical, the radical CH_2=C(CHO)-$\dot{C}H_2$↔$\dot{C}H_2$-C(CHO)=CH_2 would be formed. This radical would be essentially the allyl type with equally interacting four protons. The hfs constants of 19.5 G, however, are considerably larger than the expected value, *i. e.*, 14.4 G observed in the allyl radical.[6] It seems difficult to attribute the five line spectrum to the supposed radical.

In β-addition to an olefinic bond, the radical CH_2OH-$\dot{C}$(CH_3)-CHO↔CH_2OH-C(CH_3)=CH-$\dot{O}$ is formed. The five line spectrum may be accounted for by this radical on the assumption of a conformation as follows: 1) The methyl group rotates so rapidly that as all the hfs constants of the methyl protons are substantially equivalent. 2) The methylene group is fixed on such positions that one of the methylene protons has a hfs constant around 19.5 G, while the other less than the observed line width (8 G). According to Heller and McConnell,[7] the hfs constant of each β-proton is given by

$$a_{\beta_i} = 2Q_\beta \cdot \rho_\alpha \cdot \cos^2\theta_i \qquad (2)$$

where Q_β is a constant, ρ_α a spin density on an α-carbon, and θ_i an angle between a H_i-C_β-C_α plane and an axis of a p_z orbital occupied by an unpaired electron. For a rapidly rotating methyl proton, a value of $\cos^2\theta_{av}$ is equal to 1/2. Hence the hfs constants of the methyl protons are given by $a_\beta(CH_3)=Q_\beta\cdot\rho_\alpha=19.5$ G. Substitution of the values given above for a_{β_1} and $Q_\beta\cdot\rho_\alpha$ into Eq. (2) leads to a value of 45° for θ_1. Provided that the difference between θ_1 and θ_2 is 120°, θ_2 is either 75° or 15°. Taking the former, we found a value $a_{\beta_2}=2.6$ G from Eq. (2).

It is added here that as the π-electronic system of this radical resembles that of the allyl radical,[6] the spin density on the formyl carbon is expected to be small and also the hfs constant of a hydrogen attached to the formyl carbon is expected to be less than the observed line width. The computed curve is also shown in Fig. 2c for comparison with the observed spectrum.

6) J. E. Bennett and A. Thomas, *Proc. Roy. Soc.*, **208A**, 123 (1964).

7) C. Heller and H. M. McConnell, *J. Chem. Phys.*, **32**, 1535 (1960).

Fessenden and Schuler[8] evaluate a value $Q_\beta = 29.3$ G from their results of a number of aliphatic hydrocarbon radicals. Using the value, we found 0.667 for ρ_α. Fischer[9] showed experimentally that ρ_α in a substituted alkyl radical $X_1-\dot{C}(-X_2)-X_3$ can be calculated by use of a product rule

$$\rho_\alpha = \prod_{i=1}^{3}(1-\Delta(X_i)), \qquad (3)$$

where $\Delta(X_i)$ is a fraction which expresses the spin-density withdrawing-power of an X_i group. Substituting the values given by Fischer[9] ($\Delta(CH_3)=0.081$ and $\Delta(CH_2OH)=0.079$) and authors[10] ($\Delta(CHO)=0.198$) into Eq. (3), we obtain a value $\rho_\alpha=0.678$, which is very close to the experimentally derived value.

Acrolein. An illuminated glass of an acrolein-hydrogen peroxide mixture gave the spectrum as shown in Fig. 3a together with the spectrum observed after warming of the sample to 160°K (Fig. 3b). The spectrum at 160°K consists of unequally spaced four lines with the separations of 17.0, 13.0, and 17.0 G in turns and the intensity ratios of 1.0 : 1.4 : 1.5 : 1.2. The results suggest that the radical formed has two unequally interacting protons with the hfs constants of 17.0 and 30.0 G, respectively.

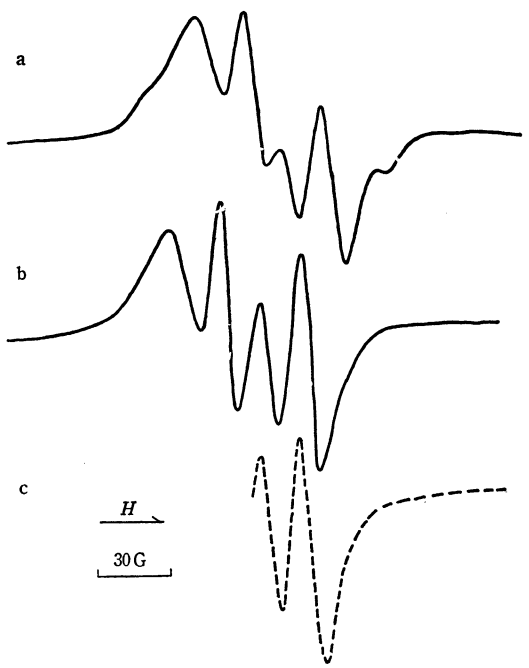

Fig. 3. ESR spectra of an illuminated glass of acrolein containing 10 mol% hydrogen peroxide.
a) Spectrum measured at 80°K
b) Spectrum measured at 160°K
c) Computed curve

The spectrum can be attributed to the radical produced by β-addition to an olefinic bond; $CH_2OH-\dot{C}H-CHO \leftrightarrow CH_2OH-CH=CH-\dot{O}$. The molecular orbital calculation[3] leads to predicted values for pi-electron spin densities on the radical as follows:

	C_1	C_2	O_3
ρ	0.758	0.048	0.194
a(G)	17.4	1.1	

On substituting a value $a_1=17.0$ G into Eq. (1), the spin density on C_1 is found to be 0.739, which shows good accordance with the calculated value.

The angle, θ_1 and θ_2 for the methylene proton can be calculated from Eq. (2) by using the values $a_{\beta_1}=30.0$ G, $Q_\beta=29.3$ G, and $\rho_\alpha=0.739$, which gives the values 34° and 86°, respectively. As a result, the angle $\theta_2=86°$ leads to a value $a_{\beta_2}=0.22$ G. The computed curve is shown in Fig. 3c.

Application of the values $\rho_\alpha=0.739$ and $\Delta(CH_2OH)=0.079$ to the Eq. (3) leads to a value $\Delta(CHO)=0.198$, which may be compared with the value $\Delta(CRO)=0.162$ given by Fischer.[8]

Summary and Conclusion

We have attempted to study by the ESR method the reaction of an OH radical in α,β-unsaturated aldehyde at low temperature. It has been found that abstraction of a methyl hydrogen by an OH radical occurs in crotonaldehyde, whereas β-addition of an OH radical to an olefinic bond takes place in methacrolein and acrolein. A formyl hydrogen seems to be unreactive with an OH radical in any case. Further work will be necessary to determine what factors are in favor of abstraction or addition especially in crotonaldehyde and methacrolein.

The values of pi-electron spin-densities obtained by the molecular orbital calculation using McLachlan procedure have shown good accordance with those estimated from experimental data on the radicals in crotonaldehyde and acrolein. Application of Fischer's treatment has been helpful for discussions on spin densities and hfs constants.

The authors wish to express their thanks to Professor Kozo Hirota for his encouragement throughout this study.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 2212—2219 (1969)

Anharmonic Potential Constants and Vibrational and Rotational Parameters for Hydrogen Cyanide

Toru NAKAGAWA and Yonezo MORINO

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo

(Received January 31, 1969)

The general fourth-order potential constants, f, for hydrogen cyanide were determined by a least-squares analysis applied to the observed values of the vibrational energies and the rotational constants for six isotopic species, $H^{12}C^{14}N$, $H^{13}C^{14}N$, $H^{12}C^{15}N$, $D^{12}C^{14}N$, $D^{13}C^{14}N$, and $D^{12}C^{15}N$. The normal frequencies, ω_i, the cubic and quartic potential constants, k_{ijk} and k_{ijkl}, the anharmonicity constants, x_{ij}, the vibration-rotation interaction constants, α_i, and the Coriolis coupling constants, ζ_{ij}^{x} were calculated for the six isotopic species.

The determination of the intramolecular potential function is one of the most important problems in molecular spectrosocpy. Once this has been done, various properties of molecules can be coordinated in a unified way upon this fundamental function. Suzuki, Pariseau, and Overend[1] determined the cubic and quartic potential constants for hydrogen cyanide by means of a least-squares fit to the observed values of the vibrational energies, ν, and the rotational constants, B_v, in various vibrational states. Though they used 87 observed values for two isotopic species, $H^{12}C^{14}N$ and $D^{12}C^{14}N$, the final values of the *nineteen* parameters still have intensive mutual correlations. Accordingly, a further refinement of the potential function is very desirable if one wants to predict various properties based on the potential function. Since the observed values of ν and B_v are available for four other isotopic species, *i. e.*, $H^{13}C^{14}N$, $H^{12}C^{15}N$, $D^{13}C^{14}N$, and $D^{12}C^{15}N$, they are also used in the least-squares analysis in the present study; the number of the observed values has increased to 124.

Another aim of the present study is to obtain the vibrational and rotational parameters, such as ω_i, k_{ijk}, k_{ijkl}, x_{ij}, and α_i and to predict the vibrational energies, ν, and the rotational constants, B_v, in various vibrational states of the six isotopic species. The uncertainties of these predicted values are also estimated on the basis of the probable errors of the potential constants, f, and their mutual correlation. It should be noticed that the estimated uncertainties of the calculated values will often become unreasonably large unless the correlations among the f constants are taken into account.

Determination of Anharmonic Potential Constants

The method described in our previous paper[2] on the anharmonic potential constants of OCS was applied to the present least-squares calculation as follows.

Observables. The observed values of the vibrational energies, ν, and the rotational constants, B_v-B_0, for the six isotopic species used in the least-squares fit are listed in Columns 2 and 6 of Table 1, together with their references.[3-10] The values for higher vibrational levels with $v_1+\frac{1}{2}v_2+v_3>4$ were not used in the analysis in order to avoid the influence of higher-order terms and accidental perturbations.

Parameters. The variable parameters to be determined were the nineteen potential constants, f, up to the fourth order in the expansion formula of:

$$V = \frac{1}{2}f_R\Delta R^2 + f_{Rr}\Delta R\Delta r + \frac{1}{2}f_r\Delta r^2 + \frac{1}{2}f_\alpha\Delta\alpha^2 + f_{RRR}\Delta R^3 + f_{RRr}\Delta R^2\Delta r + f_{Rrr}\Delta R\Delta r^2 + f_{rrr}\Delta r^3 + f_{R\alpha\alpha}\Delta R\Delta\alpha^2$$

$$+ f_{raa}\Delta r\Delta\alpha^2 + f_{RRRR}\Delta R^4 + f_{RRRr}\Delta R^3\Delta r + f_{RRrr}\Delta R^2\Delta r^2 + f_{Rrrr}\Delta R\Delta r^3 + f_{rrrr}\Delta r^4 + f_{RRaa}\Delta R^2\Delta\alpha^2 + f_{Rraa}\Delta R\Delta r\Delta\alpha^2 + f_{rraa}\Delta r^2\Delta\alpha^2 + f_{aaaa}\Delta\alpha^4, \quad (1)$$

where ΔR and Δr denote the stretching displacements of the CN and CH bonds respectively, and $\Delta\alpha$, the bending displacement. The force constants obtained by Suzuki, Pariseau, and Overend[1] were used as the initial values for the least-squares refinement. No account was taken of the resonance interactions, such as the Fermi resonance ($\omega_1 \sim 2\omega_2$ and $\omega_3 \sim 2\omega_2$) and a third-order anharmonic resonance ($3\omega_1 \sim 2\omega_3$). The equilibrium bond lengths were assumed to be $R_e(\mathrm{CN}) = 1.15313$ Å and $r_e(\mathrm{CH}) = 1.06593$ Å, according to Rank, Skorinko, Eastman, and Wiggins.[4]

Statistical Weights. The weights of ν and B_v in the least-squares analysis were evaluated by taking into account the uncertainties due to higher-order terms as well as the experimental uncertainties, according to the procedure suggested in our preceding paper.[2] The uncertainties of the former type were estimated on the basis that $\sigma_y^2 = 0.20\ (\mathrm{cm}^{-1})^2$ and $\sigma_r^2 = 0.08 \times (10^{-3}\ \mathrm{cm}^{-1})^2$ for HCN, and $\sigma_y^2 = 0.15 \times (\mathrm{cm}^{-1})^2$ and $\sigma_r^2 = 0.04 \times (10^{-3}\ \mathrm{cm}^{-1})^2$ for DCN. In Columns 5 and 9 of Table 1 the weights thus evaluated are shown in units of $(\mathrm{cm}^{-1})^{-2}$ and $(10^{-3}\ \mathrm{cm}^{-1})^{-2}$ respectively.

The calculation was carried out by using the computer program described in our preceding paper[2] on the HITAC 5020E computer at the Computer Centre, The University of Tokyo.

The general fourth-order portential constants determined are shown in Column 2 of Table 2, while their correlation factors are given in Table 3. The potential constants obtained in the present study are essentially the same as those obtained by Suzuki, Pariseau, and Overend,[1] but they are more precise than the latter, as may clearly be seen from the probable errors listed in Table 2. The calculated values of ν and $B_v - B_0$ are tabulated in Columns 3 and 7 of Table 1, and the deviations, in Columns 4 and 8.

Potential Constants in the Normal-Coordinate System and the Vibrational and Rotational Parameters

On the basis of the force constants, f, determined above, the potential constants, ω_i, k_{ijk}, and k_{ijkl}, in the normal-coordinate representation were calculated for the six isotopic species; the results are shown in Table 4. These calculated values have the advantage that the isotopic relations among them are fully taken into account. The standard errors for ω and k were evaluated according to Eq. (20) of Ref. 2, with account taken of the correlations among the f constants. The ω and k constants vary to a large extent for different isotopic species as a result of the change in normal coordinates. Table 5 shows the contributions of the f constants to the k constants; the main term is underlined for each k constant. One can see that the contributions of *bond-stretching* f constants are predominant in the cubic and quartic k constants, including even those related to the *bending* vibration. The contributions of the *cross* terms are much smaller

culated values of q_v and D_v are in good agreement with the observed values, as will be reported elsewhere.[11] This agreement offers positive support for the anharmonic potential constants obtained from ν and B_v in the present study.

Discussion

The two parameters a_3 and a_4 which are defined[12] by:

$$a_3 = -2f_{rrr}/f_r \tag{2}$$

and:

$$a_4 = [24f_{rrrr}/7f_r]^{1/2} \tag{3}$$

are convenient for expressing the bond-stretching anharmonicity. Their values for HCN are compared with those for CH and CN in Table 8. The table suggests that the potential function for a bond stretching in the HCN molecule is quite similar to that in the corresponding diatomic molecule, CH or CN.

As for the anharmonic resonance in HCN, an accidental perturbation of the $3\omega_1$—$2\omega_2$ type has been pointed out by Douglas and Sharma.[7] The perturbation of this type was disregarded in the present study without any serious effect on the potential constants determined above. This is because the perturbation mentioned above is significant only for highly-excited vibrational states, such as (00^04), (30^02), (10^04), and (40^02), and the weights of the observed values for these states were zero or small in the least-squares analysis.

Nevertheless, a problem was found in the present study concerning the Fermi resonance. In the present calculation the k_{122} and k_{223} terms were treated with a second-order perturbation theory without any special consideration of the Fermi resonances, $\omega_1-2\omega_2$ and $\omega_3-2\omega_3$. It was found, however, that the k_{122} and k_{223} constants thus obtained were not small enough compared with the energy differences, $\omega_1-2\omega_2$ and $\omega_3-2\omega_2$ respectively. Table 9 shows that the $|k_{stt}/(\omega_s-2\omega_t)|$ ratios for the $\omega_3-2\omega_2$ resonance of HCN and the $\omega_1-2\omega_2$ resonance of DCN are even larger than the ratio, 0.231, for the well-known case of the $\omega_1-2\omega_2$ resonance for OCS.[2] Rigorously speaking, these Fermi resonances must be treated separately from the usual perturbation calculation, as was done for OCS. According to such a treatment, some relations must be expected among the ν and B_v values; for instance:

$$B(02^00) - B_0 < 2[B(01^10) - B_0] \tag{4}$$

and:

$$B(02^20) > B(02^00). \tag{5}$$

The observed values, however, do not satisfy these relations. It seems likely that the discrepancies suggest the importance of such higher-order effects as the γ terms. In the present study no corrections for the third- and higher-order perturbation were taken into account; therefore, the exact diagonalization of the Fermi resonance terms remains to be done in the future.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 2220—2227 (1969)

A Study of the Low-temperature Oxidation of Cumene in the Presence of Triphenylsulfonium Chloride. Propagation and Termination Steps

Katsutoshi OHKUBO, Tokio YAMABE and Kenichi FUKUI

Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received February 3, 1969)

The low-temperature liquid-phase oxidation of cumene using triphenylsulfonium chloride was studied in order to establish the nature of the activity of sulfonium catalysts and the oxidation mechanism. The oxidation occurs in an autocatalytic fashion below 70°C, while it proceeds in an auto-retarding fashion above 85°C. This is a characteristic feature of this oxidation. The cause of the deactivation at higher temperatures is mainly the deoxygenation of the assumed complex (Cat.$\cdots O_2$). The decomposition of cumene hydroperoxide and the subsequent formation of α-cumyl alcohol, acetophenone, and dicumyl peroxide were seriously affected by the presence of sulfonium salts. The formation of acetophenone was accelerated thermally, while that of α-cumyl alcohol was not accelerated much, though it was accelerated by the catalyst-oxygen complex. Dicumyl peroxide, once formed in an appreciable amount, was gradually decomposed, both thermally and catalytically. The catalyst was deactivated by the product formed. This phenomenon was attributed to the masking action of oxygen-containing products. The mechanism oxidation was discussed on the basis of these observations.

Our previous reports[1,2] revealed the outstanding nature of sulfonium salts as a catalytic substance for the liquid-phase oxidation of cumene with molecular oxygen in the low-temperature range (55—85°C). This type of oxidation is initiated through hydrogen abstraction from cumene by a complex which is postulated to form as a consequence of the reversible association of molecular oxygen with the sulfonium catalyst.

$$\text{Cat.} + O_2 \rightleftarrows \text{Cat.}\cdots O_2$$

$$\text{Cat.}\cdots O_2 + RH \longrightarrow R\cdot + \cdot O_2H + \text{Cat.}$$

At the beginning of the reaction, the oxidation of this type proceeds in a simpler fashion; in this period the oxygen absorbed is almost quantitatively used in the formation of hydroperoxide. However, the propagation reaction is composed of several steps, in which not only hydroperoxide, but also acetophenone, dicumyl peroxide, and α-cumyl alcohol are produced in appreciable amounts.

In recent years, the mechanism of cumene oxidation at propagating and terminating steps has received considerable attention.[3-5] Certain aspects of the mechanism, however, still remain obscure. Namely, it has been left unclarified how the behavior of free radicals ($RO\cdot$, $RO_2\cdot$, $CH_3\cdot$, *etc.*) changes at different temperatures with or without catalysts in their competing reactions, including intramolecular ones. Moreover, much work has been done by means of kinetic methods, which usually do not afford much reliable information, in particular about the termination reaction. In addition, a majority of the experiments in these works were carried out at relatively high temperatures (100—200°C) with heterogeneous metal compound catalysts, which inevitably complicated the results. In this regard, the present experimental conditions are quite favorable to make the mechanism clear because of the homogeneity of the reacting system and because of the low temperature employed.

This paper will attempt to clarify the low-temperature oxidation mechanism of cumene with triphenylsulfonium chloride and the nature of its catalytic action by investigating the effects of the temperature and of catalysts upon oxygen absorption and oxidation products.

The present study gives some noticeable results: (1) The propagation reaction proceeds through the decomposition of cumene hydroperoxide, which is caused not so much thermally as by triphenylsulfonium chloride; (2) The formations of acetophenone and dicumyl peroxide are strongly influenced by the temperature, while that of α-cumyl alcohol is not so much affected by the temperature but is, rather, promoted by sulfonium salts; on the contrary, dicumyl peroxide is rather

decomposed by the catalyst; (3) The deactivation of the catalyst by certain oxidation products, especially by α-cumyl alcohol, is ascribed to thier masking actions, which retard the reaction.

Experimental

Material and Catalyst. Cumene was washed with concentrated sulfuric acid, dried on magnesium sulfate, and then rectified to collect the center fraction; bp 152.5°C, $n_D^{20}=1.4910$. The fraction was then filtered chromatographically through activated alumina (200—300 mesh) and stored under nitrogen at 0°C. As the oxidation catalyst, triphenylsulfonium chloride was synthesized by the method presented in our earlier report.[6]

Oxidation Procedure. Under a nitrogen atmosphere, triphenylsulfonium chloride and cumene (10 m*l*) were added to an oxidation flask (50 m*l* capacity) attached to a gas burette from which air was then evacuated and which was filled with oxygen several times. The oxidation flask was contained in a thermostated oil-bath, and oxygen absorption was followed in the way previously described.[2] The oxidation products were determined by the following analytical procedure.

Analytical Procedure. The main products, cumene hydroperoxide (CHP), dicumyl peroxide (DCP), acetophenone (AP), and α-cumyl alcohol (CA), were determined by the following methods.

Cumene Hydroperoxide (CHP). CHP was determined by an iodometric method which is essentially taken from Fordham and Williams,[7] but modified in the following points. A 0.5—2.0 m*l* portion of the oxidate was added to 5.0 m*l* of a saturated aqueous potassium iodide solution containing 10 m*l* of glacial acetic acid and 100 m*l* of isopropyl alcohol. The resultant mixture was flushed with nitrogen and then refluxed gently with occasional shaking for 3.0—4.0 min. The liberated iodine was titrated with a 0.1 N sodium thiosulfate solution until the yellow color disappeared. The amount of CHP was then determined from the difference between the titer of the blank and the oxidate-containing mixture.

Dicumyl Peroxide (DCP). A 0.5—1 m*l* portion of the oxidate was added to 50 m*l* of glacial acetic acid containing 3 g of sodium iodide, and then the entire mixture was heated in a nitrogen atmosphere at 110—115°C for 1 hr. After dilution by oxygen-free water (3.0 m*l*), the resulting iodine was titrated in nitrogen with a standard thiosulfate solution. The difference between this determination and that of CHP gave the amount of dicumyl peroxide.

Acetophenone (AP). AP was determined like the 2,4-dinitrophenylhydrazone; mp 248—249°C, mixed mp 249°C.

α-Cumyl Alcohol (CA). CA was determined as the reaction product with thioglycolic acid.[8]

The Solubility of Chlorides to Cumene. Commercially-pure alkali chlorides (LiCl, NaCl, KCl, RbCl, CsCl, and NH_4Cl) were calcined, fused, and then pulverized to about 200 mesh powder. The solubility of these chlorides and triphenylsulfonium chloride to cumene was determined by the following treatment. The chloride (500 mg) was added to cumene (50 m*l*); after the mixture had been vigorously stirred for one hour at two definite temperatures (20 ±0.5°C and 70±0.5°C), the upper layer (10 m*l*) of the mixture was titrated by an alcoholic solution of a N/100 silver nitrate solution, using potassium chromate as the indicator. Table 1 records the solubility of the chlorides to cumene.

Table 1. The solubility of various chlorides to cumene

Chloride (MCl) (M)	Solubility (mg-atom/100 mg of cumene)	
	Cl at 20±0.5°C	Cl at 70±0.5°C
Li	0.041	0.221
Na	0.017	0.116
K	0.017	0.116
Rb	0.029	0.150
Cs	0.029	0.231
NH_4	0.041	0.234
$(C_6H_5)_3S$	0.206	0.244

Results and Discussion

In the initial range of the reaction, the amount of oxygen absorbed is consumed only to form CHP, and the rate of its formation depends almost linearly upon the amount of the sulfonium catalyst.[2] In the propagation and termination steps, however,

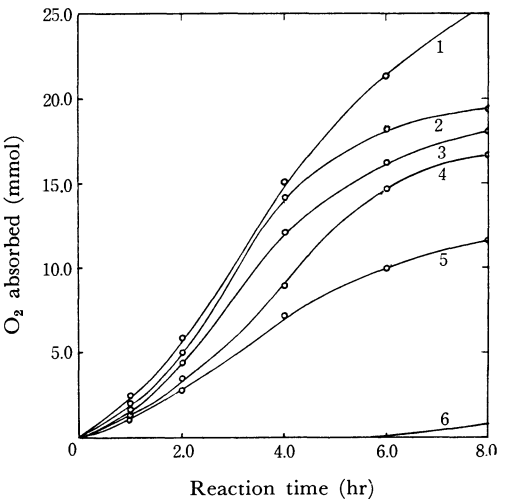

Fig. 1. The influence of the amount of triphenylsulfonium chloride on the oxygen absorption at 70°C.
The amount of $(C_6H_5)_3SCl$ (mmol/m*l*$\times 10^3$): 1, 36.85; 2, 26.80; 3, 16.65; 4, 10.05; 5, 3.35; 6, none

the hydroperoxide decomposes, both thermally and catalytically. The decomposition products (AP, DCP, and CA) complicate the oxidation mechanism. First, the catalytic effect of the sulfonium salt upon oxygen absorption and the composition of the oxidation products in these steps were investigated at 70 and 85°C. The oxygen absorption curves at 70°C in Fig. 1 indicate that the oxygen absorption of an autocatalytic nature increases monotonously with the amount of the catalyst. The dwindling of absorption began after *ca.* 4 hr, and the retardation appeared about 8 hr after the start. Therefore, the oxidation products after 4.0 and 8.0 hr may afford information about the propagation and the termination processes respectively. This point will be discussed below.

The decrease in oxygen absorption may be attributed to the deactivation of the catalyst, itself probably caused by the masking action of the accumulated CHP, as was discussed in our previous report.[2] Actually, the rates of absorption declined upon the addition of CHP, as is shown in Table 6. This may be connected with the fact that sulfonium catalysts are easily dissolved in polar solvents, especially those containing oxygen lone-pairs, which might cause a strong interaction with sulfonium ions. Namely, such molecules as CHP blocking the active sites of sulfonium ions may prevent oxygen molecules from approaching there; hence, they may depress the catalytic activity. This masking action of CHP might be assisted by the association of the hydroperoxides through hydrogen-bonds between them.*1 The circumstances of the masking action are illustrated schematically in Fig. 2.

Table 2 indicates that the accumulation of CHP diminishes in proportion to the amount of the catalyst. In fact, in the absence of any catalyst, CHP is preserved from secondary changes almost completely, even a 17.5 hr reaction. This fact suggests that CHP is decomposed essentially catalytically, whereas it is little converted thermally. Actually, the sulfonium catalyst decomposes CHP exclusively in this temperature range; this will be discussed in detail in a subsequent paper.

Mention should be made here of the decomposition of CHP. There are three possible paths to be considered for the generation of α-cumyloxy radicals, the main source of the formation of products. The first one is the unimolecular thermal decomposition:

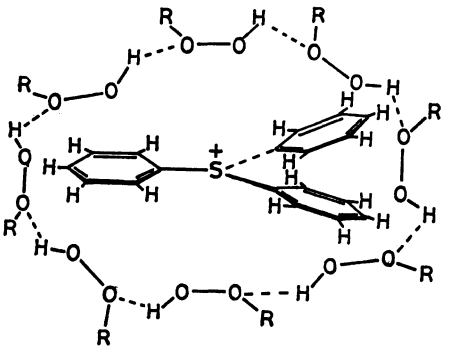
$$\mathrm{ROOH} \xrightarrow{\text{unimol. decomp.}} \mathrm{RO}\cdot + \cdot\mathrm{OH} \qquad (1)$$

This is, however, hardly conceivable, because CHP is sufficiently stable in hydrocarbons up to 130—140°C.[10]

The second is the following bimolecular decomposition through dimer formation by the hydrogen bond when the concentrations of CHP are high:

$$2\mathrm{ROOH} \rightarrow \left[\mathrm{RO\cdots O\cdots H\cdots O_2R}\right] \xrightarrow{\text{bimol. decomp.}} \mathrm{RO}\cdot + \mathrm{RO_2}\cdot + \mathrm{H_2O} \qquad (2)$$

This implies that the hydrogen-bond formation



$R = C_6H_5C(CH_3)_2-$

Fig. 2. A proposed model for the makings effect of CHP on triphenylsulfonium ion catalyst.

TABLE 2. EFFECT OF CATALYST AMOUNT UPON CHP FORMATION AT 70°C

Catalyst amount (mmol/ml $\times 10^3$)	Reaction time (hr)	O_2 absorbed (mmol)	CHP (mmol)	CHP (%)*

* Calculated as mol CHP per 100 mol oxygen absorbed.

*1 In fact, Bateman and Hughes,[9] in their study of the infrared spectrum of cyclohexenyl hydroperoxide, showed that, in a diluted hydroperoxide solution in benzene, OH groups appear at 3500 cm^{-1}, while in an undiluted solution they appear at 3350 cm^{-1}; this apparently indicates the formation of intermolecular hydrogen bonds between them.

promotes the fission of the oxygen-oxygen bond of CHP.*2 At any rate, the thermal decomposition of CHP in cumene is actually very small in the temperature range of 60—80°C.*3

Hence, the only reasonable path is the third one (reaction (3)). This may, then, be proposed as the main reaction giving α-cumyloxy radicals. A more detailed discussion of this will be presented in a subsequent paper.

$$\mathrm{ROOH} + (\mathrm{C_6H_5})_3\mathrm{SCl} \rightarrow \left[\mathrm{R}\diagup\mathrm{O}\cdots\overset{\overset{\mathrm{H}^+}{\diagup}}{\mathrm{O}}\cdots\mathrm{S}(\mathrm{C_6H_5})_3\cdots\mathrm{Cl}^- \right]$$

$$\rightarrow \mathrm{RO}\cdot + \cdot\mathrm{OH} + (\mathrm{C_6H_5})_3\mathrm{SCl} \qquad (3)$$

Products of Oxidation. The α-cumyloxy radicals thus formed are readily converted to the major products through chain-transfer reactions (4a and 4b) or a chain-terminating reaction (4c).

$$\mathrm{RO}\cdot \xrightarrow[\mathrm{RH}]{\text{hydrogen abstraction}} \mathrm{ROH(CA)} + \mathrm{R}\cdot \qquad (4a)$$

$$\mathrm{RO}\cdot \xrightarrow{\beta\text{-scission}} \mathrm{AP} + \mathrm{CH_3}\cdot \qquad (4b)$$

$$\mathrm{RO}\cdot \xrightarrow[\mathrm{RO}\cdot]{\text{coupling}} \mathrm{ROOR(DCP)} \qquad (4c)$$

$$(\mathrm{R} = \mathrm{C_6H_5C(CH_3)_2}-)$$

CA Formation. Among these products, CA was apparently formed in an amount comparable with those of AP and DCP, as is shown in Table 3. This fact is worthy of emphasis since CA formation through hydrogen abstraction by RO· from cumene is difficult in low-temperature thermal oxidation without a catalyst, even if cumene is a good hydrogen donor. This is supported by the study of Blanchard[11] on cumene oxidation at 60°C by the use of α,α'-azodiisobutyronitrile, in which CA is formed only in an extremely small amount compared with AP and DCP. Table 3 also shows, however, that the accumulation of CA gradually lessened, whereas that of AP increased remarkably, as the reaction proceeded.

Such a remarkable CA formation as is described above may be attributed to the co-existence of oxygen and the catalyst. This is because the amount of CA is very small in the thermal and catalytic decomposition of CHP in cumene at 65°C without oxygen.*4 Therefore, it may be taken into account that molecular oxygen would participate in the CA formation as a natural consequence of its free radical character in the following "concerted" single-step process:

$$\mathrm{RO}\cdot + \mathrm{RH} + \mathrm{O_2} \xrightarrow[\text{liquid phase}]{} \mathrm{ROH} + \mathrm{RO_2}\cdot \qquad (5)$$

A possible alternate pathway may be a consequent process which comprises:

$$\mathrm{RH} + \mathrm{O_2} \rightarrow \mathrm{R}\cdot + \mathrm{HO_2} \qquad (5a)$$

$$\mathrm{RO}\cdot + \mathrm{HO_2}\cdot \rightarrow \mathrm{ROH} + \mathrm{O} \qquad (5b)$$

If we simply assume that the activation energy of the reverse process of (5a) is small, then, accordingly, the activation energy for (5a) is equal to the heat of this step—it is estimated to be about 38 kcal/mol.*5 This value is nearly equal to the energy of the oxygen-oxygen bond cleavage of CHP. Considering the fact that the thermal decomposition of CHP does not take place below 100°C, the reaction (5a) is also unlikely to occur appreciably at similarly low temperatures. The circumstances are almost same for the former mechanism (5), since, from the energetic point of view, (5) might be not so very different from the combination of the reactions (5a) and (5b).

As a matter of fact, the hydrogen abstraction from RH by O_2 is difficult without activation, as in the form of (Cat.$\cdots O_2$), as was reported in the previous paper.[2] However, this "activated form" of oxygen may also promote the formation of CA as might be readily expected from the ability of hydrogen abstraction of activated O_2. This point has already been discussed.[1,2]

$$\mathrm{RO}\cdot + \mathrm{RH} + \mathrm{Cat.}\cdots\mathrm{O_2} \rightarrow \mathrm{ROH} + \mathrm{RO_2}\cdot + \mathrm{Cat.} \qquad (6)$$

On the other hand, we may consider the process to be divided into three elementary steps:

$$\mathrm{RH} + \mathrm{Cat.}\cdots\mathrm{O_2} \rightarrow \mathrm{R}\cdot + \mathrm{Cat.} + \mathrm{HO_2}\cdot \qquad (6a)$$

$$\mathrm{RO}\cdot + \mathrm{HO_2}\cdot \rightarrow \mathrm{ROH} + \mathrm{O_2} \qquad (6b)$$

$$\mathrm{R}\cdot + \mathrm{O_2} \rightarrow \mathrm{RO_2}\cdot \qquad (6c)$$

Reaction (6) would be very easy because of its small activation energy (below 5.25—6.15 kcal/mol).[2] Therefore, reaction (6) is considered to be more plausible than (5) for the mechanism of CA formation. The saturation phenomena in the CA

*2 Reaction (2) is supported by the study of Bateman and Hughes[9] on olefin oxidation, in which the bimolecular mechanism appears at a temperature lower than about 80°C.

*3 Following our preliminary experiments, the thermal decomposition of CHP (22.5 mmol) in cumene (20 ml) occurred in the amounts of 0.50 mmol for 10.3 hr and 1.20 mmol for 9.0 hr at 65 and 80°C respectively.

*4 0.50 mmol of CHP was subjected to thermal decomposition to produce 5.2 mol% of CA and 63.8 mol% of AP after 10.3 hr, while 12.5 mmol of CHP was decomposed by the use of the sulfonium catalyst to produce 9.6 mol% of CA and 41.2% of AP.

*5 The bond dissociation energies of H-O_2. and R-H are 47.1 ± 2 kcal[12] and 85 kcal respectively. Therefore, the activation energy of the reaction (5a) is estimated to be *ca.* 38 kcal. On the other hand, by the use of the D(H-O_2·)=36 kcal/mol estimated by Uri,[13] it is estimated to be *ca.* 49 kcal/mol.

formation as the reaction proceeds, as may be observed in Table 3, may thus be explained by the deactivation of the catalyst as a result of the masking action of the products.

Traylor and Russell[5] emphasized that CHP was a better hydrogen atom source than cumene, proposing the reaction:

$$RO\cdot + ROOH \rightarrow ROH + RO_2\cdot \qquad (7)$$

on the basis of the fact that CH_3OD was isolated from the decomposition of deuterated hydroperoxide (CH_3OOD).[14] However, the bond-dissociation energy of ROO–H (~89.5 kcal[15]) is rather larger than that of hydrocarbon (RH) (~85 kcal). This implies that reaction (7) is not easier than (4a), particularly at low temperatures. Moreover, reaction (7) is not probable at low concentrations of the hydroperoxide.

Further possible paths to CA, for example, $CH_3O_2\cdot + RO_2\cdot \rightarrow CH_2O + ROH + O_2$, seem not to be dominant for a reason to be discussed later.

AP Formation. Acetophenone (AP) is formed through a β-scission of the methy radical, (4b). Reaction (4b) is predominant rather than reaction (4a), as is indicated in Table 4. The difference in activation energies (about 7.3 kcal) between (4a) and (4b) was also reported by Bailey and Godin.[16]

Formation of DCP. Under the conditions of low-temerature oxidation, a chain-terminating step by coupling, (4c), is also to be taken into account. DCP is thermally stable at 70—85°C, but it should be noticed that the scission of the O–O linkage of common peroxides is easier than that of hydroperoxides. The activation energy of the O–O bond fission of dialkyl peroxides (~36.2 kcal[17]) is smaller than that of alkyl hydroperoxide (~38.5 kcal[18]). Actually, the rate of the thermal decomposition of DCP is found to be appreciably faster than that of CHP.[18] As is shown in Table 3, the amount of DCP decreases as the reaction proceeds, corresponding to the decomposition of DCP accumulated.

18) A. V. Tobolsky and R. B. Mesrobian, "Organic Peroxides," Interscience Publishers, New York (1954), pp. 88—89.

Table 4 indicates that the catalyst lessens the formation of DCP. Here it must be remarked that the catalyst accelerates the decomposition of CHP to produce RO·. Accordingly, it may rather be expected that the DCP formation would increase on that account, especially at a low temperature, provided that the catalyst does not force the decomposition of DCP. In reality, DCP is considerably decomposed by the catalyst in cumene without O_2 at 85°C, forming AP predominantly and also CA in an appreciable amount,*6 whereas thermally the decomposition is far smaller.

$$ROOR \xrightarrow{\text{sulfonium catalyst}} 2RO\cdot \rightarrow \text{(4a) or (4b)} \quad (8)$$

The decomposition of DCP is, therefore, one of the pathways to AP and CA.*7 The thermal decomposition of DCP in cumene has been studied by Bailey and Godin,[14] who reported that the ratio of AP to CA varied from 0.68 to 1.95 in the range from 111.2°C to 160°C. This phenomenon may suggest that AP formation is more strongly accelerated by the temperature than is CA formation. This point will be discussed again later.

Formation of RO_4R. Mention should be made here of the possible coupling of cumylperoxy radicals ($RO_2\cdot$) to form unstable intermediates (RO_4R).*8

$$RO_2\cdot + RO_2\cdot \longrightarrow \left[R-O-\overset{\overset{O}{\uparrow}}{O}-\overset{\overset{O}{\uparrow}}{O}-R \right] \longrightarrow 2RO\cdot + O_2 \quad (9)$$

The RO· radical produced will undergo reactions according to the three schemes (4a), (4b), and (4c).

Besides the process (4c), there seems to be another direct route to ROOR possible, as has been pointed out by Russel[19] in the case of secondary alkyl tetroxide:

$$RO_4R \rightarrow ROOR + O_2 \quad (10)$$

Boozer and his co-workers[21] suggested the following reaction in their study using deutrocumene at 65°C:

$$RO_4R \rightarrow ROOH + C_6H_5C(CH_3)=CH_2 + O_2 \quad (11)$$

This reaction is, however, doubtful in the present case because no α-methylstyrene is detected in our experiments. The unreliability of reaction (11) can also be concluded in view of the result of an ^{18}O-tracer study by Bartlett[3] of the recombination of the cumyloxy radical.

Behavior of the Methyl Radical. Methyl radicals are produced through the β-scission of RO·. They are converted to the peroxy radical in the following way:

$$CH_3\cdot + O_2 \rightarrow CH_3OO\cdot \quad (12)$$

Other possibilities for the disappearance of $CH_3\cdot$ involve various chain-transferring and chain-terminating reactions:

$$CH_3\cdot + RH \rightarrow CH_4 + R\cdot \quad (13a)$$

$$CH_3\cdot + ROOH \rightarrow CH_4 + RO_2\cdot \quad (13b)$$

$$CH_3\cdot + CH_3\cdot \rightarrow C_2H_6 \quad (14)$$

$$CH_3\cdot + RO\cdot \rightarrow CH_3OR \quad (15)$$

$$CH_3\cdot + RO_2\cdot \rightarrow CH_3OOR \quad (16)$$

Of these, (15) and (16) are not likely in the present low-temperature oxidation since neither cumylmethyl ether nor cumylmethyl peroxide was detected. Also, reaction (14) may be discarded in this case because of the low concentration of $CH_3\cdot$ radicals. Consequently, the hydrogen abstraction reactions, (13a) and (13b), seem to be almost the only pathway of $CH_3\cdot$ consumption.

The activation energy of (13a) is relatively small.*9 Actually, methane is detected in the decomposition of CHP by triphenylsulfonium chloride at 65°C.*10 Also, reaction (13b) can not be disregarded. Kharasch and his co-workers have confirmed the methane formation from thermal decomposition of CHP in decane at 140°C. In that case, however, decane can not be a good hydrogen source. In the present case, (13a) seems to be preferable.

In the presence of an appreciable amount of molecular oxygen, however, reaction (12) might be preferable to (13). The behavior of methyl-

*6 92% of the DCP (initial amount=22.5 mmol) in cumene is decomposed by triphenylsulfonium chloride (22.5 mmol) in about 11.0 hr at 85°C, thus forming AP (52.3%) and CA (36%), but thermally it decomposes only about 34% of the initial amount during the same reaction time.

*7 DCP melts at 39°C and is less stable than CHP. The scission of the O-O bond of DCP has a smaller energy of activation (34.5 kcal/mol)[16] than that of CHP (~38 kcal).

*8 The formation of RO_4R was first proposed by Russell[19] for *s*-alkylperoxy radicals. The transitory existence of this intermediate has also been supported by Milas and Djokic[20] in their study of the ozonization of potassium *t*-perbutoxide. A crystalline solid isolated at −78°C, which might be expected to be di-*t*-butyl tetroxide, decomposed spontaneously at −30 to 0°C to give equivalent amounts of di-*t*-butyl peroxide and oxygen molecules. The possibility of the presence of RO_4R is suggested by a recent thermochemical calculation by Benson.[11]

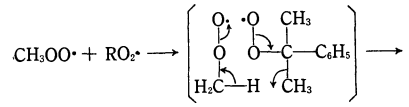
*10 Some CHP (4.50 mmol) in cumene (20 ml) is decomposed by $(C_6H_5)_3SCl$ (0.27 mmol) for 9.0 hr to produce about 30 mol% of methane.

peroxy radicals thus formed is still obscure. Traylor and Russell[5] have proposed the following path:

$$CH_3OO\cdot + RO_2\cdot \rightarrow CH_2O + ROH(CA) + O_2 \quad (17)$$

In the low-temperature oxidation, however, CA formation is depressed remarkably, as has been reported by Blanchard,[11] while AP is produced dominantly. If all of the methyl radicals formed are converted to methylperoxy radicals according to reaction (12), the amount of CA should, stoichiometrically, be not less than that of AP. In reality, however, the quantity of CA is much less than that of AP. By means of scheme (17) only, this fact can not be explained. Another route to AP may, for instance, be of the following type:



$$CH_2O + AP + CH_4 + O_2 \quad (18)$$

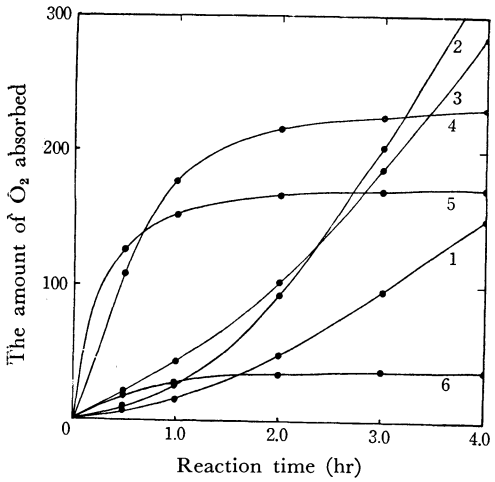


Fig. 3. temperatuee effect on oxygen absorption by the use of $(C_6H_5)_3SCl$ (16.65×10^{-3} mmol/m*l*). 1: 55°C; 2: 65°C; 3: 70°C; 4: 80°C; 5: 100°C; 6: 120°C

Such a concerted, complicated process may be possible in the solvent cage, just as in the case of Eq. (9).

Temperature Effect. The present experiment was carried out in the temperature range from 55 to 85°C; in this range sulfonium catalysts are relatively stable. In order to specify the influences of temperature on the oxidation process, a higher-temperature range up to 120°C was also employed. Figure 3 indicates that the reactions below 70°C are clearly autocatalytic, while those above 80°C are auto-retarding. The latter ones may be ascribed to the deoxygenation of the catalyst-oxygen complex according to the increase in the temperature*11 and by means of the masking action of products. The variation in the products with the reaction temperature is indicated in Table 5. The decrease in CHP with the temperature is remakable, while AP and CA apparently increase as the temperature rises, the former more than the latter. Such a difference in the temperature effect of AP and CA is reasonable. The former arises from an intramolecular reaction of RO· in which the vibrational cleavage of the carbon-methyl bond takes place as a result of the participation of adjacent π orbitals. The latter is produced by an intermolecular hydrogen abstraction from RH; the rate of such a process may be controlled by the steric hindrance of two bulky reactants. The temperature dependence of the (AP/CA) ratio has been found to be 7.3 kcal.[16] In the present catalytic process, it is noted that the CA formation through reaction (6) is also depressed with the increase in the temperature as a result of the deoxygenation of the catalyst complex.

Additive Effect. The deactivation of the sulfonium catalyst, possibly caused by a masking action of oxidation products, is deduced from the effect of various additives on the rate of oxygen absorption. Table 6 displays the decrease in the initial maximum rate[2] of oxygen absorption and the lengthening of the induction period. The decrease in the rate is particularly remarkable in

TABLE 5. EFFECT OF TEMPERATURE UPON PRODUCT COMPOSITION
(catalyst amount: 16.65×10^{-3} mmol/m*l*; reaction time: 4.0 hr)

Reaction temperature (°C)	O_2 absorbed (mmol)	Weight increase (mg)	CHP (%)*	DCP (%)*	AP (%)*	CA (%)*
55	6.26	166.9	78.3	6.37	8.10	7.8
65	13.1	247.8	60.7	5.42	21.1	12.6
80	9.46	315.4	38.47	11.7	34.4	20.8
100	6.58	—	4.57	—	56.0	28.5
120	1.25	13.1	1.44	17.0	63.2	26.2

* Per cents of CHP, AP and CA are defined by (mol of compound found)/(mol O_2 absorbed), DCP (%) is defined by $2\times$(mol of DCP found)/(mol of O_2 absorbed).

*11 The large optical density of the absorption band of a possible methyl-cyclohexane-oxygen complex is observed at lower temperatures (H. Tsubomura and R. P. Lange, *J. Chem. Phys.*, **36**, 2155 (1962)).

the case of CA. The reason may be the masking action of the additives through their shielding of *d* orbitals of the catalyst, as has been described previously.[1,2] It has been ascertained that the sulfonium catalysts are not decomposed by these reaction products.[1]

Table 6. The effect of addition of product molecules upon initial maximum rate[a] and the length of induction period at 70°C (catalyst amount 3.35×10^{-4} mmol/ml)

Product	Amount (mmol)	Rate (max.) (mol l^{-1} $sec^{-1}\times10^4$)	Induction period[b] (sec)
None	—	1.76 (0.29)*	0 (450)*
CHP	6.75	1.12 (0.31)*	70 (300)*
	9.00	1.04	75
	18.0	0.64	180
DCP	6.75	1.54 (0.33)*	40 (270)*
	18.0	1.50	60
AP	1.70	0.894 (0.26)*	30 (480)*
	4.28	0.745	70
	8.55	0.706	120
	17.0	0.297	190
CA	1.70	0.12 (0.19)*	360 (600)*
	4.28	0.00	—

a) The maximum rate appeared at the initial step in the oxidation[2] using $(C_6H_5)_3SCl$.
b) The period was determined as the time passed from the start of oxygen absorption.
* The values in the parentheses were those obtained without use of catalyst. In this case, the maximum rate was calculated from the oxygen absorption curve at the reaction time of 1.0 hr.

Table 7. The amount of oxygen absorbed and cumene hydroperoxide content in the oxidation of cumene saturated with various chlorides (reaction temperature: 70°C; reaction time: 8.0 hr)

Catalyst (MCl) (M)	O_2 absorbed (mmol)	CHP (%)[a]
Li	18.2	35.6
Na	0.64	98.7
K	1.27	100
Rb	1.36	98.5
Cs	1.48	96.6
NH_4	0.43	100
$(C_6H_5)_3S$	18.6	50.6
None	5.73[b]	98.2

a) Calculated as mol CHP per 100 mol oxygen absorbed.
b) Reaction time was 17.5 hr.

It should be taken into account that the effect of product addition appears even in autoxidation without a catalyst. The promoting effect observed in the cases of CHP and DCP might be attributed to their action as initiators. Inhibitory action of CA (and, less remarkably, of AP) in thermal processes is observed, but the extent never exceeds the usual alcohol effect.[23] It is of interest that the catalyst activity of triphenylsulfonium chloride is almost independent of the chloride anion concentration. Table 7 compares the catalytic activities of various alkali chlorides and triphenylsulfonium chloride in the oxidation of cumene saturated with them. The oxygen absorption is never in proportion to the content of the chloride anion, a proportion to be expected from Table 1.*12

Summarized Scheme of the Reaction. In conclusion, the reaction mechanism is summarized schematically in Fig. 4 for help in understanding it.

The Mechanism of the Scintillation from a Benzene Solution of *p*-Terphenyl

Tsunenari SAITO and Shin SATO

Department of Applied Physics, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received February 4, 1969)

The luminescence from a benzene solution containing *p*-terphenyl induced by γ-ray irradiation has been compared with that induced by UV irradiation at 2500 Å in the presence of various quenchers. The quenching efficiencies of electron and positive ion scavengers (SF_6, N_2O, CO_2 and NH_3) were found to be greater for the γ-ray excitation than for the UV excitation, while 1,3-butadiene, which is known as a quencher for excited benzene, ($^1B_{2u}$), showed almost the same efficiency for both modes of excitation. These results suggest that, even in a benzene solution, a series of ionic reactions is partly responsible for the formation of the scintillating state of *p*-terphenyl, and that the apparent quenching effect of ion scavengers is mainly due to their interference in the formation of the excited state of the benzene which is produced by the recombination reaction between the benzene cation and an electron. It was estimated that more than 30% of the excited state of benzene is formed by the recombination reaction.

In previous papers[1] we have shown that the luminescence from a cyclohexane solution containing *p*-terphenyl (*p*TP) irradiated with γ-rays is quenched by electron and positive ion scavengers and have suggested that the following ionic processes occur in this scintillator solution:

$$C \begin{cases} \xrightarrow{\sim\sim} C^+ + e & (1) \\ \xrightarrow{\sim\sim} C^* & (2) \end{cases}$$

$$T + e \rightarrow T^- \quad (3)$$

$$T + C^+ \rightarrow T^+ + C \quad (4)$$

$$T^- + C^+ \rightarrow T^* + C \quad (5)$$

$$T^+ + e \rightarrow T^* \quad (6)$$

$$T^+ + T^- \rightarrow T^* + T \quad (7)$$

Here, C, T, and T* denote cyclohexane, *p*TP, and a scintillating state of *p*TP respectively. The conclusions obtained in the previous papers are that the reaction (2) does not much contribute to the luminescence, and that the scintillating state of *p*TP is mainly formed by the neutralization reactions of the anions or cations of *p*TP. A similar conclusion has recently been reached by several groups of investigators. Thomas *et al.* used a pulse technique to elucidate the origin of the triplet state of scintillator molecules,[2] Ludwig analyzed the decay curve of the γ-ray induced luminescence in terms of ionic reactions,[3] and Hentz and Knight[4] used an electron-scavenging method similar to ours.

The present paper will show the results obtained by using a benzene solution containing *p*-terphenyl as a scintillator solution and will discuss the role of charged species in the γ-ray induced luminescence. Hitherto, many investigations have been carried out on this scintillator solution, but most of the investigations have not paid any attention to the participation of charged species in the mechanism of the scintillation.

Experimental

Dotite Spectrosol benzene and scintillation-grade *p*TP supplied by the Nakai Chemical Co. were used without purification. Nitrous oxide, ammonia, sulfur hexafluoride, 1,3-butadiene, and carbon dioxide purchased from the Takachiho Trading Co. were used after bulb-to-bulb distillation. The cyclohexane was purified in a manner described previously.[1]

Figure 1 shows the arrangement of the apparatus for measuring the intensity of the luminescence from a solution. A Toshiba UV-31 filter was inserted between the solution vessel and a photomultiplier (Toshiba SY-99) in order to cut off the luminescence from benzene itself. The source of γ-rays was 1.3 mCi-^{60}Co sealed in a glass tube. As the UV light sources at 3100 Å and 2400—2600 Å, a Hitachi hydrogen discharge lamp and a Beckman monochromator were used. When we

used the lights at 3100 Å, which excite only *p*TP molecules in a solution, the arrangement of the apparatus was changed so that the excitation beam could not directly enter the photomultiplier. When the UV lights used were in the 2400—2600 Å range and the apparatus was arranged as is shown in Fig. 1, essentially all the light impinging into the vessel was absorbed by benzene, since the concentration of *p*TP used in this experiment did not exceed 4.0×10^{-4} moll^{-1}, while the ratio of the optical density of benzene to that of *p*TP at 2400 Å was 250 : 1. In preparing the solutions, benzene containing a certain amount of *p*TP was degassed by freeze-and-thaw cycles in a mercury-free high-vacuum manifold. The concentration of an added gas in a solution was calculated by using the Ostwald absorption coefficient separately measured. The method of the measurement has already been described.[1] The Ostwald absorption coefficients in benzene obtained at 30°C were as follows: 2.7 for nitrous oxide, 0.67 for sulfur hexafluoride, 2.4 for carbon dioxide, and 7.5 for ammonia. 1,3-Butadiene was assumed to be completely soluble.

In order to ascertain the reactivity of electrons to nitrous oxide and sulfur hexafluoride in benzene, the *G*-value of the nitrogen from a benzene solution of nitrous oxide in the presence of sulfur hexafluoride was measured by using a method previously described.[5,6]

Results

Direct Excitation of *p*-Terphenyl. Figure 2 summarizes the effects of electron and positive ion scavengers and 1,3-butadiene on the luminescence from a cyclohexane solution of *p*-terphenyl when excited by light at 3100 Å. These experiments were carried out in order to establish whether or not any direct interaction between excited *p*TP and quenchers exists. Obviously, all the ion scavengers do not interact with the scintillating state of *p*TP, but 1,3-butadiene does a little, as was expected. The data obtained with 1,3-butadiene were well in accord with the Stern-Volmer relation (I):

$$I_0/I = 1 + \gamma[Q] \qquad (I)$$

The constant, γ, was obtained to be 0.68 $l$mol^{-1}. Here, [Q] denotes the concentration of the quencher.

excited by light at 2500 Å and by γ-rays are plotted as a function of the nitrous oxide concentration. The concentrations of pTP used were 4.4×10^{-3} and 4.0×10^{-4} moll^{-1}. Here, two points should be noticed. First, the quenching ability of nitrous oxide under γ-rays is much greater than that under the UV lights. Second, the quenching ability does not depend much on the concentration of pTP.

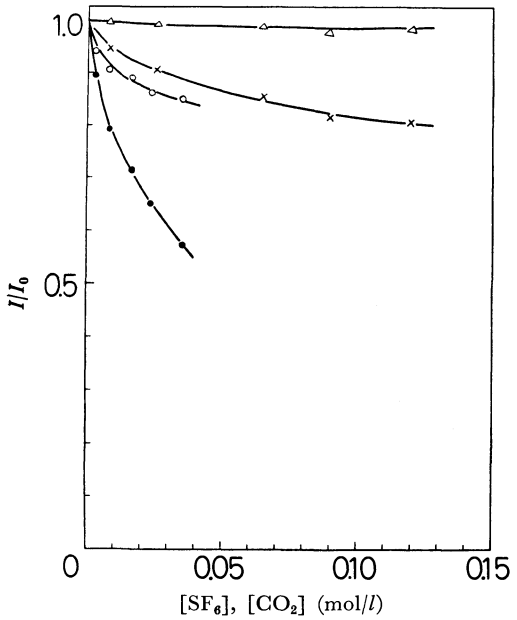

Fig. 4. Quenching by electron scavengers.

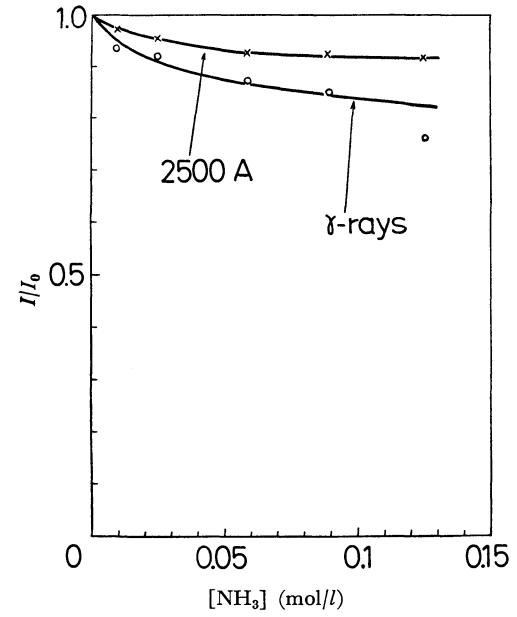

Fig. 5. Quenching by ammonia.
[pTP]$=4.0\times10^{-4}$ mol l^{-1}, ×, UV, ○, γ-rays

Similar experiments were also carried out using sulfur hexafluoride, carbon dioxide, and ammonia in place of nitrous oxide. The results are shown in Figs. 4 and 5. Obviously, the quenching abilities are in the following order: sulfur hexafluoride, nitrous oxide, carbon dioxide, and ammonia. All these quenchers are more effective under γ-rays than under UV light. Although the only UV lights used here were at 2500 Å, exactly the same quenching curves for each quencher were obtained by using the wavelengths of 2400 and 2600 Å.

Quenching by 1,3-Butadiene. Figure 6 shows the relative emission intensity as a function of the concentration of 1,3-butadiene. The quenching curves obtained under UV light and under γ-rays practically coincide with each other. This coincidence contrasts with the results obtained by using ion scavengers as the quencher.

0.35	0.027	2.0
0.37	0.15	1.1
0.36	0.35	0.84
0.37	0.59	0.57

Discussion

As is shown in Fig. 2, ion scavengers did not interact with the scintillating state of *p*TP in the range of the concentrations of *p*TP and scavengers studied. On the other hand, these scavengers did quench the luminescence induced by UV at 2500 Å, although they were not strong. The quenching by carbon dioxide was practically negligible. Since the excitation energies of these scavenger molecules are not smaller than that of the $^1B_{2u}$ state of benzene, the simple energy-transfer mechanism cannot be used in the interpretation. One possible mechanism is that involving the formation of a charge-transfer complex between an excited benzene molecule and an ion scavenger molecule in the process. Since the quenching effects were not strong, the participation of impurities cannot be excluded.

When the excitation was made by γ-rays, the quenching effects of ion scavengers became prominent, as is shown in Figs. 3, 4, and 5. Even carbon dioxide showed the effect. This compound is now known as an electron scavenger in radiation chemistry.[6] These quenching effects may, therefore, be attributed to the interference of ion scavengers in the ionic process by which the scintillating state of *p*TP is formed. There are two possible mechanisms for such interference. One (Mechanism 1) is the competition between *p*TP and ion scavengers for the charged species produced in the system. This mechanism satisfactorily explains the quenching effect of ion scavengers in a *p*TP-cyclohexane scintillator.[1] If this mechanism plays a major role in the quenching, a strong dependence on the concentration of *p*TP should be observed, as has actually been observed in a *p*TP-cyclohexane scintillator. The other mechanism (Mechanism 2) is the interference of ion scavengers in the ionic process by which excited benzene is formed. This reaction scheme may be described as follows:

$$B \begin{cases} \xrightarrow{\sim\sim} B^+ + e_B & (8) \\ \xrightarrow{\sim\sim} B^* & (9) \end{cases}$$

$$B^+ + e_B \rightarrow B^* \quad (10)$$

$$e_B + S \rightarrow S^- \quad (11)$$

$$B^+ + S \rightarrow B + S^+ \quad (12)$$

$$B^+ + S^- \rightarrow B + S \quad (13)$$

$$B^* + T \rightarrow B + T^* \quad (14)$$

Here, B, S, and T denote, respectively, benzene, scavenger, and *p*-terphenyl molecules. The suffix B is attached to the electron e, in order to indicate that the electron is in benzene. If this mechanism is operative, the quenching curves should not depend strongly on the concentration of *p*TP, but this was actually observed. This discrimination, however, is not conclusive. Another support for Mechanism 2 will be given later.

Regardless of the mechanism of the interference of ion scavengers in the ionic processes occurring in the system, the quenching curves obtained under γ-ray irradiation suggest that a large part of the luminescence results from the ionic reactions. Since the luminescence from UV-irradiated benzene solutions was quenched by ion scavengers, as is shown in Figs. 3 and 4, the following tentative correction was made in an attempt to visualize the purely ionic effects of ion scavengers:

$$(I/I_0)_{corr} = (I/I_0)_\gamma / (I/I_0)_{UV} \quad (II)$$

Here, the subscripts γ and UV denote γ-ray and UV irradiations respectively. The results are plotted in Fig. 7. If sulfur hexafluoride behaves only as an electron scavenger, the corrected curve indicates that more than 30% of the excited benzene, which is the precursor of the scintillation, is formed by an ionic reaction, probably the recombination reaction between benzene cations and electrons.

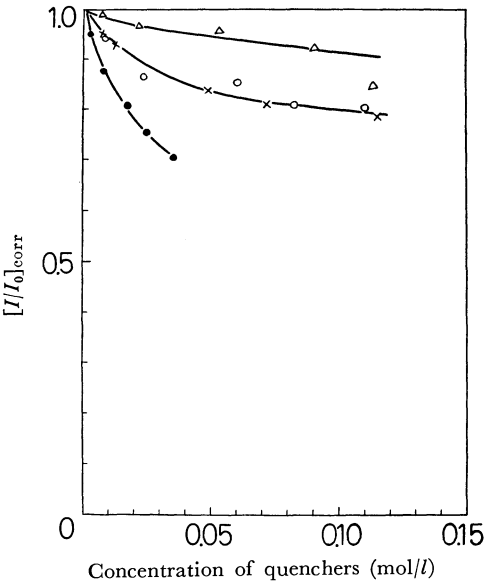

Fig. 7. $[I/I_0]_{corr}$ as a function of the concentrations of ion scavengers.
△, NH_3; ×, N_2O; ○, CO_2; ●, SF_6

According to Fig. 7, the electron-scavenging ability of sulfur hexafluoride is stronger than those of nitrous oxide and carbon dioxide. In cyclohexane solutions, however, the abilities were estimated to be almost the same for these three scavengers.[6] In order to interpret this discrepancy, we have measured the *G*-values of nitrogen from a benzene solution of nitrous oxide in the presence of various amounts of sulfur hexafluoride. The results are shown in Table 1. If a simple relation (III) is applicable to these data:[6]

$$\frac{1}{G(N_2)} = \frac{1}{G_0(N_2)}\left(1 + k\frac{[SF_6]}{[N_2O]}\right) \quad (III)$$

the slope k should show the ratio of the rate constant of the reaction of electrons with sulfur hexafluoride to that with nitrous oxide. As is shown in Fig. 8,

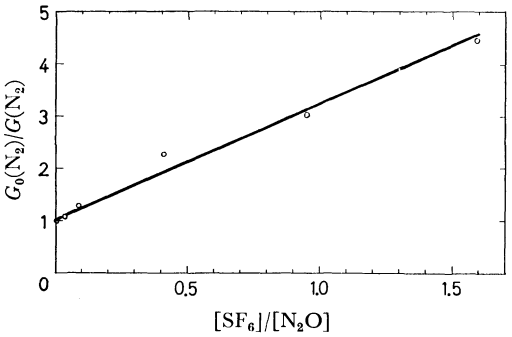

Fig. 8. Dependence of $G(N_2)$ on the concentration of sulfur hexafluoride.

a linear relationship has been obtained and the slope k has been calculated to be 2.2; this value should be compared with that of 1.0 obtained in a cyclohexane solution.[6] This difference qualitatively explains the difference between the two quenching curves obtained with sulfur hexafluoride and nitrous oxide. Electrons in benzene may be solvated more strongly than those in cyclohexane. This is not unreasonable, since aromatic hydrocarbons larger than benzene, such as naphthalene and biphenyl, are known to capture electrons to form anions.[7] Therefore, the reaction between electrons and electron scavengers in benzene may not be diffusion-controlled.

The quenching curves obtained with 1,3-butadiene are shown in Fig. 6. In the case of UV excitation, the species being quenched must be the $^1B_{2u}$ state of benzene.[8] If the ion-molecule reaction between the benzene cation and 1,3-butadiene is important in the present system, the quenching curve obtained by γ-ray irradiation should deviate from the curve obtained by UV irradiation, because the benzene cation must be the precursor of the $^1B_{2u}$ state of benzene and both the cation and the excited state of benzene are subject to the interference of 1,3-butadiene. The coincidence of the two quenching curves strongly suggests, therefore, that most of the benzene cations produced in the system are neutralized before the ion-molecule reaction with 1,3-butadiene occurs. In other words, Mechanism 2 is at least predominant in this system over Mechanism 1. However, a detailed inspection reveals that the quenching ability of 1,3-butadiene under γ-rays is a little stronger than that under UV light. This suggests that the participation of Mechanism 1 cannot be excluded conclusively. Recently, the G-value of "free electrons" in benzene has been measured as 0.053 by the conductivity method.[9] These electrons must contribute to the scintillation by the formation of p-terphenyl anions (Mechanism 1).

The Chemical Research Institute of Non-Aqueous Solutions, Tohoku University, Katahira-cho, Sendai

(Received February 10, 1969)

The ESR of bis-(*N*,*N*-diethylethylenediamine)copper(II) perchlorate has been examined in the polycrystalline state at three temperatures corresponding to the color change in the copper(II) complex due to thermochromism, in the glassy state of an aqueous solution at the temperature of liquid nitrogen, and in the magnetically-diluted state in diamagnetic bis-(*N*,*N*-diethylethylenediamine)nickel(II) perchlorate powder at three temperatures corresponding to the color change of the diluent due to thermochromism. The g and A values for square planar copper(II) complexes have been discussed in connection with the strength of the axial ligand field. The ESR results indicate that the structure of bis-(*N*,*N*-diethylethylenediamine)copper(II) perchlorate changes remarkably according to its circumstances, and possible mechanisms for the thermochromism have been suggested.

The bis-(*N*,*N*-diethylethylenediamine)copper(II) perchlorate was found to exhibit many interesting properties: (1) It is one of the few red copper(II) complexes, while it turns purplish-blue in an aqueous

solution.[1,2] (2) The copper(II) complex exhibits thermochromism, a phenomenon which accompanies changes in crystal form and color.[1,3] (3) This copper(II) complex is known to be isomorphous to the diamagnetic nickel complex bis-(*N,N*-diethylethylenediamine)nickel(II) perchlorate, which also exhibits two steps of thermochromism.[3,4]

The copper(II) complex is *trans*-square coplanar, and two perchlorate anions are located at the axial position.[2,3] As to the structure of the complex, this is the only information so far reported. No satisfactory explanation for the structural mechanism of the thermochromism has yet been given. Therefore, more detailed and reliable information on the structure of the complex in various states is needed before we can understand the many interesting properties of the complex. The ESR technique is very useful for the study of the ligand field in metal complexes, and it has been widely applied to various copper(II) complexes.[5-9] The purpose of this paper is to discuss the ESR results on the copper(II) complex with the aim of estimating its structure and properties in various states, and their dependence on its molecular circumstances.

Experimental

The *N,N*-diethylethylenediamine, represented below, was a commercially-available substance. The bis-deen copper(II) perchlorate was prepared by the method in the literature[1] and was then recrystallized from methanol. In order to obtain magnetically-diluted samples, diamagnetic nickel complexes, bis-deen nickel(II) perchlorate, bis-deen nickel(II) tetrafluoroborate, diiodo-bis-deen nickel(II), and dinitrato-bis-deen nickel(II), were prepared using nickel(II) salt containing 1% of the cupric salt of the same anion, according to the method of the literature.[4] These samples are represented as Ni-ClO_4, Ni-BF_4, Ni-I, and Ni-NO_3 respectively. Although the amount of copper in each of these samples was not determined accurately in this investigation, proper magnetical dilution seemed to have been done for all the samples judging from the resolution of hyperfine structures and the S/N ratio of their ESR spectra, as shown, for example, in Figs. 2 and 3.

The ESR spectra were measured with a Hitachi X-band and a K-band ESR spectrometer, Model MES-4001, equipped with a 100 kc/s field modulation unit; furthermore, the second derivative ESR spectra were obtained using 100 kc/s-40 c/s field modulations in order to resolve the nitrogen super-hyperfine structure clearly. The field was calibrated with an NMR probe, and then with a benzene solution of vanadyl acetylacetonate. The ESR measurements were carried out at the temperatures of −196, 22, and 80—125°C for powdered samples and at −196°C in the glassy state for a *ca.* 0.01 M solution, using an equivolume mixture of water and methanol as the solvent. The ESR spectra thus obtained are shown in Figs. 1—5.

Results and Discussion

Polycrystalline State. The ESR line shapes for the polycrystalline samples of $S=1/2$ have been studied extensively by several authors.[10-12] From the ESR spectrum of the polycrystalline copper(II) complex, three approximate principal g values can be obtained, and a rough estimate for the line width along each of the principal axes may be made. The latter is, of course, connected with the spin interaction among neighboring cupric ions in a crystal.[13]

Figure 1 shows the ESR spectra of the polycrystal of bis-deen copper(II) perchlorate measured at three temperatures. This complex is brick red at room temperature and blue above 44°C. Furthermore, the complex has been found in this study to become pale red on cooling to the temperature of liquid nitrogen. This suggests that one more step of phase transition exists between room temperature and −196°C, although the phase-transition point was not determined precisely. This fact is also strongly supported by the clear differences in line shape among the three ESR spectra shown in Fig. 1, each being measured in the temperature range corresponding to each of the transition phases. These phases are called, in the order of temperature, the lower-temperature phase, the

(A) at −196°C, (B) at 22°C, (C) at 80°C

room-temperature phase, and the higher-temperature phase respectively.

The line shapes for all of the ESR spectra shown in Fig. 1 consist of one very intense absorption in the high-field part and one very weak and broad absorption in the low-field part, the latter being hardly observable by X-band measurement. This spectral feature apparently agrees with that of square planar copper(II) complexes, where the relation among three principal *g* values (assumed as $g_1 \leq g_2 \leq g_3$) is $g_1 \fallingdotseq g_2 < g_3$, which results from an axial or near axial symmetry in the ligand field. The numbers in the ESR spectra of Fig. 1 represent the results analyzed. Spectrum (A) in this figure is quite similar in line shape to (B) except that the *g* values are somewhat greater in (B) than in (A). However, Spectrum (C) is quite different in line shape from the (A) and (B) spectra, especially in the line shape of the intense absorption in the high-field part. A possible explanation for this is that the difference between the values of g_1 and g_2 is somewhat larger in (C) than in (A) and (B). In (C) the mean value of g_1 and g_2 could be estimated to be about 2.05. Furthermore, g_3 was smaller in (C) than in (B). Accordingly, although the phase-transition of the crystal is necessarily accompanied

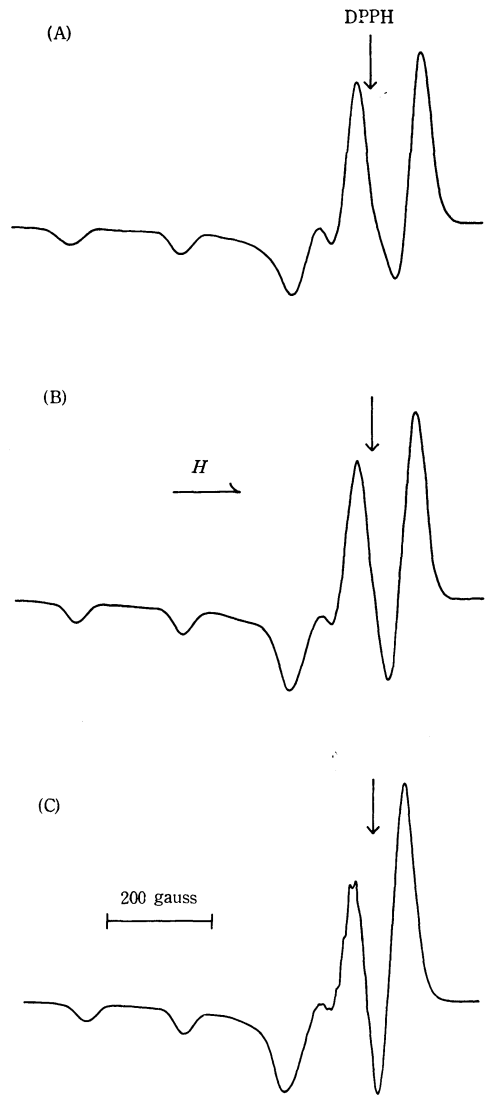

Fig. 2. The X-band ESR spectra of bis-(*N*,*N*-diethylethylenediamine)copper(II) perchlorate magnetically diluted in bis-(*N*,*N*-diethylethylenediamine) nickel(II) perchlorate powder.

by some structural change in the constituent molecules, the structural change in this copper(II) complex from the room-temperature phase to the higher-temperature phase is not of the same type as that from the lower-temperature phase to the room-temperature phase.

Magnetically-diluted Powdered Samples. Bis-deen nickel(II) perchlorate is known to be isomorphous to bis-deen copper(II) perchlorate.[3] Interestingly, the nickel complex also exhibits two steps of thermochromism: it is reddish-orange above about 90°C, orange near room temperature, and pale yellow upon being cooled to the temperature of liquid nitrogen. Figure 2 shows the ESR spectra of the copper(II) complex magnetically diluted in diamagnetic bis-deen nickel(II) perchlorate, measured using the X-band in the three temperature ranges corresponding to the transition phases of the diluent. These ESR spectra are very similar to each other in line shape except that the super-hyperfine structure observed in the high-field part is clearly resolved as the transition phase becomes a higher-temperature phase. This property of the super-hyperfine structure is also clearly indicated in the second derivative spectra shown in Fig. 3. This tendency of the super-hyperfine structure is contrary to the general rule that the line width narrows, because of the lengthening of the spin-lattice relaxation time, with a lowering in the temperature. Accordingly, it seems most reasonable that the tendency is closely related to the fact that the resolution of this kind of super-hyperfine structure depends upon the relative values among the magnetic parameters of g, A, and A_N. The super-hyperfine structure under discussion is considered to be due to the interaction of a copper unpaired electron with ligand nitrogen nuclei.[6-8]

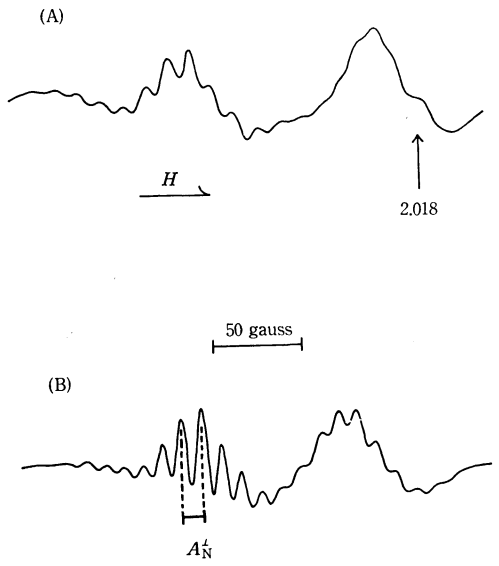

Fig. 3. The second derivative X-band ESR spectra enlarged at the high field part of the ESR spectra shown in Fig. 2.
(A) at 22°C, (B) at 120°C

The K-band ESR spectra for two temperature phases are shown in Fig. 4. These two spectra are similar to each other in line shape. The purpose of this K-band measurement is to eliminate as far as possible the complexity of absorption observed in the high-field part of the X-band spectra of Fig. 2. Judging from the line shape of these K-band ESR spectra of Fig. 4,[11] it seems reasonable to determine the values of g_1 and g_2 in such a way as is indicated by the arrows in the figure. Then, g_1 differs from g_2 by about 0.03; therefore, axial symmetry in the ligand field decreases to a certain extent in Ni-ClO_4.

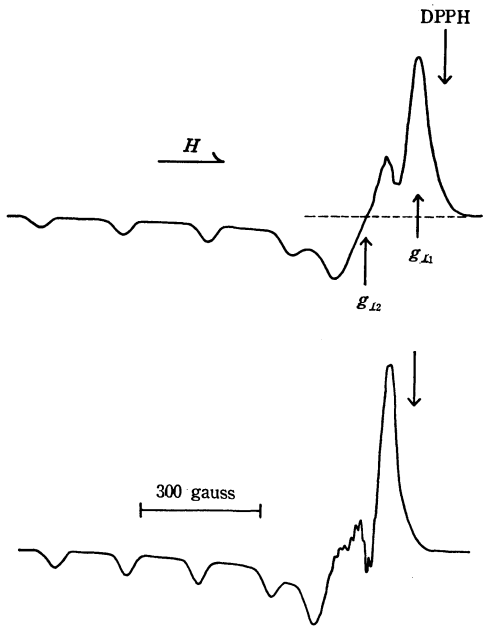

Fig. 4. The K-band ESR spectra of bis-(*N*,*N*-diethylethylenediamine)copper(II) perchlorate magnetically diluted in bis-(*N*,*N*-diethylethylenediamine)nickel(II) perchlorate powder.
(A) at 22°C, (B) at 120°C

Bis-deen nickel(II) tetrafluoroborate, diiodo-bis-deen nickel(II), and dinitrato-bis-deen nickel(II) are diamagnetic; all of these also exhibit two steps of thermochromism, much like bis-deen copper(II) perchlorate.[4] They were used as diluents in order to dilute magnetically the copper(II) complex of the same anion. The behavior of the ESR spectra for these samples, namely, Ni-BF_4, Ni-I and-NO_3, was almost the same as that of Ni-ClO_4. It is worth noting that the change in magnetic parameters for the copper(II) complexes takes place at the transition temperatures of diluents, for the change in bis-deen copper(II) perchlorate did not occur at its transition temperature of 44°C. This result indicates that the structural change in the copper(II) complexes takes place simultaneously

Table 1. The magnetic parameters of $[Cu(deen)_2]X_2$[a] magnetically diluted in the powder of $[Ni(deen)_2]X_2$

Temperature (°C)	Magnetic parameter	X			
		ClO_4^-	BF_4^-	I^-	NO_3^-
−196	$g_{//}$	2.171	2.172	2.178	2.170
	$A_{//}\times10^4\,cm^{-1}$	213	213	202	212
22	$g_{//}$	2.172	2.175	2.179	2.171
	$g_{\perp 1}$	2.018	2.018	2.021	2.015
	$g_{\perp 2}$	2.045	2.046	2.049	2.049
	$A_{//}\times10^4\,cm^{-1}$	206	205	198	206
	$A_N{}^{\perp}\times10^4\,cm^{-1}$	11.3	11.3	10.8	11.6
120	$g_{//}$	2.180	2.182	2.180	2.173
	$A_{//}\times10^4\,cm^{-1}$	193	192	190	201
	$A_N{}^{\perp}\times10^4\,cm^{-1}$	10.6	10.7	11.0	11.0

a) For example, bis-(*N*,*N*-diethylethylenediamine)copper(II) perchlorate is expressed as $[Cu(deen)_2]X_2$ where $X=ClO_4^-$.

with those of the diluents. All of the magnetic parameters experimentally determined for the magnetically-diluted samples are listed in Table 1.

The results listed in Table 1 indicate that the g and A values gradually change in one direction as the phase changes from the lower-temperature phase to the higher-temperature phase. This fact implies that the structural changes accompanied by each of the phase transitions are of the same kind and increase in one direction with the transition from the lower-temperature phase to the higher. The super-hyperfine splitting constants decrease slightly for almost all of the samples as the phase transfers from the room-temperature phase to the higher-temperature phase. This suggests that the σ covalency of copper-ligand nitrogen bonds decreases somewhat with the same phase transition.[6-8] The table also reveals that all the anions of Ni-ClO_4, Ni-BF, Ni$_4$-I, and Ni-NO_3 have almost the same effect on the cupric ion.

Solution. Figure 5 shows the X-band and K-band ESR spectra of bis-deen copper(II) perchlorate in the glassy state of an aqueous-methanolic solution measured at the temperature of liquid nitrogen. When spectrum (B) in this figure is compared with the spectra of Fig. 4, the difference between g_1 and g_2 seems to be smaller in the former than in the latter; the ligand field for the copper(II) complex is nearer to being of an axial symmetry in solution than in the diamagnetic nickel(II) complex. The spectra of Fig. 5 were analyzed as follows:

$$g_{//} = 2.212$$
$$g_{\perp} = 2.048$$
$$A_{//} = 184\times10^{-4}\,cm^{-1}$$

Attention should be given to the point that the structure of the copper(II) complex changes considerably according to its circumstances.

Ligand Field and Magnetic Dilution. In this paragraph the structure of bis-deen copper(II)

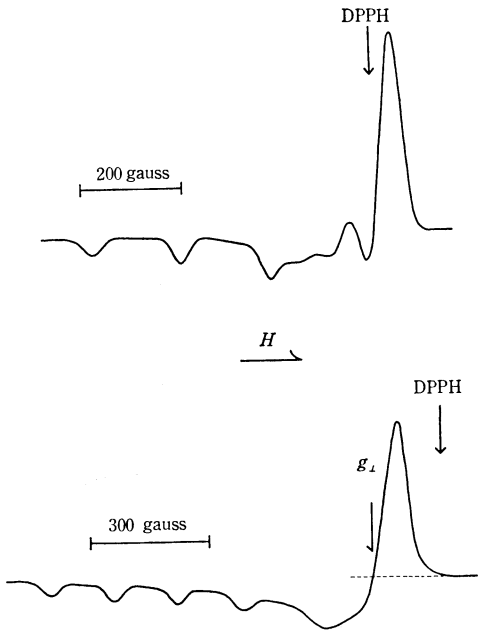

Fig. 5. The ESR spectra of bis-(*N*,*N*-diethylethylenediamine)copper(II) perchlorate in aqueous-methanolic solution at −196°C.
(A) X-band, (B) K-band

perchlorate will be discussed from the point of view of ESR. The copper(II) complex is known to be purplish-blue in an aqueous solution and red in crystal.[1,2] This color change has been speculated, on a simplified basis, to be due to the difference in strength of ligand field along the axis normal to the molecular plane.[2] Although the copper(II) complex is of a planar structure in both states, in an aqueous solution water molecules, being small in volume, can come close to the cupric ion, but in crystal perchlorate anions can not come so closely to the cupric ion as can water

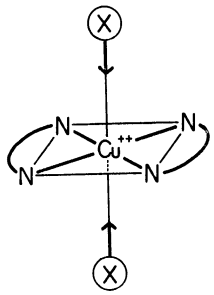

Fig. 6. The schematically represented structure of the copper(II) complex under discussion. X (ClO_4^- or H_2O) presents axial ligand field to cupric ion.

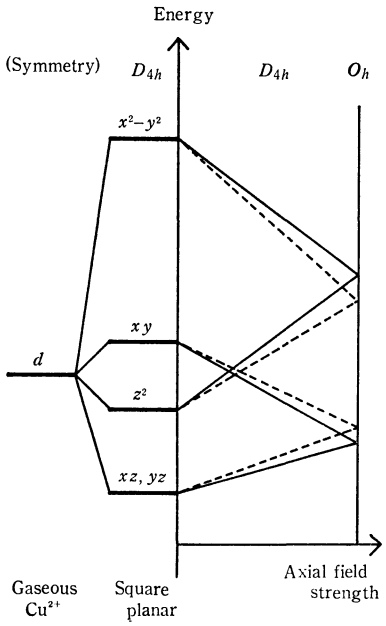

Fig. 7. Schematic representation of the energy levels cupric ion in axial ligand field of various streng of ths.

molecules because of the remarkable steric hindrance by ligand ethyl groups on the bulky anions.

In Fig. 6 the above situation is schematically pictured. Figure 7 also schematically represents, using, for convenience, the crystal field theory, the energy levels of the cupric ion of the square planar complex (D_{4h} symmetry) when two axial ligands coordinate to the cupric ion in various strengths. The dotted line in this figure represents the energy levels in a more practical case; when the axial coordination strengthens, the equatorial coordination weakens. In the planar copper(II) complex, the uppermost level of the $d_{x^2-y^2}$ orbital is half filled, and the other levels, completely occupied, with electrons, and the *d*-*d* absorption bands correspond to a one-electron transfer from the lower levels to the uppermost level. The fact that the bands shift to longer wavelengths as the axial coordination strengthens has been confirmed both theoretically and experimentally.[14]

It will be assumed that the following wave functions describe the system:

$$\left.\begin{aligned}
\psi_{x^2-y^2} &= \alpha d_{x^2-y^2} - \alpha' \sigma_L(x^2-y^2) \\
\psi_{xy} &= \beta d_{xy} - \beta' \phi_L(xy) \\
\psi_{xz,yz} &= \beta_1 d_{xz,yz} - \beta_1' \phi_L(xz, yz) \\
\psi_{z^2} &= \alpha_1 d_{z^2} - \alpha_1' \sigma_L(z^2)
\end{aligned}\right\} \quad (1)$$

In each of the wave functions, the second term on the right-hand side represents the proper ligand orbital which can be mixed with the copper *d* orbital expressed in the first term. The relations between the ESR data and the covalency parameters, α, β, and β_1, can then be expressed approximately as follows:[5-9]

$$g_{//} = 2 - \frac{8\lambda}{\Delta E_{xy}}\alpha^2\beta^2 \quad (2)$$

$$g_{\perp} = 2 - \frac{2\lambda}{\Delta E_{xz,yz}}\alpha^2\beta_1^2 \quad (3)$$

$$A_{//} = P\left[-\frac{4}{7}\alpha^2 - \kappa + (g_{//}-2) + \frac{3}{7}(g_{\perp}-2)\right] \quad (4)$$

where κ is the Fermi contact term, $\Delta E_{xy} = E_{x^2-y^2} - E_{xy}$, $\Delta E_{xz,yz} = E_{x^2-y^2} - E_{xz,yz}$, and $P = 0.036$ cm^{-1}.

It is interesting and important to learn how the *g* and *A* values change as the axial coordination varies in strength. The following theory may be derived from Fig. 7 and the three equations (2)—(4); All of the following discussion is concerned with the case in which the axial ligand field strengthens. α^2 increases remarkably, β_1^2 increases to a smaller extent, and the change in β^2 is quite small. $\Delta E_{xz,yz}$ decreases remarkably, and ΔE_{xy} decreases slightly. Therefore, $g_{//}$ remarkably increases. $g_{\perp}$ also increases, but the amount of increase is not large because of the small factor, 2, in the second terms on the right-hand side of Eq. (3). On the other hand, the situation for $A_{//}$ is rather complicated. When the axial coordination varies in strength, the change in the value of $|A_{//}|$ is dependent on the relative changes in the value of α^2, κ, and *g* in Eq. (4). However, it was experimentally indicated that, for some planar copper(II) complexes, the value of $|A_{//}|$ decreases as the axial coordination is strengthened.[15] Furthermore, cupric ions in MgO or CaO, which may be regarded as extreme cases in which the axial coordination becomes almost equal in strength to the equatorial coordination, have a very small value of $|A_{//}|$.[16] From the above-mentioned facts, it may be considered, as a general rule, that the value of $|A_{//}|$ decreases

16) P. Azurin, J. W. Orton and J. E. Wertz, "Paramagnetic Resonance," Vol. 1, ed. by W. Low, Academic Press, New York (1963), p. 90; W. Hayes and J. W. Orton, *Rept. Progr. Phys.*, **22**, 204 (1959).

as the axial coordination strengthens.

The samples employed in this work are numbered as follows: the polycrystal at −196°C is I: the polycrystal are 22°C, II; the polycrystal at 80°C, III; Ni-ClO_4 at −196°C, IV: Ni-ClO_4 at 22°C, V; Ni-ClO_4 at 120°C, VI, and the aqueous-methanolic solution at −196°C, VII. For I, II, IV, V, VI, and VII, the $g_{//}$ or g_3 values are 2.117, 2.156, 2.171, 2.172, 2.180, and 2.212 respectively, and the $g_\perp$ values, or the mean values of g_1 and g_2, are 2.034, 2.036, 2.03−2.04, 2.03—2.04, 2.03—2.04, and 2.048 respectively. For IV, V, VI, and VII, the values of $|A_{//}|$ ($\times 10^4$ cm^{-1}) are 213, 206, 193, and 184 respectively. From these results it may reasonably be concluded that, among I, II, IV, V, VI, and VII, the difference in structure lies mainly in the axial coordination and that the axial ligand field is strengthened in this order of samples. The tendency of the super-hyperfine splitting constant for V and VI, which had already been discussed, also supports this conclusion indirectly. It is a very interesting suggestion that the phase transitions from I to II, from IV to V, and from V to VI accompany such a structural change as the access of the perchlorate anion to the cupric ion. However, the phase transition from II to III is of a different kind and possibily accompanies the structural change in the equatorial coordination. It may also be noted that IV, V, and VI in the above-mentioned series of samples decreases in axial symmetry to a slightly larger extent than the others.

It should be emphasized here that, as has been described, the properties of bis-deen copper(II) perchlorate vary to a larger extent according to its circumstances. Therefore, the meaning of magnetical dilution for the metal complex of a flexible structure is rather complicated.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 2238—2242 (1969)

The Kinetics of the Autoxidation of Ferrous Ions in Aqueous Tripolyphosphate Solutions

Yoshimi KURIMURA and Hideo KURIYAMA

Chemical Laboratory, College of General Education, Ibaraki University, Watari-machi, Mito, Ibaraki

(Received July 8, 1968)

The kinetics of the autoxidation of ferrous ions in tripolyphosphate solutions (pH 2—8) at an ionic strength of 0.20 M $NaClO_4$ was studied using a spectrophotometric technique. The rate expression for the oxidation reaction is given by:

$$d[Fe(III)]/dt = 4k_I[Fe^{II}(Htpp^{4-})][O_2] + 4k_{II}[Fe^{II}(Htpp^{4-})_2][O_2],$$

and $4k_{II}$ found is to be 1.0×10^2 M^{-1} sec^{-1} at 15°C. The simultaneous reaction paths of

$$Fe^{II}(Htpp^{4-}) + O_2 \xrightarrow{k_I} Fe^{III}(Htpp^{4-}) + O_2^- \text{ and } Fe^{II}(Htpp^{4-})_2 + O_2 \xrightarrow{k_{II}} Fe^{III}(Htpp^{4-})_2 + O_2^-$$

are consistent with the results obtained. When there is an excess of the triphosphate solution in the pH range from 6 to 8, the latter may be the rate-determining step. The acceleration of the oxidation of the ferrous ions in the triphosphate solution may be due to the fact that the stabilization of the oxidation products, $Fe^{III}(Htpp^{4-})$ and $Fe^{III}(Htpp^{4-})_2$, is greater than that of the corresponding ferrous triphosphate complexes. As the activation parameters for the latter reaction, the experiments gave the values of $\Delta H^{\neq} \sim 10$ kcal mol^{-1} and $\Delta S^{\neq} \sim -25$ cal mol^{-1}. deg^{-1}. The negative and relatively small value of the entropy of activation suggests that the activated complex is more extensively hydrated than is the ferrous complex of $Fe^{II}(Htpp^{4-})_2$.

Many workers have reported that the rate of the autoxidation of ferrous ions is dependent upon the species of anions present and on the pH's of the solutions.[1-9] The observed oxidation rates

of Fe(II), at a given pH, decrease in the order: pyrophosphate,[1-4] phosphate,[5] chloride,[6] sulfate,[7,8] and perchlorate.[9] The rate, $-d[Fe(II)]/dt$, is first-order with respect to [Fe(II)] and p_{O_2} for the first three anions, while it is second-order with respect to [Fe(II)] and first-order with respect to p_{O_2} for the last two.

King and Davidson demonstrated that the rate for the oxidation of Fe(II) in an acid solution of pyrophosphate at pH's from 1 to 2 is first-order with respect to Fe(II), $H_2P_2O_7^{2-}$, and dissolved oxygen.[3] They also suggested that the effect of the pyrophsophate anions on the oxidation of Fe(II) may be due to the stabilization of such a transition state as $PP\cdots Fe\cdots O_2$, where PP is the pyrophosphate anion. It was also suggested that the rate, at a given pH, increases with an increase in the affinity of the anion towards ferric ions.[3]

In the previous work of this series, our finds on the oxidation of Fe(II) by dissolved oxygen in aqueous solutions in the presence of a chelating-agent were reported; these findings showed a linear relationship between the logarithmic rate constant and the $\log R_f$ value.[10],*1 Further extension of the work on the autoxidation of Fe(II) accelerated by the triphosphate anion was attempted spectrophotometrically; in this paper the mechanism of the reaction will be postulated.

Experimental

Materials. The ferrous ammonium sulfate, perchloric acid, sodium perchlorate, ferric ammonium sulfate, and sodium hydroxide were available G. R.-grade reagents. The sodium triphosphate was recrystallized five times from a 25% aqueous solution of ethanol. The purity of the sodium triphosphate ($Na_5P_3O_{10}\cdot 6H_2O$), as determined by means of anion exchange chromatography,[11] was above 98%. Redistilled water was used in preparing all the solutions.

Determination of Total Fe(III). The effect of the pH upon the absorption spectra of ferric ion species at wavelengths from 230 mμ to 350 mμ in an excess of triphosphate (TPP) is shown in Fig. 1. The isosbestic point at 260 mμ is invariable throughout the pH region between 2 and 7. Within this pH region, the total concentration of the ferric ions produced by the oxidation of ferrous ions can be determined by the absorption intensity at 260 mμ, whose molar extinction coefficient is 4620 $M^{-1}cm^{-1}$. In order to estimate the concentration of ferric ions at a pH value higher than 7, the value of a molar extinction coefficient at 260 mμ depending on the pH was found and used. For the purpose of determining the composition of the TPP

complex of ferric ions, the molar-ratio method was applied; the results are shown in Fig. 2. The evidence shown in Fig. 2, in which the optical density becomes nearly constant at [TPP]/[Fe(III)] values higher than 2, suggests that the composition of the Fe(III) complex with the highest number of complexing agents is $Fe^{III}(TPP)_2$.

Rate Determination. Except for a few cases, the ionic strength of the TPP solutions was kept at 0.207 by sodium perchlorate. About 50 m*l* of the TPP solution was taken into a 100-m*l* beaker and the pH of this solution was adjusted by the addition of a few drops of dilute perchloric acid or dilute sodium hydroxide. Appropriate amounts of a freshly-prepared aqueous solution of ammonium ferrous sulfate and 25 m*l* of the TPP solution were kept in a thermostated bath at 15°C for about one hour in order to saturate these solutions with air. Then, reaction was initiated by the addition of 1 m*l* of the Fe(II) solution into the stirred TPP solution by means of an injection syringe. The ionic strength of the reaction mixture was 0.20. The progress of the oxidation reaction was followed spectrophotometrically at 260 mμ using a Hitachi recording spectrophotometer. The recording of the absorption intensity of the Fe(III) produced could be started within nine seconds after the initiation of the reaction. The pH value of the reaction mixture was measured using a Hitachi-Horiba F-5-type pH meter. The reaction rate

*1 R_f represents the ratio of the chelate formation constant for the Fe(III) to that for the Fe(II) ($K_{Fe^{III}L}/K_{Fe^{II}L}$).

in an oxygen-saturated solution was observed according to a procedure described previously.[10]

Results and Discussion

Variations in the optical densities of the Fe(III)-triphosphate complex at 260 mμ in aerated solutions initially containing TPP and various initial concentrations of Fe(II) are shown in Fig. 3. The initial oxidation rate, d[Fe(III)]/dt, was determined from the slope of the starting curve. A linear relationship between the oxidation rate and the Fe(II) concentration holds well except when the total concentration of the Fe(II) is relatively higher than that of the TPP. This linear relationship indicates a pseudo-first-order dependence of the rate on the Fe(II) concentration at any particular pH value.

4 5.31 5 4.61 6 3.41

A comparison of the oxidation rates in aerated and oxygenated solutions is tabulated in Table 1. A first-order dependence of the rate on the oxygen concentration is observed since the ratio of the obtained rates on these two solutions, R_O/R_A, is about 4.9; this value agrees with the theoretical value of the ratio of the oxygen concentration in the oxygenated and in the aerated solutions, which is evaluated as 4.76 : 1. The results obtained by varying the pH value are shown in Fig. 4. With an increase in the pH value, the rate increases

markedly in the pH region between 2 and 6, finally attaining a limiting value at a pH higher than 6. Simillar rate dependences on the pH were observed in the oxygen oxidation of such Fe(II)-chelates as Fe(II)NTA and Fe(II)-EDTAOH.[10]

In these Fe(II)-chelates systems, such an increase in the rate may be attributed to an increase in the concentration of the chelated Fe(II) with the pH value. Generally, Fe(II)-chelates are oxidized more rapidly by oxygen molecules in acid and neutral aqueous solutions than are aquo ferrous ions.[10]

In order to obtain information on the order of the oxidation reaction, Job's continuous variation method[12] was employed. The results with this method are shown in Fig. 5. In this figure, the oxidation rates are plotted against the ratio of the concentrations, [Fe(II)]/{[Fe(II)]+[TPP]}, which is represented by R, the dominator of which is kept at a constant value of 5.0×10^{-4} M. A maximum is observed at R ~0.3 on the curve; this indicates that the reaction is first-order with respect to the free Fe(II) concentration and second-order with respect to the free TPP concentration at a given pH and at a given concentration of the dissolved oxygen. The small shoulder observed around R ~0.5—0.7 suggests the other rate dependence, which is first-order with respect to the concentrations of the free Fe(II) and the free

12) P. Job, *Ann. Chim.*, **6**, 97 (1936).

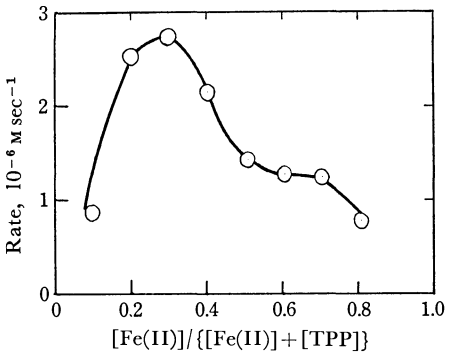

Fig. 5. Kinetic method of continuous variations. [Fe(II)]+[TPP] = 5.0×10^{-4} M, 0.20 M $NaClO_4$, pH=6.80±0.03, 15°C

TPP respectively.

From the results obtained, the rate equation at a given pH can be written as:

$$\frac{d[Fe(III)]}{dt} = k_a[Fe(II)]_f[TPP]_f[O_2] + k_b[Fe(II)]_f[TPP]_f^2[O_2] \quad (1)$$

where $[Fe(II)]_f$ and $[TPP]_f$ are the concentrations of the free ferrous ion and the free triphosphate ion respectively, and where k_a and k_b are apparent rate constants.

Under the present experimental conditions, five species of the triphosphate, H_5tpp, H_4tpp^-, H_3tpp^{2-}, H_2tpp^{3-}, and $Htpp^{4-}$, must be considered in the solution, while the completely dissociated species of tpp^{5-} can be disregarded. Fractions of the triphosphate species are calculated using the stability constants of triphosphoric acid;*2 these are plotted in Fig. 6 as a function of the pH value.

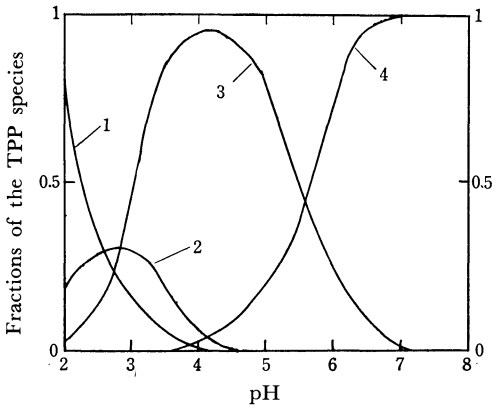

Fig. 6. Fractions of the TPP species *vs.* pH curve.
1: H_4tpp^- 2: H_3tpp^{2-} 3: H_2tpp^{3-} 4: $Htpp^{4-}$

*2 $\log K^H_{H_4L}=0$, $\log K^H_{H_3L}=2.6$, $\log K^H_{H_2L}=2.7$ and $\log K^H_{HL}=5.6$ and $\log K^H_L=7.9$ ($\mu=0.1$).[13]

13) A. E. Martell and G. Schwarzenbach, *Helv. Chim. Acta*, **39**, 653 (1956).

From a comparison of the rate-pH curve (Fig. 4) and the fraction-pH curve (Fig. 6), it is clear that the increase on the oxidation rate corresponds to the increase in the fraction of the H_4tpp^{4-}. This evidence suggests that the free TPP species in the rate equation (1) is $Htpp^{4-}$. It is reasonable to conclude from the results obtained that complex species of $Fe^{II}(Htpp^{4-})_2$ and $Fe^{II}(Htpp^{4-})$ are formed in the Fe(II)-TPP solution and that these are oxidized predominantly by dissolved oxygen. The quadratic dependence of the rate on the $Htpp^{4-}$ concentration, seen in the rate equation (1), is quite difficult to explain from kinetic point of view if complex formation between the Fe(II) and the TPP is not considered.

The reaction scheme most suited to the experimental results indicates two pre-equilibrium reactions, (2) and (3), and the simultaneous reaction paths of (4) and (5) (the (4) and (5) reactions are the rate-determining steps of the oxidation reaction):

$$Fe^{2+} + Htpp^{4-} \rightleftarrows Fe^{II}(Htpp^{4-}) \quad (2)$$

$$Fe^{II}(Htpp^{4-}) + Htpp^{4-} \rightleftarrows Fe^{II}(Htpp^{4-})_2 \quad (3)$$

$$Fe^{II}(Htpp^{4-}) + O_2 \xrightarrow{k_I} Fe^{III}(Htpp^{4-}) + O_2^- \quad (4)$$

$$Fe^{II}(Htpp^{4-})_2 + O_2 \xrightarrow{k_{II}} Fe^{III}(Htpp^{4-})_2 + O_2^- \quad (5)$$

$$O_2^- + H^+ \rightleftarrows HO_2 \quad (6)$$

$$Fe(II) + HO_2(\text{or } O_2^-) \rightarrow \text{further oxidation (fast)} \quad (7)$$

The oxidation of the Fe(II) by the HO_2 or O_2^- radical may proceed by means of Weiss's mechanism.[14,15] If so one molecule of O_2 oxidizes four atoms of the Fe(II). The above mechanism is also consistent with the results shown in Table 2, which shows little dependence of the rate on the ionic strength of the solution. Although the formation constant of the triphosphate complex of the ferrous ion has not yet been reported, complex formation between Fe(II) and TPP can be expected from the evidence that several divalent metal ion (Ba^{2+}, Cd^{2+}, Ca^{2+}, and Co^{2+}) complexes of the triphosphate with relatively greater stabilities

0.25	8.0
0.50	8.4
1.00	10.0

14) J. Weiss, *J. Chim. Phys.*, **48**, C-6 (1951).
15) J. Weiss, *Experientia*, **IX**, 61 (1953).

have been reported.[16-18] The proposed rate expression for the oxidation reaction is:

$$\frac{d[Fe(III)]}{dt} = 4k_I[Fe^{II}(Htpp^{4-})][O_2] + 4k_{II}[Fe^{II}(Htpp^{4-})_2][O_2] \quad (8)$$

The first term in this quation may be neglected in an excess of the TPP solution in the pH region between 6 and 8 since the concentration of the $Fe^{II}(Htpp^{4-})_2$ is nearly equal to the total concentration of the Fe(II) (Fig. 5). The k_{II} value is then evaluated by dividing the oxidation rate, which is obtained in an excess of the TPP solution at pH 6—8, by the total concentration of the Fe(II) and by the oxygen concentration.*3 The k_{II} value thus obtained is 25 $M^{-1}sec^{-1}$ at 15°C.

As has previously been reported,[10] the accelaration of the oxidation of ferrous ions in the presence of such chelating agents as EDTA, EDTAOH, and DTPA may be attributed to the lowering of the free energy of the activation ($\Delta G^{\neq}$) of the rate-determining step of the reaction of the following type due to the fact that the ferric state is more stable than the corresponding ferrous state:

$$Fe^{II}Z + O_2 \rightarrow Fe^{III}Z + O_2^- \quad (9)$$

where $Fe^{II}Z$ and $Fe^{III}Z$ are ferrous and ferric chelates respectively. The effect of the triphosphate anion on the oxidation of ferrous ions also seems to be attributable to a lowering of the $\Delta G^{\neq}$ values of the reaction (4) and reaction (5) by complex formations. As the activation parameters for the reaction (5), $\Delta H^{\neq} \sim 10$ kcal mol^{-1} and $\Delta S^{\neq} \sim -24$ cal mol^{-1} deg^{-1} are obtained from the temperature dependence of the rate constant, as may be seen in Table 3. The relatively small negative value of the activation entropy suggests that the activated complex formed at the transition state in (5) is more extensively hydrated than the ferrous complex, probably as a result of the cleavage of the Fe–O bond in the ferrous complex. Analogous to the oxidation reaction discussed here, it is reasonable to suggest that the acceleration of the oxidation of the Fe(II) by the pyrophsophate anion in a relatively high pH region is due to complexation between the Fe(II) and the pyrophosphate anion.

Oscillopolarographic Behaviour of Lanthanide Ions at the Dropping and Hanging-drop Mercury Electrodes

Akio IWASE and Chieko YOKOYAMA

Department of Chemistry, Faculty of Science, Yamagata University, Koshirakawa-cho, Yamagata

(Received August 21, 1968)

The oscillopolarographic behaviour of lanthanide ions at the dropping mercury electrode and hanging-drop mercury electrode was discussed. The variations of incision depth on the oscillopolarograms with a dropping mercury electrode in KSCN, KCl, KBr and $NaClO_4$ at pH 3.65 and 4.65 were found to depend on the first ionization potentials and the basicity of the lanthanide. On the basis of the results obtained it can therefore be presumed that the electrode reaction rate increases with the increase of the first ionization potentials.

It hat been reported[1,2] that the curves, $dE/dt = f(E)$, for the tervalent lanthanide ions, lanthanum, praseodymium and samarium in KI or KCl solutions, are affected by dissolved oxygen; the cathodic incision potential shifts in the negative direction and the anodic one in the positive direction and the incision depth decreases upon removal of the dissolved oxygen. This behaviour was attributed to the effect, as a catalyst, of hydroxide ions produced by the reduction of dissolved oxygen. However, little attention has been paid to the dependence of the incision depth on the characteristics of tervalent lanthanide ions.

The present investigation was undertaken to elucidate the relation between characteristics of the lanthanide ions, La^{3+}, Pr^{3+}, Nd^{3+}, Sm^{3+}, Gd^{3+}, Tb^{3+}, Dy^{3+}, Ho^{3+}, Er^{3+}, Tm^{3+} and Lu^{3+} and the incision depths in KSCN, KCl, KBr and $NaClO_4$ solutions. The data on the depolarization effect of the lanthanides reported herein indicate that the incision depths of the lanthanide ions are dependent on the first ionization potentials and the basicity.

Experimental

0.01 M solutions of lanthanide(III) chloride were prepared as follows: 99.9% lanthanide oxide was converted to the chloride and dissolved in diluted hydrochloric acid. Its concentration was standardized by a titration method[3] using an EDTA standard solution. Other reagents were all guaranteed grade and used without further purification. Adjustment of pH of the solution was done by adding 0.01 N hydrochloric acid or 0.01 N potassium hydroxide.

The curves, $dE/dt = f(E)$, were recorded with a manual Heyrovsky-Forejt type oscillopolarography constructed in this laboratory. A dropping mercury electrode (DME) and a hanging-drop mercury electrode (HME) were used as the polarizable electrode. The alternating current had a main frequency of 50 cps at 150 V. A direct current voltage in the range, -1.0 to -2.0 V, was superimposed on the alternating current. The alternating current intensities passing through the electrode were 0.12 mA for DME (surface area: 0.013 cm^2) and 0.23 mA for HME (surface area: 0.027 cm^2).

An Iwasaki SS-5051 synchroscope with WB-4 amplifier was employed and the photographs of the oscilloscope display were recorded with a Polaroid-Land camera and an Iwasaki UP-7 photo oscilloscope unit. The deflection sensitivities of the vertical axis were 3.5(DME) and 2.5 (HME) mV/cm except for Fig. 1. The positions of all incisions were measured directly on the oscilloscope and referred to a saturated calomel electrode by a comparative method[4] using the thallous or lead ions. The curves with the DME were photographed just before detachment of the mercury droplet when the surface area did not change appreciably with time. The capillary characteristics of DME used were an m value of 0.936 mg/sec and a drop time of 1.7 sec in an oxygen free 1 M potassium chloride solution for a mercury height of 57.6 cm. In order to ensure satisfactory reproducibility of the oscillopolarograms with HME, it was necessary to maintain a constant volume for the hanging-drop mercury. This was achieved by using a polarographic capillary with a mercury reservoir; after separation by means of gravitation, the mercury was caught on a glass spoon and attached to a silver wire by contact only. The weight of the mercury drop was 0.0058 g. For all experiments, the temperature was regulated at 25.0 ± 0.1°C.

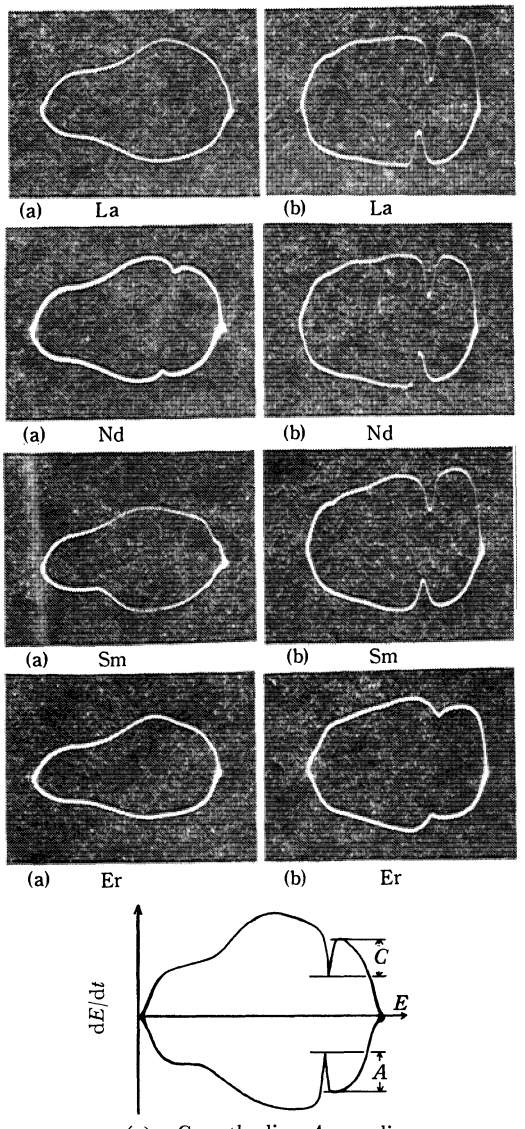
Results and Discussion

Oscillopolarographic Characteristics of Lanthanide Ions in Potassium Thiocyanate Solutions. The typical curves, $dE/dt=f(E)$, for 5×10^{-4} M lanthanide in a solution containing 1 M potassium thiocyanate at pH 3.65±0.05, are shown in Fig. 1. In this figure, curves (a) and (b) are the oscillopolarograms obtained with DME and with HME respectively. When DME was used the incision is observed for the Nd^{3+} ion only, whereas when HME was used the incision was observed for all ions in Fig. 1. It is obvious from comparison between the curves (a) and (b) that the incision depth is a function of the electrode reaction rate of the lanthanide ion. The oscillopolarographic characteristics of the lanthanide ions are shown in Tables 1*1,*2 and 2.*1,*2 In Table 1, the cathodic and anodic incision potentials obtained with DME were nearly constant and had a value of −1.41 and −1.40 V respectively. This is in agreement with the results reported by Dolezal[1] for several lanthanide ions. The incision was negligible with the removal of the dissolved oxygen in studies of the lanthanum and samarium ions, but no measurable incision was formed with Er, Tm and Lu irrespective of the presence of dissolved oxygen at pH 3.65±0.05 in an unbuffered solution. Generally, the incision depth of these ions in presence of the dissolved oxygen was greater than that with removal of the dissolved oxygen, and constant for La^{3+}, Pr^{3+} and Nd^{3+}, but for other ions studied, no regularity was found.



(c) C, cathodic; A, anodic

Fig. 1. Typical curves of the dE/dt *versus* the potential, E, of the lanthanide ions in a deoxygenated 1 M KSCN solulion. The curves were obtained with (a) a dropping and (b) a hanging-drop mercury electrode; (c), shows the method of measuring the incision depth. The deflection sensitivities of vertical axis were 10.0 (DME) 10.0 (DME) and 5.5 (HME) mV/cm.

As shown in Table 2, for the $dE/dt=f(E)$ curves obtained with HME, the quotients Q agreed with those obtained with the dropping mercury electrode and the incision depths were constant in the series, lanthanum to gadolinium, and independent of the presence of dissolved oxygen. On the basis of these observation, it seems that the electrode reaction rate of the lanthanum and samarium ions is slower than that of the other lanthanide ions (for example; Pr^{3+}, Nd^{3+}, Gd^{3+}, Tb^{3+}, Dy^{3+} and Ho^{3+}). As for erbium, thulium and lutetium, it was very difficult to identify a well-defined incision both with DME and HME because these ions may be hydrolyzed at the electrode surface under the above conditions.

In Fig. 2, curve D shows the plot of the cathodic incision depth with DME (with removal of dissolved oxygen) against the atomic numbers. This curve has two maxima, each of which is coincident with a similar maximum in the curve of the first ionization potentials[5] (curve E). As shown in Fig.3, the incision depth just before the detachment of the drop is dependent on the concentration of lanthanide ions. To determine the incision depths of neodymium, samarium and terbium, oscillopolarograms were measured on 0.5 to 5×10^{-4} M (HME), 0.5 to 5×10^{-3} M (DME, Nd^{3+}) and 0.5 to 3×10^{-3} M (DME, Tb^{3+}) lanthanide solutions containing 1 M KCl or 1 M KSCN at pH 3.65±

*1 The quotient Q is equal to the ratio of the distance between the left limiting point and the peak of the incision to the distance between the two limiting points (Fig. 1-c).

*2 Q values of the depolarization potential, incision depth and depolarization potential without removal of dissolved oxygen are shown in parentheses.

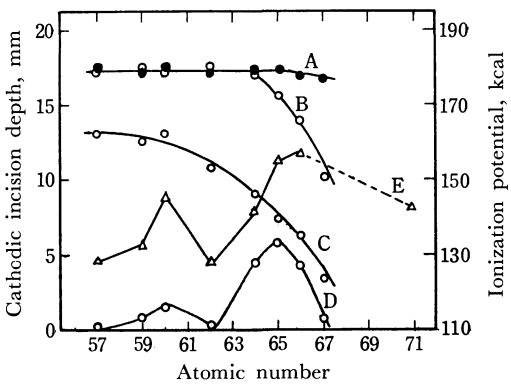

Fig. 2. Variation of cathodic incision depth with the lanthanides in 1 M KSCN solution at pH 3.65±0.05: curves A and B (without deaeration), with a HME; curve C (without deaeration) and D with a DME; curve E, the value of first ionization potential. The concentration of lanthanide added, A to D, was 0.0005 M.

0.05. As seen in Fig. 3, the incision depth increases proportionally to the lanthanide concentration

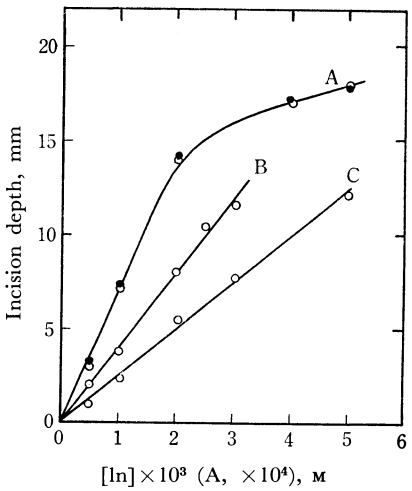

Fig. 3. Calibration curves of the lanthanides: curve A, with a HME (1 M KSCN and KCl; Tb, Sm and Nd); curves B and C, with a DME (1 M KCl; B, Tb; C, Nd).

for the range, 0.5 to 3×10^{-3} M (Tb^{3+}) and 0.5 to 5×10^{-3} M (Nd^{3+}) with the DME, and in the range, 0.5 to 2×10^{-4} M (Nd^{3+}, Sm^{3+} and Tb^{3+}) with HME.

Consequently, the variation of incision depth on curve D, Fig. 2, may be attributed to the difference in electrode reaction rate of each of the lanthanide ions.

Oscillopolarographic Characteristics of Lanthanide Ions in Potassium Chloride, Bromide and Perchlorate Solutions. The relation between the atomic number and the cathodic incision depth of the lanthanides at pH 3.65± 0.05 are shown in Fig. 4 to 6. In Fig. 4, oscillopolarograms were recorded in the range of potassium chloride concentration, 0.5 to 2.0 M. These oscillopolarograms have tendencies similar to those of the potassium thiocyanate solutions which have cathodic and anodic potentials of incision equal to

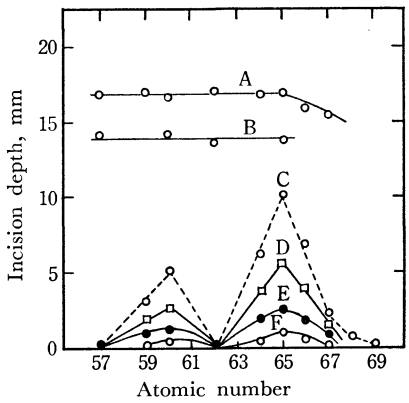

Fig. 4. Variation of the cathodic incision depth with the lanthanides in KCl solution at pH 3.65±0.05: the concentration of KCl added: A, B, C and E 1 M; D 0.5 M; F 2.0 M. The concentration of lanthanide added: A, D, E and F 0.0005; B 0.0002 M; C 0.0025 M. The kind of polarizable electrode used for A and B was a HME and C to F was a DME.

−1.42 and −1.40 V respectively. The curves C to F in Fig. 4 consist mainly of two peaks. This behaviour is also exhibited in the case of potassium thiocyanate solutions. Furthermore, the incision depths decrease to some extent as the concentration of potassium chloride increases. This effect may be attributed to the change of the potential ϕ_2[6] (which becomes less negative with increasing concentration). Curve A in Fig. 4, obtained with the HME, was similar to curve A in Fig. 2. The results measured at pH 4.65±0.05 in 1 M potassium chloride solutions are shown in Fig. 5.

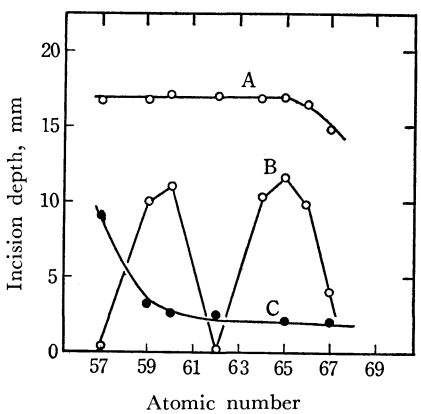

Fig. 5. Variation of the cathodic incision depth with lanthanide in 1 M KCl solution at pH 4.65±0.05. The concentration of lanthanide added was 0.0005 M and curve A was measured with a HME and curves B and C with a DME (C, without deaeration).

The value of the incision depth with HME in Fig. 5, 17.0±0.5 mm (La to Dy), was nearly equal to the value in the cases of 1 M potassium thiocyanate and of 1 M potassium chloride solutions at pH 3.65±0.05. The curve B in Fig. 5 shows the incision depths of lanthanide obtained with DME. These values were rather larger than those in the same supporting electrolyte at pH 3.65. It seems that the cathodic incision of lanthanides is attributable to the reduction of H^+ in hydrated water molecules[2] and that the anodic incision is attributable to the oxidation of lanthanide-halogeno hydride complexes,[1] which are formed by the hydride ions produced at the cathode. Consequently, the increase in the hydrogen ion concentration on the electrode surface might supress the formation of lanthanide-halogeno hydride complexes. Incision depths, without deaeration at pH 4.65, decreased with the decrease in the basicity and such behaviour may be caused by an increase of hydrolysis at the electrode surface. The incision potential was constant at −1.41±0.01 V *vs.* SCE.

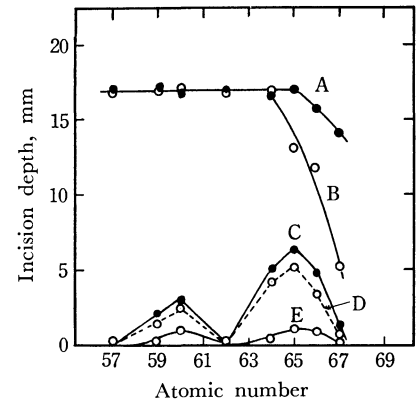

Fig. 6. Variation of the cathodic incision depth with lanthanide in 1 M KBr and $NaClO_4$ solution at pH 3.65±0.05. Supporting electrolyte: A and C, KBr; B, D (0.5 M) and E, $NaClO_4$. A and B, with HME; C to E, with DME.

In Fig. 6, curves A and B represent the results of analyses of the oscillopolarograms obtained on the solution containing 5×10^{-4} M lanthanide, 1 M potassium bromide, and 1 M sodium perchlorate, at pH 3.65±0.05 with HME. In curve B, the values of the incision depth from Tb to Ho are smaller than those of curve A. Curves C and E represent the results of analyses of the curves obtained on these solutions with DME. The values of the incision depth shown by curve C are larger than those by curve E (1 M sodium perchlorate). These results suggest the existence of halide and thiocyanato complexes of lanthanide at the electrode surface.

The authors are grateful to Professor M. Kobayashi for his interest in this work.

Refinement of the Structure of Tohdite $5Al_2O_3 \cdot H_2O$

Goro YAMAGUCHI and Masataro OKUMIYA

Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Tokyo

and Shuichiro ONO

Government Chemical Industrial Research Institute, Tokyo, Shinjuku-ku, Tokyo

(Received October 17, 1968)

The structure of tohdite, $5Al_2O_3 \cdot H_2O$, was determined by Yamaguchi Yanagida, and Ono (1964). Least-squares refinements based on their structure have been carried out using X-ray powder data. The final R factor of the reflection intensity reduced to 0.08 from the initial value of 0.26.

In previous papers the present authors reported on a new phase of alumina hydrate, tohdite $5Al_2O_3 \cdot H_2O$,[1] the conditions of its formation,[2] and its crystal structure as determined from the X-ray powder diffraction data.[3] After these articles, the authors learned of Torkar's study,[4] in which he described a mineral denoted "Al_2O_3-Form K1," but did not determine its chemical formula or atomic arrangement. The mineral described by Torkar seemed identical with tohdite.[5]

The structure of tohdite as determined by Yamaguchi, Yanagida, and Ono is as follows:

Cell dimensions: $a=5.576$ Å, $c=8.768$ Å

Space group : $P6_3mc$

O(1) 0 0 0	Al(1) 1/6 1/3 3/8
O(2) 1/2 0 0	Al(2) 2/3 1/3 1/8
O(3) 1/3 1/6 1/4	Al(3) 1/3 2/3 1/16
O(4) 1/3 2/3 1/4	

Overall temperature factor: 1.62 Å^2

These parameters were obtained on the following assumptions: the unit cell is composed of the ideal stacking of oxygen layers, every O–O distance being equal, and aluminium atoms are placed exactly at the centers of the oxygen polyhedra.

The intensities were calculated for fifty reflections (up to $\sin\theta/\lambda=0.456$ Å^{-1}), and the reliability factor, $R_I=\sum(I_o-I_c)/\sum I_o$, of 0.26 was obtained by omitting unobserved reflections. In the present paper the least-squares refinements of the structure of tohdite by means of the powder data will be reported.

Experimental

A polycrystalline sample of tohdite was prepared from Eta-Alumina by hydrothermal treatment.[3] In this powder sample the effect of the preferred orientation on the integrated intensities was confirmed to be negligible.[3] The X-ray diffraction diagrams were obtained by means of a Rigaku Denki diffractometer equipped with a Geiger counter using Cu$K\alpha$ radiation. The intensities relative to the intensity of the 202 reflection were obtained by measuring the areas of the peaks. The intensities of 51 peaks could be measured up to $\sin\theta/\lambda=0.621$ Å^{-1}. In addition, 35 reflections with negligible intensities were expected.

Structure Refinement

First, the lattice dimensions were refined from a least-squares fit of 32 reflections as follows:

$$a=5.575\pm0.001 \text{ Å}, \quad c=8.761\pm0.001 \text{ Å}.$$

Next, a least-squares analysis program was written for a HITAC 5020E computer in which the atomic parameters were varied so as to minimize $R_I'=\sum(I_o-I_c)^2$, where:

$\sum$=the summation of all peaks which can be separated in the diagram;

I_o=integrated intensity;

The calculated intensity, I_c, is presented as: $I_c=K\cdot Lp\cdot\sum_i m_i|F_i|^2$, where:

K=scale factor

Lp=Lorentz and polarization factor

m=multiplicity

F=structure factor.

In the calculation of the structure factors, only an overall isotropic temperature factor was used because the individual temperature factor for each atom did not give any physically significant results.

2) G. Yamaguchi, H. Yanagida and S. Ono, *J. Ceram. Assoc. Japan*, **74**, 84 (1966).

3) G. Yamaguchi, H. Yanagida and S. Ono, This Bulletin, **37**, 1555 (1964).

4) K. Torkar and H. Krischner, *Ber. Deut. Keram. Ges.*, **39**, 131 (1962).

5) K. Torkar and H. Krischner, This Bulletin, **39**, 1356 (1966).

As was mentioned in a previous paper,[3] the possible space groups are $P6_3mc$ and $P31c$. Therefore, refinement was undertaken in both these cases.

In $P6_3mc$ 11 parameters could be varied: that is, the x and z coordinates of Al(1), O(2) and O(3), the z coordinate of Al(2), Al(3), and O(4), the overall isotropic temperature factor, and the scale factor. The calculation was performed starting from the previous parameters[3] and by omitting hydrogen atoms. After several least-squares cycles, the reliability factor, R_I, could be reduced to 0.08 for 115 reflections. The final atomic coordinates, their standard deviations, and the overall isotropic temperature factor are listed in Table 1. The values of I_o and I_c calculated from the final parameters are given in Table 2.

TABLE 1. ATOMIC COORDINATES WITH THEIR STANDARD DEVIATIONS ($\times 10^4$)

	x	y	z
Al(1)	0.1647(9)	$2x$	0.3708(19)
Al(2)	2/3	1/3	0.1533(27)
Al(3)	1/3	2/3	0.0611(29)
O(1)	0	0	0
O(2)	0.5098(10)	$2x$	0.0143(19)
O(3)	0.8291(23)	$2x$	0.2666(20)
O(4)	1/3	2/3	0.2638(28)

Overall temperature factor 0.46(0.03)Å^2

Refinement was also attempted according to $P31c$, in which the Al(1), O(2), and O(3) atoms can shift out of the mirror plane, while the Al(2), Al(3), O(1), and O(4) atoms have to remain in the same position as in $P6_3mc$. This refinement was unsatisfactory, probably because the calculation was performed using the intensity values obtained by summarizing the hkl and $hk\bar{l}$ reflections; this was done since it is impossible to distinguish the hkl and the $hk\bar{l}$ reflections of $P31c$ in the powder diagram, although these reflections have different structure factors.

It, therefore, still remains conceivable that the atoms are slightly displaced from these special positions of $P6_3mc$ and that $P31c$ should be taken for this crystal.

Discussion

This refinement shows that the packing deviates from the postulated ideal model of the previous work. The oxygen atoms are closely packed in layers perpendicular to the c axis and are situated at z=0, 1/4, 1/2, and 3/4 but the individual atoms have different z parameters. Consequently, the oxygen layers are deformed; the first layer (at $z\approx 0$, O(1): z=0, O(2): z=0.014) and the third layer, which is symmetrically equivalent to the first layer,

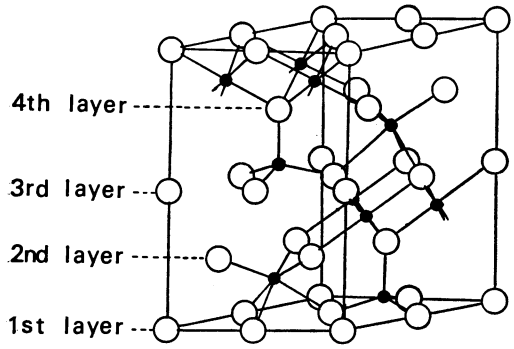

Fig. 1. The unit cell of the tohdite structure. Oxygen atoms are shown as large and aluminum atoms as small spheres.

are more deformed than the second layer (at $z \approx 1/4$, O(3): $z=0.267$, O(4): $z=0.264$) and the fourth. The distance between the first and second layers (0.26 Å) is larger than that between the second and the third layer (0.24 Å).

The interatomic distances were calculated from the coordinates of Table 1. The calculated standard deviations of the Al–O and O–O distances are from 0.01 to 0.03 Å.

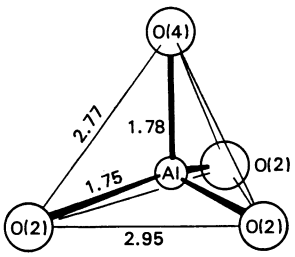

Fig. 2. Interatomic distances (Å) in $Al(3)O_4$.

The Al(3)–O distances are within the range of 1.78—1.75 Å, indicating that the $Al(3)O_4$ tetrahedra are slightly distorted (Fig. 2). In the $Al(2)O_6$ octahedra, aluminium atoms are placed at $z=0.153$, deviating from the $z=0.125$ of the ideal model, and are closer to the oxygen atoms of the upper face (in the second layer), 1.86 Å, than to the oxygen atoms of the lower face (in the first layer), 1.94 Å. The $Al(1)O_6$ octahedra are more distorted than the $Al(2)O_6$ octahedra.

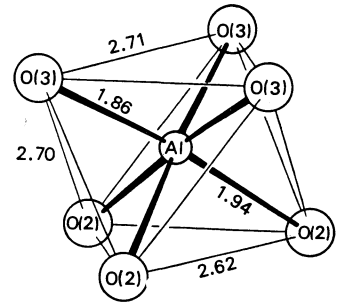

Fig. 3. Interatomic distances (Å) in $Al(2)O_6$.

The Al–O and the O–O distances in these AlO_6 octahedra are shown in Fig. 3 and Fig. 4. For comparison, the interatomic distances in AlO_6 octahedra for α-Al_2O_3[6] are also given; the Al–O distances are 1.86 and 1.97 Å, and to O–O 2.52, 2.87, 2.62, and 2.73 Å.

This refinement supports the expected nature of the distortion caused by local ionic attraction and repulsion.

All the calculations were performed with a HITAC 5020E computer of the Computation Center of Tokyo University, using programs written by the authors.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 2250—2254 (1969)

The Reaction between Mercury(II) and Organic Compounds. VII. The Formation Constant and Analytical Application of the *o*-(2-Thiazolylazo)-4-chlorophenol-Mercury(II) Complex

Fumiaki KAI

Department of Chemistry, Faculty of Science, Kumamoto University, Kurokami-machi, Kumamoto

(Received October 31, 1968)

The formation constants of the complex formed between *o*-(2-thiazolylazo)-4-chlorophenol, TACL, and mercury(II) in 2% v/v dioxane-water were log $K_{HgR^+}=6.2_1$ and log $K_{HgR_2}=6.1_0$ at $\mu=0.1$ and at room temperature. TACL was suggested as a suitable metallochromic indicator for the direct titrimetric determination of mercury(II) ions at pH 6.7—8.7 with an EDTA titrant. This optimum pH range was rather wide compared with that of the other metallochromic indicators, such as Cu-PAN, XO, and MTB. There were marked colour changes from deep blue to reddish-yellow or to violet at equivalence points. The mercury(II) ions up to 210 mg in 100 m*l* can be determined within an error of ±0.3% by this method.

o-(2-Thiazolylazo)-phenols have been found to be as excellent chromogenic reagents as pyridilazo phenols, and the properties of related chelates and analytical applications of them have hitherto been reported.

In preceding papers[1,2] the formation constants of the complexes formed between *o*-(2-thiazolylazo)-4-methoxy phenol (TAM) and *o*-(2-thiazolylazo)-cresol (TAC) and mercury(II) were shown. Moreover, these reagents were reported to be suitable metallochromic indicators for the direct titration of mercury(II) in a slightly alkaline medium. (In the case of the other indicators, such as Cu-PAN,[3] XO,[4] and MTB,[5] the optimum pHs of the direct titration for mercury(II) are pH 3—3.5(Cu-PAN) and pH 6 (XO and MTB).)

The present communication will describe the formation constant of the TACL-Hg(II) complex and its applicability to the metallochromic indicator for the determination of mercury(II) by titrimetry.

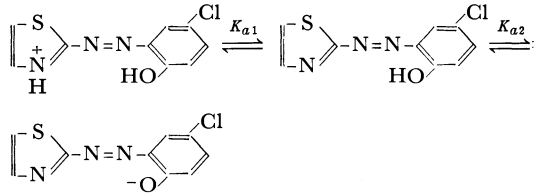
Experimental

Reagents. TACL was prepared according to the method reported in the literature[6] and was doubly recrystallized from hot ethanol. The purification of dioxane, the preparation of solutions of an EDTA titrant and of a stock solution of mercury(II), and the method of pH control were the same as those described previously.[1,2]

Instruments. The absorption spectra and the absorbances were measured with the Hitachi recording spectrophotometer (EPS-2) and a Hitachi photoelectric spectrophotometer (EPU-2) with 10-mm silica cells respectively. The pH was measured with a glass electrode pH meter (Hitachi-Horiba F-5).

Results and Discussion

Acid Dissociation Constant of TACL in a 2% v/v Dioxane-Water Solution. The dissociation scheme of TACL is as follows:



Each constant is given by Eq. (1):

$$K_{a1}=\frac{[HR][H^+]}{[H_2R^+]} \text{ and } K_{a2}=\frac{[R^-][H^+]}{[HR]} \quad (1)$$

The acid dissociation constants were obtained spectrophotometrically. For the second step only, Eq. (2) is given:

$$\log\frac{A-\varepsilon_{HR}C_{R^-}}{\varepsilon_{R^-}C_{R^-}-A}=\text{pH}+\log K_{a2} \quad (2)$$

where A is the total absorbance, C_{R^-}, the analytical concentration of TACL, and ε_{HR} and ε_{R^-}, the molar absorptivities of the HR and R^- species respectively.

The molar absorptivity was calculated from the horizontal lines of the pH-absorbance plot.

Curve 1=pH 5.40 Curve 3=pH 6.26
2= 6.01 4= 7.09

The absorption spectra of TACL in a 2% v/v dioxane-water solution at various pHs are shown in Fig. 1. They have the isosbestic point at 478 mμ and the absorption maxima at 550 mμ. At about pH> 7.6, TACL is red in colour due to the R^- species. By Eq. (2), the pK_{a2} value was obtained from the absorbances at 550 mμ. The precise pK_{a1} value was, however, not estimated because it may be considered to be in the pH<0 region. The values, which almost entirely conformed to those obtained in 20% v/v dioxane-water,[6] are listed in Table 1.

Absorption Spectra of Hg(II)-TACL Chelate in the Dioxane-Water Solution. The spectra of the mercury chelates were scanned for a 2% v/v dioxane-water solution containing various concentrations of the components at different pHs. Figure 2 shows the spectra of the mixture composed of excess mercury(II) and TACL (ten times as much mercury as TACL). From a pH of about 4.5 spectra were obtained with the isosbestic point at 502 mμ and the absorption maxima at 650 mμ, which was attributed to deep blue colour. Besides the mercury(II)-TACL chelate, an analogous blue colour was shown in the case of only the Ni(II)-TACL chelate,[6] TACL has, therefore, been suggested as a suitable metallochromic indicator for the titrimetric determination of mercury(II) ions with a proper titrant.

The spectra in the case of a reagent excess (ten times as much TACL as mercury) are illustrated in

Fig. 3. They were scanned using the TACL solution as the reference because the mixture showed a strong absorption caused by the predominant concentration of TACL itself.

Composition of the Chelate. By comparing the spectra shown in Figs. 2 and 3 it was found that almost all the figures of the curves, the wavelength, and the pH at the absorption maxima coincided; only their molar absorptivities differed. The molar absorptivities in Fig. 3 were nearly twice those in Fig. 2. Therefore the formation of the 1 : 1 chelate, HgR^+, was considered in the case of the mercury(II) excess (Fig. 2), and that of 1 : 2, HgR_2, in the case of the TACL excess (Fig. 3). The same situations have been described with respect to the analogous chelates formed between mercury(II) and thiazolylazo dyestuffs.[1,2]

Formation Constants of the Chelate. When the concentration of mercury(II) is in great excess in comparison with that of TACL, the successive formation constant can be calculated by Eq. (3):[1,2]

$$\log K_{HgR^+} = \log \frac{[HgR^+]}{[HR]} + pHg + pK_{a2} - pH \quad (3)$$

Equation (3) indicates that the plot of $\log[HgR^+]/[HR]$ against pH should give a straight line with a slope of unity, and that the formation constant can be calculated from the pH at which $\log[HgR^+]/[HR]$ equals zero, the acid dissociation constant of TACL, and the initial concentration of mercury(II) ions. Figure 4a shows the plot of $\log[HgR^+]/[HR]$ *versus* pH. The pHg value was estimated here on the assumption that it should be decreased by 10% from the initial concentration belonging to the 1 : 1 chelate formation because of the initial ratio of the components, $[Hg^{2+}]/[TACL]=10$. As a result, the successive formation constant, $\log K_{HgR^+}$, calculated was 6.2_1.

The second successive formation constant can be obtained indirectly from the over-all formation constant using Eq. (4):[1,2]

$$\log \frac{[HgR_2]}{[Hg^{2+}]} = \log K_{HgR^+} \cdot K_{HgR_2} + 2\log[HR]_t - 2pK_{a2} + 2pH \quad (4)$$

where $[HR]_t$ is the total concentration of TACL. Equation (4) shows that the over-all formation constant can be calculated by the pH at which $\log[HgR_2]/[Hg^{2+}]$ equals zero, the acid dissociation constant of TACL, and an experimental concentration of $[HR]_t$. Figure 4b shows the plot of $\log[HgR_2]/[Hg^{2+}]$ *versus* pH. In this case of a reagent excess, the $[HR]_t$ value was calculated by assuming that the initial concentration of the ligand may be decreased by 20% due to the 1 : 2 chelate formation because the initial mixture was composed of $[TACL]/[Hg^{2+}]=10$. The over-all formation constant obtained was $\log K_{HgR^+} \cdot K_{HgR_2} = 12.3_1$; therefore the second successive formation constant, $\log K_{HgR_2}$, was 6.1_0. These values are listed in Table 1.

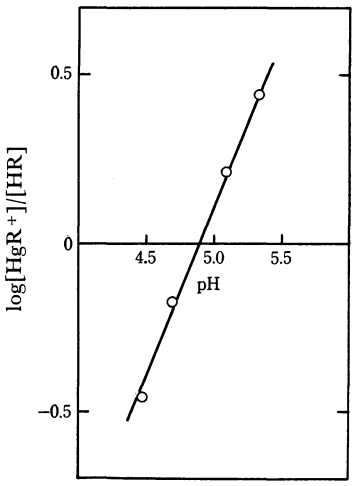

Fig. 4a. Plot of $\log [HgR^+]/[HR]$ *vs.* pH.

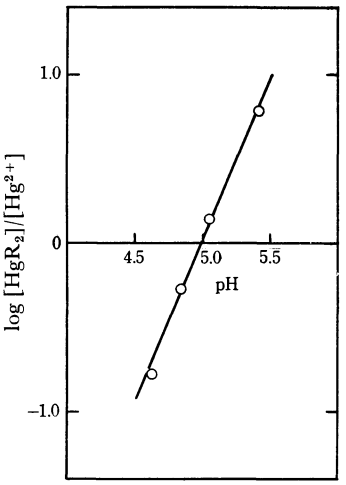

Fig. 4b. Plot of $\log [HgR_2]/[Hg^{2+}]$ *vs.* pH.

Applicability of TACL as a Metallochromic Indicator for Hg(II). In the case of the titrimetric determination of mercury(II) ions with a proper titrant (EDTA), and with TACL as the indicator, a sharp colour change may be expected because of the large difference in formation constant between the TACL-Hg(II) obtained as above and the HgY ($\log K_{HgY}=21.8$).

pH. Photometric titrations were carried out at various pHs. The concentration of mercury(II) was 5×10^{-4} M and several drops of an alcoholic TACL solution (*ca.* 10^{-2} M) were added to the sample solution. A deep blue solution was thus obtained. The concentration of the aqueous EDTA titrant was 10^{-2} M. The pH was adjusted with a 0.1 M phosphate buffer. As can be seen in Fig. 5, in the pH range of 6.7—8.7 the sharp colour changes were observed at the equivalence point. This optimum pH range seems to be rather wider than that indicated by the other indicators (BT:

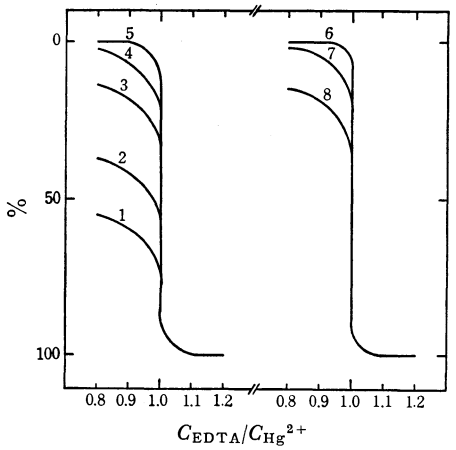

Fig. 5. Photometric titration curves.
$C_{Hg^{2+}}=5\times10^{-4}$ M, TACL$=4\times10^{-5}$ M, EDTA$=0.1$ M, Buffer$=$phosphate system.
Curve 1$=$pH 4.1 Curve 5$=$pH 6.9
2$=$ 5.0 6$=$ 8.2
3$=$ 5.9 7$=$ 8.7
4$=$ 6.5 8$=$ 9.1

pH 3—3.5; XO and MTB: pH 6). At the other pHs tested, colour changes were observed before the equivalence point, whereas no colour change such as a tailing of the colour after the equivalence point was shown at any of the tested pHs.

Error. Recovery tests were carried out at various concentrations of mercury(II) ions at pH 8.0. Table 2 shows that only a small error, within ±0.3, was given at the concentrations of mercury(II) up to 211.04 mg/100 m*l* (corresponding to 1.05×10^{-2} M as Hg^{2+}). The negative error was increased at concentrations of mercury(II) higher than about 10^{-2} M. Accordingly, it is desirable to keep the concentration of mercury(II) below *ca.* 10^{-2} M.*1

Effect of Diverse Ions. An interference study was also carried out. The depression of the absorbances at 650 mμ was checked after the titration of aqueous sample solutions containing various amounts of diverse ions with the EDTA titrant (10^{-2} M). A 100 m*l* of the sample solution (5×10^{-4} M as Hg(II) ions) was kept at pH 8.0. The results are listed in Table 3. Negative errors were given by anions which can form complex ions with mercury(II), whereas positive errors were given by metal ions which can form complexes with the EDTA titrant. Cyanide, thiocyanate, ammonium, and halide except considerable amounts of chloride gave the negative errors. On metal ions, a large positive error was given by nickel(II); the Ni(II)-TACL chelate showed a blue colour analogous to that of the Hg(II)-TACL chelate. Cobalt(II), zinc(II), cadmium(II), and copper(II)

Metal ions were added as nitrate.

*1 At concentrations higher than 10^{-2} M, mercury(II) oxide was apt to form. The excess ammoniacal buffer system may be suitable in this case: *cf.* N. Iritani, T. Tanaka and H. Sakai, *Nippon Yakugaku Zassi (J. Pharm. Soc. Japan)*, **76**, 1068 (1956); *ibid.*, **77**, 106 (1957).

ions gave errors. However, no interference was caused by the presence of silver(I), calcium(II), strontium(II), barium(II), chromium(III), iron-(III), and aluminium(III) ions up to 10 mg.

The titration could be carried out accurately without heating the sample solution.

In view of the above data, it may be suggested that TACL can also be utilized as a metallochromic indicator of mercury(II), for its sensitivity and accuracy are as good as those of TAC[1] and TAM.[2]

On the basis of the above results, the recommended procedure for the direct titrimetric determination of mercury(II) ions using TACL as the indicator is as follows: Take about 100 m*l* of a sample solution containing not more than 10^{-2} M as mercury(II) ions at pH 6.7—8.7, adjusted with a 0.1 M phosphate buffer system. Add several drops of an alcoholic solution of TACL (*ca.* 10^{-2} M) to the sample solution, and then titrate with the EDTA titrant (10^{-2} M aq. soln.). Near the end-point, carry out the titration slowly and with constant shaking. The colour change is sharp and reversible.

The author wishes to express his deep gratitude to Professor D. Yamamoto of Kumamoto University for his useful discussions and encouragement throughout this work.

Photochemical Analysis. I. Photonometric Titration of Thallic Ion by Uranyl Photoreduction Reaction

Yu YOKOYAMA and Shigero IKEDA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka

(Received November 7, 1968)

Photonometric titration of thallic ion is described, in which uranous ion, the titrant, is generated by photoreduction of uranyl ion in a sulfuric acid solution containing sodium lactate. Uranyl ion could be reduced with the light at wavelengths longer than 300 mμ, whereas thallic ion could not be reduced with the light in this wavelength range. Selective photoreduction of uranyl ion was accomplished by eliminating wavelengths below 300 mμ with a filter. In this photonometric titration, reaction solutions were irradiated without stirring at 29.5±0.5°C. The absorbance of uranous ion produced was measured at 655 mμ every fixed irradiation time, and the absorbance was plotted against the irradiation time. Induction period, which means the period during which the absorbance remains actually zero, was in a linear relation with thallic concentration. Thus the titration of thallic ion was satisfactorily carried out in the concentration range from 0.01 to 0.1 mM. The results proved the feasibility of titration in a completely sealed container and suggest a possibility of titration on a microvolume of reaction solution.

Photonometric titration was first proposed by Bricker and Schonberg.[1] In photonometric titration, titrant is photochemically generated in a solution containing a substance to be determined. However, no titration systems have been investigated except ferric-ferrous,[1] cobaltic-cobaltous,[2] and anthraquinone-reduced anthraquinone[3] systems. In the present paper, a photonometric titration by uranyl-uranous redox system is described. The photoreduction of uranyl to uranous ion has been utilized as preliminary treatment in volumetric titration of uranium by Rao *et al.*,[4,5] but in the present case this reaction is performed for generation of titrant.

The previous experiments on potentiometric titration[6,7] showed that, in spite of effective stirring of reaction solution, there existed a time lag (approximately less than one second) between addition of a titrant and indication of potential, as is the case with all conventional titrations. In the photochemical reaction, it is possible to generate a titrant homogeneously. In the present work,

therefore, an attempt was made to perform the titration in a stoppered reaction vessel without stirring. A reaction vessel of 10 mm in light path length and 5 m*l* in volume, provided with a ground stopcock, was designed, and used throughout the present work.

In photochemical reactions, some substances react with a product of the photochemical reaction and some take part in the reaction as a quencher. In a series of our photochemical experiments, these actions of coexisting substances were found to be applicable to the determination of microamounts of substances. These results will be published in succession, and hereafter *the chemical analysis based on the photochemical reaction will be called "the photochemical analysis."*

The photochemical analysis has the following advantages over other analytical methods. (1) The titrant is generated in a reaction vessel, as the titration proceeds. Consequently, unstable substances can be utilized as titrant. (2) The determinable concentration range is of the same order as, or less than, that in the coulometric titration. (3) The titration can be performed in a completely sealed container and, therefore, there is a possibility of titration on a microvolume of reaction solution. On the other hand, the shortcomings are as follows. (1) The temperature of reaction solution must be kept constant, as is usual in experiments of reaction rate measurement. (2) Interference of coexisting substances could occur in two different ways, that is, the reaction with a photochemical reaction product and the quenching reaction.

Experimental

Reagents. Uranyl standard solution (0.05 M) was prepared by dissolving G. R. uranyl acetate in water containing a small amount of sulfuric acid. The factor of this solution was determined to be 0.965 by gravimetry as uranyl oxinate. Thallic standard solution (0.025 M, f=0.937) and thallous standard solution (0.05 M, f=0.993) were prepared by dissolving thallic oxide of 99.9% purity and E. P. thallous sulfate in 1.2 N sulfuric acid solution, respectively. The factors of these solutions were determined iodometrically. Sodium lactate solution (0.2 M), and sulfuric acid solution (5 N) were also used in phtochemical reaction. In addition, sulfuric acid (1 N) solutions of the following salts were prepared: bismuth nitrate, mercuric sulfate, silver sulfate, zinc sulfate, and cadmium sulfate. The following reagents were prepared for iodometric titration of thallium: 0.01 M thallous chloride standard solution, 0.01 N sodium thiosulfate solution, 1% potassium iodide solution, 1% starch indicator solution, 20% phenol-glacial acetic acid solution, bromine mixture which was prepared by dissolving 50 g of sodium dihydrogenphosphate monohydrate and 50 g of ammonium chloride in 450 m*l* of saturated bromine water, and phosphate-chloride mixture containing 50 g of sodium dihydrogenphosphate monohydrate and 50 g of ammonium chloride in 450 m*l* water.

Apparatus. In order to follow the photoreduction of uranyl ion, a Shimadzu Ltd. Model QV-50 spectrophotometer was utilized with some modification. A side wall of the absorption cell compartment was replaced with a new side wall equipped with a window and a shutter. In front of the shutter a 120 W medium pressure mercury lamp, which was employed as the light source for photochemical reaction, was attached together with a lens system, and the optical axis was addjusted so as to intersect that of the monochromator at right angles. The cell holder was positioned at the intersection. A 10 mm × 10 mm quartz absorption cell with four transparent sides was used in place of a usual absorption cell, and also served as a photochemical reaction vessel. The cell was fitted with a ground stopcock. The mercury lamp and its power unit were components of a Hitachi Ltd. Model 203 fluorescence spectrophotometer. The light intensity from the lamp stabilized within 15 min from initial ignition. Absorption spectra were recorded with a Hitachi Ltd. Model EPS-2 automatic recording spectrophotometer.

Procedure. The reagent solutions were mixed in a 25 m*l* measuring flask, and diluted to 25 m*l*. Approximately 5 m*l* of the mixed solution was transferred into a reaction vessel, which was then set in the cell holder. For photochemical reaction, the reaction vessel was irradiated with the mercury lamp with the shutter open. After irradiation for a definite time, the absorption of uranous ion produced was measured at a wavelength of 655 mμ with the shutter closed. Irradiation was continued with the shutter open for further reaction.

Total thallium was determined according to the following procedure, which was a modification of the method proposed by Sill *et al.*[8] To a solution containing thallium was added 15 m*l* of 5 N sulfuric acid, 30 m*l* of water and 50 m*l* of the bromine mixture. The solution was boiled to oxidize completely thallous to thallic ion until the coloration of the solution became light yellow. After being cooled, 0.4 m*l* of the phenol solution was added to remove free bromine and then total thallium was titrated with 0.01 N sodium thiosulfate solution. Before titration of thallium, 0.01 N sodium thiosulfate solution was standardized against 0.01 M thallous chloride standard solution. Titration of thallic ion in the presence of thallous ion was carried out in the same way as for the determination of total thallium, except that bromine mixture was replaced with phosphate - chloride mixture and heating was omitted. The titration of thallic ion could be performed in the presence of uranyl ion without any interference of uranyl ion.

Results

Measurement of Absorption Spectra. Transmittance curves of uranyl, uranous and thallic ions were recorded in the wavelength range from 250 to 700 mμ. They are shown in Fig. 1. The curve of uranyl ion was that of a solution containing 10 mM uranyl ion, and 40 mM sodium lactate in 1 N sulfuric acid (hereafter called the uranyl mixed solution), and the curve of uranous ion was

8) C. W. Sill and H. E. Peterson, *Anal. Chem.*, **21**, 1268 (1949).

obtained with the uranyl mixed solution after exposure to the mercury lamp until the absorption characteristic of uranous ion was no further increased. Uranous ion has an absorption maximum at 655 mμ (molar absorptivity $\varepsilon=48.9$), and hence the ion was determined spectrophotometrically at this wavelength. For comparison a transmittance curve of a solution containing merely 10 mM uranyl ion in 1 N sulfuric acid was also recorded, and found to be identical with the curve for the uranyl mixed solution. The curve of thallic ion was recorded with a solution containing 10 mM thallic ion, and 40 mM sodium lactate in 1 N sulfuric acid (hereafter called the thallic mixed solution). A transmittance curve of thallous ion was also measured, which is not shown in Fig. 1, and was found merely to shift to a shorter wavelength by approximately 40 mμ compared with the curve of thallic ion.

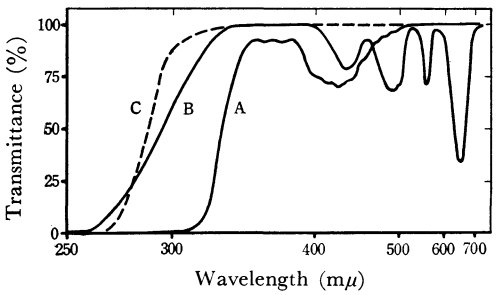

Fig. 1. Absorption spectra of uranyl, uranous, and thallic ions.

A: 10 mM uranyl ion (with 40 mM Na lactate and 1 M H_2SO_4)
B: 10 mM uranous ion (obtained by exposing the solution A to mercury lamp)
C: 10 mM thallic ion (with 40 mM Na lactate and 1 N H_2SO_4)

Irradiation without Filter. The uranyl mixed solution was transferred into the reaction vessel, and irradiated with the mercury lamp without any filter. The absorbance of uranous ion was measured every fixed irradiation time, and the amount of uranous ion produced was calculated by using the molar absorptivity of uranous ion. The thallic mixed solution was also irradiated under the same conditions. Thallous ion thus produced was determined by iodometric titration every fixed irradiation time. Results are presented in Fig. 2. Uranyl ion was reduced to a considerable extent within the irradiation time, as would be expected, and also the reduction of thallic ion took place, even if only slightly.

Irradiation with Filter. The uranyl and the thallic mixed solutions were irradiated through a soft glass filter for eliminating the light of wavelength shorter than 300 mμ. Other conditions were the same as mentioned above. The relation

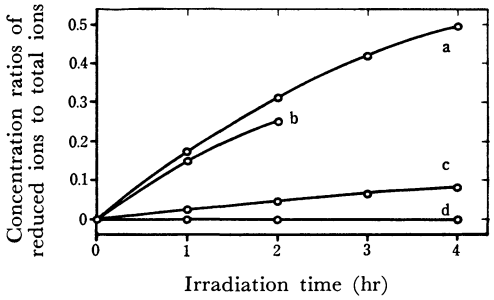

Fig. 2. Photochemical reaction of uranyl and thallic ions.

a and b: 10 mM uranyl ion (same solution as A in Fig. 2)
c and d: 10 mM thallic ion (same solution as C in Fig. 3)
a and c: without filter, b and d: with filter

between the amount of ion reduced and the irradiation time is shown in Fig. 2. The reaction of thallic ion could not be observed, and at the same time the efficiency of uranyl photoreduction was slightly lowered.

Stoichiometry of Reaction between Thallic and Uranous Ions. The uranyl mixed solution was exposed to the light of the mercury lamp to produce uranous ion. Exposure was continued until uranyl ion was completely reduced. To each 10 m*l* of the solution (containing 10 mM uranous ion) was added an aliquot of the 25 mM thallic standard solution and then water to make up to 13 m*l*. After mixing, the absorbance of of the mixture was measured. The results showed that one mole of thallic ion reacted with one mole of uranyl ion. Therefore, it is considered that the overall reaction proceeds according to the following equation.

$$U^{4+} + Tl^{3+} + 2H_2O = UO_2^{2+} + Tl^{+} + 4H^{+}$$

Photonometric Titration Curve and Calibration Curve. Uranyl ion was photochemically reduced in the presence of thallic ion. Test solutions contained various amounts of thallic ion together with 10 mM uranyl ion, 40 mM lactate and 1 N sulfuric acid. The solutions were irradiated through the filter in the cell compartment kept at 29.5±0.5°C under the same conditions as before, and the absorbance of uranous ion produced was measured at 655 mμ every fixed irradiation time. An example of a photonometric titration curve is shown in Fig. 3. It is seen that the curve consists of two parts, that is, the first part where the absorbance remains actually zero, and the second part where the absorbance steadily increases. In order to follow the change in concentration of thallic ion during irradiation, thallic ion in the test solution was iodometrically determined. While thallic ion existed before the point where the titration curve begins to rise, the ion was not detected after the

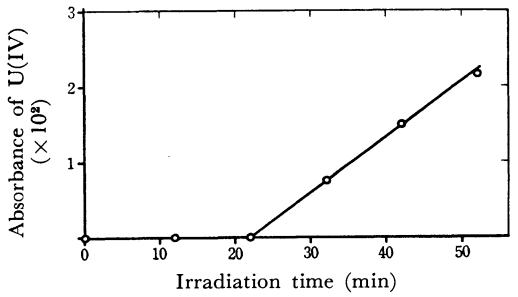

Fig. 3. Photonometric titration curve of thallic ion.
0.1 mM thallic ion (in the solution containing 10 mM uranyl ion, 40 mM Na lactate, and 1 N H_2SO_4). Measurement was made at 29.5± 0.5°C.

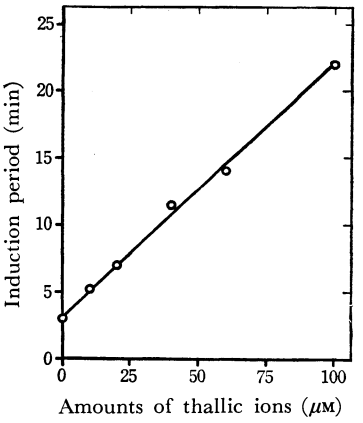

Fig. 4. Calibration curve of thallic ion.
Induction periods were obtained from a set of photonometric titration curves as shown in Fig. 3.

point. The induction period was dependent on the amount of coexisting thallic ion. Photonometric titration curves were constructed for thallic ion in a concentration range of 0 to 0.1 mM, and the induction periods were obtained from each of the curves. The measurement of the induction period was repeated three times for each thallic concentration, and the values observed were averaged. Figure 4 shows a plot of the induction periods against the concentration of thallic ion. Nearly linear relationship was obtained in the concentration range, but the plot did not pass through the origin. The effect of other metal ions on the photonometric titration of thallic ion was tested. Bi(III), Zn(II), and Cd(II) ions in concentration of 0.4 mM had no influence on the determination of thallic ion. But Hg(II) and Ag(I) were reduced under the same conditions as for the photonometric titration of thallic ion.

Discussion

Absorption Spectra. The uranyl spectrum obtained was similar in profile to those reported by Bell *et al.*,[9] Betts *et al.*[10] and others. Betts *et al.* showed that an absorption maximum of noncomplexed uranyl ion at approximately 415 mμ shifted to the vicinity of 420 mμ on complex formation with sulfate ion. Since the uranyl spectrum in Fig. 1 has the absorption maximum at 420 mμ regardless of the presence of lactate, it is reasonable to think that uranyl ions formed a sulfate complex. Bell *et al.* have recently reported that uranyl ion in two excited state energy levels (at 21270 and 20502 cm^{-1}) can be responsible for the photochemistry of uranyl ion. In the present investigation, therefore, the photochemical reaction of uranyl ion was carried out by use of the light in the wavelength range longer than 300 mμ (approximately 33000 cm^{-1}).

Thallic and thallous ions show no light absorption above approximately 320 mμ, and, therefore, in the longer wavelength range do not interfere with light absorption of uranyl ion. An intense absorption band exists below approximately 300 mμ. In consideration of the fact that thallic ions underwent the photochemical reduction by irradiation with unfiltered mercury lamp, the intense absorption band below approximately 300 mμ is supposed to be involved in the photochemical reaction of thallic ion.

Photoreduction of Uranyl and Thallic Ions. The initial concentration of uranyl ion affects not only the reaction rate of the uranyl photoreduction, but also the homogeneity of the photoreduction in the reaction solution. The number of photons absorbed by uranyl ion in the reaction vessel is diminished as the incident light from the mercury lamp proceeds from the front of the vessel to the back. Consequently there should be some difference in the amount of uranous ion produced along the path length of the incident light. An excessive increase in the uranyl concentration would enlarge the difference to such an extent that the homogeneity of the reaction solution can not be maintained by the diffusion process of the solutes. In consideration of the two factors, the reaction rate and the homogeneity of the photoreduction, the uranyl concentration of 10 mM was chosen in the present work, since in this concentration the reaction rate is moderate and a difference was not seen in the absorbance before and after vigorous mixing of irradiated reaction solutions.

The work by Rao *et al.*[4] of the photoreduction of uranyl ion in the sodium lactate-sulfuric acid system showed that the reduction rate of uranyl ion was constant over sulfuric acid concentration from 0.10 to 2.0 N and that the reduction rate

9) J. T. Bell and R. E. Biggers, *J. Mol. Spectry.*, **25**, 312 (1968).
10) R. H. Betts and R. K. Michels, *J. Chem. Soc.*, **1949**, 286.

reached a maximum value at a lactate-to-uranyl ratio as high as 4 to 1. Therefore, subsequent experiments were performed with 40 mM of sodium lactate and 1 N of sulfuric acid.

The fact that thallic ion undergoes photoreduction under certain conditions has already been reported by Benrath,[11] who observed that thallic ion was photochemically reduced in the presence of oxalic acid, tartaric acid, or alcohol. Figure 2 shows that the photoreduction took place in the presence of sodium lactate, also. However, the reaction could not be observed on irradiation through the soft glass filter.

Photonometric Titration Curve. In the photonometric titration, the absorption at 655 mμ could not be observed until the absorbance began to increase steadily, and thallic ion did not exist after the rising point of the titration curve. Thus this point could be considered to be the end point. The mechanism of the photoreduction of uranyl ion has not been made clear, and there is some possibility that thallic ion reacts with an intermediate of the photochemical reaction. Accordingly it seems that uranous ion is formed as a final product of the photochemical reaction in the absence of other reducible substances, and that, when thallic ion coexists, it is reduced preferentially before reduction of uranyl ion owing to the more positive oxidation potential of thallic ion.

The fact that the reaction solution containing no thallic ion showed a blank induction period suggests that a part of uranous ion is oxidized by something other than thallic ion. Hitherto it has been reported that uranous ion is oxidized by the air or oxygen dissolved in the solution, and the mechanism of this reaction has been studied by Halpern and Smith.[12] As a check, the uranyl mixed solution was irradiated with the mercury lamp after removal of the air with a rotary vacuum pump. The photonometric titration curve of this solution revealed that the absorbance at 655 mμ began to increase from the start of irradiation. In addition experiments done at temperatures down to 15°C indicated that there was a parallel relationship between the blank induction period and the solubility of oxygen. Thus it is certain that oxygen dissolved in solutions consumes uranous ion. However, because the temperature of reaction solutions is kept at 29.5±0.5°C, the effect of dissolved air would be unchanged for each reaction solution, and thus the plot for each thallic concentration should be shifted equally by a constant value, that is, a blank induction period.

Application. Table 1 shows the results of determination of thallic ion by use of the calibration curve presented in Fig. 4. Although the measurement for 0.15 mM thallic ion was also tried and the result showed that the plot for this concentration still lay in the extension of the calibration curve, it seems that the measurement of a too long induction period is incovenient for practical use. On the other hand, for thallic ion less than 0.01 mM the reproducibility would become relatively worse.

TABLE 1. RESULTS OF DETERMINATION OF THALLIC ION

Concentration of thallic ion, μM		
Present	Found	Average
10	13, 8, 6	9
20	19, 22, 17	20
40	41, 43, 46	43
100	107, 96, 102	102

Hence it is found that photonometric titration can satisfactorily be applied to microdetermination of thallic ion in the concentration range from 0.01 to 0.1 mM. Further improvement of accuracy would be effected by increase in the optical path length of reaction vessel for absorption measurement.

The rise of temperature increases the reaction rate of the uranyl photoreduction, and, hence, affects the induction period. Therefore, the calibration curve shown in Fig. 4 can not be applied to the data obtained at other temperatures. Hg(II) and Ag(I) interfered with the determination of thallic ion owing to their reactivity against the photoreduction product, but there was no interference from such ions as Zn(II), Cd(II), and Bi(III).

For the first time in photonometric titration, and probably in all kinds of titration, the titration procedure could be carried out without stirring the reaction solution. This fact indicates that titration can be performed in a far smaller volume of reaction solution, when allowed to make use of microspectrophotometric technique, and that it is possible to carry out titration in a cell isolated completely from outside, because both the generation of titrant and the measurement of concentration of a reaction product can be made without breaking the isolation of the reaction system.

Syntheses and Properties of Some Metal Bromo-Dithiolium Complexes*1

Akira OUCHI, Hiroshi EGUCHI, Toshio TAKEUCHI and Akiko FURUHASHI*2

Department of Chemistry, College of General Education, The University of Tokyo, Komaba, Meguro-ku, Tokyo

(Received November 9, 1968)

The bromo-3-methyl-5-phenyl-1,2-dithiol-1-ium complexes were obtained from metal benzoylacetonate, using hydrogen sulfide and bromine with a catalyst of hydrogen bromide. These complexes resemble bromo-bis(3,5-dimethyl-1,2-dithiol-1-ium) complexes and many of them are of the high-spin type. The Zn(II) and Cd(II) complexes are of the ML_2Br_4 type (where M=metal and L=3-methyl-5-phenyl-1,2-dithiol-1-ium), like 3,5-dimethyl-1,2-dithiol-1-ium complexes, while Cu(I) is of the $MLBr_2$ type. However the analytical results shows that the Mn(II), Fe(II) and Co(II) complexes are of the ML_2Br_3 type. Infrared spectra as well as electronic spectra are shown and discussed.

The tetrachloro-[1,2] and tetrabromo-[3] bis(3,5-dimethyl-1,2-dithiol-1-ium) complexes have already been synthesized and discussed, and the cobalt(II) and iron(II) tetrachlorobis(3,5-dimethyl-1,2-dithiol-1-ium) complexes were also reported on recently.[4] As the tetrabromobis(3,5-dimethyl-1,2-dithiol-1-ium) complexes are synthesized from many kinds of metal acetylacetonates without difficulty, it seemed that it would be very interesting to apply this synthesis technique in an attempt to obtain other bromo-dithiolium complexes. Consequently, the present authors have examined syntheses using many kinds of β-diketonates, including cobalt(II), nickel(II), zinc(II) complexes of benzoylacetone, trifluoroacetylacetone, dibenzylmethane, trifluorobenzoylacetone, methyl acetoacetate, and ethyl acetoacetate. However, the expected products were obtained only from the benzoylacetonates; the syntheses using other β-diketonates have not yet been successful.

Attempts to synthesize chloro(3-methyl-5-phenyl-1,2-dithiol-1-ium) complexes using hydrogen chloride and chlorine in place of hydrogen bromide and bromine were all unsuccessful. This seems due to the facts that: 1) the dithiolium ring is not easily formed from these β-diketones under the experimental condition presented above; 2) some β-diketones are more easily destroyed by free chlorine or bromine than is acetylacetone, and some side-reaction occurs predominantly; 3) steric hindrance owing to the introduced radicals on 2- or 4- carbons seriously affects the formation of complexes.

From the syntheses, two types of complexes of bivalent metals were obtained; ML_2Br_4 (where M=Zn(II) or Cd(II)) and ML_2Br_3 (where M=Mn(II), Fe(II) and Co(II)). The former seems to be isostructural to tetrabromo-bis(3,5-dimethyl-1,2-dithiol-1-ium) complexes. However, the latter compounds are of the new type. The cuprous salt has the $CuLBr_2$ formula and not the CuL_2Br_3 formula; the compound of the latter type was obtained from acetylacetonate.

Recently in our laboratory we have been successful in synthesizing some halogeno(3-methyl-5-phenyl-1,2-dithiol-1-ium) complexes by means of the reaction of metal halide and dithiolium perchlorate.[5] The products are ML_2X_4 or MLX_3-type complexes for bivalent metals and MLX_4-type complexes for tervalent metals. From manganese(II) and cobalt(II) bromides, regular ML_2X_4-type complexes and not ML_2X_3-type complexes were obtained. The colors of these two types of complexes are a little different; the ML_2X_4-type manganese(II) complex is light yellow, while the ML_2X_3-type one is deeper yellow; the former type of cobalt(II) complex is yellowish green, and the latter type is grass green. From ferric bromide a MLX_4-type complex was obtained, while a ML_2X_4-type complex was obtained from cupric bromide, as the redox reaction does not occur in the synthetic process using dithiolium salt. On the other hand, the direct synthesis of the halogeno-(dithiolium)-complex may include some different reactions because of the use of an excess of strong

reagents, such as hydrogen sulfide or bromine.

The infrared spectra and electronic spectra of the complexes of all these types, *i.e.*, ML_2X_4, ML_2X_3, MLX_2, and MLX_4, are almost identical, and so their structures are probably not very different from one another.

Experimental

Materials and Instruments. The starting materials were of a G. R. grade and were used without purification. The infrared spectra were obtained by a nujol and hexachloro-1,3-butadiene mull procedure using a DS-301-type infrared spectrophotometer of the Japan Spectroscopic Co., Ltd. Electronic spectra were obtained with a Hitachi EPS-2-type automatic recording spectrophotometer. The reflectance spectra were obtained with an Ito Model QU-3 spectrophotometer using a reflectance attachment and a magnesium oxide standard. The magnetic moments were measured with a Gouy balance at room temperature (21°C).

Synthesis of Tetrabromo-bis(3-methyl-5-phenyl-1,2-dithiol-1-ium)cadmium(II). Two and seven-tenths grams (0.010 mol) of anhydrous cadmium(II) bromide and three grams (0.018 mol)*3 (or less) of benzoylacetone were mixed with 30 m*l* of absolute ethanol. After the dissolution, a precipitate appeared. To the mixture cooled on ice dry hydrogen bromide was added over a 1 hr period; the precipitate was completely dissolved during this procedure. Then about 1.0 m*l* (0.04 mol) of bromine*4 was stirred in, drop by drop. Finally hydrogen sulfide was passed through for about 5 min until a little precipitate appeared.*5 The precipitate was filtered off and the filtrate was mixed with a half volume of petroleum ether and kept in a cold room (—about 5°C) overnight. The needle-like yellow precipitate thus obtained was filtered off, and the product was washed with ethanol, carbon disufide, chloroform, and diethyl ether (in that order) to remove the mother liquor, sulfur, the dimer of the dithiobenzoylacetone, and the washing solvents respectively. The product was then dried in a vacuum desiccator at room temperature. The yield was about 2.1 g (36.0% calculated from the quantity of benzoylacetone used).

Though the product is soluble in such polar solvents as water or alcohol, it reacts with them; on the other hand it is hardly soluble in non-polar solvents. For this reason recrystallization has not yet been successful.

The syntheses of the zinc(II) complex and of ML_2Br_3-type complexes of manganese(II) and cobalt(II) were carried out by almost the same method. The yields are shown in Table 1.

The iron(II) complex, FeL_2Br_3, was obtained from iron(III) bromide without using bromine as the ferric ion itself worked as the oxidizing agent. The copper(I) complex, $CuLBr_2$, was obtained from copper(II) bromide by the same process without bromine. In both cases no product was isolated if bromine was added during the process.

The Analyses of Bromine in Complexes. The analysis of the bromine in these complexes was difficult; the Volhard method and the iodometry, both to be described below, were examined.

i) Volhard Method. The solid sample was stirred with a silver nitrate-nitric acid aqueous solution for about 10 min and the excess silver ion was titrated with a thiocyanate solution.

Table 1. Analysis and yield of complexes (Figures are given in %.)

		Metal	C	H	S	Br	Yield

	Found	15.30	29.11	2.53	16.36	38.30	

HL = dithiobenzoylacetone ($C_{10}H_{10}S_2$)

*3 In these syntheses metal salt should be present in excess, as: i) the trapping effect of the dithio-chelate is better; ii) the dimerization reaction is minimized, and iii) the excess of metal halide is easily washed out by ethanol after the reaction.

*4 A little excess is necessary as the reaction solution contains a great excess of hydrogen sulfide. The bromine added reacts first with hydrogen sulfide to produce sulfur; then the sulfur bromine and hydrogen sulfide seem to undergo a complicated reaction (polysulfide may be produced on the way), and finally the complexes are obtained. To add too much bromine destroys the product, and the yield is not good either.

*5 If hydrogen sulfide was passed through too long, the complex precipitate on the step, the impurities, and the yield were seriously lowered.

ii) Iodometry. The solid sample was dissolved into water and oxidized with potassium permanganate in the presence of phosphoric acid at room temperature. The isolated bromine was extracted with carbon tetrachloride, the organic solvent layer was shaken and introduced into the aqueous solution of potassium iodide, and the freed iodine was titrated with a standard sodium thiosulfate solution.

Both analytical techniques were applicable to ML_2Br_4-type complexes. However, for ML_2Br_3-type complexes the Volhard method gave too high values, about 30% higher than the expected values; on the other hand, the iodometry gave us too low values, about 30—50% lower than the calculated values.

The results of the bromine analyses of ML_2Br_3 complexes given in Table 1 were obtained by the usual elemental analysis technique for organic compounds-measuring as silver bromide after other interfering substances had been removed. This method is not very suitable, either, and considerable error is inevitable. However, the results of the analyses of the other elements, metal, sulfur, carbon, and hydrogen of these complexes coincide with the expected values within the range of experimental error, thus confirming the formulae shown here.

Results and Discussion

The analytical data as well as the yields of the synthesis process are shown in Table 1. Their magnetic moments are given in Table 2.

Table 2. Magnetic moments of complexes
(Figures are given in B. M. per 1 mol of metal.)

	B. M.	Valence of the central metal

FeL_2Br_3	5.35	II
CoL_2Br_3	4.68	II
ZnL_2Br_4	diamagnetic	II
CdL_2Br_4	diamagnetic	II
$CuLBr_2$	diamagnetic	I

From the magnetic data, the manganese(II), iron(II), and cobalt(II) complexes all seem to be high-spin complexes. ML_2Br_4-type complexes of zinc(II) and cadmium(II) are diamagnetic and bivalent. The copper complex is also diamagnetic and univalent.

The colors of the solids and the reflectance spectra between 12500 and 28500 cm^{-1} are shown in Table 3. The manganese(II), zinc(II), and cadmium(II) complexes are yellow, and very little absorption is recognized in the 12500—22000 cm^{-1} region. On the other hand, iron(II) and copper(I) complexes have a deep color and have considerable absorption in this region, although the band is too broad and the wave numbers of the maximum points are not clear. The cobalt(II) complex has an absorption maximum at 14300 cm^{-1} which is probably a d–d band.

All of these complexes have the intense band at about 24000—25000 cm^{-1} which is characteristic of all of this type of compound, but it is not seen in their absorption spectra in ethanol, probably because of the dissociation of the complexes in the solution.

The absorption spectra of the ethanol solution of these complexes are shown in Table 4. The absorptions in the visible region are very weak; the absorption peaks are seen almost only in the ultraviolet region.

The wavelengths and the molar absorption coefficients of the absorption maxima of the solutions coincide with those of 3-methyl-5-phenyl-1,2-dithiol-1-ium perchlorate, which is synthesized by the method of Schmidt and Schulz.[6] Judging from these facts, the complex seems to dissociate completely into ions in the solution.

If the pure ethanol which does not contain perchloric acid was used as the solvent, the color of the solution gradually turned red at room temperature; this is due to the decomposition of the dithiolium ion, because the same color change is also seen in the solution of pure dithiolium salt.

The infrared spectra data of the complexes and the 3-methyl-5-phenyl-1,2-dithiol-1-ium perchlorate are summarized in Table 5, together with those of some related compounds.[4] The general features of the infrared spectra of these complexes, both ML_2Br_4 and ML_2Br_3-type complexes, resemble those of tetrachloro-bis(3-methyl-5-phenyl-1,2-dithiol-1-ium)iron(II) and not those

of bis-(dithiobenzoylacetonato)nickel(II). Moreover, the 3-phenyl-5-methyl-1,2-dithiol-1-ium perchlorate shows a very similar pattern as well, though the absorption in the 1050—1130 cm^{-1} region is not clear because of the overlapped absorption of the perchlorate ion.

From these facts, it can be said that in ML_2X_4-type complexes halogen atoms do not seriously effect the infrared spectra of the dithiolium ion. Therefore, their structure should be isostructural to tetrabromo-bis(3,5-dimethyl-1,2-dithiol-1-ium) complexes,[3] though an X-ray crystallographic study of them is necessary to clarify the structure in detail. By analogy, $Cu(I)LBr_2$ may have a $(-M-Br-)_n$ chain structure, where one more bromine and probably dithiolium ion bond to each tetracoordinated metal atom.

In the case of ML_2X_3-type complexes, as the central metal atom is bivalent and not abnormally charged, how the charge is distributed in the whole molecule is a problem. One dithiolium ion is

unipositive, so the other one should be zero valent. The monomer of the free dithio-β-diketone is unstable, and the dimer and the complex containing the dimers, $(Cu^{I}(C_5H_7S_2)Cl)_n$, for example,[3] show very different infrared spectra. Judging from this fact, this complex does not contain the dimer.

When the dithiolium complexes are synthesized directly from the dithiolium salt, the formulae of the products of the complexes of these metals are ML_2Br_4 and there is no difficulty in making a bromine analyses of them. Consequently, one dithiobenzoylacetone of the ML_2X_3-type complexes is not a usual dithiolium ion but is more easily hydrolyzed, and the sulfur atoms in it are apt to be isolated as sulfide ions.

As for benzoylacetone adducts, Rosenheim synthesized $SbCl_5(C_{10}H_{10}O_2)$;[7] the benzoylacetone is zero valent in it. Really the $MLCl_3$-type dithiolium compounds have already been synthesized;[5] these ML_2Br_3-type compounds may be the adducts of the zero valent dithiole to the $MLBr_3$-type complexes; then the dithiole-type ligand, which is less stable than the dithiolium type in the case of dithiobenzoylacetone, can easily be destroyed.

From these results, the other dithio-β-diketone is probably a 1,2-dithiole derivative, 3*H*-3-methyl-5-phenyl-1,2-dithiole, for example, although the evidence is not decisive. During the process of synthesis the coexistence of the Mn(II), Fe(II), or Co(II) ions in the solution may prevent the perfect oxidation of the ligand to the dithiolium cation.

However, the presence of a uni-negative-valent brominated dithiole ion, for example, cannot be denied completely. Really, such compounds may be easily produced as intermediates of the synthetic process.[8] The 3-methyl-4-bromo-5-phenyl-1,2-dithiole, for example, should be uni-negative, and its infrared spectra may be expected not to be very different from those of the usual dithiolium ion, as in the case of halogenated acetylacetonates.[9] On the other hand, if the bromine atom is attached to the 3- or 5-carbon of the ditholium ion, more serious deviations of the infrared spectra may be expected. These brominated dithiolium ions seem to be easily hydrolyzed by water or alcohol.[10] However, as our attempt to synthesize ML_2Br_2-type compounds failed, the presence of the LBr^- ion was not proved.

The authors wish to thank the Biochemistry Section of our college for doing the infrared spectra measurements. The authors wish also to express their appreciation to Professor Yasumasa Hayakawa and the staff of the Department of Chemistry of Aoyama Gakuin University and to acknowledge gratefully their helfpful discussions with Professors Yukichi Yoshino, Kunihiko Watanuki, and their laboratory colleagues.

A part of this research was carried out with a Scientific Research Grant from the Ministry of Education to which the authors' thanks are due.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 2264—2267 (1969)

Electronic Absorption Spectra of the Alkali Metal Complexes with Bipyridine

Yasuo TORII, Takanori YAZAKI, Youkoh KAIZU, Shigetaka MURASATO and Hiroshi KOBAYASHI

Department of Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received November 18, 1968)

Electronic absorption spectra of the alkali metal complexes with 2,2'-bipyridine, 4,4'-dimethyl-2,2'-bipyridine or 5,5'-dimethyl-2,2'-bipyridine have been observed in tetrahydrofuran solutions. Each spectrum has four major bands in the near infrared, visible and near ultraviolet regions, and is essentially due to the π–π^* transitions in the negative ion (extra π electron trapping state) of bipyridine or its dimethyl derivatives coordinating to a metal ion. The band about 18000 cm^{-1} is the most sensitive to the metal ion species involved and assigned to a transition with the polarization parallel to the short axis of the bipyridine molecule. Each absorption band of the bipyrdine negative ion shows characteristic spectral shift upon CH_3-substitutions in its peripheral positions. This CH_3-substitution effect on the absorption spectra of bipyridine negative ion is quite different from that of complexes including neutral bipyridines and gives a basis of the criterion to determine whether the coordinating bipyridine in a certain bipyridine complex do exist in negative ion (π electron trapping state) or not.

Alkali metals (M) react with 2,2'-bipyridine (bipy) in tetrahydrofuran (THF), dioxane, liquid ammonia and others, forming two kinds of complexes, M_2(bipy) and M(bipy). They have been isolated as various types of crystals with some solvent molecules.[1] Some studies have been done by measuring magnetic susceptibility[2] and electron spin resonance[3-6] in the solid state and the solution, but nothing has been reported on their electronic absorption spectra in detail.*1 In this paper electronic absorption spectra of the 1:1 complexes of alkali metals such as lithium, sodium and potassium with 2,2'-bipyridine, 4,4'-dimethyl-2,2'-bipyridine (4dmbip) or 5,5'-dimethyl-2,2'-bipyridine (5dmbip) in tetrahydrofuran solutions are reported.

These complexes are of reddish violet and Na-complexes, for example, show spectra given in Fig. 1. Since Li- and K-complexes also give absorption curves similar to those of Na-complexes, whole curves need not be presented, and only four major absorption maxima are tabulated in Table 1. These bands, except those near 18000 cm^{-1}, are virtually invariant in their positions with the change of metal ion species. ESR studies[5,6] have shown that the alkali metal complex is rather an ion-pair formed by a metal ion, M^+, and a negative ion, $bipy^-$, an unpaired electron being predominantly delocalized in the antibonding π^* molecular orbitals of bipyridine but partly transferred to the atomic orbitals of metal ion. These lead to an assignment of the absorption bands to the π–π^* transitions in the coordinating bipyridine negative ion.

The spectral shift of the 18000 cm^{-1} band upon metal subsitution is small but is not out of resolution. Figure 2 shows the relation between the band positions and ionic radii (r) of the metal ions,*2 where $R+r$ is the distance from the center of the metal ion to the center of bipyridine molecule. If $bipy^-$ acts as a bidentate ligand which coordinates to a metal ion through two nitrogen atoms, the π–π^* transitions may be polarized parallel to either the long axis or the short axis of bipyridine molecule. Since the latter axis passes through the metal ion, the electronic transitions polarized parallel to this are expected to be more sensitive to a positive charge on the metal ion than those

Li, Na and K denote Li(bipy), Na(bipy), and K(bipy), respectively.

polarized perpendicular to this axis. The facts that the 18000 cm^{-1} band is the most sensitive to the metal ion species and its position is proportional to $1/(r+R)$, seem to be interpreted as followes. Spectral shift due to an electrostatic interaction between a positive charge on the metal ion, Ze and the transition dipole moment μ is approximately given by

$$\delta\varepsilon = \frac{Ze\mu}{(r+R)}\cos\theta\left[1 + \frac{l^2}{8(r+R)^2}(5\cos^2\theta - 3) + \cdots\right],$$

for $r+R > (1/2)l$, where θ is an angle between the transition dipole moment and the straight line connecting both centeres of the ligand and the metal ion, and l is the real dimension of the transition dipole. If the transtion moment orients perpendicular to the ligand-metal line, the electro-

static spectral shift seems to be very small, since $\cos\theta=0$, and $\delta\varepsilon=0$. The transition moment in the direction of the line gives relatively large electrostatic shift, since $\cos\theta=1$, and $\delta\varepsilon$ is maximum. The 18000 cm^{-1} band is caused by a π-π^* transition polarized toward the metal ion, while the others insensitive to the metal substitution are polarized perpendicular to the 18000 cm^{-1} transition.

The whole absorption curve of Na(bipy) does not change its shape so much upon CH_3-substitutions at 4 and 4' or 5 and 5' positions of the conjugated system. However, each band does change its position and intensity in a characteristic way of each wave number region. This is known by Fig. 1. The lowest wave number bands, for example, are shifted to the higher wave number in the order 5dmbip<bipy<4dmbip, while the second lowest ones near 18000 cm^{-1} are in the order 5dmbip< 4dmbip<bipy. Therefore the effects of the CH_3-substitutions on the conjugated system can not be explained in terms of simple rules, whithout knowing the actual electronic structure of each energy state. The CH_3-substitution, a very weak perturbation to the π electron system, however, is reasonably expected not to give a drastic change in the whole π electronic structure but only to change slightly the energy scheme of the molecular orbitals. Experimental rules of the spectral behaviors observed upon the CH_3-substitutions in the bipyridine negative ion, rather weakly binding to the metal ion, are expected to be held even in fairly strong coordination to the metal ion with higher oxidation number than one, unless the coordination enhances drastically π electron delocalization between the coordinating negative ion and the metal ion or gives rise to a crucial electron transfer from negative ion to the metal ion.

On the other hand, in some cases where the ligand is molecular bipyridine but not negative ion, electronic absorption bands with $\log\varepsilon\geq3$ have been frequently observed in the near infrared and visible regions. $[Cr^{II}(bipy)_3]^{2+}$ ion is an example of this case. These bands are to be approximately assigned to charge transfer transitions from the d orbitals of the central metal ion to the lowest vacant π^* orbitals of bipyridine molecules.[7] The CH_3-substitutions give quite different spectral effects on the metal-ligand charge transfer bands from effects on the π-π^* bands in the coordinating bipyridine negative ion. The lowest wave number bands near 9000 cm^{-1}, for example, are shifted to the higher wave number in the order 4dmbip< bipy<5dmbip, which is reverse to the effect observed in the lowest wave number bands of the coordinating negative ion near 11000 cm^{-1}.

Tris bipyridine metal complexes with lower abnormal valency[1] such as $[M(bipy)_3]$, where M=Ti, V, Cr, Mn, Fe, Co or Al, may be divided into two extreme types; the one includes bipyridine molecules coordinating to a metal ion with abnormal oxidation number, and the other includes bipyridine negative ions coordinating to a metal ion with rather normal oxidation number, although electron delocalization possibly makes this distinction a little bit indistinguishable. They both show generally deep color and have absorption bands with $\log\varepsilon\geq3$ in the near infrared and visible regions. Their absorption curves are very complicated and apparently similar to each other, but by the use of the method of CH_3-substitutions described above, we can determine whether they include negative ion or not.[8]

Experimental

Materials. Na(bipy), Na(4dmbip), Na(5dmbip) and K(bipy) were prepared in the apparatus shown in Fig. 3. Equimolar metallic sodium and bipyridine or its dimethyl derivatives were placed at the part marked a in a branch of the H-tube, apparatus I. THF, which was used as a solvent, had been previously purified by the usual method and stored on $LiAlH_4$ in an atmosphere of nitrogen free from oxygen. A flask containing THF was connected to a vacuum system at the joint C. THF was distilled into the tube A or B from the storing flask, degassed under freezing to remove a trace of oxygen in the solvent, and distilled into the tube a. The H-tube was sealed off at the point d. All the procedures were carried out under vacuum. The tube was shaken. Bipyridine or its dimethyl derivatives were reduced by metal sodium in THF

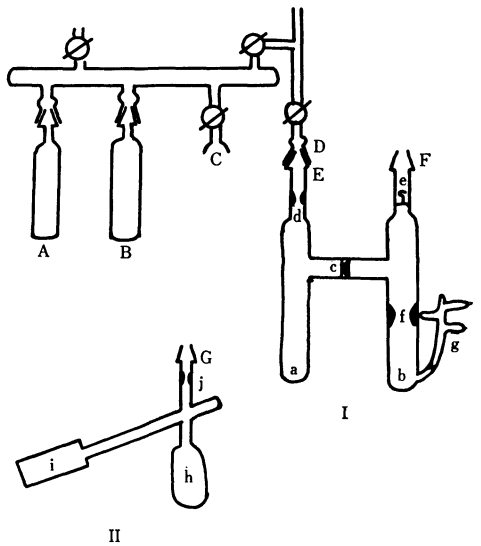

Fig. 3. Apparatus for the preparation of the materials (I) and of the sample solutions of absorption spectrum measurements (II).

8) Y. Kaizu, T. Yazaki and Y. Torii, This Bulletin, to be published.

and reddish violet solutions were obtained. The reduction was completed in about one day at room temperature. The solution was then filtrated through the glass filter c and the filtrate was collected in the tube b. Again the H-tube was connected with the vacuum system at the joint F. After the breakable seal e was broken, THF was completely distilled off and the tube was sealed off at the point f. Compounds thus obtained were stored in the tube g under vacuum. The tube g has several branches which are used to take a portion of material.

Li-complex was prepared by a method virtually identical with that described above, except for the use of apparatus II instead of the H-tube. The preparation was carried out in the flask h, and solution thus obtained were not evaporated to isolate crystalline substance but directly transferred to the quartz cell i for the measurement of its electronic absorption spectra.

Electronic Absorption Spectra. Sample solutions for spectral measurement were prepared with apparatus II connected to the vacuum system through the joints D and G. A capsule containing a small amount of the sample was placed in the quartz cell i and solvent THF was distilled directly into the flask h, in which the volume of the solvent was measured. The apparatus was then sealed off at the point j. The capsule was broken by a breaker, previously enclosed in the apparatus, in the flask h, and the compound was dissolved into the solvent. The amount of compound was estimated from the difference between weight of the unbroken capsule containing the compound and that of the capsule, taking into account the buoyancy correction for the unbroken capsule. The sample solution thus obtained in the flask h was transferred into the quartz cell i, the light path of which is 0.1 cm or 1 cm long, and electronic absorption spectra were measured using a Shimadzu multipurpose recording spectrophotometer model MPS-50.

Polarographic Study of the Cadmium(II)-Ethylenediaminetetrapropionate Chelate

Mutsuo KODAMA and Yayoe TOMINAGA

Department of Chemistry, Ibaraki University, Mito, Ibaraki

(Received November 20, 1968)

The d.c. polarographic behavior of the cadmium(II) ion in ethylenediaminetetrapropionate (EDTP) was studied in the pH range from 8.30 to 10.30. Over the entire range of experimental conditions employed, the cadmium(II)ion invariably gave a single well-defined wave corresponding to the following reversible two-electron reduction:

$$\begin{array}{l} CdZ^{2-} + nH^+ + Hg + 2e^- \rightleftarrows Cd(Hg) + H_nZ^{n-4} \\ \quad \downarrow\uparrow \\ CdZ_2^{6-} \end{array}$$

Even in the presence of ammonia or the alaninate ion, the cadmium(II) ion in the EDTP solution also behaves reversibly in a polarographic electrolysis. However, the half-wave potential was found to be shifted to the more negative potentials by the addition of ammonia or alaninate. This was ascribed to the formation of a mixed ligand chelate involving ammonia or the alaninate ion. From the relation between the shift of the half-wave potential and the concentration of ammonia or alaninate, the composition and the stability constant of the mixed ligand chelate were determined and the electrode reaction was established as:

$$\begin{array}{l} Cd(A)Z^{2-m} \rightleftarrows CdZ^{2-} + nH^+ + Hg + 2e^- \rightleftarrows Cd(Hg) + H_nZ^{n-4} \\ \qquad\qquad\quad \downarrow\uparrow \\ \qquad\qquad\quad CdZ_2^{6-} \end{array}$$

where A means the ammonia or the alaninate ion. The K_2, K^{NH_3}, and K^{ala} values determined were 5.5×10^2, 1.38×10^2, and 2.61×10^4 respectively.

The cadmium(II) chelates of ethylenediaminetetraacetic acid (EDTA) and its related compounds have been studied by numerous investigators.[1-4] The cadmium(II) chelates of several aminopolycarboxylic acids have been found to give two waves frequently. The reversible first wave is kinetic in

nature and may be attributed to the reduction of the cadmium(II) ion dissociated from the cadmium-(II)-aminopolycarboxylate chelate. The second wave, which corresponds to the direct reduction of the cadmium(II)-aminopolycarboxylate chelate is, however, irreversible. Generally, the direct reduction of the cadmium(II)-aminopolycarboxylate chelate is irreversible. Therefore, the polarographic wave due to the direct reduction of the cadmium(II)-aminopolycarboxylate chelate can hardly be used for the establishment of the electrode reaction mechanism or for the determination of an equilibrium between the cadmium(II) ion and aminopolycarboxylate. Exceptionally, the cadmium(II) chelate of ethylenediaminetetrapropionic acid (EDTP) was found to behave reversibly in a polarographic electrolysis. In this paper, the polarographic behavior of the cadmium(II) ion in the EDTP solution will be investigated systematically and the solution equilibria between the cadmium(II) ion and EDTP will be determined.

The effects of ammonia and the alaninate ion on the polarographic behavior of the cadmium(II)-EDTP chelate were also studied. The half-wave potential of the cadmium(II)-EDTP chelate shifted to more negative potentials with an increase in the concentration of ammonia or the alaninate ion. This was ascribed to the formation of a mixed ligand chelate involving ammonia or the alaninate ion.

Experimental

Reagents. The purification of EDTP and the preparation of its solution have been described previously.[5] The methods of preparing and standardizing a cadmium(II) perchlorate solution were also given in a previous paper.[6] All the other chemicals were of an analytical reagent grade and were used without further purification. The ionic strength of the sample solution was adjusted to 0.30 by adding an appropriate volume of a 1.0 M sodium perchlorate solution. The alanine used in this study was a racemic mixture.

Apparatus and Experimental Procedure. All the apparatus (mannual and pen-recording polarographs and the dropping mercury electrode (DME)) and the experimental procedures were the same as those employed previously.[5] All the polarographic measurements were conducted at 25°C.

Results and Discussion

Polarographic Behavior of the Cadmium(II) Ion in an Ethylenediaminetetrapropionate Solution in the Absence of Ammonia or Alaninate. The d. c. polarographic behavior of the cadmium(II) ion in an EDTP solution not containing ammonia or alaninate was studied in the pH range from 8.30 to 10.30. In the present study, no buffer reagent was used, because the present system always contains a large excess of un-complexed EDTP over cadmium(II) ions and, hence, is considered to have enough of a buffer capacity to maintain the pH value of the solution constant in this pH range. Over the entire pH range employed, the cadmium(II) ion invariably gave a well-defined single wave. A typical polarogram is reproduced in Fig. 1. As is shown in Fig. 2, a conventional plot of $\log(i/(i_l-i))$ against the applied d.c.

potential, E, gave straight lines with reciprocal slopes falling in the range from 32 to 35 mV. This clearly indicates that the electrode reaction is a reversible two-electron reduction process.

The wave-height was found to be exactly proportional to the bulk concentration of the cadmium(II) ion and the square-root of the effective pressure on the DME (The results are not shown here). These facts also support the above conclusion that the electrode reaction of the cadmium(II) ion in EDTP solution proceeds reversibly.

In the present pH range, the wave-height was almost independent of the pH value of the sample solution and the concentration of un-complexed EDTP, but slightly lower than that observed in an acid medium. The decrease in the wave-height may correspond to the chelate formation of the cadmium(II) ion with EDTP, because the diffusion-current constant of a complexed metal ion is usually smaller than that of un-complexed metal ion.

An EDTP is a weak acid with $pK_1=2.96$, $pK_2=3.32$, $pK_3=6.58$, and $pK_4=9.33$,[7,8] where the pK's are the acid dissociation constants of EDTP. Therefore, the conditional formation constant of the cadmium(II)-EDTP chelate must be a function of the hydrogen ion concentration; hence, the half-wave potential of the cadmium(II) ion in an EDTP solution would greatly depend on the pH value of the solution. This prediction was examined experimentally. Some typical results are shown in Table 1. The half-wave potential shifted to more negative potentials with an increase in the pH value of the solution. As was discussed in connection with the polarography of the copper(II)-*N*-(2-hydroxyethyl)-ethylenediamine-*N*,*N*',*N*'-triacetate chelate,[9] when only a normal chelate with a 1-to-1 composition is formed, the half-wave potential, $(E_{1/2})_{CdZ}$ may be expected to shift to negative potentials with a decrease in the log (α_H) value of EDTP, log $(\alpha_H)_Z$, corresponding to the following relation:

$$\frac{\Delta(E_{1/2})_{CdZ}}{\Delta \log(\alpha_H)_Z} = 29.6\,\text{mV} \qquad (1)$$

Here, $(\alpha_H)_Z$ is given by $1+[H^+]/k_4+[H^+]^2/k_4\cdot k_3+\cdots+[H^+]^4/k_4k_3k_2k_1$ and k's are the dissociation constants of EDTP. As is shown by the data in Table 1, however, the negative shift of the half-wave potential with a decrease in the log $(\alpha_H)_Z$ value was much greater than that expected from the (1) relation.

The dependence of $(E_{1/2})_{CdZ}$ on the concentration of EDTP was also investigated. The results are given in Table 2. $(E_{1/2})_{CdZ}$ shifted to more negative potentials with an increase in the concentration of un-complexed EDTP, $[Z]_f$. The shift of the half-wave potential, however, was much greater than that to be expected for the reversible two-electron reduction of the normal

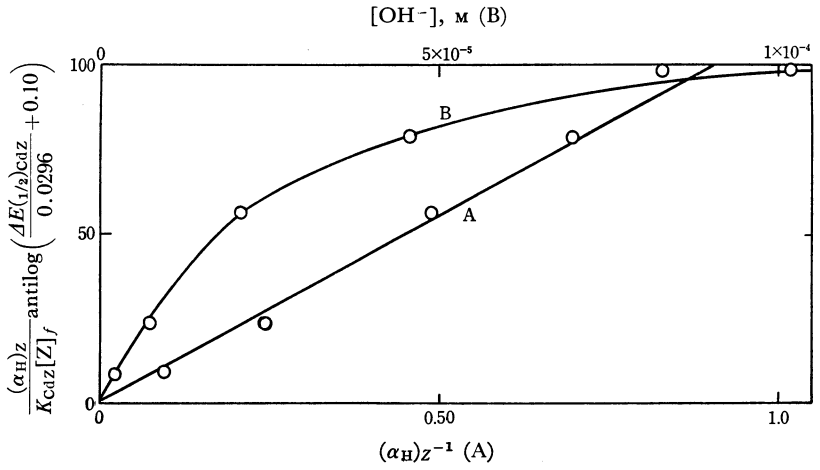

Fig. 3. The plot of $\frac{(\alpha_H)_Z}{K_{CdZ}[Z]_f}$ antilog$\left[\log\frac{k_{Cd^{2+}}}{k_{CdZ}}+\frac{\Delta(E_{1/2})_{CdZ}}{0.0296}\right]$ against $[Z]_f/(\alpha_H)_Z$ or $[OH^-]$.

chelate with a composition of 1-to-1, $\Delta(E_{1/2})/\Delta\log[Z]_f=-29.6$ mV.

Since the present study was conducted at higher pH's, the above two facts clearly indicate that, under the present experimental conditions, the cadmium(II) ion forms normal chelate with a 1-to-2 composition as well as that with a 1-to-1 composition with EDTP. Therefore, the electrode reaction can be assumed to be:

$$\begin{array}{l} CdZ^{2-} + nH^+ + Hg + 2e^- = Cd(Hg) + H_nZ^{n-4} \\ \quad\downarrow\uparrow \\ CdZ_2^{6-} \end{array} \qquad (2)$$

with the half-wave potential corresponding to:

$$(E_{1/2})_{CdZ} = E^\circ_{Cd} + 0.0296\left[\log f_{Cd^{2+}} + \log\frac{k_{Cd(Hg)}}{k_{CdZ}} - \log\frac{K_{CdZ}}{(\alpha_H)_Z}\left(1+\frac{K_2}{(\alpha_H)_Z}[Z]_f\right)[Z]_f\right] \qquad (3)$$

where E°_{Cd}, $f_{Cd^{2+}}$, $k_{Cd(Hg)}$, k_{CdZ}, and K_{CdZ} have their usual meanings and where $K_2=[CdZ_2^{6-}]/[CdZ^{2-}]\cdot[Z^{4-}]$.

From Eq. (3), the shift of the half-wave potential of the cadmium(II) ion due to the chelate formation with EDTP, $\Delta(E_{1/2})_{CdZ}$, can be derived as:

$$\Delta(E_{1/2})_{CdZ} = 0.0296\left[\log\frac{k_{CdZ}}{k_{Cd^{2+}}} + \log\frac{K_{CdZ}}{(\alpha_H)_Z}\left(1+\frac{K_2[Z]_f}{(\alpha_H)_Z}\right)\right] \qquad (3')$$

By rearranging Eq. (3') and by casting the resulting relation into antilog form, (3'') can be easily derived:

$$1+\frac{K_2}{(\alpha_H)_Z}[Z]_f = \frac{(\alpha_H)_Z}{K_{CdZ}[Z]_f} \times \text{antilog}\left[\log\frac{k_{Cd^{2+}}}{k_{CdZ}}+\frac{\Delta(E_{1/2})_{CdZ}}{0.0296}\right] \qquad (3'')$$

On the other hand, if the fact that the shift of the half-wave potential is much greater than that to be expected for the reversible two-electron reduction of the chelate with a 1-to-1 composition can be ascribed to the formation of a mixed ligand chelate involving the hydroxyl ion, OH^-, the left-hand side of Eq. (3'') should be replaced by $1+K^{OH}\cdot[OH^-]$, where K^{OH} is $[CdZ(OH)^{3-}]/[CdZ^{2-}]\cdot[OH^-]$. Using some typical data, the right-hand side of Eq. (3'') was plotted against $[Z]_f/[\alpha_H]_Z$ or $[OH]^-$. As is shown in Fig. 3, only the plot of the right-hand side of Eq. (3'') against $[Z]_f/(\alpha_H)_Z$ gave a linear relation with an intercept of 1. Furthermore, as is shown by the data in Table 2, with the increase in the concentration of un-complexed EDTP, the half-wave potential was found to shift to more negative potentials corresponding exactly to Eq. (3''). These facts strongly confirm the formation of a normal chelate with a composition of 1-to-2 and, hence, the electrode reaction (2). In the calculation of the right-hand side of Eq. (3'') the K_{CdZ} value of 2.51×10^5 ($\mu=0.30$) estimated from the K_{CdZ} value obtained in a solution with an ionic strength of 0.10 by Courtney *et al.*[7] and the activity coefficients of the ion calculated by means of the Davies equation[10] were used. From the slope of the linear relation in Fig. 3, K_2 was estimated to be 5.5×10^2.

D.C. Polarographic Behavior of the Cadmium(II) Ion in EDTA Solutions Containing Ammonia or Alanine. The d.c. polarographic behavior of the cadmium(II) ion in EDTP solutions containing ammonia or the alaninate ion was also investigated systematically. The limiting current of the cadmium (II)-EDTP chelate was little affected by the presence of ammonia or the alaninate ion, but the half-wave potential was found to shift to more negative potentials with an

10) J. N. Butler, "Ionic Equilibrium," Addison-Wesley Publishing Co., Reading, Massachusetts (1964), p. 437.

increase in the concentration of ammonia or alaninate. Considering the magnitude of formation constants of cadmium(II)-ammine, -alaninate, and -EDTP complexes,[11] it may safely be concluded that even 0.1 M ammonia or alaninate ions can not displace the EDTP anion from the cadmium(II)-EDTP chelate under the present experimental conditions. The conditional formation constant of the mixed ligand chelate involving both EDTP and ammonia or the alaninate ion is larger than that of the normal EDTP chelate, and in the polarography of the metal complexes, the increase in the value of the conditional formation constant always results in a negative shift of the half-wave potential. Therefore, the above negative shift caused by the addition of ammonia or the alaninate ion can be attributed to the formation of a mixed ligand chelate involving ammonia or the alaninate ion.

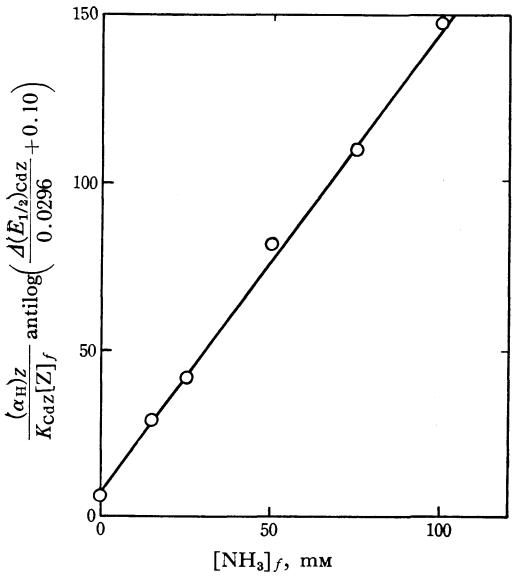

Fig. 4. The plot of $\frac{(\alpha_H)_Z}{K_{CdZ}[Z]_f}\text{antilog}\left[\log\frac{k_{Cd^{2+}}}{k_{CdZ}}+\frac{\Delta(E_{1/2})_{CdZ}}{0.0296}\right]$ against $[NH_3]_f$.
pH=9.33, Concentration of EDTP=20.0 mM

If a mixed ligand chelate with the composition of $Cd(A)Z^{2-m}$ is also formed (where A indicates ammonia or the alaninate ion), the left-hand side of Eq. (3'') should be replaced by $1+K_2[Z]_f/(\alpha_H)_Z+K^A[A]_f$. Here, K^A denotes $K^{NH_3}=[Cd(NH_3)Z^{2-}]/[CdZ^{2-}][NH_3]_f$ of $K^{ala}=[CdZ(ala)^{3-}]/[CdZ^{2-}][ala]_f$, and $(A)_f$ denotes the concentration of un-complexed ammonia, $[NH_3]_f$ or that of the un-complexed alaninate ion, $[ala]_f$. Therefore, provided that the concentration of un-complexed EDTP and the solution pH are kept constant, the plot of the right-hand side of Eq. (3'') against $[A]_f$ will give a linear relation with a intercept of $1+K_2[Z]_f/(\alpha_H)_Z$. This relation was examined successfully by means of the experimental data. The results are shown in Figs. 4 and 5. From the slopes of the linear relations in Figs. 4 and 5, K^{NH_3} and K^{ala} were estimated to be 1.38×10^2 and 2.61×10^4 respectively. On the basis of the above results and discussion, the electrode reaction of the cadmium(II)-EDTP chelate at the mercury electrode in the presence of ammonia

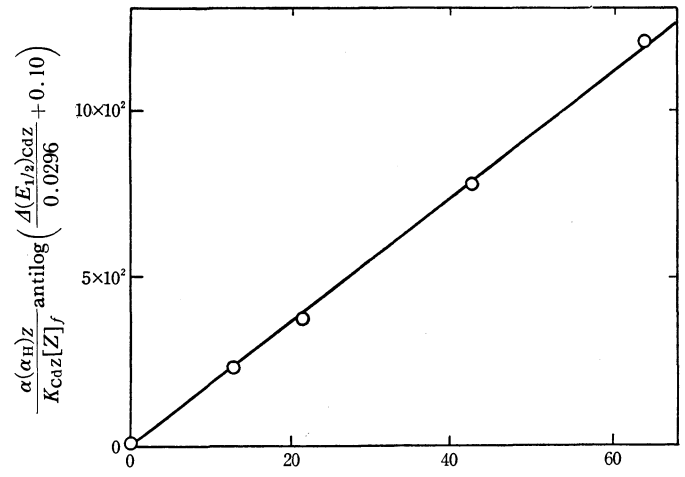

Fig. 5. The plot of $\frac{(\alpha_H)_Z}{K_{CdZ}[Z]_f}\text{antilog}\left[\log\frac{k_{Cd^{2+}}}{k_{CdZ}}+\frac{\Delta(E_{1/2})_{CdZ}}{0.0296}\right]$ against $[ala]_f$.
pH=9.45, Concentration of EDTP=10.0 mM

11) L. G. Sillen and A. E. Martell, "Stability Constants of Metal Ion Complexes," The Chemical Society, London (1964).

or the alaninate ion can be established to proceed thus:

$$\begin{aligned} Cd(A)Z^{2-m} &\rightleftharpoons CdZ^{2-} + nH^+ + Hg + 2e^- \\ &\quad \downarrow\uparrow \\ &\quad CdZ_2^{6-} \\ &\rightleftharpoons Cd(Hg) + HnZ^{n-4} \end{aligned} \qquad (4)$$

where $Cd(A)Z^{2-m}$ means $Cd(NH_3)Z^{2-}$ or $CdZ(ala)^{3-}$.

Here, it can be mentioned that the K^{ala} value found was almost identical with the K_1 value of the cadmium(II) - alaninate chelate.[12] If an alaninate anion functions as a monodentate ligand in the present mixed ligand-chelate formation, the equilibrium constant, K^{ala}, can be expected to be considerably smaller than the K_1 value of cadmium(II)-alaninate chelate. As has been reported by several authors,[11] K_1 values of cadmium(II) complexes of monodentate ammonia and the acetate ion can be expected to be thermodynamically considerably smaller than that of the cadmium(II) chelate of the bidentate alaninate anion. The steric and other effects may also reduce the stability of the mixed ligand chelate appreciably. Therefore, the above fact may indicate that an alaninate anion acts as a bidentate ligand in the present mixed-ligand-chelate formation.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 2272—2275 (1969)

The Spectrophotometric Determination of Zirconium(IV) with Bromopyrogallol Red*[1]

Takayoshi SAKAI*[2] and Yûko FUNAKI*

Chemical Department, Faculty of Science, Hirosaki University, Bunkyô-chô, Hirosaki

(Received November 25, 1968)

Zirconium(IV) reacts with an excess of bromopyrogallol red to form a violet complex. The constant absorbance of a solution containing the complex is obtained in the pH range from 5.0 to 5.4 at 670 mμ. About 25 min is required to complete the chelate formation in a boiling water bath. The complex thus formed is stable for at least 3 hr. The color system obeys Beer's law in the range from 4 to 35 μg zirconium in 25 ml. The sensitivity of the reaction is 0.002 μg per cm^2 for an absorbance of 0.001. In composition the complex has a metal-to-ligand ratio of 1:2. The molar absorptivity and the apparent formation constant of the complex are calculated to be 7.01×10^4 at 670 mμ and 1.11×10^9 at pH 5.2 respectively. The effect of diverse ions on the determination is examined.

Bromopyrogallol red (BPR or H_4L) has been used as a reagent for the spectrophotometric determination of many metallic cations, including silver(I),[1] uranium(IV),[2] yttrium(III) and cerium(III),[3] titanium(IV)[4] bismuth(III),[5] indium(III),[6] niobium(V),[7] scandium(III),[8] and thorium(IV).[9] It is found that BPR reacts with zirconium(IV) under heating to form a violet complex. The present paper describes the fundamental conditions for applying the reaction to the spectrophotometric determination of zirconium.

was prepared by dissolving a guaranteed zirconyl nitrate dihydrate in 0.2 N perchloric acid. The solution was standardized by EDTA titration, using xylenol orange[10] as the indicator.

The solutions of BPR, diverse ions, and the buffer, and the apparatus were the same as those used in a previous work.[9]

All the measurements were made at 25±0.5°C.

Standard Procedure. To a sample solution containing up to 32 μg of zirconium in a 50 ml Erlenmeyer flask, 1.2 ml of a 1×10^{-3} M BPR solution and 10 ml of a 0.25 M acetate buffer solution with a pH value of 5.2 were added. The mixture was then heated in a boiling water bath for 25 min. The solution was cooled with running water to room temperature, transferred into a 25 ml volumetric flask, and then diluted to the mark with water. After 10 min, the absorbance of the solution was measured at 670 mμ using a reagent blank as the reference.

Results and Discussion

Absorption Curves. Figure 1 shows that the maximum absorption of the zirconium - BPR complex is found at 670 mμ.

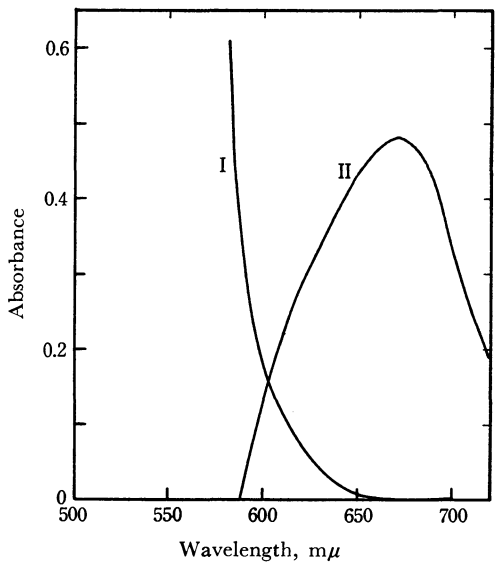

Fig. 1. Absorption curves of BPR and its zirconium complex.

BPR: 4.80×10^{-5} M, Zr(IV): 18.2 μg in 25 ml (7.97×10^{-6} M), μ: 0.1, I: BPR *vs.* water, II: zirconium-BPR complex *vs.* BPR, pH: 5.23.

The Effect of pH. As is shown in Fig. 2, the maximum absorbance is obtained in the pH range from 4.7 to 4.8. The complex formed below pH 4.9 showed a tendency to precipitate on standing, probably because of its uncharged form.*4

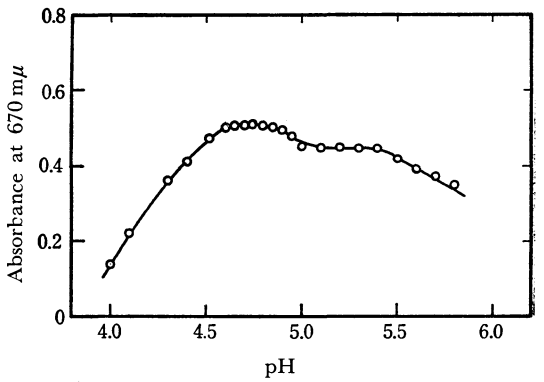

Fig. 2. Effect of pH.
Zr(IV): 18.2 μg, BPR: 4.00×10^{-5} M, μ: 0.1, Reference: Reagent blank

A constant absorbance is obtained over the pH range from 5.0 to 5.4. All the absorbance readings were taken within this range, since the absorbance of the solution containing the complex remains almost constant for at least 3 hr after heating.

The Effect of Heating Time. It requires several hours at room temperature to complete the reaction between zirconium and BPR. The reaction was, however, accelerated by heating. The maximum absorbance was obtained when a solution containing zirconium and BPR was heated in a boiling water bath for from 20 to 35 min.

The Effect of the Amount of Reagent. The maximum, and almost constant, absorbance was obtained when from 1 to 3 ml of a 1×10^{-3} M BPR solution was added to a solution containing 18.2 μg of zirconium. The order of the addition of the reagents was not critical.

Calibration Curve. Beer's law is found to hold in the range from 4 to 35 μg of zirconium in 25 ml. The sensitivity of the reaction was calculated according to Sandell's notation[11] and found to be 0.002 μg of zirconium per cm^2. The reproducibility of the method was examined using a solution containing 18.2 μg of zirconium. From the data obtained by eleven determinations, the standard deviation was calculated to be 0.003 (2.8%) in absorbance.

The Effect of Diverse Ions. The results are listed in Table 1.

A Comparison with Other Methods. Table 2 indicates that the proposed method is comparable with the morin method[16] in sensitivity.

10) K. Ueno "Kireto Tekitei (Chelatometric Titration)" (in Japanese), Nankodo, Tokyo (1960), p. 325.

*4 It was found experimentally that zirconium forms a 1 : 1 complex with BRR at lower pH values. Since, as will be mentined below, BPR may exist mainly as the anionic species, H_3L^-, in the pH range from 1 to 4, the formula of the 1 : 1 complex may be represented as an uncharged form, $ZrO(H_2L)$.

0	Cr, Fe(III), Nd, EDTA

* Value which gives less than 3% relative error

Composition of the Complex. The method described by Benesi and Hildebrand[20] is used to determine the composition of the complex. Since BPR may exist mainly as the anionic form, H_2L^{2-}, in the pH range from 5 to 8,*5 and zirconium(IV), as ZrO^{2+}, the formation of the complex with a metal-to-ligand ratio of $1:n$ can be represented as;

$$ZrO^{2+} + nH_2L^{2-} \rightleftarrows ZrO(HL)_n^{(3n-2)-} + nH^+ \quad (1)$$

$$K' = [\{ZrO(HL)_n\}^{(3n-2)-}]/[ZrO^{2+}][H_2L^{2-}]^n \quad (2)$$

where K' is the apparent formation constant at a given pH value. The following relation may finally be derived as a result of the transformation of

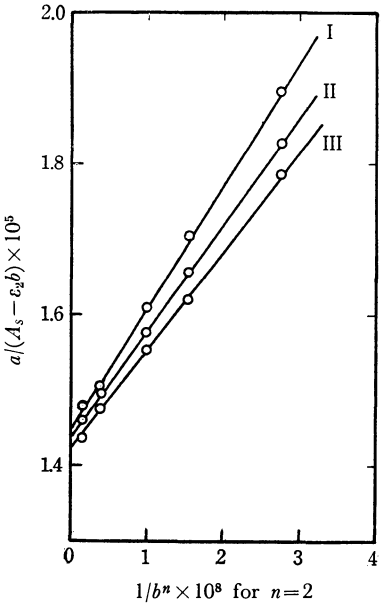

Fig. 3. Plots of $a/(A_s-\varepsilon_2 b)$ *vs.* $1/b^n$ at pH 5.5. Zr: 3.87×10^{-6} M, BPR: 7.74×10^{-5}—2.32×10^{-4} M, μ: 0.5, I: 680 mμ, II: 665 mμ, III: 670 mμ

Eq. (2):

$$a/(A_s-\varepsilon_2 b) = 1/\varepsilon_3 + 1/K'\varepsilon_3 b^n \quad (3)$$

where A_s is the absorbance of the solution containing the complex and ligand added in excess to a definite

amount of zirconium, where a and b are the total concentrations of zirconium and the ligand respectively, and where ε_2 and ε_3 are the molar absorptivities of the ligand and the complex respectively. Only a choice of n equal to two made the data interpretable, showing that a 1 : 2 complex is formed between zirconium and BPR. Some of the results are shown in Fig. 3. From the intercept of the straight line, ε_3 was calculated to be 7.01×10^4 at 670 mμ, and K', as a mean value of the values obtained at five wavelengths between 660 and 680 mμ, was found to be 1.11×10^9 at pH 5.2.

The authors wish to express their hearty thanks to Professor Kôichi Tonosaki for his kind advice and instruction throughout this study. They also wish to extend their thanks to Dr. Makoto Otomo for his valuable suggestions.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 2275—2281 (1969)

Methods of Preparing the 2,2'-Dipyridyl and 1,10-Phenanthroline Cobalt(III) Complexes of the $[CoX_2dip_2]$- and $[CoX_2phen_2]$-Type[1)]

Nobufumi MAKI

Department of Chemistry, Faculty of Engineering, Shizuoka University, Johoku, Hamamatsu

(Received November 25, 1968)

The bis(2,2'-dipyridyl) and bis(1,10-phenanthroline)cobalt(III) complexes of the $[CoX_2N_4]$-type, including the following new compounds, have been prepared: $[Co(CN)_2dip_2]NO_3\cdot 7H_2O$, $[Co(CN)_2dip_2]_2SO_4\cdot 12H_2O$, $Na[Co(SO_3)_2dip_2]\cdot 5H_2O$, $Na[Co(S_2O_3)_2dip_2]\cdot 7H_2O$ $[Co(N_3)_2dip_2]N_3\cdot 2H_2O$, $[Co(N_3)_2dip_2]ClO_4$, $[Co(N_3)_2dip_2]_2SO_4\cdot 5H_2O$, $[Co(N_3)_2dip_2]NO_3\cdot 2H_2O$, $[Co(N_3)_2dip_2]Cl\cdot 3H_2O$, $[Co(SCN)_2dip_2]NCS\cdot 5/2\ H_2O$, $[Co(SCN)_2dip_2]ClO_4\cdot 2H_2O$, $[Co(SCN)_2dip_2]Cl\cdot 3H_2O$, $K[Co(SO_3)_2phen_2]\cdot 5H_2O$, $[Co(NO_2)_2phen_2]Cl\cdot 4H_2O$, $Na[Co(S_2O_3)_2phen_2]$, $[Co(N_3)_2phen_2]N_3$, $[Co(CN)_2phen_2]NO_3\cdot 6H_2O$, $[Co(CN)_2phen_2]Cl\cdot 4H_2O$. The known compounds, including the cobalt(II) and cobalt(III) complexes of the luteo type, have also been prepared by methods other than those described hitherto in the literature. The absorption spectra in the visible and ultraviolet regions have been measured and compared with those of the bis(ethylenediamine)cobalt-(III) complexes. The rhodanato-cobalt(III) complexes, $[Co(SCN)_2dip_2]ClO_4\cdot 2H_2O$ and $[Co(SCN)_2phen_2]NCS$, have been ascertained to be the sulfur-bonded thiocyanato complexes on the evidence of the absorption spectra in the visible and infrared regions.

A number of papers have been published concerning the preparation and the absorption spectra of the bis(ethylenediamine)cobalt(III) complexes, but very few concerning the corresponding cobalt-(III) complexes with 2,2'-dipyridyl and 1,10-phenanthroline have appeared.[2)]

The purpose of this work was to prepare the cobalt(III) complexes of the $[CoX_2dip_2]$- and $[Co\ X_2phen_2]$-type and to elucidate the difference between their absorption spectra and those of the ammine and amine cobalt(III) complexes. Above all, an effort was made to solve the problem of whether or not the rhodanate ligand, SCN^-, is bound to the cobalt(III) ion by the sulfur atom within the coordination sphere of the 2,2'-dipyridyl and 1,10-phenanthroline cobalt(III) complexes, in which the contribution of the π-bonding character to their coordinate bonds is considered to be fairly large.

In addition, the cobalt(III) and cobalt(II) complexes of the $[CoN_6]$-type were prepared by a more convenient and simple method than those described hitherto in the literature.

Experimental

The dichloro complexes, *trans*-$[CoCl_2dip_2]Cl$[3)] and *trans*-$[CoCl_2phen_2]Cl\cdot 4H_2O$,[4)] were used as the starting complexes for the preparation.

Preparation of $[Co(SCN)_2dip_2]NCS\cdot 5/2H_2O$. A water solution (100 m*l*) containing 0.46 g of KNCS was stirred, a drop by drop, into 300 m*l* of a water solution of $[CoCl_2dip_2]Cl$ (1.0 g). First, a green precipitate

4) P. Pfeiffer and Br. Werdelmann, *ibid.*, **236**, 31 (1950).

immediately separated from the solution; then, its gradually turned a reddish brown. The product was filtered and washed with water several times. The crude complex was recrystallized from hot 60% ethanol twice. Ruby-like red crystals were thus obtained. Found: Co, 9.71; C, 46.93; N, 16.60; H, 3.81%. Calcd for $[Co(SCN)_2dip_2]NCS\cdot\frac{5}{2}H_2O$: Co, 9.98; C, 46.78; N, 16.60; H, 3.58%.

The perchlorate and chloride salts were obtained by treating the complex with 10% $HClO_4$ and 6 N HCl respectively. Found: Co, 9.31; C, 42.37; N, 13.53; H, 3.48%. Calcd for $[Co(SCN)_2dip_2]ClO_4\cdot 2H_2O$: Co, 9.46; C, 42.42; N, 13.49; H, 3.24%.

Found: Co, 10.19; C, 45.88; N, 14.71; H, 4.02%. Calcd for $[Co(SCN)_2dip_2]Cl\cdot 3H_2O$: Co, 10.21; C, 45.79; N, 14.57; H, 3.84%. The complex is insoluble in water, but soluble in alcohol.

Preparation of $[Co(NO_2)_2dip_2]Cl\cdot 5H_2O$. One gram of *trans*-$[CoCl_2dip_2]Cl$, dissolved in 40 m*l* of water, was mixed with 0.4 g of KNO_2 dissolved in 10 m*l* of water, and the mixture was heated on a water bath for half an hour. The yellow product was recrystallized from hot water containing acetic acid.[5] Found: Co, 9.87; C, 40.77; N, 14.32; H, 4.23%. Calcd for $[Co(NO_2)_2dip_2]Cl\cdot 5H_2O$: Co, 10.01; C, 40.80; N, 14.27; H, 4.45%.

Preparation of $Na[Co(SO_3)_2dip_2]\cdot 5H_2O$. A water solution (100 m*l*) of $[CoCl_2dip_2]Cl$ (1.0 g) was mixed with 0.53 g of Na_2SO_3 dissolved in 20 m*l* of water, and the mixture was warmed on a water bath below 60°C. The yellow precipitate which deposited from the solution was filtered and washed with water, ethanol, and ether. The complex is scarcely soluble in water or ethanol. Found: Co, 9.02; C, 37.05; N, 8.80; H, 3.89%. Calcd for $Na[Co(SO_3)_2dip_2]\cdot 5H_2O$: Co, 9.14; C, 37.27; N, 8.69; H, 4.07%.

Preparation of $[Co(N_3)_2dip_2]N_3\cdot 2H_2O$. A water solution (100 m*l*) of *trans*-$[CoCl_2dip_2]Cl$ (1.0 g) was heated on a water bath (60—70°C) with 0.26 g of NaN_3. On cooling, lustrous brown crystals deposited on the wall of the beaker. The crude complex was recrystallized twice from hot water below 70°C. The azido complex is very soluble in both water and ethanol. Found: Co, 11.00; C, 44.94; N, 34.21; H, 3.89%. Calcd for $[Co(N_3)_2dip_2]N_3\cdot 2H_2O$: Co, 11.05; C, 45.04; N, 34.14; H, 3.75%.

By treating the complex with 5% $HClO_4$, 3 N H_2SO_4, 3 N HNO_3, and 3 N HCl, the salts of each the respective acid were obtained. Found: Co, 10.71; C, 43.28; N, 25.18; H, 3.05%. Calcd for $[Co(N_3)_2dip_2]ClO_4$ (anhydrous): Co, 10.62; C, 43.30; N, 25.25; H, 2.91%.

Found: Co, 11.02; C, 43.76; N, 25.40; H, 3.97%. Calcd for $[Co(N_3)_2dip_2]_2SO_4\cdot 5H_2O$: Co, 10.93; C, 43.80; N, 25.54; H, 3.86%.

Found: Co, 10.71; C, 43.34; N, 27.95; H, 3.80%. Calcd for $[Co(N_3)_2dip_2]NO_3\cdot 2H_2O$: Co, 10.65; C, 43.41; N, 27.84; H, 3.62%.

Found: Co, 11.20; C, 45.49; N, 26.63; H, 3.99%. Calcd for $[Co(N_3)_2dip_2]Cl\cdot 2H_2O$: Co, 11.19; C, 45.60; N, 26.59; H, 3.80%.

Preparation of $Na[Co(S_2O_3)_2dip_2]\cdot 7H_2O$. Two grams of *trans*-$[CoCl_2dip_2]Cl$, suspended in 30 m*l* of water, were mixed with 20 m*l* of a water solution containing 2.1 g of $Na_2S_2O_3\cdot 5H_2O$. The mixture was then heated on a water bath at 55°C for ten minutes. The solution assumed a brown color. When the solution was then allowed to stand under ice cooling, bright brown crystals separated from the solution, they were filtered and washed with cold 80% ethanol and ether. More crystals were obtained by the drop-by-drop addition of cold absolute ethanol to the mother liquor. The complex solution tends to decompose slowly, even at room temperature, evolving hydrogen sulfide. The complex is very soluble in water, but less soluble in ethanol. Found: Co, 7.99; C, 32.13; N, 7.60; H, 4.21%. Calcd for $Na[Co(S_2O_3)_2dip_2]\cdot 7H_2O$: Co, 7.91; C, 32.23; N, 7.52; H, 4.03%.

Preparation of $[Co(CN)_2dip_2]NO_3\cdot 7H_2O$. Fifteen grams of *trans*-$[CoCl_2dip_2]NO_3$(anhydrous), suspended in 500 m*l* of distilled water, were mixed with 10 g of AgCN, and the mixture was heated on a water bath (80°C) for three hours. The color of the solution changed from green to yellow. The solution was filtered, and the residue containing AgCl was repeatedly extracted with hot water. Then, the filtrate and the extracted solution were joined and concentrated into one-third in the former volume by evaporation. When the solution was then allowed to stand, lustrous, needle-shaped yellow crystals deposited from the solution; they were filtered and washed with cold water, ethanol, and ether. The crude product was recrystallized from hot water. Found: Co, 9.58; C, 43.15; N, 15.97; H, 5.03%. Calcd for $[Co(CN)_2dip_2]NO_3\cdot 7H_2O$: Co, 9.64; C, 43.22; N, 16.04; H, 4.95%. Before elementary analysis, the complex was dried overnight at room temperature in a vacuum desiccator on silica gel. In a preliminary report,[6] however, the elementary analysis was carried out on a sample of the complex which had been dried out *in vacuo* for three hours at 110°C, because the complex lost part of its crystallization water in the vacuum desiccator on concentrated sulfuric acid. The anhydrous complex is hygroscopic.

The corresponding sulfate of the complex was obtained by treating *trans*-$[CoCl_2dip_2]_2SO_4$ (anhydrous) with an excess of AgCN at 80°C. Found: Co, 10.12; C, 45.54; N, 14.45; H, 5.01%. Calcd for $[Co(CN)_2dip_2]_2SO_4\cdot 12H_2O$: Co, 10.17; C, 45.60; N, 14.50; H, 4.88%.

The attempt to react the dithiosulfato complex, $Na[Co(S_2O_3)_2dip_2]\cdot 7H_2O$, with KCN has failed due to the disruption of the complex. Hence, the analogous method of synthesis for *cis*-$[Co(CN)_2en_2]Cl$[7] is not suitable for obtaining the dicyanobis(2,2'-dipyridyl)-cobalt(III) complex.

Preparation of $[Co(gly)dip_2]Cl_2$.*1 To a water solution (100 m*l*) containing 9.56 g of *trans*-$[CoCl_2dip_2]$-Cl (anhydrous) **1.6** g of glycine were added, and the mixture was heated on a water bath (80°C) for three hours. When the reaction was over, the solution was further concentrated *in vacuo* with a rotatory evaporator

5) Independent of this work, another method of preparation has already appeared in R. G. Pearson, R. E. Meeker and F. Basolo, *J. Inorg. Nucl. Chem.*, **1**, 341 (1955).

6) N. Maki, T. Hamazaki and S. Sakuraba, This Bulletin, **41**, 1735 (1968).

*1 gly=a glycinato ligand, $NH_2CH_2COO^-$

below 50°C. Into the deep-violet viscous liquid thus obtained there were then stirred, in small portions, 50 ml of ethanol containing 30% ether. Violet or almost black powders were thus obtained; they were stocked in the vacuum desiccator over concentrated sulfuric acid. The purifications were carried out in the usual manner, *i. e.*, by the addition of ethanol and ether to a water solution of the complex, since the solubility of the complex in water is quite large. The complex is hygroscopic. The absorption spectrum in the visible and ultraviolet regions agrees with that obtained by Murakami *et al.*[8] Found: Co, 11.31; C, 51.09; N, 13.37; H, 3.80%. Calcd for $[Co(gly)dip_2]Cl_2$: Co, 11.42; C, 51.18; N, 13.57; H, 3.90%.

The carbonato complexes, $[Co(CO_3)dip_2]Cl\cdot 3H_2O$ and $[Co(CO_3)dip_2]NO_3\cdot 5H_2O$, were prepared according to the directions of Jaeger and van Dijk.[9] Found: Co, 11.03; C, 48.51; N, 10.70; H, 4.09%. Calcd for $[Co(CO_3)dip_2]Cl\cdot 3H_2O$: Co, 11.32; C, 48.43; N, 10.76; H, 4.26%.

Found: Co, 10.04; C, 43.11; N, 11.93; H, 4.58%. Calcd for $[Co(CO_3)dip_2]NO_3\cdot 5H_2O$: Co, 10.10; C, 43.24; N, 12.01; H, 4.49%.

The 2,2'-dipyridyl reagent used was synthesized according to the method of Badger and Sasse.[10] Namely, the pyridines undergo condensation in the presence of Raney nickel to yield 2,2'-dipyridyl. As a by-product, 2,2',2''-terpyridyl (black powder) was obtained. The crude dipyridyl was purified by sublimations.

Preparation of $[Co(NO_2)_2phen_2]Cl\cdot 4H_2O$. Analogously to the case of the dipyridyl complex, a solution (100 ml) of *trans*-$[CoCl_2phen_2]Cl\cdot 4H_2O$ (5.98 g) was treated with 1.8 g of KNO_2 at 80°C for half an hour. The product was recrystallized from hot water containing acetic acid. Found: Co, 9.42; C, 46.83; N, 13.55; H, 4.02%. Calcd for $[Co(NO_2)_2phen_2]Cl\cdot 4H_2O$: Co, 9.52; C, 46.58; N, 13.58; H, 3.91%.

Preparation of $[Co(CO_3)phen_2]Cl\cdot 5H_2O$. A solution (150 ml) of *trans*-$[CoCl_2phen_2]Cl\cdot 4H_2O$ (5.98 g) was treated with 1.4 g of K_2CO_3 at 80°C for fifteen minutes. Orange-red crystals were thus obtained.[11] Found: Co, 9.80; C, 50.00; N, 9.29; H, 4.42%. Calcd for $[Co(CO_3)phen_2]Cl\cdot 5H_2O$: Co, 9.74; C, 49.64; N, 9.26; H, 4.33%.

Preparation of $K[Co(SO_3)_2phen_2]\cdot 5H_2O$. By treating *trans*-$[CoCl_2phen_2]Cl\cdot 4H_2O$ (5.98 g) with 3.2 g of K_2SO_3 in 100 ml of water at 60°C, lustrous brown crystals were obtained. The product was purified by recrystallization from hot water below 60°C. Found: Co, 8.40; C, 40.81; N, 8.01; H, 3.87%. Calcd for $K[Co(SO_3)_2phen_2]\cdot 5H_2O$: Co, 8.32; C, 40.68; N, 7.91; H, 3.70%.

Preparation of $[Co(CN)_2phen_2]NO_3\cdot 6H_2O$. Analogously to the case of the dicyano-bis(2,2'-dipyridyl) cobalt(III) complex, 20 g of *trans*-$[CoCl_2phen_2]NO_3$ were treated with 15 g of AgCN in 500 ml of distilled water at 70—80°C for three hours. The suspension was filtered, and the filtrate was concentrated by evaporation. When the solution was then allowed to stand, silky yellow crystals deposited on the wall of the beaker. The complex was stored in the vacuum desiccator over silica gel.[12] Found: Co, 9.11; C, 48.39; N, 15.17; H, 4.67%. Calcd for $[Co(CN)_2phen_2]NO_3\cdot 6H_2O$: Co, 9.19; C, 48.68; N, 15.29; H, 4.40%.

The chloride of the complex was obtained by treating the nitrate with a solution of KCl, because the chloride of the complex is less soluble in water than the nitrate. Found: Co, 10.08; C, 54.07; N, 14.66; H, 4.52%. Calcd for $[Co(CN)_2phen_2]Cl\cdot 4H_2O$: Co, 10.18; C, 53.95; N, 14.52; H, 4.18%.

Preparation of $[Co(bathophen)_3]Cl_3$ (anhydrous). To a suspension (50 ml) of $[CoCl(NH_3)_5]Cl_2$[13] (0.25 g) there were added 1.1 g of bathophenanthroline,*2 and the mixture was heated on a water bath (80—85°C) for an hour. The starting complex dissolved slowly in solution and reacted, evolving ammonia, to yield the tris(bathophenanthroline)cobalt(III) complex. The product was purified by recrystallizations in ethanol, since the complex is more soluble in ethanol than in water. The complex was dried out *in vacuo* on concentrated sulfuric acid before the elementary analyses. Found: Co, 4.95; C, 74.48; N, 7.03; H, 4.33%. Calcd for $[Co(bathophen)_3]Cl_3$: Co, 5.07; C, 74.39; N, 7.23; H, 4.16%.

Preparation of $[Co\ trip_2]Cl_3\cdot 7H_2O$. Quite analogously to the previous case, the bis(2,2',2''-terpyridyl)cobalt(III) chloride was prepared directly from the pentamminecobalt(III) complex. Namely, the suspension (80 ml) of $[CoCl(NH_3)_5]Cl_2$ (0.54 g) in a 50% ethanol-water solution was refluxed for ten hours with 1.05 g of terpyridyl in a flask equipped with a reflux condenser. Lustrous brown crystals separated from the solution when the reaction was over. Found: Co, 7.83; C, 47.44; N, 10.96; H, 4.91%. Calcd for $[Co\ trip_2]Cl_3\cdot 7H_2O$: Co, 7.78; C, 47.54; N, 11.09; H, 4.79%. The absorption spectrum agreed with that of the complex obtained by the method of Morgan and Burstall.[14]

Preparation of $[Co(N_3)_2phen_2]N_3$. A water solution (100 ml) containing 5.98 g of *trans*-$[CoCl_2phen_2]Cl\cdot 4H_2O$ was treated with 1.9 g of NaN_3 dissolved in 50 ml of water at 70°C for half an hour. The product was recrystallized from ethanol and dried out *in vacuo* on $CaCl_2$. Found: Co, 10.92; C, 52.84; N, 33.42; H, 3.05%. Calcd for $[Co(N_3)_2phen_2]N_3$: Co, 10.81; C, 52.85; N, 33.39; H, 2.96%. The complex is more soluble in ethanol than in water.

Preparation of $Na[Co(S_2O_3)_2phen_2]$ (anhydrous). A water solution (100 ml) of 5.98 g of *trans*-$[CoCl_2$-

$phen_2]Cl\cdot 4H_2O$ was treated with 5.0 g of $Na_2S_2O_3\cdot 5H_2O$ at room temperature. The mixture turned dark brown. To this solution there were added drop by drop under ice cooling 100 m*l* of a mixture of ethanol and ether. The brown powder which separated from the solution was filtered and washed with ethanol and ether. The product was purified in the same manner. Found: Co, 8.92; C, 43.38; N, 8.57; H, 2.61%. Calcd for $Na[Co(S_2O_3)_2phen_2]$: Co, 8.84; C, 43.24; N, 8.41; H, 2.42%. The complex is unstable in solution and tends to decompose in itself, evolving hydrogen sulfide, thus producing the metallic cobalt.

Preparation of $[Co(bathophen)_3]Cl_2\cdot 8H_2O$. The water solution (30 m*l*) of 0.13 g of hexaquocobalt(II) chloride was treated with 1.0 g of bathophenanthroline at 80°C for five minutes. On cooling, brown crystals were obtained. Found: Co, 4.58; C, 67.95; N, 6.58; H, 5.24%. Calcd for $[Co(bathophen)_3]Cl_2\cdot 8H_2O$: Co, 4.64; C, 68.03; N, 6.61; H, 5.08%. The complex is more soluble in ethanol than in water.

Preparation of $[Co\,dip_3]Cl_2\cdot 3H_2O$. To a 30% methanol-water solution (100 m*l*) in which 5 g of $[CoCl(NH_3)_5]Cl_2$ had been suspended, 9.4 g of 2,2'-dipyridyl were added; the mixture was then refluxed on a water bath for eight hours. The crude product was recrystallized from hot water containing acetic acid. Found: Co, 8.52; C, 52.43; N, 12.41; H, 4.51%. Calcd for $[Co\,dip_3]Cl_3\cdot 3H_2O$: Co, 8.59; C, 52.38; N, 12.22; H, 4.40%.

Preparation of $[Co\,phen_3]Cl_3\cdot 7H_2O$. A suspension (130 m*l*) of a 30% methanol-water solution containing 5 g of $[CoCl(NH_3)_5]Cl_2$ and 12.1 g of 1,10-phenanthroline was refluxed on a water bath for ten hours. Dark brown crystals were thus obtained. Found: Co, 6.97; C, 51.98; N, 9.98; H, 4.80%. Calcd for $[Co\,phen_3]Cl_3\cdot 7H_2O$: Co, 7.08; C, 51.97; N, 10.10; H, 4.60%.

Preparation of $[Co(SCN)_2phen_2]NCS$ (anhydrous). To a hot water solution (50 m*l*) containing 1.2 g of *trans*-$[CoCl_2phen_2]Cl\cdot 4H_2O$ there were added 1.1 g of KNCS dissolved in 50 m*l* of water, and the mixture was heated on a water bath for an hour. Dark brown precipitates separated from the solution, they were filtered and washed with water several times, and then with ethanol and ether. Found: Co, 9.79; C, 54.80; N, 16.72; H, 2.86%. Calcd for $[Co(SCN)_2phen_2]$-NCS: Co, 9.93; C, 54.63; N, 16.52; H, 2.72%. The complex is insoluble in both water and alcohol, but soluble in dimethyl sulfoxide.

Measurement. The absorption spectra in the visible and ultraviolet regions were determined manually with a Beckmann DU spectrophotometer. The IR spectra were recorded on a Perkin-Elmer grating infrared spectrophotometer, Model 337, equipped with a KBr-pellet.

Results and Discussion

Figure 1 shows the absorption spectra of the cobalt(III) complexes of the $[Co^{III}X_2dip_2]$-type measured in the aqueous phase except that of the thiocyanato complex. The first spin-allowed band, which is assigned to a d–d transition, shifts towards a shorter wavelength according to this order of the ligands: $S_2O_3^{2-}$, SCN^-, N_3^-, CO_3^{2-}, gly$^-$, dip, NO_2^-, CN^-. This order of the ligands agrees with that of the spectrochemical series[15] except for the SCN^- ligand. The absorption intensity of the first band for the $[Co(SCN)_2dip_2]^+$ ion is seen to be abnormally larger than those of the corresponding 2,2'-dipyridyl cobalt(III) complexes of the nitrogen-hexacoordinated $[Co\,N_6]$-type. This fact may be explained as being due to the hyperchromic effect of the sulfur-bonded ligand, SCN^-. As far as the cobalt(III) complexes are concerned, the rhodanato-ligand has been well known to be

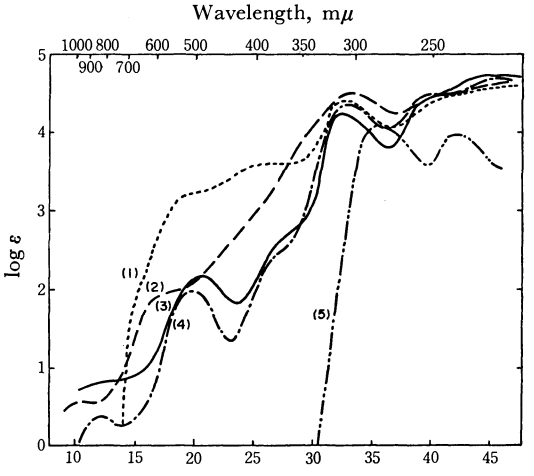

Fig. 1. The absorption spectra of the bis(2,2'-dipyridyl)cobalt(III) complexes of the $[CoX_2\,dip_2]$-type: (1) ---- $[Co(SCN)_2dip_2]ClO_4\cdot 2H_2O$ in methanol; (2) —— $Na[Co(S_2O_3)_2dip_2]\cdot 7H_2O$ in methanol; (3) —— $[Co(gly)dip_2]Cl_2$; (4) ——— $[Co(CO_3)dip_2]Cl\cdot 3H_2O$; (5) —·— 2,2'-dipyridyl in ethanol.

bound to the central cobalt(III) ion by the nitrogen atom; indeed, the isothiocyanatocobalt(III) complexes are more familiar than the thiocyanato complexes, in which the SCN^- ligand is bound by the sulfur atom.

Several years ago, however, the pentacyanocobaltate(III) complex, $K_3[Co(CN)_5SCN]$, was described as belonging to the group of thiocyanato complexes.[16] Recently, Stotz *et al.*[17] have reported the synthesis of an isothiocyanato complex, $K_3[Co(CN)_5NCS]$ (a linkage-isomer).

The dithiocyanato-bis(2,2'-dipyridyl) and bis(1,10-phenanthroline)cobalt(III) complexes, $[Co(SCN)_2dip_2]ClO_4\cdot 2H_2O$ and $[Co(SCN)_2phen_2]$-NCS, prepared here have also been ascertained to

$[Co(NCS)(NH_3)_5]SO_4\cdot 2H_2O$	2140_s	848_m 803_m

s=strong; m=medium; w=weak

The linkage-isomers of the rhodanato-complexes can be distinctly distinguished from each other on the evidence of their polarographic behavior in solution. The isothiocyanato-complexes, such as *trans*-$[Co(NCS)_2en_2]Cl\cdot H_2O$ and $[Co(NCS)(NH_3)_5]Cl_2$, exhibit the strong adsorption on the surface of the dropping mercury electrode (DME) which was pointed out by Tanaka *et al.*[19] as being due to interaction between the naked sulfur and the mercury of the electrode, while the thiocyanato complexes, which have no naked sulfur on the outside of the coordination sphere, show no adsorption at the DME. The adsorptions of *trans*-$[Co(NCS)_2en_2]^+$ and $[Co(NCS)(NH_3)_5]^{2+}$ ions were observed to exist at the range +0.2——0.5 V *vs.* SCE on the electrocapillary curves and on the current-time curves. No adsorptions were observed for the $[Co(SCN)_2dip_2]^+$ ion on the

DME in the 80% methanol-water solution containing 1 M lithium chloride.

The 2,2'-dipyridyl and 1,10-phenanthroline are considered to have a strong π-bonding character as ligands in the sphere of coordination; *i. e.*, these are considered to have the nature of the "back coordination." In such mixed ligand cobalt(III) complexes, the rhodanate ion is interpreted as having a tendency to coordinate to the cobalt(III) ion by means of the sulfur atom rather than by means of the nitrogen atom, since the six coordinate bonds also tend, in general, to resemble each other in the nature of bonding as far as possible within the same coordination sphere.

Figure 2 shows the absorption spectrum of the bis(2,2',2''-terpyridyl)cobalt(III) complex, [Co-trip$_2$]Cl$_3$·7H$_2$O, in comparison with that of [Co-dip$_3$]Cl$_3$·3H$_2$O.[20] The first absorption band is located at a shorter wavelength than that of the corresponding tris(2,2'-dipyridyl)cobalt(III) ion.

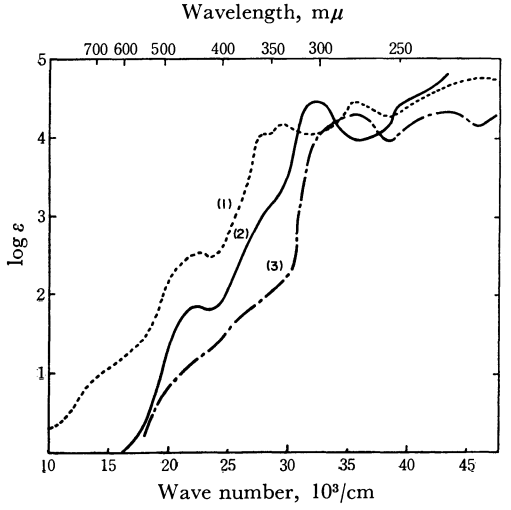

Fig. 2. The absorption spectra of the bis(2,2',2''-terpyridyl)cobalt(III) complex and of its ligand only: (1) ---- [Co trip$_2$]Cl$_3$·7H$_2$O; (2) —— [Co dip$_3$]Cl$_3$·3H$_2$O; (3) —·— 2,2',2''-terpyridyl in ethanol.

Figure 3 shows the absorption spectra of the tris(bathophenanthroline)cobalt(III) complex and of its ligand only.

The first d-d band for the d^6-complexes of the [Co N$_6$]-type shifts to a shorter wavelength according to this order of the ligands: phen, dip, trip, bathophen.

Figure 4 shows the absorption spectra of the bis-(1,10-phenanthroline)cobalt(III) complexes of the [CoX$_2$ phen$_2$]-type. The first band shifts towards a shorter wavelength in this order of the ligands: $S_2O_3^{2-}$, N_3^-, SO_3^{2-}, CO_3^{2-}, phen, NO_2^-, CN^-.

Figure 5 shows the absorption spectra of the dinitro-bis(2,2'-dipyridyl) and bis(1,10-phenanthroline)cobalt(III) complexes in relation to the *cis*- and *trans*-bis(ethylenediamine)cobalt(III) complexes. The d-d bands shift to a shorter wavelength according to this order of the ligands: phen, dip, en.

*3 No description of the preparation of $[Co(CN)_2phen_2]OH \cdot 7H_2O$ has been found, but the complex might have been prepared by treating the praseo-salt with KCN in solution.

The author is indebted to Mr. Taihei Hamazaki for his experimental assistance of preparing the dicyano cobalt(III) complexes. The author also wishes to express his appreciation to the late Professor Ryutaro Tsuchida and Professor Shukichi Sakuraba for their encouragements and discussions throughout this work.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 2282—2286 (1969)

Spectrophotometric Determination of L-Ascorbic Acid*[1]

Yoshiro OGATA and Yoshio KOSUGI

Department of Applied Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya

(Received January 16, 1969)

A novel quantitative determination of L-ascorbic acid by UV spectrophotometry in a HCl-KCl buffer has been developed. Ascorbic acid (λ_{max} 244 mμ) of over 2×10^{-5} M can quantitatively be determined by this method. Several oxidizing, reducing, acidic or basic reagents and other organic compounds which may be present together with ascorbic acid in ordinary drugs and drinks do not interfere the determination.

A considerable amount of L-ascorbic acid (Vitamin C) is now consumed as medicine and also as an antioxidant and additive in drinks and foods. A number of estimations of ascorbic acid assay have been developed, *i. e.*, visual titration,[1] spectrophotometry (or colorimetry),[1] polarography,[2] gas chromatography,[3] gravimetry,[4] bioassay method,[5] *etc.* have been postulated. Among them, titration and spectrophotometry are prevailing. The color change of indicators such as Tillman's reagent (2,6-dichlorophenolindophenol), Folin's reagent (phosphomolybdate), methylene blue and iodine are often employed for titration and colorimetry. Although some modifications of these methods have been reported,[6] they have shortcomings; *i.e.*, they are difficult to carry out, when a sample is either colored or contaminated with acidic or reducing substances which may react with the indicators. Fujita *et al.*[7] used a metaphosphoric acid solution and Robertson[8] added KCN to the sample solution, and they determined ascorbic acid content by the estimation of difference of absorbances before and after disappearance of ascorbic acid by oxidase or cupric ion. Reducible substances, however, often react with other reducing agents as well as ascorbic acid. In view of a large absorbance of ascorbic acid in UV region, the spectrophotometry was examined in detial. The present paper is a summary of our data concerning the suitable conditions of this very simple procedure for the spectrophotometric analysis in the presence of a number of additives.

Ascorbic acid (H_2A) is unstable in aqueous solutions, especially in the presence of heavy meta ions such as cupric and ferric ions. Though the rate of autoxidation to dehydroascorbic acid (DA) decreases in less polar organic solvents,[9] the solubility of the acid is generally small in these solvents, but the common organic compounds are very often soluble and their UV absorption bands overlap that of ascorbic acid.

The authors have previously studied kinetics of the copper-salt catalyzed autoxidation of ascorbic acid (H_2A) to dehydroascorbic acid (DA).[10]

$$H_2A + \tfrac{1}{2}O_2 \rightarrow DA + H_2O \qquad (1)$$

According to our mechanism,[10] ascorbic acid should be more stable in more acidic media. However, the cuprous ion formed by the reaction of cupric ion with ascorbic acid may easily be oxidized in acidic media to cupric ion (Eq. (2)), a catalyst for the autoxidation.

$$Cu(I) + \tfrac{1}{4}O_2 + H^+ \rightarrow Cu(II) + \tfrac{1}{2}H_2O \qquad (2)$$

It is known[11] that halide ion, *e. g.*, chloride ion, retards reaction (2) and also inhibits the formation of complex of ascorbic acid and cupric ion. These mechanisms suggest that hydrochloric acid free of metal ion is effective to prevent autoxidation. Even a trace of cupric ion, *e. g.*, 1.5×10^{-9} M,

however, acts as an effective catalyst[12] and the complete removal of these metallic ions are often difficult. Furthermore, the very low concentration of chloride ion accelerates the autoxidation,[11] but its high concentration retards the overall reaction. Thus, as a source of chloride ion a large amount of alkali chlorides besides HCl should be advantageous for the stabilization of ascorbic acid.

Experimental

Ultraviolet Spectroscopy. An automatic recording spectrophotometer (Type Simadzu SV-50A) equipped with quartz cells (light path of 10 mm) was used.

Materials. Ascorbic acid was of 99.5% pure with decomposition point of 190.9°C [lit. 190—192°C (dec.)[13]] and optical rotation of $[\alpha]_D^{25}$ +20.94° [lit. 20.5—21.5°[13]]. Dehydroascorbic acid was prepared from ascorbic acid by the method of Fujimura *et al.*,[14] and crystallized from acetic acid[15]: decomposition point 218—222°C (dec.) [lit. 196°C (dec.),[14] 225°C (dec.),[16] 237—240°C (dec.)[15]]. Potassium chloride and the following organic compounds were of commercial guaranteed reagent grade; saccharose, oxalic acid, nicotinamide, sodium cyclohexylsulfamate, D-fructose, DL-methionine. Hydrochloric, phosphoric, metaphosphoric acids and other organic compounds were of commercial extra pure grade and were used without further purification. Oxygen and nitrogen gases were of over 99.7% and 99.95% pure, respectively. Distilled water was used. Cupric and ferric chlorides were estimated by iodometry and chelation with EDTA, respectively.

Procedure. Sample solutions of given concentrations in stoppered volumetric flasks were kept standing at constant temperature (20°C) for a known period. There was no appreciable difference in the decreasing rate of ascorbic acid concentration between 2—3 day's storage of samples in a glass flask and that in a polyethylene bottle. After being kept for a certain period, ascorbic acid was diluted to *ca.* 5×10^{-5} M and the absorption curve ranging 238—255 mμ was drawn. The ascorbic acid concentrations in the dilute solutions were obtained by means of a calibration curve.

Titration with the Indophenol Method.[1] Samples were diluted to the concentration of *ca.* 10^{-1} M ascorbic acid and titrated with a 0.012% 2,6-dichlorophenolindophenol solution.

Results and Discussion

Absorption Spectrum and Molar Extinction Coefficient. Ultraviolet absorption peak (λ_{max}) of ascorbic acid varies with solvent, pH and temperature. The variation of λ_{max} may be caused by the change of the degree of solvation, ionization and/or association of ascorbic acid. The peak (λ_{max}) was 244 mμ in these acidic solutions in the present experiment. In a solution of 0.4 N HCl and 0.4 M KCl, the absorbance (E_{244}) at 244 mμ of various concentrations of ascorbic acid had the relation $E_{244}=10^4[H_2A]-0.035$ with the concentration ($[H_2A]$), at least, at 2×10^{-5}—9×10^{-5} M. Molar extinction coefficient (ε_{244} or ε_{max}) was found to be 10000.

Acidic Solutions. Acids can suppress the dissociation of ascorbic acid. The stability of ascorbic acid was examined under various conditions in a mixture of 0.4 N HCl and 0.4 M KCl, 0.1 N HCl, 0.4 N HCl, 0.1 N H_3PO_4 or *ca.* 2% metaphosphoric acid.

In all of these solutions, λ_{max} and ε_{max} were the same, *i. e.*, 244 mμ and 10000, respectively. Metaphosphoric acid may be advantageous in the presence of cupric chloride of *ca.* 15 ppm in a dilute solution. However, polymerization degree (n) of commercial metaphosphoric acid, $(HPO_3)_n$, and hence the degree of dissociation in solution is not measurable by means of the usual titration method. Further, the solution of metaphosphoric acid for UV measurements should be filtered to remove the turbidity and stored in a refrigerator to prevent depolymerization. Because of this troublesome treatment as well as instability of the solution (safe storage is within a week), metaphosphoric acid was less suitable as a stabilizer of ascorbic acid. A mixture of aqueous HCl and KCl (a modified Clark-Lubs buffer solution) was found to be the most advantageous solution. All experiments described below were carried out in this buffer solution of 0.4 N HCl and 0.4 M KCl.

Effects of Other Factors. Our kinetic study[10] shows that the rate of autoxidation of ascorbic acid decreased at high concentration of ascorbic acid and at lower partial pressure of oxygen. These facts imply that ascorbic acid is more stabilized at its high concentration and in the absence of oxygen. These effects are shown in Table 2 combined with the result in Table 1. Ascorbic acid is more stable in nitrogen than in air or oxygen, but the effect was too low to necessitate determination under nitrogen atmosphere, except for the presence of a large amount of metallic ion.

Ferric ion also catalyzes the autoxidation of ascorbic acid, but the examination of the effect of ferric chloride (Table 3) shows that ferric ion of the concentration below *ca.* 13 ppm in a dilute solution does not affect stabilization.

Absorption of Organic Compounds. For the application of this analytical method to drugs, drinks and foods, it is necessary to know the possibility of the overlap of the absorption band with those of organic compounds which may be present

together with ascorbic acid.

Results are shown in Table 4 as ε_{244}, ε_{max} and ε_{275}, where ε_{275} of ascorbic acid is only 400. Common vitamins are usually slightly soluble in the buffer solution and hence they are not examined. Extraction of ascorbic acid from solid samples with a small amount of the buffer solution can avoid contamination of such less soluble substances. If a sample is liquid, extraction with diethyl ether is recommended to remove vitamins A, D, E, *etc.*, and other many organic compounds.

A given amount of ascorbic acid was mixed with organic compounds whose ε's at suitable wavelengths were known (*e. g.*, see Table 4) and analyzed

spectrophotometrically.

The results in Table 5 indicate that this method is satisfactory, when two absorbances at 244 mμ and at an appropriate wavelength of additives are known.

Applications. A commercial vitamin pill (Sample I) contains many organic compounds. For example, the indicated composition was as follows: vitamin A palmitate 2500 I. U., calciferol 250 I. U., thiamine tetrahydrofurfuryl disulfite 2 mg, vitamin B_2 2.5 mg, nicotinamide 10 mg, vitamin B_6 2.5 mg, folic acid 0.25 mg, calcium pantothenate 5 mg, vitamin B_{12} 0.001 mg, vitamin C 37.5 mg, DL-α-tocopherol acetate 1 mg in one tablet. The pill (0.5506 g) was powdered and extracted with the KCl-HCl buffer solution of less than 20 m*l*. The filtrate was further extracted twice with diethyl ether (each *ca.* 50 m*l*). The residual aqueous solution was diluted to 1 tablet/6250 m*l* buffer solution and its absorbance at 244 mμ was measured to be 0.357. Accordingly, the content of ascorbic acid in the pill was calculated to be 37.7 mg/tablet using a calibration curve. The observed content agreed with the indicated content (37.5 mg/tablet) of ascorbic acid and also with the content estimated by indophenol method (37.0 mg/tablet).

Besides ascorbic acid, tannic acid and caffeine are main components of green tea (Sample II). The sum of these two components was estimated to be 2.68×10^{-4} mol/g using $E_{275}=0.495$, assuming that they have the same ε_{275} and ε_{244} values of 7.2×10^3 and 2.65×10^3, respectively (*cf.* Table 4). Thus the ascorbic acid content was calculated from $E_{244}-0.316$ and dilution degree of 1 g/4 *l*.

E_{244}(obs.)$-E_{244}$(tannic acid + caffeine)$=0.316-0.177=0.139$

This value of 0.139 corresponds to 1.67×10^{-5} M ascorbic acid solution and the concentration gives an approximate content of the acid in Sample II

to be *ca.* 11.8 mg/g. The sample was diluted to 1 g/100 m*l* and titrated with indophenol method. The content of ascorbic acid was determined to be 9.6—13.1 mg/g. This uncertainty may be due to the coloration of the sample.

Ascorbic acid content in an orange juice (Sample III) or a purified drink (Sample IV) was also difficult to be estimated exactly by the indophenol method even by employing the xylene extraction technique.[1] But the UV method is not interfered by coloring materials; moreover the sample is so diluted (*ca.* 5×10^{-5} M of ascorbic acid) that it is almost colorless. In addition, the additive property of the UV absorbance enables the accurate determination of the acid content. In the present experiments, a known amount of ascorbic acid (0, 1.25×10^{-5}, 2.5×10^{-5} or 3.5×10^{-5} M) was added to a sample and a straight line, obtained from plots of *E vs.* concentration, afforded an exact value of the acid content.

In these two cases of drinks (Samples III and IV), the values found were higher than the labeled values. This may be caused by the fact that the makers added the acid in a greater amount than that indicated on the label taking the consumption of ascorbic acid during storage into consideration.

Conclusion

The strong UV absorption band of ascorbic acid (λ_{max} 244, ε_{max} 10000 in an acidic solution) enables its facile quantitative determination with a very simple procedure, even if a sample contains a small amount of the acid (10^{-4} M). Oxidizing agents (*e. g.*, some metallic ions) and reducing agents (*e. g.*, oxalic acid and dextrose) which may react with ordinary titration indicators do not interfere with this direct spectophotometry. Also, colored materials which may sometimes be contained, do not interfere with it. Even when their compositions are unknown, the following circumstances may take place: (i) some components of drugs, drinks or foods have only small absorbance at 244 mμ on high dilution of the sample, (ii) some components of the sample are slightly soluble in a buffer solution consisting of 0.4 N HCl and 0.4 M KCl, and (iii) the total absorbance of a sample is known, as is often the case, before adding ascorbic acid.

The authors would like to thank Takeda Pharmaceutical Ind. Co., Sankyo Pharmaceutical Co. and The Aichi Food Research Institute for their gifts of some of the materials, and also Mr. M. Gotoh for his helpful assistance.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 2286—2291 (1969)

Separation Factors of Adjacent Rare Earths between the Aqueous and Resin Phases in the Presence of EDTA

Masaru NOGUCHI,*1 Akashi YOSHIFUJI*1 and Zenzi HAGIWARA

Department of Chemical Engineering, Tohoku University, Sendai

(Received January 21, 1969)

In order to find the accurate separation factors of two adjacent rare earths between the aqueous and resin phases, measurements were performed at 30°C in the presence of EDTA and using Dowex 50W, X-8, 50—100 mesh. The following results were obtained under the same experimental conditions as were employed in ion-exchange system for the isolation of the rare earth series. The separation factors were 2.05 for Er-Tm, 1.88 for Dy-Ho, 1.61 for Y-Dy, 1.76 for Tb-Y, 1.30 for Eu-Gd, and 3.77 for Sm-Nd. In the Er-Tm separation factor, a fairly large discrepancy was observed between the calculated and experimental values. It is concluded from the experimental results that the separation factors of pairs of lanthanons should be directly measured.

A successful ion-exchange process[1] was first developed by the Reasearch Group of the Ames Laboratory, USAEC, in combination with a cation exchanger and using EDTA (ethylenediamine-*N,N,N',N'*-tetraacetic acid: H_4Y) as the eluant. In order to treat theoretically the elution system[2,3] of the rare earths with the EDTA eluant, it is

necessary to get precise information on the separation factors of the lanthanide elements in the presence of a chelating agent.

The separation factor (α) of adjacent rare earths, Ln_1 and Ln_2, is approximately expressed as the ratio of the two stability constants: $\alpha^{Ln_2}_{Ln_1} \cong K_{Ln_1Y}/K_{Ln_2Y}$ It is possible to calculate the α-value using the stability constants[4,5] measured at an ionic strength of 1/10 M. In the isolation of rare earths from each other, a dilute eluant such as approximately 0.015 M EDTA buffered with ammonium hydroxide (pH$\cong$8.5) is widely used. Therefore, it may be valuable to find more accurate separation factors of the lanthanide series suitable for a real system and to compare them with the calculated values. For the complete solution of the Eu-Gd pair, the minimum elution distance calculated by using $v=(1+\varepsilon N_0)/\varepsilon$ and $\varepsilon=\alpha^{Eu}_{Gd}-1=(K_{GdY}/K_{EuY})-1$ is quite different from the experimental results. The symbol v indicates the minimum number of displacements of the mixed adsorption band necessary to carry out separation, while N_0 represents the mole fraction of the Eu component in the binary mixture of Eu and Gd being separated. Powell[6] indicated that the reason for this is the utilization of the separation factor unsuitable for the real exchange system, and that the Eu-Gd separation factor appears to be approximately 1.1.

The principal purpose of this research is to find the separation factor for pairs of adjacent lanthanons and to use them for analyzing the elution system of rare earth with EDTA.

Experimental

Materials Used. The rare earth oxides, such as Nd_2O_3, Sm_2O_3, Eu_2O_3, Gd_2O_3, Tb_4O_7, Y_2O_3, Dy_2O_3 Ho_2O_3, Er_2O_3, and Tm_2O_3, had high purities, greater than 99.9%. They were produced by the Shinetsu Chemical Industry Corp. Each oxide was dissolved with hydrochloric acid, and the rare earth ion was adsorbed in a resin bed of the hydrogen form in order to prepare the rare earth form. All the other chemicals used were of an analytical grade, and Dowex 50W, X-8, 50—100 mesh, was employed as the cation exchanger.

Experimental Procedures. An I.D.-22 mm Pyrex glass column containing Dowex 50W,X-8, 50—100 mesh was used for the elution experiment (Fig. 1). The resin was supported by a sintered glass disk.

Prior to the equilibrium experiment, a saturated form of the rare earth band was first prepared by passing the rare earth chloride solution through a Pyrex glass column involving a hydrogen form of Dowex 50W, X-8, 50—100 mesh; the column was then connected to the copper retaining bed (B-column). The latter was further connected to the C-column in the copper form. Using the 0.015 M EDTA buffered with ammonium hydroxide (pH$\cong$8.5) and the flow rate of 2 ml/min,

the rare earth band was displaced to a distance corresponding to several band lengths. After the C-column had been completely displaced by the rare earth, the elution was stopped. The steady-state band of the rare earth in the C-column was then washed with a 60% ethyl alcohol solution and then dried. The dried resin was finally used for the experiments. By employing the above method, various rare earth forms of resins involving ammonium and hydrogen were prepared; they are listed in Table 1.

On the other hand, a rare earth solution containing ammonium and hydrogen was prepared by the column method, shown in Fig. 2. After making the rare-earth-saturated bed, it was eluted with the 0.015 M EDTA (pH≅8.5). After a movement proportional to approximately 3-4 band lengths, the rare earth fraction from the main column was collected for the equilibrium experiments. Several types of rare earth fractions prepared are listed in Table 1, in which the two symbols Ln and NH_4 express the total concentrations of rare earth and ammonium in the aqueous phase.

Equilibrium Experiment. After mixing definite portions of the prepared rare earth form of resin containing small amounts of ammonium and hydrogen with 300, 450, and 600 ml of the rare earth fraction, the mixtures were maintained at 30°C for 96 hr in a thermostat under occasional stirring. After equilibration, the resin was separated from the aqueous phase, and both phases were analyzed in order to find the separation factor in the presence of EDTA.

Analysis. The constituents in the resin were eluted with 2 M NaCl. The rare earth in the resin and aqueous phases was determined as a mixed oxide after precipitating the oxalate. Further, each rare earth in the mixed oxide was determined by spectrophotometry as well as by X-ray fluorescent spectrometry. The determination of ammonium was performed by the Kjeldahl method, and the excess of EDTA (Y_f), which was present in the uncombined form with rare earth, was determined volumetrically with a standard solution of $NdCl_3$, using an arzenoazo indicator [3-(2-arzono-phenylazo)-4,5-dihydroxy-2,7-naphthalene-disulfonic acid] and pyridine as the buffer solution.

Results and Discussion

The compositions of adjacent rare earths at equilibrium are given in Tables 2 to 7, in which the rare earths in both phases are expressed in the mole fraction:

$$m_{Ln_1} + m_{Ln_2} = 1, \quad m_{\overline{Ln}_1} + m_{\overline{Ln}_2} = 1$$

where the barred quantities refer to the resin phase, and the unbarred, the aqueous phase. The observed separation factors are also represented; these are found by the following relation:

$$\alpha_{Ln_1}^{Ln_2} = \left(\frac{m_{\overline{Ln}_2}}{m_{\overline{Ln}_1}}\right)\left(\frac{m_{Ln_1}}{m_{Ln_2}}\right)$$

whether or not a chelating agent is present in the system, the separation factor of the two adjacent rare earths is defined as the concentration ratio of these species in the resin and aqueous phases. The dimensionless separation factor is not affected by the selection of the concentration units. The average values of the separation factors for the two adjacent rare earths are tabulated in Table 8. The values calculated from the stability constants of the rare earth-EDTA chelates also appear in the same table.

In this study, the Er-Tm separation factor showed 2.05. This is too far from the value calculated using the stability constants ($\alpha_{Tm}^{Er} \cong K_{TmY}/K_{ErY}$). The α_{Tm}^{Er}-value[7] at 60°C is 2.02 under almost the same experimental conditions at 30°C. Powell[8] pointed out that a linear relation is seen in the plot of the logarithm of the stability constants as a function of the ionic radius of rare earth from Gd through Lu (See Table 8). Considering a regular decrease in stability with an increase in the radius and the difference in cationic radius between the tripositive rare earth ions, one would speculate that the differences between K_{Ln_1Y}/K_{Ln_2Y} and K_{Ln_2Y}/K_{Ln_3Y} will be small. The differences in radius are 0.02 Å for Ho^{3+}–Er^{3+}, 0.01 Å for Er^{3+}–Tm^{3+}, and 0.01 Å for Tm^{3+}–Yb^{3+}. The following sequence can be estimated for pairs of elements from Ho through Yb:

$$\alpha_{Yb}^{Tm} < \alpha_{Tm}^{Er} < \alpha_{Er}^{Ho}$$

8) J. E. Powell, *J. Chromatog.*, **29**, 210 (1967).

The α-value of 2.05 at 30°C is concluded to be reasonable on the basis of the following facts. The Er-Tm separation factor at 30°C can be calculated employing the thermodynamic quantities ($\Delta H°$, $\Delta S°$ and $\Delta F°$) obtained by a calorimetric study[9] of the formation of the rare earth-EDTA chelate

(LnY) in solutions at 25°C and $\mu=0.1$.

$$\Delta F^\circ_{Er} = -\boldsymbol{R}T \ln K_{ErY} = \Delta H^\circ_{Er} - T\Delta S^\circ_{Er}$$
$$\Delta F^\circ_{Tm} = -\boldsymbol{R}T \ln K_{TmY} = \Delta H^\circ_{Tm} - T\Delta S^\circ_{Tm}$$

The above relation lead to the following form:

$$\log \alpha_{Tm}^{Er} = \log \frac{K_{TmY}}{K_{ErY}} = -\frac{(\Delta H^\circ_{Tm} - \Delta H^\circ_{Er}) - T(\Delta S^\circ_{Tm} - \Delta S^\circ_{Er})}{2.303\boldsymbol{R}T}$$

Introducing $\Delta H^\circ_{Tm} = -1870$ cal/mol, $\Delta H^\circ_{Er} = -1708$ cal/mol, $\Delta S^\circ_{Tm} = 79.1$ cal/mol per deg. and $\Delta S^\circ_{Er} = 78.3$ cal/mol per deg., a value of 1.96 is obtained as the separation factor of the Er-Tm pair at 303°K. Further, the same treatment as above gives 1.91 as the α_{Tm}^{Er}-value at 333°K. The α_{Tm}^{Er}-values found experimentally at temperatures of 30°C and 60°C are in fair agreement with the calculated values.

The observed separation factor of 1.30 for Eu and Gd is greater than the calculated value; the former approaches 1.1,[6] as predicted from the results of the ion exchange elution of a mixture of Eu and Gd. On the other hand, slight differences in the separation factors for pairs of rare earths, such as Y–Dy, Tb–Y, and Nd–Sm, are observed between the calculated and experimental values. This may be attributed to the following facts: the α-measurement was performed at an ionic strength of *ca.* 0.015 M in order to get suitable values for the real exchange system, while the stability constants of the rare earth-EDTA chelates were determined at $\mu=0.1$. However, the difference in the separation factor due to the ionic strength may be insignificant between the adjacent rare earth pair. As may be clear from the stability constants of Ln-EDTA chelates,[4,5,9] fairly large differences have been reported in the literature. The accuracy in determining the stability constant is naturally limited to some degree by the very stable chealte formation. The above factors are considered to exert a serious effect on the calculation of the separation factor using the values of the stability constants.

It is convenient to calculate the separation factor by means of the difference in the stabilities of two adjacent rare earths. However, the experimental results show that the separation factor should be directly measured under conditions similar to those in the ion-exchange system employed for the elution.

The authors wish to thank Mr. Matsuji Sato for his X-ray fluorescent analysis.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 2291—2295 (1969)

Preparation and Properties of Di-μ-alkoxo-bis(3-alkyl-5-methylsalicylaldehydato)dicopper(II)

Takako INAZU, Hisashi OKAWA, Takahiko INAZU and Tamotsu YOSHINO

Department of Chemistry, Faculty of Science, Kyushu University, Hakozaki, Fukuoka

(Received January 24, 1969)

In this paper, the syntheses of copper(II) complexes of 3-alkylsalicylaldehydes, B, as well as the syntheses and properties of dimeric copper(II) complexes, C, with bridged alkoxy groups are reported.

In the course of our studies of the effects of large-membered chelate rings on the stabilities of such complexes as A, copper(II) complexes of 3-alkylsalicylaldehydes were synthesized as reference compounds. The copper(II) complexes thus obtained were normal, monomeric copper(II) chelates, B (ligand: Cu=2 : 1); when these copper(II) complexes, B, were refluxed with alcohol without any bases, the monomeric complexes could be converted to dimeric copper(II) complexes, C. The structures of the dimeric copper(II) complexes, C, with bridged alkoxy groups were verified by the study of the infrared spectrum, the ultraviolet spectrum, the nuclear magnetic resonance spectrum, by elementary analysis, a molecular-weight determination, electrophoresis, and by considering the magnetic moment of di-μ-ethoxo-bis(3-ethyl-5-methylsalicylaldehydato)dicopper(II), XVII, as a representative of the dimeric copper(II) complexes, C.

Several complexes containing alkoxide, especially methoxide, have been reported,[1,2] but very few

stable dimeric copper(II) complexes with bridged alkoxy groups have been reported. In some cases,[1] dimeric copper(II) complexes have been obtained by refluxing with a base such as potassium hydroxide. In these experiments, the dimeric copper(II) complexes could be obtained by merely refluxing with alcohol without any bases. In the case of monomeric copper(II) complexes of salicylaldehydes without an alkyl group at the 3 position, such as salicylaldehyde or 5-methylsalicylaldehyde, dimeric copper(II) complexes could not be isolated by refluxing in alcohol without any bases.[3] Therefore, the alkyl group in the 3 position must have exerted some steric effects.

Four 3-alkyl-5-methylsalicylaldehydes, II, III, IV, and VI, were synthesized as is shown in Fig. 4 by the Duff reaction of 2-alkyl-4-methylphenols, XXVI,[4] with boric acid and hexamethylenetetramine in glycerol. The 2-alkyl-4-methylphenols were synthesized by the Clemmensen reduction of 2-acyl-4-methylphenols, XXV, which had themselves been obtained from the aryl ester, XXIV, by the Fries rearrangement.

In each case, a monomeric copper(II) complex, B, was obtained by the addition of an ethanolic

solution of a ligand. By refluxing the brown-colored monomeric complexs, B, with alcohol, green complexes were obtained. The green crystals thus obtained were suggested to be dimeric

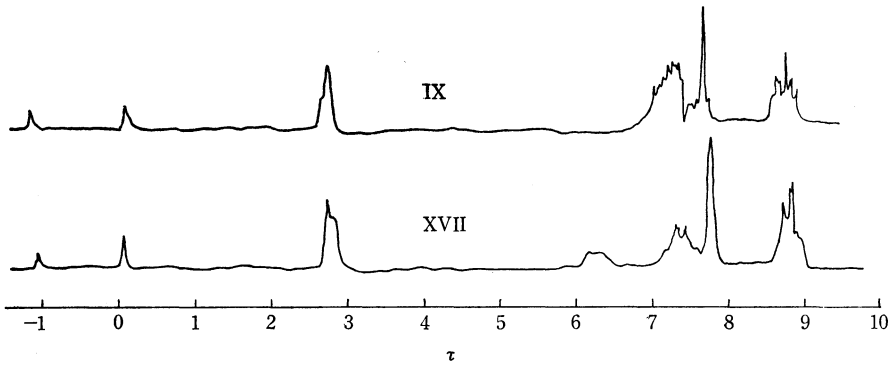

Fig. 5. The NMR spectra of the monomeric complex, IX and the dimeric complex, XVII.

3) The dimeric complexes can be obtained by refluxing in alcohol with potassium hydroxide; T. Shono, M. Mori and K. Shinra, Paper presented at the 18th Symposium on Coordination Chemistry, Kyoto, October, 1968.

4) The $R=CH_3$ in XXVI was commercially obtained. The $R=$cyclo-C_6H_{11} in XXVI was obtained by the Friedel-Crafts reaction of *p*-cresol with cyclohexene. See Y. Koike, H. Okawa, T. Inazu and T. Yoshino, *Mem. Fac. Sci., Kyushu Univ., Ser. C, Chem.*, **6**, 5 (1967).

by elementary analyses and by molecular-weight determinations. In the infrared spectra of the dimeric complexes, C, the bands over the 1040—1070 cm^{-1} range are assigned to the C–O stretching vibration of the bridged alkoxy groups, which are not observed in the case of the monomeric complexes, B. The data of the infrared spectra are given in Table 1.

The magnetic moments of the compounds were calculated using the expression; $\mu_{eff}=(8\chi_A T)^{1/2}$. The value obtained, 1.36 B. M., for the dimeric copper(II) complex, XVII, was considerably below the value for one unpaired electron. The value obtained for the monomeric copper(II) complex, IX, was 2.03 B. M. The dimeric nature, the low magnetic moment, and the tendency of copper(II) to achieve four-coordination suggest that there are bridging groups present in the complex.

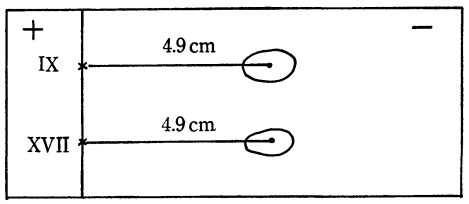

Fig. 6. Paper electrophoresis of the monomeric complex, IX and the dimeric complex, XVII.

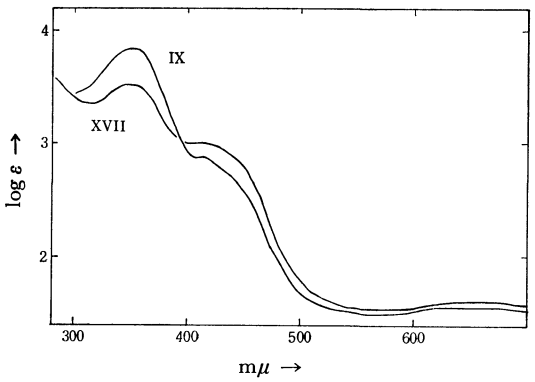

Fig. 7. Visible and ultraviolet spectra of the monomeric complex, IX, and the dimeric complex, XVII, in benzene.

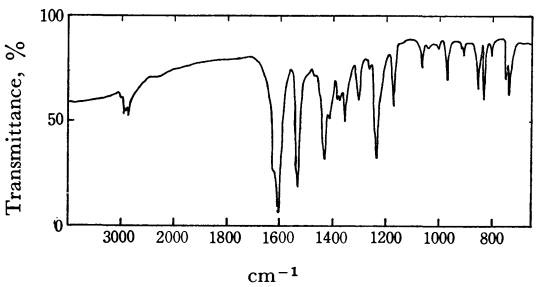

Fig. 8. Infrared spectrum of the monomeric complex, IX, in KBr disk.

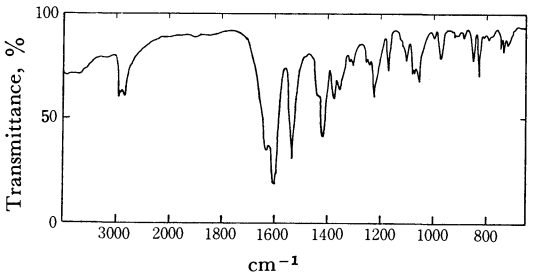

Fig. 9. Infrared spectrum of the dimeric complex, XVII, in KBr disk.

The NMR spectrum of the dimeric copper(II) complex, XVII, was in accord with that assumed for the dimeric structure; $\tau=8.75$ multiplet for terminal methyl protons at the 3 position and the bridged ethoxy groups, $\tau=7.67$ singlet for methyl at the 5 position, $\tau=7.40$ quartet for methylene protons at the 3 position, $\tau=6.27$ broad for methylene groups of the bridged ethoxy groups, and $\tau=0.12$ singlet for aldehyde protons. In the NMR spectrum of the monomeric copper(II) complex, IX, the absorption bands in the region $\tau=6.3$ were not observed, while other bands were observed at comparative positions. In both cases, protons for the dissociated salicylaldehyde, $\tau=-1.13$ for the dimeric complex, XVII, and -1.17

for the monomeric complex, IX, were observed.

A large number of copper(II) compounds, including bissalicylaldehydato copper(II), are square-planar. The visible spectra of the IX and XVII complexes consist of a broad band centered around 650 mμ. The absorption is similar in wavelength and in intensity to that of square-planar complexes of copper(II).[1] The close resemblance of the ultraviolet and visible spectrum of the dimeric copper(II) complex, XVII, to that of the monomeric copper(II) complex, IX, revealed that the dimeric complex, XVII, is square-planar. With the aid of paper electrophoresis, it was proved that copper atoms in the dimeric complex, XVII, are not in a reduced univalent state. All the experimental evidence is consistent with a planar, dimeric structure.

Experimental

All the melting points are uncorrected. The physical properties and analytical data of the products are summarized in Tables 2, 3, and 4. The ultraviolet and visible spectra were measured on a Hitachi EPS-3T spectrophotometer. The infrared spectra were measured on a Hitachi EPI-S2 spectrophotometer. The NMR spectra were recorded on a Varian Associates A-60 model, using tetramethylsilane as the internal standard and $CDCl_3$ as the solvent. The molecular weights were obtained with a Hitachi 115 vapor-pressure osmometer, using benzene as the solvent.

Magnetic Moment Determination. The magnetic susceptibilities of the compounds were measured with a Gouy balance at 27°C. The corrected molar susceptibilities were 771.5×10^{-6} c.g.s. unit for the dimeric complex, XVII, and 1725.4×10^{-6} c.g.s. unit for the monomeric complex, IX.

Paper Electrophoresis. Toyo Roshi No. 51 filter paper was used, with a solvent system of 8% formic acid - acetic acid - methanol - water (1 : 3 : 6 : 10 by vol) (600 V, 3 mA, 30 min). Without further treatment, pale blue spots of cupric ions were obtained.

3-Ethyl-5-methylsalicylaldehyde, II. The mixture of 150 g of glycerol and 35 g of boric acid was heated on a water bath under diminshed pressure for 2 hr and then on an oil bath at 200°C for 30 min. To the mixture there were added 25 g of hexamethylenetetramine and 36.2 g of 2-ethyl-*p*-cresol. The mixture thus obtained was heated at 150—165°C for 50 min. After cooling, 25 m*l* of concentrated sulfuric acid in 75 m*l* of water was added to the reaction mixture. The mixture was steam-distilled, and the 3-ethyl-5-methylsalicylaldehyde thus obtained was extracted with ether. The organic layer was washed with water and dried over anhydrous sodium sulfate, and the ether was removed. The residual oil was distilled, bp 122—124°C/20 mmHg, in a 12.5% yield (5.45 g).

Bis(3-ethyl-5-methylsalicylaldehydato)copper(II), IX. A solution of 2.00 g of 3-ethyl-5-methylsalicylaldehyde in 10 m*l* of ethanol was mixed with a solution of 1.60 g of copper(II) acetate monohydrate in 30 m*l* of ethanol. The mixed solution was left standing under diminished pressure at room temperature. The brown needles thus formed were collected and washed with a little ethanol. Yield, 516 mg, 21.7%. Mp 152—154°C.

Conversion of the Monomeric Complex, IX, to the Dimeric Complex, XVII. A mixture of 305 mg of the monomeric complex, IX, and 30 m*l* of ethanol was refluxed for 30 min. After cooling, 157 mg of green needles of the dimeric complex, XVII, were collected and washed with a little ethanol. They were soluble in chloroform and insoluble in water.

Deprotonation of Oxime Complexes: Dimethylglyoxime-Cobalt(III) Complexes*[1]

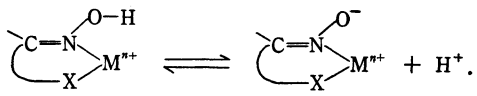
Isao MASUDA, Mitsuhiro SAKANO and Koichiro SHINRA

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamada, Suita, Osaka

(Received February 4, 1969)

Dimethylglyoxime-Co(III) complexes with the formula $[Co(dmgH)_2A_2]^n$ (I), where dmgH is dimethylglyoximato mono-anion, A is an axial ligand such as aniline, *p*-anisidine, pyridine, γ-picoline, imidazole, NH_3, CN^-, and NO_2^-, and n is -1, 0, or $+1$, were found to change their electronic absorption spectra reversibly depending on the pH of the solution. These changes have been attributed to the dissociation of the proton from the intramolecular hydrogen bridges of the complex; the changes are accompanied by the formation of the complex $[Co(dmgH)(dmg)A_2]^{n-1}$, where dmg represents the dimethylglyoximato di-anion. The proton dissociation constants (pK_a) obtained by the spectrophotometric method indicated that the complex I is generally a weak acid of $pK_a=7.7$—12.6. With the exception of the pyridine and the γ-picoline ligand, axial ligands do not appreciably affect the pK_a values. However, axial pyridine and the γ-picoline ligand increase the tendency of the hydrogen bridges to dissociate the proton.

Some metal chelate-complexes coordinated with oxime derivatives are thought to dissociate the proton reversively depending upon the pH of the solutions. The reaction can be generally represented as follows:



This phenomenon has been observed in Fe(III) complexes of Schiff bases derived from 1,2-diketonemonoximes and amines[1] and in complexes of methyl-2-pyridyl ketoxime.[2] As for pyridine-2-aldoxime complexes of Fe(II), Fe(III), Ni(II), Pd(II), and Pt(II), proton dissociation constants (pK_a) corresponding to the above reaction have been determined.[3,4]

In the present paper an extensive investigation with respect to such proton dissociation as is described above has been made on Co(III)-dimethylglyoxime complexes of the $[Co(dmgH)_2A_2]^n$*[2] type, this investigation has revealed that the hydrogen in the intramolecular, hydrogen bridges of the complexes can be ionized as an proton depending on the pH of the aqueous solution. Moreover, the ionization constants have been expeditiously obtained by the spectrophotometric method.[5]

Experimental

Measurements. The electronic absorption spectra were measured with a Hitachi EPS-3 spectrophotometer. An aqueous complex solution was buffered to a desirable pH by adding a Mcllavine or Kolthoff's buffer solution. The pH measurements of the solution was made on a glass-electrode pH meter calibrated against the standard buffer. All measurements of both the spectra and pH were carried out at room temperature from 20 to 25°C.

Complexes. *Bis(dimethylglyoximato)-di(imidazole)cobalt(III) Chloride*, $[Co(dmgH)_2(imidazole)_2]Cl\cdot 2H_2O$. This complex was newly prepared for the present study. Into an aqueous solution containing 5 g of cobalt(II) chloride hexahydrate, 5 g of dimethylglyoxime and 7 g of imidazole dissolved in ethanol were added. The subsequent passing of air through the solution for 30—40 min at room temperature resulted in the precipitation of a reddish-brown complex. This complex was recrystallized from hot water.

Found: Co, 11.66; C, 33.89; H, 5.19; N, 22.51; Cl, 6.81%. Calcd for $Co(C_{14}H_{18}N_8O_4)Cl\cdot 2H_2O$: Co, 11.86; C, 33.85; H, 5.27; N, 22.56; Cl, 6.70%.

The other complexes studied were prepared and purified according to the methods in the articles noted in Table 1.

Table 1. pK_a values of the complexes associated with the equillibrium (1)

Complex	pK_a	Isosbestic point (mμ)
$[Co(dmgH)_2(Aniline)_2]Cl\cdot 4H_2O$[6]	10.5	250, 347
$[Co(dmgH)_2(p\text{-}Anisidine)_2]Cl\cdot H_2O$[7]	10.9	249
$[Co(dmgH)_2(Pyridine)_2]Cl\cdot H_2O$[6,8]	7.7	250
$[Co(dmgH)_2(\gamma\text{-}Picoline)_2]Cl\cdot H_2O$	8.0	248
$[Co(dmgH)_2(Imidazole)_2]Cl\cdot 2H_2O$	9.9	246
$[Co(dmgH)_2(NH_3)_2]Cl\cdot 5H_2O$[6]	10.5	245
$[Co(dmgH)_2NH_3\cdot Cl]$[8,9]	12.0	248
$K[Co(dmgH)_2(CN)_2]\cdot 1.5H_2O$[10]	12.6	242
$NH_4[Co(dmgH)_2(NO_2)_2]\cdot H_2O$[9,11]	12.6	240

Results

The complexes of the type $[Co(dmgH)_2A_2]^{n*2}$ listed in Table 1 change their electronic absorption spectra with a change in the pH in an aqueous solution. For instance, the spectrum of the aniline complex with A=aniline in an alkaline medium differs from that in an acid medium, as is shown in Fig. 1. With a change in the pH the complex undergoes a series of reversible spectrum changes, with the isosbestic points at 250 and 347 mμ, as may be seen in Fig. 2. Moreover, a plot of the absorbances at 280 mμ against the pH values gave the curve shown in Fig. 4-a. These spectral evidences seem to indicate that the complex exists

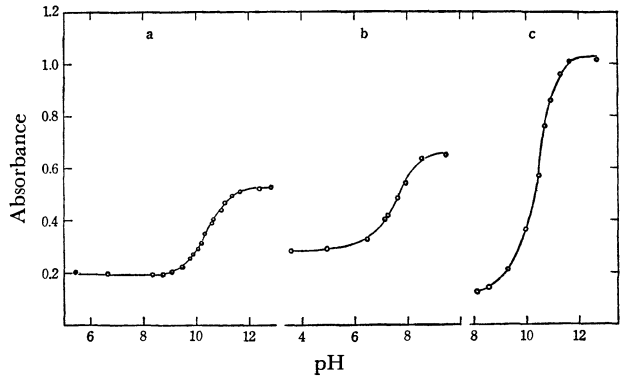

Fig. 4. Absorbance : pH curves.
a: $[Co(dmgH)_2(Aniline)_2]Cl \cdot 4H_2O$, initial concentration $=2.18\times10^{-5}$ M, $\lambda=280$ mμ
b: $[Co(dmgH)_2(Pyridine)_2]Cl \cdot H_2O$, initial concentration $=1.01\times10^{-4}$ M, $\lambda=300$ mμ
c: $[Co(dmgH)_2(NH_3)_2]Cl \cdot 5H_2O$, initial concentration $=1.00\times10^{-3}$ M, $\lambda=420$ mμ
Cell length $=1.0$ cm

The complex thus isolated, given in Table 1, has the formula $[Co(dmgH_2)(aniline)_2]Cl$; in an aqueous solution it shows a spectrum which quite agrees with that of the type A described above. Moreover, the photometric titration of this complex on an aqueous solution with a standard aqueous sodium hydroxide indicated that one mole of the complex is equivalent to one mole of sodium hydroxide, as is shown in Fig. 3.

Thus the above experimental results show that the conversion of the type A to the type B is accompanied by an proton dissociation of the complex. The ionization constants (pK_a) associated with this proton dissociation for the aniline complex was, then, spectrophotometrically obtained as 10.5 on the basis of the following relation: in the absorbance : pH curve shown in Fig. 4-a the pH value corresponding to the absorbance which is equal to $(D_A+D_B)/2$ should represent the pK_a. In this equation, D_A and D_B are the absorbances due to the complexes of the type A and of the type B respectively; they can be evaluated from the curve extrapolated according to the method of Stenström and Goldsmith.[5]

All the other complexes listed in Table 1 display spectral changes analogous to those of the aniline complex. The isosbestic points of the spectral changes are shown in Table 1. Also listed in Table 1 are the pK_a values with respect to each complex determined from the absorbance : pH curves shown in Figs. 4 and 5.

Discussion

It has been considered on the basis of NMR[12,13] and IR[13,14] spectroscopic studies and the chemical

axial ligands. As for the ammine complex with A=NH_3, X-ray crystallography has confirmed it to have a planar chelate structure.[15]

The electronic spectra of the complexes with A=NH_3, NO_2^-, or a halide anion have also been reported by several workers.[16] Matsumoto[7] has stated that the complexes with A=aniline derivatives are characterized by two intense ($\log \varepsilon \doteqdot 4$) absorption bands; one is due to the Co(III)→dmgH charge transfer observed around 300 mμ, and the other, to the axial ligand A→Co(III) charge transfer in the range of 350—410 mμ. However, there seems to have been no study which has dealt, in detail, with the spectral changes in the complexes.

As has been shown in the present study, the $[Co(dmgH)_2A_2]^n$ complexes, listed in Table 1 change their electronic spectra reversibly depending on the pH of the solution. From such spectral changes as those shown in Figs. 4 and 5, the complexes may be considered to exist in the solution in two forms, the type A in acid and neutral media and the type B in an alkaline medium. The isolated complexes with the $[Co(dmgH)_2A_2]^n$ composition show, in aqueous solutions, electronic spectra which agree with those of the corresponding A-type complex, and they consume one equivalent of an aqueous sodium hydroxide to change into a B-type complex.

From a consideration of these experimental results and in view of the structure of the complexes, it seems most reasonable to conclude that the electronic spectral changes of the $[Co(dmgH)_2A_2]^n$ are due to the proton dissociation of hydrogen in the hydrogen bridges of the complexes, as is shown in Eq. (1).

Further support for the above conclusion comes from the fact that, in the case of 1,2-cyclohexanedionedioxime (niH_2), which is analogous to the dimethylglyoxime, two types of complexes, $[Co(niH)_2(p\text{-anisidine})_2]Cl$ and $[Co(niH)(ni)(p\text{-anisidine})_2]$, have been isolated.[17] As to α-benzildioxime(bzH_2), the complex with the $[Co(bzH)(bz)(p\text{-anisidine})_2]$ formula is also known.

The dissociation constants, pK_a(Table 1), associated with Eq. (1) indicate that the $[Co(dmgH)_2A_2]^n$ complex is generally a very weak acid. With the exception in the pyridine complex, monovalent complex-cation always shows pK_a=9.9—10.9, and the monovalent complex-anion, pK_a=12.6, while a neutral complex shows pK_a values between them (Table 1).

In the cobalt complexes with dimethylglyoxime, the tendency to form O–H–O hydrogen bonding shown in Fig. A has been considered to be very strong. In fact, the complex with the $Co(dmgH)_3$ composition, where a similar hydrogen bonding is lacking, can be synthesized only in a strong alkaline solution.[14] However, as has been seen in the present work, the $[Co(dmgH)_2A_2]^n$ complexes (Fig. A) may be characterized as acids, though they are very weak (Table 1). As for their conjugate bases $[Co(dmgH)(dmg)A_2]^{n-1}$ (Fig. B), the remaining hydrogen bridge was not observed to dissociate the proton under the experimental conditions (pH≦13) employed. This seems to be mainly due to the stronger hydrogen bonding in the $[Co(dmgH)(dmg)A_2]^{n-1}$ than in the corresponding $[Co(dmgH)_2A_2]^n$, since the increase in the negative charges of a complex ion of this type may only slightly increase the pK_a value in 1—2, as is indicated in Table 1.

In general, an oxime group may be expected to increase its tendency to dissociate the proton when coordinated to a transition metal ion. The iron(II) complex with pyridine-2-aldoxime, $[Fe(PAO)_3H_2]^+$,*3 dissociates proton showing pK_a=3.36, and as to $[Fe(PAO)_3H]$, its pK_a=7.13; in the case of the palladium complex, $[Pd(PAO)_2H]^+$, the pK_a is 4.0, though a free pyridinealdoxime gives pK_a=10.22 referred to its oxime group.[3,4]

In comparison with the above facts, in the case of dimethylglyoxime-Co(III) complexes, the oxime group shows a much larger pK_a value than that expected from the pK_a value of free dimethylglyoxime, which is known to be about 11.[18] The

larger pK_a values for the complexes may be attributable to the hydrogen bonding in the dimethylglyoxime-Co(III) complexes (Fig. A).

Finally, it is of interest to note that pyridine and γ-picoline complexes show somewhat lower pK_a values than those of the other complexes, as may be seen in Table 1; this indicates that axial pyridine derivatives tend to facilitate the proton dissociation of hydrogen bridges in the complexes. It appears that this can be understood by assuming a double bonding character between the nitrogen atom in the pyridine ring and the central cobalt, which would make easy the transmittance of an electronic effect of the axial ligand to the oximato radical. A study of this point in some detail will be presented in a subsequent paper.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 2300—2302 (1969)

Electrochemical Behavior of Platinum in Solutions Containing Ethylenediaminetetraacetate

Nobuyuki TANAKA

Department of Chemistry, Faculty of Science, Tohoku University, Katahira-cho, Sendai

and Tadashi FUJISAWA

Department of Applied Chemistry, Yamagata Technical Junior College, Jonan, Yonezawa

(Received February 21, 1969)

The electrochemical behavior of platinum in solutions of ethylenediaminetetraacetate(EDTA) has been investigated by the measurements of current-potential and current-time curves and by the controlled-potential electrolysis. EDTA gives the anodic limiting current, which is much smaller than that of one-electron transfer obtained for the ordinary diffusion-controlled electrode reaction. Platinum was detected by the spectrophotometric method in the solution which was subjected to the electrolysis at controlled potential. The results suggest that the anodic current is due to the electrolytic dissolution of the platinum electrode by the reactions,

$$Pt + 2H_2O \rightarrow Pt(OH)_2 + 2H^+ + 2e \quad (1)$$

$$Pt(OH)_2 + H_2Y^{2-} \rightarrow PtY^{2-} + 2H_2O \quad (2)$$

where Y^{4-} represents a quadrivalent anion of EDTA.

The anodic limiting current of ethylenediaminetetraacetate (EDTA) which was obtained at the platinum electrode was found to be much smaller than the diffusion-controlled limiting current obtained for the electrode reaction of one-electron transfer and to be independent of the rate of rotation of the platinum electrode. Recently, Stulik and Vydra[1] have investigated the electrode reaction of EDTA at the platinum electrode and stated that the anodic limiting current is due to the oxidation of EDTA itself.

However, our preliminary experiments suggested that the anodic limiting current was due to the electrolytic dissolution of the platinum electrode in the solution of EDTA.

This paper describes the electrochemical behavior of platinum in the solution of EDTA which was revealed from the voltammetric measurements and the controlled-potential electrolysis.

Experimental

Apparatus. A recording polarograph, Yanagimoto Model P 102 was used for the measurements of current-potential and current-time curves. A Hokuto Denko linear scanning unit Model LS-1D, potentiostat PS-500 B and XY recorder F-3B were used for the measurements of cyclic voltammetric curves and for the electrolysis at controlled potential. A Hitachi-Horiba pH meter Model F was used for the measurement of pH. All measurements were made in a thermostat at 25.0°± 0.1°C except those which were made at various temperatures. The measurement of absorbancy was made with a Hitachi Model 139 spectrophotometer.

Electrode. A platinum wire electrode was sealed into a glass tube which was filled with mercury for electrical contact. The electrode was 0.7 mm in diameter and 5 mm in length, its geometric surface area being approximately 0.11 cm^2. The electrode was rotated with a synchronous motor at a rate of 600 rpm. The counter electrode which was used for the

1) K. Stulik and F. Vydra, *J. Electroanal. Chem.*, **16**, 385 (1968).

electrolysis at controlled potential was a platinum spiral of 0.7 mm in diameter and 40 mm in length.

Pretreatment of Electrode. The platinum wire electrode was treated with 10 N nitric acid and washed with distilled water. Before use, it was subjected to several cycles from −0.5 to +1.5 V *vs.* the saturated caromel electrode (SCE) in a deaerated 0.1 M perchloric acid. Then the electrode which was finally polarized anodically was short-circuited against SCE. If the electrode showed such a characteristic that the current decreased practically to zero within 2 or 3 min, it was called a "clean electrode."[2] When the electrode did not show such a characteristic, the cycled polarization was repeated. The clean electrode was stored usually in a deaerated distilled water.

Reagents. All reagents used were of reagent grade.

Spectrophotometric Measurements. The solution (50 m*l*) which was subjected to the controlled potential electrolysis was concentrated to about 1 m*l* in volume. The residual solution was treated with bromine water and concentrated hydrochloric acid and evaporated to almost dryness in order to convert Pt(II) to Pt(IV).[3] Ten milliliters of 1 : 1 hydrochloric acid was added and the solution was concentrated again to about 1 m*l* to remove bromine completely. The residual solution was treated according to Ayres and Meyer:[4] 10 m*l* of 6 N hydrochloric acid, 10 m*l* of 20% ammonium chloride solution and 10 m*l* of 1.0 M tin(II) chloride solution containing 3.5 N hydrochloric acid were added and the developed color was extracted with isoamyl acetate containing 1% resorcinol, of which absorption spectra were obtained.

Results and Discussion

Current-potential Curves. Current-potential curves of 5 mM EDTA in 0.1 M acetate buffer solutions were obtained with the rotated or stationary platinum electrode in the absence of oxygen, which are shown in Fig. 1. An arrow sign represents the direction of scanning potential. In both cases, the anodic limiting currents gave almost the same value which was independent of the rate of rotation of the electrode and was much smaller than that of one-electron transfer of ordinary compounds at this electrode. This indicates that the anodic current is not controlled by diffusion. In addition, the cathodic peak current was smaller in the presence of EDTA than in the absence of EDTA in the solution. This may indicate that the oxide film produced on the electrode surface was dissolved partly by the chemical reaction with EDTA.

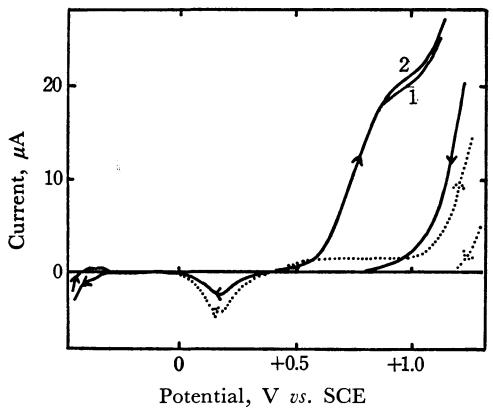

Fig. 1. Voltammetric curves of 5 mM EDTA in 0.1 M acetate buffer solutions at (1) rotated and (2) stationary Pt electrode. ····· indicates voltammetric curve of 0.1 M acetate buffer.

The anodic current increased with the increase of the concentration of EDTA, but it was not exactly proportional to the latter, as is given in Table 1. In the acetate buffer solution, the anodic current decreased with increasing pH's, and at higher pH's adjusted with other buffers no anodic current could be obtained. (Fig. 2).

The above results suggest that the anodic current is due to the electrode reaction given by

$$Pt + 2H_2O \rightarrow Pt(OH)_2 + 2H^+ + 2e \quad (1)$$

$$Pt(OH)_2 + H_2Y^{2-} \rightarrow PtY^{2-} + 2H_2O \quad (2)$$

The species H_2Y^{2-} is predominant in a pH range where the anodic current is obtained.

Current-time Curves. Current-time curves of EDTA were measured with the rotated and the stationary electrodes at +0.9 V. They are shown in Fig. 3 after correction for the residual current. Although the current decreased rapidly at first, it was nearly constant after the elapse of 5 min. There was practically no difference in current at the rotated and at the stationary electrode. The product $it^{1/2}$ which was found not to be constant also supports that the anodic current is not diffusion-controlled.[5]

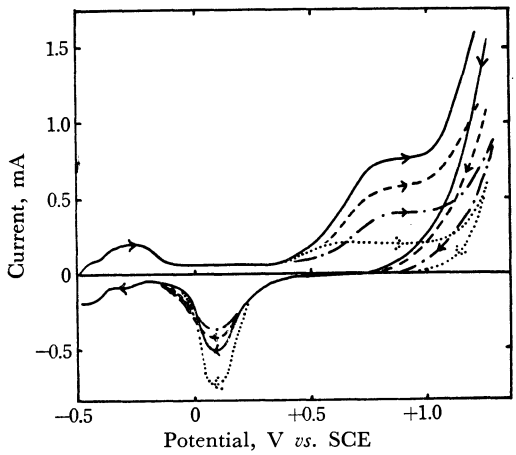

Fig. 4. Cyclic voltammetric curves of 5 mM EDTA in 0.1 M acetate buffer solutions at 25°C (—·—), 40°C (——) and 55°C (——). ····· indicates that of base electrolyte at 55°C. Scan rate is 0.2 V/sec.

5) P. Delahay, "New Instrumental Methods in Electrochemistry," Interscience, New York (1954), p. 51.

Cyclic Voltammetric Curves. Cyclic voltammetric curves of 5 mM EDTA in 0.1 M acetate buffer solutions were measured at various temperatures. Some of the curves are given in Fig. 4. The cathodic peak current obtained in the presence of EDTA was found to be always smaller than that obtained in the absence of EDTA. The anodic limiting current was enhanced with increasing temperature.

Electrolysis at Controlled Potentials. The solutions containing 5 or 10 mM EDTA and 0.1 M acetate buffer were electrolyzed for 10 hr at controlled potential of +0.9 V or at potentials cycled in the range of −0.1 V to +1.3 V, and the ultraviolet absorption spectra were obtained with the procedure mentioned above, which are shown in Fig. 5. The absorption band is considered to be due to the formation of Pt(IV)-Sn(II) complexes. In Fig. 5, the absorption spectra of the solution which was prepared with a standard platinum(IV) solution and a tin(II) chloride solution are shown. These spectra clearly indicate that platinum is dissolved electrochemically into the solution to a greater amount in the presence of EDTA than in the absence of EDTA.

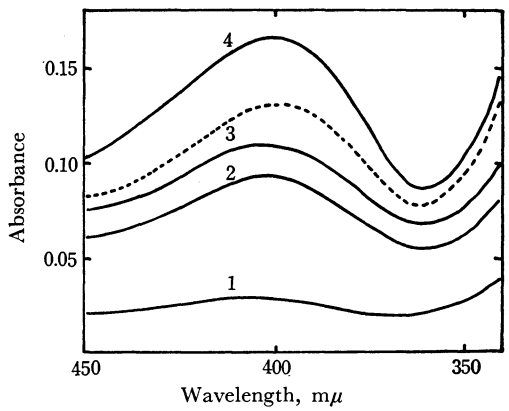

Fig. 5. Absorption spectra of Pt(IV)-Sn(II) chloride complex in isoamyl acetate solution. —— indicates absorption spectra of the solutions which were prepared with the solution subjected to the electrolysis at potentials cycled in the range of −0.1 to +1.3 V (1, 2 and 3) and at controlled potential at +0.9 V (4) for 10 hr. The concentrations of EDTA in electrolysis solutions were 0(1), 5(2) and 10 (3 and 4) mM. ---- indicates absorption spectra of the solution which was prepared with 2.45 mM Pt(IV) standard solution and tin(II) chloride solution.

Conclusion. From all of the results obtained in this study, it may be concluded that the anodic current obtained in the solution of EDTA is not due to the oxidation of EDTA itself but due to the electrolytic dissolution of platinum electrode with EDTA.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 2303—2307 (1969)

Oligomerization of Isoprene by Zirconium Catalysts

Akira MISONO, Yasuzo UCHIDA, Ken-ichi FURUHATA and Shohei YOSHIDA

Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Tokyo

(Received August 6, 1968)

The oligomerization of isoprene by catalyst systems consisting of a zirconium compound and an organoaluminum compound was studied. Isoprene was dimerized to 2,6-dimethyl-1,*trans*-3,6-octatriene by a catalyst system consisting of zirconium(IV) *n*-butoxide and diethylaluminum chloride. The selectivity for this dimer was increased to more than 90% by adding triphenylphosphine or tetrahydrofuran to this catalyst system. The effects of the molar ratio of the catalyst components and those of catalyst species were studied.

It is well known that the oligomerizations of olefins are catalyzed by transition metal complexes. The structures of the oligomers are affected by the transition metal and other catalyst components. We reported previously the cyclic dimerization of isoprene to a mixture of 1,5- and 2,5-dimethyl-1,5-cyclooctadiene with a catalyst system consisting of iron(III) acetylacetonate, 2,2'-dipyridyl, and triethylaluminum.[1]

Some catalyst systems containing titanium or chromium have been reported to give a linear dimer of isoprene, 2,6-dimethyl-1,3,6-octatriene along with other oligomers.[2,3]

We now wish to report on the selective linear dimerization of isoprene by catalyst systems consisting of zirconium(IV) *n*-butoxide, diethylaluminum chloride, and an additive, such as triphenylphosphine or tetrahydrofuran. The dimer was 2,6-dimethyl-1, *trans*-3,6-octatriene. The effects of the molar ratios of the catalyst components on the selectivity for the dimer were studied.

Experimental

Reagents. Isoprene was dried over anhydrous sodium sulfate, distilled, and deoxygenated by the freeze-thaw method with pumping.

Allyl chloride was dried over calcium sulfate and distilled under an atmosphere of nitrogen.

Organoaluminum compounds were distilled at reduced pressures and dissolved in benzene.

Benzene, toluene, tetrahydrofuran, and ethyl ether were purified by conventional procedures.

Zirconium(IV) *n*-butoxide was prepared according to the reported method.[4]

Zirconium(IV) acetylacetonate was prepared by the reaction of pyridinium hexachlorozirconate and excess acetylacetone in benzene, to which mixture triethylamine was added, drop by drop, over a 30-min period, and was then purified by recrystallization from acetylacetone.

Tetra-π-allylzirconium was synthesized according to the method reported by Wilke.[5]

Triphenylphosphine and 2,2'-dipyridyl were commercial reagents.

Reactors. The reaction was carried out in a 30 m*l* glass tube, a 200 m*l* glass autoclave, or a 100 m*l* stainless steel autoclave.

Reaction Procedure. In a typical reaction, 5.4 mmol of triphenylphosphine were put into a stainless steel autoclave; the autoclave was swept several times with dry nitrogen, and then 6.28 g of benzene, 50 mmol of isoprene, 0.5 mmol of zirconium(IV) *n*-butoxide (16.7 wt% benzene solution), and 5.0 mmol of diethylaluminum chloride (19.9 wt% benzene solution) were added, in this order, under a dry nitrogen stream. The total amount of benzene was controlled so as to be 8.3—8.5 g. Then the autoclave was closed and kept at 100°C for 2 hr.

Analysis. For the separation of the products, the reaction solution was washed with diluted hydrochloric acid and with water, and then dried over anhydrous sodium sulfate and fractionally distilled. For the determination of the products, gas chromatography, infrared spectrography and nuclear magnetic resonance spectrography were applied, together with elementary analysis and molecular weight measurement. The gas chromatography was also used in calculating the conversion percent of isoprene and the yields of the products. A 2 m stainless steel column, 4-mm in diameter and packed with polydiethylene glycol succinate on Shimalite, was used. Operation conditions: column temperature, 112°C and 180°C for dimers and trimers respectively; Flash evaporator temperature, 300°C;

carrier gas (helium) speed, 30 ml/min. Benzene was used as the internal standard.

Infrared spectra of the products were taken with a Nihon Bunko Model DS-301.

Nuclear magnetic resonance spectra were recorded on a Nihon Denshi Model C-60.

Molecular weights were measured by the cryoscopic method in benzene.

Results and Discussion

Structures of the Products. The reaction mixtures were analyzed by gas chromatography (Table 1).

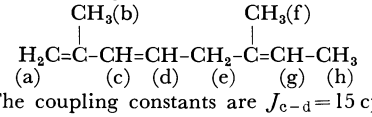
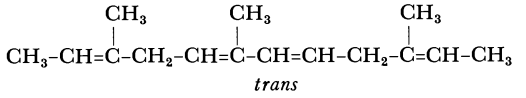
* The protons of 2,6-dimethyl-1,*trans*-3,6-octatriene are represented as follows.



The coupling constants are $J_{c-d}=15$ cps, $J_{d-e}=6$ cps, and $J_{g-h}=6$ cps.

A product with the relative retention time of 2.8 (112°C) was the main product. For analysis, it was isolated by distillation. The structure of the product was identified as 2,6-dimethyl-1,*trans*-3,6-octatriene by means of its nuclear magnetic resonance spectra, shown in Table 2; this structure was supported by the infrared spectra, which showed absorptions due to methyl and methylene groups (2960, 2905, 2840, 1455, 1440, and 1375 cm^{-1}), conjugated and isolated double bonds (1655, 1645, and 1610 cm^{-1}), a *trans* double bond (965 cm^{-1}), a terminal methylene group (885 cm^{-1}), and a tri-substituted double bond (815 cm^{-1}). A mixture of the products whose relative retention times were 4.9, 6.8, and 9.9 (180°C) was also separated by distillation. These compounds were confirmed to be trimers by molecular weight measurements (Found: 200, Calcd for $C_{15}H_{24}$: 204). The products whose relative retention times were 4.9 and 9.9 (180°C) were obtained in a relatively highly pure state by the fractional distillation. The infrared spectra of the product whose relative retention time was 9.9 showed absorptions due to methyl and methylene groups (2960, 2910, 2840, 1440, and 1375 cm^{-1}), a *trans* di-substituted double bond (965 cm^{-1}), and a tri-substituted double bond (810 cm^{-1}). No absorption was observed due to a terminal methylene or a vinyl group. The structure of this trimer has not yet been confirmed, but we assume it to be as shown below:



trans

The absorption characteristic of a conjugated double bond was not observed, but this can be explained by the fact that this compound has a nearly symmetric structure. The nuclear magnetic resonance spectra of this compound showed absorptions at about $\tau=8.4$ due to a methyl group which was attached to an unsaturated carbon atom, at $\tau=7.3$ (doublet) due to methylene protons between double bonds, and at $\tau=4$—5 (multiplet) due to olefinic protons; these absorptions do not contradict the structure shown above. This compound might be formed by the addition of isoprene to the 1-position of the dimer, 2,6-dimethyl-1,*trans*-3,6-octatriene. The infrared spectra of the trimer whose relative retention time was 4.9 showed absorptions due to methyl and methylene groups (2960,

2910, 2840, 1455, 1440, and 1380 cm^{-1}), *trans* di-substituted, tri-substituted, and conjugated double bonds (1660, 1645, 1610, 965, and 815 cm^{-1}), and a terminal methylene group (885 cm^{-1}). This trimer can be considered to be linear, but its structure has not yet been confirmed. The trimer with a relative retention time of 6.8 could not be isolated in sufficient purity for its structure to be studied in detail.

The Time Dependence of the Reaction. The time dependence of the reaction of isoprene by the catalyst system consisting of zirconium(IV) *n*-butoxide, and diethylaluminum chloride was studied (Fig. 1). The conversion of isoprene became almost 100% in 2 hr. The yield of 2,6-dimethyl-1,*trans*-3,6-octatriene reached a maximum at about 1 hr, and then it decreased slightly. It is probable that the dimer was consumed in the successive reaction to higher oligomers.

The Effects of the Molar Ratio of the Catalyst Components. The effects of the molar ratio of the components of the catalyst consisting of zirconium(IV) *n*-butoxide and diethylaluminum chloride or triethylaluminum are shown in Figs. 2 and 3 respectively.

In the case of diethylaluminum chloride, the conversion of isoprene increased with the increase in the molar ratio. The yield of 2,6-dimethyl-1,*trans*-3,6-octatriene reached a maximum at the molar ratio of 10. The yield of trimers was almost constant when the molar ratio exceeded 10, and the polymer yield was increased as the molar ratio was increased. On the other hand, in the case of

triethylaluminum the maximum conversion of isoprene appeared at the molar ratio of 18. By this catalyst system, isoprene was consumed mainly by high polymerization, and the yield of 2,6-dimethyl-1,*trans*-3,6-octatriene was small (0—7%) at the molar ratios between 7 and 22.

As other organoaluminum compounds, diethylaluminum ethoxide and ethylaluminum dichloride were used. In the case of diethylaluminum ethoxide, however, the reaction of isoprene did not take place. The binary system of zirconium(IV) *n*-butoxide and ethylaluminum dichloride polymerized isoprene immediately. The infrared spectrum of the polymer obtained by this binary catalyst system showed only methyl and methylene absorptions and did not show any absorption due to carbon-carbon double bonds. This spectrum was identical with that of the polymer obtained by ethylaluminum dichloride only. Ethylaluminum dichloride was reported to cause the cationic polymerization of isoprene to a ladder polymer.[6]

The best organoaluminum compound as a catalyst component was thus found to be diethylaluminum chloride, and the best yield of the dimer of isoprene was accomplished when the molar ratio of diethylaluminum chloride to zirconium(IV) *n*-butoxide was about 10.

The Effects of Additives. In the oligomerization of olefins, the addition of an electron donor to the reaction system strongly affects the reaction

6) B. A. Dolgoplosh, G. P. Belonovskaja, I. I. Boldgreva, E. N. Kropacheva, K. V. Nelson, Ja. M. Rosinoer and J. D. Chernova, *J. Polymer Sci.*, **53**, 209 (1961).

products, *e.g.*, in the oligomerization of butadiene with iron complex catalysts.[7] In the present study some electron donors were added to the catalyst system consisting of zirconium(IV) *n*-butoxide and diethylaluminum chloride (Al/Zr; 10). The results are shown in Fig. 4.

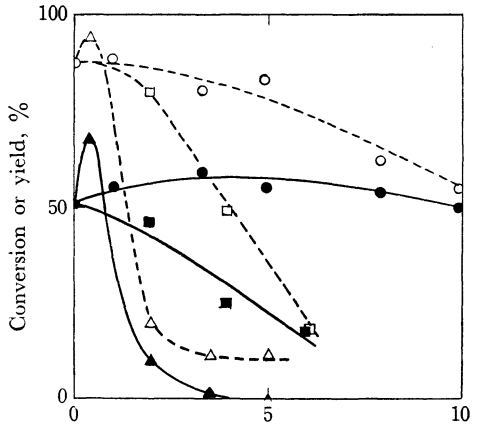

Fig. 4. Effects of additives.

$AlEt_2Cl$/Zr(O^{n}C$_4$H$_9$)$_4$ mol ratio: 10

The addition of triphenylphosphine lowered only the conversion of isoprene, while the yield of 2,6-dimethyl-1,*trans*-3,6-octatriene was slightly increased. In the case of tetrahydrofuran, both the conversion and the yield were decreased. The formation of higher oligomers was strongly suppressed in both cases, and the selectivity for the dimer increased to more than 90%. The addition of 2,2'-dipyridyl suppressed the reaction of isoprene.

The Reaction with Catalyst Systems Consisting of Other Zirconium Compounds. Zirconium(IV) acetylacetonate, zirconium(IV) chloride, and tetra-π-allylzirconium were used in place of zirconium(IV) *n*-butoxide in the reaction of isoprene.

When zirconium(IV) acetylacetonate and diethylaluminum chloride were used as catalysts, no oligomerization of isoprene took place, but polymerization did occur. The polymer obtained was a white powder melting at 123°C; the infrared spectrum of the polymer showed methyl and methylene absorptions and two absorptions at 890 cm^{-1} and 980 cm^{-1}.

In the case of the catalyst system consisting of zirconium(IV) chloride and triethylaluminum or diethylaluminum chloride, the reaction solution was not homogeneous and only a small amount of polymer was formed at the surface of zirconium(IV) chloride.

In tetra-π-allylzirconium, the π-allyl ligand is supposed to be replaced with isoprene. In the reaction of isoprene by tetra-π-allylzirconium alone, the dimerization of isoprene to 2,6-dimethyl-1,*trans*-3,6-octatriene was observed along with the polymerization reaction. When diethylaluminum chloride was employed as a catalyst component, the conversion of isoprene and the yield of the dimer increased as the molar ratio of diethylaluminum chloride to tetra-π-allylzirconium increased. However, the formation of the dimer became constant at the higher molar ratio. The effect of the molar ratio of diethylaluminum chloride to tetra-π-allylzirconium is shown in Fig. 5. From this result, the addition of diethylaluminum chloride seemed to be necessary to produce an effective catalyst for the dimerization.

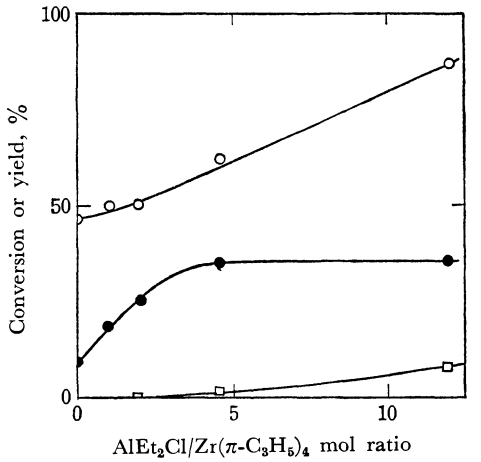

Fig. 5. Effect of the molar ratio of diethylaluminum to tetra-π-allylzirconium.

Isoprene/Zr(π-C$_3$H$_5$)$_4$ mol ratio: 100

In the oligomerization of dienes with the catalyst system consisting of a transition metal and an alkylaluminum, the alkylaluminum is considered to act as an alkylating reagent of the transition metal. A low-valent transition metal species is then formed by the homolytic splitting of the carbon-metal bond. The catalyst systems consisting of zirconium(IV) *n*-butoxide and diethylaluminum chloride, with or without a stoichiometric amount of isoprene, were diamagnetic at room temperature and after having been heated at 100°C for 30 min.

7) M. Hidai, K. Tamai, Y. Uchida and A. Misono, This Bulletin, **39**, 1357 (1966).

From these results, we assume that zirconium is in its four-valent state during the dimerization reaction.

The small difference between triphenylphosphine and tetrahydrofuran in the effects on the dimerization of isoprene by the catalyst system consisting of zirconium(IV) *n*-butoxide and diethylaluminum chloride can be explained on the assumption presented above. If zirconium is in its four-valent state (d^0), the back donation to ligands does not play an important part in the catalytic reaction.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 2307—2309 (1969)

Studies on Stable Free Radicals. IV.*[1] Decomposition of Stable Nitroxide Radicals

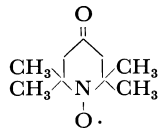
Keisuke MURAYAMA and Takao YOSHIOKA

Central Research Laboratories, Sankyo Co., Ltd., Shinagawa-ku, Tokyo

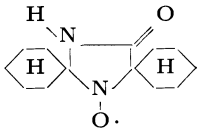
(Received December 4, 1968)

Decomposition studies of extremely stable free radicals such as 2,2,6,6-tetramethyl-4-oxopiperidine-1-oxyl (I), 2,2,6,6-tetramethylpiperidine-1-oxyl (VIII) and 2,2,6,6-tetramethyl-4-hydroxypiperidine-1-oxyl (IX) were carried out: although radical I decomposed to give 1-hydroxy-2,2,6,6-tetramethyl-4-oxopiperidine (IV) both in the light and dark, radicals VIII and IX were more stable under these reaction conditions. Therefore it was confirmed that i) a source of hydrogen was the ketonic α-methyene hydrogens, ii) a radical which could give a thermodynamically stable conjugated product by a cycloelimination was easily decomposed and iii) the decomposition of radical I was only accelerated by heating and was independent of the action of light.

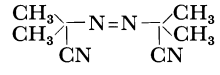
In a previous study on reactivity of extremely stable free radicals,[1] it was reported that the reaction of stable free radicals such as 2,2,6,6-tetramethyl-4-oxopiperidine-1-oxyl (I) and cyclohexane-1-spiro-2'-(4'-oxoimidazolidine-1'-oxyl)-5'-spiro-1''-cyclohexane (II) with a *C*-radical derived from α,α'-azo-bis(isobutyronitrile) (ABIN) (III) gave the corresponding coupled products. Although the reaction of II with III proceeded in a high yield, the reaction of I with III only gave a coupled product in a poor yield and a by-product, 1-hydroxy-2,2,6,6-tetramethyl-4-oxopiperidine (IV), in 38.4% yield.[1] We wish to explain the differences in the mechanism in the case of I and II in this paper.



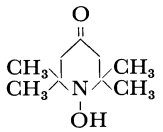
(I)



(II)



ABIN (III)



(IV)

Results and Discussion

It appears that the by-product (IV) arose from a hydrogen abstraction reaction of I. *A priori* following sources of hydrogen would be possible: i) hydrogen from the solvent (MeOH), ii) a trace of water, iii) a methyl-hydrogen in ABIN (III), iv) that in radical I, v) a methylene-hydrogen in I. In order to exclude the possibilities i) ii) and iii), a solution of radical I in anhydrous benzene was refluxed for 30 hr under a dry nitrogen atmosphere. Under these conditions radical I afforded the >N–O–H (IV) and a polymeric substance[2] in 60% and 30% yields, respectively. A trace of 2,6-dimethyl-2,5-heptadien-4-one (phorone) (V) was also isolated and identified by comparison of melting point, IR and NMR spectra and vpc retention time with those of an authentic sample. Furthermore heating of radical I at 105—110°C in the absence of solvent for 3 hr under a

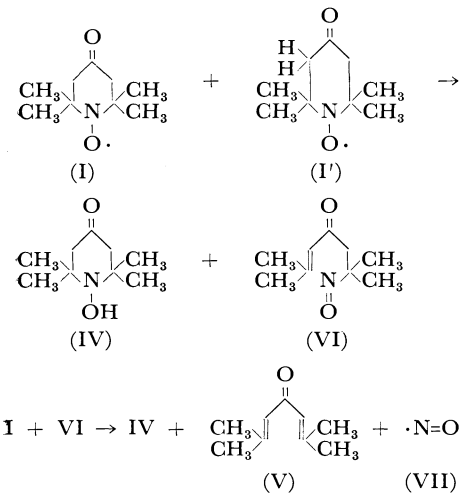
1) K. Murayama, S. Morimura and T. Yoshioka, This Bulletin, **42**, 1640 (1969).

2) The structure of a polymeric substance was uncertain.

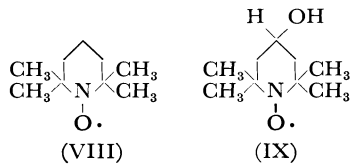
dry nitrogen atmosphere, gave the same results. These observations would suggest the following mechanism. The stable radical I abstracts a hydrogen atom from an α-methylene of the ketone in another radical I (=I') to give a reactive intermediate (VI). A second stable radical I abstracts a hydrogen atom from the intermediate VI to give a second >N–O–H (IV), a thermodynamically stable conjugated ketone (phorone) (V) and nitric oxide (VII).[3] Thus three moles of I give two moles of IV and therefore the theoretical yield of IV is 66.6% based on the weight of the starting material. This supposition is therefore compatible with our observation. Phorone (V) prepared from I may be further polymerized by nitric oxide (VII).[4]



I + VI → IV + (V) + ·N=O

Thus : 3·(I) → 2·(IV)

The following additional argument was made for the sake of confirming the action of a hydrogen atom on a α-carbon of the ketone group in the piperidine ring. If such α-methylene hydrogens were effective, 2,2,6,6-tetramethylpiperidine-1-oxyl (VIII) and 2,2,6,6-tetramethyl-4-hydroxypiperidine-1-oxyl (IX), which had no ketone group, should be more stable than radical I.



Under the same reaction conditions, as expected, radicals VIII and IX were almost recovered, and additionally no ketonic compound I was detected by the vpc technique, although the ketone I was anticipated to be prepared from the corresponding secondary alcohol IX by the attack of the *N*-oxyl radical IX just as acetone was prepared from isopropyl alcohol by the attack of the free radicals derived from diacetyl peroxide.[5] Similarly, no formation of acetone was observed during the hydrogen abstraction reaction by the radical IX from isopropyl alcohol.

A similar cycloelimination has been reported by Keana *et al.*[6] They have attempted a photolysis of the stable free radical, *e.g.* 3-carbamoyl-2,2,5,5-tetramethylpyrroline-1-oxyl, to obtain the thermodynamically stable conjugated corresponding ketone and nitric oxide (VII). This fact suggests that the stable free radical I may decompose photochemically. In order to investigate the possibility of photocycloelimination of radical I, a solution of I in anhydrous benzene was refluxed in the dark for 30 hr under a dry nitrogen atmosphere. Thus radical I converted into the >N–O–H (IV) in a high yield just as in the light. Accordingly, the photocycloelimination observed in the study of 3-carbamoyl-2,2,5,5-tetramethylpyrroline-1-oxyl[6] was excluded in a case of the

stable free radical I. Table 1 shows reaction conditions and properties of products.

It was therefore confirmed that i) a source of hydrogen was the α-methylene hydrogen of the ketone group in the piperidine ring (I), ii) a stable radical which could give a thermodynamically stable conjugated product by a cycloelimination was easily decomposed and iii) the decomposition of radical I was only accelerated by heating and was independent of the action of light.

Experimental

Melting points were uncorrected.

The NMR spectra were obtained with a Varian A-60 NMR spectrometer, using tetramethylsilane as an internal standard at 32°C.

The IR spectra were determined by means of Nujol mull and liquid film.

Materials. 2,2,6,6,-Tetramethyl-4-oxopiperidine-1-oxyl (I) was prepared by the oxidation of the corresponding amine by hydrogen peroxide in the presence of sodium tungstate and ethylenediaminetetraacetic acid (EDTA).[7] 2,2,6,6-Tetramethylpiperidine-1-oxyl (VIII) and 2,2,6,6-tetramethyl-4-hydroxypiperidine (IX) were derived from I.[8,9]

General Procedure for the Decomposition of the Extremely Stable Free Radicals. a) A solution of 17.0 g (0.10 mol) of radical I in anhydrous benzene was refluxed for several hours under a dry nitrogen atmosphere. After the solvent was evaporated under reduced pressure and the IR spectrum of the residue was taken, the residue was distilled under reduced pressure at low temperature (below 80°C). The distillate ($bp_{0.05}$ 75—80°C) was scratched to induce crystallization and the solid obtained was filtered and recrystallized from petroleum benzine to give an analytically pure sample which was identified by comparison of a melting point, IR and NMR spectrum and vpc retention time with that of an authentic 1-hydroxy-2,2,6,6-tetramethyl-4-oxopiperidine (IV),[10] mp 90—91°C. A mixed melting point with the authentic IV was undepressed. Found: C, 63.47; H, 10.19; N, 7.98%. Calcd for $C_9H_{17}NO_2$: C, 63.16; H, 10.04; N, 8.19%.

b). After heating radical I at 110°C for 3 hr under a dry nitrogen atmosphere, the oil was distilled under reduced pressure below the reaction temperature, 105—110°C. In the same manner as a), 1-hydroxy-2,2,6,6-tetramethyl-4-oxopiperidine (IV) was obtained, mp 90—91°C. A mixed melting point with the authentic sample was undepressed.

The Detection and the Identification of a Trace of 2,6-Dimethyl-2,5-heptadien-4-one (Phorone) (V). Phorone (V) was detected from the first distillate (bp_5 60—70°C) both in the general procedure a) and b), and was identical with the authentic V (mp 28°C, IR, NMR, vpc retention time). A mixed melting point with the authentic V was undepressed.

The authors wish to thank Dr. I. Iwai of these laboratories for his helpful guidance during the course of this work and Mr. S. Higashida for his technical assistance.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 2310—2312 (1969)

Synthetic Studies of 4-Oxo- and 4-Imino-3,4-dihydro-1,3-oxazoles*[1]

Akiko CHINONE, Shigeru SATO, Toshiyasu MASE and Masaki OHTA

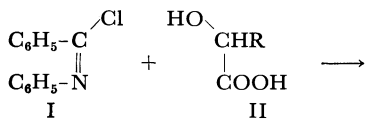
Laboratory of Organic Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received December 14, 1968)

For the purpose of synthesizing new mesoionic compounds of oxazole ring system having oxo group at 4 position, reaction of *N*-phenylbenzimidoyl chloride with glycolic acid was examined. Only an unexpected rearranged product was obtained. The reaction of *N*-phenylbenzimidoyl chloride with glycolonitrile successfully afforded the intermediate, which was treated with hydrogen chloride or with picric acid or with acetyl perchlorate to give 4-imino-3,4-dihydro-1,3-oxazole derivatives. Condensation of *N*-phenylbenzimidoyl chloride with mandelonitrile followed by treatment with acetyl perchlorate gave 4-imino-3,4-dihydro-1,3-oxazole derivative.

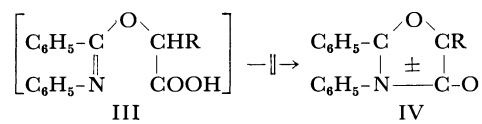
Of the possible mesoionic oxazoles, only 5-oxo-[1,2] and 5-imino-3,5-dihydro-1,3-oxazoles[3] have been reported. Though they are unstable in comparison with mesoionic thiazoles, some reactions were reported.[4] In the present study, we undertook the synthesis of 4-oxo- and 4-imino-3,4-dihydro-1,3-oxazoles because their structural relationship to 4-oxo- and 4-imino-3,4,-dihydro-thiazoles[5] is of considerable interest.

As a possible route towards a synthesis of 4-oxo-3,4-dihydro-1,3-oxazole (IV), we tried the reaction of *N*-phenylbenzimidoyl chloride (I) with glycolic acid (IIa) anticipating the formation of an intermediate **III**. When this reaction was carried out in an ether solution in presence of triethylamine, the reaction product was benzoyloxyacetanilide (Va), its structure being deduced from its elementary analysis and infrared spectrum. Treatment of I with lactic acid (IIb) or mandelic acid (IIc) under the same conditions gave also rearranged products, Vb and Vc respectively.



I II

IIa: R=H
IIb: R=CH_3
IIc: R=C_6H_5

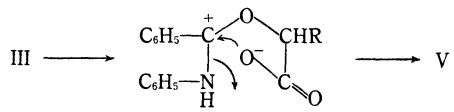


III IV

V

Va: R=H
Vb: R=CH_3
Vc: R=C_6H_5

The reaction of *N*-phenyl-*p*-methoxybenzimidoyl chloride with IIa also afforded the rearranged product. Attempts to obtain III and IV under various conditions were unsuccessful. For the formation of V the C=N bond in I must be cleaved. The same type of rearrangement has been reported for the reaction of thiobenzanilide with bromoacetic acid in boiling benzene.[5] The formation of V may proceed through the intermediate III which is not stable enough to be isolated, presumably due to the enhanced electrophilic character of imidate carbon atom as compared with thio-analog. The rearrangement occurred even in the presence of less equimolar triethylamine. As a possible mechanism, it seems that the reaction is initiated by a nucleophilic attack of carboxyl oxygen toward imidate carbon atom as shown below.



As a first step in the formation of 4-imino-3,4-dihydro-1,3-oxazole (VIII), I was condensed with glycolonitrile (VIa) in the presence of sodium hydride in THF to yield VIIa. Relatively unstable intermediate without purification gave undetectable brownish oil.

Treatment of this intermediate with hydrogen chloride in benzene gave the expected product, 4-imino-2,3-diphenyl-3,4-dihydro-1,3-oxazole hydrochloride (VIIIa). The infrared spectrum was consistent with that expected for VIIIa, but the elementary analysis indicated that the solid contained a small amount of dihydrochloride. The hydrochloride VIIIa, which was unstable and decomposed gradually into an unknown brownish compound, was converted to stable perchlorate (VIIIb) by treatment with silver perchlorate. The perchlorate showed a characteristic band at 308 mμ (ε, 9200) in its ultraviolet spectrum suggestive of its heteroaromatic system. On treating VIIa with picric acid, ring formation took place to produce the picrate (VIIIc) as yellow needles. *N*-Acetyl derivative IXa was obtained by treatment of VIIa with perchloric acid in acetic anhydride. Condensation of I with mandelonitrile followed by addition of acetyl perchlorate, without isolation of the intermediate (VIIb) because of its unstability, gave 5-phenyl derivative of *N*-acetyl perchlorate (IXb). These ring formations seem to proceed as a result of interaction of two polar groups, by a mechanism similar to that of sydnone imine salts.[6] The treatment of IXa and IXb with sodium bicarbonate afforded benzanilide, sodium perchlorate and an unidentified compound, and did not give free bases, probably because it has a high unstability unlike *N*-acylthiazone-imines.[7] The ring formation of VIIa with acetyl chloride, benzenesulfonyl chloride, oxalyl chloride and malonyl chloride was unsuccessful.

The structure of these products were established by infrared spectra, which showed strong bands at 3150—3350 cm^{-1} resulting from N–H stretching vibration, and at 1630—1680 cm^{-1} resulting from oxazole ring. They are very similar to those of 4-thiazone-imines. *N*-Substituted carbonyl group showed absorption band at relatively high frequency, 1690—1705 cm^{-1}, probably due to the effect of positive charge of the ring.

Some 4-imino-3,4-dihydro-1,3-oxazole salts showed absorption maxima in their ultraviolet spectra at about 300 mμ just as 4-thiazone-imine salts.

Experimental

All melting points were determined on a micro hot stage, and are not corrected. Infrared spectra were taken on KBr tablets.

Benzoyloxyacetanilide (Va). To a solution of 0.8 g of glycolic acid (IIa) and 2.0 g of triethylamine in 30 m*l* of dry ether, 2.2 g of *N*-phenylbenzimidoyl chloride (I) was added. The precipitates which separated out gradually were allowed to stand overnight, filtered and washed repeatedly with water. Recrystallization of the solid from benzene gave 2.2 g of white needles; mp 152—153°C. IR: 3295, 1725, 1670 cm^{-1}.

Found: C, 70.33; H, 4.78; N, 5.49%. Calcd for $C_{15}H_{13}NO_3$: C, 70.59; H, 5.13; N, 5.49%.

Benzoyloxymethylacetanilide (Vb). To a solution of 4.3 g of I and 1.8 g of lactic acid in 30 m*l* of dry ether, 6.0 g of triethylamine was added dropwise and the solution was stirred for an hour at room temperature. The precipitates which separated out were collected by filtration, washed with water, recrystallized from benzene to give 4.3 g of white needles; mp 154—155°C. IR: 3260, 1725, 1670 cm^{-1}.

Found: C, 71.15; H, 5.90; N, 5.46%. Calcd for $C_{16}H_{15}NO_3$: C, 71.38; H, 5.61; N, 5.20%.

Benzoyloxyphenylacetanilide (Vc). A solution of 2.3 g of I in 10 m*l* of dry ether was added to a solution of 1.5 g of mandelic acid and 1.2 g of triethylamine in 30 m*l* of dry acetonitrile under cooling with water. The precipitates separated out gradually. After stirring for an hour, the precipitates were filtered off and the filtrate was concentrated under vacuum. Then the crystalline product was collected and washed repeatedly with ether. The product was recrystallized from benzene to give 2.8 g of white needles; mp 170.5—171.5°C. IR: 3220, 1723, 1663 cm^{-1}.

Found: C, 76.24; H, 5.41; N, 4.07%. Calcd for $C_{21}H_{17}NO_3$: C, 76.12; H, 5.17; N, 4.23%.

***p*-Methoxybenzoyloxyacetanilide.** A solution of 0.8 g of IIa and 2.0 g of triethylamine and 2.5 g of *N*-phenyl-*p*-methoxybenzimidoyl chloride was allowed to stand overnight at room temperature. Precipitates which separated out gradually were collected and washed with water repeatedly. The solid was reprecipitated from benzene solution with ligroin to give 1.5 g of white needles; mp 104—105°C. IR: 3280, 1728, 1673 cm^{-1}.

Found: C, 67.05; H, 5.26; N, 5.56%. Calcd for $C_{16}H_{15}NO_4$: C, 67.36; H, 5.30; N, 4.91%.

***o*-Cyanomethyl-*N*-phenylbenzimidate (VIIa).** To a solution of 2.8 g of I and 2.8 g of glycolonitrile (VIa) in 30 m*l* of THF, a suspension of 4.8 g of sodium

6) P. Brookes and J. Walker, *J. Chem. Soc.*, **1957**, 4409.

7) H. Chosho, K. Ichimura and M. Ohta, This Bulletin, **37**, 1670 (1964).

hydride in THF was added dropwise under cooling with an ice-salt bath, resulting in a violent evolution of hydrogen gas. After stirring for an hour, the solid was filtered off and the filtrate was concentrated under vacuum without heating. The resulting oily product was washed a few times with *n*-hexane, which was cooled with dry ice in acetone, in order to crystallize the product. Recrystallization of the product from the minimum amount of *n*-hexane gave 2.2 g of white needles; mp 61—62°C. IR: 1680 cm^{-1}.

Found: C, 76.06; H, 4.95; N, 11.76%. Calcd for $C_{15}H_{12}N_2O$: C, 76.25; H, 5.12; N, 11.86%.

4-Imino-2,3-diphenyl-3,4-dihydro-1,3-oxazole hydrochloride (VIIIa). To a solution of 0.7 g of VIIa in 15 m*l* of benzene, 10 m*l* of benzene containing 0.2 g of gaseous hydrogen chloride was added and an exothermic reaction took place. The precipitates which separated out were collected and recrystallized from chloroform to give 0.27 g of VIIIa; mp 116—122°C. IR: 1680, 1650 cm^{-1}. The elementary analysis of the product was slightly inconsistent with that expected for VIIIa, probably because of a small amount of dihydrochloride.

4-Imino-2,3-diphenyl-3,4-dihydro-1,3-oxazole perchlorate (VIIIb). To a solution of 0.27 g of VIIIa in 15 m*l* of dry acetonitrile, was added dropwise a solution of 0.20 g of silver perchlorate in chloroform-ethanol. The precipitated silver chloride was filtered off and the filtrate was concentrated under vacuum to give a white solid. Reprecipitation from chloroform solution with ether gave 0.16 g of white needles; mp 160—166°C. $\lambda_{max}^{CH_3CN}$ 298 mμ (ε, 13600).

Found: C, 53.50; H, 3.89; N, 8.32%. Calcd for $C_{15}H_{13}N_2O_5Cl$: C, 53.49; H, 3.86; N, 8.32%.

4-Imino-2,3-diphenyl-3,4-dihydro-1,3-oxazole picrate (VIIIc). A benzene solution of VIIa was treated with a solution of picric acid in benzene to yield picrate which was recrystallized from isopropyl alcohol to give yellow needles; mp 108—109°C. IR: 3320, 3150, 1660, 1628 cm^{-1}.

Found: C, 53.86; H, 2.94; N, 15.15%. Calcd for $C_{21}H_{15}N_5O_8$: C, 54.20; H, 3.25; N, 15.05%.

***N*-Acetyl-4-imino-2,3-diphenyl-3,4-dihydro-1,3-oxazole perchlorate (IXa).** To a solution of 1.6 g of VIIa in 40 m*l* of acetic anhydride, 2 g of 70% aqueous perchloric acid was added dropwise with stirring and cooling with ice-salt bath. After 10 min ether was poured into the solution to give white precipitates, which were reprecipitated from chloroform solution with ether to give 1.1 g of white needles; mp 178—178.5°C. IR: 3260, 3215, 1690, 1640 cm^{-1}. $\lambda_{max}^{CH_3CN}$ 308 mμ (ε, 9200), 244 mμ (ε, 9200).

Found: C, 53.23; H, 3.97; N, 7.02%. Calcd for $C_{17}H_{15}N_2O_6Cl$: C, 53.62; H, 3.99; N, 7.40%.

***N*-Acetyl-4-imino-2,3,5-triphenyl-3,4-dihydro-1,3-oxazole Perchlorate (IXb).** To a solution of 5.4 g of I and 3.3 g of mandelonitrile (VIIb) in 20 m*l* of benzene, 5 g of triethylamine was added dropwise. After stirring for 2 hr at room temperature, precipitates which separated out were filtered off and the filtrate was concentrated under vacuum, until no triethylamine was detected. The concentrated solution was diluted with 30 m*l* of acetic anhydride, to which 7 g of 70% aqueous perchloric acid was added under cooling with ice-salt bath. Precipitates, which gradually separated out, were collected and recrystallized from ethanol to give 2.6 g of white needles; mp 228.5—230°C. IR: 3215, 3170, 1705, 1670 cm^{-1}.

Found: C, 60.48; H, 4.54: N, 5.97%. Calcd for $C_{23}H_{19}N_2O_6Cl$: C, 60.73; H, 4.18; N, 6.16%. $\lambda_{max}^{CH_3CN}$ 312 mμ (ε, 17600), 251 mμ (ε, 21900).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 2312—2318 (1969)

Cooxidation of Hydrocarbons in Liquid Phase. VI. Reactivities of Hydrocarbons and Peroxy Radicals

Etsuo NIKI, Yoshio KAMIYA and Nobuto OHTA

Department of Fuel Engineering, The University of Tokyo, Hongo, Tokyo

(Received December 14, 1968)

Cooxidation of all the combinations of two hydrocarbons among styrene, α-methylstyrene, tetralin and cumene was studied at 70°C in the presence of azobisisobutyronitrile as a thermal initiator. The reactivity ratios for each binary mixture were determined by several appropriate methods. The relative reactivities of styrene, α-methylstyrene, tetralin and cumene toward the peroxy radicals were approximately in the ratio 15 : 10 : 5 : 1. It was also concluded that the secondary peroxy radicals were more reactive than the tertiary peroxy radicals and that the polymeric peroxy radicals were more reactive than the normal alkylperoxy radicals.

The cooxidation of the binary mixtures of styrene, α-methylstyrene, tetralin and cumene was studied and the reactivity ratios were determined by several methods in order to obtain an information on the reactivities of the hydrocarbons and of the peroxy radicals toward each other.

Results

The rates of cooxidations of 6 systems are shown in Fig. 1. In all cases, the observed rates of oxygen absorption were corrected for nitrogen evolved by the decomposition of AIBN, oxygen absorbed by the dimethylcyanomethyl radical, and oxygen evolved in the termination step.[1] The reactivity ratios, r, were determined by several methods discussed in a previous paper.[1]

▲: Tetralin (I) - cumene (II)

Styrene (S) and α-Methylstyrene (M). The reactivity ratios were determined from the rates of cooxidations by our rate method[1,2] and the values of 1.6 and 0.71 were obtained for r_S and r_M respectively. The product of the two reactivity ratios is 1.1.

Styrene (S) and Tetralin (T). This system was studied previously.[1] Our rate method gave the values of $r_S=2.7$ and $r_T=0.49$, while the Fineman-Ross method gave the values of $r_S=3.0$ and $r_T=0.45$.[1]

Styrene (S) and Cumene (C). The reactivity ratios were determined by measuring the oxygen uptake and hydroperoxide formed, which was first employed by Mayo and his co-workers.[3] The results are summarized in Table 1. Hydroperoxide was determined by the Wibaut method.[4] The oxidation of styrene gives mostly styrene polyperoxide with small amounts of benzaldehyde and formaldehyde.[5] The Wibaut method[4] gives little titer for the oxidation of styrene,[1] while cumyl hydroperoxide can be determined quantitatively by this method (Table 1). The slightly greater yield of cumyl hydroperoxide than expected in the oxidation of cumene may be ascribed to the oxidation which proceeds after the absorption measurement is completed, while the product is being removed from the reaction vessel for analysis. It was demonstrated that the titrable hydroperoxide was unstable in the oxidizing styrene.[6] In order to minimize this complication, the conversions were kept very low. Thus, the hydroperoxide determined by the Wibaut method was taken as the amount of cumene reacted, and styrene reacted was calculated from the difference between oxygen uptake and hydroperoxide formed. The reactivity ratios were determined by the Fineman-

Ross method:[7]

$$\frac{F}{f}(f-1) = r_S\frac{F^2}{f} - r_C, \qquad (1)$$

where $F=[S]_0/[C]_0$ and $f=\Delta S/\Delta C$. Figure 2 gives the values of 18 and 0.045 for r_S and r_C respectively. These values are reasonably in agreement with the values of $r_S=20$ and $r_C=0.05$ at 60°C obtained by Mayo and his co-workers.[3]

α-Methylstyrene (M) and Tetralin (T). Previously, we obtained the values $r_M=5.5$ and $r_T=0.70$ by our rate method.[2] Since the product of these two reactivity ratios exceeds unity considerably, the reactivity ratios for this binary mixture were determined by two other methods.

The amounts of oxygen uptake and hydroperoxide formation determined by the Wibaut method in the cooxidations of α-methylstyrene and tetralin are shown in Table 2. This method is the same as that employed in the cooxidations of styrene and cumene. The Fineman-Ross plot obtained by the results in Table 2 is shown in Fig. 3, which gives the values of 6.1 and 0.41 for r_M and r_T respectively. The product of the two reactivity ratios is 2.5.

The r_T value was determined separately by the hydroperoxide method which was first employed

7) M. Fineman and S. D. Ross, *J. Polymer Sci.*, **5**, 259 (1950).

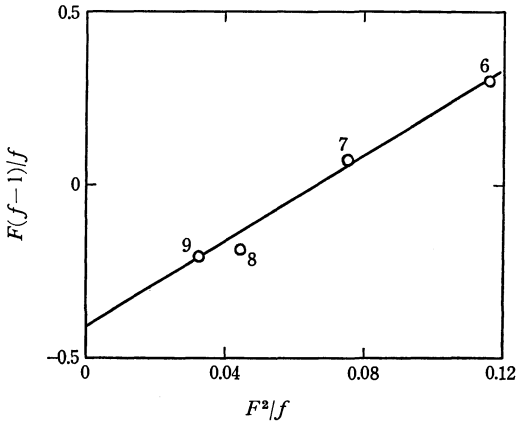

Fig. 3. Fineman-Ross plot for the cooxidation of α-methylstyrene and tetralin.
70°C, oxygen pressure=760 mmHg

by Howard, Schwalm and Ingold.[8] This method was devised on the basis that the peroxy radicals abstract the hydrogen atom from hydroperoxides much faster than they abstract the hydrogen atom from the hydrocarbons or add to the double bond.

When enough tetralyl hydroperoxide is added in the oxidation of α-methylstyrene, the tetralylperoxy radical contributes as a chain carrier, and the rate of oxidation is given by

$$-dO_2/dt = k_{TM}[M]R_i^{1/2}/(2k_{tTT})^{1/2} = k_{TM}[M](ek_i[AIBN]/k_{tTT})^{1/2}, \quad (2)$$

where R_i is the rate of initiation, e the efficiency of the radical production, and k_{TM} and k_{tTT} the rate constants of the following reactions:

$$TO_2\cdot + M \xrightarrow{k_{TM}} TOOM\cdot ,$$

$$TO_2\cdot + TO_2\cdot \xrightarrow{k_{tTT}} \text{tetralone} + \text{tetralol} + O_2 .$$

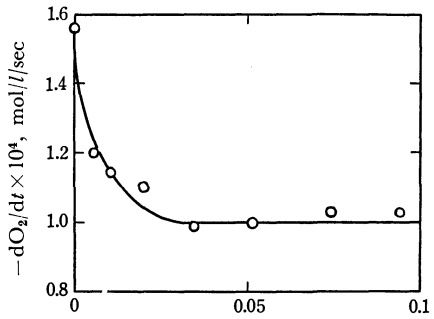

Fig. 4. Oxidation of α-methylstyrene in the presence of tetralin hydroperoxide.
70°C, oxygen pressure=760 mmHg,
AIBN=1.00×10⁻² M

The rates of the oxidation of α-methylstyrene in the presence of tetralyl hydroperoxide are shown in Fig. 4 as a function of the concentration of tetralyl hydroperoxide. The rates of the oxidation of α-methylstyrene decrease with an increase in the concentration of tetralyl hydroperoxide; this is because the rapid termination by the two secondary tetralylperoxy radicals replaces the slower termination by the tertiary α-methylstyrylperoxy radicals. But when the concentration of tetralyl hydroperoxide exceeds 3.5×10^{-2} mol/l, the rates of the oxidation of α-methylstyrene are virtually constant, 1.00×10^{-4} mol/l/sec. The rate constants for the individual step in the oxidation of tetraline were determined by several investigators,[9-11] and the compilation and extrapolation to 70°C of the reported data give the values 30 and 8.0×10^6 l/mol/sec for k_p and k_t respectively. Substitution of the values 1.00×10^{-4} mol/l/sec, 7.70 mol/l, 0.65, 3.96×10^{-5} sec^{-1}, 1.00×10^{-2} mol/l, and 8.0×10^6 l/mol/sec for the rate of oxidation, [M], e, k_t, [AIBN], and k_{tTT}, respectively, into the Eq. (2) gives k_{TM} to be 72. Therefore, the r_T is calculated to be 30/72=0.42.

α-Methylstyrene (M) and Cumene (C). In a previous paper[12] of this series, we have obtained the reactivity ratios for this system as $r_M=9.3$ and $r_C=0.10$ by using Mayo-Lewis method.[13]

2.57	4.80	0.872	1.77	0.535	4.92

The rates of disappearance of α-methylstyrene and cumene were followed by gas-liquid chromatography, and as a result the conversion of the hydrocarbons, especially that of α-methylstyrene, was rather high. In order to avoid the complicated effects of the oxidation products and of the variation of the medium, the r values were determined using the rates of oxidation of both hydrocarbons at the initial stage. The concentrations of the two hydrocarbons were measured periodically and the in logarithm was plotted against time as shown in Fig. 5. The calculated rates of oxidations of α-methylstyrene and cumene are given in Table 3, and the Fineman-Ross plot obtained from these data are shown in Fig. 6. The solid line in Fig. 6 corresponds to $r_M=9.3$ and $r_C=0.10$.

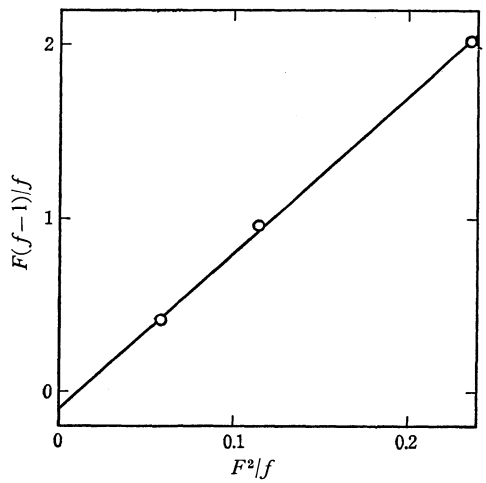

Fig. 6. Fineman-Ross plot for the cooxidation of α-methylstyrene and cumene.
The solid line corresponds to $r_M=9.3$ and $r_C=0.10$.
70°C, oxygen pressure=760 mmHg

Tetralin (T) and Cumene (C). The values 4.2 and 0.19 were obtained for r_T and r_C respectively at 70°C from the rates of cooxidations using our rate method.[14]

Discussion

In the past, it was generally accepted that the peroxy radicals derived from the hydrocarbons had approximately the same reactivities independent of their structures, and the rates of the reactions of peroxy radicals with hydrocarbons were determined solely by the hydrocarbons. If the reactivities of the peroxy radicals are really independent of their nature, the product of the two reactivity ratios is necessarily unity, since, in the cooxidations of the binary mixture of the hydrocarbons A and B,

$$k_{AA} = k_{BA},\ k_{BB} = k_{AB}$$

hence,

$$r_A r_B = (k_{AA}/k_{AB})(k_{BB}/k_{BA}) = (k_{AA}/k_{BA})(k_{BB}/k_{AB}) = 1$$

Alagy *et al.* determined the reactivity ratios for several systems and concluded that the reactivities of the peroxy radicals were dependent on the structure on the basis that the products of the two reactivity ratios deviated from unity.[15] On the contrary, Russell and Willamson[16] concluded that the reactivities of the peroxy radicals are fairly independent of their nature. Recently, this problem has received much attention. Howard and Ingold demonstrated by determining the absolute rate constants for hydrocarbon oxidations that the reactivities of the peroxy radicals are dependent on their structure, and that the primary peroxy radicals are more reactive than the secondary peroxy radicals and in turn the secondary peroxy radicals are more reactive than the tertiary ones.[10,17-19] They attributed the differences in the reactivities of the peroxy radicals to the steric effect. On the other hand, Mayo and his coworkers reported that the relative reactivities of the hydrocarbons toward various peroxy radicals were nearly independent of the alkylperoxy radicals involved.[3]

It is worth pointing out that the fact that the product of two reactivity ratios is unity does not always imply the same reactivities of the various peroxy radicals. Even if the absolute reactivities

19) J. A. Howard and K. U. Ingold, *ibid.*, **46**, 2655, 2661 (1968).

of the peroxy radicals are different, the product of two reactivity ratios can be unity. For example, when the peroxy radical $AO_2\cdot$ is more reactive than the peroxy radical $BO_2\cdot$ by a factor of p toward both hydrocarbons A and B, the product of r_A and r_B is:

$$r_A \times r_B = (k_{AA}/k_{AB})(k_{BB}/k_{BA}) = (k_{AA}/k_{BA})(k_{BB}/k_{AB}) = p/p = 1$$

Another problem is the error involved in the reactivity ratios. It is extremely difficult to obtain accurate r values in the cooxidation of the hydrocarbons. If it is assumed that the reactivity ratios contain 10, 20, 30, and 50% of error, then the product of two r values lies in the range of 0.81—1.2, 0.64—1.4, 0.49—1.7, and 0.25—2.3, respectively. Thus, it would be risky to estimate whether the reactivities of the different peroxy radicals are the same or not from the product of two reactivity ratios.

After all, the reactivities of the peroxy radicals may be evaluated from the absolute propagation rate constants and the reactivity ratios. In Table 4 are summarized the reactivity ratios obtained for the cooxidation of styrene, α-methylstyrene, tetralin and cumene at 70°C.

Table 4. The reactivity ratios at 70°C

Hydrocarbon A	Hydrocarbon B	r_A	r_B	$r_A r_B$
Styrene	α-Methylstyrene	1.6	0.71	1.1
Styrene	Tetralin	2.9	0.47	1.4
Styrene	Cumene	18	0.045	0.81
α-Methylstyrene	Tetralin	5.7	0.51	2.9
α-Methylstyrene	Cumene	9.3	0.10	0.93
Tetralin	Cumene	4.2	0.19	0.80

The calculated rate constants for the reactions of styryl, α-methylstyryl, tetralyl and cumyl peroxy radicals with these four hydrocarbons are shown in Table 5. The absolute rate constants at 70°C for styrene,[20] α-methylstyrene[10,21] tetralin,[9-11] and cumene[11,22-26] were calculated from the compilation of the values in literature. Table 5 indicates that the rate constants for the reactions of hydrocarbons with peroxy radicals are dependent on both of them. The relative reactivities of the hydrocarbons toward the peroxy radicals and *vice versa* calculated from Table 5 are shown in Tables 6 and 7 respectively. Table 6 indicates that the relative reactivities of styrene, α-methylstyrene, tetralin, and cumene are approximately in the ratio 15 : 10 : 5 : 1. On the other hand, Table 7 shows that the secondary peroxy radicals are more reactive than the tertiary peroxy radicals, and that the polymeric peroxy radicals are more reactive than the usual monomeric aralkylperoxy radicals.

The results and discussion given above suggest that the rates of the reactions between hydrocarbons and peroxy radicals depend not only on the hydrocarbons being attacked but also on the attacking peroxy radicals. The reactivities of the hydrocarbons may be determined mostly by the bond dissociation energy of the bond being broken and the degree of the resonance stabilization of the radical newly formed. Probably, both steric and polar effects may be responsible for the differences in the reactivities of the peroxy radicals. Howard and Ingold[10,18] emphasized the steric effects to explain the differences in the reactivities of the peroxy radicals. Indeed the relative reactivities of cumene and tetralin toward various free radicals and atoms suggest the considerable steric effects of the attacking species,[27] but it is not clear whether

Table 5. Rate constants for the reactions of peroxy radicals with hydrocarbons at 70°C

Tetralin	11	1.3	4.8	1
Cumene	10	4.3	5.9	1

the volume of the hydrocarbon portion of the peroxy radicals is so important in determining the reactivities of the peroxy radicals. The thermodynamic data also throw doubt upon the importance of the steric effects of the peroxy radicals. Most alkyl-alkyloxy bond strengths are about 78 kcal.[28] But the bond strength of the *t*-butyl - *t*-butoxy bond is 69 kcal.[28] The 9 kcal lowering of the C–O bond dissociation energy observed in the *t*-butyl ether is attributed to the repulsion of closely bound bulky *t*-butyl groups.[28] On the other hand, the O–O bond dissociation energies of dimethyl, diethyl, dipropyl, and di-*t*-butyl peroxides are approximately the same.[28] These facts suggest that the volume of R in ROOR does not give a significant steric effect in contrast with ROR. Howard and Ingold related the differences in the reactivities of the primary, secondary and tetrtiary peroxy radicals to the chain termination reactions of these peroxy radicals.[10] However, the rates of chain terminating bimolecular interactions of the peroxy radicals may be dependent more on the mechanism of the reaction and statistical factors, *i. e.*, absence or presence of α-hydrogen atoms and their number than on the steric effects.

If the steric effects of the attacking peroxy radicals are really important, the steric structure of the hydrocarbons being attacked may also have at least large effects. In this case, the product of two reactivity ratios is expected to deviate from unity. For example, if cumylperoxy radical is less reactive than tetralylperoxy radical due to the steric factors, then the steric effects may be more significant when the peroxy radicals abstract a hydrogen atom from cumene than from tetralin. That is

$$k_{TT}/k_{CT} < k_{TC}/k_{CC}\,.$$

Hence

$$r_T r_C = (k_{TT}/k_{TC})(k_{CC}/k_{CT}) < 1\,.$$

Thus, if the steric factors affect the reactivities of the hydrocarbons and the peroxy radicals, the product of the two reactivity ratios deviates from unity.

Experimental

Styrene and α-methylstyrene were washed with dilute alkali and water, dried, and distilled under reduced pressure of nitrogen. Tetralin and cumene were washed successively with sulfuric acid, water, alkali and water, dried, and then distilled under reduced pressure of nitrogen. All these four hydrocarbons were passed down the activated alumina column before use. Tetralyl hydroperoxide was prepared by the air oxidation of tetralin at 65°C for 50 hr in the presence of AIBN followed by the repeated recrystallization from *n*-hexane. Commercial AIBN was recrystallized from methanol.

The rate of cooxidation was measured by following the oxygen uptake periodically in a constant pressure closed system. The formation of hydroperoxide was measured by the iodometric titration employed by Wibaut *et al.*[4] In the cooxidation of α-methylstyrene and cumene, the disappearance of the two hydrocarbons was determined by the gas - liquid chromatography using Apiezon-L column at 170°C. The calculation of the data was performed at the Data Processing Center of the University of Tokyo.

Coumarins. VI. The Acid-catalyzed Reaction of Phenols with β-Aminocrotononitrile[1]

Kikumasa SATO and Masao ŌHASHI

Department of Applied Chemistry, Faculty of Engineering, Yokohama National University, Minami-ku, Yokohama

and Takeshi AMAKASU and Katsuhiko TAKEDA

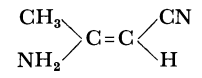
Chemical Laboratory, Seimi Chemical Co., Ltd., Chigasaki, Chigasaki-shi, Kanagawa

(Received December 19, 1968)

A new synthesis of 4-methylcoumarins has been developed by means of the acid-catalyzed condensation of phenols with β-aminocrotononitrile. Such monohydric phenols as phenol or cresols reacted with β-aminocrotononitrile in polyphosphoric acid (PPA) to give 4-methylcoumarins in poor yields, along with a good yield of 6-amino-3-cyano-2,4-lutidine (III). In contrast, 7-substituted-4-methylcoumarins were obtained in 23—44% yields from resorcinol and its monomethyl ether. On the other hand, when β-aminocrotononitrile was heated in PPA, the lutidine (III) was obtained in a high yield. Its precursor, 4-amino-1,3-dicyano-2-methylpenta-1,3-diene (XI), was isolated under mild conditions. These results suggest that β-aminocrotononitrile may undergo the preferential self-dimerization to the lutidine (III) rather than the intermolecular condensation with phenols.

The preceding paper in this series[2] described the direct synthesis of several coumarins by the acid-catalyzed reaction of phenols with β-oxonitriles. These studies have now been extended to β-aminocrotononitrile, *i. e.*, diacetonitrile. Although the hydrogen chloride-catalyzed reaction of polyhydric phenols such as resorcinol with β-aminocinnamonitriles has previously been shown[3] to give the corresponding 4-phenylcoumarins, we could find no report concerning the acid-catalyzed reaction of phenols with such aliphatic β-amino-α,β-unsaturated nitriles as β-aminocrotononitrile.

The sodium-induced dimerization of acetonitrile has been shown[4-6] to give β-amino-*cis*-crotononitrile (Ia) and mixture (Ic) of Ia and Ib. The *cis*-isomer (Ia) may be readily isomerized, in part, to the *trans*-configuration (Ib) by placing it in contact with a protic solvent such as ethanol.[5,6] The conversion is subject to an acid-base catalyst.[6]



Ia

III

When equimolar amounts of resorcinol and Ic were treated in a PPA solution, 4-methylumbelliferone (IIe) (44%) was obtained along with 6-amino-3-cyano-2,4-lutidine (III). Resorcinol monomethyl ether behaved analogously when treated with Ic under the same conditions and gave the corresponding coumarin, IId, as well as III.

In contrast, a poor yield of 4-methylcoumarins (IIa—c) was isolated from the reaction of such less reactive phenols as cresols with Ic under similar conditions. The structure of the coumarins II follows from the infrared spectra, which showed

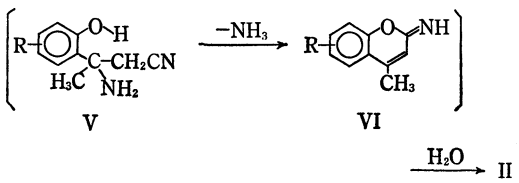
lactone C=O bands at 1680—1730 cm^{-1}, and the ultraviolet data, which make it possible to distinguish[7] clearly between coumarins II and isomeric chromones IV. These results, summarized in Table 1, indicate that the reactions proceed through the addition of phenols to Ic, as is shown below:



V VI II

The resulting addition product (*i.e.*, V) is then converted, by the intramolecular cyclization, to an iminocoumarin, VI. The intermediate VI then readily undergoes acid hydrolysis to II. Neither V nor VI could be isolated in any case, whereas the acid-promoted condensation of phenols with benzoylacetonitrile has been demonstrated[2] to furnish 4-phenyl-2-iminocoumarins, VII, corresponding to VI, while 3-cyano-4-methyliminocoumarin (VIII)[8] and 3-substituted-2-iminocoumarins, IXa—d,[9] may be obtained by the base-catalyzed condensation of 2-hydroxyacetophenone as malononitrile. This is probably to be attributed and salicylaldehyde respectively, with such cyano compounds to the difference in resonance stability between the intermediate VI and VII, VIII, or IX. It is interesting to note that no para condensation product, X, could be isolated from the reaction of phenol, while the acid-catalyzed reaction of phenol

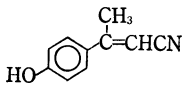
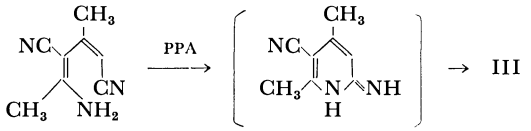
with benzoylacetonitrile may furnish β-(*p*-hydroxyphenyl)cinnamonitrile as the sole product.[2]



X

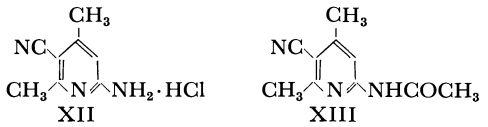
Although the dimerization of β-aminocrotononitrile (Ic) under various conditions has previously been reported to give the lutidine III[4,10] *via* 4-amino-1,3-dicyano-2-methylpenta-1,3-diene (XI),[6,11] no report could be found concerning the use of PPA for the condensation.

The nitrogenous product, III, described above, was obtained together with 4-methylcoumarins, II, when phenols were treated with Ic in the presence of PPA. The analytical data agreed with the formula $C_8H_9N_3$, which is itself in accord with the structure of the lutidine derivative, III, and the precursor, XI. The physical properties, along

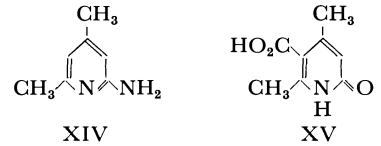


XI

with the infrared and ultraviolet spectra, suggest that the product is assignable to the cyclic compound III. When treated with 12 N hydrochloric acid, the product, III, was converted to the salt, XII, while treatment with acetic anhydride gave the N-acetyl-derivative, XIII. Moreover, this lutidine, III, when refluxed with 75% sulfuric acid, yielded 6-amino-2,4-lutidine (XIV), while when it was refluxed with 48% hydrobromic acid, it afforded



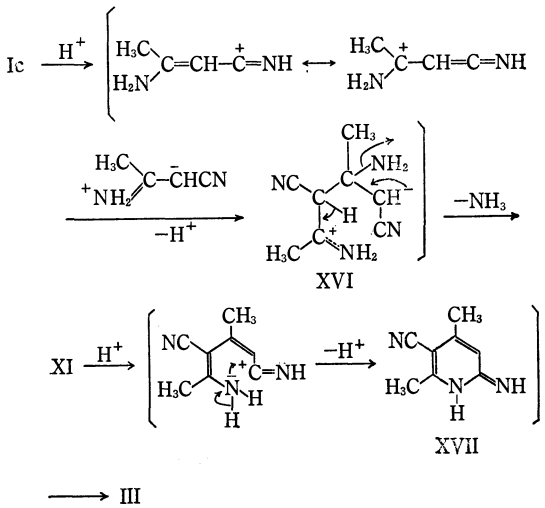
XII XIII



XIV XV

2,4-lutid-6-on-3-carboxylic acid (XV). These results confirm the structure III for 6-amino-3-cyano-2,4-lutidine. On the other hand, we have found a convenient method for preparing III by means of the PPA-catalyzed self-condensation of Ic. When the nitrile Ic was heated in PPA at 160—165°C for 1 hr, the lutidine, III, was obtained in an 81% yield. In contrast, under mild conditions Ic gave a dienaminonitrile, XI (13%), as well as III. The dienaminonitrile, XI, readily underwent intramolecular cyclization, through isomerization, to III when heated in PPA or an alkaline solution. The results, along with the infrared spectra and the ultraviolet spectra, confirm the structures of III and XI for the lutidine and pentadiene derivatives respectively.

The following discussion is presented to account



XVI XVII

for the formation of XI and III from β-aminocrotononitrile (Ic). The protonation of Ic, followed by interaction between the electrophilic β- and nucleophilic α-centers of Ic, provides, *via* deprotonation, the unstable betaine XVI, which then undergoes deamination to XI. Furthermore, compound XI is converted to III through intramolecular cyclic addition to XVII and subsequent isomerization. The data are consistent with this view.

Accordingly, the usual poor yield of 4-methylcoumarins II, is due to such a predominant dimerization of Ic as is shown above.

Experimental[12]

Materials. β-Aminocrotononitrile (Ic), mp 52—53°C, was prepared by the dimerization of acetonitrile

Infrared and ultraviolet spectra were recorded, respectively, on a Hitachi Model EPI-S2 and Hitachi Model EPS-3T spectrophotometers. NMR spectra were taken in d_6-dimethylsulfoxide on a JEOL Model C-60H instrument with tetramethylsilane as an internal standard.

with sodium metal.[4b] The monoetherification of resorcinol with dimethylsulfate was carried out by means of the procedure of Kinugawa and his co-workers.[13] 3-Cyano-2,4-lutid-6-one was obtained by the treatment of Ic with boiling water.[4a]

PPA-Catalyzed Reaction of Phenols with Ic; 4-Methylcoumarins. *General Procedure.* Finely-powdered Ic (4.1 g, 0.05 mol) was added slowly to a mixture of the phenol (0.05 mol) and 41 g of PPA at 90°C, after which stirring was vigorously continued at 90—100°C. Then the mixture was gradually heated on an oil bath and kept under the conditions shown in Table 1. Thereafter the resulting mixture was chilled, poured into water containing crushed ice (200—300 m*l*), and extracted with ether. After the extract had been washed with water and dried over anhydrous magnesium sulfate, the removal of the solvent, followed by recrystallization from aqueous ethanol, gave the pure 4-methylcoumarin (II). The results with individual compounds are presented in Table 1.

The aqueous layer was basified with 10% sodium hydroxide and then filtered to afford orange crystals. Recrystallization from 95% ethanol furnished 6-amino-3-cyano-2,4-lutidine (III) as colorless needles; mp 226—227°C (lit[6] 227—228°C); sublimed at *ca.* 160°C; ν_{max}^{KBr} 3400, 3330 (N–H), 3130, 2200 (C≡N), 1665 (C=N), 1605, 1492 (C=C), 1413, 1380 (CH_3), 1175, and 840 cm^{-1}; NMR: τ 7.76 (2-CH_3), 7.60 (4-CH_3), 6.50 (NH_2), and 3.75 (nuclear proton).

Found: C, 65.39; H, 6.43%. Calcd for $C_8H_9N_3$: C, 65.31; H, 6.12%.

4-Amino-1,3-dicyano-2-methylpenta-1,3-diene (XI). *a)* Compound Ic (1.0 g) was added to 10 g of PPA at room temperature. A vigorously exothermic reaction occurred. The mixture was allowed to stand at 30—50°C for 1.5 hr, during which time the solution was sometimes stirred by means of a glass rod. The neutralization of the resulting mixture with an alkaline solution, followed by filtration, gave quantitatively a mixture of crude-orange products, III and XI. Fractional crystallization from water afforded III, mp 226—227°C. XI (0.12 g, 13%) was obtained from the mother liquor; mp 167—168°C (lit[6] mp 166—166.5°C) (from water). ν_{max}^{KBr}: 3380, 3320, 3200 (NH_2), 2200 (C≡N), 1655 (C=N), 1600, 1545 (C=C), 1250 cm^{-1}; λ_{max}^{EtOH} mμ (ε): 220 (6920), 256 (4530), 327 (9920); NMR: τ 7.83 (CH_3, 6H), 6.57 (NH_2, 2H), and 4.57 (olefinic proton, 1H).

Found: C, 65.51; H, 6.44%. Calcd for $C_8H_9N_3$: C, 65.31; H, 6.12%.

b) Acetyl chloride (5.0 g) was stirred, drop by drop, into a solution of Ic (2.5 g) in absolute ether (30 m*l*) over a period of 10 min and then kept for 30 min at room temperature. Thereafter the yellow mass which was deposited was filtered to afford the adduct, which was then washed with ether. The treatment of the adduct with water (7 m*l*), followed by filtration, gave the crude XI; this product was recrystallized from water to provide the pure XI (0.7 g, 31%) as colorless needles, mp 167—168°C. The infrared spectrum was identified with that of XI presented above.

6-Amino-3-cyano-2,4-lutidine (III). *a) From Ic.* The nitrile Ic (2.1 g) was added slowly to 21 g of PPA at 90—100°C over a period of 10 min; the mixture was then gradually heated and stirred on an oil bath at 160—165°C for 1 hr. After the resulting mixture had cooled to about 90°C, it was poured into an ice-water slurry (80 g), and neutralized with 10% sodium hydroxide; then the mixture was allowed to stand for a long time. Filtration gave a yellow crystal mass, which was recrystallized from aqueous ethanol to provide the pure III (1.5 g, 81%) as colorless needles, mp 226—227°C; λ_{max}^{EtOH} 272 mμ (ε=7200). A mixed-melting-point determination with an authentic sample such as that already prepared (mp 226—227°C) showed no depression.

b) From XI. A mixture of XI (140 mg) and PPA (1.4 g) was heated on an oil bath at 160°C for half an hour. A treatment of the resulting mixture similar to that shown above gave III (80 mg, mp 226—227°C).

c) The Base-catalyzed Cyclization of XI.[6] A mixture of XI (100 mg) and 5% potassium hydroxide (10 m*l*) was stirred at 100°C for 3 hr chilled to room temperature, and allowed to stand for some time. Filtration, followed by recrystallization from ethanol, afforded the pure III (28 mg); mp 226—227°C.

6-Amino-3-cyano-2,4-lutidine Hydrochloride (XII). A mixture of III (130 mg) and 12 N hydrochloric acid (5 m*l*) was heated at 100—105°C for 2.5 hr. The removal of the hydrochloric acid furnished the crude salt XII (160 mg), which was then recrystallized from ethanol to give the pure product as colorless needles; mp 248—249°C; ν_{max}^{KBr}: 3300 (N-H), 2650—2750 ($-\overset{+}{N}H_3\overset{-}{Cl}$) cm^{-1}.

Found: C, 52.04; H, 5.74%. Calcd for $C_8H_{10}ClN$: C, 52.32; H, 5.45%.

6-Acetylamino-3-cyano-2,4-lutidine (XIII). A solution of III (140 mg) in acetic anhydride was warmed at 80°C for 1 hr and then chilled. After the solution had stood in an ice-box for 1 day, filtration and subsequent recrystallization from ethanol provided the product, XIII, as colorless needles; mp 255—256°C (lit[10] mp 250°C); ν_{max}^{KBr}: 3230 (N–H), 2230 (C≡N), 1680 (C=O), 1580, 1530 (C=C) cm^{-1}.

Found: C, 63.22; H, 6.11; N, 21.97%. Calcd for $C_{10}H_{11}N_3O$: C, 63.47; H, 5.86; N, 22.21%.

6-Amino-2,4-lutidine (XIV). A mixture of III (1.0 g) and 75% sulfuric acid (10 g) was heated at 150—160°C for 3 hr. The cooled mixture was neutralized with dilute sodium hydroxide and extracted with ether (30 m*l*). After the extract had been washed with water and dried over anhydrous magnesium sulfate, the solvent was removed; recrystallization from ethanol then gave colorless plates (0.6 g, 72%); mp 66—67°C (lit[14] 65—67°C); ν_{max}^{KBr}: 3450, 3350 (NH_2), 3130, 1615 (C=C), 1570, 1450, 1390, 1380 (CH_3), 1235, 820, and 810 cm^{-1}.

2,4-Lutid-6-on-3-carboxylic Acid (XV). A solution of III (1.0 g) in 48% hydrobromic acid (10 m*l*) was heated at 120—130°C for 3 hr. The removal of the hydrobromic acid gave the crude product; this was recrystallized from ethanol to give pure XV (0.62 g, 55%) as colorless needles; mp 271—272°C (dec); ν_{max}^{KBr}: 3400 (w. OH), 3000, 2800, 1670, 1640—1620, 1460, 1420, 1385 (CH_3), 1350, 1240, 955, 905, 825, and 710 cm^{-1}.

Found: C, 57.25; H, 5.71; N, 8.12%. Calcd for

14) B. Rudner, U. S. Pat. 2892841 (1959).

$C_8H_9NO_3$: C, 57.48; H, 5.43; N, 8.38%.

3-Cyano-2,4-lutid-6-one. This compound was prepared from III according to the procedure of Bullock and Gregory.[6] The treatment of III with sodium nitrite in dilute hydrochloric acid gave the product; mp>300°C (lit mp 293°C[4]; mp 305—307°C[6]). A mixed-melting-point determination with an authentic sample from III[4] (mp>300°C) indicated no depression. ν_{max}^{KBr}: 3400 (w. OH), 1660 (C=O), 1615 (C=C), 1410, 1370 (CH_3), 870, and 720 cm^{-1}.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 2323—2326 (1969)

Photochemical Reactions of Some Thioparabanates

Teijiro YONEZAWA, Masakatsu MATSUMOTO, Yoichi MATSUMURA and Hiroshi KATO

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Kyoto

(Received December 23, 1968)

1,3-Disubstituted thioparabanates (I) were reduced with ethanol under the action of light tc yield 2-mercaptoimidazolidine-4,5-diones (II) with or without 2-(1-hydroxyethyl)-2-mercaptoimidazolidine-4,5-dione (III). It seems that these reactions may be initiated by the n–π^* transition of the lone pair in the 2-thiocarbonyl group. When dimethylthioparabanate (Ic) was irradiated with a high-pressure mercury arc in a chloroform solution of amylene, a photocycloaddition product, a trimethylene sulfide (IVa), was obtained.

Recently several investigations[1-3] into the photochemical reduction of thiobenzophenone in alcoholic solvents and the photocycloaddition of the same compound with such olefins as 1-butene and 1,3-cyclooctadiene have been made. Its photochemical behavior has been found to be considerably different from that of benzophenone; in the photochemical reduction reaction, the former gave benzhydryl mercaptan, dibenzhydryl disulfide, and a tetrasulfide as reduction products,[1] whereas dibenzopinacol was produced from the latter.[2] In the photocycloaddition reaction thiobenzophenone with olefins gave 1:1 adducts and 2:1 adducts, or olefins formed by the decomposition of these adducts,[3] while it is well known that oxetanes are produced from many carbonyl compounds.

However, the photochemical reactivities of the ureid carbonyl group and the thioureid group have scarcely been studied at all. A purpose of the present work is to compare the photochemical reactions of thioparabanates containing a thioureid group with those of thiobenzophenone and benzophenone.

Results

Electronic Spectra. All the thioparabanates (I) are yellow. The ultraviolet and visible spectra of these compounds are shown in Table 1, together with those of thioparabanic acid, parabanic acid, and tetramethylthiourea. For all the derivatives of thioparabanic acid (I), the electronic spectra in ethanol showed an n–π^* absorption band at 400—440 mμ and a π–π^* absorption band at about 300 mμ. The former is probably due to an n–π^* transition which is mainly localized on the thiocarbonyl group in thioparabanates (I); parabanic acid has an n–π^* absorption band due to the carbonyl group of the oxalyl group at 314 mμ, and thioparabanates (I) are expected to have an n–π^* absorption band of the oxalyl group in the same region. The n–π^* absorption band of the thiocarbonyl group in tetramethylthiourea is at 324 mμ[4] and the imidazolidinetrione molecule is nearly planar,[5] so if the thioparabanic acid molecule has a similar structure, the π orbitals of 2-thiocarbonyl group may overlap with the lone-pair orbitals of N atoms and also with the π orbitals of the oxalyl group. Consequently, the n–π^* absorption band of the thiocarbonyl group is thought to shift longer wavelength region than that of tetramethylthiourea. The results of the ASMO SCF calculation[6] (zero differential approximation) indicate that the singlet-singlet transitions for thioparabanic acid are as follows; the $n_{C=S}$–π^* transition at 341 mμ,

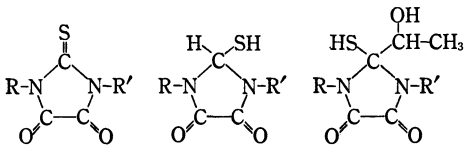
the lowest π-π* transition at 286 mμ, and a very weak σ-π* absorption at 436 mμ (though this third transition has never been detected).

Photoreduction. 1,3-Diphenylthioparabanate (Ia) in an ethanol solution was irradiated under a nitrogen atmosphere with a 200-W high-pressure mercury arc. The yellow color of the solution gradually faded, and the reduction product, 1,3-diphenyl-2-mercapto-imidazolidine-1,5-dione (IIa) was formed in a quantitative yield. As in the case of diphenylthioprarabanate, the irradiation of most 1,3-disubstituted thioparabanates led to the corresponding mercaptans (II). The melting points and NMR parameters of these reduction products

are shown in Table 2. In Table 2, when the substituent group is a methyl or an ethyl group, the reduction product (IIc or IId) could not be obtained in a pure form. The mercaptan (IIc) and (IId) were very unstable and were oxidized by air to form the corresponding thioparabanate.

When the substrate had one or two active hydrogen atoms bonded to the nitrogen, the photochemical reactions of these compounds gave complex products. In the case of thioparabanic acid, thiourea, carbon monoxide, and trace of formaldehyde were obtained, while in the case of monoesters, tarry products were obtained. In these photoreductions, active protons bonded to the nitrogen atom may labilize the reduction form (II) of thioparabanate containing an active mercapto proton.*1

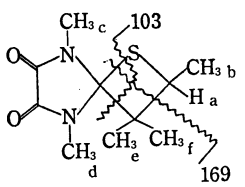
In the reduction of diethylthioparabanate, the mercaptan (IId) was obtained, plus 2-(1-hydroxyethyl)-1,3-diethyl-2-mercapto-imidazolidine-4,5-dione (III) as a by-product. The mercaptan (III) can reasonably be assumed to be produced by a combination of the thioketyl radical (A) and the α-hydroxyethyl radical (B). Moreover, the thioketyl radical (A) may be produced from the excited molecule of I resulting from the n–π^* transition of the thiocarbonyl group, but not from a π–π^* transition. Thus, the mechanism of the photochemical reduction of thioparabanates (I) may be considered to be as is shown in Scheme 1.



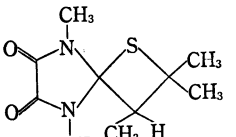
(I) (II) (III)

In the photochemical reduction in ethanol, thioparabanates seem to behave in a considerably different fashion from thiobenzophenone; in the case of thiobenzophenone, it is significant that the benzhydryl-thiyl radical $(C_6H_5)_2CHS\cdot$ is formed through the abstraction of the hydrogen atom from the solvent,[2] while in the case of thioparabanates the ketyl radical seems to be formed through the reaction.

Photocycloaddition. The photochemical addition reaction of dimethylthioparabanate (Ic) with amylene was attemtped in chloroform with a 200-W high-pressure mercury arc under a nitrogen atmosphere. A 1 : 1 addition product (IV) of dimethylthioparabanate and amylene was obtained as colorless crystals melting at 136.0—137.0°C. The mass spectrum of the adduct (IV) gave fragment ions at m/e 169.098 ($^{12}C_8{}^1H_{13}{}^{14}N_2{}^{16}O_2$ requires 169.0982) and m/e 103.058 ($^{12}C_5{}^1H_{11}{}^{32}S$ requires 103.0576). The NMR spectrum showed a quartet (a-methyne proton, 1H, J=6 Hz) at τ=6.54, a doublet (b-methyl protons, 3H, J=6 Hz) at τ=8.71, and four singlets, due to c-, d-, e-, and f-methyl protons, at τ=6.63, 6.78, 8.70, and 8.95. From these results, the adduct (IV) was identified as a trimethylenesulfide (IVa). The fragmentation patterns in the mass spectrum exclude the isomer (IVb) as a product since the fragment, C_3H_6S, coming from the C–S and C–C bond fission could not be detected.



(IVa)



(IVb)

In the cases of the other thioparabanates, no photocycloaddition reaction occurred.

Experimental

Materials. The thioparabanates (I) were prepared by the treatment of a ethylene dichloride solution of the corresponding thiourea with oxalyl chloride.[7] The thiourea were obtained from the reaction of the corresponding isothiocyanate and amine. The thioparabanates were purified by recrystallization from ethanol.

Amylene was prepared by treating t-amyl alcohol with concentrated H_2SO_4. This was purified by fractional distillation; bp 37.0—38.5°C.

Spectra. The visible and ultraviolet spectra were measured in an ethanol solution at 25°C using a Shimadzu UV50M spectrophotometer.

Irradiation of Diphenylthioparabanate (Ia). A solution of 7.0 g (0.025 mol) of the ester (Ia) in 500 m*l* of absolute ethanol was purged with nitrogen for 1 hr and then irradiated under nitrogen with a 200-W high-pressure mercury arc. The yellow solution of Ia completely faded within 15 hr. From the reaction mixture, ethanol was evaporated *in vacuo;* then the white residue was recrystallized from benzene, giving 1,3-diphenyl-2-mercapto-imidazolidine-4,5-dione (IIa) as silky crystals melting at 200.0°C; yield, 98%. The infrared spectrum in KBr showed the absorption of the oxalyl group at 1745 cm^{-1}. The NMR spectrum in hexadeuterio-dimethyl sulfoxide (d_6-DMSO) showed one proton at τ=2.51 as a sharp doublet (J=9.0 Hz), one proton at τ=4.28 (a sharp doublet, J=9.0 Hz), and a complex absorption (10H) centered at τ=2.75. Upon the addition of D_2O, the doublet at τ=2.51 disappeared and the doublet at τ=4.28 turned into a singlet at τ=4.28.

Found: C, 63.38; H, 4.26; N, 9.86; S, 11.26%. Calcd for $C_{15}H_{12}O_2N_2S$: C, 63.60; H, 4.04; N, 9.79;

*1 Most α-aminomercaptans, –NHC(SH)–, like these analogs, *gem*-diols and α-hydroxymercaptans, are unstable and have never been isolated.

7) T. Yonezawa, M. Matsumoto, S. Tanimoto and H. Kitano, *Nippon Kagaku Zasshi (J. Chem. Soc. Japan, Pure Chem. Sect.)*, **89**, 784 (1968).

S, 11.01%.

Irradiation of Benzylphenylthioparabanate (Ib). A solution of 7.4 g (0.025 mol) of the ester (Ib) in absolute ethanol (500 m*l*) was irradiated under a nitrogen atmosphere for 15 hr. In this case the solution was not faded. After irradiation the solvent was evaporated from the reaction mixture *in vacuo*. The oily residue was chromatographed on alumina in benzene, thus giving 1-benzyl-3-phenyl-2-mercapto-imidazolidine-4,5-dione (IIb) (5.9 g), mp 173.0°C after crystallization. The NMR spectrum showed complex absorption due to two phenyl groups centered at τ=2.61 (11H), containing a signal of the mercapto proton, a sharp doublet at τ=4.28 (1 H, J=9.0 Hz), and a singlet at τ=6.82 (2H).

Found: C, 65.68; H, 4.59: N, 9.11%. Calcd for $C_{17}H_{14}O_2N_2S$: C, 65.80; H, 4.55; N, 9.03%.

Irradiation of Dimethylthioparabanate (Ic). A 0.05 mol/*l* solution of the ester (Ic) in ethanol (500 m*l*) was irradiated under a nitrogen atmosphere for 2 hr. Then the solution was concentrated under nitrogen at reduced pressure. The almost colorless oily residue was used for the measurement of its NMR spectrum. In this case the expected mercaptan (IIc) was very unstable and was easily oxidized by air to form the starting materials. The mercaptan (IIc) was characterized only by its spectroscopic properties, the NMR spectrum of the oil described previously showed a mercapto proton (a sharp doublet, J=9.0 Hz) at τ=2.82 and a 2-methyne proton (a sharp doublet, J=9.0 Hz) at τ=4.89.

Irradiation of Diethylthioparabanate (Id). The ester (Id) was treated by the similar manner to that employed in the case of dimethylthioparabanate (Ic). The NMR spectrum of the crude mercaptan (IId) showed a mercapto proton as a sharp doublet (J=9.0 Hz) at τ=2.93 and a 2-methyne proton as a sharp doublet (J=9.0 Hz) at τ=4.89. The crude reaction products was chromatographed on alumina in chloroform, and when the resultant pale yellow oil was allowed to stand for two weeks, colorless needles separated out, giving 2-(1-hydroxyethyl)-1,3-diethyl-2-mercapto-imidazolidine-4,5-dione (III), mp 134.0—135.0°C, by crystallization from cyclohexane. The NMR spectrum in d_6-DMSO showed a singlet (mercapto proton, 1H) at τ=3.02, a doublet (hydroxy proton, 1H, J=4.5 Hz) at τ=4.87, a complex absorption composed of a multiplet (methyne proton, 1H) centered at τ=6.35 and a quartet (two methylene protons, 4H, J=6.3 Hz) at τ=6.38, and a complex absorption composed of two triplets (methyl protons of two ethyl groups, 6H, J=6.3 Hz) at τ=8.75 and 8.91 and a doublet (methyl protons of hydroxyethyl group, 3H, J=6.3 Hz) at τ=8.85. These assignment were confirmed by spin-decoupling experiments.

Found: C, 46.39; H, 6.99; N, 12.25%. Cacld for $C_9H_{16}O_3N_2S$: C, 46.54; H, 6.94; N, 12.06%.

Irradiation of Thioparabanic Acid. A 0.05 mol/*l* solution of thioparabanic acid in ethanol was irradiated with a 200-W high-pressure mercury arc under a nitrogen atmosphere for 10 hr. During irradiation the evolution of carbon monooxide and hydrogen sulfide was observed. A trace of formaldehyde was also detected in the reaction mixture by Denigès' method. The evaporation of ethanol from the solution gave crude thiourea in the yield of 73%.

Irradiation of Some Monoesters of Thioparabanic Acid. The photochemical reduction reactions were attempted for phenylthioparabanate and benzylthioparabanate. In these cases the formation of acetaldehyde was recognized and no corresponding mercaptan (II) was obtained, only a tarry product.

Irradiation of Dimethylthioparabanate (Ic) with Amylene in Chloroform. A solution of dimethylthioparabanate (Ic) (5.0 g, 0.032 mol), and amylene (40.0 g, 0.57 mol) in chloroform (25 m*l*) was irradiated with a 200-W high-pressure mercury arc under a nitrogen atmosphere for 20 hr. After irradiation, the unreacted amylene and solvent were distilled off from the reaction mixture. Then an oily residue was dissolved in 20 m*l* of chloroform and chromatographed on alumina (150 g) in 1:1 chloroform and petroleum ether. This gave, successively, colorless needles (IV) (210 mg), colorless leaflects (V) (30 mg), and dimethylparabanate (200 mg) as a colorless leaflets which showed a mp of 152.0°C, after crystallization from cyclohexane (Biltz and Topp[8] give mp 154.0°C). The recrystallization of IV from cyclohexane yielded the trimethylenesulfide (IVa), mp 136.0—137.0°C. The NMR spectrum in deuteriochloroform showed a complex absorption comprised of a quartet (a-methyne proton, 1H, J=6.0 Hz) at τ=6.54, two singlets (c- and d-methyl protons, 6H) at τ=6.63 and τ=6.78, a doublet (b-methyl protons, 3H, J=6.0 Hz) at τ=8.71, and two singlets (e- and f-methyl protons, 6H) at τ=8.70 and τ=8.95. These assignments were confirmed by spin-decoupling experiments. The infrared spectrum in chloroform showed $\nu_{C=O}$ at 1740 cm^{-1}. The mass spectrum exhibited fragment ions at *m/e* 103.058 ($^{12}C_5{}^1H_{11}{}^{32}S$ requires 103.0576) and *m/e* 169.098 ($^{12}C_8{}^1H_{13}{}^{14}N_2{}^{16}O_2$ requires 169.0982).

Found: C, 52.45; H, 6.92; N, 12.20%. Calcd for $C_{10}H_{16}O_2N_2S$: C, 52.55; H, 7.00; N, 12.25%.

The identification of V is not yet complete, but we presume, from its NMR and mass spectra, and from the results of elemental analysis, that V is a 2 : 2 adduct of dimethylthioparabanate (Ic) and amylene.

Synthetic Studies of the Flavone Derivatives. XII.*1 The Synthesis of 8,3'-Dimethoxy-5,7,4'-trihydroxyflavone

Kenji FUKUI and Mitsuru NAKAYAMA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashi Sendamachi, Hiroshima

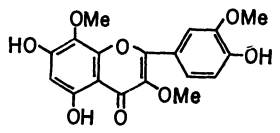
and Tokunaru HORIE

Department of Applied Chemistry, Faculty of Engineering, University of Tokushima, Tokushima

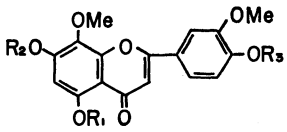
(Received December 28, 1968)

The partial benzylation of 3-methoxy-2,4,6-trihydroxyacetophenone gave a mixture of 2,4-dibenzyloxy-6-hydroxy- and 4,6-dibenzyloxy-2-hydroxy-3-methoxyacetophenone. The latter was esterified with 4-benzyloxy-3-methoxybenzoyl chloride, and the resulting ester was converted into 8,3'-dimethoxy-5,7,4'-tribenzyloxyflavone *via* the corresponding diketone. The catalytic debenzylation of the flavone gave 8,3'-dimethoxy-5,7,4'-trihydroxyflavone. Its diethyl ether was also prepared from 3,6-dimethoxy-4-ethoxy-2-hydroxyacetophenone by an unambiguous method.

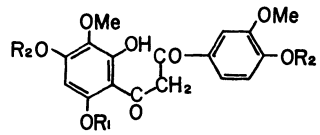
Recently, several new 5,7-dihydroxy-8-methoxyflavone derivatives have been isolated in nature[1] and their structures have been identified on the basis of spectral comparison with the known flavones. The synthesis of 3,8,3'-trimethoxy-5,7,4'-trihydroxyflavone (I) and related compounds have previously been reported.[2] It was considered useful to synthesize 8,3'-dimethoxy-5,7,4'-trihydroxyflavone (II), which may be expected to occur in nature, and to compare its properties with that of I and related compounds. The present paper will report on the synthesis of II from 3-methoxy-2,4,6-trihydroxyacetophenone (III).[3]



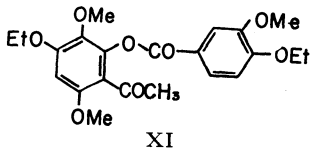
I



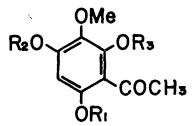
II $R_1=R_2=R_3=H$
VII $R_1=R_2=R_3=C_6H_5CH_2$
VIII $R_1=R_2=R_3=CH_3CO$
IX $R_1=H$, $R_2=R_3=Et$
XII $R_1=Me$, $R_2=R_3=Et$



VI $R_1=R_2=C_6H_5CH_2$
XIII $R_1=Me$, $R_2=Et$



XI



III $R_1=R_2=R_3=H$
IV $R_1=H$, $R_2=R_3=C_6H_5CH_2$
V $R_1=R_2=C_6H_5CH_2$, $R_3=H$
X $R_1=Me$, $R_2=Et$, $R_3=H$

When the III ketone was treated with benzyl chloride in the presence of anhydrous potassium carbonate in anhydrous acetone, two kinds of benzylated ketones, A (a crystalline fraction, mp 140—141°C) as the minor portion and B (an oily fraction) as the major portion, were separated from the reaction mixture. The former, A, shows

the analytical data for $C_{23}H_{22}O_5$ corresponding to the dibenzyl ether of III and a positive ferric chloride reaction. The latter, B, could not be crystallized, but it was identified as crude 2,4-dibenzyloxy-6-hydroxy-3-methoxyacetophenone (IV) on the basis of further experiments.[4] Consequently, the structure of A was postulated to be 4,6-dibenzyloxy-2-hydroxy-3-methoxyacetophenone (V).

The V dibenzyloxyketone was esterified with 4-benzyloxy-3-methoxybenzoyl chloride in the presence of anhydrous pyridine, and then the resulting ester was converted into 4,6-dibenzyloxy-2-hydroxy-3-methoxy-ω-(4-benzyloxy-3-methoxybenzoyl)-acetophenone (VI) by Baker-Venkataraman transformation.[5] The cyclodehydration of the VI diketone with anhydrous sodium acetate in acetic acid afforded a flavone, mp 149.5—150.5°C, which gave a red color when treated with magnesium and hydrochloric acid. The NMR spectrum*2 of the flavone indicated the presence of two methoxyl groups, three benzyloxy groups, and five aromatic protons (Table 1). Further, a set of proton signals at 6.51 and 6.64 (each 1 H, singlet) in the aromatic region could, by the application of the study of Farid,[6] be assigned to the C-6 and C-3 protons*3 respectively. Therefore, this flavone may be formulated as 8,3'-dimethoxy-5,7,4'-tribenzyloxyflavone (VII). The debenzylation of VII with hydrogen gave the desired flavone II, which was then easily derived to triacetate (VIII) by the usual method.

In order to establish the structure of the trihydroxyflavone (II), the diethyl derivative (IX) of II was also synthesized by the following unambiguous method. 2-Hydroxy-3,6-dimethoxy-4-ethoxyacetophenone (X),[7] when esterified with 4-ethoxy-3-methoxybenzoyl chloride, yielded 2-(4-ethoxy-3-methoxybenzoyloxy)-3,6-dimethoxy-4-ethoxyacetophenone (XI). The subsequent reaction of the XI ester gave 7,4'-diethoxy-5,8,3'-trimethoxyflavone (XII) *via* the corresponding diketone, XIII. The partial demethylation of XII with anhydrous aluminum chloride afforded 7,4'-diethoxy-8,3'-dimethoxy-5-hydroxyflavone, which was found to be identical with the IX mentioned above by a mixed-melting-point determination and by infrared spectra comparison. The NMR spectra of VIII and IX (Table 1) show one proton signal corresponding to the C-6 proton at 6.86 and 6.40 respectively; these spectra were in accordance with those of the flavone derivatives described in earlier reports.[1,6,8]

TABLE 1. NMR DATA OF FLAVONES*2,*4

Proton	Compounds		
	VII	VIII	IX
C-3	6.64_s	6.68_s	6.58_s

C-6'		7.57_q	7.69_q

*4 s, singlet; bs, broad singlet; d, doublet (J_{meta}=2.5 Hz); d', doublet (J_{ortho}=9.0 Hz); q, quartet (J_{ortho}=9.0 Hz, J_{meta}=2.5 Hz); m, multiplet.

Experimental*5

4,6-Dibenzyloxy-2-hydroxy-3-methoxyacetophenone (V). A mixture of the acetophenone III[3] (2.5 g), anhydrous potassium carbonate (7.0 g), and benzyl chloride (3.5 g) in anhydrous acetone (50 ml) was refluxed for 16 hr and then diluted with water (150 ml). After the solution had been concentrated in a vacuum to *ca.* 50 ml, the residue was extracted with ether. The ether layer was washed with a 3% sodium hydroxide solution and with water, and the solvent was removed. After the oily residue had then been dissolved with methanol-ether (20 : 1), the mixture was kept overnight in a refrigerator. The resulting precipitate was collected, washed with methanol, and recrystallized from ethyl acetate to give V as pale yellow prisms, mp 140—141°C, which gave a dark brown color with ferric chloride; yield, 290 mg (6%). UV: λ_{max} mμ (log ε); 289.5 (4.24), 322 (3.53).

Found: C, 72.94; H, 5.70%. Calcd for $C_{23}H_{22}O_5$: C, 73.00 H, 5.86%.

The acetate: acetic anhydride-pyridine method; mp 87—88°C (colorless needles from aqueous methanol). UV: λ_{max} mμ (log ε); 263.5 (3.85), 302 (3.71).

Found: C, 71.64; H, 5.52%. Calcd for $C_{25}H_{24}O_6$: C, 71.41; H, 5.75%.

The solvent of the mother liquor was removed by evaporation to give crude 2,4-dibenzyloxy-6-hydroxy-3-methoxyacetophenone (IV) (*ca.* 1.5 g), which had been converted into some 5,7-dihydroxy-6-methoxyflavone derivatives in a previous paper.[4]

4,6-Dibenzyloxy-2-hydroxy-3-methoxy-ω-(4-benzyloxy-3-methoxybenzoyl)-acetophenone (VI). A mixture of V (0.5 g) and 4-benzyloxy-3-methoxybenzoyl

*5 All the melting points are uncorrected. The ultraviolet spectra were measured in ethanol.

chloride (0.8 g) in pyridine (6 ml) was heated for 2 hr in an oil bath at 120°C. The cooled reaction mixture was poured into diluted hydrochloric acid. The mixture was extracted with ether, and the ether layer was washed with a sodium carbonate solution and then with water. The solvent was removed, and the resulting semi-solid was dried in a desiccator.

A mixture of the above crude ester, powdered potassium hydroxide (1.0 g), and pyridine (10 g) was heated for 4 hr at 60°C with stirring. The reaction mixture was acidified with diluted hydrochloric acid and then solidified by the addition of ether. The resulting precipitate was collected and recrystallized from ethyl acetate to give VI as yellow needles; mp 146.5—148°C; yield, 330 mg (40%). From the ether layer, VI was also obtained according to the ordinary procedure; yield, 135 mg (17%). It gave a green color with ferric chloride. UV: λ_{max} mμ (log ε); 301 (4.17), 390 (4.44), 408_{sh} (4.39).*6

Found: C, 73.96; H, 5.68%. Calcd for $C_{38}H_{34}O_8$: C, 73.77, H, 5.54%.

8,3′-Dimethoxy-5,7,4′-tribenzyloxyflavone (VII). A mixture of VI (225 mg) and anhydrous sodium acetate (1.0 g) in acetic acid (10 ml) was heated for 2 hr at 140°C. The reaction mixture was then diluted with water and extracted with ether. The ether layer was washed with a sodium carbonate solution and with water, and allowed to stand overnight in a refrigerator. The separating crystals were collected, and recrystallized from ethyl acetate to give VII as colorless needles, mp149.5—150.5°C, which gave a negative ferric chloride reaction; yield, 155 mg (71%). IR: 1635 cm^{-1} (KBr). UV: λ_{max} mμ (log ε); 247_i (4.36),*7 272 (4.37), 338 (4.40). NMR:*2,*4 5.28_s (2H); 5.19_s (4H) (C_6H_5-$C\underline{H}_2$); 3.99_s (6H, $C\underline{H}_3O$); (Table 1).

Found: C, 76.20; H, 5.16%. Calcd for $C_{38}H_{32}O_7$: C, 75.98; H, 5.37%.

8,3′-Dimethoxy-5,7,4′-trihydroxyflavone (II). A solution of VII (130 mg) in ethyl acetate - methanol (1 : 1; 50 ml) was submitted to catalytic hydrogenolysis at room temperature in the presence of Pd-C (10%: 75 mg). After the catalyst had been filtered, the filtrate was evaporated under a vacuum. The residue was recrystallized from diluted ethanol to give II as yellow plates, mp 274—276°C, which gave a dark green color with ferric chloride; yield, 60 mg (91%). IR: 3540, 3470, 3400, 1649, 1613, 1578, 1556, 1508 cm^{-1} (KBr). UV: λ_{max} mμ (log ε); 244.5 (4.18), 253 (4.19), 276 (4.27), 343 (4.28).

Found: C, 61.61; H, 4.10%. Calcd for $C_{17}H_{14}O_7$: C, 61.82; H, 4.27.

The triacetate (VIII): hot acetic anhydride - pyridine method; mp 196—196.5°C (colorless needles from ethanol). IR: 1762, 1644 cm^{-1} ($CHCl_3$). UV: λ_{max} mμ (log ε); 241 (4.35), 263 (4.28), 316 (4.28). NMR:*2,*4 4.05_s, 3.94_s (each 3H, $OC\underline{H}_3$); 2.45_s, 2.40_s 2.36_s (each 3H, $OCOC\underline{H}_3$); (Table 1).

Found: C, 60.79; H, 4.40%. Calcd for $C_{23}H_{20}O_{10}$: C, 60.52; H, 4.42%.

2-(4-Ethoxy-3-methoxybenzoyloxy)-3,6-dimethoxy-4-ethoxyacetophenone (XI). A mixture of X[7] (2.5 g), 4-ethoxy-3-methoxybenzoyl chloride (2.8 g), and anhydrous pyridine (8.0 ml) was heated in an oil bath at 110°C for 2.5 hr. The cooled mixture was poured into ice-cold dilute hydrochloric acid and then solidified by the addition of ether. The resulting precipitate was collected and recrystallized from ethanol to give XI as colorless plates; mp 132.5—133.5°C; yield, 2.75 g (63%). From the ether layer, XI was also obtained according to the ordinary procedure; yield, 0.75 g (17%). UV: λ_{max} mμ (log ε); 265 (4.17), 300 (3.99).

Found: C, 63.30; H, 6.38%. Calcd for $C_{22}H_{26}O_8$: C, 63.15; H, 6.26%.

3,6-Dimethoxy-4-ethoxy-2-hydroxy-ω-(4-ethoxy-3-methoxybenzoyl)-acetophenone (XIII). A mixture of the XI ester (2.3 g), powdered potassium hydroxide (4.0 g), and pyridine (16 g) was treated by the procedure described for VI. The product was then recrystallized from ethanol to give XIII as pale yellow needles, mp 145—146°C, which gave a green color with ferric chloride; yield, 1.65 g (72%). UV: λ_{max} mμ (log ε); 298 (4.31), 387 (4.17), 405_{sh} (4.10).*6

Found: C, 63.32; H, 6.28%. Calcd for $C_{22}H_{26}O_8$: C, 63.15; H, 6.26%.

7,4′-Diethoxy-5,8,3′-trimethoxyflavone (XII). To a solution of XIII (1.17 g) in acetic acid (15 ml), a solution of acetic acid - concentrated sulfuric acid (5 : 1; 6 ml) was added, and then the mixture was heated at 70°C for 3 min. The cooled mixture was diluted with water (200 ml) and then heated on a steam-bath for 10 min. The resulting precipitate was collected and recrystallized from ethyl acetate to give XII as colorless prisms; mp 158—159°C; yield, 930 mg (83%). IR: 1652 cm^{-1} (Nujol). UV: λ_{max} mμ (log ε); 249 (4.21), 271.5 (4.23), 339 (4.25). NMR:*2,*4 7.59_q (C-6′); 7.46_d (C-2′); $6.99_{d'}$ (C-5′); 6.63_s (C-6); 6.46_s (C-3); 4.26_q, 4.19_q (each 2H, $CH_3C\underline{H}_2$, J=7.0 Hz); 3.97_s (9H, $C\underline{H}_3O$); 1.52_t (6H, $C\underline{H}_3CH_2$, J=7.0 Hz).

Found: C, 66.05; H, 6.06%. Calcd for $C_{22}H_{24}O_7$: C, 65.99; H, 6.04%.

7,4′-Diethoxy-8,3′-dimethoxy-5-hydroxyflavone (IX). *a) From II.* A mixture of II (33 mg), anhydrous potassium carbonate (500 mg), and diethyl sulfate (200 mg) in anhydrous acetone (15 ml) was refluxed for 6 hr and then diluted with water (50 ml). The resulting precipitate was collected and recrystallized from ethanol to give IX as colorless needles, mp 178—179.5°C, which gave a green color with ferric chloride; yield, 25 mg (65%). IR: 1663, 1613 cm^{-1} (Nujol). UV: λ_{max} mμ (log ε); 253.5 (4.26), 275 (4.32), 339 (4.31). NMR:*2,*4 12.6_{bs} (O$\underline{H}$); 4.19_q (4H, $CH_3C\underline{H}_2$, J=7.0 Hz); 3.96_s, 3.93_s (each 3H, $C\underline{H}_3O$); 1.51_t (6H, $C\underline{H}_3CH_2$, J=7.0 Hz); (Table 1).

Found: C, 65.19; H, 5.80%. Calcd for $C_{21}H_{22}O_7$: C, 65.27; H, 5.74%.

b) From XII. To a solution of XII (760 mg) in anhydrous nitrobenzene (8 g), a solution of anhydrous aluminum chloride (4 g) in ether (12 g) was added. The mixture was heated at 47°C for 3 hr. After the mixture had then been poured into 1% hydrochloric acid (250 ml), the solution was concentrated in a vacuum to 150 ml. The resulting precipitate was collected and recrystallized from ethanol to give IX, mp 178—179.5°C; yield, 360 mg (49%), which was identical with that of the sample a.

Found: C, 65.33; H, 5.82%. Calcd for $C_{21}H_{22}O_7$: C, 65.27; H, 5.74%.

The acetate: hot acetic anhydride - pyridine method; mp 175.5—176.5°C (colorless needles from ethyl acetate).

*6 sh=Shoulder.

*7 i=Inflection point.

IR: 1753, 1645 cm^{-1} (Nujol). UV: λ_{max} mμ (log ε); 246 (4.39), 263.5 (4.27), 340 (4.41). NMR:[*2,*4] 7.67_q (C-6′); 7.43_d (C-2′); $6.98_{d'}$ (C-5′): 6.67_s (C-3); 6.55_s (C-6); 4.20_q (4H, $CH_3C\underline{H}_2$, J=7.0 Hz); 4.02_s, 3.96_s (each 3H, $C\underline{H}_3O$); 2.44_s ($OCOC\underline{H}_3$); 1.52_t (6H, $C\underline{H}_3CH_2$, J=7.0 Hz).

Found: C, 64.63; H, 5.74%. Calcd for $C_{23}H_{24}O_8$: C, 64.48; H, 5.65%.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 2330—2332 (1969)

Studies of the *N*-Oxides of *N,N*-Dialkylamino Acids. II. The Syntheses of *N,N*-Dialkylglycine and Corresponding *N*-Oxides

Yoshikazu IKUTANI

Department of Chemistry, Osaka Kyoiku University, Tennoji-ku, Osaka

(Received December 31, 1968)

The reductive condensations of glycine with various aliphatic straight-chain aldehydes, such as acetaldehyde, propionaldehyde, and *n*-butyraldehyde, give the corresponding *N,N*-dialkyl derivatives. The *N*-monoalkyl derivative has not been obtained in any case. In another type of reactions, those with aliphatic branched-chain aldehydes, such as isobutyraldehyde and isovaleraldehyde, considerable *N*-monoalkylation takes place besides the dialkylation. The oxidations of *N,N*-dialkylglycine to the corresponding *N*-oxides have been successfully performed using an aqueous mixture of hydrogen peroxide and acetic acid except in the case of *N,N*-diisobutylglycine. Similar reductive condensations of sarcosine with various aliphatic aldehydes, such as acetaldehyde, propionaldehyde, *n*- and iso-butyraldehyde, and isovaleraldehyde, gave the corresponding *N*-alkylsarcosines. *N*-Isobutyl and *N*-isoamyl sarcosine were also obtained by the methylation of the corresponding *N*-monoalkylglycine. The *N*-oxides of *N*-alkylsarcosine were synthesized by a procedure similar to that described above.

In the preceding paper of this series,[1] the *N,N*-dimethylations of various neutral amino acids, such as glycine, L-alanine, DL-alanine, L-valine, DL-valine, L-leucine, L-phenylalanine, and L-tyrosine, and the oxidations to the corresponding *N*-oxides were investigated. In the present study, the preparations of *N,N*-dialkylglycine *N*-oxides have been studied. The alkylations of glycine by the catalytic reductive condensation with various aliphatic aldehydes were performed by a procedure similar to that reported in the preceding paper. The results obtained are summarized in Table 1.

These results clearly indicate that the corresponding *N,N*-dialkyl derivatives were obtained as the alkylation products when aliphatic straight-chain aldehydes were employed in these reactions. The *N*-monoalkyl derivatives initially formed seem to be more reactive to the carbonyl group of the aldehydes and readily react with an excess of aldehydes to give the corresponding *N,N*-dialkyl derivatives.

On the other hand, in the case of the reductive alkylation of glycine with aliphatic branched-chain aldehydes, such as isobutyraldehyde and isovaleraldehyde, considerable monoalkylation took place besides the dialkylation. However, when an excess of the aldehyde was used, the *N,N*-dialkyl derivative was obtained in a nearly quantitative yield. These results show the bulkiness of the substituent of aliphatic branched-chain aldehydes considerably inhibits the condensation reaction of the *N*-monoalkyl glycine initially formed and the aldehyde. This assumption is supported by the fact that the *N,N*-dialkylation of glycine with isovaleraldehyde proceeds more rapidly than that of the similar reaction with isobutyraldehyde. The analytical data and some properties of *N,N*-dialkylglycine are summarized in Table 2.

The oxidations of *N,N*-dialkyl derivatives of glycine to the corresponding *N*-oxides were performed successfully by the method described in the preceding paper. However, in the case of *N,N*-diisobutylglycine, all attempts to obtain the corresponding *N*-oxide were unsuccessful and the unchanged *N,N*-diisobutylglycine was recovered. This unfavorable result is probably brought about by the steric hindrance of the bulky isobutyl residue. The analytical data and some properties of the *N*-oxides of *N,N*-dialkylglycine are summarized in Table 3.

Similar reductive condensations of sarcosine with various aliphatic aldehydes, such as acetaldehyde, propionaldehyde, *n*- and iso-butyraldehyde, and isovaleraldehyde, gave the corresponding

1) Y. Ikutani, This Bulletin, **41**, 1679 (1968).

N-alkylsarcosines. These analytical data and some properties are summarized in Table 4.

N-Isobutyl and *N*-isoamyl sarcosine were also synthesized by the reductive methylation of the corresponding *N*-monoalkylglycine with formaldehyde.

The oxidations of *N*-alkylsarcosine to the *N*-oxides were performed by a procedure similar to

Table 1. The catalytic reductive condensation of glycine with various aliphatic aldehydes

that described in the preceding paper. The analytical data and some properties of *N*-alkylsarcosine *N*-oxides are summarized in Table 5. The optical resolutions of *N*-alkylsarcosine *N*-oxides are currently under investigation, the results will be reported in detail elsewhere.

Experimental

The Dialkylation of Glycine with Various Aliphatic Straight-chain Aldehydes. The *N,N*-dialkyl derivatives of glycine were obtained by the catalytic reductive condensation of glycine with various aliphatic straight-chain aldehydes, such as acetaldehyde, propionaldehyde, and *n*-butyraldehyde, according to a procedure smilar to that described in the preceding paper.

The Alkylation of Glycine with Aliphatic Branched-chain Aldehydes. A mixture of 15 g of glycine, 1.5 g of the silk-palladium catalyst, 29 g of isobutyraldehyde, 100 m*l* of ethanol, and 130 m*l* of water was shaken with hydrogen in an autoclave at 50—55°C for 9 hr. The catalyst was then removed by filtration, and the filtrate was evaporated to dryness under reduced pressure. The residue was suspended to a small volume of ethanol, and the suspension was dried up under reduced pressure to remove a trace of water. The residue was then extracted with two 50 m*l* portions of hot ethanol to dissolve the *N*-isobutyl and *N,N*-diisobutyl glycine. Unreacted glycine was removed as a precipitate. The combined extract was dried up under reduced pressure. The residue was then re-extracted with two 50 m*l* portions of hot acetone to dissolve *N,N*-diisobutyl glycine, while *N*-isobutylglycine remained as a precipitate. The yield of crude *N*-isobutylglycine was 10.5 g. The pure substance was obtained by the recrystallization of the crude product from hot ethanol, it melted at 207°C with decomposition.

Found: C, 54.52; H, 9.95; N, 10.71%. Calcd for $C_6H_{13}O_2N$: C, 54.94; H, 9.99; N, 10.68%.

When the extracted filtrate was dried up under reduced pressure, 13.5 g of crude *N,N*-diisobutylglycine was obtained. The product was dissolved in a minimum volume of a hot mixture of acetone and isopropyl ether (1 : 1), decolorized with a small amount of charcoal, and filtered. About the same volume of isopropyl ether was then added in small portions, and the mixture was stored in a refrigerator overnight. Fine crystals of *N,N*-diisobutylglycine were then collected by filtration, washed with a small amount of isopropyl ether, and dried under reduced pressure.

The reductive alkylation of glycine with isovaleraldehyde was performed in the same manner. The dialkyl derivative was extracted using three 100 m*l* portions of a hot mixture of acetone and ethanol (9 : 1). The *N*-isoamylglycine melted at 235°C with decomposition.

Found: C, 58.12; H, 10.37; N, 9.41%. Calcd for $C_7H_{15}O_2N$: C, 57.90; H, 10.41; N, 9.65%.

***N,N*-Dialkylglycine *N*-Oxides.** These substances were prepared by the oxidation of the corresponding *N,N*-dialkylglycine with an aqueous mixture of hydrogen peroxide and acetic acid according to a procedure similar to that described in the preceding paper except in the case of *N,N*-diisobutylglycine.

***N*-Alkylsarcosine.** The *N*-alkylsarcosines were obtained by the catalytic reductive condensation of sarcosine with the corresponding aliphatic aldehyde. For example, a mixture of 15 g of sarcosine, 1.5 g of the silk-palladium catalyst, 12 g of propionaldehyde, and 150 m*l* of water was shaken with hydrogen in an autoclave at 45—50°C for 6 hr. The catalyst was then removed by filtration, and the filtrate was evaporated to dryness under reduced pressure. The residue was dissolved in a small volume of ethanol, and the solution was dried up to remove a trace of water. After this procedure had been repeated three times, the residual syrup was stored in a desiccator for a week. The crude *N*-*n*-propylsarcosine thus crystallized was filtered with a small amount of isopropyl ether and recrystallized from a hot mixture of acetone and isopropyl ether. Other *N*-alkyl derivatives of sarcosine were obtained by a similar procedure.

The author is indebted to Professor Eizo Matsumura for his constant guidance in the course of the work, and to Professor Yoshiharu Izumi of Osaka University for his valuable advice and encouragement.

An Automatic Chromatographic Method for the Separation of Flavonoid Compounds

Masatake HORI

Research and Development Division, Takeda Chemical Ind., Ltd., Juso, Higashiyodogawa-ku, Osaka

(Received Junuary 6, 1969)

A new chromatographic method for the separation of flavonoids was developed using Amberlite XAD-2 adsorption resin as the stationary phase and a gradient system of ethanol-water as the eluent. The advantage of the method lies in the fact that a number of flavonoids can be separated by a single operation with good reproducibility. The accuracy of this method determined with pure flavonoids was within ±2%. In addition, the method is useful for preparative purposes, because the solvents used are readily removable by evaporation. The elution time of 56 flavonoids was determined by this method; moreover, the method was applied to the determination of flavonoids in crude methanol extracts from plants (*Scutellaria baicalenisis, Citrus aurantium* and *Crataegus cuneata*).

The chemistry of flavonoids has been a subject of interest for many organic chemists, and hence a number of the compounds have been recorded, which differ considerably in structure. In general, flavonoids can be separated by the chromatography on Magnesol, silica gel, cellulose powder, or alumina, *etc.*[1] These adsorbents, however, have to be selected for each experiment, because the polarity of flavonoids differs considerably among these compounds. Moreover, the adsorbents mentioned above have to be refilled in each experiment.

In this paper the author wishes to report a new method for the separation of flavones, flavonols, flavanones, and flavanonols, *etc.* by the use of an Amberlite XAD-2 column an dethanol-water as an eluant, with a gradient increase of the ethanol concentration from 20% to 90%.

Experimental

Instruments. All the experiments in this work were carried out using Beckman Model-130 Spectrochrom Analyzer.

Procedure. A glass column (9×1600 mm, with jacket) was packed with Amberlite XAD-2 adsorption resin (200—400 mesh) up to 1500 mm in height, and was kept at 45°C by circulating water in the jacket, except when investigation of the effect of column temperatures was made. Then the column was allowed to equilibrate with 20% ethanol at a flow rate of 60 ml/hr.

A solution of two to four flavonoids, each less than 500 μg in 1 m*l* of 20% ethanol solution, was placed on top of the column. If the sample was sparingly soluble in 20% ethanol, a suspension of the sample in the same solvent was applied. In the case of morin, the UV-absorbancy of which is very low, 2 mg of the sample was applied; by the same reason myricetin was applied as much as 20 mg. As for the solvent, 100 m*l* of 20% ethanol was run first; a successive linear gradient elution then followed with a total volume of 1 *l* raising the ethanol concentration from 20 to 90%. The eluate was determined automatically at three wavelengths, 270, 300 and 330 mμ, and collected by a fraction collector every ten minutes.

Materials. The flavonoids used in this study, except morin (E. Merck), myricetin (Fluka A. G.), naringenin (Tokyo Kasei), were all supplied by courtesy of Drs. S. Imai and N. Morita.*1

Methanol extracts of *Scutellaria baicalensis, Citrus aurantium* and *Crataegus cuneata* were prepared by repeated extraction of the dried plants with methanol at 70°C, followed by evaporation of the solvent. The residue was then dissolved in 20% ethanol and subjected to chromatography. The yields of extracts are shown in Table 1.

Results and Discussion

As is clear from theoretical plate concept in chromatography that the use of smaller granules as a stationary phase results in more efficient separation of the peaks, the resin used in this investigation was granulated and sieved in water and 200—400 mesh granules were collected. It is also known that the temperature of a column affects the separation and the elution time of the peaks. By a preliminary investigation, it was found that the peaks are tailing at low temperatures such as 25°C and the elution time becomes shortened with the rise in temperature (Fig. 1). However, the temperature of the column was maintained at 45°C to prevent bubble formation in the column at higher temperatures.

The chromatograms obtained with 56 authentic

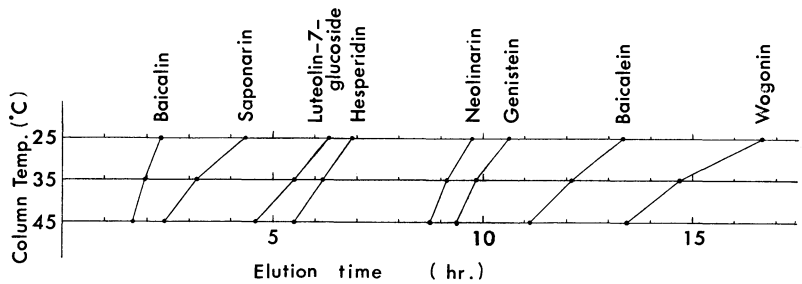

Fig. 1. Effect of the column temperature on the elution time of flavonoids.

flavonoids are summarized in Fig. 2. The number given to each peak corresponds to the sample number listed in Table 2.

In the actual chromatography each peak was drawn at three wavelengths. However, the peaks in Fig. 2 were drawn schematically to avoid complication of the chromatogram.

The elution curve of apiin (No. 26) consisted of two peaks, indicating that both peaks were due to an impurity. The broad peak of morin (No. 30) was far from being a Gaussian distribution. The fact suggests that the shape of the elution curve might be affected by an impurity.

Correlation of the elution time of these substances with their structure led to the conclusion that in this chromatography the polar flavonoids elute with shorter elution time. Thus, the following generalizations are possible.

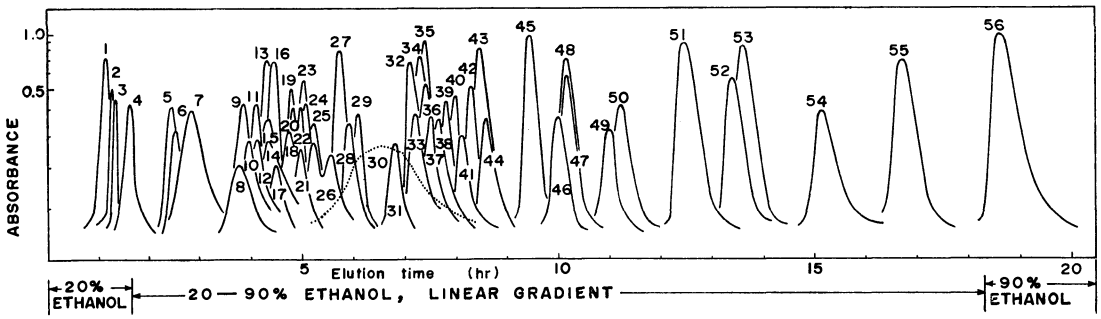

Fig. 2. The elution time of flavonoids.

Column: Amberlite XAD-2, 200—400 mesh, 9×1500 mm, 45°C
Solvent: Aqueous ethanol
Flow rate: 60 ml/hr

i) The elution is in the order of sugar esters→glycosides→aglycones.

ii) Among the aglycones the compounds having more hydroxyl groups elute faster than the compounds having fewer hydroxyl groups. The stereochemical nature of the hydroxyl groups also affects the elution time of these aglycones.

iii) The elution time of glycosides varies considerably depending on the position where the sugar moiety is attached, even if the aglycone and the sugar are the same among the glycosides.

iv) The elution time for glycosides is greatly affected by the number of hydroxyl groups and sugars.

As is seen in Fig. 2, many of the glycosides and aglycones, which are eluted in the range of retention time, 4—8 hr, are difficult to be separated if they are present in one sample. In such a case, the measurement of the absorbances at three different wavelengths on the chromatogram becomes very significant, because the shape of the absorption spectra differs considerably from one flavonoid to another.[2] The ratios of the absorbance ($E_{270\,m\mu}/E_{300\,m\mu}$, $E_{330\,m\mu}/E_{300\,m\mu}$) calculated from chromatograms are listed in the right column of Table 2. The calibration curves of ten flavonoids calculated by the height-width

method*2 are shown in Fig. 3. The accuracy of these measurements lies within ±2%.

Application in the Chromatography of Plant Extracts. Methanol extracts of *Scutellaria baicalensis*, *Citrus aurantium* and *Crataegus cuenata* were prepared by the method as described above. The chromatogram of the extract from *Scutellaria baicalensis*, Fig. 4(a), indicates the presence of baicalin, baicalein and wogonin, all of which have been isolated from these plants. Similarly, the chromatogram of *Citurs aurantium* indicates the presence of hesperidin. Other peaks, which are seen in Fig. 4(b) and designated as peaks I and II, have not yet been characterized. These compounds, however, seem to be akin to hesperidin in their structures, because the absorption spectra resemble that of hesperidine. The chromatogram of the extract from *Crataegus cuneata* was complex as shown in Fig. 5, and the peaks of quercetin and vitexin, which have been isolated from this plant, were indistinguishable. The complexity is due to a large quantity of impurities extracted by methanol, and some pretreatment would be needed.

The author is grateful to Professor Hiroyuki Hatano (Kyoto University) and Dr. Katsura Morita (these laboratories) for valuable discussions. The author is also grateful to Drs. Shunji Imai and Naokata Morita for providing the samples. Thanks are due to Miss Michiyo Miyazaki for her assistance in the experimental work.

*2 The height-width method has been used in the amino acid analysis.

Anionic Telomerizations of Styrene with Some Secondary Amines*1

Teruzo ASAHARA, Manabu SENŌ, Sadayoshi TANAKA and Norio DEN

Institute of Industrial Science, The University of Tokyo, Roppongi, Minato-ku, Tokyo

(Received January 7, 1969)

The anionic telomerizations of styrene with some secondary amines catalyzed by sodium metal were investigated. In this reaction a secondary amine was used as a telogen and styrene as a taxogen. Three telomers, *i. e.* *N,N*-disubstituted 2-phenylethylamine, *N,N*-disubstituted 2,4-diphenylbutylamine and *N,N*-disubstituted 2,4,6-triphenylhexylamine were separated from the mixture of the produced telomers under vacuum distillation. Proton NMR spectra of these telomers in carbon tetrachloride were consistent with the expected structural formulas. The reaction scheme was proposed to explain the formation of telomers.

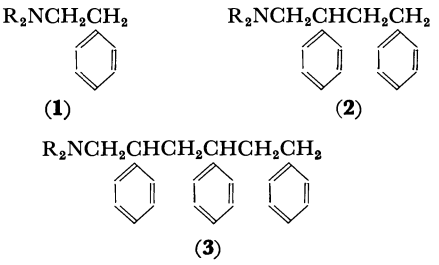
Anionic telomerization may be characterized to be an anionic polymerization of vinyl, vinylidene and diene compounds so that the initiation reaction, the propagation reaction and the chain transfer reaction can take place to a comparable extent in the polymerization reaction. If the propagation reaction exceeds the chain transfer one, polymerization reaction, in the ordinary sense, would occur to produce high polymers, and if the chain transfer reaction overcomes the propagation one, the anionic addition reaction would be realized. In fact many of the anionic addition reactions of vinyl and diene compounds with alkylaromatic compounds which contain the α-hydrogens in the side chain have been reported by Pine and his coworkers[1-11] and by other authors.[12-15]

The small unbalance between the rate constants of the initiation, the propagation and the chain transfer reactions can sometimes be compensated by controlling the concentrations of a telogen and a taxogen. In other words the molar ratio of a telogen to a taxogen during the telomerization reaction influences the composition and the average molecular weight of the produced telomers.

In this paper the results on the telomerization of styrene with some secondary amines, the separation of the telomers and NMR spectra of the separated telomers will be reported. The formation of the telomers will be discussed with the proposed reaction scheme.

Results and Discussion

Reactions of Styrene with Secondary Amines. Secondary amines were subjected to reaction with styrene to produce telomers, from which were separated the telomers with $n=1$, 2 and 3, respectively, *i.e.* *N,N*-disubstituted 2-phenylethylamines (**1**), *N,N*-disubstituted 2,4-diphenylbutylamines (**2**) and *N,N*-disubstituted 2,4,6-triphenylhexylamine (**3**).



The higher homologs of these telomers were formed at the same time, but remained undistilled in residue under vacuum distillation. Diethylamine, di-*n*-propylamine, di-*n*-butylamine and diisobutylamine were reacted as a telogen. The reaction products obtained are listed in Table 1. The molar ratio of styrene to the amine influenced greatly the

compositions of telomers. Table 2 gives the reaction conditions and the reaction products. Column 1 lists the amines used, and columns 6, 7 and 8 report the yields of the separated telomers.

Structures of the Separated Telomers. The telomer **1a** has a methyl triplet (1 : 2 : 1) at 9.03 τ and a methylene quartet (1 : 3 : 3 : 1) at 7.52 τ. These are the typical signals of ethyl group and are assigned to the two equivalent ethyl groups of the telomer **1a**. The signal at 7.38 τ is that of the methylene protons (a) and (b) between the nitrogen atom and the phenyl group. The protons constituting the phenyl group show a singlet at 2.94 τ. The telomer **2a** gives the signals at 9.12, 2.92 and 2.99 τ which are assigned to methyl protons (k), phenyl protons (c) and phenyl protons (f), respectively. The signals due to five methylene and a methine groups were not assigned completely, but the signals at 7.45, 7.56, 7.68 and 7.80 τ seem to form a methylene quartet due to protons (j). The telomer **3a** shows a methyl triplet and three phenyl singlets at 9.16, 2.93, 2.96 and 3.01 τ which are assigned to protons (k), (c), (f) and (i), respectively. The NMR signals of other telomers were assigned, and the results on the assignments of the signals to the protons of the separated telomers **1**, **2** and **3** are listed in Table 3. It was confirmed from IR spectra that none of the separated telomers has a –NH– group. The results on the

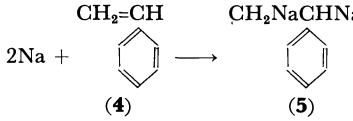
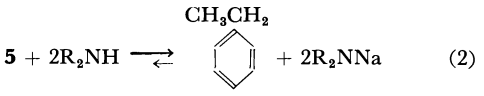
NMR and IR spectra of the produced telomers are consistent with the structural formulas of the telomers **1**, **2** and **3** listed in Table 1.

Reaction Scheme. The reaction scheme is considered as follows. The initiation reaction may be the addition of sodium to styrene (**4**), and the organometallic compounds **5** transmetalates with a secondary amine **6** to give the compound **7**.

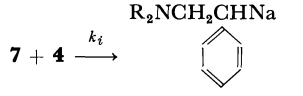


(1)



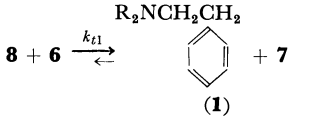
(2)

The compound **7** is able to react with styrene.

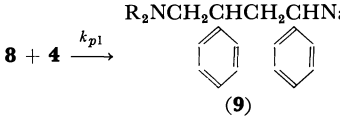


(3)

The resulting sodium salt **8** transmetalates with the amine **6** to produce the compound **1** and at the same time reacts with styrene (**4**).

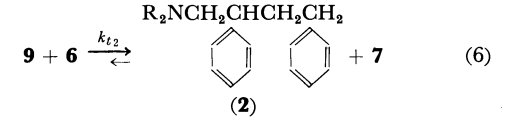


(4)

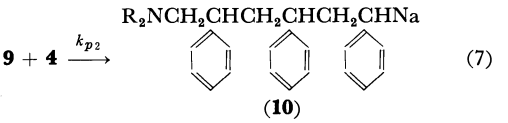


(5)

The reactions (4) and (5) compete for the compound **8**. Both the chain transfer reaction (6) and the propagation reaction (7) take place also competitively for the compound **9**.

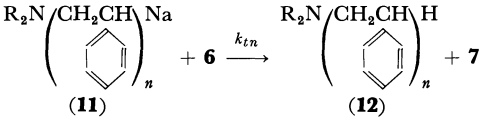


(6)

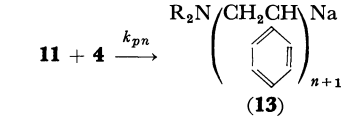


(7)

Generally, the competitive reactions (8) and (9) take place for the organosodium compound **11**.

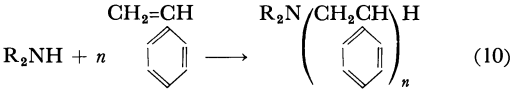


(8)



(9)

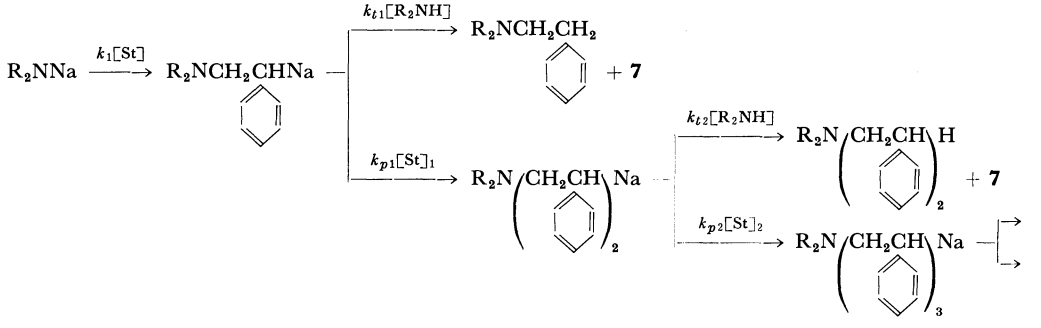
In the above equations, the notations k_t, k_{tn} and k_{pn} express the rate constants of the initiation reaction (3), the transfer reaction (8) and the propagation reaction (9), respectively. The reactions (3), (4), (5), (6), (7), (8) and (9) constitute a typical telomerization reaction. In fact, on combining Eqs. (3), (8) and (9) for $n=1, 2, \cdots, n-1$, the general equation of telomerization is obtained.



(10)

It may be understood from this reaction scheme that the telomers **1**, **2** and **3** are prepared by the anionic telomerization of styrene with the secondary amines.

Compositions of the Telomers. The reaction scheme proposed in the preceding section may be described as follows.



In the reaction styrene was added dropwise, and so the concentrations of styrene with which the organometallic compounds **7**, **8**, **9**, **10** and **11** reacted were different and were in the following order.

$$[St] > [St]_1 > [St]_2 > [St]_3 > \cdots \quad (11)$$

If we suppose that the rate constants of the propagation reactions and the chain transfer reactions are approximately independent of n and the concentration of amine remains almost unchanged in a few minutes, the ratios of the rates of the transfer reactions to those of the propagation reactions

$C_{32}H_{43}N$ $isoBu_2NCH_2CHCH_2CHCH_2CH_2$ 	(**2d**)	C H N	87.02 9.81 3.17	87.10 9.84 3.01	441.67	···	432	1.5403	194/0.04

give the following inequality.

$$\frac{k_{t1}[R_2NH]}{k_{p1}[St]_1} < \frac{k_{t2}[R_2NH]}{k_{p2}[St]_2} < \frac{k_{t3}[R_2NH]}{k_{p3}[St]_3} < \cdots \quad (12)$$

Equation (12) shows that there may be a maximum in the yields of the telomers. The reactivities of the amines in the transfer reactions are supposed to be in the following order mainly because of the steric effects of the alkyl groups attached to nitrogen atoms.

$$k_{tn(Et_2NH)} > k_{tn(n\text{-}Pr_2NH)} > k_{tn(n\text{-}Bu_2NH)} > k_{tn(IsoBu_2NH)} \quad (13)$$

The smaller the rate constants of the transfer reactions, the larger the average degrees of polymerization or the average degree of telomerization become. In this experiment only the telomers with $n=1$, 2 and 3 were separated, but some of the higher homologs of telomers are considered to have been formed and to have remained undistilled in residue. On controlling the ratio of styrene to the amine during the reaction, one can prepare the mixture of telomers with arbitrary average molecular weight in the region of oligomers.

Experimental

Physical Data. For mass spectral analysis, a Hitachi RMU-6D mass spectrometer was employed with the electron beam energy at 80 eV. The molecular weight determination by vapor pressure osmometry was carried out in benzene at 37°C on a Hewlett Packard Model 302 vapor pressure osmometer. IR spectra were recorded on a Hitachi Perkin-Elmer 125 grating infrared spectrophotometer. Proton NMR spectra were obtained on a Hitachi Model R-20 spectrophotometer using tetramethylsilane as an internal standard in carbon tetrachloride.

Materials. Styrene was dried over anhydrous magnesium sulfate for a day or more and was distilled under reduced pressure. Amines were dried over sodium hydroxide and were distilled under atmospheric or reduced pressure according to their boiling points.

General Procedure for Telomerization. In a four-necked round-bottomed flask, provided with a mechanical stirrer, a reflux condenser, a dropping funnel and an inlet of nitrogen, are placed a secondary amine and finely sliced sodium. The flask was heated to a prescribed temperature in an oil bath. The oil was agitated mechanically and its temperature was controlled by a thermostat. Styrene was added dropwise to the amine in 0.3 to 1.3 hr, and thereafter the mixture was kept standing for reaction for further 3 hr. Then the solution was cooled to room temperature and the alkali was decomposed by adding an equivalent amount of methanol and was neutralized by a 0.1 N hydrochloric acid. A small amount of benzene was added to this reaction mixture, if necessary, in order to make the solution uniform and the resulting solution was washed with water, dried and distilled *in vacuo*.

Diethyl-2-phenylethylamine (1a), Diethyl-2,4-diphenylbutylamine (2a) and Diethyl-2,4,6-triphenylhexylamine (3a). To 21.1 g of diethylamine and 0.7 g of sodium which were heated to 50.0±0.5°C, 62.3 g of styrene was added dropwise during 0.5 hr and the reaction took place for a further 3 hr. To the reaction mixture that was cooled to room temperature were added 3.1 m*l* of methanol and 10.0 m*l* of water. Then the solution was neutralized with 0.1 N hydrochloric acid, washed with 50 m*l* of water, and the organic layer was separated, dried and distilled *in vacuo* to give 42.2 g (39.67%) of the telomer **1a** at 77°C/4 mmHg, 5.78 g (6.84%) of the telomer **2a** at 136°C/4 mmHg and 4.74 g (6.18%) of the telomer **3a** at 212°C/0.02 mmHg. The other telomers were obtained in similar procedures.

(Received January 20, 1969)

A Study of the copolymerization of formaldehyde and succinic anhydride was carried out in a liquid carbon dioxide solution without adding any catalyst. A copolymer, in which a small number of succinic units was inserted into the sequence of oxymethylene units because of the low rate of copolymerization of succinic anhydride, was formed. With enhancing the concentration of succinic anhydride, the content of succinic units in the copolymer slightly increased. At reaction temperatures up to 120°C, the molecular weight of the copolymer decreased with a rise in the temperature, whereas the content of succinic units increased to about 3 mol%. The copolymerization proceeded rapidly, so the reaction immediately reached equilibrium. From the results of the study by X-ray diffractiometry, the crystal structure of the copolymer can be said to be similar to that of polyoxymethylene, but the crystallinity of the copolymer decreased as the content of succinic units increased. The rate of thermal degradation, which started from the end-groups of the copolymer was decreased by ester linkgae. The thermal-degradation temperature was enhanced as the content of succinic units increased. The copolymer also showed a high resistivity to the folding of the film, even though it had not been treated so as thoroughly to esterify the endgroups of the copolymer.

The present authors have studied the polymerization of formaldehyde in a liquid carbon dioxide solution in the presence of acetic anhydride. They have thus determined that the resulting polyoxymethylene can easily and thoroughly be acetylated by discharging the unreacted monomer and carbon dioxide from the reaction system and then heating, *in situ*, the remains.[1] A perfect acetylation of the polymer end-groups is achieved with acetic anhydride, which is added, in advance of polymerization, into the reaction system at a concentration of only 5 mol% to the monomer. This fact suggests that the acetic anhydride added is selectively located in the neighborhood of the growing polymer chain end in the stage of propagation. If a cyclic acid anhydride is used instead of acetic anhydride, the formation of a copolymer in which the sequence of oxymethylene units is connected with both ends of the ring-opening acid anhydride may be inferred. This work is devoted to a study of how to prepare the copolymer composed of oxymethylene and ester units by the copolymerization of formaldehyde and succinic anhydride in the presence of carbon dioxide; it will also attempt to establish the properties of the copolymer.

Experimental

Preparation of Materials. The formaldehyde monomer was prepared by the pyrolysis of dried α-polyoxymethylene from 150 to 180°C in a stream of carbon dioxide, after which the gas mixture thus produced was cooled at −78°C in order to condense the formaldehyde and carbon dioxide, as has been described before.[2] The concentration of formaldehyde in the thus-prepared solution of carbon dioxide was 60.1 wt%. The succinic anhydride was purified by recrystallization from a chloroform solution.

Procedure of Polymerization. A stainless-steel pressure vessel, with a capacity of 30 ml was used for the polymerization. The weighed succinic anhydride was placed in the vessel, after which the vessel was evacuated at room temperature and then cooled by liquid nitrogen. The monomer solution, which had previously been prepared in a monomer reservoir, was fed into the evacuated pressure vessel through a tube connecting the vessel to the monomer reservoir. The amount of the monomer solution thus fed in was determined by weighing the vessels before and after the feeding. The polymerization was carried out by keepting the pressure vessel in an oil-bath controlled within ±1°C. After the polymerization, the pressure vessel was cooled to 20°C; the unreacted monomer and carbon dioxide were then purged out.

After it had been cooled at −78°C, the product was

2) H. Yokota, M. Kondo, T. Kagiya and K. Fukui, *J. Polymer Sci.*, **A-1**, **6**, 425 (1968).

washed with ethyl ether cooled at −78°C and then with acetone. The succinic anhydride remaining in the resulting polymer was extracted with chloroform for 24 hr by using a Soxhlet extractor. The obtained polymer was dried *in vacuo* at room temperature.

Procedure for Measuring Properties of the Copolymer. The inherent viscosity, η_i was determined by an Ostwald viscometer; the starting solution contained 0.5 g of the copolymer in 100 m*l* of *p*-chlorophenol in which 2% of α-pinene had been dissolved at 60°C.

The thermal stability of the copolymer was evaluated by the first-order reaction rate constant, k_{222} for thermal degradation at 222°C in an inert atmosphere. By heating the copolymer in a nitrogen atmosphere, which was kept at 222°C by means of a vapor bath of boiling methyl salicylate, the weight loss of the copolymer was followed continuously. The rate constant was estimated from the slope of the linear relation between the heating time and the logarithm of the weight loss of the polymer.

The folding endurance was represented by the number of creasing cycles which the copolymer film withstood before breaking when a film 120 μ thick was subjected to the creasing test of ASTM D-643-43. The film was prepared by pressing under heating.

The X-ray diffraction spectra were measured by the powdered-crystal method with a Rigaku-Denki DF-3 automatic X-ray diffractiometer. Filtered Cu$K\alpha$ radiation was used in this study.

Differential thermal analysis was carried out by a Shimadzu DT-10 differential thermoanalyzer. The powdered copolymer was dispersed in α alumina at a concentration of 20 wt%.

Determination of Copolymer Composition. The mole fraction of the copolymers was determined by measuring the infrared absorption intensity at 1737 cm^{-1} of the carbonyl group of the ester linkage. The absorption intensity at 1740 cm^{-1} of the carbonyl group, which was divided by the absorption intensity at 2930 cm^{-1} of the methylene group in order to eliminate the influence of sample thickness, was measured at a variety of compositions in a mixture of polyoxymethylene and methyl succinate, and the calibration curve thus obtained served to quantify the carbonyl group in the resulting copolymer. The infrared spectrum was measured by using a Hitachi EPI-2 infrared spectrometer. The polymer sample was molded as a KBr pellet or film. The film was prepared by pressing the copolymer powder at room temperature.

Results and Discussion

Influence of the Monomer Composition on the Copolymerization. The influence of the monomer composition on the copolymerization of formaldehyde and succinic anhydride in a liquid carbon dioxide solution at 100°C was investigated; the results are shown in Table 1.

Figure 1 shows a typical example of the infrared spectrum for the resulting polymer, in which the absorption band of the carbonyl group is exhibited only at 1740 cm^{-1}. This band was ascribable to the ester carbonyl group. This fact indicates that succinic anhydride gives ester linkage in the copolymer by means of ring-opening reaction. The present authors have already presented the following equation for the relation of the inherent viscosity, η_i and the number-average degree of polymerization, $\overline{P}_n$ to polyoxymethylene[2]:

$$\eta_i = 2.14\times10^{-2}\overline{P}_n^{0.61}$$

Assuming this equation to be applicable also in the case of a copolymer containing a low content of succinic anhydride as a comonomer, the number-average degree of polymerization of the copolymer shown in Figure 1 was found to be 1500. On the other hand, the determined content of succinic units in the copolymer was 0.71 mol%. Admittedly, the concentration of succinic units was about six times that of the polymer end-groups, the latter figure having been calculated from the number-average degree of polymerization.

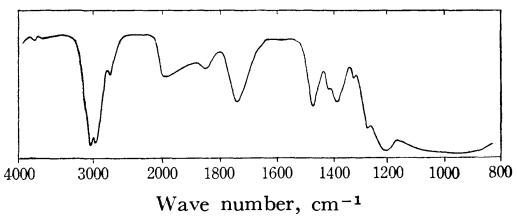

Fig. 1. Infrared spectrum of formaldehyde-succinic anhydride copolymer.
The sample; η_i 1.6 d*l*/g, succinic unit content 0.71 mol%.

Reaction conditions: formaldehyde 3.2 g, succinic anhydride 1.1 g, carbon dioxide 2.1 g, time 60 min.
*1 Values in parentheses are defined the same as in Table 1.
*2 The definition is the same as in Table 1.

Thus, it was concluded that succinic units are inserted at several places in the sequence of oxymethylene units.

The results shown in Table 1 indicate that the content of succinic units in the resulting copolymer increased slightly with an increase in the concentration of succinic anhydride, but the content was, in general, lower than 1 mol%. Regarding formaldehyde as M_1 and succinic anhydride as M_2, it seems that the monomer reactivity ratio r_1 is extremely large and that r_2 is nearly zero.

The polymer yield increased as the concentration of succinic anhydride became less. However, the polymer yield based on the formaldehyde monomer was almost independent of the concentration of succinic anhydride. The degree of polymerization was also constant in a like manner. These facts were ascribed to the fact that the addition polymerization of formaldehyde proceeded predominantly, because the monomer reactivity ratio r_2 was extremely small.

Influence of the Reaction Time. The influence of the reaction time on the copolymerization was also studied as is shown in Table 2. The degree of polymerization, the inherent viscosity, and the content of succinic units were not at all affected by the reaction time. Accordingly, it seems that the rate of polymerization was very large at the temperature of 100°C, so that the reaction immediately reached equilibrium.

Influence of the Reaction Temperature. Table 3 shows the influence of the reaction temperature on the copolymerization of formaldehyde with succinic anhydride. The inherent viscosity and the succinic-unit content of the resulting copolymer are plotted against the reaction temperature in Fig. 2. The succinic-unit content rapidly increased with an enhancement in the reaction temperature, although it was less than 3 mol% even in the copolymer resulted at 120°C. This fact indicates an increase in the monomer reactivity ratio r_2 with the reaction temperature. The copolymer yield was independent of the temperature, whereas the inherent viscosity decreased reciprocally with the temperature. It seems, therefore, that the initial concentration of initiating species increases with an enhancement of the temperature.

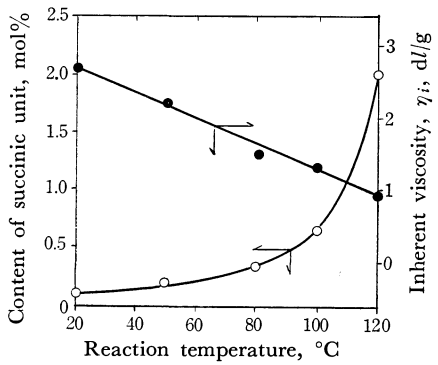

Fig. 2. Influence of reaction temperature on the degree of polymerization and succinic unit content of the copolymer.

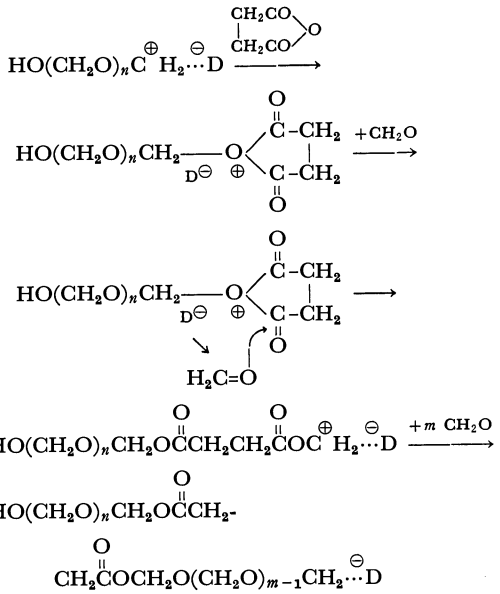
Mechanism of Copolymerization. As has been mentioned above, formaldehyde and succinic anhydride copolymerized in a liquid carbon dioxide solution under pressure, while the addition polymerization of formaldehyde proceeded predominantly because of the low value of the monomer reactivity ratio r_2. Accordingly, it was concluded that an occasional insertion of succinic anhydride into the growing polyoxymethylene chain took place by means of the following schemes:



Structure and Properties of the Copolymer. It has been disclosed by infrared-spectrometric study that there is formed a copolymer into which succinic units are inserted in some places in the sequence of formaldehyde units. In this section, the structure and properties of the above copolymer will be discussed. The X-ray diffraction spectrum of the copolymer, which contained 0.68 mol% of succinic units, is shown in Fig. 3; the spectrum of α-polyoxymethylene, which was chosen as an example of the homopolymer of formaldehyde, is also shown in the same figure for the sake of comparison. The maximum peak for α-polyoxymethylene occurred at a scattering angle of 22.6°, whereas it occurred at 22.7° and there was an extra peak at 20.5° for the copolymer. The peak at 20.5° was ascribed to the amorphous part in the copolymer.[3] Furthermore, the crystallinity of the copolymers, which contained a variety of succinic units, was studied; the results are shown in Table 4. The crystallinity decreased as the succinic unit content rose. This fact indicates that a disturbance of the crystal lattice took place because of the insertion of succinic-units into the polymer chain.

TABLE 4. INFLUENCE OF COPOLYMER COMPOSITION ON CRYSTALLINITY OF THE COPOLYMER

Content of succinic unit, mol%	η_i dl/g	Crystallinity %
0	0.95	98.0
0.40	1.79	94.6
0.67	1.75	88.7
1.1	0.30	82.1

The thermal properties of the copolymer were also investigated. A typical thermal degradation curve of a copolymer which had been constantly heated at 222°C in a nitrogen atmosphere is shown in Fig. 4. It was found that the rate constant of thermal degradation decreased with the heating time. The thermal degradation of polyoxymethylene, in general, follows a first-order rate equation; therefore, the rate constant does not vary

Sample; η_i 1.34 dl/g, succinic unit content 0.64 mol%, initial rate constant of decomposition 5.2 wt%.

with the time.[4] On the contrary, the thermal stability of the copolymer investigated improved with heating. This may be ascribed to the fact that the successive degradation begun at the endgroups of the copolymer chain was lowered at the ester linkage, which is thermally more stable than the ether linkage.

Figure 5 shows the curves for the differential thermal analysis of the copolymer. With an increase in the content of succinic units, the melting point shown by the first peaks did not vary, but the degradation temperature by the second peaks increased. This may be caused by the thermal stability of the ester linkage in the copolymer chain.

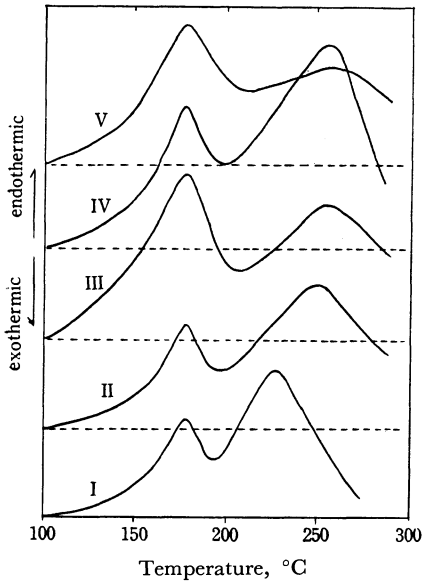

Fig. 5. DTA curves of the copolymer.
Succinic unit content and η_i of the sample: (I) 0.091 mol%, 2.7 dl/g; (II) 0.19 mol%, 2.2 dl/g; (III) 0.33 mol%, 1.5 dl/g; (IV) 0.64 mol%, 1.3 dl/g; (V) 2.04 mol%, 0.98 dl/g.

Table 5. Folding endurance of the copolymer

Sample*1		Folding endurance*2 $\times 10^{-3}$ times
Content of succinic unit, mol%	η_i dl/g	
3.5	1.8	87
2.0	1.8	78
1.1	1.7	92

*1 Sample thickness 120 μ
*2 Mean value for five runs

Lastly, the folding endurance of the copolymer film was studied; the results are shown in Table 5. Although there was no treatment for esterifying the endgroups in the copolymer, the film showed a high resistivity to folding. On the other hand, the folding endurance of polyoxymethylene diglycol has been reported to be less than 100 times.[5] The high resistivity of the film to folding may be a characteristic of the copolymer.

The authors wish to express their gratitude for the guidance and encouragement received from Dr. K. Fujimura. They also wish to express their thanks to Mr. T. Nishida, who carried out much of the experimental work.

Kinetic Studies of the Triethylenediamine-catalyzed Transamidation of 1,3-Diphenylurea with *n*-Butylamine in Dioxane

Yoshiaki FURUYA,* Kazuo ITOHO** and Harue MIYAGI**

* *Department of Industrial Chemistry, Faculty of Engineering, Kumamoto University, Kumamoto*
** *Daiichi College of Pharmaceutical Sciences, Fukuoka*

(Received February 6, 1969)

The rates of the transamidation of 1,3-diphenylurea (abbreviated as DPU) with *n*-butylamine (BA) in dioxane in the presence of triethylenediamine (TED), forming *n*-butylphenylurea (BPU), aniline and carbon dioxide, were followed ultraviolet-spectrophotometrically. The rate of the reaction satisfied the following equation:

$$v = \{k_1' + k_2'[\mathrm{TED}]\}[\mathrm{DPU}] + \{k_2'' + k_3[\mathrm{TED}]\}[\mathrm{BA}][\mathrm{DPU}] .$$

The first and second terms correspond to the non- and the TED-catalyzed hydrolysis of diphenylurea, while the third and fourth terms represent, respectively, the non- and the TED-catalyzed transamidation. In both the non- and the TED-catalyzed transamidation, a probable mechanism which involves the nucleophilic attack of the lone pair of the N-atom on the carbonyl C-atom of diphenylurea, followed by the formation of ion pairs of quaternary ammonium salt and of quaternary ammonium type salt, was discussed.

The transamidation of 1,3-diphenylurea with primary amines in the presence of tertiary amine in dioxane has been previously reported.[1] In the present paper, the TED-catalyzed transamidation of 1,3-diphenylurea with *n*-butylamine will be measured by means of ultraviolet spectrophotometry, and its probable mechanism discussed.

Experimental

Materials. 1,3-Diphenylurea (DPU) was recrystallized three times from aqueous methanol; mp 244°C. *n*-Butylamine (BA) was rectified; bp 182°C. *n*-Butylphenylurea (BPU) was prepared by the reaction of phenyl *N*-phenylcarbamate with BA[2] and recrystallized from aqueous methanol; mp 130—131°C (Found: N, 14.3%; Calcd: 14.6%). Triethylenediamine (TED) obtained from Meisei & Co., Ltd., was purified by sublimation under reduced pressure; mp 110°C. Dioxane was refluxed for 7 hr with 10% of its volume of 1 N aqueous hydrochloric acid, while a slow stream of air was passed through the condenser in order to remove the acetaldehyde formed. The organic layer was then separated after treating it with potassium hydroxide. It was then distilled from metal sodium; bp 102°C.

Ultraviolet Spectrophotometry and Chemical Analysis. The absorption maxima of DPU and BPU were 255 and 238 mμ, while the minima of DPU and BPU were 227 and 217 mμ, respectively (see Fig. 1). The absorptions of BA, TED, and aniline are negligible at these wavelengths. Mixtures of DPU, BA, TED, and BPU of known concentrations (corresponding to 0, 20, 40, 60, 80, and 100% conversion) were prepared at 90°C; a plot of the difference in extinctions, $(E_{255}-E_{227})$ *vs.* $(E_{255}-E_{238})$, gave a straight line,[3] and the conversions calculated from the values of $(E_{255}-E_{238})$ at 0 and 100% conversion agreed well with the conversions calculated from the composition of the mixture within a 1% error.

The aniline liberated from DPU in a reaction mixture was detected by paper chromatography[1] and by Anger's reaction.

A Typical Run for the Rate Measurements. A solution of 1.6 m*l* of 0.5 M BA in dioxane was added to a solution of 34.4 m*l* of 0.0233 M DPU in dioxane; then

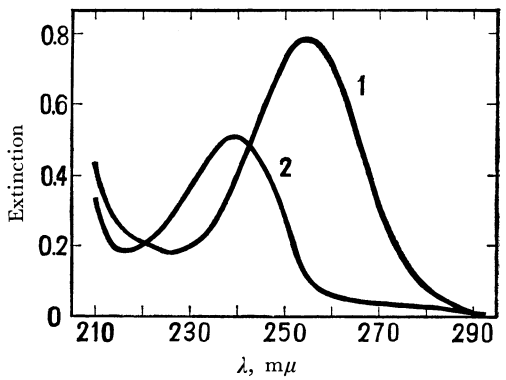

Fig. 1. Ultraviolet spectra of reactant and product in 2×10^{-5} M methanolic solution: 1, DPU; 2, BPU.

1) Y. Furuya and K. Itoho, *Chem. & Ind.*, **1967**, 359.

2) Y. Furuya, S. Goto, K. Itoho, I. Urasaki and A. Morita, *Tetrahedron*, **24**, 2375 (1968).

3) Y. Ogata, Y. Furuya and M. Ito, *J. Am. Chem. Soc.*, **85**, 3649 (1963).

a solution of 4.0 m*l* of 0.05 M TED in dioxane was poured into this mixture in order to start the reaction after the three solutions had attained temperature equilibrium at 90°C. Aliquots (0.2 m*l* each) were pipetted out at appropriate time intervals; for spectrophotometry each one was diluted with methanol to a 2×10^{-5} M initial concentration of the reactant. Then, the extinctions at 255, 238, and 227 mμ were measured. The conversion was calculated graphically from the observed value of $(E_{255}-E_{238})$, and the value of the first-order rate constant, $k_{1\,obs}$, was calculated.

Determination of the Water in the Reaction Medium. The remaining water in the dioxane was determined to be 0.047 M by the Karl Fischer method.

A Typical Procedure for the Conductivity Measurement. A 20 m*l* portion of the dioxane solution of DPU (0.02 M), BA (0.02 M), and TED (0.005 M) was heated at 90°C for 40 hr, after which the solution was diluted with 20 m*l* of conductivity water. The precipitate thus formed was filtered off by a glass filter. Then the conductivity of the solution was measured by means of a Yokogawa-Hewlett-Packard universal bridge 4255A(BV-Z-13C) at 25±0.2°C. The values of the conductivity of each member and couple for the reaction of DPU with BA in the presence of TED are indicated in Table 1.

Table 1. Specific conductivities of the reactants and products at 25±0.2°C

Reaction concn. of DPU, BA and aniline: 0.02 M
concn. of TED: 0.005 M
Measurement concn.: half of the values described above

Substance or couple of substances	Specific conductivity $\kappa\times10^6\ \Omega^{-1}\,cm^{-1}$ at 0 hr		at 40hr	at 90 hr
Cond. water	1.553			
Dioxane	2.848			
DPU	5.180			
BA	21.41			
TED	3.023			
Aniline	3.075			
DPU+TED	10.87	(1.33)*	(1.56)	(1.36)
DPU+BA	69.64	(2.62)	(0.88)	(0.46)
BA+TED	21.95	(0.90)	(0.56)	(0.89)
Aniline+TED	7.880	(1.29)	(2.95)	(2.75)
DPU+BA+TED	33.69	(1.14)	(0.40)	(0.40)

* The values in parentheses are the ratios of an actual value of each couple by the sum of the components.

Results and Discussion

The reaction follows the first-order kinetics with DPU, as is shown in Fig. 2. The plots of the first-order rate constant *vs.* the concentration of BA gives a straight line which does not pass through the point of origin, as is illustrated in Fig. 3. Therefore, the observed first-order rate constant is given by the following equation:

$$k_{1\,obs} = k_1 + k_2[BA] \qquad (1)$$

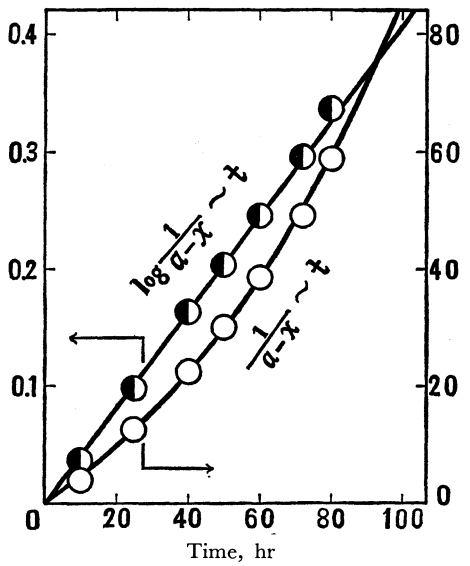

Fig. 2. Determination of reaction order in dioxane at 90°C.
Initial concn. of DPU and BA: 0.02 M,
concn. of TED: 0.005 M

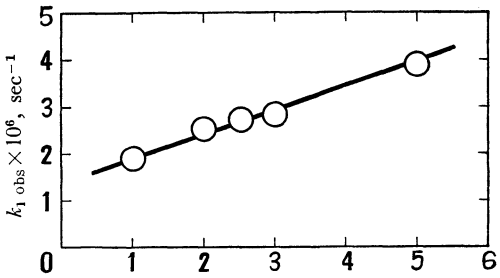

Fig. 3. The plots of $k_{1\,obs}$ *vs.* concentration of BA for the TED-catalyzed transamidation of DPU with BA in dioxane at 90°C.
Initial concn. of DPU: 0.02 M,
concn. of TED: 0.005 M

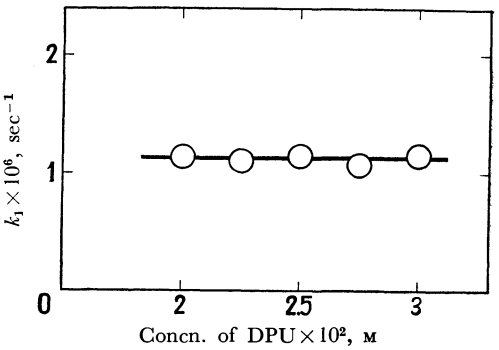

Fig. 4. The plots of k_1 *vs.* concentration of DPU for the TED-catalyzed transamidation of DPU with BA in dioxane at 90°C.
Initial concn. of BA: 0.02 M,
concn. of TED: 0.005 M

The values of k_1 and k_2 did not vary with the concentration of DPU (Figs. 4 and 5). However, these values contain the concentration of TED, as is obvious in Figs. 6 and 7.

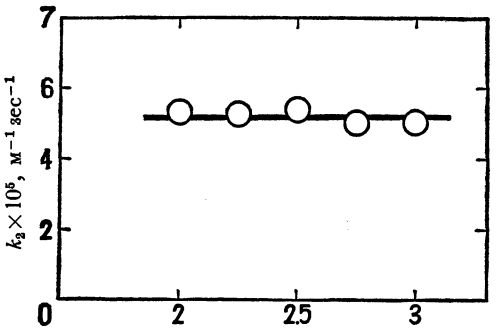

Fig. 5. The plots of k_2 *vs.* concentration of DPU for the TED-catalyzed transamidation of DPU with BA in dioxane at 90°C.
Initial concn. of BA: 0.02 M,
concn. of TED: 0.005 M

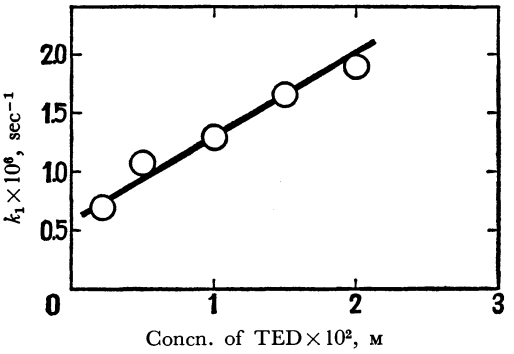

Fig. 6. The plots of k_1 *vs.* concentration of TED for the TED-catalyzed transamidation of DPU with BA in dioxane at 90°C.
Initial concn. of DPU and BA: 0.02 M

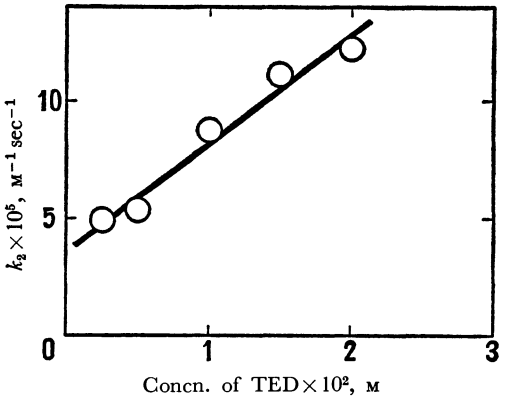

Fig. 7. The plots of k_2 *vs.* concentration of TED for the TED-catalyzed transamidation of DPU with BA in dioxane at 90°C.
Initial concn. of DPU and BA: 0.02 M

Hence, the k_1 and k_2 rate constants should be expressed as follows:

$$k_1 = k_1' + k_2'[\mathrm{TED}] \quad (2)$$

$$k_2 = k_2'' + k_3[\mathrm{TED}] \quad (3)$$

The total kinetics is, therefore, given by following equation:

$$v = \{k_1' + k_2'[\mathrm{TED}]\}[\mathrm{DPU}] + \{k_2'' + k_3[\mathrm{TED}]\}[\mathrm{BA}][\mathrm{DPU}] \quad (4)$$

The values of $k_1'\times10^6$ sec^{-1}, $k_2'\times10^5$ M^{-1} sec^{-1}, $k_2''\times10^5$ M^{-1} sec^{-1}, and $k_3\times10^3$ M^{-2} sec^{-1} were 0.57, 7.00, 3.50, and 4.69 respectively. The first and second rate constants are those of the hydrolysis of DPU in the absence and in the presence of TED as a catalyst. The values agree well with the experimental values of 0.56×10^{-6} sec^{-1} and 6.85×10^{-5} M^{-1} sec^{-1} obtained by the non- and the TED-catalyzed hydrolysis of DPU respectively (see Fig. 8). The conversions of the non- and the TED-catalyzed hydrolysis were *ca.* 6 and 30% respectively in the reaction heated at 90°C for 90 hr.

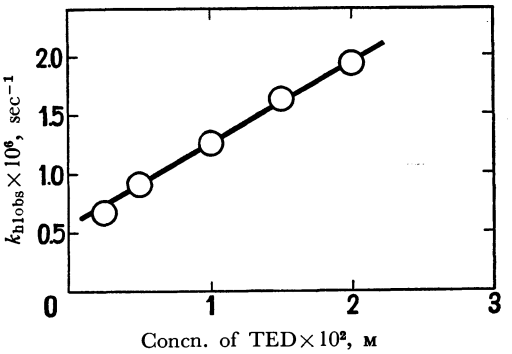

Fig. 8. The plots of k_{h1obs} *vs.* concentration of TED for the TED-catalyzed hydrolysis of DPU in dioxane at 90°C.
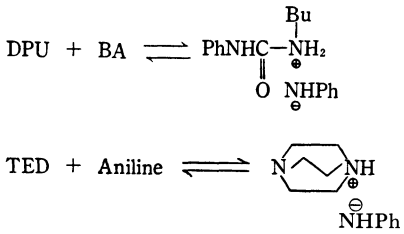
Initial concn. of DPU: 0.02 M.

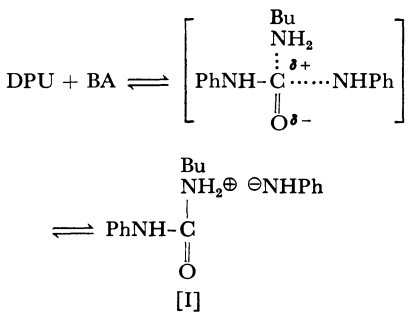
The reaction is accelerated by a tertiary amine, especially TED. The conductivities of the couples of (DPU+TED) and (DPU+BA) are larger than the sum of the conductivities of the components, as is shown in Table 1. In the couples of (DPU+TED) heated at 90°C for 0 and 90 hr, the existence of quaternary ammonium salt was indicated by Wagner's and Dragendorff's reagents. The couple of (BPU+TED) heated for 0 hr indicates weakly the formation of quaternary ammonium salt by Dragendorff's reagent. No positive results were obtained in the couple of (DPU+BA) and/or (Aniline+TED) by Wagner's, Mayer's, and Dragendorff's reagents, for these couples do not form the quaternary ammonium salt. The conductivities of these couples probably depend on the formation of the ion pairs like a quaternary ammonium salt.



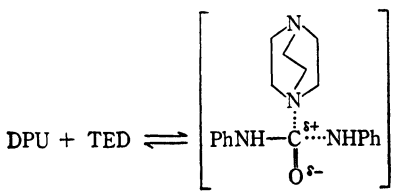
From these findings, a probable mechanism, which involves the nucleophilic attack by the lone pair of the N-atom of amine on the carbonyl C-atom of DPU, followed by the formation of a quaternary ammonium-type ion pair, may be suggested as follows:

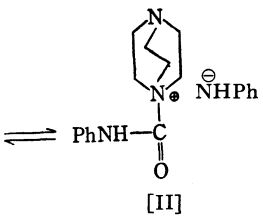
Transamidation

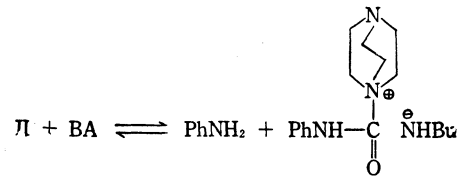
Non-catalyzed



TED-catalyzed

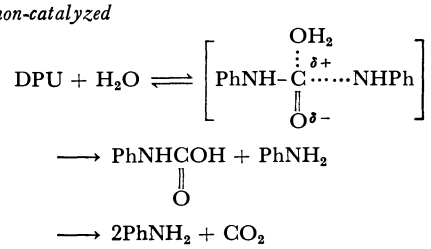




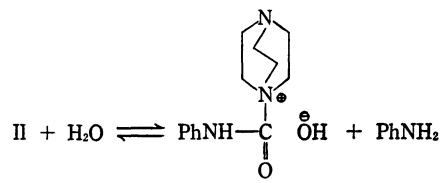


Hydrolysis

non-catalyzed



TED-catalyzed



The authors are grateful to Mr. U. Ueda and Miss N. Araki for their aids in performing the work, and also to Mesei & Co. Ltd. for his gift of material.

Aminosugars. XVII. Synthesis of Benzyl 2-Acetamino-2-deoxy-α-D-glucopyranosiduronic Acidamides and *N*-(2-Acetamino-2-deoxy-D-glucuronyl)-aminoacids[1]*

Juji YOSHIMURA, Tadahide SATO and Hiroaki ANDO

Laboratory of Chemistry for Natural Products, Faculty of Science, Tokyo Institute of Technology, Meguro-ku, Tokyo

(Received February 13, 1969)

Benzyl 2-acetamino-2-deoxy-α-D-glucopyranosiduronic acid was obtained by direct oxidation of the corresponding glucoside, and converted to esters (methyl, ethyl and benzyl) and amides (methyl, ethyl, phenyl and benzyl). Condensation of the uronic acid with aminoacid benzylesters (gly, L-ala, L-asp, and L-glu) by dicyclohexylcarbodiimide gave the corresponding amides, some of which were hydrogenated to *N*-(2-acetamino-2-deoxy-D-glucuronyl)-aminoacids. Acid hydrolysis of the peptides were examined.

Hexosaminuronic acids which attract attentions as a polyfunctional sugar have been recently found in V_1-antigen of *Salmonella typhosa*[1] and other natural sources.[2] Heyns and Paulsen[3] first succeeded in the catalytic oxidation of methyl and benzyl 2-(benzyloxycarbonyl)amino-2-deoxy-α-D-glucopyranoside to the corresponding uronic acid in about 40% yield, using gaseous oxygen in the presence of platinum charcoal in a weakly alkaline solution, but had no success in the catalytic oxidation of the corresponding 2-acetamino-2-deoxy derivative. A few years later, Marsh and Levvy[4] obtained phenyl 2-acetamino-2-deoxy-α- and -β-D-glucopyranosiduronic acid in a yield of 29 and 49%, respectively, by a similar method using platinum oxide. Recently, Weidmann and Zimmerman[5] improved the method of Heyns and Paulsen,[3] and synthesized several derivatives of 2-acetamino-2-deoxy-D-glucuronic acid, starting from benzyl 2-(benzyloxycarbonyl)amino-2-deoxy-α-D-glucopyranosiduronic acid.

We synthesized several esters and amides of benzyl 2-acetamino-2-deoxy-α-D-glucopyranosiduronic acid (**1**) which was derived from the corresponding glucoside by direct oxidation, and in connection with our studies[6] on the carbohydrate-aminoacid linked compounds, carried out synthetic and hydrolytic works on *N*-(2-acetamino-2-deoxy-D-glucuronyl)aminoacids.

Results

Benzyl 2-acetamino-2-deoxy-α-D-glucopyranoside which was obtained in an excellent yield by an improved method of Kuhn *et al.*,[7] was oxidized by the method of Heyns and Paulsen[3] until the starting material was consumed, and the solution was filtered, deionized, and evaporated to give **1** in 70—90% yield. The use of secondary alcohols as an antiforming agent and antioveroxidant improved the yield.

Condensation of **1** with methanol, ethanol or benzyl alcohol in benzene by refluxing and azeotropic removal of water formed gave the corresponding esters (**2**, **3** and **4**) in about 50% yield. Treatment of **1** with saturated methanolic ammonia in a sealed tube at 90°C for 2 hr gave the corresponding amide (**5**) in a quantitative yield, which was identical with that synthesized by Weidmann and Zimmerman[8] from benzyl 2-(benzyloxycarbonyl)amino-2-deoxy-α-D-glucopyranosiduronic acid

Comparison of the NMR spectra (Figs. 1 and 2) of 3,4-di-*O*-acetyl derivative of **6** and **9** (**6'** and **9'**) made the first-order analysis possible. Common signals to both figures, *i. e.*, the doublet at 4.28τ (J_{2,C_2-NH}=9.8 Hz), the quintet at *ca.* 4.81 τ (H_3: 4.72 τ; H_4: 4.90τ; $J_{2,3}=J_{3,4}=J_{4,5}$=10.0 Hz), the doublet at 5.01 τ ($J_{1,2}$=3.2 Hz), the AB-quartet at 5.30 and 5.53 τ ($J_{A,B}$=12 Hz), the sextet at 5.75 τ, and the doublet at *ca.* 5.80 τ in the former, and those at 4.25 τ ($J_{2,-C_2NH}$= 9.5 Hz), at *ca.* 4.69 τ (H_3: 4.61 τ; H_4: 4.76 τ; $J_{2,3}=J_{3,4}=J_{4,5}$=9.5 Hz), at 4.95 τ ($J_{1,2}$=3.5 Hz), at 5.23 and 5.46 τ ($J_{A,B}$=12 Hz), at *ca.* 5.66 τ, and at *ca.* 5.53 τ in the latter were respectively assigned to C_2-NH, partly superimposed H_3 and H_4, H_1, C_1-OCH_2, H_2, and H_5 protons from the intensity ratio and the aids of the double resonance technique. The broad signal at *ca.* 3.7 τ and the doublet at 7.22 τ in the former and the broadend-triplet at 3.30 τ in the latter were assigned to C_6-NH, N-CH_3 ($J_{C_6-NH,\ N-CH_3}$=6Hz), and C_6-NH protons, respectively.

Condensation of **1** with *p*-toluenesulfonates of amino acid benzylester (amino acid: glycine, L-alanine, L-aspartic acid, and L-glutamic acid) in pyridine by DCC method gave the corresponding amides (**10, 11, 12** and **13**) in 20–30% yield, of which **10** and **13** were successfully hydrogenated in the presence of palladium-charcoal and a small amount of hydrochloric acid in methanol to give *N*-(2-acetamino-2-deoxy-D-glucuronyl)-glycine and L-glutamic acid (**14** and **15**), but the corresponding compounds for **11** and **12** could not be purely isolated.

The physical constants, analyses and yield of new compounds obtained here are summarized in

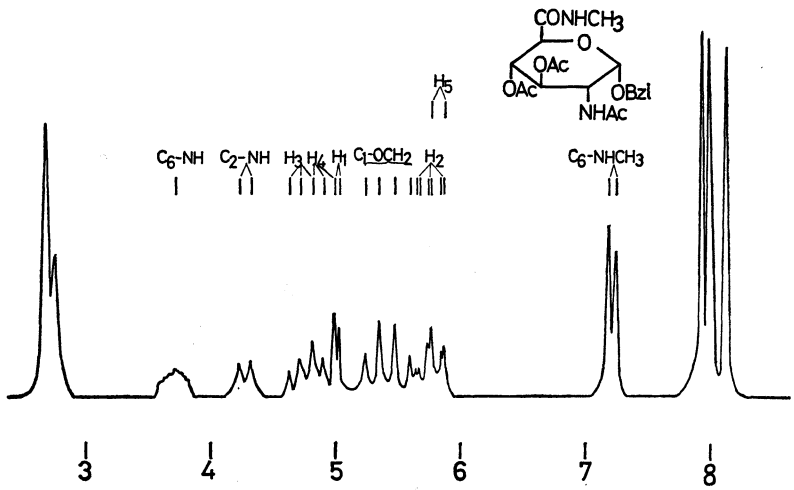

Fig. 1. MNR spectra of benzyl 2-acetamino-2-deoxy-3,4-di-*O*-acetyl-α-D-glucopyranosiduronic acid methylamide (100 Mc, $CDCl_3$).

Table 1.

In order to compare the stability of *N*-(2-acetamino-2-deoxy-D-glucuronyl)-amino acid with that of other carbohydrate-amino acid compounds having peptide bond, **14** and **15** was hydrolysed in 2 N hydrochloric acid at 100°C, and glycine and L-glutamic acid liberated was estimated at suitable intervals with an amino acid analyser. The first-order rate constant of **14** and **15** was 4.45 and 4.25×10^{-3} min^{-1}, respectively. These values indicate that the stability of the peptide bond between the uronic acid and amino acid is the same order as that of *N*-aminoacyl-D-glucosylamine and *N*-aminoacyl-D-glucosamine,[10] and consequently, the oxo-structure of sugar moiety has no effect on the stability of the peptide bond in the same molecule.

Experimental

All melting points were uncorrected. The solutions were evaporated under diminished pressure at a bath temperature usually not exceeding 45°C. Optical rotations were measured in a 0.5-dm tube at 578 mμ with a Carl-Zeiss Polarimeter. The content of water of crystallization was calculated from the analytical

10) G. S. Marks, R. D. Marshall and A. Neuberger, *Biochem. J.*, **87**, 274 (1963); J. Yoshimura and H. Hashimoto, *Carbohyd. Res.*, **4**, 435 (1967).

values.

Benzyl 2-Acetamino-2-deoxy-α-D-glucopyranoside. A suspended solution of 2-acetamino-2-deoxy-D-glucose (80 g, 0.36mol) in benzyl alcohol (900 m*l*) and boron trifluoride etherate (10 m*l*) was heated for 2 hr at 95—100°C, and after the addition of hydrogen chloride (2 g) in benzyl alcohol (100 m*l*) the solution was again heated for 1 hr at the same temperature. After cooling, the reaction mixture was poured into ether (500 m*l*) and filtered. The precipitate was dissolved in water (1 *l*) and the solution was extracted with ether to remove benzyl alcohol. The water layer was evaporated, and the residue was treated with charcoal in ethanol, crystallized by the addition of ether to give 80 g (67%) of fine crystals. Mp 182—183°C, $[\alpha]_D^{23}$ 178° (*c* 1, water) (Lit,[7] mp 183—184°C).

When the reaction mixture was directly evaporated without being poured into ether, and treated by the same procedure, the crystals weighed 97 g (85%). In the course of evaporation, the deposition of a small amount of benzyl 2-acetamino-2-deoxy-4,6-*O*-benzylidene-α-D-glucopyranoside[11] was always observed.

Benzyl 2-Acetamino-2-deoxy-α-D-glucopyranosiduronic Acid (1). In a four-necked flask equipped with stirrer, reflux condenser, dropping funnel, and in-let capillary was placed benzyl 2-acetamino-2-deoxy-α-D-glucopyranoside (25 g, 80 mmol) and platinum-charcoal (10%, 15 g) in water (500 m*l*), and air or oxygen was blown into the solution with violent stirring at 95°C, under the adjustment of pH at 6.8—7.7 with sodium bicarbonate solution. A secondary alcohol such as isopropyl alcohol or isobutyl alcohol was added at a suitable interval as an antifoaming agent and antioveroxidant, and the reaction was continued until the starting material had disappeared on TLC. After cooling, the catalyser was filtered off, and the solution was evaporated. The residue was extracted with ethanol to remove the starting material and dissolved in water. The solution was deionised with Amberlite IR-120 and evaporated to give a sirup which was decolorized and crystallized from ethanol. Yield, 19 g (77.3%). The second crop (3.7 g, 15.6%) was obtained from the mother liquid.

Benzyl 2-Acetamino-2-deoxy-α-D-glucopyranosiduronic Acid Esters (2, 3 and 4). The solution of benzyl 2-acetamino-2-deoxy-α-D-glucopyranosiduronic acid (2 g, 6.2 mmol) in an alcohol (20 m*l* of methanol, ethanol or benzyl alcohol) and benzene (200 m*l*) was refluxed on a boiling water bath for 3 hr, and the water formed was removed azeotropically. The solution was evaporated and the sirup obtained was crystallized from a small amount of hot ethanol and ether. The physical constants, analytical data and yields of these compounds are shown in Table 1.

Benzyl 2-Acetamino-2-deoxy-α-D-glucopyranosiduronic Acidamide (5). The uronic acid (28 g, 86 mmol) was heated with methanolic ammonia (200 m*l*) at 90°C for 2 hr in a sealed tube, and the solution was evaporated. Crystallization of the residual sirup from ethanol (20 m*l*) gave the amide in a quantitative yield. Mp 242°C, $[\alpha]_D^{17}$ 178° (*c* 1, water) (Lit,[9] mp 243°C)

Found: C, 55.86; H, 6.43; N, 8.57%. Calcd for $C_{15}H_{20}O_6N_2$: C, 55.55; H, 6.22; N, 8.64%.

Benzyl 2-Acetamino-2-deoxy-α-D-glucopyranosiduronic Acid Methyl- and Ethylamide (6 and 7). A solution of the uronic acid (2 g, 6.2 mmol) and methylamine or ethylamine (2 m*l* of 40% aqueous solution) in a large amount of methanol was stirred at room temperature for 12 hr, and evaporated to give a sirup which was crystallized from a small amount of hot acetone and ether. The physical constants, analytical data and yields are shown in Table 1.

Benzyl 2-Acetamino-2-deoxy-α-D-glucopyranosiduronic Acid Anilide and Benzylamide (8 and 9). A solution of the uronic acid (3.2 g, 9.9 mmol), dicyclo-hexylcarbodiimide (2.5 g, 12 mmol) and aniline (1.1 g, 12 mmol) or benzylamine (1.3 g, 12 mmol) in pyridine was agitated for 2 days, and dicyclohexylurea deposited was filtered off. The filtrate was evaporated, and the sirup obtained was crystallized from a small amount of methylene chloride and ether. Several data on these compounds are shown in Table 1.

Benzyl 2-Acetamino-2-deoxy-3,4-di-*O*-acetyl-α-D-glucopyranosiduronic Acidnitrile. Benzyl 2-acetamino-2-deoxy-3,4-di-*O*-acetyl-α-D-glucopyranosiduronic acidamide (0.5 g, 1.2 mmol) prepared from **5** by the procedure of Zimmerman *et al.*[9] was heated with *p*-toluenesulfonyl chloride (1.17 g, 6 mmol) in pyridine (7 m*l*) for 3 hr at 80—90°C. After cooling, the solution was poured into ice-water (100 m*l*) and extracted three times with chloroform (50 m*l*). The combined extracts was washed in turn with 1 N hydrochloric acid, sodium bicarbonate and water, dried and then evaporated. The sirup (0.5 g) obtained was crystallized from ethanol and ether. Yield, 0.3 g (63%), mp 165—165.5°C (Lit,[9] mp 159°C).

Found: C, 58.15; H, 5.33; N, 6.98%. Calcd for $C_{19}H_{22}O_7N_2$: C, 58.45; H, 5.68; N, 7.18%.

Benzyl 2-Acetamino-2-deoxy-3,4-di-*O*-acetyl-α-D-glucopyranosiduronic Acid Methylamide and Anilide (6′ and 9′). Acetylation of **6** and **9** with 4 mol equivalent of acetic anhydride in the same amount of pyridine was carried out in the usual manner. The physical constants, analyses and yield are shown in Table 1.

***N*-(Benzyl 2-Acetamino-2-deoxy-α-D-glucopyranosiduronyl)-aminoacid Benzyl Esters (10, 11, 12 and 13).** A solutions of the uronic acid (6.5 g, 20 mmol) and DCC (5 g, 24 mmol) in pyridine was added to a chilled solution of amino acid benzyl ester *p*-toluene sulfonate (each 20 mmol of gly, L-ala, L-asp and L-glu) and triethylamine (2 g, 20 mmol) in pyridine with stirring. After standing the solution at room temperature for 2 days, dicyclohexylurea separated was filtered off, and the filtrate was evaporated to give a sirup which was crystallized from a small amount of hot ethanol, and recrystallized from methylene chloride. The physical constants, analytical data and yield are listed in Table 1.

***N*-(2-Acetamino-2-deoxy-D-glucuronyl)-glycine and -L-glutamic Acid (14 and 15).** A solution of **10** or **13** (0.5 g) and palladium-charcoal (0.5 g) in aqueous ethanol was adjusted to pH 2 with diluted hydrochloric acid and hydrogenated until the theoretical amount of hydrogen was taken up. The catalyst was filtered off, and the filtrate was evaporated to give a sirup which was purified from ethanol and ether. Several data on these compounds are listed in Table 1.

Hydrolysis of *N*-(2-Acetamino-2-deoxy-D-glucu-

11) J. Yoshimura, M. Funabashi, S. Ishige and T. Sato, This Bulletin, **39**, 1760 (1966).

ronyl)-glycine and -L-Glutamic Acid. Each sample (22.5 μmol) was dissolved in 2 m*l* of 2 N hydrochloric acid, and the solution was heated at 100°C in a sealed tube. After 40, 60 and 80 min, the hydrolysate was analyzed with an amino acid analyzer Hitachi Model KLA-2, using a column packed with Amberlite CG-120 Type III, 1×50 cm; the eluent was 0.2 N citric buffer (pH 3.25) percolating at 30 m*l*/hr at 30°C. Glycine and glutamic acid were eluted with an elution time of 3.8 and 5.3 hr, and the amount was determined by comparison with standard. The first-order rate constant of **14** and **15** was 4.45 and 4.25×10^{-3} min^{-1}, respectively.

The authors are indebted to Mr. Kiyofumi Fukukawa of our Laboratory for the NMR measurements.

Hot-Atom Chemistry of Bromine. II.[1] Application of the Szilard-Chalmers Process to Organic Molecular Compound-Pyrenebromanil and Related Compounds[2]

Chiro SHINOMIYA, Akira OYOSHI and Toshiaki KISHIKAWA

Department of Industrial Chemistry, Faculty of Engineering, Kumamoto University, Kurokami-cho, Kumamoto

(Received July 10, 1968)

In spite of a number of investigations of the application of the Szilard-Chalmers process[3] to organic halogen compounds, no organic molecular compounds have been tested. Two of the present authors (C. S. and T. K.) have previously reported[4] the formation of organic radiobromides activated by the ^{82m}Br-isomeric transition in a solid mixture of a bromine-benzene-molecular compound and benzene. The present note will deal with the chemcial effects of the recoil bromine atoms in pyrenebromanil (1 : 1).[5] It has a sandwich-type structure composed of pyrene and bromanil (tetrabromo-*p*-benzoquinone) molecules. The result will be compared with those on its related compounds—bromanil, bromopyrene, a pyrene-bromanil mixture, and others.

Experimental[6]

Materials. The 1 : 1 molecular compound-pyrene-bromanil (P−B) was prepared by mixing equimolar solutions of pyrene (P) and bromanil (B), both in toluene. The 1 : 1 mixture of P and B (P+B) was prepared by pestling the components on an agate mortar. Bromo derivatives[7] of P (PBr_n) were prepared and purified according to Lock[8] and Hock[9] respectively. 2-Bromohydroquinone (HQBr) was prepared according to Sarauw.[10]

Neutron Irradiation. Irradiation was carried out at the reactor temperature (*ca.* 40°C) in a pneumatic tube of KUR[11] with a thermal neutron flux of 5×10^{12} n/cm^2/sec and with an accompanying γ-dose rate of 2.7×10^7 R/hr.

Extraction and Measurement of Radioactivity. After having been cooled for more than two hours[12] at room temperature, the sample was transferred into a separatory funnel containing a carbon disulfide solution of bromine. Then the inorganic species were separated by means of extraction into an aqueous mixture of bromide and bromate (I). The bromine (II) was back-extracted from the carbon disulfide layer (III). A carbon disulfide-insoluble residue which was filtered out was extracted, first with ethyl ether[13] (IV),

13) 2-Bromo-, 2,5- and 2,6-dibromo-*p*-benzoquinones are soluble in ethyl ether.

and then with benzene[14] (V).

The ^{82}Br activities in each layer were then measured. The total organic yield, defined as the percentage of activities remaining in the organic layers, is given by;

$$OY\ (\%) = \frac{\text{Activities in (III, IV and V)} \times 100}{\text{Activities in (I, II, III, IV and V)}}$$

Paper Chromatography and Paper Electrophoresis. In order to evaluate the distribution of the activities distributed in the layer (III), paper chromatography was carried out (on Toyoroshi No. 50 filter-paper by the ascending method, with *i*-AmOH-Py-H_2O 3 : 2 : 1.5 in V/V as developer). The distribution of the activities on the paper strips was examined by autoradiography. Readioactive bands on them corresponding to the autoradiograph patterns were cut in pieces, and the activities were counted.

The water-soluble species distributed in the layer (I) were analyzed by paper electrophoresis[1] (on Toyoroshi No. 50 filter-paper with a potential gradient of 54.5 V/cm and with 0.1 M aqueous ammonium acetate as the electrolyte solution), followed by autoradiography and measurement of the activity.

Results and Discussion

The relationship between the percentage of the ^{82}Br atoms remaining in the organic layers and the irradiation time is shown in Fig. 1. The extraction curve vary over a short period of irradiation (1—10 min), but the curves (except for P+B) seem to show no remarkable change with an increase in the irradiation time. This exception may be due to the difference in the composition of the target; *i. e.*, it is heterogeneous (mixture), where the others are all homogeneous (compounds).

The percentages of the activity distributed on the chromatographed strips are listed in Table 1.[15] In each sample, the relative activity in the components of R_f 0.12—0.17 decreased with an increase in the irradiation time, and *vice versa*. This may indicate that the distribution of the activities distributed in the layer (III) is affected by the irradiation period in the reactor.

Table 1. Distribution of ^{82}Br-labeled recoil products parted in carbon disulfide layer at two irradiation times

Target	Irra. time min	Yield, %, at R_f 0.12—0.17	Yield, %, at R_f 1
P−B	10	43.6	56.4
	30	41.5	58.5
P+B	10	70.7	29.3
	30	64.1	35.9
B	10	71.3	28.7
	30	69.4	30.6
PBr	10	0	100
	30	0	100
PBr_2[a]	10	35.8	64.2
	30	25.8	74.2
HQBr[a]	10	71.5	28.5
	30	62.0	38.0

a) Dissolved in carbon disulfide. No extraction.

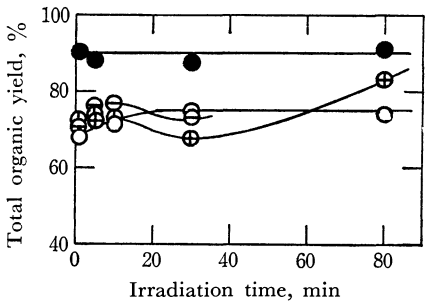

Fig. 1. Total organic yield as a function of the irradiation time.
⊖: pyrenebromanil, ⊕: pyrene-bromanil mixture, ○: bromanil, ●: bromopyrene

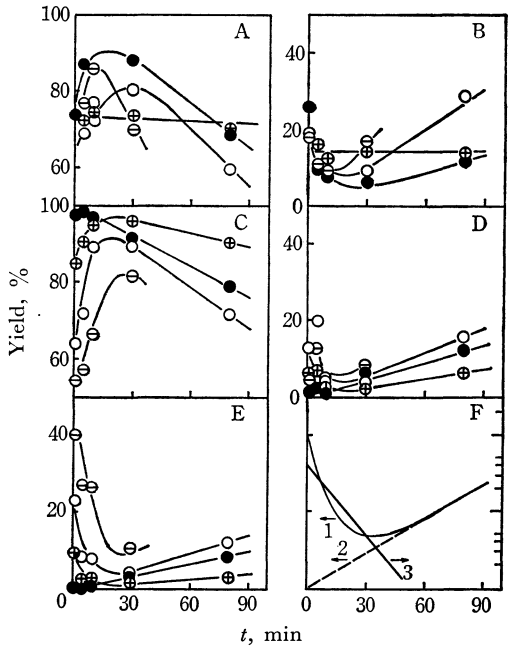

Fig. 2. Distribution of activities parted in aqueous or organic layers as a function of the irradiation time. A and B are distribution of bromide and bromine in the aqueous layers respectively. C, D and E are distribution of activities parted in the carbon disulfide, the ethyl ether and the benzene layers respectively. F is a schematic view of the analysis of a curve.
⊖: pyrenebromanil, ⊕: pyrene-bromanil mixture, ○: bromanil, ●: bromopyrene.

14) 1-Bromo-, 1,6- and 1,8-dibromo-, and 1,3,6-tribromopyrenes are soluble in benzene.

15) The standard R_f values were not determined. The present research was made on the distinction of distribution patterns of the recoil products for the two irradiation times.

TABLE 2. DISTRIBUTION OF ^{82}Br-LABELED RECOIL PRODUCTS PARTED IN AQUEOUS LAYERS AT VARIOUS IRRADIATION TIMES

Target	Irra. time, min	Yield,[a] %			
		Br_2	Br^-	Sum of unknowns	Origin[b]
P−B	5	10.5	76.8	6.4	6.3
	10	9.4	85.5	4.2	0.0
	30	16.6	70.1	12.4	0.8
P+B	5	15.3	72.2	9.6	3.1
	10	13.1	74.8	8.3	1.9
	30	14.2	73.6	14.5	1.4
	80	13.9	70.0	10.5	4.7
B	5	10.7	68.2	—	6.4
	10	12.9	72.6	10.2	1.0
	30	8.5	80.0	8.8	1.2
	80	28.6	59.2	10.2	1.8
PBr	5	9.9	87.0	0	0.6
	10	8.4	83.5	0	7.4
	30	6.2	87.9	0	2.1
	80	11.9	68.4	0	19.5
PBr_2[c]	10	—	41.8	0	53.7
	30	—	55.8	0	37.4
	80	—	56.3	0	33.5
HQBr[c]	5	—	39.8	27.4	20.1
	10	—	65.1	12.4	19.2
	30	—	58.3	19.7	26.5
	80	—	47.1	4.7	31.4

a) The relative yield was calculated from activities in the aqueous layers I and II. The values of Br^-, sum of unknowns and origin were calculated from activities distributed on the paper electrophoregrams. The sum of less than 100% was due to a "smear" of activity extending.[16]

b) Yield on an original spot may be of bromine and/or an organic bromide which has remained in the layer I.

c) Dissolved in carbon disulfide. The paper electrophoresis was carried out without extraction.

Among the samples, PBr, PBr_2, and P−B showed higher relative activities at the component of R_f 1, while the rest, B, HQBr, and P+B, showed more at the components of R_f 0.12—0.17. As compared with B, the distribution of P+B is not definitely affected when P is mixed in. When P−B is compared with P+B, on the other hand, the contribution of P is clear. The greater values at the component of R_f 1 in the irradiated P−B suggest the presence of a pyrene-radiobromine combination.

Table 2 lists the distribution of the ^{82}Br-labeled recoil products among the irradiated samples distributed in the aqueous layers (I and II) at various irradiation periods. In each case the major portion of the activities was found in the form of bromide. Three or four components, the mobilities of which were comparatively small, were obtained on paper strips of B, P−B, P+B, and HQBr. These components were not obtained on strips of PBr and PBr_2. These facts suggest that the components may be fragments of organic radiobromides originating in bromanil.

Figure 2 shows the relationship between the percentages of the ^{82}Br activities distributed in the aqueous or the organic layers and the irradiation time. The curves of the bromide and the bromine in P+B (see Figs. 2A and B) show a less remarkable change with the irradiation time. This may be because of the different behavior of the curve of its total organic yield.

The curves decreased (or increased) with an increase in the irradiation time. The longer the irradiation period, the better the (negative) proportionality to the irradiation time the curves seemed to show. To analyze the curve (see Fig. 2F) the final proportional portion was extrapolated back to time zero; on substracting the extrapolated line (2) from the original curve (1), another straight line (3) on a semilogarithmic scale was obtained. From the analyses of the curves, the following experimental equations were established;

$$Y = Y_0 \cdot e^{-rt} + mt \qquad (m>0)$$

16) J. Jack and G. Harbottle, *Trans. Faraday Soc.*, **54**, 520 (1958).

or; $Y = Y_0 \cdot e^{-rt} + mt + (1 - e^{-rt}) \quad (m<0)$

where Y, Y_0, m, and r are the yield at time t, the initial yield, the proportion constant, and the inclination of the semilogarithmic plot respectively. The quantitative treatment of such values as Y_0, m, and r should be discussed primarily on the basis of the theoretical derivation as functions of the reactor irradiation time and other considerable parameters. This question will be discuss in another paper.

The authors are indebted to Dr. Shiro Iwata, Dr. Yoshiyuki Kiso, and the personnel of the Research Reactor Institute, Kyoto University, for their assistance in the irradiation, and also to Mr. Masaya Tanizaki of their laboratory for his assistance in the experimental work.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 2359—2361 (1969)

Benzyne Addition Induced Rearrangement to *N*-Methyl-*N*-(1-phenethyl)aniline*[1]

Angelo G. GIUMANINI

Istituto di Chimica Organica ed Industriale, Università di Bologna, 40136 Bologna, Italy

and Arthur R. LEPLEY

Department of Chemistry, Marshall University, Huntington, West Virginia 25701, U.S.A.

(Received April 25, 1968)

In a continuing interest in the chemistry of α-dialkylamino carbanions and nitrogen ylids, we have studied the reaction between *N,N*-dimethylbenzylamine (DMBA) and benzyne, the latter being generated *in situ* by means of the reaction of a phenyl halide (Hal=F or Cl) and *n*-butyllithium. This technique, previously applied by the present authors to the system fluorobenzene/*n*-butyllithium/*N,N*-dimethylaniline,[1] allowed to predict that an *ortho*-ylid I formed which, in turn, could quickly isomerize to the *N*-ylids II and III by a prototropic shift. The ylids II and III are the postulated intermediates to the observed products IV and V of the reaction of the benzyldimethylanilinium ion VI with *n*-butyllithium[2] (Scheme 1). In the frame of this schematic and simplified picture, the environmental and physicochemical conditions for the generation of II and III should be closely similar for the two routes. It was therefore expected that the rates of the possible reactions involved[2] would closely parallel for the two cases, a fact that must be reflected into final product distribution. In a series of experiments with VI and *n*-butyllithium, we found[2] V to VI ratios between 0.81: 1 and 9.4 : 1 depending on experimental conditions.

In a related work by Jones *et al.* using VI and sodamide, only V was detected.[4]

We have now found in a preliminary study of the reaction in question that the benzyne generated betaine I affords practically a single (Stevens) rearrangement product, IV, as inequivocably shown by vapour phase chromatographic analysis[5] of the crude mixture combined with product separation and conventional analytical techniques. It also appears that no significant amounts of *o*-rearranged amine VII (Sommelet rearrangement) are present. Infrared and nuclear magnetic resonance spectral evidences ruled out that the isolated amine contained either product of 1,3 migration directly derived from the primary betaine I, apparently a very elusive compound, namely VIII and IX. Authentic IV was synthetized through an independent route[6] for definitive comparison.

There still remain the possibilities of direct displacement of the halogen atom by metallated

*1 This work was supported by U. S. Public Health Service grant GM-09136 from the National Institute of General Medical Science and the National Research Council of Italy. Parts of the work were presented before the 145th National Meeting of the American Chemical Society and the 10th National Meeting of the Italian Chemical Society.

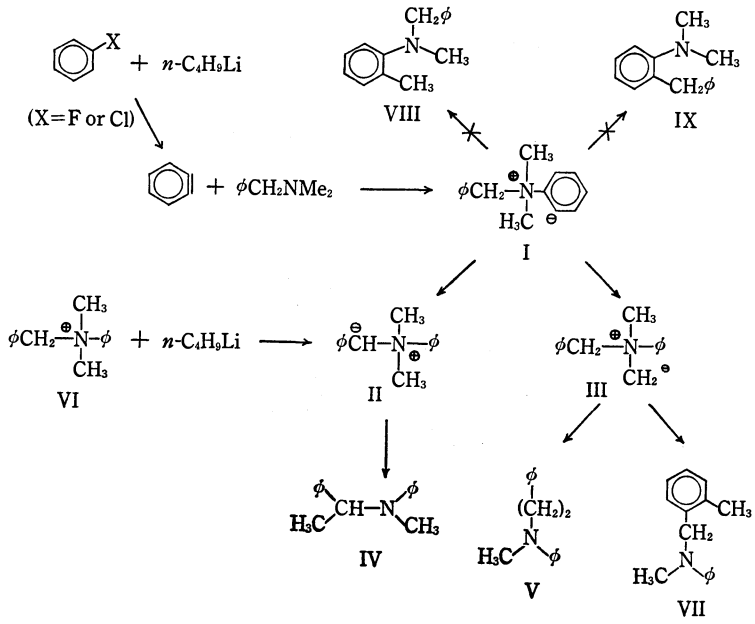
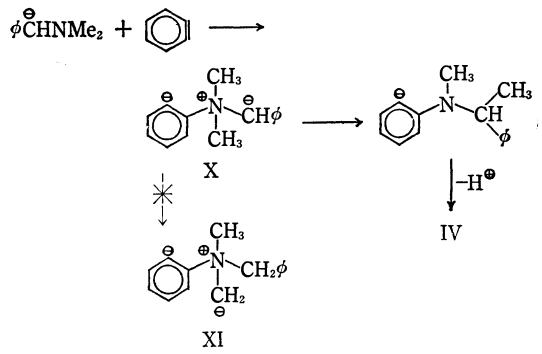


Scheme 1.

amine and of a benzyne reaction of the latter.[7] Indeed, BDMA reacts with *n*-butyllithium as evidenced by the bright colour appearing upon mixing with *n*-butyllithium. Once again the spectral characteristics of the separated amine ruled out such a hypothesis. The proton resonance spectrum indicated two methyls (a doublet centered at 1.46 ppm and split by methine with $J=6.7$ cps and a singlet at 2.56 ppm), a methine (quartet centered at 5.03 ppm and split by methyl with $J=7.0$ cps) and a phenyl (broad multiplet centered at 6.92 ppm) with relative intensities in the ratio 3/3/1/10.

Since the chromatic reaction between BDMA and *n*-butyllithium is instantaneous, it seems reasonable to conclude that either the metallated amine generates the benzyne to which it subsequently adds or the benzyne generated by excess butyllithium reacts with the metallated amine to yield the benzyl betaine anion X.



Scheme 2.

Since only a methyl shift occurs to produce IV, it is likely that the dianion X is involved in the rearrangement and at such a rate that prototropic shift to the methyl betaine anion XI cannot compete. Formation of ylid anions in the reactions of quaternary ammonium salts was previously advanced.[8]

To generate the benzyne, both chlorobenzene and fluorobenzene were used. The latter gave a better absolute yield in the rearranged amine (33% *vs.* 18%).

Experimental[9]

Chemicals. The best available grades of halobenzenes were used without purification. BDMA was a greatly appreciated gift of Miles Chemical Co. *n*-Butyllithium, 15% in hexane, was obtained from Foote Mineral Co. or prepared from 1-chlorobutane (Erba, Italy) and Li (Merk, W. Germany) in hexane under hydrogen.

Preparation of *N*-Methyl-*N*-(1-phenethyl)aniline (IV). *n*-Butyllithium (200 m*l*, 15%) was stirred and a solution of 200 m*l* BDMA in 400 m*l* anhydrous ether was rapidly added. The solution instantly turned bright yellow. Fluorobenzene (0.2 mol) in 150 m*l* ether

8) A. R. Lepley and A. G. Giumanini, *J. Org. Chem.*, **32**, 1706 (1967).

9) Essential experimental data are presented here. Further details and progresses of the research will be given at a later date. Physical properties (infrared and PMR spectra, refractive indexes and specific gravities) were measured in the standardized method previously described, *loc. cit.* and related analytical methods: A. R. Lepley, *Anal. Chem.*, **34**, 322 (1962); A. R. Lepley and W. A. Khan, *J. Org. Chem.*, **31**, 2064 (1966).

was added in one lot. After 15 min a heavy precipitation of salt was observed. The stirring was continued at 26°C for 24hr. Then 150 m*l* of water was added slowly with cooling, the ether layer was separated, dried over potassium hydroxide and distilled. A 33% yield was obtained of product boiling 181—2°C/20 Torr, $n_D^{25°}$ 1.5946. Gas chromatography showed less than 3% impurity in this product. The product was identical with material prepared by reaction of 1-bromoethylbenzene and *N*-methylaniline.

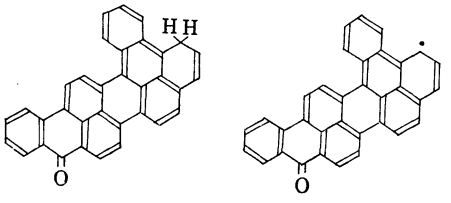
The Paramagnetism of Violanthrone-B

Tsuneo MAEKAWA

Department of Chemistry, College of General Education, The University of Tokyo, Komaba, Meguro-ku, Tokyo

(Received September 18, 1968)

It is well established that the compound named violanthrone-B is a mixture of $C_{34}H_{18}O$ (I) and $C_{34}H_{17}O$ (II). The formula (I) has been suggested by Aoki[1] and the shape of the carbon skeleton of (I) and (II) has been proved to be right by the author with X-ray analysis.[2] In a previous paper[3] the magnetic and some other physicochemical behaviors of violanthrone-B were reported. The present paper deals with the temperature dependence of the paramagnetism of the compound in a lower temperature region.



(I) (II)

Violanthrone-B was recrystallized from a solution in *o*-dichlorobenzene. Washed by ethanol, the precipitate was dried for several hours at 80°C under a pressure of 10^{-5} mmHg. Although this procedure of purification was much shorter than that reported in the previous paper, this method was sufficient to prepare the specimens for the measurement of the magnetic susceptibility.

The magnetic susceptibility was measured by the Faraday method. For the measurement of force on the specimen, the vacuum microbalance of Sartorius was used. The powdered sample was placed in a quartz container, which was suspended with a fine quartz rod from the balance arm and was placed at the point of the maximum field strength. A Faraday type magnet was used. For the temperature measurement the gold-cobalt alloy *vs.* copper thermocouple was used. The measuring-junction was placed under the quartz container as close as possible, since the maximum safe load of the balance was so small that we could not hang the thermocouple wire on the balance arm. In order to make uniform the temperature around the specimen and the thermocouple junction, a cylinder of copper foil was inserted around the specimen. The cryostat used was a simple double Dewar vessel type.

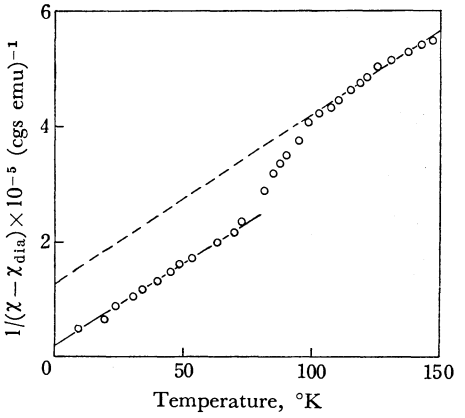


Fig. 1. The temperature dependence of the specific susceptibility of violanthrone-B.

We can summarize the result in Fig. 1, plotting the curve $1/(\chi-\chi_{dia})$ against T, where χ is the specific susceptibility, χ_{dia}, the diamagnetic part, for which the value estimated in the previous paper[3] is used, and T, the absolute temperature. The curve consists of two linear parts and both can be described by the Curie-Weiss law.

$$\chi = \frac{C}{T-\theta} + \chi_{dia} \qquad (1)$$

From the higher temperature region the Curie constant and the Curie temperature can be decided

1) J. Aoki, This Bulletin, **34**, 1817, 1820 (1961).
2) T. Maekawa, to be published.
3) H. Akamatu, T. Maekawa, Y. Iida and M. Kinoshita, This Bulletin, **37**, 849 (1964).

as

$$C=0.343\times10^{-3}\ \text{emu°K/g}$$
$$\theta=-41\text{°K}$$

which are nearly equal to the values reported before,[4] while from the lower temperature region we obtain

$$C=0.344\times10^{-3}\ \text{emu°K/g}$$
$$\theta=-5\text{°K}$$

It has been often observed that the magnetic susceptibility of the impure species becomes predominant at low temperature especially for the system of the singlet-triplet equilibrium.[5] In our case, however, the Curie constant observed at low temperature is equal to that of higher temperature, and consequently we obtain the constant density of the magnetic species in all the temperature region. It is accordingly conceivable that the magnetic behavior at low temperature of violanthrone-B is not because of any impurities but due to its own nature. It has been also observed for DPPH[6] that the Curie temperature changes very slightly at low temperature. These phenomena may be due to the phase transition of the crystal.

The author wishes to express his thanks to Professor Hiroo Inokuchi and Dr. Noriko Ohigashi for use of the equipment.

4) In the previous paper, Ref. 3, we decided the values $C=0.306\times10^{-3}$ emu°K/g and $\theta=-45$°K, where the magnetic susceptibility was measured also by the Faraday method over the temperature of liquid nitrogen up to the room temperature.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 2362—2363 (1969)

Contribution of Charge Transfer Structure to Exchange Interaction in the Crystal of Organic Free Radical

Tsuneo MAEKAWA

Department of Chemistry, College of General Education, The University of Tokyo, Komaba, Meguro-ku, Tokyo

(Received September 18, 1968)

It has been well known that the relatively high negative Curie temperature θ is often obtained from the susceptibility *vs.* temperature data for the crystalline-stable free radicals. For instance, $\theta=-17°K$[1] and $-45°K$[2] for DPPH and violanthrone-B, respectively. Furthermore, for a number of solid ionic aromatic free radicals such as TCNQ ionic radical[3] the large singlet-triplet splitting Δ has been observed in the ESR measurement. Both θ and Δ can be related to the exchange interaction J in the crystal. If we assume that every molecule in solid has interaction with one nearest neighbor, the relation can be derived by the Weiss field theory as

$$\Delta=2J=4k|\theta| \tag{1}$$

It seems improbable for the molecular crystals that such values of the Curie temperature or the S-T splitting are attributable to the simple exchange interaction. The large S-T splitting has been discussed by Hausser and Murrell[4] and McConnell[5] introducing the charge transfer structure of Mulliken type.

In the present paper we discuss the problem by the LCMO approach, which will give a simpler physical image.

The orbitals of the unpaired electrons of two interacting radicals A and B may be written in the form of LCMO as

$$\left.\begin{aligned}\varphi_A&=a\varphi_A{}^\circ+b\varphi_B{}^\circ\\ \varphi_B&=a\varphi_B{}^\circ+b\varphi_A{}^\circ\end{aligned}\right\} \tag{2}$$

in which $\varphi^\circ{}_{A,B}$ is the orbital for the isolated molecule. Then we have the wave function for a pair of radicals

$$\Psi_{AB}(1,2)=C[\varphi_A(1)\varphi_B(2)\pm\varphi_A(2)\varphi_B(1)] \tag{3}$$

4) K. H. Hausser and J. N. Murrell, *ibid.*, **27**, 500 (1957).

5) H. M. McConnell, "Molecular Biophysics," ed. by B. Pullman and M. Weissbluth, Academic Press, New York and London (1965), p. 317.

or

$$\Psi_{AB}(1,2) = c_1\Psi_1(1,2) + c_2\Psi_2(1,2) + c_3\Psi_3(1,2) \quad (4)$$

where

$$\left.\begin{aligned}\Psi_1(1,2) &= \varphi_A^\circ(1)\varphi_B^\circ(2)\\ \Psi_2(1,2) &= \varphi_A^\circ(2)\varphi_B^\circ(1)\\ \Psi_3(1,2) &= C'[\varphi_A^\circ(1)\varphi_A^\circ(2) + \varphi_B^\circ(1)\varphi_B^\circ(2)]\end{aligned}\right\} \quad (5)$$

C and C' are the normalization constants.

The secular equation derived from (4) is

$$\begin{vmatrix} H_{11}-W & H_{12}-S_{12}W & H_{13}-S_{13}W \\ H_{12}-S_{12}W & H_{11}-W & H_{13}-S_{13}W \\ H_{13}-S_{13}W & H_{13}-S_{13}W & H_{33}-W \end{vmatrix} = 0 \quad (6)$$

where the relations $H_{22}=H_{11}$, $H_{23}=H_{13}$ and $S_{23}=S_{13}$ are used. Readily factorized, Eq. (6) can be reduced to

$$\begin{vmatrix} \dfrac{H_{11}+H_{12}}{1+S_{12}} - W & \dfrac{H_{13}-S_{13}W}{1+S_{12}} \\ 2(H_{13}-S_{13}W) & H_{33}-W \end{vmatrix} = 0 \quad (7)$$

and

$$(H_{11}-H_{12}) - (1-S_{12})W = 0 \quad (8)$$

Equation (7) can be solved by the ordinary method of approximation and gives the energy of the lowest singlet state

$$W_s = W_s^\circ - \frac{2(H_{13}-S_{13}W_s^\circ)^2}{(1+S_{12})(H_{33}-W_s^\circ)} \quad (9)$$

corresponding to

$$c_1 = c_2, \quad c_3 \neq 0$$

where

$$W_s^\circ = \frac{H_{11}+H_{12}}{1+S_{12}} \quad (10)$$

On the other hand, from Eq. (8) we can obtain the solution for the triplet state

$$W_T = W_T^\circ = \frac{H_{11}-H_{12}}{1-S_{12}} \quad (11)$$

corresponding to

$$c_1 = -c_2, \quad c_3 = 0$$

W_S° and W_T° are the eigenvalues corresponding to the wave functions

$$\Psi_0^s(1,2) = \frac{1}{\sqrt{2+2S_{12}}}[\varphi_A^\circ(1)\varphi_B^\circ(2) + \varphi_A^\circ(2)\varphi_B^\circ(1)] \quad (12)$$

and

$$\Psi_0^T(1,2) = \frac{1}{\sqrt{2-2S_{12}}}[\varphi_A^\circ(1)\varphi_B^\circ(2) - \varphi_A^\circ(2)\varphi_B^\circ(1)] \quad (13)$$

respectively. Furthermore, it can be readily verified that Eq. (9) is equivalent to the equation obtained by Mulliken's method, that is, the eigenvalue for $\Psi = a\Psi_0^s + b\Psi_3$, while the triplet state is unaffected by the introduction of the charge transfer structure. This is the natural consequence resulting from Pauli's principle.

Finally, we can obtain the energy of the S-T splitting

$$\Delta = W_s - W_T = W_s^\circ - W_T^\circ - \frac{(H_{03}^s - S^s{}_{03}W_s^\circ)^2}{H_{33}-W_s^\circ} \quad (14)$$

where

$$H^s{}_{03} = \int \Psi_0{}^s H \Psi_3 d\tau, \quad S^s{}_{03} = \int \Psi_0{}^s \Psi_3 d\tau \quad (15)$$

If the higher orbitals $\varphi_A{}^1$ and $\varphi_B{}^1$ are taken into consideration, starting from

$$\left.\begin{aligned}\varphi_A &= a\varphi_A{}^\circ + b\varphi_B{}^\circ + c\varphi_B{}^1\\ \varphi_B &= a\varphi_B{}^\circ + b\varphi_A{}^\circ + c\varphi_A{}^1\end{aligned}\right\} \quad (16)$$

we can finally obtain

$$W_s - W_T = W_s^\circ - W_T^\circ - \frac{(H^s{}_{03} - S^s{}_{03}W_s^\circ)^2}{H_{33}-W_s^\circ} - \frac{(H^s{}_{01} - S^s{}_{01}W_s^\circ)^2}{H^s{}_{11}-W_s^\circ} + \frac{(H^T{}_{01} - S^T{}_{01}W_T^\circ)^2}{H^T{}_{11}-W_T^\circ} \quad (17)$$

where $H^s{}_{01}$, $S^s{}_{01}$, $H^T{}_{01}$, $S^T{}_{01}$, $H^s{}_{11}$ and $H^T{}_{11}$ are the quantities related to

$$\Psi_1{}^s = C''[\varphi_A^\circ(1)\varphi_A{}^1(2) + \varphi_A^\circ(2)\varphi_A{}^1(1) + \varphi_B^\circ(1)\varphi_B{}^1(2) + \varphi_B^\circ(2)\varphi_B{}^1(1)] \quad (18)$$

$$\Psi_1{}^T = C'''[\varphi_A^\circ(1)\varphi_A{}^1(2) - \varphi_A^\circ(2)\varphi_A{}^1(1) - \varphi_B^\circ(1)\varphi_B{}^1(2) + \varphi_B^\circ(2)\varphi_B{}^1(1)] \quad (19)$$

in which C'' and C''' are the normalization constants.

In Eq. (17) the fourth and the fifth terms on the right-hand side are the correcting terms of small value and tend to cancel each other. Thus, it seems to be probable that Eq. (14) is a good approximation for the S-T splitting. In Eq. (14) the last term on the right-hand side is the contribution of the intermolecular charge transfer structure. It should be noted that in this approximation the intermolecular charge transfer in the triplet state is absent owing to Pauli's principle.

Ultrasonic Effect on Phosphate Coating Formation*1

Takao UMEGAKI, Hiroshi ITO*2 and Taijiro OKABE

Department of Applied Chemistry, Faculty of Engineering, Tohoku University, Sendai

(Received October, 5, 1968)

The recent development of high power generators of ultrasonic wave has broadened its scope of application. If it is applied to the phosphatizing process, the cavitation caused by ultrasonic radiation in the phosphatizing solution is expected to prevent passivation of iron, and, removing hydrogen gas from the iron surface, to bring about a stirring effect. Ultrasonic cavitation is considered to eliminate the hindrance of Al^{3+} which has been recognized as one of the most undesirable contaminators when wet-process phosphoric acid is used as raw material for phosphatizing solution.[1] A few investigations of the ultrasonic effects[2-4] on the phosphate coating have been already reported, but the pH range of the phosphatizing solution and the condition of radiation for these investigations are limited. The present investigation has been undertaken to obtain the optimum condition for the formation of the phosphate coating under ultrasonic radiation.

Experimental

A) Phophatizing Solution. The phosphatizing solution was prepared by diluting phosphoric acid and dissolving a certain amount of $NaNO_3$, Na_2CO_3 and $Zn_3(PO_4)_2$. Differing from a commercial phosphatizing solution, the solution used in this experiment contained a large amount of zinc phosphate precipitates. The relationship between Na_2CO_3 and H_3PO_4 is shown in Fig. 1. The concentrations of $NaNO_3$ and $Zn_3(PO_4)_2{\cdot}4H_2O$ were fixed at 3.3 g/*l* and 19.3 g/*l*, respectively. The pH of the solution, as shown in Fig. 1 varied largely with the composition of the solution.

B) Apparatus and Procedure for Measurement. The apparatus consisted of a high frequency oscillator of alternate current and several magneto-restriction vibrators. The frequency of ultrasonic wave was altered by changing magneto-restriction vibrators within the range from 16 kc to 100 kc. The intensity of ultrasonic wave was continuously changeable from 0 W to 500 W. A polyethylene beaker containing the phosphatizing solution was placed on the radiation plane of the vibrator and a metal specimen was suspended with nylon fiber in the solution. The apparatus is schematically show in Fig. 2. Before the phosphatization the specimens were treated by the method describ-

ed in a previous paper.[1] The composition of the specimens is shown in Table 1.

C) Amount of Phosphate Film. The weight of the coating was estimated by measuring the weight change of the specimens by dipping in a stripping solution containing 20% of CrO_3.

D) Corrosion Test. The corrosion resistivity of the phosphate coating was tested in the same manner as described in the preceding paper.[1] In this test the dipping time was cut to 5 hr, whereas the ten-hour test has been adopted previously.

Results and Discussion

The optimum composition of the phosphatizing solution under radiation of ultrasonic wave was sought at 50°C by microscopic observation on the phosphate coating. All experiments were done under radiation of ultrasonic wave with a frequency of 20 kc and an intensity of 25 W/cm². This ultrasonic radiation was adopted, taking the stability and feasibility in the generation of ultrasonic wave into consideration. As a preliminary experiment, commercial phosphatizing solutions were used for

phosphatization. So far as the microscopic observation on the phosphate coating showed, under ultrasonic radiation, no excellent coating was obtained in these solutions with considerably low pH. In the course of experiments under ultrasonic radiation, however, a slurry solution containing insoluble zinc phosphate was found to give a thin but sturdy coating. The relationship between the weight of the phosphate coating and the composition of the phosphatizing solution is shown in Table 2. At high concentration of H_3PO_4 and at low concentration of Na_2CO_3, a bulky and coarse coating was obtained. The solution which belonged to region B of Fig. 1 gave a coating such as shown in Fig. 3. Figure 4 shows the typical coating produced in the solution belonging to region A in Fig. 1. Compared with the solution in region B, the solution in region A gave thin coating, and the specimen used was uniformly covered with fine crystals. As shown in Fig. 5, a uniform coating was not obtained in the phosphatizing solutions of Nos. 10, 11, 12 and 14 listed in Table 1, the compositions of which belonged to neither of those in region A nor in region B. From microscopic observation of the coating surfaces, the solution region A was assumed to have the optimum composition under ultrasonic radiation. The optimum

pH range of the solution of the phosphatizing process under ultrasonic radiation is 3—4, which is favorable for the precipitation of Al^{3+} and the elimination of its hindrance. The changes of the coating weight with the duration of phosphatization at 50, 75 and 95°C are shown in Figs. 6, 7 and 8. Figures 6 and 7 indicate that, under ultrasonic radiation, the saturation of the coating weight was present in the phosphatizing process, whereas the coating weight without radiation of ultrasonic wave increased gradually with time. The coating surface obtained at 95°C, in spite of its large thickness, was coarse and deficient in uniformity as shown in Fig. 9. On the other hand, the coatings obtained at 50 and 75°C were thin but sturdy. In Fig. 10, the amount of dissolved iron indicating the relative resistivity of coating, in the air-bubbled 3% NaCl solution, is plotted against the coating weight. The coating obtained under radiation of ultrasonic wave was found to be more sturdy than that treated by the ordinary dipping method, as is shown in Fig. 10. Figures 11 and 12 show the films obtained on the surfaces which had been oxidized by concentrated HNO_3 before phosphatization. In spite of the presence of oxide film on the specimen, a uniform film, shown in Fig. 11 was obtained by ultrasonic radiation. From comparison of Fig. 13 with Fig. 14, it has been revealed that ultrasonic wave also facilitated the film formation on the surface stained with mineral oil.

Studies on Cow's Urine. V. Determinaton by Gas-liquid Chromatography of an Acidic Part Obtained from Cow's Urine (Supplement)*1

Rikisaku SUEMITSU, Shin-ichi FUJITA, Mitsuo YOSHIMURA and Isao KONDO

Department of Applied Chemistry, Faculty of Engineering, Doshisha University, Kamikyo-ku, Kyoto

(Received November 14, 1968)

In the recent literature studies of aromatic acids in human urine[1-3] and amino acids in healthy rabbit urine[4,5] have been reported.

In a previous paper[6] we examined, by gas-liquid chromatography, phenolic and acidic parts obtained from the urine of Nihon-ushi (*Bos taurus* Linneaus) and presented a new metabolic pathway of phenylalanine and its derivatives.

In the present paper, seven components were newly identified in addition to nineteen compounds detected previously;[6] all are shown in Table 1.

The peak numbers are the same as those of Table 1 in a previous report.[6] Peak No. 25 was previously reported as unidentified, and No. 26, as 3-indoleacetic acid (?); however, the former is corrected to 3-indoleacetic acid, and the latter is here regarded as unidentified.

It is noteworthy that a small amount of 3-indoleacetic acid and β-3-indolepropionic acid are newly detected in the urine. They may be supposed to be degradation products of tryptophan *in vivo*.

Experimental

The gas-chromatographic analysis was performed as has been previously described.[6] In this experiment, 25% SE-60, coated on 80—100 mesh Diasolid L, was also used as the polar stationary phase in order to effect a good separation.

TABLE 1. AROMATIC ACIDS ADDITIONALLY DETECTED IN COW'S URINE

Stability Constants of Dimethyltin Dichloride and Tin Tetrachloride Complexes of *p*-Substituted Benzaldehydes, Acetophenones and *N,N*-Dimethylbenzamides

Gen-etsu MATSUBAYASHI, Noboru NISHII and Toshio TANAKA

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadakami, Suita, Osaka

(Received November 16, 1968)

Many stable dimethyltin dichloride - organic donor adducts have been isolated and their configurations in the solid state discussed by several workers.[1] Only a few quantitative data on them[1-3] in solution have been reported, however, although the stability constants of other organotin chlorides[4-7] and tin tetrachloride adducts[8] have been obtained. Recently we have reported that dimethyltin dichloride forms stable 1 : 1 adducts with some aromatic carbonyl donors and that their stability constants are quite small.[1] The present report will describe the stability constants for several dimethyltin dichloride and tin tetrachloride-aromatic carbonyl donor (XC_6H_4COR) complexes and the effect of the substituents, X and R groups.

Experimental

Materials. *N,N*-Dimethylbenzamide and its *p*-substituted derivatives were prepared according to the methods in the literature.[9] *p*-Nitro-*N,N*-dimethylbenzamide. Found: C, 55.90; H, 5.18; N, 14.87%. Calcd for $C_9H_{10}N_2O_3$: C, 55.66; H, 5.19; N, 14.42%. *p*-Chloro-*N,N*-dimethylbenzamide. Found: C, 58.53; H, 5.61; N, 7.84%. Calcd for $C_9H_{11}NO$: C, 72.45; H, 7.43; N, 9.39%. *p*-Methyl-*N,N*-dimethylbenzamide. Found: C, 73.18; H, 7.80; N, 8.64%. Calcd for $C_{10}H_{13}NO$: C, 73.59; H, 8.03; N, 8.58%. *p*-*N,N*-Dimethylamino-*N,N*-dimethylbenzamide. Found: C, 68.42; H, 8.59; N, 14.52%. Calcd for $C_{11}H_{16}N_2O$: C, 68.72; H, 8.39; N, 14.57%. The *p*-methoxy-*N,N*-dimethylbenzamide, kindly supplied by Professor Komori of this Department, was also analytically pure. The *p*-*N,N*-dimethylacetophenone was prepared according to the literature, and excellent analyses for carbon, hydrogen, and nitrogen were obtained on it.[1] The other acetophenone- and benzaldehyde derivatives were commercially-available materials and were distilled under nitrogen before use. Dimethyltin dichloride and dibromide, tin tetrachloride and 1,2-dichloroethane were purified according to the conventional methods.[3]

Spectrophotometers. The IR and UV spectrophotometers used here were previously described.[1]

Results and Discussion

The stability constants (K) of the complexes are defined by the following equation;

$$K = [A \cdot D]/[A] \cdot [D], \text{ in } A + D = A \cdot D$$

where A is dimethyltin dichloride or tin tetrachloride and where D is a carbonyl donor. The K values were determined from the infrared (Fig. 1) or ultraviolet spectra (Fig. 1 in Ref. 1) for the carbonyl donor molecules with varying amounts of the tin(IV) compounds in 1,2-dichloroethane, according to the method described previously.[1]

The results obtained for the dimethyltin dichloride and tin tetrachloride complexes are summarized in Tables 1 and 2, respectively. Dimethyltin dichloride - carbonyl donor complexes were isolated stably as 1 : 1 adducts rather than as 1 : 2 adducts,[1] and under the present experimental conditions a large excess of dimethyltin dichloride exists in

solution in comparison with the donors. Therefore, the formation of the 1 : 1 adducts may be predominant in solution. In the cases of tin tetrachloride, the 1 : 2 adducts were isolated stably.[10,11] However, the K values obtained here may also be considered to be those for the 1 : 1 adducts, because of the large excess of tin tetrachloride compared with the donors. Tables 1 and 2 indicate that the acceptor strength of tin chlorides toward carbonyl donors is; $SnCl_4$: $(CH_3)_2SnCl_2$ ≒500—100 : 1. Furthermore, we can compare the acceptor strength of the latter toward *N,N*-dimethylbenzamide derivatives with that of iodine studied by Drago:[9] $(CH_3)_2SnCl_2$: I_2 ≒5 : 1.

Generally, the order of the electron-releasing tendency of R in XC_6H_4COR is known to be $H < CH_3 < N(CH_3)_2$. This is indicated in the C=O

10) G. A. Olah, "Friedel-Crafts and Related Reactions," Interscience, New York (1964).

stretching frequencies of the free ligands (Table 3); the frequency decreases with a stronger electron-releasing group, R or X. Table 3 also shows the C=O frequency shift to a lower region due to the complex-formation with dimethyltin dichloride. The magnitudes of the frequency lowering are compared with the K values. The association constants of the substituted acetophenones with protons were reported to be larger than those of substituted benzaldehydes.[12,13] In the cases of tin chloride complexes, however, the K value and the C=O frequency lowering become larger in the following order of R groups; $CH_3<H<N(CH_3)_2$, as may be seen in Tables 1, 2, and 3. This order for H and CH_3 groups may be due to the steric effect of the methyl group on the complex formation of tin chlorides.

There is an almost linear relationship between the $\log K$ and σ^+ values of p-substituents, X, in XC_6H_4COR (R=H, CH_3 and $N(CH_3)_2$). Similarly, linear relationships of $\log K$ against σ^+ values have been previously mentioned for boron trifluoride complexes of substituted benzamides[14] and for the protonation of substituted acetophenones and benzaldehydes.[12,13]

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 2371—2372 (1969)

Intensity Ratio between (00*l*) Diffraction Lines of a Coke and a Simple Model of Carbon Layer Plane

Michio INAGAKI

Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya

(Received November 16, 1968)

It is known that the (004) diffraction line of non-graphitizing carbon is hardly detectable and that it develops gradually to become so with the increase in heat treatment temperature.

In the present work, the X-ray diffraction intensities of (00*l*) lines were measured on polyvinylchloride cokes heat-treated at different temperatures and the change of the intensity ratio between the (00*l*) lines was discussed from the standpoint that it was caused by the change of displacement of carbon atoms in the *c*-direction from the carbon layer plane.

Experimental and Results

The original sample was PV-7, a polyvinylchloride coke carbonized at 680°C. This sample was heat-treated at different temperatures between 1000 and 2600°C for 60 min in the flow of nitrogen by using a graphite resistance tube furnace. The heat treatment temperature (HTT) was measured by an optical pyrometer, which was calibrated by a standard lamp for optical pyrometry. For the heat-treated samples, intensities of (002) and (004) diffraction lines were measured by a fixed counting technique, using a goniometrer with Geiger counter. The measured intensity at each diffraction angle θ was corrected, being divided by Lorentz-polarization, the square of atomic scattering and absorption factors. The corrected intensities were plotted as a function of $\sin\theta$. The area under the profile of (00*l*) line, measured by a planimeter, is the integrated intensity of diffracted beames $I(00l)$ and is proportional to the square of the geometrical structure factor of the line. This proportionality for (002) and (004) lines must be equal to each other since both profiles of the lines were measured on the same specimen. Therefore, the ratio of intensities of (004) to (002) lines, $I(004)/I(002)$, is equal to the ratio of the square of geometrical structure factors of (004) to (002) lines, $|A(004)|^2/|A(002)|^2$.

The observed ratio $I(004)/I(002)$ is shown in

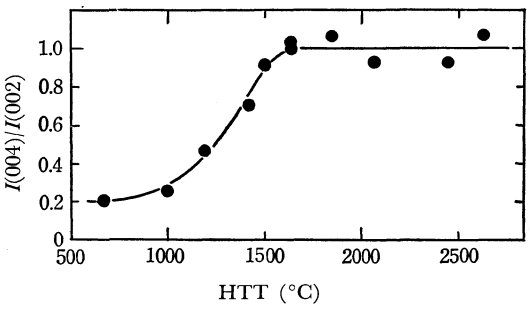

Fig. 1. Change of the observed intensity ratio $I(004)/I(002)$ with HTT.

Fig. 1, as a function of HTT. The ratios for the carbon subjected to heat treatment at low temperature are practically smaller than 1.00. They appear to equal 1.00 above 1600°C.

For the heat-treated samples, the c_0-spacing was measured by using the inner standard of silicon and a recording goniometrer. In Fig. 2, the intensity ratio $I(004)/I(002)$ is plotted against the c_0-spacing of the sample. The sample having c_0-spacing larger than 6.86 Å has an intensity ratio smaller than 1.00.

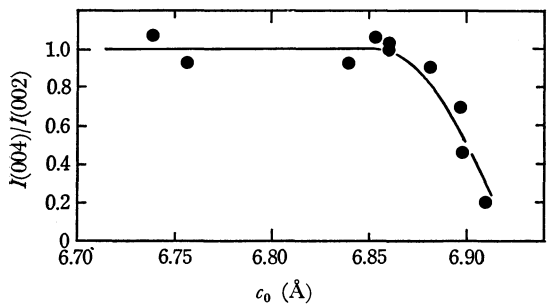

Fig. 2. Change of the observed intensity ratio $I(004)/I(002)$ with c_0-spacing.

Discussion

The measured intensity ratio can have a relatively large error, about ± 0.05 for the sample heat-treated at 2600°C and even greater for the samples subjected to heat treatment at low temperature such as 1400°C. Though no corrections for the instrumental factors were performed, the omission of such corrections was not the cause of the error in the ratio. A large part of the error resulted from the ambiguity of the determination of the background of X-ray diffraction. Even if the ratio $I(004)/I(002)$ has a relatively large ambiguity, the ratios of the carbons heat-treated at low temperatures were found to be actually smaller than the value of graphite 1.00.

The geometrical structure factor of $(00l)$ diffraction lines is given by

$$|A(00l)|^2 = \{\sum \cos 2\pi lz\}^2 + \{\sum \sin 2\pi lz\}^2$$

It depends only on relative position z along c-axis of carbon atoms in a unit cell. In graphite, all carbon atoms are coplanar, having the z-value of 0 and 1/2. The geometrical structure factors of $(00l)$ lines, of which l-index is even, equal one another and the ratio of the two of them equals unity. If some carbon atoms displace from the normal position of graphite by Δz along c-axis, the value of the geometrical structure factor becomes smaller than that of ideal graphite. The effect of reduction is greater for larger l-index lines. Therefore, the observed small ratio of $I(004)/I(002)$ can be interpreted as the result of out-of-plane displacements of carbon atoms. This means that the carbon layers are uneven or wrinkled.

According to the idea mentioned above, the present result shows that the displacement of carbon atoms disappears, in other words, all carbon atoms in carbon layer become coplanar, at about 1600°C or when the c_0-spacing becomes 6.85—6.86 Å. With the idea that the graphitization process is divided into two stages at the c_0-spacing of about 6.85 Å,[1-3] the present result suggests that the structural change in the first stage of the graphitization process ($c_0 > 6.85$ Å) is the decrease in the displacement of carbon atoms, in other words, "dewrinkling" of carbon layer planes, and that the three-dimensional ordering proceeds only after the carbon layer planes are straightened.

The idea of the displacement of carbon atoms is similar to that of Ruland.[4] However, he considered the displacement of carbon atom not only on the first stage but also on the second stage of graphitization process. This wrinkling model presented herewith is also consistent qualitatively with the electron microscopic observation by Kuroda.[5] He observed mosaic structure in a flake of carbon. In the present model, however, wrinkling of carbon is in the atomic scale.

The author wishes to thank Dr. T. Noda, president of Mie University, for his valuable discussions and thorough review of the paper, and Professor Y. Takagi and Professor S. Naka of Faculty of Engineering, Nagoya University, for their valuable discussions.

Asymmetric Hydrogenation of C=O Double Bond with Modified Raney Nickel. XII

Yoshiharu IZUMI, Susumu TATSUMI and Masami IMAIDA

Division of Organic Chemistry, Institute for Protein Research, Osaka University, Kita-ku, Osaka

(Received December 6, 1968)

The asymmetric hydrogenation of methyl acetoacetate to optically active methyl 3-hydroxybutyrate with a Raney nickel catalyst modified with optically active α-amino or α-hydroxy acid has been reported in previous papers of this series.[1,2] In these previous papers, the correlation between the asymmetric activity of the catalyst and the structure of modifying reagent, and the roles of the substituents at the α-asymmetric carbon of a modifying reagent have been discussed, and it has been found that the direction of the asymmetric activity of the catalyst with respect to the optical rotation of the product is decided by the absolute configuration of α-carbon and by the nature of the α-substituents of the modifying reagent. However, the asymmetric activities of the catalysts modified with α-substituted α-amino acids have not been discussed except with 2-methyl- and 2-benzylglutamic acids.

In the present paper, the asymmetric activities of the catalysts modified with (+)-isovaline and with (−)-2-methylaspartic acid are decribed; the results are compared with those obtained with 2-aminobutyric acid and aspartic acid in Table 1 and Fig. 1 respectively, in order to investigate the effect on the asymmetric activity of the replacement of an α-hydrogen of the modifying reagent with a methyl group. Moreover, as the absolute configuration of (+)-2-benzylglutamic acid was confirmed by means of the X-ray diffraction method by Kakudo *et al.*,[3] the relationship between the direction of the asymmetric activity of the catalyst with respect to the optical rotation of the product and the absolute configuration of the α-substituted amino acid used for modification is discussed in this report.

	5.85	100	−1.61

Experimental

Preparation of Catalyst. One and a half grams of Raney nickel alloy (Ni : Al=40 : 60) were added in small portions to 20 m*l* of a 20% sodium hydroxide solution over a 5-min period, and then the solution was allowed to stand for 45 min at 80°C. The nickel catalyst was washed several times with water.

Modification of Catalyst. An aqueous solution of the modifying reagent, the pH and the temperature of

1) Part X: Y. Izumi, K. Matsunaga, S. Tatsumi and M. Imaida, This Bulletin, **41**, 2515 (1968); Part XI: Y. Izumi, M. Imaida, T. Harada, T. Tanabe, S. Yajima and T. Ninomiya, *ibid.*, **42**, 241 (1969).

3) T. Ashida, Y. Sasada and M. Kakudo, This Bulletin, **40**, 476 (1967).

which had been adjusted to specified values, was added to a newly-prepared Raney nickel catalyst, and then the mixture was allowed to stand at the specified temperature, with occasional shaking, for 1.5 hr. After the modifying solution had been removed by decantation, the catalyst was washed once with water and twice with methanol.

Measurement of the Asymmetric Activity of the Catalyst. Redistilled methyl acetoacetate (18 ml) was hydrogenated in the presence of a modified Raney nickel catalyst which had been prepared from 1.5 g of an alloy. The reaction was run at 60°C under an initial hydrogen pressure of 80—100 kg/cm² in a shaking autoclave. The reduction product was filtered to remove the catalyst and then distilled under reduced pressure (bp 61—62°C/12 mmHg). The purity of the methyl 3-hydroxybutyrate was tested by gas chromatography. The optical rotatory power of the distilled product was measured by a conventional polarimeter in 1-dm tube at 20°C without dilution; the value was taken as the specific rotation because the density of methyl 3-hydroxybutyrate is nearly 1.0. According to Levene and Haller,[4] the optical rotatory power of methyl D-3-hydroxybutyrate is $[\alpha]_D^{20}$ −20.9.

Results and Discussion

Effect of the Modifying Temperature.[*1]

1) Isovaline. The effect of the modifying temperature on the catalyst modified with isovaline is shown in Table 1. No remarkable change in the asymmetric activity of the catalyst with the modifying temperature was found.

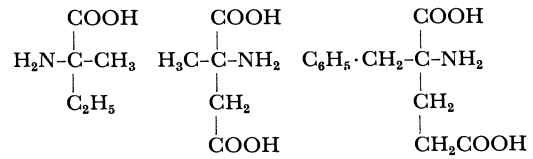
2) 2-Methylaspartic Acid. As is shown in Fig. 1, the asymmetric acitivity of the catalyst increases with the elevation of the modifying temperature, while on modification with aspartic acid it decreases with the elevation of the modifying temperature.[5] The tendency found in the modification with 2-methylaspartic acid was also observed in the cases of modification with 2-methyl- and 2-benzylglutamic acid, as has been reported in a previous paper.[6]

Effect of the Modifying pH.[*2]

The modifying pH does not so strongly affect the asymmetric activity of the catalyst in the case of modification with 2-methylaspartic acid as in the case of modification with 2-methyl- or 2-benzylglutamic acid,[6] as is shown in Fig. 1.

Correlation of the Direction of the Asymmetric Activity of the Catalyst and the Absolute Configuration of α-Substituted α-Amino Acid.

The configurations of (+)-isovaline,[7] (−)-2-methylaspartic acid,[8] and (+)-2-benzylglutamic acid[3] are written in the conventional Fischer diagram as follows:



(+)-isovaline (−)-2-methylaspartic acid (+)-2-benzylglutamic acid

Thus, (+)-isovaline can be assigned either an L- or a D-configuration, depending on whether it is considered as a derivative of L-2-aminobutyric acid or of D-alanine. In a like manner, (+)-2-benzylglutamic acid and (−)-2-methylaspartic acid can be considered as a derivative of L-phenylalanine or of D-glutamic acid and as a derivative of L-alanine or of D-aspartic acid respectively. Moreover, Meister and his co-workers have suggested, after investigations using the biochemical method, that the (+)-isomer of 2-methylglutamic acid can be considered as a derivative of L-glutamic acid.[9] Meanwhile, catalysts modified with (+)-isovaline, with (−)-2-methylaspartic acid, and with (+)-2-benzylglutamic acid at 0°C gave predominantly methyl D-(−)-, L-(+)- and L-(+)-3-hydroxybutyrate respectively as the hydrogenation products.

These facts show that the direction of the asymmetric activity of the catalyst modified with α-substituted α-amino acid conforms to the general rule that the catalyst modified with L (or D)-α-amino acid at 0°C gives methyl D (or L)-3-hydroxybutyrate as the hydrogenation product when the α-substituted α-amino acid is considered as a derivative of the α-amino acid, which is more effective for the preparation of a catalyst with a high asymmetric activity. For example, the catalyst modified with optically active 2-aminobutyric acid at 0°C has a higher asymmetric activity than that modified with optically active alanine, and so in the case of the catalyst modified with (+)-isovaline at 0°C, the direction of the optical rotation of the product conforms to the general rule when the compound is considered as a derivative of L-2-aminobutyric acid.

Effect of the α-Alkyl Substituent of α-Amino Acid on the Formation of the Asymmetrically Active Center. The asymmetric activities of the catalysts modified with isovaline and with 2-methylaspartic acid are increased or

at least not affected with the elevation of the modifying temperature. On the contrary, those with 2-aminobutyric acid and with aspartic acid decrease with the elevation of the modifying temperature. As the same results were obtained with α-substituted amino acids and with β-alkyl substituted amino acids, it can be assumed that the α-substituent has the same effect as the β-alkyl substituent on the formation of an asymmetrically active center on the surface of the catalyst. That is, in the case of modification with α- or β-alkyl substituted α-amino acid, the proportion of the (−)- to the (+)-asymmetrically active centers*3 on the surface of the catalyst does not greatly change with the modifying temperature.

The authors wish to express their thanks to Professor Masao Kakudo for the determination of the absolute configuration of (+)-2-benzylglutamic acid by means of the X-ray diffraction method.

This research was supported by the Kawaken Fine Chemicals Co., Ltd., Tokyo.

*3 "(+) (or (−))-asymmetrically active center" means the asymmetric center on the surface of the catalyst in which methyl L-(+) (or D-(−))-3-hydroxybutyrate is preferentially produced in hydrogenation of methyl acetoacetate. For example, on modification with L-glutamic acid, the catalyst modified at 0°C, which produces predominantly methyl D-(−)-3-hydroxybutyrate, contains predominantly (−)-asymmetrically active center, while the catalyst modified at 100°C, which produces predominantly methyl L-(+)-3-hydroxybutrate, contains predominantly (+)-asymmetrically active center.

Studies of Japanese Lacquer: Isolation of a Diphenyl Dimer of Urushiol

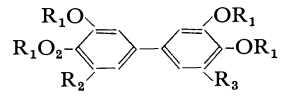
Takashi KATO and Ju KUMANOTANI

The Engineering Research Institute, Faculty of Engineering, The University of Tokyo, Bunkyo-ku, Tokyo

(Received December 9, 1968)

It is well known that Japanese lacquer oxidatively polymerizes under the action of laccase to form dried films with excellent properties. Previously, in order to elucidate the behavior of urushiol in the drying process, we have separated by thin-layer chromatography (TLC) three unknown components (with R_f 0.37, 0.27 and 0.20; 1 : 1 : 0.5 by wt, respectively) from a mildly-oxidized sap of the Japanese lacquer tree (*Rhus vernicifera* D. C. in Japan).[1]

It is the aim of the present paper to clarify the point that the component with R_f 0.20 (designated as D) is a diphenyl derivative (Ia) of urushiol. This has been proved by the separation of the hydrogenated D (Ib; 3,4,3',4'-tetrahydroxy-5,5'-dipentadecyldiphenyl) from the hydrogenated polymeric urushiol by TLC and by its derivation to the acetyl derivative (Ic). The identification of (Ic) was performed as follows: It is evident that the acetyl derivative of the hydrogenated D was a derivative of a dimeric urushiol on the basis of the results of elemental analysis and molecular weight measurement. The diphenyl structure was confirmed by the UV spectral absorption (λ_{max}^{EtOH} 256 mμ, ε 2.15×10^4).[2] Among the possible six isomers the identity of the compound with Ic was established by the NMR spectrum of the phenyl protons. A quartet (4H, $J=2$ cps) characteristic of the AB system[3] was observed in the region of τ 2.5—2.8. The small J-value indicates that two protons in the AB system were present in the meta position.[3]



(I)

chol in an aqueous medium,[4,5] and that urushiol quinone is formed[6] at an early stage of the oxidative polymerization of the sap of the Japanese lacquer tree. It seems, therefore, reasonable to assume that D (Ia) was formed by the reaction between urushiol and urushiol quinone.

Experimental[7]

Separation of a Diphenyl Dimer of Urushiol. The polymeric urushiol was obtained by the method reported previously[1] from a mildly-oxidized sap of the Japanese lacquer tree. The polymeric urushiol was hydrogenated at room temperature under an atmospheric pressure of hydrogen over 5% Pd-on-charcoal. The hydrogenated polymeric urushiol was dissolved in chloroform and applied as a spot on the silica-gel layer (thickness, 0.25 mm), which was made from Silica Rider (silica-gel with 12—14% calcium sulfate, purchased from the Daiichi Pure Chemicals Co.) and activated at 105°C for 1.5 hr. It was then chromatographed in a chloroform - ethyl acetate (87 : 13 v/v) solvent tank using the ascending technique. The developing distance was 12—14 cm. A filter paper (20×20 cm) impregnated with the developing solvent was inserted into the tank in order to saturate the atmosphere with the solvent-vapor. The chromatogram gave, when sprayed with a methanol-1% $FeCl_3$ solution, spots with R_f values of 0.50 (urushiol, dark violet), 0.37 (dark brownish green), 0.27 (dark violet) and 0.20 (dark violet), and others with smaller R_f values including a spot of the starting point. The compound with R_f 0.20 (the hydrogenated D) was then collected by TLC in the same manner as that described previously.[1] About 0.1 g of the purified, hydrogenated D which gave only one spot (with R_f 0.20) in its TLC, was obtained from 4 g of the hydrogenated polymeric urushiol. The hydrogenated D (91 mg) was acetylated at 50—60°C for 1 hr in a mixture of acetic anhydride (5 m*l*) and phosphoric acid (0.1 m*l*) under stirring, and the solution was further allowed to stand overnight at room temperature. The reaction mixture was shaken well with water (50 m*l*, *ca.* 60°C), and extracted with benzene (50 m*l*). The benzene extract was then washed with water (50 m*l*×3), and dried over calcium chloride. An oily material was obtained by the removal of the benzene in vacuum. It was examined by TLC (Silica Rider: thickness, 0.25 mm; developing solvent, chloroform - *n*-hexane, 3 : 2 v/v). The spots were detected by spraying with an aqueous sulfuric acid solution (1 : 1) and by heating at 150°C for 30 min, and the compound with R_f 0.26 was found to be a major product. It was collected by TLC using two silica-gel plates (1 mm thick). The separated material was crystallized from *n*-hexane - ether, and a white crystal (20 mg) was obtained, mp 99—100°C (corr.). UV λ_{max}^{EtOH} 256 mμ (ε 2.15×10^4); IR ν(KBr) 2920 (vs), 2860(s), 1770 (vs), 1599(w), 1478(s), 1378(s), 1259(m), 1208(vs), 1175(vs) 1113(w), 1030(m), 1014(m), 900(m), 873(w), 826(w), 775(w) and 720 cm^{-1} (w); NMR ($CDCl_3$) τ 2.5—2.8 (4H, quartet, J=2 cps, phenyl protons), 7.42 (4H, triplet, J=7 cps, protons of methylenes adjacent to benzene ring), 7.65 and 7.70 (each 6H, singlet, acetyl protons), 8.1—8.9 (52H, methylene protons), 9.11 (6H, triplet, J=5 cps, methyl protons).

Found: C, 74.48; H, 10.46%; mol wt, 760. Calcd for $C_{50}H_{78}O_8$: C, 74.40; H, 9.74%: mol wt, 807.2.

Laser-induced Chemical Reaction. II. Reaction Induced by a Giant Pulse Laser

Ko TAKI, Pil Hyon KIM and Susumu NAMBA

The Institute of Physical and Chemical Research, Yamato-machi, Saitama

(Received December 9, 1968)

In a previous paper,[1] the reaction of hydrocarbons with carbon vapor produced by the irradiation of a normal laser on graphite carbon has been reported. From the distribution of the reaction products and from the results of a spectroscopic analysis, it was assumed that diatomic carbon (C_2) plays a dominant role. In this paper, the investigation of the reaction induced by a giant pulse ruby laser is described.

Experimental

The output power and the pulse width of the giant pulse laser used were 30 MW and 20 nsec respectively. The total output energy was 0.6 J, one-fifth of that of the normal laser in the previous report. The laser beam was focused by a lens 30 mm in focal length upon a carbon target placed in a 7 cc Pyrex cell filled with the vapor of hydrocarbons. After a 10—20 pulse irradiation, an analysis was peformed by gas chromatography using a silica gel and a squalane column. A quantitative analysis was also performed by mixing standards in the sample.

Results and Discussion

The reaction products in hydrogen are listed in Table 1, while the reaction products in ethylene and methane vapor at 10 Torr pressure are shown in Table 2. The gas pressure of 10 Torr was chosen so as to avoid any breakdown caused by the focused giant pulse laser. At a pressure higher than 100 Torr a breakdown was observed, as will be described later. Although the main products were C_2 compounds, as in the case of a normal laser reaction,

TABLE 1. REACTION PRODUCTS IN HYDROGEN

Product	Yield ($\times 10^{-6}$ mol)	
	Normal laser (10 pulse irradiation in 700 Torr H_2)	Giant pulse laser (20 pulse irradiation in 720 Torr H_2)
Methane	0.3—0.4	0.1
Ethane	0	0.01
Ethylene	0	0
Acetylene	15.0—20.0	0.4

the ratios of methane and ethane to acetylene were higher than those in normal laser reactions. This fact suggests that the distribution of carbon oligomers produced by the giant pulse laser is different from that produced by the normal laser; that is, the fraction of the monoatomic carbon (C_1) is larger in the former than in the latter. This may be due to the difference in the surface temperature of the carbon target. The estimated temperature[2,3] in the giant pulse laser is higher than in the normal laser.

The breakdown[4,5] of the gas is known to be caused by the focused giant pulse laser. When the laser beam was focused on a carbon target, a breakdown of gases was observed in the focused-on region. In this case, the product ratios were a little different from those in the breakdown without a target. This may be due to the fact that most of the energy of the laser beam is spent producing the breakdown. The yields of products in the breakdown of various substrates are shown in Table 3.*1 Spectroscopically, C_2 Swan bands were observed in the breakdown of these gases, as had previously been observed by Adelman.[6] These facts suggest that the products are mainly formed by the reaction of the substrate with the C_2 produced in the breakdown.

It is hard to produce the breakdown in gas at a low pressure.[5] No breakdown was, for instance, observed at 10 Torr ethylene or methane. However, in a mixture of 10 Torr ethylene and 750 Torr argon (ethylene mol fraction is 0.013), a breakdown was observed and argon lines were detected spectroscopically.

The product ratios, CH_4/C_2H_2 and C_2H_6/C_2H_2, and that of C_3 products to C_4 products are plotted as a function of the partial pressure of ethylene in the mixture with argon in Fig. 1. The figure shows

TABLE 4. RELATIVE YIELD IN THE γ-RADIOLYSIS AND IN THE LASER IRRADIATION IN THE MIXTURE OF ETHYLENE AND ARGON

Product	Relative G value in γ-radiolysis			Relative yield in laser irradiation
	Ethylene mol fraction in Ar			
	1.0*	0.7*	0.013	0.013
Methane			0.13	0.38
Ethane	0.26	0.18	0.16	0.57
Acetylene	1.00	1.00	1.00	1.00
n-Butane	0.33	0.26	0.18	0.35
C_3-Products			0.17	0.27

* From Ref. 7.

that the product ratios remain constant in the region of higher mol fractions (0.15) of ethylene, but at lower concentrations (0.013) these ratios rise sharply. At a higher partial pressure of ethylene, a breakdown reaction may occur on the ethylene molecule because its ionization potential (10.5 eV) is lower than that of argon (15.7 eV). On the other hand, at a lower concentration, breakdown may occur mainly on the argon rather than on the ethylene molecule, and the reaction products may be almost entirely formed by the decomposition of the excited ethylene produced by energy transfer to ethylene from the excited argon formed by the breakdown. The radiolysis of an inert gas and hydrocarbon mixture has been known to involve energy transfer reaction. However, the product ratios in the radiolysis of a 10-Torr-ethylene and 750-Torr-argon mixture are different from those in laser irradiation, as Table 4 shows. Radiolysis was performed at room temperature, and the total dose was about 10^{19} eV. This difference might be due to the difference between the reactions in the excited states of ethylene.

The methane and argon system showed almost identical results; ethane was the only condensable product at the pressure of 10 Torr methane and 750 Torr argon. In the presence of nitric oxide (4 Torr), the breakdown of the mixture of methane (12 Torr) and argon (744 Torr) did not give ethane. This suggests that the reaction involves free radical processes, as in the case of radiolysis. The radiolysis of methane[8-10] and a methane-argon mixture[11] has been known to involve free radical processes and to produce hydrogen and ethane, but not acetylene.

In the giant pulse laser-induced reaction, diatomic carbon (C_2) is considered to play a dominant role, but at a low concentration of the substrate in the argon mixture the reaction process may be due to the energy transfer from argon.

The authors wish to express their appreciation to Miss Kumiko Motegi for her valuable assistance.

Synthetic Studies of the Flavone Derivatives. XI.*1 The Synthesis of 4′,5,7-Trihydroxy-3,8-dimethoxyflavone, A Pigment from *Cyanostegia angustifolia* Turcz.

Kenji FUKUI, Takashi MATSUMOTO and Sachihiko TANAKA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashi-sendamachi, Hiroshima

(Received December 17, 1968)

Recently, Ghisalberti *et al.*[1] reported the isolation of two new pigments from the leaves and terminal branches of *Cyanostegia angustifolia* Turcz.; they proposed, on the basis of chemical and spectral studies, that the structures of these pigments were 4′,5,7-trihydroxy-3,3′,8-trimethoxyflavone (I) and 4′,5,7-trihydroxy-3,8-dimethoxyflavone (II).

In a previous paper,[2] we reported on the total synthesis of I and its identity with a natural pigment. The present paper will describe a total synthesis of II. The experimental details of the present work are essentially the same as those of the previous paper,[2] involving an oxidative demethylation[3] of the 5,8-dimethoxyflavone derivative with nitric acid.

According to Allan-Robinson's flavone synthesis,[4] the condensation of 2,4-dihydroxy-3,6,ω-trimethoxyacetophenone[5] (III) with 4-benzyloxybenzoic anhydride[6] (IV) gave 4′-benzyloxy-7-hydroxy-3,5,8-trimethoxyflavone (V), which was then benzylated to the 7-benzyl ether (VI). The compound VI was also obtained by a similar condensation of 4-benzyloxy-2-hydroxy-3,6,ω-trimethoxyacetophenone[5] (VII) with IV. The oxidative demethylation of VI with nitric acid gave the 5,8-quinone derivative (VIII) as an intermediate; this was then easily reduced to the corresponding 5,8-dihydroxy compound (IX). The partial methylation of IX with diazomethane gave 4′,7-dibenzyloxy-5-hydroxy-3,8-dimethoxyflavone (X), which was then debenzylated to give the desired flavone (II), mp 247—249°C and 257—258°C, by catalytic hydrogenolysis over Pd-C. The synthetic flavone (II) was shown to be identical with the natural pigment by a mixed-melting-point determination and by a comparison of their IR and UV spectra.

We next turned our attention to an investigation of another effective method. Since it is well known that 3,5-dimethoxyflavone derivatives are demethylated at the 5-position with anhydrous aluminum chloride in ether,[7] a partial demethylation of 4′,7-dihydroxy-3,5,8-trimethoxyflavone (XI), prepared from V, with anhydrous aluminum chloride in ether was carried out in the hope of obtaining the 5-hydroxy compound (II). The product obtained was yellow crystals, mp above 300°C, which were characterized as triacetate, mp 173—175°C,*2 and trimethylated ether (XIII). The flavone (XIII) was also obtained by the methylation of XI with diazomethane; this proved that there was no isomeric change during the demethylation of XI.

The physical properties of the demethylated flavone did not agree with those of the natural pigment. The NMR spectrum of the demethylated flavone in dimethyl sulfoxide-d_6 showed the presence of two methoxyl groups, at δ 3.84 and 3.87 (each a 3H singlet); of five aromatic protons, at δ 6.51 (singlet, C_6–H), 7.01 (doublet, $C_{3'}$–H and $C_{5'}$–H) and 8.12 (doublet, $C_{2'}$–H and $C_{6'}$–H), and three hydroxyl groups, at δ 8.74, 10.04, and 10.50 (each a 1H singlet). In the UV spectra summarized in Table 1, a long-wavelength band of the demethylated flavone in ethanol undergoes a large bathochromic shift (59 mμ) upon the addition of aluminum chloride;[8] this shows the presence of a free 3-hydroxyl group. The demethylated flavone is unstable in an alkaline solution, for when

the alkaline solution is acidified, the long-wavelength band of the parent spectrum in ethanol disappears. This suggests the presence of a free 3,4'-dihydroxyl group.[8] The presence of a free 7-hydroxyl group is also indicated by the bathochromic shift (10 mμ) of the short-wavelength band in the presence of fused sodium acetate.[8] From this spectral evidence, the structure of the demethylated flavone was established to be 3,4',7-trihydroxy-5,8-dimethoxyflavone (XII).

Experimental*8

4'-Benzyloxy-7-hydroxy-3,5,8-trimethoxyflavone (V). A mixture of III (7.2 g), IV (33.0 g), and potassium 4-benzyloxybenzoate (16.0 g) was ground together and heated at 180°C in an oil bath for 5 hr. The reaction mixture was cooled, powdered, and then refluxed for 30 min with a solution of ethanol (300 m*l*) and potassium hydroxide (30 g) in water (60 m*l*). The solvent was removed under a vacuum and washed with water; then the residue was again treated with an ethanolic alkaline solution as described above. The crude product was washed with hot water and hot acetone successively. The acetone-insoluble part was recrystallized from acetic acid to give yellow needles of V; mp 240—242°C; yield 2.0 g.

Found: C, 68.85; H, 4.97%. Calcd for $C_{25}H_{22}O_7$: C, 69.11; H, 5.10%.

4',7-Dibenzyloxy-3,5,8-trimethoxyflavone (VI). *a) From V.* The compound V (30 mg) was benzylated to give colorless needles of VI, mp 149—150°C (from aqueous methanol), which gave a negative ferric chloride reaction in ethanol; yield, 20 mg.

Found: C, 73.12; H, 5.39%. Calcd for $C_{32}H_{28}O_7$: C, 73.27; H, 5.38%.

b) From VII. A mixture of VII (1.9 g), IV (4.0 g), and potassium 4-benzyloxybenzoate (2.5 g) was treated by a method similar to that used for V. The crude product was recrystallized from methanol to give VI mp 149—150°C, which was undepressed on admixture with the sample of a); yield, 0.5 g.

4',7-Dibenzyloxy-5,8-dihydroxy-3-methoxyflavone (IX). A suspension of VI (320 mg) in nitric acid (45%: 7.0 m*l*) was stirred vigorously at 40°C for 10 min. After the mixture had been cooled, the dark brown precipitate (VIII) was collected, washed with water, and dissolved in acetic acid (10 m*l*). The solution was heated on a steam bath with sodium sulfite heptahydrate (1.5 g) for 1 min, and then diluted with water. The yellow precipitate was collected, washed

*8 All the melting points are uncorrected. The NMR spectra were taken on a Hitachi Model R-20 NMR spectrometer (60 Mc/sec), using tetramethylsilane as the internal standard; their chemical shifts are presented in terms of δ values; s: singlet, d: doublet.

with water, and recrystallized from acetone to give yellow needles of IX, mp 201—203°C, which gave a green ferric chloride reaction in ethanol; yield, 180 mg.

Found: C, 72.39; H, 4.68%. Calcd for $C_{30}H_{24}O_7$: C, 72.57; H, 4.87%.

4′,7-Dibenzyloxy-5-hydroxy-3,8-dimethoxyflavone (X). The flavone IX (120 mg) was methylated with diazomethane to give yellow needles of X, mp 161—162°C (from acetone-methanol), which gave a green ferric chloride reaction in ethanol; yield, 100 mg.

Found: C, 73.19; H, 5.11%. Calcd for $C_{31}H_{26}O_7$: C, 72.93; H, 5.13%.

4′,5,7-Trihydroxy-3,8-dimethoxyflavone (II). A solution of X (80 mg) in ethyl acetate (25 m*l*) was submitted to catalytic hydrogenolysis at room temperature in the presence of Pd-C (10%: 100 mg). The product was recrystallized from aqueous methanol to give yellow needles of II, mp 247—249°C and 257—258°C, which gave a green ferric chloride reaction in ethanol; yield, 35 mg. This flavone was shown to be identical with the natural pigment (mp 246—248°C and 256—258°C)*[9] by a mixed-melting-point determination and by a comparison of their IR and UV spectra.

Found: C, 61.82; H, 4.39%. Calcd for $C_{17}H_{14}O_7$: C, 61.82; H, 4.27%.

4′,7-Dihydroxy-3,5,8-trimethoxyflavone (XI). A mixture of V (1.8 g), Pd-C (5%: 1.5 g), and acetic acid (350 m*l*) was treated by a method similar to that used for II. The crude product was recrystallized from acetic acid to give XI, mp 290—292°C; yield, 1.0 g.

Found: C, 62.67; H, 4.55%. Calcd for $C_{18}H_{16}O_7$: C, 62.79; H, 4.68%.

3,4′,7-Trihydroxy-5,8-dimethoxyflavone (XII). A mixture of XI (600 mg), anhydrous aluminum chloride (5.0 g), and dry ether (60 m*l*) was refluxed for 8 hr. The mixture was poured into dilute hydrochloric acid (3 N: 200 m*l*). After the ether had been removed, the precipitate was collected, washed with water, and then recrystallized from aqueous pyridine to give pale yellow needles of XII, mp above 300°C, which gave a brown ferric chloride reaction in ethanol; yield, 250 mg.

Found: C, 62.12; H, 4.33%. Calcd for $C_{17}H_{14}O_7$: C, 61.82; H, 4.27%.

Triacetate of XII. Hot acetic anhydride - pyridine method; mp 173—175°C (from aqueous methanol); the substance gave a negative ferric chloride reaction.

Found: C, 60.30; H, 4.29%. Calcd for $C_{23}H_{20}O_{10}$: C, 60.52; H, 4.42%.

3,4′,5,7,8-Pentamethoxyflavone (XIII). The compound XI was methylated with diazomethane to give colorless needles of XIII, mp 157—159°C (from aqueous methanol) (lit,[9] 156—158°C), which gave a negative ferric chloride reaction. This compound was also obtained by the methylation of XII. NMR in $CDCl_3$: 3.92, 3.97 and 4.03 (each s, 5MeO), 6.49 (s, C_6-H), 7.10 (d, J=9.5 cps, $C_{3'}$-H and $C_{5'}$-H), 8.26 (d, J= 9.5 cps, $C_{2'}$-H and $C_{6'}$-H).

Found: C, 64.43; H, 5.35%. Calcd for $C_{20}H_{20}O_7$: C, 64.51; H, 5.41%.

The authors are grateful to Professor P. R. Jefferies, the University of Western Australia, for his gift of the natural pigment. This work was supported by a grant-in-aid from the Ministry of Education.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 2382—2384 (1969)

A Method of Synthesizing Pyrimidine Derivatives

Isao SHIBUYA and Masahiro KURABAYASHI

Government Chemical Industrial Research Institute, Tokyo, Mita, Meguro-ku, Tokyo

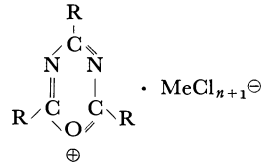
(Received December 18, 1968)

The reaction of nitriles (2 mol), 1 mol of acid chlorides, and 1 mol of metal chlorides (Lewis acids) gives 1,3,5-oxadiazin-1-ium salts (I), while I gives various heterocyclic compounds, such as *s*-triazine, triazole, and oxadiazole derivatives, when treated with ammonia, hydrazine, hydroxylamine, and urea.[1)]

The present report is concerned with the reaction of Ia with substituted acetonitriles (XCH_2CN), *i. e.*, malonitrile (X: CN), methyl cyanoacetate (X: $COOCH_3$), and benzoylacetonitrile (X: COC_6H_5).

When Ia was refluxed with each of the above-mentioned reagents under basic conditions, II, III, and IV respectively were obtained in good yields. The molecular weights of II, III and IV were

$$2RCN + RCOCl + MeCl_n \rightarrow$$



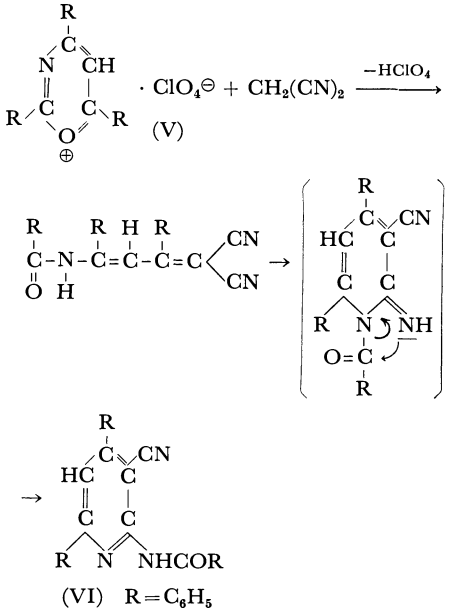
(I)

Ia: $R = C_6H_5$
$MeCl_n = SnCl_4$

1) R. R. Schmidt, *Chem. Ber.*, **98**, 334 (1965).

determined to be 376, 409, and 455 respectively by the mass spectrometric method. These results and the elementary analysis showed that these compounds are the adducts of the cation from Ia and of the anions from substituted acetonitriles. The fact that the IR spectra of these compounds were very similar to one another except for the characteristic absorptions of substituted groups of acetonitriles strongly suggests that these compounds all have a structure containing the same heterocyclic ring.

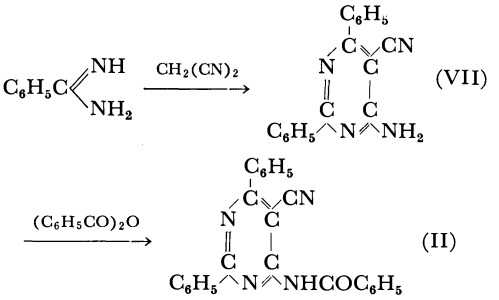
On the other hand, 1,3-oxazin-1-ium salt (V), which is regarded as a compound analogous to I, gives the acylaminopyridine derivative (VI) when treated with malononitrile;[2] the mechanism of this reaction has been proposed to be as follows;



(V) (VI) $R=C_6H_5$

Therefore, it was supposed that the reaction of Ia with substituted acetonitriles would proceed in a manner similar to that of the above reaction, and that II, III, and IV would be the corresponding pyrimidine derivatives.

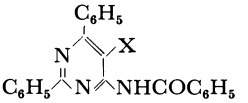
II was identified as follows:



(VII)

(II)

4-amino-5-cyano-2,6-diphenylpyrimidine (VII) was derived from benzamidine and malononitrile,[3] and its benzoyl derivative was prepared by heating VII with benzoic anhydride. The IR and mass spectra of II were in good agreement with those of this benzoyl derivative. A mixed-melting-point determination with both samples showed no depression. It was, consequently, concluded that II was 4-benzoylamino-5-cyano-2,6-diphenylpyrimidine, and that III and IV were the corresponding pyrimidine derivatives. It was thus proved that pyrimidine derivatives are synthesized from 1,3,5-oxadiazin-1-ium salt in good yields by the treatment with substituted acetonitriles, and it was inferred that the mechanism of these reactions is similar to that of the reaction of 1,3-oxazin-1-ium salt with malononitrile.



(II), (III), (IV)

II: X=-CN
III: =-$COOCH_3$
IV: =-C_6H_5

Experimental

4-Benzoylamino-5-substituted-2,6-diphenylpyrimidine (II), (III), and (IV). To a solution of 0.002 mol of each of the substituted acetonitriles and 0.30 g of triethylamine in 10 ml of dioxane, 1.30 g of Ia were added, and then the mixture was refluxed for 1 hr. The solvent was distilled off under reduced pressure, and the residue was washed with dilute hydrochloric acid, aqueous sodium hydroxide, and water, and recrystallized from acetic acid (II), ethanol (III), and acetone

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 2384—2386 (1969)

On the Ionic Association of Alizarine Saphirol SE in Water-dioxane Mixtures

Masaru MITSUISHI, Yasuko FUNATSU and Nobuhiko KUROKI*[1]

Faculty of Fiber Science and Technology, Shinshu University, Ueda, Nagano

(Received December 19, 1968)

In the previous paper, we have concluded from spectroscopic and conductance measurements that Alizarine Saphirol SE (sodium salt of 1,5-dihydroxy-4,8-diaminoanthraquinone-2-sulfonic acid) exists in the form of ionic associates in water-ethanol mixtures with a low dielectric constant.[1] This association was ascribed to the increase of Coulombic attraction between the dye ion and the counter ion. It may be reasonable to expect that Alizarine Saphirol also exists in the ionic associate in water-dioxane mixtures having lower dielectric constants than those of water-ethanol mixtures. Such interactions between the dye ion and the counter ion in the mixtures is supposed to be expressed quantitatively in terms of ion association constant of the dye ion with the counter ion in the solution.

Since literatures on the association constant of a dye in water-organic solvent mixtures can hardly be found, it seems valuable to examine the dissociation constant of Alizarine Saphirol in water-dioxane mixtures in order to obtain some suggestive information not only on the dispersed state of the dye but also on the effect of dioxane on the ultraviolet and visible spectra of the dye in the mixtures.

In this paper, the conductance data were used to determine the equivalent conductance at infinite dilution and ion association constant by means of Shedlovsky's treatment[2] based on Onsager's limiting theory.

Experimental

Materials. The Alizarine Saphirol SE (sodium salt of 1,5-dihydroxy-4,8-diaminoanthraquinone-2-sulfonic acid) was taken from the laboratory stock used in the previous work[1]. The dioxane was purified as follows. Dioxane of a guaranteed reagent grade was boiled with potassium hydroxide under reflux for several hours. It was distilled after dehydration with metallic sodium through a 40 cm refluxing column.

Conductance Measurements. The conductance measurements were made with a Yokogawa-Hewlett Packard Universal Bridge BV-2-13 B. A simple dilution cell with cell constant 0.0688 was used. All the measurements were made at 25±0.01°C. The specific conductance of the solvents was always less than 1.0×10^{-6} mhos.

Dielectric Constant Measurements. Dielectric constant measurements were made by means of heterodynebeat method at 500 Kc/sec. The heterodyne circuit was prepared in our laboratory, and an oscilloscope was used as a detector. The electric capacity was determined with a precision condenser of Ando Electric Co., Ltd. The sample cell was Yamato Kagaku's Dielectric cell EL-25. Benzene ($\varepsilon=2.273$) was used as a standard material.

Viscosity Measurements. The viscosity of the solvent was determined with an Ostwald type viscometer.

Results and Discussion

Shedlovsky's equation to obtain the association constant K_A and the equivalent conductance at infinite dilution Λ_0 of 1-1 electrolyte is based on Onsager limiting theory expressed as

$$\frac{1}{\Lambda S_{(z)}}=\frac{1}{\Lambda_0}+\frac{c\Lambda S_{(z)}f_{\pm}^{2}}{K\Lambda_0^{2}}, \qquad (1)$$

where Λ is the equivalent conductance at concentration c, and $f_{\pm}^{2}$ is given by the Debye-Hückel limiting law. The values of $S_{(z)}$ have been tabulated by Daggett.[3] K is the dissociation constant and equal to $1/K_A$.

According to Eq. (1), the plot of $1/(\Lambda S_{(z)})$ against $c\Lambda S_{(z)}f_{\pm}^{2}$ should give a straight line,

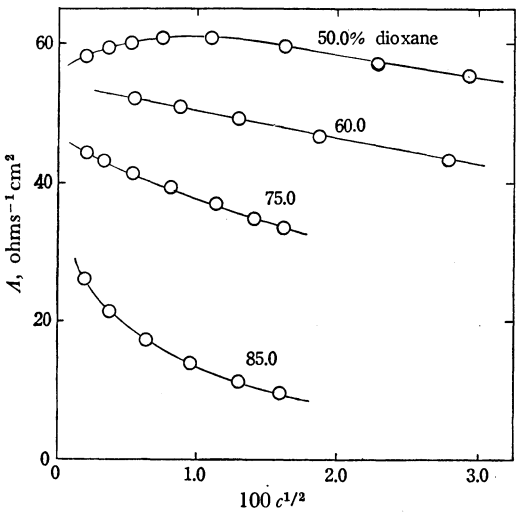

Fig. 1. Conductance of Alizarine Saphirol SE in water-dioxane mixtures.

passing through $1/\Lambda_0$ with a slope equal to $1/(K\Lambda_0)^2$; thus the association constant K_A and the equivalent conductance at infinite dilution Λ_0 can be determined.

The conductance of Alizarine Saphirol in water-dioxane mixtures is plotted against $\sqrt{c}$ in Fig. 1. In the solutions above 60% dioxane, the so-called McBain effects are not found on the Λ - $\sqrt{c}$ curves, so that Alizarine Saphirol is supposed to be monomeric in the solution.

In the previous paper, Alizarine Saphirol has been considered to be in the form of ionic associate in water-ethanol mixtures with a low dielectric constant from the conductance data.[1] It is reasonable to expect that Alizarine Saphirol exists in the form of ionic associate in the water-dioxane mixtures having dielectric constant lower than that of the water-ethanol mixtures. As shown in Fig. 1, the Λ - $\sqrt{c}$ curve of alizarine Saphirol in 85% dioxane is similar to that of weak electrolyte; thus the association constant is supposed to be appreciable.

Shedlovsky's treatment was used to determine Λ_0 and K_A, and the parameters resulting from the data analysis are given in Table 1.

The dielectric constants of the solvents in Table 1 are a little lower than those of Kunze and Fuoss,[4] and the viscosities of the solvents are comparable to those of Kunze and Fuoss

From Table 1, the ionic association constant K_A is seen to become larger with the increase of the proportion of dioxane in the mixtures; thus K_A becomes larger with the lowering of the dielectric constant of the solvent. This indicates obviously that the interaction between the dye ion and the counter ion increases with the lowering of the dielectric constant of the solvent.

In an attempt to analyze the data further, log K_A was plotted against $1/\varepsilon$ for the dye, and the result is shown in Fig. 2. Since the resulting plot is quite linear, the ionic associate in water-dioxane mixtures is considered to be formed entirely by the electrostatic interaction between the dye ion and the counter ion.

The Walden products ($\Lambda_0\eta$) are given in Table 1. It is found that $\Lambda_0\eta$ decreases steeply with the lowering of the dielectric constant of the solvent. The Walden products of some inorganic electrolytes in water-organic solvent mixtures have been found to become smaller than those in pure water by Atkinson *et al.*[5] who reported on the behavior of $MnSO_4$ in the mixtures of dioxane, methanol or acetone with water. A similar result has been obtained by Yokoi *et al.*[6] on Cu-*m*-benzenedisul-

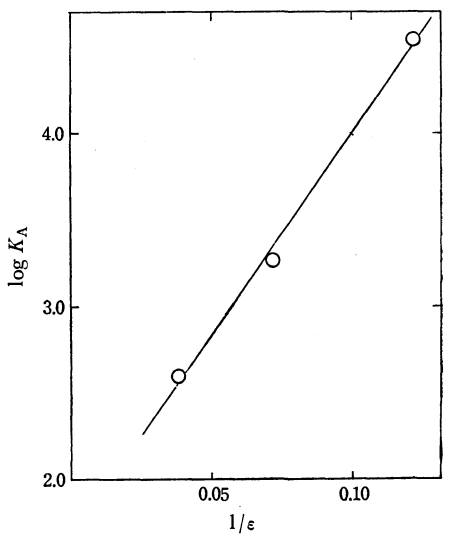

Fig. 2. Dependence of association constant on the reciprocal dielectric constant of the solvent.

fonate in water-methanol mixtures. These results have been explained in terms of the competition between water and polar organic molecules for positions in the first coordination sphere of the ions. In addition to this effect, in the case of Alizarine Saphirol, the dye contains electron donating or electron accepting groups, such as $>C=O$, $-NH_2$ and $-OH$, so that there would be strong and specific interactions between dioxane and these groups, and these interactions presumably affect the conductance behavior of the dye.

The conductance data alone, however, will not be sufficient to clarify the specific interactions between the dye ion and solvent molecule, so that it is necessary to investigate further by ultraviolet-visible, ESR and NMR spectroscopic measurements.

The authors wish to thank Professor Haruo Gotoh and Professor Masatoki Yokoi for their helpful discussions.

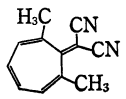
The Synthesis and Physical Properties of 1,6-Dimethyl-8,8-dicyanoheptafulvene

Masaji ODA, Makoto FUNAMIZU and Yoshio KITAHARA

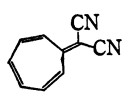
Department of Chemistry, Faculty of Science, Tohoku University, Katahira-cho, Sendai

(Received December 27, 1968)

In the course of our investigation of 8,8-dicyanoheptafulvenes, we needed to prepare 1,6-dimethyl-8,8-dicyanoheptafulvene (**1**). We wish here to report the synthesis of **1** and on its abnormalities in physical properties.



(**1**)



(**2**)

According to the method of the convenient synthesis[1] of 8,8-dicyanoheptafulvenes from tropones, refluxing 2,7-dimethyltropone[2] with malononitrile in acetic anhydride gave **1** in a 17% yield upon the separation of the reaction mixture by silica-gel-column chromatography. The IR, UV, and NMR spectra showed marked changes compared to those of 8,8-dicyanoheptafulvene (**2**)[3] (*cf.* Table 1). That is, the infrared absorption of the cyano group (2225 cm^{-1}) of **1** is at a higher frequency and its intensity is relatively weaker, while the ultraviolet absorption at the longest wavelength (390 mμ) is markedly weaker in intensity and the chemical shifts of ring protons are higher than those of **2**. These observations indicate that the conjugation of the cyano group with the seven-membered ring is appreciably hindered. This hindrance could be attributed to the deviation of **1**[4] from the planarity observed in **2**[5] by X-ray analysis, a deviation resulting from the intramolecular steric interaction between the methyl and the cyano groups. This is further supported by the fact that the dipole moment, 5.68 D (in benzene at 25°C), is far smaller than the value, 6.94 D,[6] calculated by regarding the seven-membered ring as a planar and regular heptagonal.

Experimental

8,8-Dicyanoheptafulvene (2). A solution of tropone (1.125 g, 10.6 mmol) and malononitrile (1.05 g, 15.9 mmol) in 10 m*l* of acetic anhydride was heated to reflux for 1.5 hr. The volatile substances were then removed *in vacuo*, leaving reddish crystals. The crystals were collected by filtration and washed with ethyl alcohol, giving 0.860 g of **2** as orange needles. The filtrate was concentrated and chromatographed on silica-gel eluted with benzene, this provided a further 0.315 g. Total yield, 1.175 g (72%). The melting point (201—202°C) and spectral data are all identical with those of an authentic sample.

Fluorescence Spectra of Aromatic Hydrocarbons in Polystyrene under High Pressure

Ichimin SHIROTANI, Takashi KAJIWARA and Hiroo INOKUCHI

The Institute for Solid State Physics, The University of Tokyo, Roppongi, Tokyo

(Received January 9, 1969)

The effect of pressure on the fluorescence spectra of aromatic compounds in the solid phase has been studied. Under pure hydrostatic pressures up to 8 kbar, ordinary fluorescence spectra of crystalline anthracene were observed.[1] However, when a quasi-hydrostatic pressure*1 of 7—10 kbar was applied to an anthracene crystal placed in the optical cell, a new broad emission band located in the 600 mμ wavelength region appeared.[2-4]

Between the new fluorescence band and the absorption spectra, no mirror image symmetry was found[5]; this new anomalous emission can be explained as an excimer fluorescence produced at high pressure. Similar phenomena were found on the fluorescence spectra of naphthalene, chrysene, 1,2-benzanthracene, 9,10-diphenylanthracene, and 2-methylanthracene. The increase in the fluorescence intensity of naphthacene doped in the anthracene host crystal with an increase in the pressure may be produced predominantly by the increment in the probability of energy transfer from the host to the guest.[6]

In this note, the fluorescence spectra of aromatic hydrocarbons dissolving in polystyrene under high pressure will be presented.

The high-pressure apparatus and the optical measurement attachment have already been reported.[6] A pressure up to 52 kbar was applied to the optical cell. A polystyrene sample containing aromatic hydrocarbons of about 0.05 wt% was prepared by the thermal polymerization of the monomer styrene containing dissolved hydrocarbons. The hydrocarbons used in this experiment were anthracene, perylene, benzo[*g,h,i*]perylene, and violanthrene B.

Figures 1 and 2 illustrate the fluorescence spectra of benzo[*g,h,i*]perylene and violanthrene B in polystyrene at several isobars. The fluorescence intensity of anthracene increased remarkably in the pressure range of 0—30 kbar,[6] but the intensity for perylene and violanthrene B decreased with an increase in the pressure. The peak shifts were smaller than that of the crystalline states, and a similar pressure effect has been found on their absorption spectra.[7] As is shown in Figs. 1 and 2, diffuse bands were observed at 52 kbar, but

*1 As a pressure transmitting medium, sodium chloride was used.

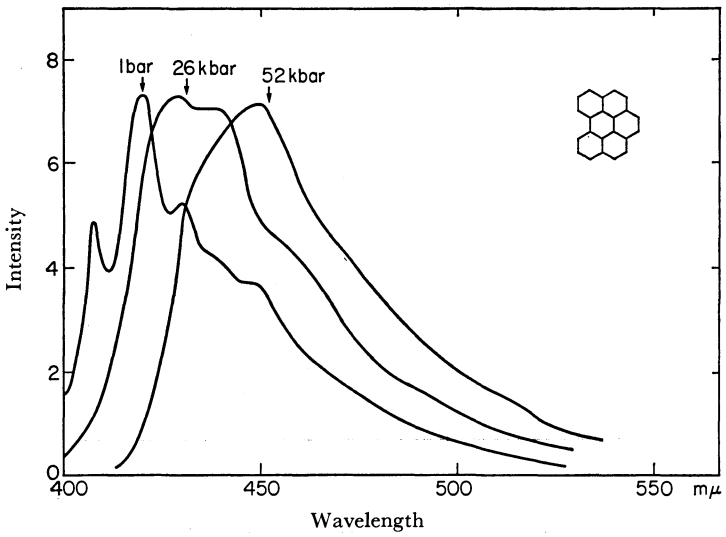

Fig. 1. The fluorescnce spectra of benzo[*g,h,i*] perylene in polystyrene matrix as a function of applied pressure.

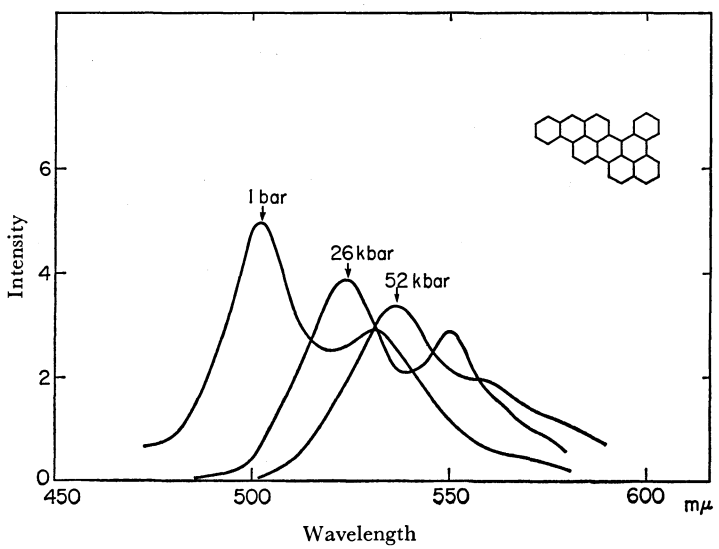

Fig. 2. The fluorescence spectra of violanthrene B in polystyrene under high pressure.

these broad emissions cannot be identified as the fluorescence of an excimer formed under high pressure. When benzo[*g,h,i*]perylene of 10^{-3}mol/*l* dissolved in polystyrene, the average intermolecular distance is not less than 30 Å, which is too large to form an "excimer." From the relation between the pressure and the volume given by Samara and Drickamer,[8] the average intermolecular distance at 52 kbar was estimated to be 94% of that at atmospheric pressure. Therefore, since the decrease in the molecular distance of the aromatic hydrocarbon-polystyrene system with the pressure is very small compared with the distance among the molecules in the polystyrene matrix, the formation of an excimer is difficult even at high pressure.

Figure 3 shows the fluorescence spectra at several isobars when two components—anthracene (5×10^{-2} mol/*l*) and perylene (10^{-4} mol/*l*)—were dissolved in polystyrene. The emission from anthracene was quenched with an increase in the pressure. On the contrary, the fluorescence intensity of perylene increased as the applied pressure increased. This behavior may arise from the energy transfer from anthracene to perylene. However, as has

8) G. A. Samara and H. G. Drickamer, *J. Chem. Phys.*, **37**, 474 (1962).

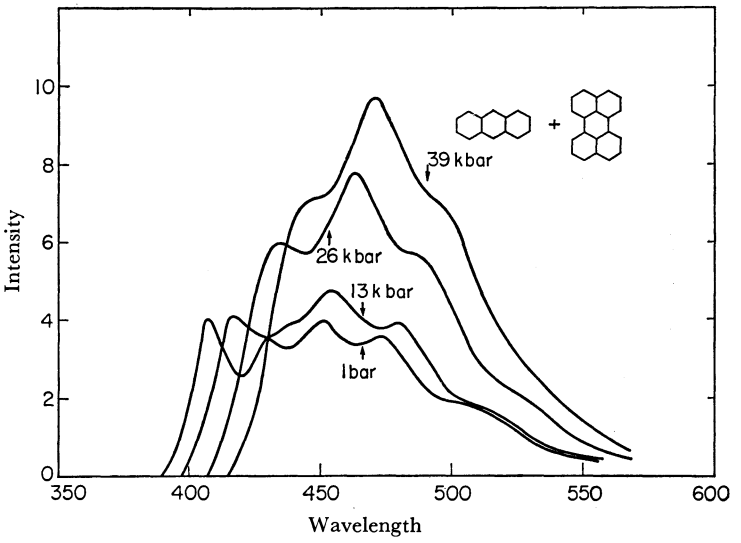

Fig. 3. The fluorescence spectra of anthracene-perylene mixture (guest)-polystyrene-(host)system under high pressure.

been mentioned previously, the discrepancy between the experimental and theoretical results for the anthracene-naphthacene mixed crystal system is very large.[6] For the anthracene-perylene mixture (guest) in polystyrene (host), a large discrepancy was also found. Therefore, the increase in energy transfer from anthracene to perylene may partly contribute to the effect of the pressure on these fluorescence phenomena.

The authors wish to thank Professor Junji Aoki and Mr. Satoshi Iwashima for their gift of the chemicals.

A New Synthetic Method of 4(1*H*)-Pyridones

Choji KASHIMA, Makoto YAMAMOTO, Susumu KOBAYASHI and Noboru SUGIYAMA

Department of Chemistry, Tokyo Kyoiku University, Otsuka, Tokyo

(Received January 16, 1969)

β-Diketones have been condensed with some nucleophilic reagents, such as ketones, aldehydes and esters, in the presence of alkali amide in liquid ammonia.[1,2] It has also been reported that Schiff bases have been condensed with β-diketones to give the corresponding dihydropyridiones.[3] Much like Schiff bases, nitrile is expected to condense with β-diketone to give 4(1*H*)-pyridone. Hauser and his co-workers reported[4] that acetanilide condensed with benzonitrile in the presence of two equivalents of butyllithium in *n*-hexane-tetrahydrofuran to give only ω-benzimidoylacetanilide. By the use of β-diketones instead of acetanilide in liquid ammonia, we obtained 4(1*H*)-pyridones directly. Many reports of 4(1*H*)-pyridone syntheses have appeared in the literature,[5-8] but this kind of 4(1*H*)-pyridone synthesis

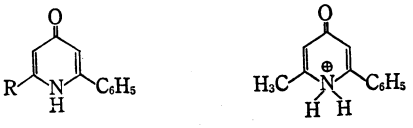
has never before been described.

Results and Discussion

In liquid ammonia, acetylacetone (I) was condensed with benzonitrile (IV) in the presence of alkali amide. When three moles of lithium amide were used, neither imino compounds nor 4(1*H*)-pyridones were obtained, but when two moles of sodium amide were used 6-methyl-2-phenyl-4(1*H*)-pyridone hydrochloride (VIII) was obtained in a 35% yield. When three moles of potassium amide were used, the yield of VIII increased to 42%. The structure of VIII was proved by a study of the spectral data and by elemental analyses. The treatment of VIII with sodium carbonate in a 90% ethanol solution gave 6-methyl-2-phenyl-4(1*H*)-pyridone (V) quantitatively; it was identified with an authentic sample.[9]



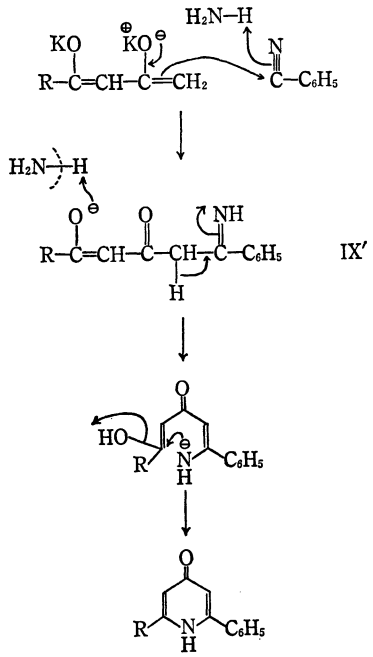
VIII

Scheme 1

In the same way, 6-phenyl-2,4-hexanedione (II) was condensed with IV. II has an activated terminal methyl group at C-1 and two activated methylene groups, at C-3 and C-5. Much as with the reaction of II with benzylidene aniline,[3] the reaction was effected to occur at the C-1 or C-5 position. However, the reaction of II occurred at C-1 and it afforded only one product, 6-phenethyl-2-phenyl-4(1*H*)-pyridone (VI).

The structure of VI was supported by the spectral data and by the elemental analyses. The infrared absorption spectrum of VI showed bands at 3260 (νNH), 1615 (conjugated ketone), 1580, 1520 (a pyridone-ring double bond), 1590, and 690 cm^{-1} (phenyl). The ultraviolet absorption spectrum showed absorption maxima at 242 and 261 mμ in an ethanol solution. The nuclear magnetic resonance spectrum in a deuterochloroform solution showed signals at τ 7.10 (singlet, 4H, phenethyl ethylene group), a doublet centered at τ 3.86 (2H, olefinic protons), a singlet at τ 2.85 (5H, aromatic protons of phenethyl group), and a multiplet centered at τ 7.32 (5H, C-2 substituted phenyl protons). These data supported the idea that the structure of VI is 6-phenethyl-2-phenyl-4(1*H*)-pyridone.

The condensation of benzoylacetone (III) with IV gave 2,6-diphenyl-4(1*H*)-pyridone (VII). The structure of VII was identified with that of an authentic sample.[10] It is considered that VII was



IX′

Scheme 2

produced *via* an intermediate imino compound (IX). However, an attempt to detect IX failed. This fact suggests that the cyclization of IX was accomplished before the neutralization.

We speculated that the reaction mechanism of this series is as follows: β-diketone and benzonitrile condense to give imino β-diketone (IX′) in the first step, and then IX′ is cyclized by dehydration to yield X, as is illustrated in Scheme 2.

Experimental

6-Methyl-2-phenyl-4(1*H*)-pyridone (V). *The Selection of the Reaction Conditions. A)* In a 500-m*l* three-necked flask, 300 m*l* of anhydrous liquid ammonia was placed. A small amount of potassium was then added and dissolved completely. Into the blue solution there was stirred a catalytic amount of ferric chloride, and then 5.85 g (0.15 g atom) of potassium were added in small portions. The resulting blue solution turned dark gray within 60—90 min. To this solution there was added 0.05 mol of I in 30 m*l* of anhydrous ether in small portions. After stirring for 60 min, 5.51 g (0.05 mol) of IV in 20 m*l* of anhydrous ether were added. After having been stirred for three hours at −33°C, the reaction mixture was neutralized with ammonium chloride. The liquid ammonia was evaporated rapidly on a water bath, and 100 m*l* of water was added from a dropping funnel. After 15 minutes' stirring, the ethereal layer was separated. To the alkaline aqueous layer 100 m*l* ether were added, and then the solution again extracted. To the remaining aqueous layer was added 100 m*l* of 2 N hydrochloric acid were added, after with the solution was allowed to stand at room temperature for 30 min. The resulting precipitate was recrystallized from hot water to give 4.94 g (42%)

of VIII as a white powder; mp 235—237°C, Beilstein test (+).

Found: C, 64.69; H, 5.64; N, 6.25%. Calcd for $C_{12}H_{12}NOCl$: C, 64.99; H, 5.43; N, 6.32%.

IR(KBr): 3250, 3400 (νNH), 1645, 1630 (νC=O, conjugated ketone and double bond) and 700 cm^{-1} (phenyl).

UV: λ_{max}^{EtOH} 235, 277 mμ.

B) According to the method *A*, 0.10 mol of sodium amide was used; 4.12 g (35%) of VIII was thus obtained.

C) According to the method *A*, 0.15 mol of lithium amide was used; VIII was not obtained.

To a solution of 1.0 g of VIII in 50 m*l* of 90% ethanol 5 g of anhydrous sodium carbonate was added; this mixture was then refluxed for two hours in a water bath. The resulting solution was filtered, and the solvent was removed under reduced pressure. The residue was recrystallized from hot water to give 0.75 g (93%) of V as a white powder; mp 174—176°C (lit 177—178°C[9]).

IR(KBr): 3300, 1625, 1580, 1525 and 700 cm^{-1}.

UV: λ_{max}^{EtOH} 240 mμ (ε 24800), 262 mμ (ε 15100).

NMR(in $CDCl_3$): τ 7.64 (3H, methyl, singlet), τ 4.00 (1H, olefinic proton, doublet), τ 3.73 (1H, olefinic proton, doublet), τ 2.35—2.72 (5H, aromatic protons, multiplet) and τ 1.50—1.90 (1H, NH, broad singlet).

6-Phenethyl-2-phenyl-4(1*H*)-pyridone (VI). According to the method *A*, VI was prepared from 8.0 g (0.05 mol) of II and 0.05 mol of IV. The product was dried in the air and then recrystallized from ethanol-acetone to give 7.1 g (51%) of VI as pale yellow plates; mp 172—173°C.

Found: C, 82.53; H, 6.36; N, 5.07%. Calcd for $C_{19}H_{17}NO$: C, 82.88; H, 6.22; N, 5.09%.

UV: λ_{max}^{EtOH} 241 mμ (ε 37500), 261 mμ (ε 25000).

2,6-Diphenyl-4(1*H*)-pyridone (VII). According to the method *A*, VII was prepared from 8.1 g (0.05 mol) of III and 5.15 g (0.05 mol) of IV. After the solution had been stirred for three hours at −33°C, the liquid ammonia was evaporated without neutralization. To the residue a 100 m*l* portion of water was added, and then 7.5 g (0.14 mol) of ammonium chloride in 100 m*l* of water. The ethereal layer was separated. The alkaline aqueous layer was extracted with three 100 m*l* portions of chloroform. After dried over calcium chloride, the chloroform solution was evaporated; the residue was chromatographed on a silica gel column (Merck 7734, 0.05—0.2 mm) with a benzene - ethyl acetate (4 : 1 v/v) mixture. The fraction (R_f-value: 0.18*[1]) was collected and concentrated to give only VII, which was then recrystallized from benzene to yield 3.83 g (31%) as white crystals: mp 178—179°C (lit 178°C[11]). No imino compound was detected.

IR(KBr): 3250, 1615, 1517, 1535 and 690 cm^{-1}.

UV: λ_{max}^{EtOH} 249 mμ (ε 32200), 280 mμ (ε 15000).

NMR (in $CDCl_3$): τ 3.25 (2H, olefinic protons, singlet), τ 3.00—3.80 (1H, NH, broad singlet) and τ 2.10—2.68 (10H, aromatic protons, multiplet).

The Epoxidation of α,β-Unsaturated Terpene Ketones

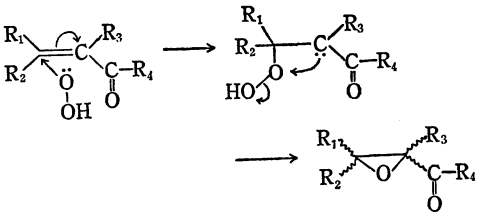
Jun KATSUHARA

Sun Star Dentifrice Company, Research Laboratory, Takatsuki, Osaka

(Received January 23, 1969)

It has recently been reviewed by Klein and Ohloff[1] that in a variety of α,β-unsaturated cyclic terpene ketones, the base-catalyzed epoxidation of exocyclic double bonds in conjunction with carbonyl groups proceeds in a non-stereoselective manner to produce a mixture of two diastereomeric epoxides, whereas in endocyclic double bonds, the steric course of epoxidation is highly stereoselective, resulting in the formation of a single product. However, they did not refer to the factors which govern the steric course of the epoxidation reaction.

The epoxidation of polarized double bonds with hydrogen peroxide in aqueous alkaline media was first reported by Weitz[2] and the reaction mechanism involving the intervention of a hydroperoxycarbanionic intermediate was proposed by Bunton.[3]



Dewar[4] advanced a theory for a facile bimolecular nucleophilic displacement of halogen α to

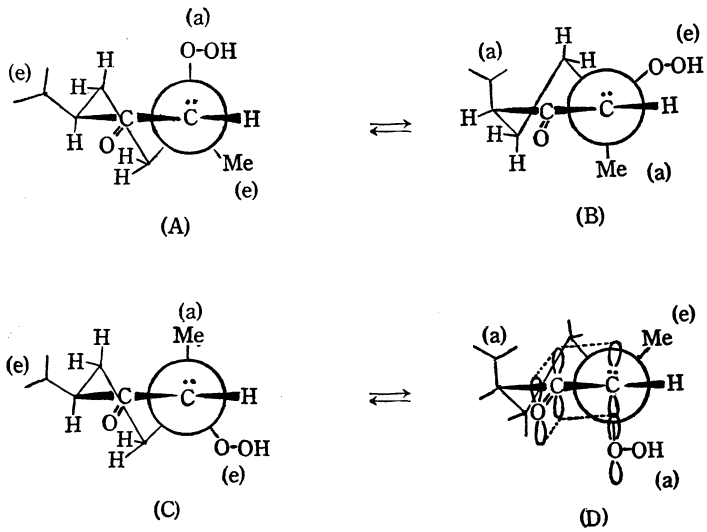
a keto group and his theory states that the transition state is stabilized by overlap and conjugation of the C=O π-orbital with the orbitals of the bonds being formed and broken at the α-carbon atom. This concept was successfully applied by Zimmerman[5] for the stereochemical interpretation of the alkaline epoxidation reaction, in which the stereochemical preference in epoxide products was overlap controlled.

We wish herewith to mention that the Zimmerman overlap-control theory holds for the epoxidation of α,β-unsaturated cyclic terpene ketones as well, and that the conformational analysis of the transition state carbanion, which fulfilled the stereoelectronic requirements for the maximum stabilization by orbital overlap and charge delocalization, may provide a useful means of assigning an absolute configuration to the epoxide to be expected from the epoxidation of cyclic terpene ketones containing either endocyclic or exocyclic ethylene linkage.

In accordance with this view, the available data[1] actually indicate that upon epoxidation, cyclic terpene ketones containing α,β-endocyclic double bonds afford stereospecifically the enantiomer to be expected from the intermediate hydroperoxycarbanion which was stabilized by the orbital-overlap and charge delocalization in the conformation with the minimized non-bonded repulsive interactions of substituents in the preferred equatorial disposition. This may be exemplified in detail by (−)-(4R)-piperitone (**1**) which upon epoxidation, yielded exclusively (+)-(1R : 2R : 4R)-piperitone oxide (**2**): the nucleophilic attack of hydroperoxide anion to the β-carbon (here $C_{(1)}$) of the polarized double bond in **1** would produce two conceivable transition state carbanions *i. e.* **A** resulted from the attack of the anion to the 1 *re*-2 *re* face of the double bond and **C** resulted from that to the 1 *si*-2 *si* face. The transition state carbanion **A** in which both the anchoring isopropyl and methyl groups are disposed equatorially and the hydroperoxy group is in an axial position, should naturally be in a conformational equilibrium with **B** where both isopropyl and methyl groups are disposed axially and hydroperoxy group is in an equatorial position. A similar conformational equilibrium should obtain in the diastereomeric transition state conformer **C**. Of the four conceivable transition states **A**, **B**, **C** and **D**, only **A** and **D** can fulfill the stereoelectronic requirements for oxirane ring formation by intramolecular nucleophilic displacement since in these two conformations, the axial hydroperoxy group is so disposed as to permit the cyclization and also to possess the maximum stabilization by orbital overlap and charge delocalization. Further choice of these two conformers, then, would be made from a purely steric point of view, *i. e.* the comparison of relative conformational stability as demonstrated by inspection of scale models clearly indicates that the transition state carbanion **A** with both the anchoring isopropyl and methyl groups oriented equatorially should be more favored than the diastereometric counterpart **D** with the bulky isopropyl group disposed in an axial position and methyl group in an equatorial position. Since the first step of hydroperoxide anion attack is reversible, the steric course of the epoxidation should be directed to proceed through the most favored transition state **A** and the chemical consequence of this situation should naturally be the exclusive

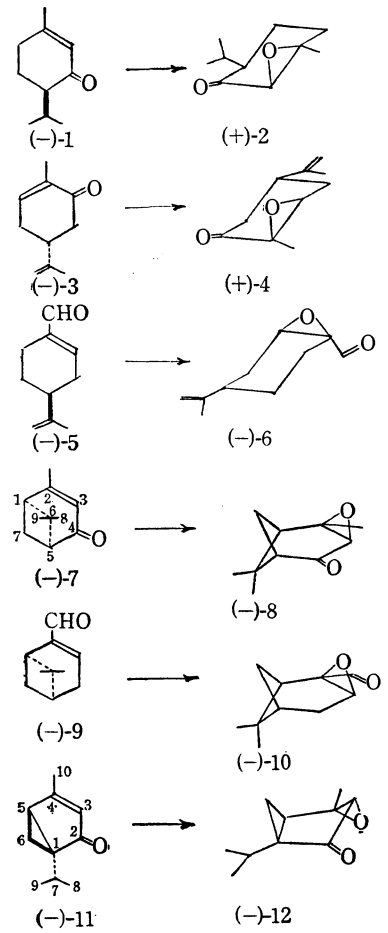


Scheme I

5) H. E. Zimmerman, L. Singer and B. S. Thyagarajan, *J. Am. Chem. Soc.*, **81**, 108 (1959).

formation of (+)-(1R:2R:4R)-piperitone oxide **2**. This is just what was found experimentally by the product analysis and the absolute assignment of configuration to **2**: the conformation of the most favored transition state **A** has been reflected as such in the epoxide product **2**.

Literature[1] affords cogent support for the stereochemical interpretation of epoxidation in terms of the overlap-control stabilization combined with conformational analysis, as demonstrated by the epoxidation of (−)-(4R)-piperitone (**1**) into (+)-(1R : 2R : 4R)-piperitone oxide (**2**); of (+)-(4S)-**1** into (−)-(1S:2S:4S)-**2**; of (−)-(4R)-carvone (**3**) into (+)-(1R : 2R : 4R)-carvone oxide (**4**); of (+)-(4S)-**3** into (−)-(1S : 2S : 4S)-**4**; of (−)-(4S)-perillaldehyde (**5**) into (−)-(1S : 2R : 4S)-perillaldehyde oxide (**6**); of (−)-(1R : 5S)-verbenone (**7**) into (−)-(1R : 2R : 3S : 5S)-verbenone oxide (**8**); of (+)-(1S:5R)**7** into (+)-(1S : 2S : 3R : 5R)-8; of (−)-(1R: 5S)-myrtenal (**9**) into (−)-(1R : 2R : 3S : 5S)-myrtenal oxide (**10**); of (−)-(1R : 5S)-umbellulone (**11**) into (−)-(1R : 3S : 4S : 5R)-umbellulone oxide (12),[6,7] respectively.



Scheme II

In a manner similar to the above-mentioned piperitone (**1**), the chair conformation of the intermediate hydroperoxy-carvone anion, with the isopropyl group disposed in an equatorial position and the hydroperoxy group in an axial position and thus with the advantage of overlap stabilization, would be more favored than the othewise-conformed counterpart, so that it would result in the end product **4** with the oxirane ring *trans* to the isopropyl group. What has been mentioned with carvone holds for (−)-perillaldehyde (**5**) as well. Verbenone (**7**) permits readier access to the 2 *si*-3 *re* face of the double bond because of the smaller bulkiness of $C_{(7)}$-hydrogen than the geminal dimethyl in the opposite side, thus naturally proceeding through the overlap-stabilized intermediate and resulting in the formation of the corresponding epoxide (**8**) (*trans* relative to geminal dimethyl). The situation is also the same with myrtenal which gave the *trans*-epoxide (**8**). (−)-Umbellulone (**11**), in which the bicyclo(3,1,0) system adopts the boat conformation as demonstrated by NMR-analysis,[8,9] also gave the corresponding *cis*-epoxide (**12**) (relative to isopropyl group) *via* the overlap-stabilized intermediate.

Based on these data, it may be generalized that in the epoxidation of endocyclic double bond involved in pinane skeleton, the isomer with the oxirane ring *trans* relative to geminal dimethyl groups is formed exclusively, and in other terpene ketones, the oxirane ring is stereospecifically introduced to the double bond so as to enable sterically the most favored intermediate conformation to be

stabilized by an effective and concomitant orbital-overlap stabilization.

When this generalization is applied to some endocyclic α,β-unsaturated terpene ketones, (1R)-3(4)-menthen-2-one (**13**) and (1R)-4(5)-menthen-3-one (**14**), the following configurations of the exclusive epoxide products may be predicted, experimental verification of which will be the subject of future publications.

Although available data for the epoxidation of exocyclic double bonds are scarce in literature, the epoxidation of (+)-(1R)-pulegone[10] (**15**), (+)-(1S : 5R)-pinocarvone[11] (**16**), (+)-(1R : 4S)-isopropylidenecamphor[12] (**17**) and (+)-(1S : 2S)-piperitenone oxide[10] (**18**) clearly shows that a mixture of diastereomeric epoxides is always obtained in a definite isomer ratio except in the last example, the sterically more favored and therefore the more stable isomer being dominant in every case. Since the exocyclic double bonds are not locked in a rigid cyclic skeleton and consequently the rotation around the single bond connecting the carbanionic sp^2-carbon (α) with the β-carbon carrying the hydroperoxy group is quite free, the hydroperoxy group is capable of fulfilling the stereoelectronic requirements for the maximum orbital overlap at both sides of the carbanionic sp^2-carbon and consequently to undergo nucleophilic displacement to form oxirane ring in two ways—one with axial oxirane-oxygen and equatorial carbon, and the other with the reversed conformational orientation of oxirane ring. The energy difference between these two diastereomeric transition states is thus purely steric in origin and is not so great as in the endocyclic counterparts, so that the stereoselectivity of epoxidation is dependent on the relative conformational stability of these two conformers, as was actually observed in product distribution.

Table 1

Starting material	Product isomers	Yield %
(+)-Pulegone	(−)-(1R:4R)-*trans*-**19**	64.5
	(+)-(1R:4S)-*cis*-**20**	35.5
(+)-Pinocarvone	(−)-(1R:2S:5R)-*trans*-**21**	35.5
	(+)-(1R:2R:5R)-*cis*-**22**	64.5
(+)-Isopropylidenecamphor	(−)-(1R:3S:4S)-*trans*-**23**	67
	(+)-(1R:SR:4S)-*cis*-**24**	33
(+)-Piperitenone oxide	(−)-(1S:2S:4S)-*cis*-**25**	

In pulegone oxide, the *trans* epoxide (**19**) (relative to $C_{(7)}$ and $C_{(10)}$) with the conformation involving both isopropyl and methyl groups in equatorial position is preferred to the *cis*-**20** with an axial methyl. The red shift in CD found for diastereomeric pinocarvone oxides showed the axial orientation of the oxirane-oxygen atom in both *trans*-**21** (relative to $C_{(6)}$ bridge carrying geminal dimethyl and $C_{(10)}$ methyl group) and *cis*-products (**22**) and on the basis of such conformations, the non-bonded interactions between the oxirane-oxygen and the $C_{(6)}$-dimethyl grouping favor the *cis*-**22** more than the *trans* epoxide (**21**), thus the former being the major product of epoxidation. The oxirane ring, $O-C_{(3)}-C_{(11)}$, in isomeric isopropylidenecamphor oxides is so situated as to be bisected by the carbonyl group and then the isomers differ in the non-bonded interactions between $C_{(7)}$-geminal dimethyl and isopropyl moiety of oxirane. Model inspection reveals that the the *trans* isomer (**23**) (relative to $C_{(7)}$ and $C_{(11)}$) is sterically more favored and stable than the *cis* **24**, in accordance with the result of product analysis. In the case of piperitenone oxide, the sole dioxide isolated (42%) was (−)-(1S : 2S : 4S)-diastereomer[10] (**25**) which has sterically the more favored conformation with both isopropyl moiety of oxirane and $C_{(1)}$-methyl group disposed equatorially. Although another diastereomeric *trans*-dioxide product was missing, the failure of its isolation may probably be due to experimental difficulties; this highly strained system containing two sensitive epoxide functions in an unfavorable conformation and a carbonyl group in a single C_{10}-molecule would supposedly be too labile to permit successful separation without any decay.

The author wishes to thank Professor T. Matsuura of Hiroshima University and Professor Y. Inouye of Kyoto University for many helpful discussions during this work.

BULLETIN OF THE CHEMICAL SOCEITY OF JAPAN VOL. 42 2395—2396 (1969)

Syntheses of Pterocarpans. IV.*1 A New Synthesis of 3,8,9-Trimethoxypterocarpan*2

Kenji FUKUI, Mitsuru NAKAYAMA and Kenji TSUZUKI

Department of Chemistry, Faculty of Science, Hiroshima University, Higashi-sendamachi, Hiroshima

(Received January 24, 1969)

In previous papers, the present authors reported a new method for synthesizing pterocarpans (*e.g.*, (±)-pterocarpin (I),[1] (±)-maackiain (II)[2] and (±)-4-methoxypterocarpin (III)[3]) from the corresponding benzofuro[3',2':3,4]coumarins. This paper will describe the synthesis of 3,8,9-trimethoxypteocarpan (IV) from 7,5',6'-trimethoxybenzofuro[3',2' : 3,4]coumarin (V)[4] in a manner similar to that described earlier.[1-3]

The coumarin (V) was subjected to lithium aluminum hydride reduction in refluxing tetrahydrofuran. As expected, the reduction proceeded smoothly, giving the expected product, 5,6-dimethoxy-2-(2-hydroxy-4-methoxyphenyl)-3-hydroxymethylbenzo[*b*]furan (VI), in a 50% yield. The infrared spectrum of VI exhibits absorption bands at 3450 and 3200 cm^{-1} which are attributable to two hydroxyl groups. The diacetate of VI was easily prepared with acetic anhydride in pyridine. The subsequent dehydration of the diol (VI) in boiling diethyleneglycol afforded 3,8,9-trimethoxy-6a,11a-dehydropterocarpan (VII), mp 145—146°C. The NMR spectrum*3 of VII is closely similar to that of anhydropisatin (*O*-methyl anhydrosophorol) (VIII)[1,5] in having a methylenedioxyl group instead of dimethoxyl groups. Then, VII was hydrogenated in acetic acid with 10% Pd-C to the desired pterocarpan (IV), mp 135—136°C. This substance was found to be identical with an authentic sample which had been obtained by a different route[6] in a mixed melting-point determination and by infrared, ultraviolet, and NMR spectral comparisons.

Infrared Spectra of Bis(2,4-dichloro-6-ethoxymercapto-isocyano-*s*-triazino-*N*,*S*) Copper(II)

Kiyoyasu KAWAI, Fujio MIZUKAMI and Yutaka KODAMA*1

Faculty of Literature and Science, Toyama University, Gofuku, Toyama

(Received February 3, 1969)

In a previous paper, the infrared and Raman spectra of 2,4-dichloro-6-isocyanodichloro-*s*-triazine(tetrameric cyanogen chloride: DCT-$NCCl_2$) have been reported[1]. The present paper will deal with the preparation of the bis(2,4-dichloro-6-ethoxymercaptoisocyano-*s*-triazino-*N*,*S*) copper(II) complex, [Cu(DCT-$NCSOC_2H_5)_2$], and with the infrared spectra of the complex and 2,4-dichloro-6-ethoxythiocarbamido-*s*-triazine, DCT-$NHCSOC_2H_5$, which is a derivative of DCT-$NCCl_2$ and the parent molecule of the ligand of the complex, in order to assign the observed spectra.

Experimental

2,4-Dichloro-6-ethoxythiocarbamido-*s*-triazine: DCT-$NHCSOC_2H_5$. This was prepared by the method described previously[2] and was identified analytically.

By the addition of sodium hydroxide to an aqueous solution of cupric nitrate (0.02 mol), its pH was adjusted to 7.4; it was kept at about 0°C. A solution of DCT-$NHCSOC_2H_5$ (0.02 mol) in chloroform was stirred drop by drop into the aqueous solution of cupric nitrate. The stirring continued for about five hours. The reaction mixture was then placed in a separatory funnel in order to separate the chloroform portion from the aqueous one. By evaporating the chloroform portion under reduced pressure, the red-brown colored crystal was precipitated and dried *in vacuo*. Recrystallization from carbon tetrachloride gave bis(2,4-dichloro-6-ethoxymercaptoisocyano-*s*-triazino-*N*,*S*) copper(II).

Found: Cu, 10.01; C, 25.34; N, 19.56; H, 1.90%. Calcd for $CuC_{12}N_8O_2S_2H_{10}Cl_4$: Cu, 11.19; C, 25.39; N, 19.74; H, 1.90%.

The infrared spectra were recorded by a Nujol or hexachloro-1,3-butadiene mull from 4000 to 250 cm^{-1} with Hitachi-Perkin-Elmer 125 and Hitachi EPI-L spectrometers. The frequencies of the observed bands may be expected to be accurate to ± 2 cm^{-1}; they may tentatively be assigned as is shown in Table 1.

The NMR spectra were also recorded, using a Japan Electron Optics C-60H spectrometer at the frequency of 60 Mcps in deuterium-chloroform, with tetramethylsilane as an internal standard; this examination revealed the signals of two groups, a quartet at τ 5.38 and a triplet at τ 8.60, in the complex, and the signals of three groups, a singlet at τ 1.18, a quartet at τ 5.45, and a triplet at τ 8.55, in DCT-$NHCSOC_2H_5$.

Results and Discussion

The absence of the band assigned to the N-H stretching vibration in the infrared spectra of the complex is confirmed by its NMR spectra, in which only the signals due to the presence of a typical ethyl group have been observed.

A very strong and broad band at 1488 cm^{-1} assigned to the triazine ring-stretching vibration of the complex may be the overlap of two or more bands; the frequency has shifted toward frequencies lower than the 1526 and 1503 cm^{-1} of DCT-$NHCSOC_2H_5$ or those assigned to the ring-stretching vibration in several triazine derivatives.[1,3-5] This frequency shift suggests that there may be small differences in the nature of the bonds in the triazine ring and a decrease in the C=N stretching force constant of the ring as a result of the formation of the complex with the chelate ring.

The great difference between the infrared spectra of DCT-$NHCSOC_2H_5$ and those of the complex may arise from the C=S and C=N stretching frequencies in the chelate ring. By comparing the spectra of the two compounds, the strong band at 1403 cm^{-1} and the two bands at 1100 and 1295 cm^{-1} of DCT-$NHCSOC_2H_5$ may be assigned to the C=S stretching vibration and the symmetric and asymmetric C-N stretching vibrations of the $-\overset{\|}{C}(ring)-\overset{|}{N}-\overset{\|}{C}-$ group respectively; the C=S stretching frequency of the complex shifts lower by means of the coordination of the sulfur atom, that is, by the contribution of $C-S^- \rightarrow Cu$. On the other hand, the C=N stretching frequencies in the chelate ring shift higher because of the increase in the double-bond character. On the basis of the above facts and the assignment of other bands, the three bands at 1112, 1291, and 1355 cm^{-1} of

the complex may be assigned to C=S stretching, symmetric C=N stretching, and asymmetric C=N stretching vibrations of the chelate ring respectively. Although some of the observed bands, including most of those in the lower frequency region, have not been assigned, the infrared spectra suggest that the complex is the chelate compound shown in Scheme I.

The Spectrophotometric Determination of Scandium with Eriochrome Azurol G

Katsuya UESUGI

Laboratory of Chemistry, Himeji Institute of Technology, Himeji

(Received February 3, 1969)

Some dyes of the triphenylmethane series react with many metallic ions in a weakly or a slightly acidic medium to form colored complexes. In preceding papers,[1,2] the present author and his co-workers described how pontachrome azure blue B and chromal blue G, dyes of this series, were excellent reagents for the spectrophotometric determination of scandium.

This paper will describe a spectrophotometric determination of scandium using eriochrome azurol G (sodium-2'',5'',6''-trichloro-4'-hydroxy-3,3'-dimethylfuchsone-5,5'-dicarboxylate, color index 43855), which is one of the compounds of this series. It is based on the reddish-violet complex formation between scandium ions and eriochrome azurol G in a slightly acidic medium. Several conditions under which small amounts of scandium can be determined, the influences of diverse ions, and the composition of the complex will be investigated. This reagent has been examined as an indicator of the titrimetric determination of potassium by tetraphenylborate and benzalkonium chloride.[3]

Experimental

Reagents and Apparatus. *Standard Scandium Solution.* 153 mg of scandium oxide (Mitsuwa Chemicals) were dissolved in small amounts of concentrated hydrochloric acid, and the solution was diluted to 1 *l* with water. This standard stock solution (100 ppm of scandium) was diluted further as required.

0.1% Eriochrome Azurol G Solution. Eriochrome azurol G (Tokyo Kasei Kogyo Co., Ltd., Tokyo) was further purified by recrystallization from ethanol before use, and then 0.1 g of it was dissolved in 100 m*l* of 95% ethanol. This reagent solution was stable for at least a month.

All the other reagents and apparatus used were the same as those reported previously.[2]

Procedure. Into a 25 m*l* volumetric flask place the standard solution or a sample solution containing 2.5—25 μg of scandium, and then add 2 m*l* of the 0.1% eriochrome azurol G solution. Add 10 m*l* of the buffer solution (pH 6.0, 0.2 M in acetate), mix thoroughly, and then dilute to the volume with distilled water. Measure the absorbance at 610 mμ using a reagent blank as a reference. Calculate the amount of scandium from the calibration curve.

Results and Discussion

Absorption Spectra. The absorption spectra of the reagent at various pH's are shown in Fig. 1. The maximum absorption of the reagent solution is found at 490 mμ below pH 4.5, at 430 mμ between pH 5.5 and 10, and at 590 mμ above pH 10.5. The absorbance curves of the scandium-eriochrome azurol G complex at various pH are shown in Fig. 2. The maximum absorption of the complex between 450 and 700 mμ is found at 610 mμ above pH 5.0. At pH 4.0, the complex in the visible region has two maxima, one at 600 mμ and another at 530 mμ. Below pH 3.5,however, the absorption maximum is found at 530 mμ.

Effect of the pH. The effect of the pH on the color reaction was investigated by taking absorbance measurements at 610 mμ of solutions containing scandium and eriochrome azurol G at various pH values. The results are shown in Fig. 3, from which it can be seen that the maximum absorbance of the scandium complex occurs in the pH range from 5.6 to 6.6. The reagent blank curve was

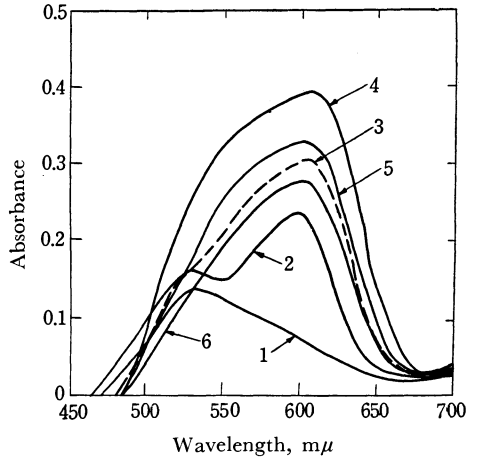

Fig. 2. Absorption spectra of scandium complex at various pH.
Reagent 80 ppm, Sc 0.6 ppm,
Reference: Reagent blank
pH 1: 3.4, 2: 4.0, 3: 5.0, 4: 6—6.4, 5: 7.0, 6: 8.0

obtained in the same manner, using the same amount of reagent. The acetate - acetic acid buffer, pH 6.0, was found to be satisfactory. The volume of the pH 6.0 buffer used was found to have no effect on the absorbance of a 0.5-ppm scandium solution over the range from 5 to 10 m*l* per 25 m*l* of solution.

Effect of Eriochrome Azurol G Concentration. The effect of the reagent concentration on the complex was investigated by measuring the absorbance at 610 mμ on solutions containing constant concentrations of scandium and the buffer and varying amounts of eriochrome azurol G. The absorbance increases as the reagent concentration increases. Therefore, it is desirable to keep the reagent concentration constant. Two milliliters of a 0.1% reagent solution was found to be sufficient for less than 1.0 ppm of scandium.

Color Stability. At room temperature, the formation of the scandium-eriochrome azurol G complex is substantially instantaneous, and its intensity is stable for at least one hour; only a 2% decrease in absorbance occurs after one hour when measured against a reagent blank.

Effect of the Temperature. The effect of the temperature on the color development was investigated by measuring the absorbance of solutions kept for 20 min at various temperatures. The absorbance does not change over the temperature range of 10 to 40°C. Over 40°C, the absorbance gradually decreases. Hence, normal temperature changes in the laboratory seem to have no effect.

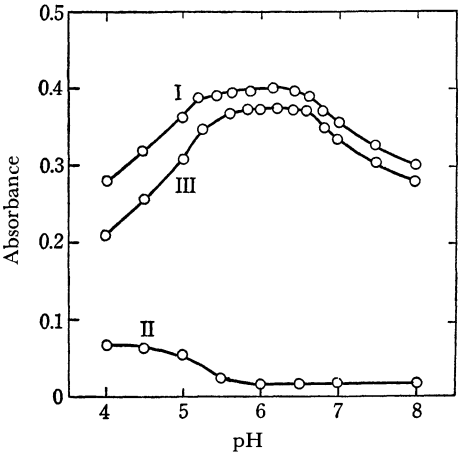

Fig. 3. Effect of pH on color intensity.

II: Reagent 80 ppm (Reference: water)
III: Reagent 80 ppm + Sc 0.6 ppm (Reference: Reagent blank)

Beer's Law and Sensitivity. Various amounts of a standard scandium solution containing up to 35 μg of scandium were used following the procedure mentioned above. Beer's law is obeyed over the range from 0.1 to 1.0 ppm of scandium. At 610 mμ the molar extinction coefficient is 29600. The spectrophotometric sensitivity is estimated to be 1.5×10^{-3} μg of scandium per cm², corresponding to log $I_0/I=0.001$.

The present method is very sensitive. Its sensitivity is much greater than that of the methods using eriochrome cyanine R (molar extinction

coefficient, $\varepsilon=19000$),[4] pyrocatechol violet ($\varepsilon=17300$),[5] arsenazo I ($\varepsilon=17000$),[6] pontacyl violet 4BSN ($\varepsilon=13700$),[7] tiron ($\varepsilon=8000$),[8] and naphthyl azoxine S ($\varepsilon=8000$);[9] its sensitivity is slightly higher than that of chromazurol S ($\varepsilon=27000$),[10] and it is comparable with that of the method using pontachrome azure blue B ($\varepsilon=31500$),[1] chromal blue G ($\varepsilon=31400$),[2] and xylenol orange ($\varepsilon=29410$).[11]

Precision and Accuracy. Nine determinations of 0.5 ppm of scandium gave a standard deviation of ±0.0074 ppm or a relative standard deviation of $\pm1.5\%$.

Effect of Diverse Ions. The effect of 26 cations and some anions on the determination of scandium was examined (Table 1). Many diverse cations, especially beryllium, copper(II), aluminum, iron(III), yttrium, thorium, and rare earth elements, interfere seriously with the determination of scandium, for they form complexes with eriochrome azurol G under the present experimental conditions (Fig. 4). The following anions do not interfere under the conditions described: sulfate, chloride, nitrate, and acetate, even when they are present in an anion-to-scandium ratio of 1 to 6000. The presence of oxalate, fluoride, citrate, and EDTA bleaches the color of the complex.

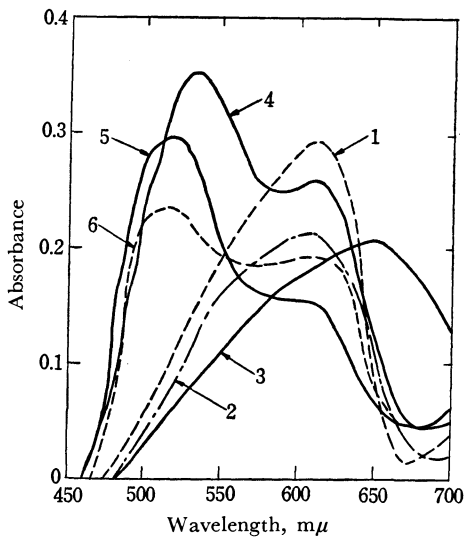

Fig. 4. Absorption spectra of beryllium, aluminum, iron(III), yttrium, lanthanum, and neodymium complexes at pH 6.0.
Reagent 80 ppm, Reference: Reagent blank
1: Be 0.15 ppm, 2: Al 0.13 ppm, 3: Fe(III) 0.3 ppm, 4: Y 2 ppm, 5: La 2 ppm, 6: Nd 2ppm

The absorption curves of the complexes of beryllium, aluminum, iron(III), yttrium, and some rare earth elements at pH 6.0 are shown in Fig. 4. The maximum absorbances of the beryllium and aluminum complexes are at 610 mμ, much like that of the scandium complex, and that of iron(III) complex is shifted toward a longer wavelength. The complexes of yttrium, lanthanum, gadolinium, and erbium have two absorption maxima, as is shown in Fig. 4.

Complex Formation. The composition of the scandium-eriochrome azurol G complex was

determined by the continuous-variation method[12] and the mole-ratio method.[13] The results indicated that a 1 : 2 complex between scandium and eriochrome azurol G is formed at pH 6.0, and a 1 : 1 complex below pH 4.0. The formation constant of the scandium complex was determined spectrophotometrically by the same method as in a previous paper.[2] The formation constant for the complex at pH 6.0 and 25°C was calculated, from the curves of the continuous variation, as 2.6×10^{10}.

SHORT COMMUNICATIONS

Mechanochemical Spin Generation in a Solid Charge Transfer Complex

Masatake OHMASA, Minoru KINOSHITA and Hideo AKAMATU

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received May 27, 1969)

In a previous paper, we have reported on electronic interactions in the solid charge-transfer complexes formed between tetracyanoquinodimethan (TCNQ) and a series of aromatic diamines, and have shown that most complexes can be divided into two main groups according to whether their ground electronic state is non-bonding or ionic.[1] In the course of the study, however, we found that the solid complex of benzidine and TCNQ could not be classified definitely to either of these two groups, as its infrared absorption spectrum was not explained either by a superposition of the spectra of neutral components or by a superposition of the spectra of ionic components.

We report here an interesting phenomenon found during the course of the work to elucidate the character of the ground electronic state of the benzidine-TCNQ system. Solid samples were precipitated from a solution in a similar manner to that described before[1] using several different solvents. Spectroscopic analysis of these solid complexes has indicated that there are two kinds of complexes with respect to occlusion of solvent molecules. The results obtained from the analysis of solution spectra in the UV and visible region are given in Table 1. As an example, the complex prepared in chloroform does not contain any solvent molecule, whereas that prepared in dichloromethane contains solvent molecules in mole ratios of approximately 1 : 1 : 1.5 (benzidine: TCNQ: solvent).*1

These two types of complexes are quite different in their infrared and ESR behaviors. As is shown in Fig. 1, the solid complex composed only of the donor and acceptor molecules exhibits the infrared absorption spectrum well explained by a superposition of the spectra of neutral component molecules, but, in the case of the complexes containing solvent molecules, the spectrum is distinctly different from that for the solvent-free complexes even apart from the bands assigned to the solvent molecules. (See also Fig. 2(c) of Ref. 1.)

TABLE 1. COMPOSITION OF THE BENZIDINE-TCNQ-SOLVENT SYSTEM AS DETERMINED SPECTROSCOPICALLY

$CHCl_3$	1.0 : 1.0 : 0
CH_3CHCl_2	1.0 : 1.1 : 0
CH_2Cl_2	1.0 : 1.1 : 1.6
$(CH_3)_2CO$	1.0 : 0.8 : 0.8
CH_3CH_2Br	1.0 : 1.1 : 1.6

* (Benzidine) : (TCNQ) : (Solvent)

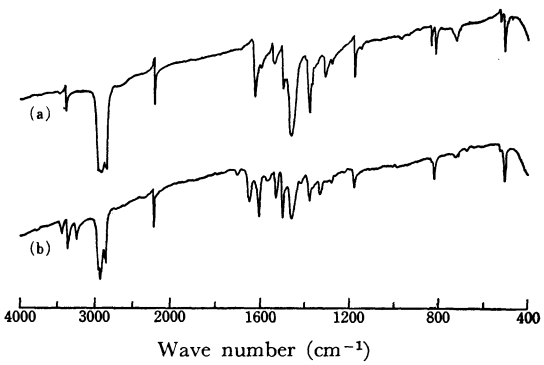

Fig. 1. Infrared absorption spectra of the benzidine - TCNQ complexes; (a) Solvent-free complex and (b) Solvent(acetone)-occluded complex.

In the ESR experiments, a well-grown crystalline sample of benzidine - TCNQ complex containing dichloromethane showed no ESR absorption, but it did give a strong ESR absorption signal (g= 2.0027) when it was ground to fine powder. On the other hand, the solvent-free complexes did not show ESR absorption at all, whether they were ground to fine powder or not.

Preliminary measurements showed that the electrical conductivities for the solvent-occluded samples were always higher by a factor of 10^4—10^5 compared to those for the solvent-free samples. These prominent effects of solvent occlusion on the electronic properties of the system are of great interest and further detailed studies including structural analysis are now in progress in our laboratory.

Preparation of a Dimeric Copper(II) Complex with Dithio α-Diketone

Seizo MISUMI and Kazuo KOYA

Inorganic Chemistry Laboratory, Faculty of Science, Kyushu Universiy, Fukuoka

(Received June 2, 1969)

Stilbenedithiol is a bidentate ligand containing two sulfur atoms. Several metal complexes with this ligand have been prepared by Schrauzer.[1] Regarding the copper(II) complex, however, only bis(maleonitrile dithiolato)Cu(II)[2] and bis(toluene-3,4-dithiolato)Cu(II)[3] have been reported. In this paper, we will describe the preparation of a novel copper(II) complex with stilbenedithiol as a dithio α-diketone complex.

By using the benzoin-P_4S_{10} method,[4] a copper(II)-stilbenedithiolate complex was prepared through the reaction of the thiophosphoric ester of stilbenedithiol and an excess of copper(II) in benzene; a dark violet complex was thus isolated. This complex, recrystallized from dioxane, is soluble in dichloroethane, chloroform, and ethanol, and it was found by elementary analysis to have the formula of $Cu_2S_2(S_2C_2(C_6H_5)_2)_2$. (Found: C, 49.98; H, 3.22; S, 26.95±3; Cu, 19.1%. Calcd for $Cu_2S_2(S_2C_2(C_6H_5)_2)_2$: C, 49.75; H, 2.99; S, 28.46; Cu, 18.08%). A molecular-weight determination by the use of the "Vapour Pressure Osmometer" showed that this compound was dimeric (Found: 661, Calcd: 676) and had a sulfur-bridged structure, one similar to the dimeric compounds of iron(II)[5] and molybdenum.[6] The structure may be supposed, as is shown in Fig. 1, to be a dimeric copper(II)-stilbeneditiolate complex.

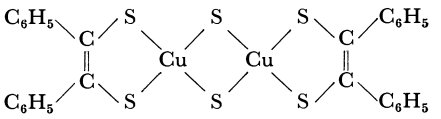

Fig. 1

It was found that this complex is diamagnetic. The absorption spectrum of the complex in dichloromethane shows that all the electronic transitions are at slightly longer wavelengths than those of the monomer; this fact is probably due to the dithion resonance *via* the sulfur bridges.

In the infrared spectrum, the C=C band was observed at 1445 cm^{-1}; this indicates about a 75% double-bond character, according to Schrauzer's relationship between the C=C stretching frequencies and the calculated % of the C=C character.[5] The peak at 328 cm^{-1} in the far-infrared region is probably to be assigned to the Cu-S stretching frequency. The detailed results will be reported shortly.

Isotope Effects on the Reactions of ^{82}Br Activated by Isomeric Transition between CH_4 and CD_4

Enzo TACHIKAWA

Division of Chemistry, Japan Atomic Energy Research Institute, Tokai-mura, Ibaraki

(Received June 9, 1969)

^{82}Br activated by the isomeric transition originally has a high charge and a high energy resulting from the Auger process following the internal conversion.[1] Thus, it can react with a reactant *via* the energetic process and also *via* the thermal ionic process.

Spicer and Gordus[2] studied the reaction of ^{80}Br activated by the (I.T.) process with CH_4 and CD_4 and found that the total organic yield in the reaction with CH_4 is higher than in that with CD_4 by a factor of 1.5. On the other hand, Nicholas and Rack[3] attempted to prove that equal organic yields result from both the ^{82m}Br-CH_4 and ^{82m}Br-CD_4 systems. However, these measurements do not offer any information concerning the isotope effects in the individual reaction processes, energetic and thermal ionic.

This paper will described the study of the influence of the moderator gas on the individual products from both the ^{82m}Br-CH_4 and the ^{82m}Br-CD_4 systems; this study was undertaken in order to ascertain the isotope effects on each reaction process separately. The details of the experimental methods may be found elsewhere.[4] In all samples the ratio of Br_2 as a scavenger relative to CH_4 or CD_4 was kept constant, 0.11 ± 0.01, and the total pressure was 51 ± 1 cmHg.

Figure 1 shows the moderator effects on the products. $CH_3{}^{82}Br$ and $CD_3{}^{82}Br$ are $5.0\%\pm0.5\%$ and $2.1\%\pm0.2\%$ respectively at zero mole fraction of the moderator, and both can be extrapolated to $0.5\%\pm0.2\%$ at a 1.0 mol fraction of the moderator. On the other hand, $CH_2{}^{82}BrBr$ and $CD_2{}^{82}BrBr$ are constant at $1.1\%\pm0.2\%$ at any mole fraction of the moderator. This indicates that the $CH_3{}^{82}Br$ and $CD_3{}^{82}Br$ formed *via* the energetic process are $4.5\%\pm0.5\%$ and $1.6\%\pm0.2\%$ respectively. It may, then, be concluded that there is an isotope effect between CH_4 and CD_4 in the energetic reaction but not in the thermal ionic reactions.

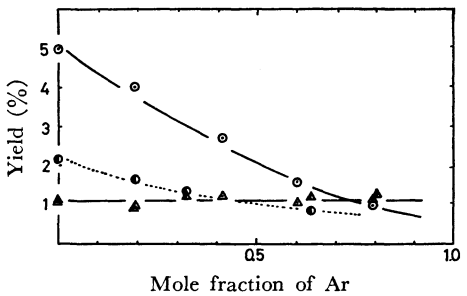

Fig. 1. Moderator effects on the yields of CH_3Br and CH_2Br_2.
system: ^{80m}Br-CH_4 ◐ $CH_3{}^{80}Br$ ◭ $CH_2{}^{80}BrBr$
system: ^{82m}Br-CH_4 ⊙ $CH_3{}^{82}Br$ △ $CH_2{}^{82}BrBr$

Several possible sources for the observed isotope effect in the energetic reaction can be considered, such as in the case of the reaction of the recoil tritium atom[5]: the moderator isotope effect, the probability-integral isotope effect, and the average-energy isotope effect. The present results demonstrate that the yeild of $CH_3{}^{82}Br$ is consistently higher than that of $CD_3{}^{82}Br$ at any mole fraction of the moderator and that the $CH_3{}^{82}Br/CD_3{}^{82}Br$ ratio for the energetic reaction is rather constant (3.0 ± 1.0). These findings are consistent with the moderator isotope effect and /or the probability-integral isotope effect. However, the moderator isotope effect is particularly important in the low mole fraction of the moderator; it becomes less important with an increase in the mole fraction of the moderator, since the energy loss through the nonbonding collisions with the moderator then become predominant. Thus, it would appear that the probability integral isotope effect is more important than the moderator isotope effect.

At this moment, it is not clear why the isotope effect was not found for the total organic yields in the work by Rack et al.[3] One possible reason is the inclusion of a polymer tagged with ^{82}Br in their analytical results.

Natural Occurrence of Humulol and Tricyclohumuladiol

Yoko NAYA and Munio KOTAKE

The Institute of Food Chemistry, Dojimanaka, Kita-ku, Osaka

(Received June 11, 1969)

In our series papers[1] we have reported new constituents of hop oil. This communication will deal with two sesquiterpene alcohols, humulol (I) and tricyclohumuladiol (II), isolated from the same source.

The alcohol (I) is a viscous oil, $C_{15}H_{26}O$, $[\alpha]_D^{24}$ $-1.2°$ ($c=0.87$, MeOH), which exhibited hydroxyl group absorptions (3370 and 1110 cm^{-1}) in the IR spectrum. The other characteristic absorption bands were shown at 1380, 1365 (*gem*-dimethyl), and 980 cm^{-1} (C=C *trans*). The IR and NMR spectra of the compound I were identical with those of the alcohol, which had been isolated by Buttery *et al.*[2] They suggested[3,4] that the alcohol might be the same as Chapman's luparenol,[5] also isolated from hop oil; this suggestion was made on the basis of the molecular formula, $C_{15}H_{24}O$. If the two are the same, the molecular formula must be corrected. However, the identity of the compound (I) and "luparenol" can not be confirmed because of insufficient evidence. To avoid confusion, therefore, we propose the name "humulol" for the compound (I).

Its NMR spectrum*1 showed two singlets, at 1.05 and 1.10 (each 3H), and a doublet at 1.59 (3H, $J=1$ Hz), due to tertiary methyl groups and a vinyl methyl group respectively; and a singlet at 1.15 (3H) assignable to a methyl attached to a carbon atom bearing a hydroxyl group; complex multiplets located between 4.90—5.20 account for three vinyl protons (HC=CH and $CH=CCH_3$). The mass spectrum exhibited its molecular ion peak at *m/e* 222 and its base peak at *m/e* 82.

The hydrogenation of I with PtO_2 in acetic acid gave the saturated compound, $C_{15}H_{30}O$ (M^+, *m/e* 226).

When the alcohol (I) was injected in a preparative GLC (SF-96) at 220°C, the greater part of it was converted into β-humulene, which was identical with the authentic compound (IR, NMR, and MS). The above evidence indicates the structure I for humulol.

The diol II, named tricyclohumuladiol, $C_{15}H_{26}O_2$, $[\alpha]_D^{24}$ 0° ($c=2.7$, MeOH), was recrystallized from methanol - ether as colorless plates; mp 207°C. II exhibited hydroxyl absorptions (3300, 1135 cm^{-1}) and bands (1010, 895 cm^{-1}) assignable to cyclopropane ring in the IR spectrum; other peaks of diagnostic value were at 1360 and 1375 (*gem*-dimethyl). Its NMR spectrum ($(CD_3)_2SO$) showed singlets at 0.89, 0.95, 0.96, and 1.03 (each 3H, tertiary methyls); a multiplet centered at 2.98 (1H) is assignable to a proton on the carbon atom bonded to a hydroxyl group; a complex multiplet located between 0.10—0.70 accounts for three protons on a cyclopropane ring. The mass spectrum exhibited its molecular ion peak at *m/e* 238 and its base peak at *m/e* 43.

On acetylation with acetic anhydride and pyridine, II gave a monoacetate (III), $C_{17}H_{28}O_3$ (M^+, *m/e* 280), mp 69—70°C (rhombic). Upon treatment with $SOCl_2$ - pyridine or hydrochloric acid in a methanol solution, a tertiary hydroxyl group of III was replaced by chlorine; yielded was a viscous oil (IV), $C_{17}H_{27}O_2Cl$, which did not exhibit any hydroxyl absorption in its IR spectrum.

When II was oxidized with CrO_3 - pyridine, it afforded a hydroxy-ketone (V), $C_{15}H_{24}O_2$, which could be purified by GLC. The IR and UV spectra indicated that V is a macro-cyclic ketone conjugated with a cyclopropane ring (1670 cm^{-1} (C=O); λ_{max}^{hexane} 203 mμ (ε 2800)). V was characterized as a chloro-compound (VI), $C_{15}H_{23}OCl$, mp 115—116°C, by the method described above.

The chemical properties and physical constants of the diol (II) were quite simiar to those of the authentic compound[6] prepared from humulene; the absolute conformation is shown as the formula (II).

Living Anionic Polymerization of 3-Vinylpyrene with Sodium-Naphthalene Complex

Kiyoshi TANIKAWA, Hirotaka HIRATA, Shigekazu KUSABAYASHI and Hiroshi MIKAWA

Department of Chemical Technology, Faculty of Engineering, Osaka University, Yamada-Kami, Suita, Osaka

(Received June 11, 1969)

With the cationic, radical and Ziegler-Natta catalysts we have already succeeded in polymerizing 3-vinylpyrene (3-VP), a vinyl monomer having the largest aromatic group hitherto known.[1] We have now found that the living anionic polymerization of this monomer is possible if the monomer is purified finally by sublimation in high vacuum and used without being exposed to air.

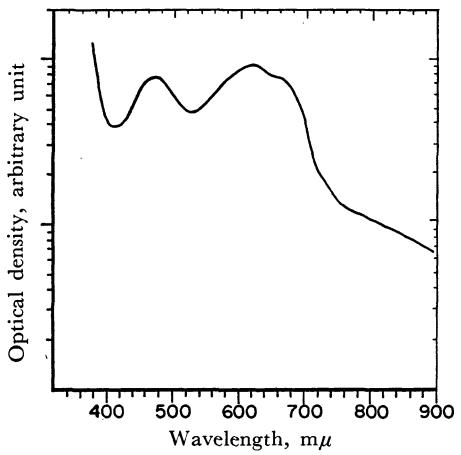

Fig. 1. Absorption spectrum of living PVP in THF at room temperature.

Polymerization was carried out by using high vacuum technique, and by adding the tetrahydrofuran (THF) solution of the sublimed monomer into the THF solution of the initiator, sodium-naphthalene, at room temperature. Typical results are shown in Table 1.

On addition of the monomer solution (pale yellow color), the green color of the solution of the initiator changed immediately to blue, showing absorption maximum at 620 mμ (Fig. 1). This band is attributed to the absorption of the living poly-3-vinylpyrene (PVP) for the following reasons. (1) The wavelengths of the absorption peaks of the living polystyrene,[2] polyvinylbiphenyl,[3] and poly-1-vinylnaphthalene[4] are 342, 405 and 558 mμ, respectively. It seems, therefore, reasonable that the spectrum of the living PVP shows a maximum at 620 mμ. (2) The color of the solution of the living PVP does not change appreciably by further addition of the monomer solution, while the total polymer yield increases considerably with the simultaneous increase of the intrinsic viscosity of the isolated polymer, as shown in Table 1.

Electronic Spectra of Organic Charge Transfer Salts of 2-Dicyanomethylene-1,1,3,3-tetracyanopropane

Seiki SAKANOUE, Toshiaki TAMAMURA, Shigekazu KUSABAYASHI, Hiroshi MIKAWA, Nobutami KASAI, Masao KAKUDO and Haruo KURODA*

Department of Chemical Technology, Faculty of Engineering, Osaka University, Yamada-kami, Suita, Osaka
** Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo*

(Received June 21, 1969)

In some compounds charge transfer bands between organic cation and organic anion have been observed in the electronic spectrum.[1] However, there has been no explanation of these charge transfer bands on the basis of the crystal structure.

The absorption spectra of quinolinium 2-dicyanomethylene-1,1,3,3-tetracyanopropanediide (Q_2DMTP) in various solvents are shown in Fig. 1. In chloroform-ethanol solution, two new shoulder bands appeared near 380 and 410 mμ in addition to the absorption of the component ions. The apparent extinction coefficient of these shoulder bands decreased with the increase of the polarity of the solvents. In the same solvent the apparent extinction coefficient of the absorption in 410 mμ increased with the increase of the concentration, while that of the absorption in 380 mμ decreased. This may be explained from the equilibrium between the dissociated ions and the ion-pairs, Q_2DMTP and/or QDMTP$^-$, and the new absorption bands due to the ion-pairs.

To elucidate the origin of the new absorption band, the polarized absorption spectrum of a single crystal was measured by means of a microspectrophotometer. The crystal of this salt is orthorhombic with the unit cell dimensions, $a=13.18$, $b=15.40$, $c=11.56$ Å; $Z=4$, and the space group, *Pbcn*. In the crystal, one unit consists of the propeller-shaped DMTP anion sandwiched with two planar quinolinium cations on both sides, and the unit is stacked in finitely along the *a*-axis. The tilt angle of the plane of the cation to the *a*-axis is about 60°. In the solid absorption spectrum, a new band was also observed. The spectrum of *a*-polarization and that of *c*-polarization are shown in Fig. 2. It can be seen that the optical density is higher in the *a*-polarization spectrum than in the *c*-polarization spectrum. In connection with the crystal structure, this result proves that the new band in solid is a charge transfer band between ions within an ion-pair.

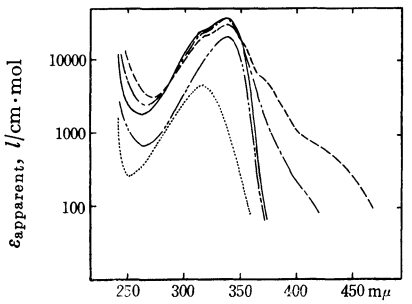

Fig. 1. The absorption spectra of Q_2DMTP in various solvents and its component ions (Q^+, $DMTP^{2-}$) in water.
····· Quinoline in HCl aqueous solution
–––– Na_2DMTP in H_2O
—— Q_2DMTP in H_2O 3.24×10^{-4} mol/l
—— Q_2DMTP in C_2H_5OH 3.16×10^{-4} mol/l
---- Q_2DMTP in $CHCl_3$-C_2H_5OH 5.00×10^{-4} mol/l

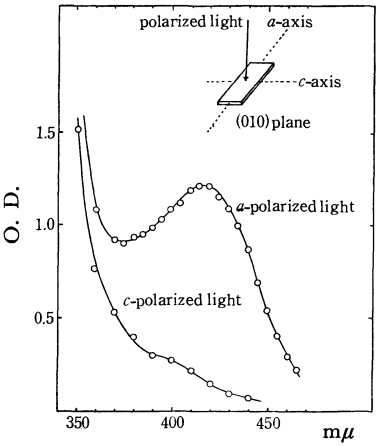

Fig. 2. Polarized absorption spectrum of Q_2DMTP.

Several other salts of DMTP were also prepared with *N*-heteroaromatic cations, such as pyridinium, quinolinium and *N*-methylacridinium. These salts showed characteristic colors, white, yellow and red, respectively. The wavelengths of the new absorption bands of these salts increased as the electron affinity of the *N*-heteroaromatic cations increased. Therefore the color of the salts may be also attributed to the electronic transition from the anion to the cation.

The results show that the new absorption band both in solid and in solution is a charge transfer band between ions within an ion-pair.

The Crystal Structure of an Organic Charge Transfer Salt, $[2(C_9H_8N)^+ \cdot (C_{10}N_6)^{2-}]$

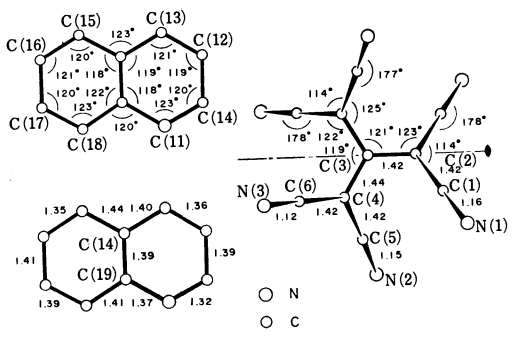
Seiki SAKANOUE, Noritake YASUOKA, Nobutami KASAI, Masao KAKUDO, Shigekazu KUSABAYASHI and Hiroshi MIKAWA

Department of Applied Chemistry, Osaka University, Yamada-Kami, Suita, Osaka

(Received June 23, 1969)

The crystal of quinolinium 2-dicyanomethylene-1,1,3,3-tatracyanopropanediide, $[2(C_9H_8N)^+ \cdot (C_{10}N_6)^{2-}]$, is orthorhombic with the unit cell dimensions of $a=13.18$, $b=15.40$, $c=11.56$ Å; $Z=4$, $D_m=1.31_8$, and $D_c=1.31_4$ g/cm^3, and with the space group *Pbcn*. The intensities of 2003 reflections were measured visually from the multiple-film equi-inclination Weissenberg photographs taken with nickel-filtered Cu$K\alpha$ radiation around the *a* and *c* axes. The structure was solved by the symbolic addition, phase-determining procedure developed by Karle and Karle.[1] The $\sum_2$ formula was applied to 247 reflections with $|E| \geqq 1.60$. After six cycles, the signs of 161 reflections were determined; the *E*-map based on these signs allowed us to locate all the non-hydrogen atoms. The positional and thermal parameters of each atom were refined by the block-diagonal least-squares method ($R=15.2\%$).

Figure 1 shows the structures of the anion and the cation. The $(C_{10}N_6)^{2-}$ anion in this crystal has a C_2-2 symmetry instead of the C_3-3 symmetry (or approximately D_3-32) found in crystals of the hexahydrated calcium salt.[2] The four central carbon atoms are exactly co-planar. The three cyano-substituents, $-C(CN)_2$ are, however, tilted out of this plane, and the anion takes a propeller-shape. The one arm which lies on the 2-fold axis is rotated by 13° from the completely planar conformation, the other two being 24°. On the other hand, in the calcium salt[2] the three angles of tilt are all 24°. The decrease in the angle from 24° to 13° may be due to weak interaction between the anion and the cation. The bond distances and angles in the anion are similar to those found in the calcium salt. The quinolinium cation is co-planar within the limits of experimental error.



(a) (b)

Fig. 1. Structure of component ions.
(a) Quinolinium cation, $(C_9H_8N)^+$
(b) 2-Dicyanomethylene-1,1,3,3-tetracyanopropane anion, $(C_{10}N_6)^{2-}$
(Estimated standard deviations in distances are 0.013–0.02Å, and those in angles are 0.83–1.4°.)

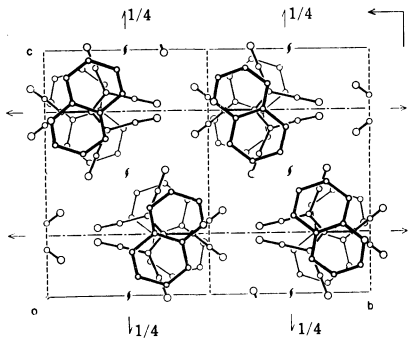


Fig. 2. Crystal structure of $[2(C_9H_8N)^+ \cdot (C_{10}N_6)^{2-}]$ projected onto the (010) plane.

Figure 2 shows the projectional view along the *a* axis. The packing unit consists of one di-anion and two mono-cations, and the anion lies on a 2-fold axis between two identical cations forming a sandwich. The N(1)–N(11) distance is 3.00 Å, which is the closest atomic contact between ions in this unit. These units stack infinitely along the *a* axis. In the contacts between these stacks along the *b* axis, a hydrogen bond exists between the N(3) of one unit and the N(11) of the other unit; the distance is 2.84 Å. The other intermolecular contacts are almost comparable with the sum of the van der Waals radii.

These results are interesting compared with the structures of other charge-transfer salts, 1-ethyl-2-methylquinolinium iodide[3] and tropylium iodide.[4]

New Empirical Formulae for the Mass Effect in the Countercurrent Electromigration of Molten Metal Halides

Nobufusa SAITO and Hitoshi KANNO

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received June 23, 1969)

The mass effect of the cation in the countercurrent migration of molten metal halides has long been known to correlate with the cation-to-anion mass ratio according to Klemm's formulae:[1,2]

$$\mu = -0.15/(1+m_+/2.1m_-)$$
(for halides with layer lattices)

and $\mu = -0.078/(1+m_+/2.1m_-)$
(for halides with coordination lattices)

where μ, m_+, and m_- stand for the mass effect, the mass of the cation, and the mass of the anion, respectively.

However, recent investigations[3-6] have revealed that there are several cases in which the values of μ calculated by the Klemm formulae deviate considerably from the experimental values. Although a new empirical formula for the same sort of correlation was proposed by Jordan and Klemm[5] in 1966, it applies only to a group of alkali halides.

After a careful examination of the available data on μ, we have found that a clear correlation exists between the mass effect and the cation-to-anion radius ratio of the halide. In Fig. 1, the experimental values of μ for various metal halides are plotted as a function of the cation-to-anion radius ratio.

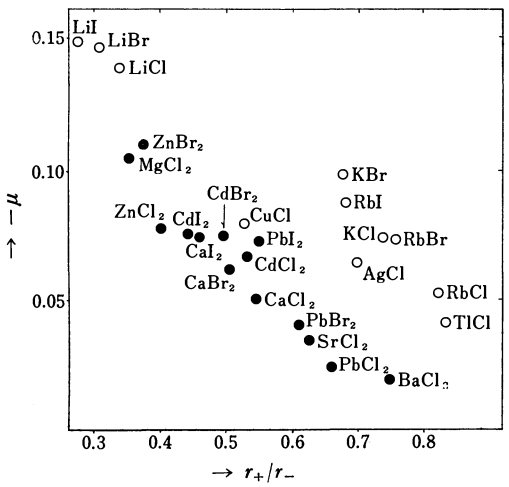

Fig. 1. Correlation of the mass effect of molten halides with the cation-to-anion radius ratio.
○ monovalent metal halide
● divalent metal halide
Sources of data: KBr and RbI—N. Saito, H. Kanno and I. Tomita, unpublished work; CaI_2, CdI_2 and PbI_2—J. Romanos and A. Klemm, *Z. Naturforsch.*, **19a**, 1000 (1964); $CdBr_2$—I. Holmlid, *ibid.*, **21a**, 270 (1966); other data—A. Klemm, "Molten Salt Chemistry," ed. by M. Blander, Interscience Publishers, New York, N. Y. (1964), p. 597.

We may see from Fig. 1 that a linear correlation exists between the mass effect and the cation-to-anion radius ratio of the halide. In addition, it is clear that the data for a group of monovalent metal halides show a linear correlation similar to, but clearly displaced from, the correlation line for a group of divalent metal halides.

Fitting the set of the data for each group of the halides in Fig. 1 to an equation of a linear form, $\mu = a(r_+/r_-)+b$, where a and b are constants, by a standard least-square procedure, we have obtained two empirical formulae:

$$\mu = 0.181(r_+/r_-) - 0.203$$
(for monovalent metal halides)

$$\mu = 0.233(r_+/r_-) - 0.185$$
(for divalent metal halides)

The experimental μ values of several halides are listed in Table 1, along with the values calculated by both Klemm's and our formulae.

TABLE 1. COMPARISON OF THE CALCULATED μ VALUES WITH EXPERIMENTAL DATA

Salt	$-\mu$ Found by experiments	$-\mu$ Calculated by Saito-Kanno's formulae	$-\mu$ Calculated by Klemm's formulae
RbCl	0.052	0.054	0.070
RbBr	0.073	0.065	0.099
RbI	0.087	0.079	0.113
LiCl	0.140	0.142	0.138

Pulse Radiolysis with Electric Conductivity. A Method of Obtaining the Rates of Propagation in the Radiation-induced Polymerization of α-Methylstyrene*[1]

Meiseki KATAYAMA, Hatsuo YAMAZAKI and Yasutomo OZAWA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo

(Received June 24, 1969)

The present authors previously studied intermediates in irradiated dry α-methylstyrene by means of pulse radiolysis with optical absorption measurements.[1] Following that work, similar studies have been reported by Swallow and Schneider[2] and by Metz and his coworkers[3] for styrene as well as α-methylstyrene. All three groups agreed that one of the intermediates is the anion radical of these compounds. Now we wish to report on further investigations in which we applied a method of electric conductivity measurements after a pulse irradiation in order to obtain the rates of propagation in the reaction. The method is, in principle, similar to that used for determining the mobilities of a carrier in semiconductors[4] and later applied to the studies of radiation chemistry by Hummel and Allen[5] in order to obtain the yield of ions in some liquid hydrocarbons.

As is shown in Fig. 1, a very thin layer of ions, both anion and cation, is produced by a single pulse of X-rays in a sample very close to one electrode, E_1, which is negatively polarized in the present case. The cation then discharges on the electrode immediately after its formation, while the anion moves to the other electrode, E_2, for measurements over rather a long period of time. In this way, the mobility of anion can, in principle, be measured separately. The mobility of the cation can also be measured by simply reversing the polarity of E_1. When a polymerizing system is studied, an anion, or an anion radical, will polymerize as it moves to E_2. Since the diffusion constant, or the mobility, of ions generally decreases as their molecular weights increase, we can compare the rate of the propagation of anionic species directly with that of cationic species by comparing the respective measured mobilities by just changing the polarity of E_1. An example of such measurements is shown in Fig. 2.

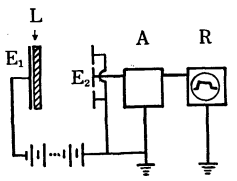

Fig. 1. The diagram of mobility measurements. E_1, E_2; electrode, L; layer of ions, A; ammeter and R; recorder.

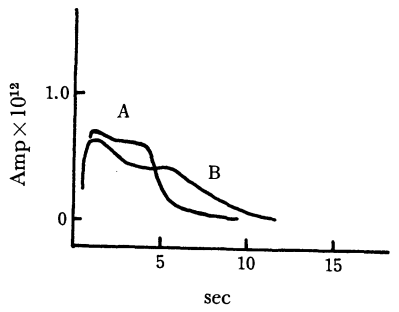

Fig. 2. The current-time curves with dry α-methylstyrene. A, positive ions and B, negative ions.

TABLE 1. THE MOBILITIES OF IONS IN α-METHYLSTYRENE
$[cm^2 V^{-1} sec^{-1}] \times 10^4$

Cation	Anion	Condition
5.0	1.9—1.4	dry[G(-monomer)≥7300]
5.0	4.0	saturated with water

Some data on mobility thus obtained in α-methylstyrene are given in Table 1. From these data and from the fact that the polymerization proceeds much faster in a dry sample than in wet ones,[6] it may be concluded that the anionic reaction is more important than the cationic one in the radiation-induced polymerization of α-methylstyrene.

Anodic Oxidations. I. The Electrochemical Cyanation of 2,5-Dimethylfuran

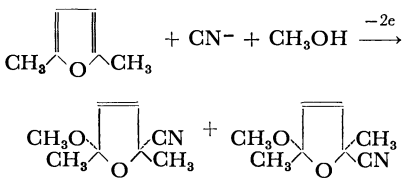
Kunihisa YOSHIDA and Takayuki FUENO

Faculty of Engineering Science, Osaka University, Toyonaka, Osaka

(Received June 30, 1969)

Koyama and co-workers developed a method for the electrochemical cyanation of aromatic compounds.[1-4] With the exception of anisole, however, this method affords very poor yields of aromatic nitriles, and according to circumstances methoxylation is predominant. An improved approach to cyanation of aromatic compounds has recently been reported by Andreades and Zahnow.[5] Cyanation of olefins has also been studied without much success.[3,6,7]

We wish to report a new cyanation reaction of 2,5-dimethylfuran to olefinic cyano ethers.



The over all reaction involves the attack of the cyanide ion on an anodically generated electrophilic intermediate.

Electrolysis was carried out by using a two-compartment cell which was equipped with a platinum wire electrode in the cathode compartment, and with the saturated calomel reference electrode and a platinum plate electrode having an area of 8 cm^2 in the anode compartment. A methanolic solution (40 m*l*) of 2,5-dimethylfuran (0.8 M) and sodium cyanide (0.8 M) was electrolyzed at 21°C for 7.5 hr, using an anode potential of 1.3 V *vs.* SCE. The catholyte was a methanolic solution of sodium cyanide (0.8 M). The current was about 60 mA. Vacuum distillation of the electrolyzed mixture afforded 0.92 g of colorless liquid boiling at 80°C/10 mmHg. The products were identified by infrared, mass and NMR spectroscopy to be a 2.4 : 1 mixture of the *cis* and *trans* isomeric 2,5-dihydro-2-cyano-2,5-dimethyl-5-methoxyfurans[8]; the molecular weight 153, the current yield 74%. Found: C, 62.78; H, 7.30; N, 9.06%. Calcd for $C_8H_{11}NO_2$: C, 62.73; H, 7.24; N, 9.14%.

Current-potential measurements were also carried out on a 0.8 M solution of sodium cyanide in methanol at 25°C, both in the presence and absence of 2,5-dimethylfuran, by using the same cell as that used for electrolysis. The measurements clearly showed that at 1.3 V the cyanide ion was not discharged to any discernible extent. Under the present conditions, therefore, it is 2,5-dimethylfuran that has predominantly been discharged at the anode. The electrophilic intermediate thus formed may have then reacted with both cyanide ion and methanol to form olefinic cyano ethers.

One major advantage of the present reaction lies in its relatively high yield in producing cyanated derivatives. Under the experimental conditions here adopted, the current yield was as high as 74% although the total yield of the cyano ethers based on 2,5-dimethylfuran used was *ca.* 20%. Another merit is that the reaction is accompanied by no undesirable side reactions.

Investigations of the mechanistic details of the reaction and its extension to other substrates are now under way and will be reported elsewhere.

The Crystal Structure of Diamminecadmium(II) Tetracyanoniccolate(II) Benzene Clathrate, $Cd(NH_3)_2Ni(CN)_4 \cdot 2C_6H_6$*[1]

Yukiyoshi SASAKI

The Institute for Solid State Physics and Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo

(Received July 16, 1969)

During the course of our studies on "Hofmann-type" benzene clathrates, $M(NH_3)_2M'(CN)_4 \cdot 2C_6H_6$ where M=Mn(II), Fe(II), Co(II), Ni(II), Cu(II), Zn(II), or Cd(II) and M'=Ni(II), Pd(II) or Pt(II),[1] it was assumed that these complexes would have structures similar to that of $Ni(NH_3)_2Ni(CN)_4 \cdot 2C_6H_6$ known as Hofmann's clathrate.[2] And it was considered highly desirable to carry out additional studies using single crystals.

The present communication reports results of the crystal structure determination which proved the above mentioned structure in the case of M=Cd and M'=Ni which has been already subjected to IR[3] and NMR[4] studies.

The crystals are tetragonal, with the space group of $P_{4/m}$-C'_{4h}. One formula unit is contained in a cell of the dimension: $a=b=7.575\pm0.006$ Å and $c=8.317\pm0.005$ Å. No piezo-electricity was observed.

The intensities of the three-dimensional reflections were measured visually from equi-inclination Weissenberg photographs around the a and c axes taken with Ni-filtered Cu$K\alpha$ radiation. In total, 356 reflections were collected. Table 1 shows the atomic parameters which give the R-factor of 11.8%.

On the whole, the crystal has a lameller structure, inorganic polymer sheets and layers of benzene being alternated. As shown in Fig. 1, the cadmium atom at 0, 0, 0 and the nickel atom at 1/2,1/2,0 are joined together by cyanide bridges to form planar sheets parallel to the plane (001). Four nitrogen atoms of cyanide anions and two ammonia molecules at *trans*-positions coordinate to a cadmium atom forming an octahedron. Four carbon atoms of cyanide ligands take square planar configuration in a $Ni(CN)_4$ unit. Benzene molecules are arranged between these sheets with their molecular planes parallel to the c axis making an angle of 58°30′ to a or b axis.

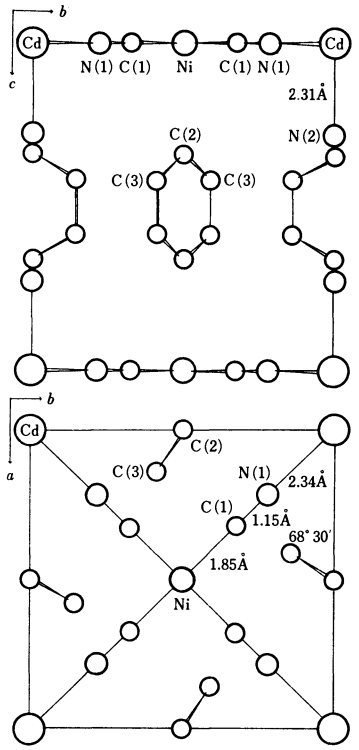

Fig. 1. Projections of the unit cell along a and c axes.
The standard deviations of the bond lengths are 0.03 Å for C-N and Cd-NH_3 and 0.02 Å for Ni-C and Cd-N(C).

TABLE 1. ATOMIC PARAMETERS WITH STANDARD DEVIATIONS

	$10^4X/a$	$10^4Y/b$	$10^4Z/c$	B(Å^2)
Cd	0000(0)	0000(0)	0000(0)	0.472(0.039)
Ni	5000(0)	5000(0)	0000(0)	1.909(0.108)
C(1)	3276(29)	3261(29)	0000(0)	1.422(0.368)
C(2)	0000(0)	5000(0)	3410(59)	4.451(0.267)
C(3)	1427(55)	4153(58)	4179(50)	7.447(0.891)
N(1)	2203(29)	2180(29)	0000(0)	2.389(0.409)
N(2)	0000(0)	0000(0)	2777(37)	1.804(0.466)

The electron clouds of the benzene molecules seem to be closely packed and are almost in contact with each other. These layers thus can be regarded as two-dimensional crystals of benzene between inorganic polymer sheets, $[Cd(NH_3)_2Ni(CN)_4]_\infty$.

The Autoxidation of Ethylbenzene in the Presence of the Aqueous Phase

Hiroshi HOTTA, Masayuki ITO and Hiroaki MURASHIMA

Japan Atomic Energy Research Institute, Takasaki, Gunma

(Received May 6, 1968)

Ethylbenzene was oxidized to acetophenone and a small amount of benzaldehyde in the presence of the aqueous phase under oxygen pressure at 190°C. The yield of acetophenone decreased in the presence of sulfuric acid, sodium sulfate, and iron and copper sulfates. The formation of benzaldehyde was promoted in the presence of iron and copper sulfates and sulfuric acid. These effects can be explained mainly by the decomposition of α-phenylethyl hydroperoxide by the solutes in the aqueous phase.

The autoxidation of benzene and toluene in the aqueous phase catalyzed by metal ions have been studied between 100°C and 200°C, and their reaction mechanisms have been confirmed by using stable isotopes.[1-4] In contrast, the autoxidation of ethylbenzene occurs without any metal ions in the aqueous phase. The yields of the products are affected by various solutes in the aqueous phase. In the present paper, these effects will be discussed in comparison with the results of previous studies.

Experimental

The oxidation procedure, using a 50 cc stainless-steel reactor, has been described in detail in a previous paper.[1] That is, 3 cc of ethylbenzene was placed in a hard-glass tube with 15 cc of an aqueous solution, containing various solutes, under an oxygen pressure of 30 atm, then the mixture was kept at 190°C for 30 min by a controlled heater.

The products were analyzed by gas chromatography using a column of PEG 6000 at 170°C; they were identified mainly by the retention time, but partly also by means of the mass spectrum and the NMR spectrum. An amount less than 10^{-4} mol is meaningless quantitatively in the present paper; it means just "less than 10^{-4} mol." The amount of iron species was analyzed by spectrophotometry by previously-reported methods.[5]

Results

The products were acetophenone, benzaldehyde, and a small amount of a product which has a longer retention time than that of acetophenone and which is produced upon the autoxidation of acetophenone. Although benzoic acid could not be detected by gas chromatography under the present conditions, the amount produced for each run may be the highest in the order of 10^{-5} mol, as estimated from the pH change in the aqueous phase after experimentation.

The autoxidation of ethylbenzene was carried out with the aqueous phase at various pH's, which were controlled by the addition of sulfuric acid or sodium hydroxide. After experimentation, the pH was nearly 3 for the runs; the pH was more than 3 initially. The yield of acetophenone decreased for an acidic medium of less than pH 3. Since the pH was measured at room temperature, the pH at 190°C is not known.

The effect of sodium sulfate is shown in Fig. 1 as a function of its concentration in the aqueous

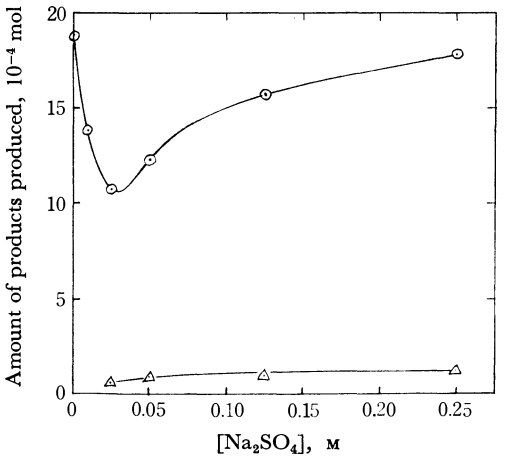

Fig. 1. The yields of acetophenone (⊙) and benzaldehyde (△) at 190°C in the sodium sulfate aqueous solution of various concentrations.

phase. The yield of acetophenone decreases at first and then increases upon further addition.

The effects of iron and copper sulfates were also examined. The amounts of acetophenone (open marks) and benzaldehyde (solid marks) produced are shown in Fig. 2 as a function of the initial concentrations of ferrous (⊙ and ●), ferric (■ and ▲), and cupric (⊡ and ■) sulfates. The yield of acetophenone decreases in the presence of these sulfates; especially, it gives a minimum at 0.001M in the case of ferric sulfates. On the other hand, the amounts of the total iron species and ferrous species, dissolved in the aqueous phase after experimentation, are shown in Fig. 3 as a function of the initial concentration of iron sulfates. The initial concentration in Figs. 2 and 3 is represented not by that of sulfate, but by that of iron.[1]

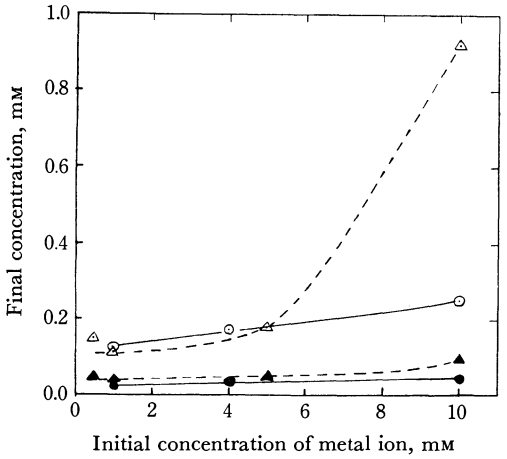

Fig. 3. The concentration of total iron species (open marks) and ferrous species in it (solid marks), dissolved in the aqueous phase after experimentation at 190°C in the aqueous solution of ferrous (⊙ and ●) and ferric (△ and ▲) sulfates.

When the autoxidation of ethylbenzene was initiated at 70°C by Fenton's reagent, as has been described in a previous paper,[4] the yield of methyl phenyl carbinol was more than twice that of acetophenone.

Discussion

So far, commercially-available ethylbenzene of a special grade was used without further purification. When this reagent was shaken several times with an aqueous solution of 0.1M ferrous sulfate, washed with water, and then distilled carefully, the amount of the products, oxidized with water at 190°C, decreased gradually with further purification, as is shown in Table 1. The amount of benzaldehyde produced was less than 10^{-5} mol in all the cases. The gas chromatogram of the reagent did not change with the purification.

Table 1. Purification of ethylbenzene

Shaking times	Acetophenone, 10^{-4} mol
0	17.7
4	12.1
10	9.7

When the autoxidation of ethylbenzene was carried out by adding it up to 7 cc to 15 cc of water, the yield of acetophenone increased linearly with the amount of ethylbenzene added. On the other hand, when 0.5 cc of ethylbenzene was oxidized without water, the yield of the products decreased with further purification. The pattern of the products was almost the same as in the presence of water.

These facts indicate that the autoxidation is not initiated by the thermal decomposition of ethylbenzene itself, but by that of a trace amount of some hydroperoxide in ethylbenzene; this substance is probably α-phenylethyl hydroperoxide to be stable at room temperature:

$$\mathrm{ROOH} \rightarrow \mathrm{RO\cdot} + \cdot\mathrm{OH} \qquad (1)$$

where R represents α-phenylethyl radical (ϕ–$\dot{\mathrm{C}}$H–$\mathrm{CH_3}$). The bond dissociation energy of this reaction is much less than that required for either hydrogen abstraction or C–C bond scission.[6-8]

The autoxidation is propagated in both the ethylbenzene and aqueous phases. On the other hand, the present findings indicate that the yield of the products is remarkably affected by solutes in the aqueous phase. This means that at least the main part of the propagation processes in a

6) L. A. Muzychenko, *Chem. Abstr.*, **59**, 5782d (1963).
7) J. A. Kerr, *Chem. Revs.*, **66**, 465 (1966).
8) S. W. Benson and J. Buss, *J. Chem. Phys.*, **29**, 546 (1958).

system containing the aqueous phase occur in the aqueous phase or in the participation of the hydrated solutes dispersed in the ethylbenzene phase. Since the oxygenated species are hydrophilic, they prefer either to be extracted in the aqueous phase or to be oriented to the hydrated solutes in the ethylbenzene phase. In the present paper, the effects of the solutes will be illustrated below by reactions in the above aqueous environment. Although some reactions independent of the solutes might occur in the non-aqueous phase, reactions with the solutes occur in the aqueous envivonment in the above meaning.

After reaction (1), the autoxidation is propagated as follows:

$$RH + \cdot OH \rightarrow R\cdot + H_2O \quad (2)$$

$$R\cdot + O_2 \rightarrow ROO\cdot \quad (3)$$

$$ROO\cdot + RH \rightarrow ROOH + R\cdot \quad (4)$$

with reaction (1). Furthermore, the following reactions may be expected in the aqueous phase, containing metal ions, M^+ (ferrous or cuprous ions) and M^{2+} (ferric or cupric ions):

$$H_2O \xrightarrow{M^+,O_2} \cdot OH \quad (5)$$

$$ROOH + M^+ \rightarrow RO\cdot + OH^- + M^{2+} \quad (6)$$

$$ROOH + M^{2+} \rightarrow ROO\cdot + H^+ + M^+ \quad (7)$$

The chain process is terminated by:

$$RO\cdot \rightarrow \text{Acetophenone} \quad (8)$$

$$2ROO\cdot \rightarrow RO\cdot \textit{ etc.} \quad (9)$$

The yield of acetophenone decreases upon the addition of a small amount of sodium sulfate, as may be seen in Fig. 1. Since the sulfate group becomes sulfur trioxide as a transient state at higher temperatures due to equilibrium thermal decomposition, according to studies as using oxygen-18:[9,10]

$$Na_2SO_4 \rightleftarrows \cdot SO_3 + NaO \quad (10)$$

This intermediate might scavenge the hydroxyl radical from reaction (1) as an initiator of the propagation process (reaction (2)) in this manner:

$$OH + \cdot SO_3 \rightarrow \cdot HSO_4 \quad (11)$$

The curve between 0 and 0.02M in Fig. 1 is almost identical with the curve of cupric sulfate in Fig. 2, as suggesting that these curves correspond to this effect of the sulfate group.

On the other hand, the sulfate group can initiate the autoxidation of hydrocarbons at higher temperatures, as has been discussed in a previous paper,[9] because the sulfur trioxide of reaction (10) becomes a sulfur peroxide in the oxygenated aqueous phase. This peroxide can abstract the hydrogen atom of ethylbenzene, as in reaction (4). It has been reported that various aromatics are oxidized by sulfuric acid and aqueous sulfates.[11,12] The increase in the yield at the higher concentrations of sodium sulfate in Fig. 1 may be attributed to this action. Since the sulfur peroxide is not very reactive, and since the propagation step of reaction (7) is lacking in this system, as may be seen in Fig. 1, the yield decreases abruptly, and then gradually rises.

The decrease in the yield in the acidic medium, as has been mentioned already, can be interpreted by the following acid-catalyzed decomposition of the hydroperoxide for reaction (1);

$$ROOH + H^+ \rightarrow RO^+ + H_2O \quad (12)$$

Then, spontaneously;

$$RO^+ \rightarrow \text{acetophenone} + H^+ \quad (13)$$

These reactions give only stable species. In a previous paper,[4] reaction (8) in the presence of metal ions was illustrated as;

$$RO + M^{2+} \rightarrow \text{acetophenone} + H^+ + M^+ \quad (14)$$

Reaction (14) is analogous with reactions (12) and (13).

In Fig. 2 the yield of acetophenone in the iron sulfate solution is seen to decrease to a greater extent than in the cupric sulfate solution. Since iron sulfates are precipitated as ferric oxides at temperatures higher than 150°C, as is shown in Fig. 3,[1,5] an aqueous solution of iron sulfates becomes an aqueous solution of sulfuric acid containing a small amount of iron species. Therefore, the effect of iron sulfates in Fig. 2 can be attributed to the superposition of the actions of sulfate and acid (reactions (11) and (12)). On the other hand, since cupric sulfate is not decomposed even at 190°C, the aqueous solution is still neutral. Therefore, the curve of cupric sulfate in Fig. 2 is almost identical with that of neutral salt, namely, sodium sulfate, as has been mentioned already.

In Fig. 2, the yield of acetophenone in the ferric solution is smaller at first, and then it becomes larger in a more concentrated solution than in the ferrous solution. In the ferrous solution, the autoxidation is initiated by the production of the hydroxyl radical (reaction (5)), while it is terminated through reaction (6). On the other hand, in the ferric solution it is propagated by reaction (7). The phenomena in Fig. 2 result from these effects in addition to the above effects of sulfate and acid.

In Fig. 3, the fraction of ferrous species in the

total iron sepcies is low in comparison with benzene[1] and toluene.[3] This suggests that most of the acetophenone is formed by some termination process independent of metal ions, for example, reaction (12) rather than reaction (14) and/or some reaction in the non-aqueous phase.

Some benzaldehyde is produced with acetophenone under all conditions. The ratio of benzaldehyde to acetophenone is comparatively large in the presence of iron and copper sulfates and sulfuric acid, and it increases with an increase in the temperature. Since benzaldehyde was not formed from acetophenone under the present conditions, it might be formed competitively from the same intermediate with that for acetophenone.

The authors wish to express their appreciation to Dr. Toshio Sugiura for his cooperation in the mass spectrometry and to Mr. Hironao Hayakawa for his measurement of the NMR spectrum.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 2416—2421 (1969)

Electrolytic Polymerization of Acrylonitrile. Kinetic Approach and Effect of Supporting Electrolytes

Teruzo ASAHARA, Manabu SENŌ and Mitsuru TSUCHIYA

The Institute of Industrial Science, The University of Tokyo, Roppongi, Minato-ku, Tokyo

(Received June 6, 1968)

The electrolytic polymerization of acrylonitrile in constant current was examined by using several supporting electrolytes and the reaction mechanism was discussed. An explanation was given for the anomaly characteristic of the cathodic polymerization using sodium nitrate as a supporting electrolyte, which was reported by Funt. It was revealed that the polymerization is initiated by a radical mechanism at the anode and by an anionic mechanism at the cathode. The termination reaction of the anionic polymerization was analyzed by a kinetic approach and from the structural information of polymers obtained.

Recently, studies have been carried out on the electrode reaction and the following chemical reactions of acrylonitrile.[1] However, no definite conclusion has been obtained as to how many electrons are transferred in the electrolytic reduction, what chemical species are formed at the electrode, and what chemical reactions and termination follow.

In order to clarify these problems, the electrode reduction of acrylonitrile was studied by means of polarography, coulometry and electron spin resonance and the results were examined.

Experimental

Materials. Acrylonitrile was dried with barium oxide and calcium sulfate and distilled under reduced pressure. Sodium nitrate and sodium perchlorate of reagent grade were used without further purification. Tetrabutylammonium perchlorate was prepared from tetrabutylammonium hydroxide and perchloric acid and purified by recrystallization. Tetraethylammonium *p*-toluenesulfonate was synthesized by the reaction of ethyl *p*-toluenesulfonate and triethylamine and recrystallized.

Apparatus. The 500 m*l* cell used for electrolysis has no separatory membrane, because it has been confirmed that no polymer formation takes place in the anodic side. A source of direct current connected with a voltage stabilizer was used. The reaction temperature was maintained at 30°C and the solution was stirred with a magnetic stirrer. During electrolysis nitrogen gas was bubbled in. The electrolysis cell was equipped with a stirrer, a reflux condenser, an inlet tube of N_2 gas, a thermometer and a tube for sampling.

Reaction Kinetics. Every one hour, 10 m*l* of the reaction solution was taken out and poured into 100 m*l* of an aqueous sodium hydrosulfite solution. The resulting polymer precipitate was then separated and weighed after drying.

Measurement of ESR and Absorption Spectra. The ESR measurement was done on a Varian or a Japan Electron Optics Laboratory apparatus with an electrolysis cell. The anode was a platinum wire and the cathode a mercury pool. The measurement of absorption spectra was carried out with a Shimadzu Multipurpose Spectrophotometer using a 1 cm cell equipped with platinum electrodes. The viscosity of the

1) B. L. Funt and F. D. Williams, *J. Polymer Sci.*, **A2**, 865 (1964).

solution of resulting polymers in dimethylformamide was measured as usual at 30°C.

Results and Discussion

Electrode Reaction. Generally, an electrolytic reaction consists of two steps. One is the electrode reaction involving the electron-transfer reaction between ions or neutral molecules and the electrode. The other is the chemical reaction following or followed by the electrode reaction.

The reactivity on electrode changes with the electronic structure of reactants. It has been recognized in many cases that the electronic structures have certain relations to the half-wave potential.[2] The electronic energy state may be estimated by the molecular orbital theory.

The application of this procedure to vinyl compounds gives results as shown in Fig. 1. This shows a good correlation between the energy of the lowest unoccupied level and the half-wave potential of the polarographic reduction.

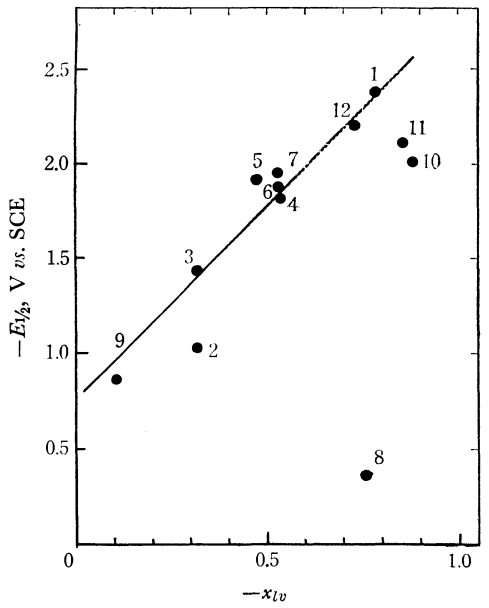

Fig. 1. The relation of coefficient of resonance integral in the lowest vacant orbital and the half-wave potential of various vinyl compounds.

coulometry showed that two electrons were consumed for the reduction of one acrylonitrile molecule. The polarogram of acrylonitrile has a simple one-step reduction wave; the number of electrons for reduction was two from the limiting diffusion current density. On the other hand, the analysis of polarogram using the Nernst equation shows that the apparent number of electrons is 0.6. If the number of electrons is assumed to be 2, the transfer coefficient becomes 0.3, a reasonable value.[3] All these results lead to the conclusion that the two-electron reduction of acrylonitrile would be reasonable. Therefore, the following reaction mechanism could be proposed for the cathodic reduction:

$$CH_2=CHCN + 2e \rightarrow \overset{\ominus}{C}H_2\text{-}\overset{\ominus}{C}HCN$$

$$\overset{\ominus}{C}H_2\text{-}\overset{\ominus}{C}HCN + CH_2{=}CHCN \rightarrow$$

$$(2CH_2\text{-}\overset{\ominus}{C}HCN) \rightarrow NC\overset{\ominus}{C}H(CH_2)_2\overset{\ominus}{C}HCN$$

It is expected from the energy consideration that the reverse reaction, a disproportionation, hardly occurs. The formation of propionitrile and adiponitrile would take place according to the following reactions:

$$H_2O \rightleftarrows H^+ + OH^-$$

$$\overset{\ominus}{C}H_2\text{-}\overset{\ominus}{C}HCN + 2H^+ \rightarrow CH_3CH_2CN$$

$$NC\overset{\ominus}{C}H(CH_2)_2\overset{\ominus}{C}HCN + 2H^+ \rightarrow NC(CH_2)_4CN$$

It follows from this mechanism that the increase in water content gives rise to an increase in the yield of propionitrile. On the contrary, the decrease in water content gives an increase in the yield of adiponitrile and oligomers such as hydrotrimer. At a higher current density the formation rate of acrylonitrile dianion increases and the yield of propionitrile is depressed.

Beck[4] examined this reaction by the analysis of Tafel line in many systems containing acrylonitrile, and proposed the following reaction mechanism.

2) K. Higasi and H. Baba, "Quantum Organic Chemistry," Asakura Publishing Co., Tokyo (1965).

4) F. Beck, *Chem. Ing. Tech.*, **37**, 607 (1967).

$$CH_2{=}CHCN + e + H_2O \xrightarrow{\text{slow}} \cdot CH_2CH_2CN + OH^-$$

$$\cdot CH_2CH_2CN + e \rightarrow : \overset{\ominus}{C}H_2CH_2CN$$

$$: \overset{\ominus}{C}H_2CH_2CN + CH_2{=}CHCN \rightarrow NCCH_2CH_2CH_2\overset{\ominus}{C}HCN$$

$$NCCH_2CH_2CH_2\overset{\ominus}{C}HCN + H_2O \rightarrow NC(CH_2)_4CN + OH^-$$

He considered that cyanoethyl iodide is reduced more easily than acrylonitrile, and that therefore cyanoethyl radical also would be reduced more easily than acrylonitrile, and reported that a weak signal was observed in the ESR measurement during electrolysis. However, there are ambiguities in his argument; for example, a cyanoethyl radical is an unstable primary radical and, if this was formed, it would enter into polymerization. Actually, polymer formation was scarcely observed. As to the ESR spectrum, the *g*-value and the hyperfine structure were not reported, and therefore the observed signal could not be assigned to a cyanoethyl radical. From these considerations, together with the polarographic result it could not be expected that the complex mechanism proposed by Beck is reasonable.

Electrolytic Polymerization of Acrylonitrile. Many researches have been carried out recently on the electrolytic polymerization of vinyl compounds. The principal feature of this method lies in the possibility of the control of the initiation reactions at electrodes by electrode potential and of the reaction rate by current density.

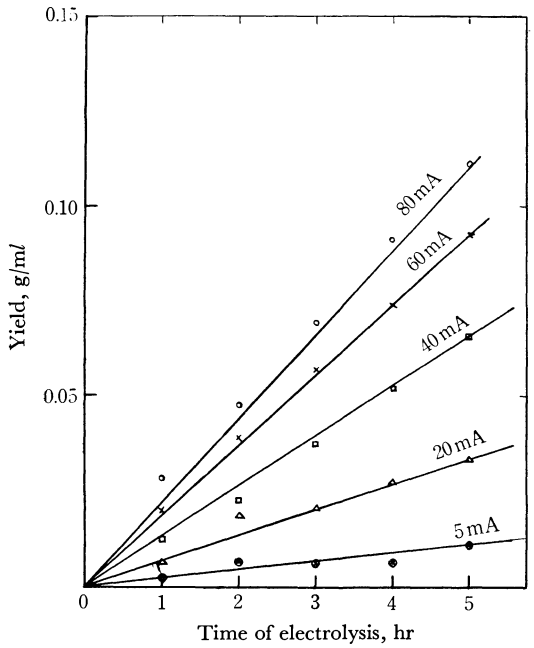

Fig. 2. The time dependence of the yield of polymers.

Funt and Williams[1] reported the anomaly in the electrolytic polymerization of acrylonitrile in dimethylformamide, using sodium nitrate as a supporting electrolyte. That is, there is a decrease in the rate of the formation of polymer with the increasing monomer concentration over a certain value. It should be noted that sodium nitrate is not soluble in acrylonitrile, but in dimethylform-

amide, and sodium perchlorate is soluble both in acrylonitrile and dimethylformamide. It is of interest to use tetraethylammonium *p*-toluenesulfonate as a supporting electrolyte. However, Funt neither reported the structural analysis of the polymer obtained nor examined the reaction kinetics. As this reaction is interesting as a typical example of anionic addition reaction, the electrolytic polymerization of acrylonitrile was investigated.

AN-DMF-$NaNO_3$ System. A typical result in the system of acrylonitrile(AN)-dimethylformamide-(DMF)-$NaNO_3$ is shown in Fig. 2, where polymer yields are plotted against the reaction time corresponding to various current densities. When the molar ratio of AN to DMF is less than unity, the experimental results are expressed by the following equations (Figs. 3, 4, 5 and Table 2).

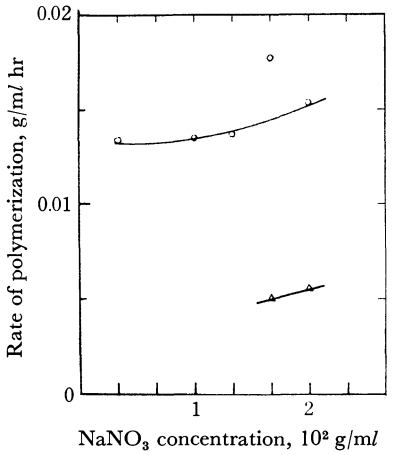

Fig. 5. The dependence of the rate of polymerization on $NaNO_3$ concentrations.

2.08*	40	1.4	8.33	40	0.14
8.33	40	0.2	12.5	40	0.12
12.5	40	0.2	16.7	40	0.10
16.7	40	0.2			
8.33	20	0.2	8.33	20	0.11
8.33	60	0.2	8.33	60	0.24
8.33	80	0.3	8.33	80	
8.33	100	0.8	8.33	100	0.29

*In these cases, polymers are formed at anode and the analysis of IR spectrum of polymers suggests the following initiation mechanism:

$$NO_3^- \xrightarrow{-e} NO_3\cdot$$
$$NO_3\cdot + CH_2{=}CH{-}CN \rightarrow \text{polymers}$$

Rate of polymer formation: $\frac{d[P]}{dt} = k[M]\,[I]$

Degree of polymerization: DP = const.

The reaction might be assumed to consist of the following steps:

$$M + I \xrightarrow{k_i} C^* \quad (1)$$
$$C^* + M \xrightarrow{k_p} C^* \quad (2)$$
$$C^* + M \xrightarrow{k_{t1}} P \quad (3)$$
$$C^* \xrightarrow{k_{t2}} P \quad (4)$$

where M is monomer, C* active species with growing ends and P polymers. This reaction process was analyzed kinetically, using the stationary state method, and the following equations are obtained:

$$\frac{d[P]}{dt} = k_i\,[M][I]$$
$$DP = \frac{k_p\,[M]}{k_{t1}[M] + k_{t2}}$$

The experimental result requires that $k_{t1}[M]$ is much larger than k_{t2}. Therefore, the significance of the termination reaction (3) must be recognized. During electrolysis the bulk solution becomes yellow which remains after the electrolysis. This coloration would be caused not by reaction intermediates, but by resulting polymers, because polymers are yellow after purification. However, a question remains as to whether the color is due to the decomposition of supporting electrolytes. In order to confirm the possibility, the change in absorption

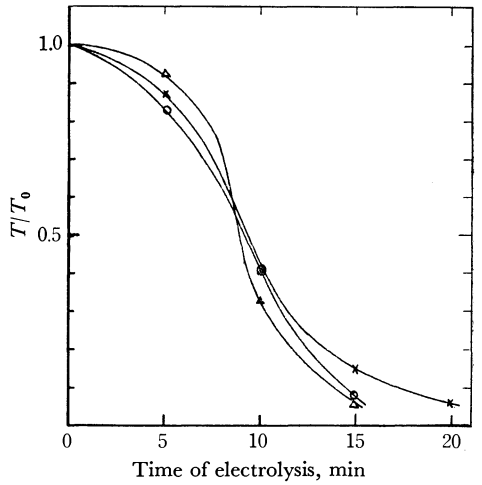

Fig. 6. Relation between the transmittance and the time of electrolysis.
○ 270 mμ, △ 310 mμ, ×340 mμ in DMF
T: Transmittance of sampe solution at given times
T_0: Transmittance of reference (t=0)

spectra of products was measured during electrolysis at various AN concentrations. The result is shown in terms of transmittance at the absorption peak (270 mμ) and other two wavelengths in Fig. 6. The change in transmittance T with time (t) obeys the exponential law $T=T_0e^{-\alpha/t}$, where T_0 is the transmittance at $t=0$. In Fig. 7, the values of α are plotted against the AN concentration. From this result it may be concluded that the decomposition of the supporting electrolyte has no correlation with the observed coloration.

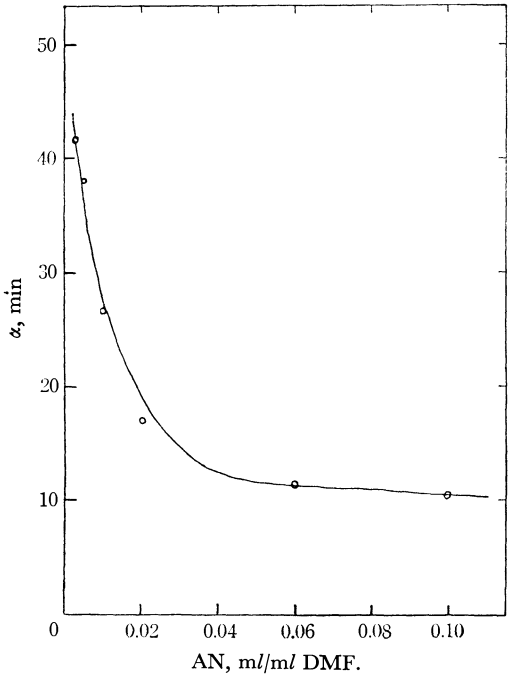

Fig. 7. The dependence of rate of coloration at 270 mμ on AN concentration in DMF.

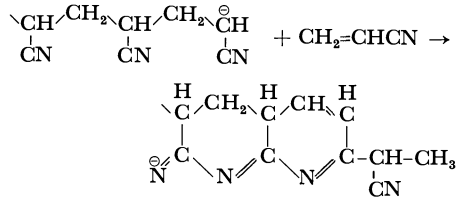
Moreover, the identification of IR spectrum of polymers shows the existence of methyl and imino groups. Therefore, it seems that the coloration is due to the cyclization of nitrile groups. These observations suggest clearly the following termination reaction:



The anomaly in Fig. 4 might be attributed to the presence of the supporting electrolyte which is hardly soluble in acrylonitrile and causes an increase in the activation energy of the initiation step. This might be explained as follows. The dissociation of sodium nitrate is in equilibrium.

$$NaNO_3 \overset{K_1}{\rightleftarrows} Na^+ + NO_3^-$$

On the other hand, we have

$$[Na^+] = [NO_3^-] + [C^*]$$

An excess charge discharges at electrodes. If C* is small enough, we get

$$[Na^+] = \sqrt{K_1[NaNO_3]} \equiv K_1'$$

The following equilibrium would take place also for the active anions

$$C_f^* + Na^+ \overset{K_2}{\rightleftarrows} C_{nf}^*$$

where C^*_f and C^*_{nf} refer to the free active anions and the active ion-pairs respectively. C^*_f would be more active than C^*_{nf}.
Then

$$[C^*] = [C_f^*] + [C_{nf}^*]$$

$$= [C_f^*](1 + K_1'K_2)$$

Therefore

$$DP = \frac{k_p[C_f^*][M]}{k_{t1}[M][C^*] + k_{t2}[C^*]}$$

$$= \frac{k_p[M]}{(k_{t1}[M] + k_{t2})(1 + K_1'K_2)}$$

When the AN concentration increases, K_1' decreases and DP increases. In addition, it is suggested that the loss in the solvation energy of sodium cations results in the relative instability of the reactive point according to the linear free energy relationship, and the activation energy for the initiation reaction increases and the reaction rate decreases. This anomaly is not observed when McKee's salt is used as a supporting electrolyte.

AN-DMF-McKee's Salt System. In the system of AN, McKee's salt, and DMF, the polarogram of AN suggests the complex formation of AN with *p*-toluenesulfonate anion.[5] In this system, the current effect shows saturation for the rate of polymer formation at a certain current density as shown in Fig. 3. This would be interpreted on the assumption that the complex has a negative charge and the polymerization process in the neighborhood of the electrode is of the diffusion control even at a relatively low electrode potential. However, the decomposition of the supporting electrolyte would lead to the same result.

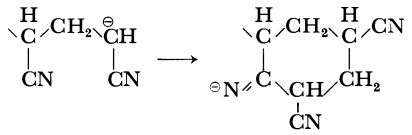
The increasing AN concentration causes an increase in the rate of polymer formation and the degree of polymerization as shown in Fig. 4 and

5) T. Arai, private communication.

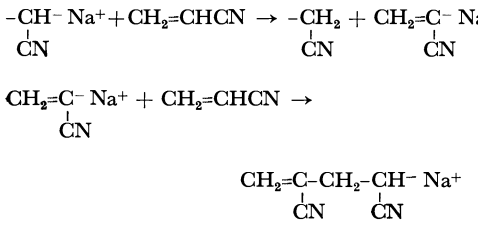
Table 2. This behavior may be described as follows:

$$\frac{d[P]}{dt} = k_i[M][I] \qquad DP = k[M]$$

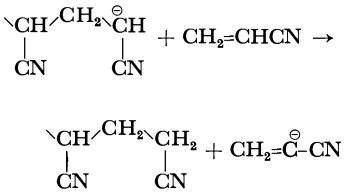
The kinetic analysis agrees with the result when $k_{t2} \gg k_{t1}[M]$, and suggests that the termination reaction (4), *i. e.*, the self-consumption of the reactive points, predominates. The IR spectrum of polymer obtained has no absorption assigned to methyl groups and the UV spectrum shows that the polymer has a cyclic unit. From these observations, the following termination seems reasonable.

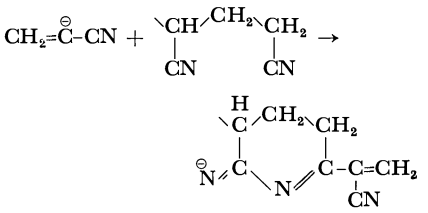


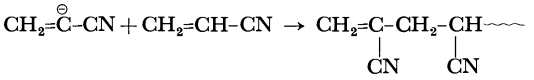
Electrolysis without Solvents. When sodium nitrate was used as a supporting electrolyte, the IR spectrum of the polymer obtained suggests the following reaction scheme:



The electrolysis of acrylonitrile at the cathode without solvent using sodium perchlorate as a supporting electrolyte would proceed according to the following scheme:







In this system, the polymerization proceeds at the anode through a radical mechanism, that is

$$ClO_4^- - e \rightarrow ClO_4\cdot$$

$$ClO_4\cdot + CH_2{=}CH{-}CN \rightarrow \text{polymers}$$

This is supported by the observation that the IR spectrum of the polymer formed at the anode has an absorption assigned to perchloro groups and the polymer has a very high molecular weight (the intrinsic viscosity in DMF is 4.0) and no coloration.

The information obtained in the present investigation is summarized as follows:

(1) The half-wave potentials and therefore the reactivity of vinyl compounds could be estimated from the molecular orbital calculation.

(2) Acrylonitrile undergoes a two-electron reduction in the cathode reaction.

(3) The lowering of the rate in the formation of polymer over a certain AN concentration in the system AN-DMF-$NaNO_3$ would be caused by the decrease in the rate constant of the initiation step.

(4) When the polymer is obtained at the cathode in the electrolysis of acrylonitrile, it is formed by the anionic polymerization mechanism. The termination reaction involves the cyclization of nitrile groups, and results in the formation of yellow-colored polymers.

(5) When the polymer is obtained at the anode it is initiated by the radical which is formed by the oxidation of supporting electrolytes. The degree of polymerization of polymers formed at the cathode is much lower than that of polymers formed at the anode.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 2422—2425 (1969)

Evaluation of the Activation Energies of Radical Substitution Reactions in the Gaseous Phase. II. An Approximate Formula with Two Constants

Tsutomu KAGIYA, Yūzō SUMIDA and Tokuji INOUE

Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received October 31, 1968)

The following approximate formula for evaluating the activation energies of radical substitution reactions has been derived from the formula proposed in a previous paper:

$$E_a = D_i - \varepsilon D_f(1 + \delta D_i)$$

where D_i and D_f are the bond dissociation energies of the initial and the final bonds. The calculated values are in good accordance with the observed values within ± 2.0 kcal/mol. The empirical formulae, proposed by Evans-Polanyi and Semenov *et al.*, between the activation energy and the reaction heat have been derived from this approximate formula. The Hammett-type rule has also been observed to hold in radical substitution reactions, and the substituent constants and the reaction constants have been determined by the use of the formula. A good correlation between the bond dissociation energy of the initial molecule and the radical reactivity index, delocalizability, based on the quantum chemical standpoint, has also been observed.

Evans and Polanyi have made a theoretical investigation of the activation energy of the radical substitution reaction and have obtained, in a homologous reaction, a quantitative relation between the activation energies and the reaction heats.[1] Bagdasaryan,[2] Tikhomirova-Voevodskii,[3] and Semenov[4] indicated that the correlation between the activation energies and the reaction heats is roughly independent of the kind of reaction components.

In a previous paper,[5] the present authors made an empirical study of the energy changes along the radical substitution reaction path, and proposed a theoretical equation for the evaluation of the activation energies employing the Morse potential energy functions. The equation is very useful, but it is rather complicated.

The purpose of this report is to present an approximate formula for the theoretical equation obtained in the previous paper, and to discuss the above empirical rules in connection with this formula.

Derivation of Approximate Formula

The reactions with which we are concerned in this paper are radical substitution reactions of the three-center type, such as

$$A + BC \rightarrow AB + C \qquad (1)$$

where A, B, and C are reacting atoms or groups.

As has been described previously,[5] the energy of the transition state and the activation energy of any reaction (1) may, respectively, be given as follows:

$$E^* = \frac{4\alpha(1-\alpha)D_iD_f(D_f - \alpha D_i)}{(D_f - \alpha^2 D_i)^2} \qquad (2)$$

$$E_a = \frac{D_i\{(1-2\alpha)D_f + \alpha^2 D_i\}^2}{(D_f - \alpha^2 D_i)^2} \qquad (3)$$

where D_i and D_f are the bond dissociation energies of the initial and the final molecules, and where α is related to the reaction heat Q (in kcal/mol) by $\alpha = \exp(\beta Q)$, where β is a constant equal to 0.0190.

For the reaction heats, Q, ranging from -20 to 20 kcal/mol, α and α^2 are approximated as:

$$\left.\begin{aligned} \alpha &= 1 + \beta Q \\ \alpha^2 &= 1 + 2\beta Q \end{aligned}\right\} \qquad (4)$$

By substituting Eq. (4) into Eq. (2) and by using the two relations: $Q \simeq D_f - D_i$ and $\beta Q \ll 1$, we obtain:

$$E^* = \varepsilon D_f \times \frac{D_i(\beta D_i - 1)}{(1 - 2\beta D_i)^2} \qquad (5)$$

where $\varepsilon = 4\beta = 0.0760$. The second factor on the

right side of Eq. (5), $D_i(\beta D_i-1)/(1-2\beta D_i)^2$, is a function only of the bond dissociation energy, D_i, of the initial molecule. In order to approximate this factor by a simpler expression, let us use:

$$\frac{D_i(\beta D_i-1)}{(1-2\beta D_i)^2} \simeq 1+\delta D_i \qquad (6)$$

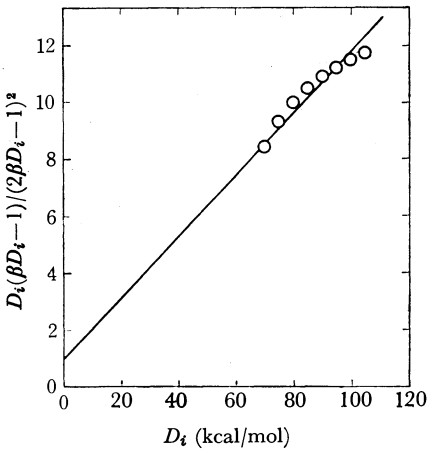

Fig. 1. Plot of $D_i(\beta D_i-1)/(2\beta D_i-1)^2$ *versus* D_i. The straight line represents the equation, $\frac{D_i(\beta D_i-1)}{(2\beta D_i-1)^2} = 1+0.108D_i$

Figure 1 shows that the linear approximation (6) with $\delta=0.108$ holds fairly well in the range of D_i with which we are concerned, *i. e.*, $D_i=70$ to 105 kcal/mol. By substituting Eq. (6) into Eq. (5), we obtain:

$$E^* = \varepsilon D_f(1+\delta D_i) \qquad (7)$$

Hence,

$$E_a = D_i - \varepsilon D_f(1+\delta D_i) \qquad (8)$$

and

$$\frac{D_i-E_a}{D_f} = \varepsilon + \varepsilon\delta D_i \qquad (9)$$

The linear relation (9) between $(D_i-E_a)/D_f$ and D_i has been checked by using the available experimental values of E_a for radical substitution reactions such as those given in the legend of Fig. 2. The results indicate that Eq. (9) works well when the constants ε and δ are chosen to be 0.0850 and 0.0944 respectively. These values are in good agreement with those of $\varepsilon=0.0760$ and $\delta=0.108$ which we have obtained earlier. By using $\varepsilon=0.0850$ and $\delta=0.0944$, we obtain:

$$E_a = D_i - 0.0850D_f(1+0.0944D_i) \qquad (10)$$

Results and Discussion

The activation energies of the various types of radical substitution reactions are calculated by means of Eq. (10); they are plotted against the observed values in Fig. 2. For both exothermic and endothermic reactions, the calculated values of

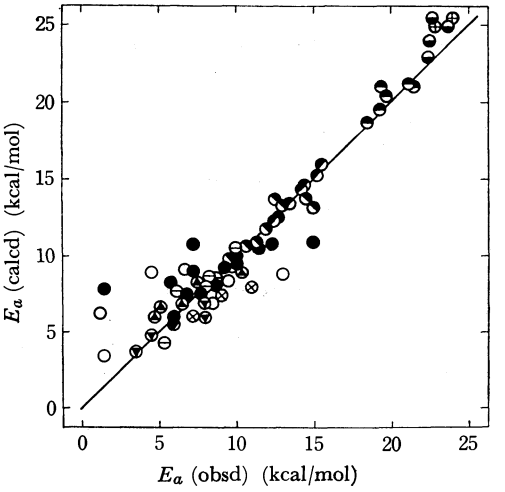

Fig. 2. Comparison of the calculated values of the activation energies of radical substitution reactions with the observed ones.

▲ CF_3+RH→CF_3H+R,
⊕ CH_3CO+RH→CH_3CHO+R,
▼ H+RCl→HCl+R, ⊖ Na+RCl→NaCl+R

the activation energies are in good agreement with the observed values within ±2.0 kcal/mol. It may be concluded from the results that Eq. (10) is a good approximate formula for evaluating the activation energies of radical substitution reactions.

The Evans-Polanyi Rule. Evans and Polanyi have studied the reactions of various alkyl chlorides with a sodium atom:[1]

$$\mathrm{Na} + \mathrm{RCl} \rightarrow \mathrm{NaCl} + \mathrm{R} \qquad (11)$$

and have found a simple parallelism between the activation energies and the reaction heats; *i. e.*,

$$\Delta E_a = -x\Delta Q \qquad (12)$$

where ΔE_a is the increase in the activation energy; ΔQ, the increase in the reaction heat, and x, a constant equal to about 0.25.

From Eq. (8) we may calculate the change in the activation energy of a radical substitution reaction (such as those taken up in Fig. 2) caused by changing the alkyl group, R:

$$\Delta E_a = E_a - E_{a_0} = (1-\varepsilon\delta D_f)(D_i - D_{i,0}) \qquad (13)$$

where the subscript "0" indicates the value in a certain standard reaction. The $(D_i-D_{i,0})$ factor may be equated to $-(Q-Q_0)$; hence,

$$\Delta E_a = -(1-\varepsilon\delta D_f)\Delta Q \qquad (14)$$

which may be brought into the form of Eq. (12) by setting:

$$x = 1 - \varepsilon\delta D_f \tag{15}$$

The x value calculated with $\varepsilon=0.0850$, $\delta=0.0944$, and $D_f=97.5$ kcal/mol,[6] that is the bond dissociation energy of the Na-Cl bond, is 0.22; this is nearly equal to the Evans-Polanyi value, 0.25. It is also found from Eq. (15) that the x value in Eq. (12) does not change with the bond dissociation energy of the initial molecule, while it does with that of the final molecule.

The Semenov Rule. Bagdasaryan,[2] Voevodskii,[3] and Semenov[4] have extended the Evans-Polanyi rule and have found that the activation energy can be calculated from Eq. (16) for exothermic reactions and from Eq. (17) for endothermic reactions:*1

$$E_a = A - yQ \tag{16}$$

$$E_a = A + (1-y)Q \tag{17}$$

where $A=10$ to 18 kcal/mol and $y=0.2$ to 0.4.

By substituting the relation, $D_i \simeq D_f - Q$, into Eq. (8),

$$E_a = (1 - \varepsilon - \varepsilon\delta D_f)D_f - (1 - \varepsilon\delta D_f)Q \tag{18}$$

for both exothermic and endothermic reactions. By comparing Eq. (18) with Eqs. (16) and (17), we obtain:

$$A = (1 - \varepsilon - \varepsilon\delta D_f)D_f \tag{19}$$

$$y = 1 - \varepsilon\delta D_f \text{ (for exothermic reactions)} \tag{20}$$

$$y = 2 - \varepsilon\delta D_f \text{ (for endothermic reactions)} \tag{20'}$$

From Eqs. (19) and (20) we find that the calculated values of A and y of exothermic reactions are in the ranges $11<A<19$ kcal/mol and $0.20<y<0.32$ respectively, provided that $85<D_f<100$ kcal/mol. This is in accordance with the Semenov empirical rule.

The Hammett-type Rule. The following is a list of various types of radical substitution reactions (1) changing a reacting radical in three reactions (A, B, and C):

$$A + BC_j \rightarrow AB + C_j \tag{21}$$

$$A_j + BC \rightarrow A_jB + C \tag{22}$$

$$A + B_jC \rightarrow AB_j + C \tag{23}$$

where the subscript j indicates the changing radical.

The increase in the activation energy, ΔE_a, of (21) caused by changing the standard radical, C_0, to C_j is given by:

$$\Delta E_a = (1 - \varepsilon\delta D_f)(D_{i,j} - D_{i,0}) = \dot{\rho}\dot{\sigma} \tag{24}$$

$$\dot{\rho} \equiv k(1 - \varepsilon\delta D_f) \tag{25}$$

$$\dot{\sigma} \equiv (1/k)(D_{i,j} - D_{i,0}) \tag{26}$$

In Eqs. (25) and (26) above, which define $\dot{\rho}$ and $\dot{\sigma}$, k is a constant whose value is chosen so that the value of $\dot{\rho}$ for the $CH_3+RH \rightarrow CH_4+R$ reaction is 10.0 (see below and Table 2). Notice that $\dot{\rho}$ and $\dot{\sigma}$ depend only on the final and the initial molecules respectively. We may regard them as analogues of Hammett's ρ and σ; we shall, then, call $\dot{\rho}$ the reaction constant, and $\dot{\sigma}$, the substituent constant.

Similarly, the increase in the activation energy, ΔE_a, of (22) caused by changing the attacking radical, A_0 to A_j is given by:

$$\Delta E_a = -\varepsilon(1 + \delta D_i)(D_{f,j} - D_{f,0}) \tag{27}$$

The $-\varepsilon(1+\delta D_i)$ and $(D_{f,j}-D_{f,0})$ are the factors depending only on the initial and the final molecules respectively. It may be considered that the former corresponds to the reaction constant, $\dot{\rho}'$, and the latter, to the substituent constant, $\dot{\sigma}'$.

When changing the parent radical B_0 to B_j, however, the increase in the activation energy, ΔE_a, is represented by a complicated expression and is not given by a simple Hammett-type formula:

$$\Delta E_a = (D_{i,j} - D_{i,0}) - \varepsilon(D_{f,j} - D_{f,0}) - \varepsilon\delta(D_{i,j}D_{f,j} - D_{i,0}D_{f,0}) \tag{28}$$

6) A. G. Gaydon, "Dissociation Energies and Spectra of Diatomic Molecules," 1st Ed., Dover Publications, N. Y. (1947).

*1 Equation (16) for exothermic reactions holds fairly well, but Eq. (17) for endothermic reactions is not very good. Knox *et al.* have observed that y should be 0.91 for hydrogen abstraction reactions by a chlorine atom (endothermic reaction).[7] This value is in good agreement with the y value, 1.18, calculated by using (20') and $D_f=102$ kcal/mol,[8] which is the bond dissociation energy of the H-Cl bond.

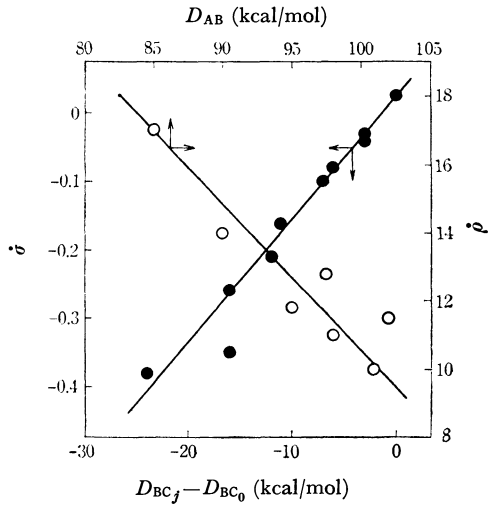

Fig. 3. Relation between the substituent constant $\dot{\sigma}$ or the reaction constant $\dot{\rho}$ and the bond dissociation energy.

$$\Delta E_a=(1-\varepsilon\delta D_{AB})(D_{BC_j}-D_{BC_0})=\dot{\rho}\dot{\sigma}$$

In fact, the increase in the activation energy caused by the change in the radical B_j is not expressed by a simple functional formula of the reaction heat.

In order to evaluate the substituent constants and the reaction constants of the type (21) of reactions, we choose the hydrogen abstraction reactions ($\dot{\rho}=10.0$) by a methyl radical as the standard reactions and a methyl group ($\dot{\sigma}=0$) as a standard substituent, C_0. By substituting the differences in the observed activation energies of the standard reactions into the relation, $\dot{\sigma}=\Delta E_a/\dot{\rho}$, where $\Delta E_a=E_{a(CH_3-H)}-E_{a(R-H)}$, we can evaluate the substituent constants, $\dot{\sigma}$ (Table 1). Moreover, the reaction constants, $\dot{\rho}$, of the other reactions are evaluated by the use of the substituent constants determined by such operations (Table 2).

As has been defined above, the substituent constants, $\dot{\sigma}$, and the reaction constants, $\dot{\rho}$, are, respectively, proportional to the $(D_{i,j}-D_{i,0})$ and $(1-\varepsilon\delta D_f)$ factors. As Fig. 3 shows, each constant can be expressed as a function of the bond dissociation energy.

The Radical Reactivity Index, D_r^R. Fukui *et al.*,[9] from the quantum chemical point of view, have proposed the delocalizability, D_r^R, as a radical reactivity index of radical substitution reactions (1):

$$D_r^R=\sum_j^{occ}\frac{(C_r^j)^2}{\lambda_j}+\sum_j^{unocc}\frac{(C_r^j)^2}{-\lambda_j} \qquad (29)$$

where C_r^j is the coefficient of the rth atomic orbital in the jth molecular orbital of the BC molecule, and λ_j, the coefficient of β in the energy of the jth molecular orbital of the BC molecule. Using this index, it has been assumed that the activation energy is written in the form:[10]

$$E_a=c_1-c_2D_r^R \qquad (30)$$

where it has been assumed that c_1 is a constant for a definite type of reactions and that c_2 is a constant depending only on the radical A.[10]

Equation (8) is rewritten as:

$$E_a=(1-\varepsilon\delta D_f)D_i-\varepsilon D_f \qquad (31)$$

For the hydrogen abstraction reactions by a methyl radical, $CH_3+RH\rightarrow CH_4+R$, the final bond dissociation energy, D_f, in Eq. (31) is constant, and the coefficient, c_2, in Eq. (30) should not change if the above assumption is satisfied. Therefore, the values of $D_r^R(H)$ should be expressed as a linear function of $D_{i(RH)}$, with a negative slope. This linear relation between $D_r^R(H)$ and $D_{i(RH)}$ has been checked in Fig. 4.

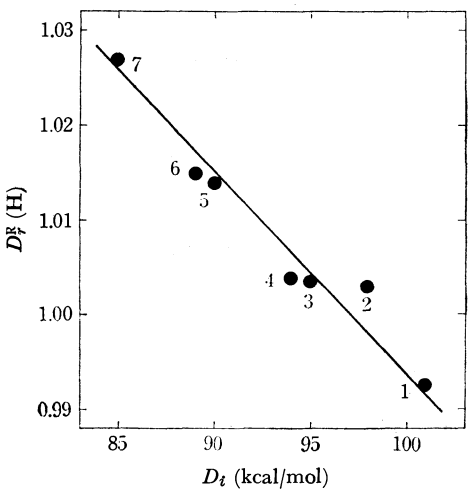

Fig. 4. Relation between the delocalizability of hydrogen abstraction reaction and the bond dissociaion energy. B=hydrogen atom
$E_a=(1-\varepsilon\delta D_f)D_i-\varepsilon D_f$
$E_a=c_1-c_2D_r^R$
1 Me–H, 2 Et–H, 3 *n*-Pr–H, 4 *n*-Bu–H, 5 *i*-Pr–H, 6 *s*-Bu–H, 7 *t*-Bu–H

On the basis of the above considerations, it may be concluded that Eq. (8) is not only a good approximate formula for the evaluation of the activation energies of radical substitution reactions, but also corresponds well with the empirical rules described previously.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 2426—2431 (1969)

Studies on Formaldehyde-Condensation Resin. VII.*1 Isolation of Mono-, Di-, Tri-, and Tetramethylolacetoguanamines

Tadashi URAGAMI and Masayoshi OIWA

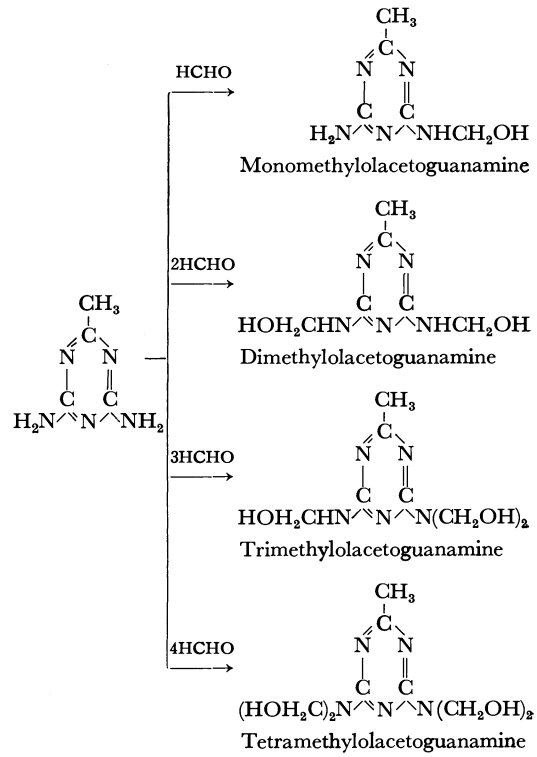
Department of Applied Chemistry Faculty of Engineering, Kansai University, Senriyama, Suita-shi, Osaka

(Received November 11, 1968)

The reaction of acetoguanamine with formaldehyde was carried out in the presence of basic catalyst under various conditions, and mono-, di-, tri-, and tetramethylol derivatives of acetoguanamine were purely isolated. Their structures were identified by elemental analyses, infrared absorption spectra, NMR spectra, and chemical analyses of methylol groups.

The isolation of some intermediates of phenol, urea, melamine, and guanamine resins, well-known as the addition-condensation resin, has been studied by many workers.[1-9] Recently, there have been interesting presentations[10,11] on the syntheses of some kinds of benzoguanamine-formaldehyde resin intermediates, but no reports on any detailed studies of the methylol derivatives of acetoguanamine.

Acetoguanamine can be hydroxymethylated to form mono-, di-, tri-, tetramethylolacetoguanamines as follows:



The present paper deals with the isolation of the methylol derivatives which were obtained from the base-catalyzed reaction of acetoguanamine with formaldehyde under various conditions.

Experimental

Materials. Nippon Gosei Chem. Ind. Co. best grade acetoguanamine was recrystallized from water, mp 269—271°C. Commercial formaline (*ca.* 37 wt%) was used. Pure commercial dimethylsulfoxide (DMSO) was purified by the usual method[12]: bp 88°C/25 mmHg.

Hydroxymethylation of Acetoguanamine. In a four-necked flask equipped with a reflux condenser and a stirrer, formaline was added to 1 mol of acetoguanamine in the formaldehyde/acetoguanamine molar ratio of 1—8 (in some cases, water was added), and the pH was adjusted to the desired value with sodium hydroxide solution (the pH was measured with a glass electrode using Hitachi Horiba M-5 pH meter.). This mixture was heated for an hour with stirring in a thermostat regulated at 80°C, and then the flask containing the reaction products was cooled in ice-water or allowed to stand at room temperature until crystals precipitated. The obtained crystals [A] were collected on a Büchner funnel and the filtrate was allowed to stand for 1—2 days (in the cases of the formaldehyde/acetoguanamine molar ratio of 7 and 8, the filtrate was allowed to stand for a week) in a refrigerator. The crystals [B] deposited from the filtrate were filtered off, and the filtrate was treated again as mentioned above.

The conditions for preparation of methylol acetoguanamines are shown in Table 1.

Table 1. The conditions for preparation of methylolacetoguanamines

No.	AG g	F ml	Water ml	Molar ratio AG: F	pH
1	90	54.1	360	1 : 1	9.04
2	31	22	50	1 : 1.2	9.40
3	125	150.1	287	1 : 2	8.81
4	125	225.2	0	1 : 3	9.00
5	87.5	210	0	1 : 4	9.20
6	75	270	0	1 : 6	9.01
7	50	210	277	1 : 7	9.00
8	50	240	309	1 : 8	9.00

Acetoguanamine and formaldehyde are abbreviated as AG and F respectively.

Monomethylolacetoguanamine. To a suspension of 31 g (0.248 mol) of acetoguanamine in 50 m*l* of water was added 22 m*l* (0.2976 mol) of formaline. The mixture was adjusted to pH 9.40, heated at 80°C for about an hour after complete dissolution, and then cooled to 10°C. The deposited crystals were collected and dissolved in methyl cellosolve to remove unreacted acetoguanamine monomer. The crystals 2-A (see Table 2) recrystallized from acetone were separated, washed with cold water, air-dried and then dried at room temperature *in vacuo*.

Dimethylolacetoguanamine. A mixture of 125 g (1 mol) of acetoguanamine and 225.2 m*l* (3 mol) of formaline was adjusted to pH 9.00. This mixture became a transparent solution within a few minutes, and after 20 min, the reaction solution changed into a milky turbid solution, and then the reaction was continued for 40 min. The separated product 4-A was washed with petroleum ether and dried *in vacuo* (room temperature). The pure crystals 4-A′ were obtained by repeated crystallization from DMSO.

Trimethylolacetoguanamine. A mixture of 87.5 (0.7 mol) of acetoguanamine and 210 m*l* (2.8 mol) of formaline was heated for an hour at pH 9.20 and 80°C. This mixture became homogeneous after 10 min, and the reaction solution was clear until the reaction came to an end. The resulting solution was allowed to stand at room temperature until crystals formed, then the crystalline product 5-A was separated by filtration and the filtrate was kept to stand for 2 days in a refrigerator. The crystals 5-B obtained from this filtrate were collected, washed with cold water and methanol, and air-dried.

Tetramethylolacetoguanamine. Acetoguanamine (50 g, 0.4 mol) was suspended in 240 m*l* (3.2 mol) of formaline and about 310 m*l* of water. This mixture immediately became clear by heating at 80°C and pH 9.00. The product 8-A was obtained by setting the reaction solution for a week in a refrigerator. The

Calcd % of methylol F and N are for pure mono-, di-, tri-, and tetramethylolacetoguanamines.

yield of crystals 8-A was lower than those of crystals 2-A, 4-A′, and 5-B. The filtrate, after the crystals 8-A were separated off, was kept for a week in a refrigerator and a small amount of the product 8-B was obtained.

Analyses of the Products. The products were analyzed by the iodometric[13] and the Levenson (phosphoric acid decomposition[14-16]) methods; the molar ratio of the hydroxymethylated formaldehyde and the combined total formaldehyde to acetoguanamine were calculated respectively. The amount of the methylene linkage was estimated from the difference between the two values obtained by the two methods. The infrared absorption spectra were observed by KBr disk method using the IR-27G infrared spectrophotometer of Shimadzu Co., Ltd. The NMR spectra of acetoguanamine derivatives in DMSO were recorded on a Japan Electron Optics Lab. NMR spectrometer, model JNM-3H (60 Mc), using tetramethylsilane as an internal reference.

The analyses of No. 2-A, 4-A′, 5-B, and 8-A crystals and their yields and melting points are shown in Table 2.

Results and Discussion

Chemical Analysis of Methylol Derivatives. It may be first considered from Table 2 that in products No. 2-A, 4-A′, 5-B, and 8-A the methylene linkage is not found at all, because the content of the methylol group agrees very closely with that of the combined total formaldehyde. Tollens reagent was reduced by these compounds, indicating the presence of the methylol groups. The molar ratio of the hydroxymethylated formaldehyde of these compounds were 1.01, 1.98, 2.97, and 3.99 respectively. It was also recognized that the agreement between the calculated and found values (elemental analyses) of No. 2-A, 4-A′, 5-B, and 8-A is within the error of the analysis and that the sharp melting point of each compound indicates a good quality. Accordingly, each of the crystals No. 2-A, 4-A′, 5-B, and 8-A was assumed to be a pure methylol derivative of mono-, di-, tri-, and tetramethylolacetoguanamines, respectively. Henceforth, they will be represented as AGF, AG2F, AG3F, and AG4F respectively.

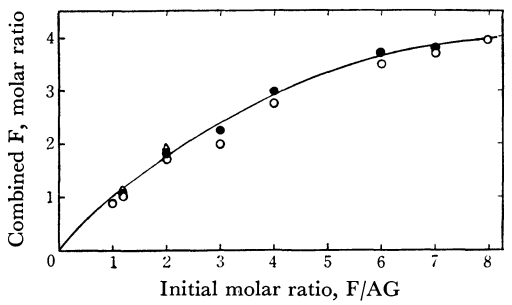

Fig. 1. The relationship between the initial molar ratio, F/AG and the observed molar ratio in methylol compounds.
○: crystal A, ●: crystal B, △: crystal C

The relationship between the initial molar ratios of formaldehyde and acetoguanamine and the observed molar ratios in methylol compounds is plotted in Fig. 1 based on data in Table 2. As can be seen from Fig. 1, the molar number of the combined formaldehyde to acetoguanamine increases with the increase of the reaction molar ratio. But in all the above results, each expected methylol compound is formed when an excess amount of formaldehyde is present in the reaction system, and especially in the preparation of AG4F, 8 mol of formaldehyde is needed which corresponds to two equivalents of acetoguanamine. This fact may easily be understood from the presence of four equilibriums in the formation of AG4F.

An increase of the content of the methylol group in the order of crystals [A], [B], and [C] in Table 2 indicates the formation of the higher order methylol compound.

Infrared Absorption Spectra of Mono-, Di-, Tri-, and Tetramethylolacetoguanamines. In Fig. 2 are shown the infrared absorption spectra of acetoguanamine and its methylol derivatives, AGF, AG2F, AG3F, and AG4F. In these spectra, the absorption bands near 3000 cm^{-1} can not definitely be assigned, because in acetoguanamine (Fig. 2(a)) the $-NH_2$ and C–H stretching vibrations overlap with each other and in methylol derivatives (Fig. 2(b)—(e)) the N–H and O–H stretching bands[17,18] additionally overlap. The characteristic absorption bands at 1655 and 1626 cm^{-1} are assigned to the $-NH_2$ scissor vibration[19] and decreased with an increase of the number of methylol groups. The absorption at 1620 cm^{-1} shown in Fig. 2(c) (AG2F) is due to the N–H deformation vibration. The variation of the characteristic bands in the region of 1655 to 1620 cm^{-1} in Fig. 2(a)—(c) indicate that $-NH_2$ and –NH– groups on acetoguanamine take part in a series of reactions leading to the formation of methylol compounds, especially in Fig. 2 (e) (AG4F) where these peaks disappeared completely. The absorption in 1555—1400 cm^{-1} region seems to be due to the overlaps of the C–H stretching vibrations[19-21] of the triazine ring system and the side chain, and the C–H deformation band of the substituent group, $-CH_3$ on the triazine ring. It is known[22] that the bands of the C–H stretching vibration corresponding to primary, secondary, and tertiary amines appear at 1360—1250 cm^{-1}, but in these spectra, it is difficult to distinguish each peak clearly. The absorption near 1000 cm^{-1} due to the C–O stretching[23,24] indicates the presence of methylol group, which has been known[25] in the infrared absorption spectra of *o*- and *p*-methylolphenol. The intensity of this peak shows a prominent increase in proportion to the number of methylol groups. This fact suggests in connection with the absorption bands of

the $-NH_2$ scissor and the N–H deformation that the number of methylol groups increases in the order of Fig. 2(a)—(e). It has been known[20,21,26] that the sharp band at 815 cm^{-1} is assigned to out-of-plane deformation vibration of the triazine ring.

The results of the infrared spectra may allow us to conclude, at least qualitatively, that the characteristic absorption bands, especially the peaks in 1655—1620 cm^{-1} region and at 1000 cm^{-1}, can be used as a measure of the degree of hydroxymethylation of acetoguanamine with formaldehyde.

NMR Spectra of Mono-, Di-, Tri-, and Tetramethylolacetoguanamine. The measurements of NMR spectra were also carried out to identify the above results. Since the signals of the methylene protons from acetoguanamine and DMSO (solvent) overlapped with each other, the signals of $-NH_2$ groups, –NH–, $-CH_2-$, and –OH on $-NHCH_2OH$ groups, and $-CH_2-$ on $-N(CH_2OH)_2$ were inquired. These spectra are shown in Fig. 3 and their chemical shifts are given in Table 3, in which the circle and saltire-cross marks indicate the presence and absence of the signals, respectively.

The signal at 3.4 ppm is observed both in the spectrum of acetoguanamine and AGF but not in that of the other compounds, and acetoguanamine has only this peak (Fig. 3(I)). Therefore, this singlet signal can be identified due to protons of primary amine. The protons which are possessed in AGF, AG2F, and AG3F, but not in acetoguanamine and AG4F, correspond to the imino proton and methylene protons of $-NHCH_2OH$ groups. It has been revealed[27] that the broad signal centered at 2.5 ppm can be assigned to a proton of secondary amine. From these results, the peak at about 2.3 ppm mentioned above may be assigned to the imino proton. On the other hand, the appearance of the triplet in the region of 5.1 to 5.4 ppm is due to the absorption for the methylene protons on $-NHCH_2OH$. The signal near 4.5 ppm can be identified with the hydroxyl group proton on methylol group, because this signal does not appear in acetoguanamine (Fig. 3(I)) but appears in AGF, AG2F, AG3F, and AG4F possessing the methylol group (Fig. 3(II)—(V)). The doublet signal in the region of 4.7 to 5.0 ppm appears in AG3F and AG4F as shown in Fig. 3(IV) and (V), in the spectrum of AG4F, the other absorption other than this doublet peak (e) and the hydroxyl group proton peak (c) can not be detected. Thus the peak (e) may be assigned as coming from the methylene protons on $-N(CH_2OH)_2$. It has become apparent that if the methylene protons on the methylol groups are the same, the methylene protons on $-NHCH_2OH$ and on $-N(CH_2OH)_2$ give the different signals respectively, and from the difference of these signals that the AG2F isomer of $-N(CH_2OH)_2$ type is not contained in the AG2F, *i.e.* the AG2F isomer is very difficult to be formed compared with AG2F bonding two methylol groups on both sides of amino groups. This fact may be explained by the difference of the reactivity of $-NH_2$ and –NH– groups as found by Jong and Jonge[28] on urea resin. If this isomer exists in the obtained AG2F compound, the absorption peaks of a primary amine should remain and that of the methylene on $-N(CH_2OH)_2$ should appear in Fig. 3(III).

The assignment of each proton in acetoguanamine and its methylol derivatives is shown in Table 3. The ratio of the absorption intensities of the signals is recognized to be in reasonable harmony with the calculated one for pure methylol compounds. It may be concluded that the results of the NMR spectra can be used as an indicator of the degree of hydroxymethylation by observing the characteristic absorption signals.

From results of chemical analysis, infrared absorption spectra and NMR spectra analyses, it was found that four kinds of pure methylol derivatives of acetoguanamine, *i.e.*, mono-, di-, tri-, and tetramethylolacetoguanamines, can easily be synthesized by selecting the reaction conditions, especially the molar ratio of formaldehyde and acetoguanamine.

The authors wish to express their thanks to Professor Masaya Ogawa and Dr. Fukiko Yamada for their valuable discussions and encouragement, Mr. Isao Niwa for his experimental assistance, Mrs. Toshiko Kōno for her measurements of NMR spectra, and Miss Hisako Nishikawa for her elemental analysis. They are also grateful to Nippon Gosei Chem. Ind. Co., Ltd., for the generous gift of acetoguanamine.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 2431—2437 (1969)

ESR Spectra of the System of the Transition Metal Compound and Trialkyl Aluminum. II.*1 The System of the Vanadium Compound and Trialkyl Aluminum*2

Yasuo NOZAWA and Masatami TAKEDA

Department of Chemistry, Faculty of Science, Science University of Tokyo, Shinjuku-ku, Tokyo

(Received January 16, 1969)

The ESR spectra of the homogeneous organometallic catalyst system of VOA_2-$AlEt_3$ (I) and VCl_4-$AlEt_3$ (II) were measured in benzene, toluene, *n*-hexane and tetrahydrofuran solutions. A superhyperfine structure of nine lines with a *g*-value of 1.9917, and with a hyperfine splitting of 4.2 gauss on each eight line due to the ^{51}V nucleus, was observed in the systems of I and II in the aromatic solvents at any Al/V ratio from 1 to 15. The same type of spectrum was observed in the VA_3-$Al(isoBut)_3$ system in a benzene solution at Al/V ratios higher than 3. In the system of II, the single line was observed at Al/V ratios up to 5. At higher ratios the superhyperfine structure appeared to overlap on the single line. On the basis of these facts, it may be considered that the vanadium atom was reduced to the zerovalent state and was then complexed with aromatic solvents in these systems. This suggests the presence of a sandwich complex such as where X=H or CH_3.

Homogeneous catalytic systems of the vanadium (V) compound and aluminum alkyl for the polymerization of ethylene and its copolymerization with α-olefin have been investigated in detail.[1-4] Natta[5] has shown, by means of electron spin resonance (ESR) measurements, that the active species of vanadium complexes for the syndiotactic polymerization of polypropylene have a valence state of 3. The active oxidation state of the V compound has also been extensively discussed by Lehr.[6] The formation of a chlorine-bridged complex as the reaction product of vanadium tetrachlolide (VCl_4) and triethylaluminum ($AlEt_3$) in the VCl_4-$AlEt_3$ system has been proposed by Sciulydin.[7] The same type of ESR spectrum has, however, been obtained in the system of vanadyl acetylacetonate (VOA_2) and $AlEt_3$, in which chlorine atoms are not present. Therefore, it seems to be worthwhile to study further the chemical structure of the complex produced in the system of the V compound and $AlEt_3$.

The present paper describes ESR measurements

of the VOA_2-$AlEt_3$ (I) and VCl_4-$AlEt_3$ (II) systems in various organic solvents; the formation of a sandwich complex of the V atom with aromatic solvents will be discussed on the basis of our observations.

Experimental

Reagent and Preparation of Samples. Vanadium trisacetylacetonate was prepared as described in the literature[8] and was purified by recrystallization from benzene. Commercially-obtained vanadium tetrachloride and triethylaluminum (Ethyl Co) were used without further purification. The solvents used were refluxed over a sodium ribbon and distilled immediately before use.

The samples for ESR measurements were prepared in a 30-milliliter glass vessel under a dried nitrogen atmosphere at room temperature. One milliliter of the 1/5 mol/*l* solution of the V compound was taken into the vessel and a predetermined aliquot of an $AlEt_3$ solution with the same concentration as the V compound was added; then the solvent was added to bring the total volume to 20 m*l*. Thus the concentration of the sample solution was 0.01 mol/*l* with respect to the V compound. The solution was introduced into a sample tube for ESR measurements by means of a hypodermic syringe. The concentration of the sample solution for the VOA_2-$AlEt_3$ system in *n*-hexane was small because of the low solubility of the species involved.

ESR Measurements. The ESR spectrometer used was a JES-3BSX-type apparatus (Japan Electron Optics Co. Ltd.) with 100 kHz field modulation and TE_{011} mode cavity. The *g*-value was determined by the aid of DPPH.

Results

1. The VOA_2-$AlEt_3$ System (I). The ESR spectra of VOA_2 and the VOA_2-$AlEt_3$ system in a benzene solution are shown in Fig. 1 and Fig. 2-a respectively. The eight-line signal with a *g*-value of 1.9843 and with a hyperfine (hf) splitting of 109 gauss was observed in a benzene solution of VOA_2. In the VOA_2-$AlEt_3$ system in benzene, similar line spectra with a *g*-value of 1.9917 and with a hf splitting of 62 gauss were obtained at an Al/V ratio from to 15. The eight-hf signal in each spectra is due to the interaction between an odd electron and the ^{51}V of the nuclear spin moment, 7/2. As is shown in Fig. 2-b, with a lower sweep rate a superhyperfine (shf) structure which apparently has nine-line signal with a splitting of 4.2 gauss was obtained on each line of the eight hf components in this system. The same spectral feature appeared also in the region where the Al/V ratio was higher than 15. The nine-shf structure, however, could not be detected in a benzene solution of VOA_2.

The spectra of this system in toluene are given in Fig. 3, the nine-line shf signal that overlapped on each component of the eight hf lines was also observed at Al/V ratios from 3 to 15. The spectrum was exactly the same as that obtained in the benzene solution.

The ESR spectra of this system in an *n*-hexane solution at an Al/V ratio of 7 are shown in Fig. 4. A signal with a *g*-value of 1.9928 containing an eight-line signal (a splitting of about 66 gauss) was observed on samples with Al/V ratios from 1 to 15. The shf structure could not, however, be detected at all on any eight-hf component. This spectrum is different from those of benzene and toluene solutions in that the eight-hf structure is missing in the former, apparently indicating that the radical species in an *n*-hexane solution is different from those in benzene and toluene.

The ESR signal of the system of VOA_2 and $AlEt_3$ could not be observed at any Al/V ratio when tetrahydrofuran was used as the solvent.

2. The VCl_4-$AlEt_3$ System (II). The ESR spectrum of the VCl_4-$AlEt_3$ system in a benzene

solution at Al/V ratios up to 5, as shown in Fig. 5, consists of a single line signal with a *g*-value of 1.9775 and has a maximum slope width of approximately 170 gauss. At higher Al/V ratios, as is shown in Fig. 6, an eight line signal with a *g*-value of 1.9917 and containing a nine shf structure on each hf component similar to that found in the system I was superimposed on the single line signal described above.

In a toluene solution of this system, only a single line was observed at Al/V ratios up to 5. At higher ratios (7 and 15), the single line and the eight-line signal were observed again, the two signals overlapping.

The spectrum in an *n*-hexane solution has only a single line signal with a *g*-value of 1.9771, and its maximum slope width is approximately 200 gauss. No other signal (*e. g.*, the nine line shf signal) could be observed when the Al/V ratio was varied from 1 to 15. These single-line spectrum of this system can be exactly assigned to the signal of the VCl_2 compound by reference to those observed in a solid state and in a hydrocarbon solution.[5]

In view of the present observations, it is clear that the ESR-active species in a benzene and a toluene solution are different from that in *n*-hexane solution, as is the case for the system I. The results observed in both systems are summarized in Table 1.

The addition of various alcohols to the system I and II did not alter the line shapes of the spectra and the *g*-values of the signals, though the signal intensity decreased. This is in sharp contrast to the system of bis-cyclopentadienyltitanium dichloride ($(C_5H_5)_2TiCl_2$) and AlR_3, which will be described again later.

Discussion

As Fig. 1 and Fig. 2 show, the hf splitting of the eight-line signal for the benzene solution of VOA_2 is approximately 109 gauss, but the splitting width changes to 62 gauss in the systems of both I and II when $AlEt_3$ is added. It is, therefore, apparent that vanadium is reduced to a lower oxidation state from its initial state, +4, as a result of the reaction of the original compound with $AlEt_3$. A

Table 1. Summary of *g*-values and hyperfine coupling constants in various systems

System	Solvent	Al/V	*g*-Value	hf constant (8) (gauss)	shf constant (9) (gauss)

correlation of the hf splitting with the oxidation state of ^{51}V has been reported,[9] it was found that the separations for V^{4+}, V^{3+} and V^{2+} in α-Al_2O_3 are 140, 110, and 88 gauss, respectively. The steady decrease in the splittings in this series also supports the idea of the formation of a reduced vanadium compound in the present system.

In the ESR spectrum for the system of VOA_2-Al(isoBut)$_3$ in toluene, eight-line signal with an hf splitting of 63 gauss, each of the signal with an shf structure of nine line similar to the spectra shown in Fig. 2, were also observed at Al/V ratios from 3 to 8. The oxidation state of vanadium is reduced to a lower state by Al(isoBut)$_3$ also.

For the system of vanadium trisacetylacetonate (VA_3) and Al(isoBut)$_3$ in benzene solution, no ESR signal was observed at Al/V ratios of 1 and 2.

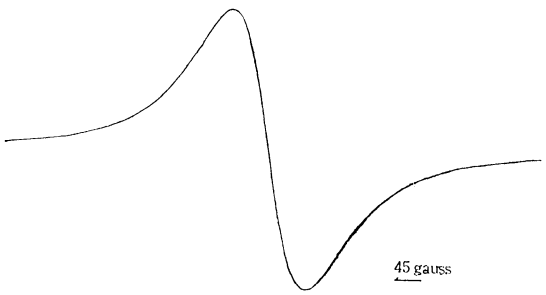

Fig. 5. The ESR spectrum of the system of VCl_4-$AlEt_3$ in benzene solution. Al/V=5.

The oxidation state of vanadium in VA_3 may be regarded as +3, and the species does not give rise to any ESR signal. Apparently, VA_3 is not reduced by Al(isoBut)$_3$ under such conditions. If the Al/V ratio was raised to above 3, however, the same spectra as those of I and II were obtained.

In the system of II in benzene and toluene, only a single broad line is observed at the Al/V ratio of 5, as is shown in Fig. 5. The spectra may be assigned to that of VCl_2. As Fig. 6 shows, at Al/V ratios higher than 5 the shf structure appears to overlap on the single line. The spectra with an shf structure may be attributed to the signal of vanadium, which has been reduced further from the divalent state to possibly that of zerovalent vanadium.[10]

Note that the nine-line shf structure described above could not be observed when *n*-hexane was used as a solvent instead of benzene and toluene.

Sciulydin[7] reported that the eight-line signal with a *g*-value of 1.992 aws observed in the VCl_4-$AlEt_3$ system in a benzene solution and that each hf component of the eight-line signal gave an shf structure of 11 or 13 lines; be proposed a chlorine-bridged structure such as $R_2Al\langle^{Cl}_{Cl}\rangle V\langle^{Cl}_{Cl}\rangle AlR_2$ its hf structure being attributable to interaction between an odd electron of the vanadium atom and four chlorine and two aluminum atoms. However, since we have observed the same spectral features in the VOA_2-$AlEt_3$ system in which no chlorine

atom is involved, the structure postulated above is not adequate to explain the spectra.

To aid the investigation of the complex formation of the V atom in the system, ESR measurements of the system of chromium trisacetylacetonate (CrA_3) and $AlEt_3$, analogous to the system of the vanadium compound and $AlEt_3$, were carried out. As is shown in Fig. 7, a nine-line spectrum[11] with a *g*-value of 1.986 was detected for the sample in a benzene solution at Al/Cr ratios higher than 4. The same type of spectrum consisting of a seven- or nine-line signal with a *g*-value of 1.987 in various aromatic solvents at the Al/Cr ratio of 10, was also reported by Angelescu *et al.*[12] They proposed the formation a sandwich-type complex of the chromium atom with aromatic species in these systems; they did so on the basis of the evidence that the shapes of the signals and the values of the *g*-factor were in agreement with those of $Cr(C_6H_6)_2^+$ [13] and its derivatives.[14]

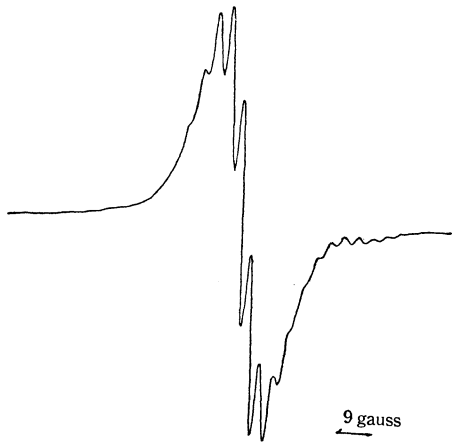

Fig. 7. The ESR spectrum of the system of CrA_3-$AlEt_3$ in benzene solution. Al/Cr=4.

By analogy with Angelescu's interpretation, the formation of a certain complex similar to $Cr(C_6H_6)_2^+$ may be expected for the system of the V Compound and $AlEt_3$ also. In fact, the shape of nine line signal observed in the system I and II (benzene and toluene being used as solvents) was apparently similar to that of the CrA_3-$AlEt_3$ system in various solvents.

Hence, we propose that the V compound in these systems is in the form of a sandwich-type complex with aromatic solvent molecules, as in the cases of CrA_3 and $AlEt_3$. The shf structure appearing in the spectra may, then, be attributed to the hf interaction between an odd electron and 12 (or 10) equivalent protons on the aromatic ring. Such an interaction would give rise to 13 equally-spaced lines with an intensity ratio of 1, 12, 66, 220, 495, 792, 924, 792, 495, 220, 66, 12 and 1 if $V(C_6H_6)_2$ is produced in the systems. Only nine-line signal was observed, however, this disagreement may be attributed to the poor signal-to-noise ratio of the spectra.

On the other hand, Hausser[15] has measured the ESR spectrum of $V(C_6H_6)_2$ in a mixed solvent (toluene and methylcyclohexane, (1 : 1)); he has observed eight-line signal due to the ^{51}V nucleus with a *g*-value of 1.9920, having an hf separation of 63.5 ± 1 gauss and an shf structure of nine line with a splitting of 4.0 ± 0.1 gauss superimposed on each hf component. The results obtained in our experiments are in good agreement with those obtained by Hausser with respect to the *g*-value, the shf splitting constant, and the pattern of the spectra.

In conclusion, the presence of an shf structure on eight-line spectrum observed in these systems (I and II) suggests the formation of a sandwich structure such as where X=H or CH_3, in which the chlorine-bridged structure proposed by Sciulydin is not involved.

Previously, in the system of $(C_5H_5)_2TiCl_2$-AlR_3 the six-line spectrum caused by hf interaction between an odd electron of the Ti^{3+} and the Al^{27} nucleus had been observed when methyl alcohol and the like were added to this system. This fact was interpreted by assuming the structure of the product to involve a di-μ-alkoxo bridge between the Ti and Al atoms.[16] On the other hand, as has been mentioned before, the *g*-value and the line shape of the spectra for the systems of I and II did not change when methyl alcohol was added, except for the decrease in the signal intensity. Therefore, as far as the results of the ESR measurement are concerned, it seems that the V atom does not form a di-μ-alkoxo bridge complex with the Al atom upon the addition of alcohol.

Conclusion

From the study of the ESR spectra in the systems of VOA_2-$AlEt_3$ (I) and VCl_4-$AlEt_3$ (II), the formation of a sandwich complex of zerovalent vanadium with aromatic solvents has been suggested; the

formation of an oxo-complex involving Al and V atoms could not be deduced in these systems, even in the presence of alcohol, as long as the ESR spectra of such systems were used as the criterion.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 2437—2449 (1969)

Semi-empirical Unrestricted SCF-MO Treatment for Valence Electron Systems. I. Application to Small Doublet Radicals

Teijiro YONEZAWA, Hiroshi NAKATSUJI, Takashi KAWAMURA and Hiroshi KATO*1

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Kyoto

(Received January 20, 1969)

A semi-empirical SCF method for valence electron systems including a differential overlap previously proposed by the present authors is here extended to molecules with an open-shell structure. The unrestricted Hartree-Fock method is applied, and the one-centre and part of two-centre σ–π-type exchange repulsion integrals, playing an essential role in spin-density calculations, are included in the calculations. The calculated spin densities are divided into the mechanistic (spin-polarization and spin-delocalization) contributions. The spin-polarization mechanism is shown to be important even in cases where the spin delocalization mechanism has usually been considered to be dominant (*e. g.*, ethyl and vinyl radicals). The calculated spin densities of π-electron radicals (methyl, ethyl, allyl, and *trans*-butadienyl anion radicals) and of σ-electron radicals (vinyl, formyl, NO_2, CO_2^-, CN) are discussed. Their *hfs* constants and mechanistic contributions are calculated; for the methyl and vinyl radicals these are shown to be strongly angular-dependent. The calculated potential curve and the *hfs* constants of the vinyl radical lead to the CCH_α angle, $\theta \simeq 135°$; furthermore, the H_α and C_β *hfs* constants are shown to be negative. Generally, the calculated proton *hfs* constants agree satisfactorily with the experimental data and with other calculations except in the case of the formyl radical. The atomic dipoles of some σ-electron radicals are calculated, and some interesting features common to all the σ-electron radicals studied are found.

Recently semi-empirical SCF methods for valence electron systems have been generally applied[1-5] to calculations of certain physical and chemical properties of molecules. We have previously proposed a semi-empirical SCF method including differential overlaps for valence electron systems and applied it to various closed-shell molecules.[4] Here, we extend this method to molecules with an open-shell structure. As in the preliminary reports,[5] the unrestricted Hartree-Fock (UHF) method[6] is applied. Since the UHF wave function is not an eigenfunction of the spin-squared operator, S^2, the lowest contaminating spin functions are annihilated[7] after energy minimization.

The spin density calculated by the UHF method originates from two main mechanisms,[8] the spin-polarization (SP) and spin-delocalization (SD) mechanisms. In order to clarify the nature of the spin-density, these mechanistic contributions are

separated by the method reported previously.[8] In π-electron radicals, the SP mechanism is dominant and is reduced to small σ–π-type electron repulsion integrals. In the present calculation, the one-center and part of two-center σ–π-type exchange repulsion integrals are included, although the latter was neglected previously.[5]

The method is applied mainly to the spin-density calculations of π-electron radicals, such as the methyl, ethyl, allyl, and *s-trans*-butadienyl anion radicals, and of some σ-electron radicals, such as vinyl, formyl, NO_2, CO_2^- and CN radicals. The mechanistic contributions to the spin density are separated, and some interesting features of spin density are revealed. Lastly, the dipole moments of the σ-electron radicals are analyzed.

Method

An unrestricted wavefunction for a system with p α-spin and q β-spin electrons has the form:

$$\psi_{\mathrm{uhf}} = |\varphi_1^\alpha(1)\alpha(1)\cdots\varphi_p^\alpha(p)\alpha(p)\varphi_1^\beta(p+1)\beta(p+1)\cdots \varphi_q^\beta(n)\beta(n)|, \quad (1)$$

where $n=p+q$. For the doublet radicals considered here $p=q+1$. The molecular orbital is expanded as a linear combination of all the valence atomic orbitals (VAO's), χ_r, of the constituent atoms:

$$\varphi_i^\alpha = \sum_r C_{ir}^\alpha \chi_r$$

and:

$$\varphi_i^\beta = \sum_r C_{ir}^\beta \chi_r. \quad (2)$$

The unrestricted SCF equations of the LCAO approximation are:

$$F^\alpha C_i^\alpha = \varepsilon_i^\alpha S C_i^\alpha$$

and:

$$F^\beta C_i^\beta = \varepsilon_i^\beta S C_i^\beta \quad (3)$$

in the usual notations.[6]

Estimation of Integral Valeus. One of the main features of the unrestricted SCF theory is its inclusion of spin correlation, thus enabling us to calculated negative spin densities. In the case of π-electron radicals, the spin densities appearing in the σ-type AO's are due to the σ–π-type spin-polarization mechanism.[9,10] In order to study these radicals, the following exchange integrals are considered in the calculations:

(a) The one-center exchange repulsion integrals*2 are evaluated by the approximate relations:[4c]

$$(sp|sp) = 0.045 Z_A (ss|pp)$$

and:

$$(pp'|pp') = 0.011 Z_A (pp|pp), \quad (4)$$

where s denotes the $2s$ AO.

(b) A part of the two-center σ–π-type exchange repulsion integrals is approximated by the following semi-empirical estimation:

$$(h\pi_X|h\pi_X)_{\text{semi-empirical}} = k(h\pi_X|h\pi_X)_{\text{Slater}}$$
$$(\mu_X\bar{\pi}_{X'}|\mu_X\bar{\pi}_{X'})_{\text{semi-empirical}} = k(\mu_X\bar{\pi}_{X'}|\mu_X\bar{\pi}_{X'})_{\text{Slater}} \quad (5)$$
$$(\mu_X\nu_{X'}|\mu_Y\nu_{Y'}) = \{(\mu_X\nu_{X'}|\mu_X\nu_{X'})\cdot(\mu_Y\nu_{Y'}|\mu_Y\nu_{Y'})\}^{1/2}$$

where h is a hydrogen $1s$ AO, where μ is a $2s$, $2p\sigma$ or $2p\pi$ AO, and where X and Y denote the first-row elements of the periodic table. The value of the parameter, k, is chosen so that the calculated proton spin densities of the methyl and ethyl radicals obtained before annihilation may reasonably be compared with the experimental results; the value is equal to 0.58 throughout these calculations.*3 For the $2s$ AO spin density of the carbon atom, the above two-center σ–π-type exchange repulsion integrals are not so important as are those for the proton spin density.*4

Note that many other two-center σ–π-type electron repulsion integrals are omitted. However, the parameter k, introduced in Eq. (5), may effectively include these neglected integrals for the proton-spin density in the C–H bond;*5 this assumption will, however, break down for heteropolar cases such as for the N–H and O–H bonds,

8) a) T. Yonezawa, H. Nakatsuji, T. Kawamura and H. Kato, *Chem. Phys. Letters*, **2**, 454 (1968). b) T. Yonezawa, H. Nakatsuji, T. Kawamura and H. Kato, *J. Chem. Phys.*, in press. c) H. Nakatsuji, H. Kato and T. Yonezawa, *ibid.*, in press.

10) M. Karplus and G. K. Fraenkel, *J. Chem. Phys.*, **35**, 1312 (1961).

*2 The inclusion of one-center exchange repulsion integrals destroys the invariance[1a] of the Mulliken approximation, since $(pp|p'p') = (pp|pp) - 2(pp'|pp')$. Therefore, the one-center exchange repulsion integrals are included in the method after the Mulliken approximation for $(rs|tu)$ is completed, and the term $-2(pp'|pp')$ is introduced as a correction to $(pp|p'p')$. Thus, the present method is invariant to rotation around local atomic axis.

*3 The ratios of the adopted one-center exchange integrals to the theoretical values calculated from Slater AO's are 0.51 for $(pp'|pp')$ and 0.58 for $(sp|sp)$.

*4 For the methyl radical, the contributions of the one- and the two-center σ–π-type exchange repulsion integrals are -0.0787 and $+0.0512$ for the proton-spin density, and 0.1788 and -0.0301 for the carbon $2s$ AO spin-density (before annihilation).

*5 The contribution of the σ–π-type ionic integrals is zero if the C–H bond is assumed to be homopolar. For example, the configuration interaction treatment of the methyl radical, using the simple MO's based on the hybrid orbitals, showed that the contribution due to the two center σ–π-type ionic integrals amounts to only 6% of the total proton spin density.

where the omitted σ–π type ionic integrals may become important.

The method of estimating all the other integral values is the same as has been previously reported.[4-5]

Spin-polarization and Spin-delocalization Contributions. As has been shown in previous papers,[8] the spin-polarization (SP) contribution to the calculated spin density at the i position is given by the following equations for doublet radicals:

$$(\rho^i_{ba})_{SP} = \frac{3}{2}(\rho^i_{ba} - \rho^i_{aa}),$$

$$(\rho^i_{aa})_{SP} = \frac{1}{2}(\rho^i_{ba} - \rho^i_{aa}). \quad (6)$$

$(\rho^i_{ba})_{SP}$ is the SP contribution to the spin density, ρ^i_{ba}, calculated by the UHF method, and $(\rho^i_{aa})_{SP}$ is the SP contribution to the spin density, ρ^i_{aa}, obtained after annihilation.*6 The spin-delocalization (SD) contributions are the same for both stages (ba and aa) and are approximated[8] by:

$$(\rho^i)_{SD} = \rho^i - (\rho^i)_{SP}. \quad (7)$$

Estimation of the Isotropic *hfs* Constants. The isotropic proton *hfs* constant, a, is expressed approximately by: $a_H = A_H\rho_H$,[9c] while the values for the first-row nuclei of the periodic table are given as the sum of the $2s$ contribution ($A_{2s(N)} \cdot \rho_{2s(N)}$) and of the inner $1s$ contribution.

In the present calculations, A_H is regarded as a proportionality constant determined by "best fitting" the calculated spin densities (before annihilation) to the observed *hfs* constants.*7 A_H is set equal to 743 gauss throughout this paper. The $2s$ contribution to the *hfs* constant of the ^{13}C nucleus is calculated by setting $A_{2s(C)} = 1110$ gauss.[11] However, the present method does not give the quite important contributions to *hfs* constants by inner $1s$ AO's.[10,12] These contributions are opposite in sign to those of the $2s$ AO's.[10,12]

Application of the Method

In this section we will present the results obtained by applying the above method to three types of radicals: 1) organic π-electron radicals, such as methyl, ethyl, allyl, and *trans*-butadienyl anion radicals; 2) organic σ-electron radicals, such as vinyl and formyl radicals, and 3) inorganic σ-electron radicals, such as NO_2, CO_2^-, and CN radicals. The geometries and the numberings are illustrated in Fig. 1. In this section we will first show the general features common to the three types of radicals. Secondly, the characteristic features of each type of radical will be compared with the experimental results, and lastly, the dipole moments of the σ-electron radicals will be analyzed.

General Features. The calculated ionization potentials and electron affinities are given in Table 1, together with the experimental values. The calculated ionization potentials are generally larger than the observed values.

Table 2 gives the expectation values of the spin-squared operator, S^2, before and after the annihilation of the quartet spin function. The annihilation of the lowest contaiminating spin state yields a sufficiently pure eigenstate of S^2. If the sextet and higher spin states are neglected, the UHF wavefunction for doublet radicals may be written as:

$$\psi_{uhf} = C_{1/2}\psi_{1/2} + C_{3/2}\psi_{3/2},$$

and the relative weight, $(C_{3/2})^2/(C_{1/2})^2$, may be calculated by:[7]

$$(C_{3/2})^2/(C_{1/2})^2 = \frac{4\langle S^2\rangle_{uhf} - 3}{15 - 4\langle S^2\rangle_{uhf}}. \quad (8)$$

In the last column of Table 2, these values are given for various radicals; they are less than 0.04 for all the cases studied here.

That annihilation of the lowest contaminating spin state weakly influences the total charge densities[7b] is shown in Table 3 for the methyl and NO_2 radicals. This fact can be deduced generally.[8c] However, the annihilation causes large changes in the spin-density distributions, as will be shown below.

Organic π-Electron Radicals. *i) Methyl Radical.* The geometry, *hfs* constants, and some other properties of the methyl radical have been examined theoretically[1d,10,12,13] and experimental-

*6 Hereafter, the spin densities calculted befor and after annihilation will be wyitten as $\langle\rho\rangle_{ba}$ and $\langle\rho\rangle_{aa}$, and the charge densties, as $\langle q\rangle_{ba}$ anb $\langle q\rangle_{aa}$, $\langle\rho\rangle_{ba}$ has the same meaning as the ρ_{uhf} in the previous paper.[8]

*7 For the proton, the *hfs* constants calculated only from $(\rho_h)_{ba}$ are compared with the experimental results. The reasons for this are as follows: As may be seen from Eq. (6), the SP contributions satisfy the relation: $(\rho^i_{ba})_{SP} = 3(\rho^i_{aa})_{SO}$, while the SD contributions satisfy $(\rho^i_{ba})_{SD} = (\rho^i_{aa})_{SD}$. For example, in the ethyl radical, the spin density of the H_7 atom is due to both mechanisms, while that of the H_3 atom is due only to the SP mechanism. (See Fig. 1 and Table 4.) Thus, $\rho_{ba} \simeq 1.2\rho_{aa}$ for the H_7 atom and $\rho_{ba} \simeq 3\rho_{aa}$ for the H_3 atom. This example shows that, if the σ–π-type electron repulsion integrals are so adjusted that ρ_{ba} correlates well with the experimental values, then ρ_{aa} correlates poorly with the observed values in the least-mean-square's sense. For a comparison of the spin densities calculated by the various methods, see the article by Harriman and Sando (*J. Chem. Phys.*, **48**, 5138 (1968)).

ly[14] in great detail. In this paper we examine its structure, force constant, and *hfs* constants.

In Fig. 2, the calculated potential curve for the out-of-plane bending of the methyl radical is shown. The present calculation predicts a planar configuration[14] and gives a force constant of 0.183 mdyn/A, which is comparable with the experimental values, 0.2527 in a solid-argon matrix[14f] and 0.177 in a nitrogen matrix.[14g]

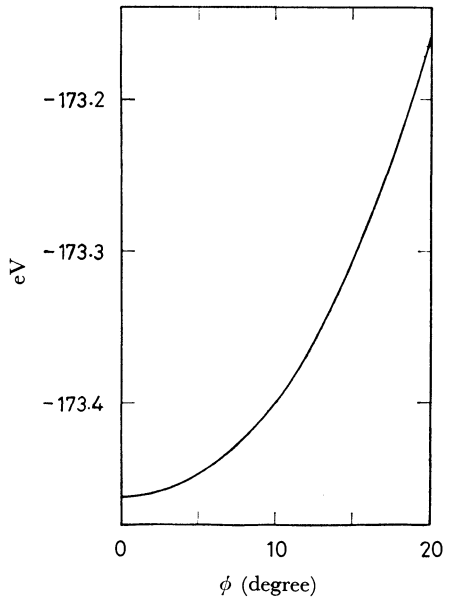

Fig. 2. Potential curve for out-of-plane bending of the methyl radical.

Recently, the isotope effects on the *hfs* constants of the methyl radicals have been reported by Fessenden;[14e] the spin densities on both the proton and the carbon nuclei have been seen to increase with an increase in the angle ϕ of Fig. 1. Here, we will examine the angular dependence of the spin densities in order to clarify the mechanism of these angular dependencies. The results are summarized in Table 4, while those for the carbon 2*s* AO are illustrated in Fig. 3. They predict reasonably well the angular dependences of the spin densities on both the hydrogen 1*s* and the carbon 2*s* AO's, which is in accordance with the experiments. Note that as the angle ϕ increases, the $(\rho_{2s(C)})_{SD}$ value increases, and that this increase exceeds the decreasing tendency of $(\rho_{2s(C)})_{SP}$, *vis.* Fig. 3. For the proton-spin density, the observed tendency may be explained by the increasing contribution of the SD mechanism with an increase in the angle. Note that the SP contribution is almost constant over the angular range considered and that the SD contribution is very small, even in the tetrahedral configuration.

In Table 5, these isotope effects of the methyl radicals are summarized and compared with the experimental values,[14e] the temperature effects[13] are neglected and the calculated *hfs* constants are averaged over the zero-point vibration, and the force constant of the CH_3 radical obtained by Milligan and Jacox[14g] is used for all the isotopical-

a) This value must be zero by symmetry, and the error results from the approximation used to derive Eq. (7) (See Ref. 8).
b) Tetrahedral angle.

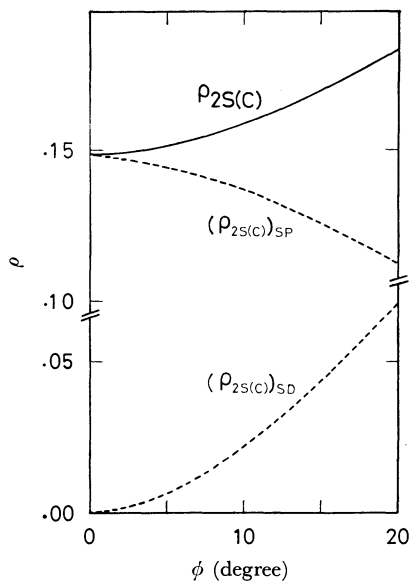

Fig. 3. $\langle\rho_{2s(C)}\rangle_{ba}$ and its mechanistic contributions *versus* the bending angle ϕ in the methyl radical. Only the curves obtained bofore annihilation are given, but the characteristic features are the same in both stages.

ly-substituted methyl radicals. As Table 5 shows, the rate of the change in the calculated *hfs* constants with an increase in the number of the deuterium atom is less than that required to explain the observed *hfs* constants; this has also been noted by Morokuma, Pedersen and Karplus.[13d] The vibrational corrections to the spin density are +0.0004 (0.29 gauss) and +0.0156～+0.0052 (17.31～5.77 gauss) for the hydrogen 1*s* AO and for the carbon 2*s* AO respectively. (See also Table 7.)

ii) Ethyl, Allyl and Butadienyl Anion Radicals. In this section, the spin densities of the ethyl, allyl, and *s-trans*-butadienyl anion radicals are discussed. The calculated spin densities and their mechanistic contributions are summarized in Table 6, while the proton *hfs* constants calculated from $\langle\rho_h\rangle_{ba}$ are shown in Table 7.

Previously,[8] the methyl proton *hfs* constants of the ethyl radical have been shown to be due to a major SD contribution and a minor SP contribution. When we assume the experimentally observed relation[15] for the methyl proton *hfs* constant, $a_H = B_0 + B_1\cos^2\theta$, where θ is the rotational angle about the C–C single bond, the values of B_0 and B_1 may be calculated as −1.49 and 55.28 gauss respectively.*8 The average a_H value over the rotational angle, θ, is 26.15 gauss, which may be compared with the observed value,[14d] 26.87 gauss.

a) See Ref. a) of Table 4.

The allyl radical has been extensively studied[16] using the π-approximation method. The π-spin densities calculated by the UHF method by Berthier[16a] are 0.812 for $2p_z(C_1)$ and −0.619 for $2p_z(C_2)$ AO, and the projected values[16b] are 0.609 and −0.185 respectively. The corresponding values obtained by the present method are given in Talbe 6. The SP contribution to the spin density in the $2p_z(C_1)$ AO is as great as 10—25%.[16d] The spin densities on the $2p_z(C_2)$ and the h_6 AO's are calculated to be negative and positive in sign respectively, which is in agreement with earlier theoretical works.[16]

The electron-spin resonance study by Fessenden and Schuler[14d] of the allyl radical in a liquid medium showed a slight difference in the *hfs* constants for the two methylene protons (H_4 and H_5 in Fig. 1). Obviously, McConnell's relation,[9a] $a_H=Q_H\rho_c^\pi$, can not interpret this observed difference. However, the present valence electron treatment yields a small difference in the spin densities on the H_4 and H_5 nuclei. Therefore, the observed *hfs* constants of 13.93 and 14.83 gauss may be assigned

a) Calculated from $\langle\rho\rangle_{ba}$. See footnote *6.
b) Refs. 14e, 18, and 22.
c) The relation, $a_H=B_0+B_1\cos^2\theta$, is assumed.

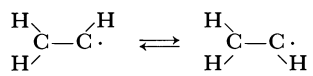
to the H_4 (H_8) and H_5 (H_7) nuclei respectively. This assignment is the same as the one previously reported.[5a] However, the recent calculations by Hincliffe and Atherton[17] and by Pople, Beveridge, and Dobosh[1d] gave an assignment opposite to that reported here. Further experimental work is necessary to settle this point.*9

The proton *hfs* constants of the butadienyl anion radical have been observed by Levy and Myers.[18] The calculated values, assuming the *s-trans* configuration, are shown in Table 6. The CH_2 protons of butadiene are non-equivalent and different *hfs* constants are predictd; this is in contrast to the observed identical *hfs* constants for these protons.[18]

As is well known, the spin densities in the σ-type AO's of planar π-electron radicals and in the $2p_z(C_2)$ AO of the allyl radical are due only to the SP mechanism. Therefore, the $\langle\rho\rangle_{ba}=3\langle\rho\rangle_{aa}$ relation,[7c,8] is fairly satisfactory, except for the $2p_z(C_2)$ AO of the allyl radical.*10

Organic σ-Electron Radicals. *i) Vinyl Radical.* The *hfs* constants of the vinyl radical have recently been observed,[14d,14e,19] and its structure and the sign of the *hfs* constant of its α-proton have been intensely investigated.[2,5a,19,20] Previously,[5a] we suggested that the *hfs* constant of the α-proton is negative in sign. Here, we will examine theoretically the structure*11 and the *hfs* constants of this radical.

The calculated potential curve with respect to the bending of the θ angle of Fig. 1 is illustrated in Fig. 4. The minimum in the potential curve appears near 135°, the calculated barrier to inversion:



is 1.6 kcal/mol, which is comparable with the value, ~2 kcal/mol, estimated by the ESR technique.[14d]

One of the main features of the present method lies in its consistent applicability to the spin-density calculations of both σ- and π-electron radicals. Good examples in which the σ–π-type SP mechanism, the "bulk" SP mechanism, and the SD mechanism are all competing with one another are the spin densities on the α-hydrogen and the α- and β-carbon atoms of the vinyl radical. None of these mechanisms can be ignored. This may be understood from the fact that the unpaired orbital of this radical

*11 The present method predicts the angular geometry of ethylene in fair agreement with the experiment; this will be reported in detail at a later date.

at $\theta=135°$, calculated with the open-shell restricted Hartree-Fock (RHF) method,*[12] is

$$\varphi_{\mathrm{rhf}} = 0.2848(2s(\mathrm{C}_\alpha)) + 0.3542(2p_x(\mathrm{C}_\alpha)) + 0.8630(2p_y(\mathrm{C}_\alpha)) - 0.0609(2s(\mathrm{C}_\beta)) - 0.0664(2p_x(\mathrm{C}_\beta)) + 0.0368(2p_y(\mathrm{C}_\beta)) - 0.1910(h_c) + 0.2737(h_t) - 0.1319(h_\alpha),$$

and is mainly localized in the $2p_x(\mathrm{C}_\alpha)$ and $2p_y(\mathrm{C}_\alpha)$ AO's.

The spin densities and their mechanistic contributions are given in Table 8 for various configurations of the vinyl radical. The dependence of the carbon $2s$ AO spin density on the θ angle is illustrated in Fig. 5, while that of the proton spin density is illustrated in Fig. 6.

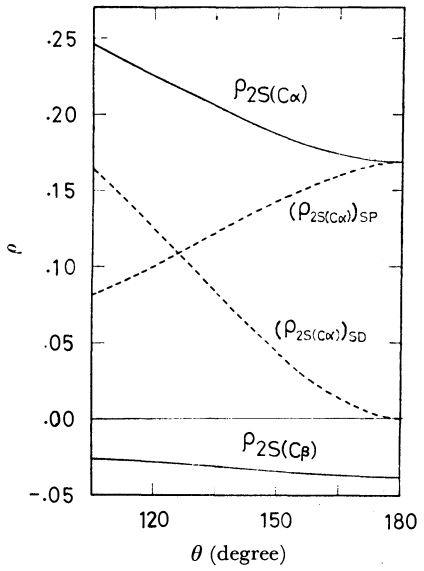

Fig. 5. $2s$ AO spin densities of carbon atoms *versus* the bending of CCH_α in the vinyl radical. Only the curves obtained before annihilation are shown, but the characteristic features are the same in both stages.

Figure 5 shows that the angular dependence of the SD contribution to the α-carbon $2s$ AO spin density is opposite to that of the SP contribution, and that it determines the dependence of the total spin density. At $\theta=135°$, $\rho_{2s}(\mathrm{C}_\alpha)$ is due to the 41—67% SD and 59—33% SP contributions. For the β-carbon atom, the angular dependence is exceptionally small and its $2s$ AO spin density is always negative.

Figure 6 shows that the spin density on the α-proton is the sum of the negative SP and the positive

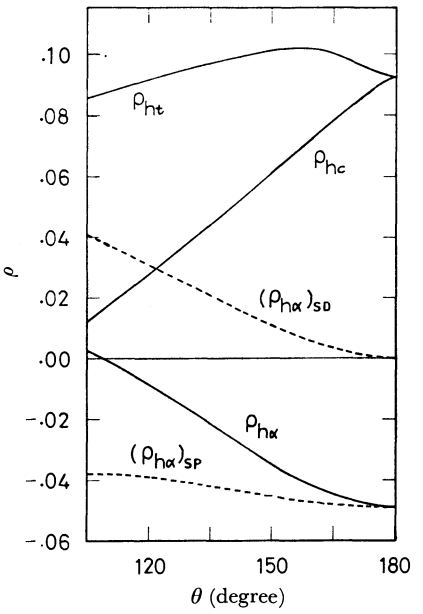

Fig. 6. Proton spin densities (ba) *versus* bending of CCH_α in vinyl radical.

SD contributions. They depend oppositely on the angle θ, and at $\theta=135°$, where the minimum potential lies, the α-proton spin density is due to the 97% SD and -197% SP contributions. For the *cis*- and *trans*-protons, their spin densities also show a large angular dependence, and they are also due to both the SD and SP mechanisms. At $\theta=135°$, the spin density of the *trans*-proton is due to the 73% SD and 27% SP contributions, while that of the *cis*-proton is due to the 80% SD and 20% SP contributions.

The calculated proton *hfs* constants at the minimum potential ($\theta=135°$) are $a_{\mathrm{H}c}=32.54$, $a_{\mathrm{H}t}=72.37$, and $a_{\mathrm{H}\alpha}=-15.83$ gauss (Table 7). These values agree satisfactorily with the experimental values. Moreover, as may be seen in Table 8 and Fig. 6, the calculated proton *hfs* constants obtained near $\theta=135°$ agree most reasonably with the experimental values, thus lending support to the vinyl radical configuration with $\theta=135°$.

Note that the calculated *hfs* constant of the α-proton is negative in sign.[5a] However, recent INDO calculations by Pople, Beveridge and Dobosh[1d] have predicted the opposite sign. Further experimental work, such as with isotope effects,[14e] will be necessary to settle this point. Figures 5 and 6 will be very useful when one experimentally determines the sign of the α-proton *hfs* constant. When the α-proton is replaced by deuterium, a smaller *hfs* constant (except for a constant factor $g_{\mathrm{H}}/g_{\mathrm{D}}=6.514$) should be observed if $a_{\mathrm{H}\alpha}$ is negative, and *vice versa*.

Let us now comment on the recent theoretical spin-density studies of the vinyl radical, in which

*[12] C. C. J. Roothaan, *Rev. Mod. Phys.*, **32**, 179 (1960). The estimations of the integral values are the same as for the present UHF calculations, except that the two center σ-π-type exchange repulsion integrals are not included in the RHF calculation.

a) See Ref. a) of Table 4.

only the SD contribution was taken into account.[20b,20c] For instance, if the SP mechanism is neglected, the α-proton spin density will be about +0.021 ($(\rho_{H\alpha})_{SD}$ shown in Table 8), which is of the same magnitude, but of the opposite sign, as the present result, −0.0213. Thus, even if the SP contribution is neglected, a value which is apparently reasonable in magnitude can be obtained for the α-proton spin density. Furthermore, neglect of the SP contribution leads to serious errors in the calculation of the spin densities even of other protons and of the carbon 2*s* AO's, as is shown in Table 8, Fig. 5, and Fig. 6. This is probably true for other σ-electron radicals as well; namely, one should not neglect the spin polarization mechanism even in σ-electron radicals, especially in AO's near the radical-center atom.[8b,20a]

ii) Formyl Radical. Recently, the results of a non-empirical UHF calculation of the formyl radical *hfs* constants have been reported by Hincliffe and Cook[21] to be in good agreement with the experimental values.[22] However, most of the semi-empirical MO calculations[1d,2,20b,20d] have failed to yield such a large proton *hfs* constant as was experimentally observed value, 137.0 gauss.[22] As may be seen in Table 9, the present result for the proton *hfs* constant is also disappointing. It is necessary to examine the present result to determine its failing by comparing it with the result of the non-empirical calculation.

From the $(\rho)_{SD}$ shown in Table 9 we can see that the unpaired orbital consists mainly of the $2p_y$(C) and $2p_y$(O) AO's. This implies that the SP mechanism is very important to the *hfs* constant of this radical. The nonempirical calculation of the proton *hfs* constant gave 154.58 gauss before annihilation and 133.95 gauss after single annihilation. The SP and SD contributions calculated from these values (see Eq. (20) of the previous report.[8b]) are 61.89 and 92.69 gauss before annihilation. In the present calculations, they are −5.94 and 44.58 gauss respectively. Very large differences exist in both contributions. The SP contributions of both methods differ especially even in sign. The reason for this is perhaps that σ–π-type exchange repulsion integrals other than those included in the present calculation (especially the two center σ–π-type ionic integrals which make a positive contribution to the proton *hfs* constant) can not be neglected in this case.

Inorganic σ-Electron Radicals. We chose here, as sample calculations for the inorganic σ-electron radicals, the isoelectronic NO_2 and CO_2^- radicals, where the spin densities on the VAO's

a) Ref. 23a.

are assumed from the anisotropy of the ESR parameters[23)] and the CN radical, which is especially interesting in its dipole moment. Table 10 summarizes the spin densities calculated on the various VAO's of these radicals, along with those estimated from the experiments.[23)] The NO_2 spin densities theoretically calculated by McEwen[24a)] and by Green and Linnett[24b)] gave small magnitudes (0.263 and 0.222 respectively) for the spin density on the $2p_x$(N) AO, but the present method gave $\rho_{2px(N)}=0.457$, which is in closer agreement with the experimental estimations.

Table 10 shows that the present calculation qualitatively predicts almost all features of the spin densities of the isoelectronic NO_2 and CO_2^- radicals. For example, the spin density on the $2p_x$(N) AO of NO_2 is smaller than that on the $2p_x$(C) AO of CO_2^-, the delocalization of the unpaired spin to oxygens is greater in NO_2 than in CO_2^-, *etc.*

Note that the $2s$ spin densities shown in the last column of Table 10 are estimated from the observed values without paying any attention to the inner $1s$ contributions. Hence, these $2s$ contributions cannot be compared directly with the calculated contributions.

Analyses of Dipole Moments of σ-Electron Radicals. The dipole moment of a neutral molecule may be expressed approximately as the sum of the atomic dipole (μ_{AD}) and the charge dipole (μ_{CD}). The atomic dipole (x-direction) of the first-row atoms of the periodic table is given by:

$$\mu_{AD}(x) = -7.3370\sum_A(P^A_{sp(x)}/\zeta_A)$$

in debye units, and the charge dipole is:

$$\mu_{CD}(x) = 4.8029\sum_A(Z_A-N_A)x_A,$$

if we adopt the Mulliken approximation:

$$(\chi_r|x|\chi_s) = \frac{1}{2}S_{rs}\{(\chi_r|x|\chi_r)+(\chi_s|x|\chi_s)\}.$$

ζ_A is the Slater exponent, and N_A is the atomic population of the A atom. $P^A_{SP(x)}$ is the off-diagonal density matrix element between the $2s$ and $2p_x$ AO's of the A atom.

The analyses of the dipole moment of vinyl, formyl, NO_2, and CN radicals are given in Table 11; they were obtained by using the values obtained before annihilation. μ^α_{AD} and μ^β_{AD} are the contributions to the atomic dipole from all the occupied α- and β- spin orbitals respectively. These contributions may be further divided into those due to the first-row atoms in the molecule. As is shown in the forth and fifth columns of the table, μ^α_{AD} due to the radical center atom (*e.g.*, C_α in vinyl) surpasses the μ^α_{AD} due to the other atoms and the μ^α_{AD} values of all the constituent atoms. The values of μ^α_{AD}(HO) in the sixth column give contributions to the atomic dipole only from the highest occupied (HO) α-spin orbital. Note that the μ^α_{AD} (HO) at the radical-center atom makes the dominant contribution to μ^α_{AD} and even to μ_{AD}. Thus, the most unstable HO orbital of the σ-electron radical extends considerably out of the molecule from the radical center atom. The direction of the $-\mu^\alpha_{AD}$ (HO) of the vinyl radical is 113° from the C_α–C_β bond.

In NO_2 and CN radicals, the contributions due to the charge dipole cancel those due to the atomic dipole. In the CN radical especially, these two contributions are almost the same in magnitude, but reverse in direction, so the resultant dipole moment is very small. This should be compared with the well-known example of the CO molecule, where its atomic dipole surpasses its charge dipole and makes it a powerful ligand in the chemistry of metal complexes. The calculated dipole moment of NO_2 is -1.301 debye, which is too large if compared with the oserved value, -0.29 debye. However, the above qualitative discussion will not be altered by more rigorous calculations.

Summary and Conclusions

As has been seen in the previous sections, the semi-empirical method for valence electron systems including differential overlap can be satisfactorily extended to systems with open-shell structures.

TABLE 11. ANALYSES OF DIPOLE MOMENTS OF σ-ELECTRON RADICALS (in debye units)

a) μ^α_{AD} denotes the contribution to atomic dipole (μ_{AD}) from all the occupied α-spin orbitals.
b) μ^α_{AD}(HO) denotes the contribution to atomic dipole from the highest occupied α-spin orbital.
c) $\mu_{AD} = \mu^\alpha_{AD} + \mu^\beta_{AD}$.
d) The experimental value is −0.29 debye; C. H. Townes and A. L. Schawlow, "Microwave Spectroscopy," McGraw-Hill Book Co., New York (1955).

The results of the present study are as follows:

(1) The separation of the mechanistic contributions to spin density makes it possible to enter into detailed discussions of the nature of the spin density; *e.g.*, the spin-polarization mechanism is shown to be very important even when the spin-delocalization mechanism has hitherto been considered dominant (*e.g.*, ethyl and vinyl radicals).

(2) A good correlation between the calculated *hfs* constants and the configurations of radicals is found for methyl and vinyl radicals. The geometry of the vinyl radical is predicted to be $\theta \simeq 135°$ from both the potential curve and the calculated *hfs* constants. Since there are many radicals with known *hfs* constants, but with unknown configurations, the agreement between the configuration expected from the calculated potential curve and that expected from the calculated *hfs* constants is ideal for a reliable prediction of the configuration of the radical from the theoretical point of view.

(3) The analyses of the atomic dipole moments of the σ-electron radicals revealed some interesting features. For example, the highest occupied orbitals of these σ-electron radicals make decisive contributions to the total atomic dipole.

The calculations were carried out on a HITAC 5020 E computer at the computation center of the University of Tokyo.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 2449—2453 (1969)

The Acidic Nature of Synthetic Zeolites: Acid Strength and Its Correlation with the Catalytic Activity

Hiroshi OTOUMA, Yoshimasa ARAI and Hiroshi UKIHASHI

Research Laboratory, Asahi Glass Co., Ltd., Hazawa-cho, Kanagawa-ku, Yokohama

(Received January 22, 1969)

The acidic characters of the X and Y zeolites exchanged by hydrogen, calcium, and lanthanum ions were investigated. Very characteristic features of the acid sites were found as compared with those of an amorphous silica-alumina cracking catalyst. The acidity is generally larger in the zeolites (2—3 meq/g) than in a silica-alumina (0.5 meq/g). The acid strength is more widely distributed in the zeolites ($H_0 = +3.3$ —< -8.2) than in a silica-alumina ($H_0 < -8.2$). Very important is the fact that the acid site increases not only in number but also in strength with an increase in the degree of ion exchange. The results on cumene cracking are in line with these results.

Zeolite catalysts exchanged by hydrogen ion or metal cations have been widely used in various reactions,[1] especially in the industrial cracking of gas oil.[2,3] The ion-exchanged zeolite catalyst has the ability to crack various hydrocarbons, the product distribution of which is similar to that obtained with a silica-alumina cracking catalyst.[4,5] These facts suggest that the zeolite catalyst is an acid solid. However, few data are available in the literature regarding the acidic character of zeolites, *i. e.*, the acid strength and its distribution, their correlation with the catalytic activity, and the difference in acidic character from amorphous silica-alumina.

The present work aims at clarifying the acidic characters of ion-exchanged zeolites by comparing them with that of silica-alumina.

Experimental

Materials. The X and Y zeolites were used, the former being Molecular Sieve 13X (a commercial product of Linde Co.) and the latter having been prepared in our laboratory by a method given in the literature.[6] Chemical analysis showed the compositions of $Na_2O \cdot$

$Al_2O_3 \cdot 2.69SiO_2$ and of $Na_2O \cdot Al_2O_3 \cdot 4.73SiO_2$ for the X and Y zeolites respectively. X-ray diffraction examination revealed a good crystallinity in both types of zeolites. A commercial amorphous silica alumina catalyst which was 13% Al_2O_3 (a fluidized cracking catalyst) was used.

Ion Exchange. The cation-exchange on zeolites was carried out by bringing the sodium ion form of zeolites in contact with a 0.2N solution of nitrates or of chlorides. The desired degree of ion exchange was controlled by the number of repeating the ion exchange process. The ion exchanged zeolite was calcined after repeated washings with pure water and after drying at 110°C. Zeolites exchanged by the calcium and the lanthanum ions were also prepared as has been described above. The protonated zeolite was obtained in a different way, by the calcination of the ammonium ion form of zeolite, which was prepared by bringing zeolite in contact with an ammonium chloride solution.

Acidity and Acid Strength. The acidic character was determined by the Benesi method[7,8] by the use of *n*-butylamine as a titer and Hammett indicators. Samples were calcined at 10^{-3}—10^{-4} mmHg for 2 hr and then transferred into weighing bottles in a dry box and measured.

The total acidity was defined as the amount of the acid determined with Butter Yellow ($pK_a = +3.3$). The acid strength was determined by using indicators of various pK_a's.

Catalysts and Cumene Cracking. Ion-exchanged zeolite powders (1—5 μ in diameter) were pressed into pellets, and then they were crushed into pilled catalysts 60—100 in mesh size. The cumene-cracking reaction was carried out over a pilled catalyst calcined at 600°C for 2 hr prior to use. This activity test was carried out in a flow system. Figure 1 shows a schematic diagram of the apparatus used for cracking.

A simple cracking reaction was conducted over various cationic forms of zeolites under definite conditions: weight of catalyst 0.6 g; reaction temperature, 450°C; LHSV, 1.2. The products were condensed for 1 hr after the start of the reaction. The condensate was then analyzed by gas chromatography in order to determine the amount of the conversion of cumene to benzene.

In the case of the lanthanum ion exchanged form of the X zeolite, a more detailed experiment was undertaken in order to determine the correlation between the catalytic activity and the acidic character of zeolite. The reaction was carried out when the conversion of cumene was below ten percent, in which region the reaction rate was proportional to the amount of catalyst employed. Nitrogen gas was passed over the La–X catalyst for 1 hr at the reaction temperature, and then the cumene-nitrogen mixture was intoduced. The cracking activity was so high at the start that the sampling of products for 1 hr was begun 1 hr after the introduction of the reactant.

Results and Discussion

Acidic Character. The color changes of Hammett indicators, showing the end point of titration, were similar in both silica-alumina and zeolites, except that some of the latter catalysts showed less obvious color changes in the indicators. This is probably due to the difference in acid strength, as will be discussed below.

The distribution curve of the acid strength is cumulatively shown in Figs. 2 to 4 as a function of H_0, together with that of a FCC silica-alumina. In the figures and hereafter the symbols M–X and M–Y refer to the X and Y zeolites exchanged by the cation of the element, M. Figure 2 indicates that, in general, the zeolites have, in striking contrast to the silica-alumina, which has a strong acid site only, acid sites over a wide range of strengths and a larger acidity. The dotted line for the Ca–X (95.7) in Fig. 2 denotes that the detection of the color change of the indicators (benzalacetophenone, $pK_a = -5.6$; anthraquinone, $pK_a = -8.2$) was disturbed because of the yellow surface of this sample.

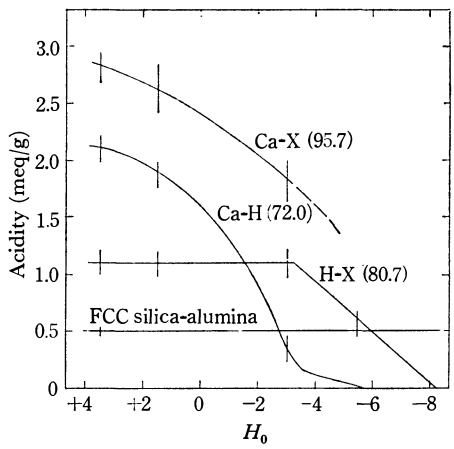

Fig. 2. Distribution of acid strength of the H–X, Ca–X and FCC silica-alumina.
The vertical lines and figures in bracket denote the uncertainty in titration and degree of the ion exchange, respectively. These remarks are also used in Figs. 3 and 4.

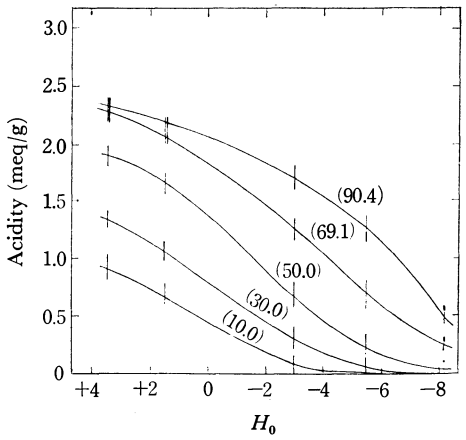

Fig. 3. Distribution of acid strength of the La–X with various degree of the ion exchange.

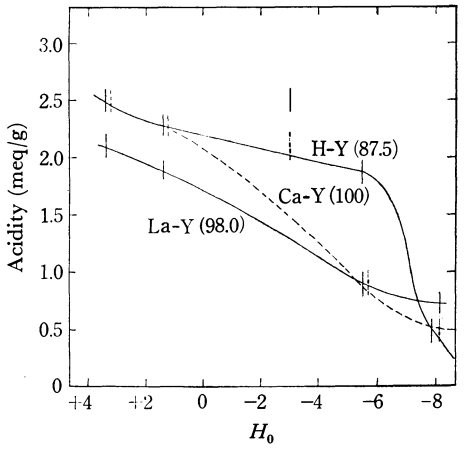

Fig. 4. Distribution of acid strength of the H–Y, Ca–Y and La–Y

Figure 3 shows the dependence of the distribution of the acid strength for the La–X on the degree of the ion exchange. The uniform crystalline structure of the zeolite leads us to expect that the distribution of the acid strength will be the same at any level of the ion exchange, whereas the total amount of acid will increase in proportion to the degree of the ion exchange. However, this is not the case. As may be seen in Fig. 3, stronger acid sites appear with an increase in the degree of ion exchange. Moreover, Figs. 2 and 3 show that the acid strength is dependent upon the kind of cation. These acidic characters are reasonable if the structure of the zeolite is considered. It has been established[9,10] that there are three kinds of sites occupied by sodium ions in the X and Y zeolites. It has also been found that, in the Ca–X, calcium ions occupied two kinds of sites, S_I and S_{II}, differing from each other in the number of oxygen atom coordinated to the calcium ion. The former site was located in the interior of the hexagonal prism, positioned between two puckered O_6 rings. It was effectively hidden from the surface of the large pore. The latter one was found in the O_6 ring, which formed a hexagonal face. It was positioned on the surface of the large pore. The results of the calculation of the electrostatic field strengths at these sites revealed that the charge distribution differed between the two sites, with the S_I site being energetically more stable than the S_{II} site. Thus, it follows that the calcium ion prefers the S_I site to the S_{II} site at a lower level of ion exchange.

Although the origin of the acid site in the zeolites has not been clarified well,[1] it is conceivable that the different states of the cation sites causes the occurrence of acid sites of different strengths.

Figure 4 indicates that the distribution of the acid strength also depends on the type of zeolite. A large proportion of the acid sites is distributed in the strong region in the Y zeolite, unlike as in the X zeolite. The total quantity of acid sites in the Y zeolite is less than that in the X zeolite, except for the protonated zeolite, corresponding to the difference in their ion exchange capacities. The X and Y zeolites are nearly the same in structure. The ratio of the silicon atom to the aluminum atom is higher in the Y zeolite. Rabo and his associates[9,10] have pointed out, however, that the electrostatic field strength at cation sites is much larger in the Y zeolite. It seems reasonable, therefore, that there is a difference in acid strength between the two types of zeolites.

In the case of the protonated zeolites, the H–X has less acidity than the H–Y. This can reasonably be explained by the results of the experiment given below. The crystalline structure of the NH_4–X collapsed, as was revealed by an X-ray diffraction

Table 1. Cumene cracking activity for various types of zeolites

Reaction temp. 450°C; LHSV=1.2; weight of catalyst; 0.6 g

Sample	Degree of ion exchange (%)	Amount of cations in zeolite (meq/g)	Conv. of cumene (%)
H-X	80.7	4.48	79.8
H-Y	87.5	3.73	95.3
Ca-X	72.0	4.02	8.7
Ca-X	95.7	5.37	68.3
Ca-Y	100	4.26	96.3
La-X	95.7	5.37	86.0
La-Y	86.0	3.67	97.1

10) J. A. Rabo, C. L. Angell, P. H. Kasai and V. Shomaker, *Discussions Faraday Soc.*, **41**, 328 (1966).

examination, during the formation of the H-X from the NH_4-X (NH_4-X $\xrightarrow{heat}$ H-X + $NH_3\uparrow$), while the surface area of the zeolite was being lowered. The surface area of the H-X was found to be 371 m^2/g, only one half those of the Na-X (723 m^2/g) and Na-Y (898 m^2/g). On the other hand, the H-Y remains crystalline in spite of undergoing the same calcination step as in the H-X.

Cumene Cracking. Table 1 lists the results of cumene cracking conducted over various forms of zeolites under the definite reaction conditions described above. Figures 6 and 7 show the cumene cracking activity for the La-X as functions of degree of ion exchange and of the reaction temperature.

The kinetics of the reaction was analyzed as follows. The mechanism of cumene cracking may be supposed to be:[11]

$$\text{Cumene} + \text{free site} \underset{k_2}{\overset{k_1}{\rightleftharpoons}} \text{cumene-site complex} \xrightarrow{k_3} \text{benzene} + \text{propylene} + \text{free site}$$

Assuming the adsorption step in equilibrium during the reaction, the following relationship is derived:

$$P_c/r = 1/k_3B_0 \cdot P_c + 1/k_3B_0K, \quad K = k_1/k_2 \qquad (1)$$

where:

P_c: partial pressure of cumene,
r: reaction rate,
B_0: number of active sites,
K: adsorption equilibrium constant.

The rate constant, k_3, is a measure of the ability to crack the complex. However, it is not determined directly because the value of B_0 is unknown. The value of k_3B_0, which is also a measure of the cracking activity, is determined from a reciprocal of the slope of a straight line plotted P_c/r *vs.* P_c, as is shown in Fig. 5.

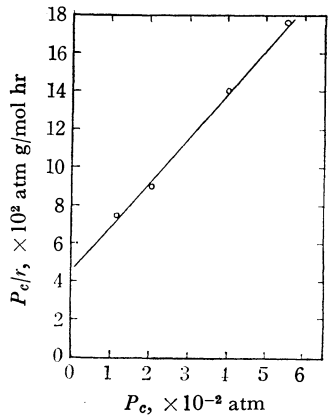

Fig. 5. Plots of P_c/r *vs.* P_c.
Catalyst: La-X (50.0);
Reaction temp.: 330°C

In the X zeolite the catalytic activity is in the following order:

La-X (percentage of the ion exchange: 95.7) > H-X (80.7) > Ca-X(95.7) > Ca-X(72.0); in the Y zeolite, although the amount of the cation exchange is less than that in the X zeolite, there is a very high activity in any cationic form. These results are in good agreement in order with the acid strength and not with the acidity, as is shown in Figs. 2 to 4. It is obvious from Figs. 6 and 7 that the catalytic activity increases more than linearly with an increase in the degree of ion exchange. Such a phenomenon,

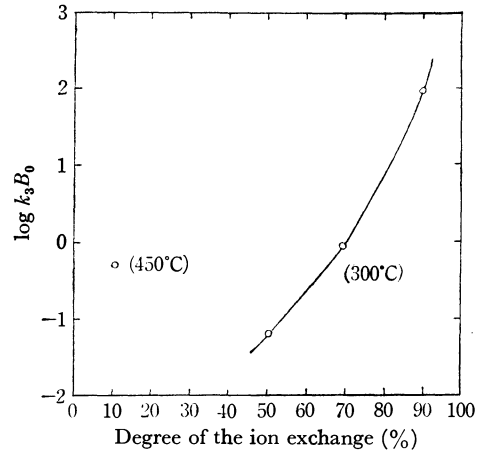

Fig. 6. Correlation between cumene cracking activity and degree of the ion-exchange for the La-X.
Figures in bracket denote the reaction temperature.

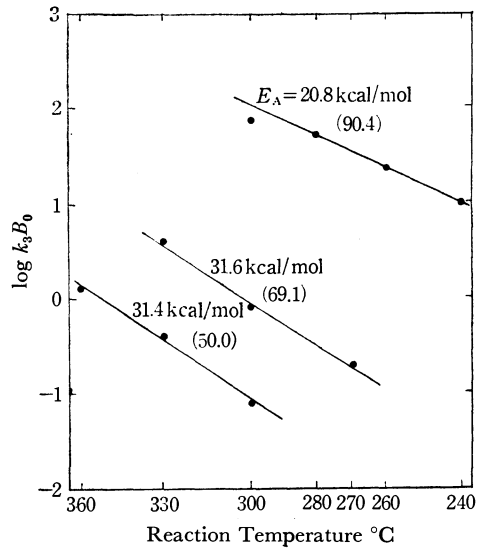

Fig. 7. Temperature dependence of cumene cracking activity and apparent activation energy for the La-X.
Figures in bracket denote degree of the ion-exchange.

11) W. F. Pansing and J. B. Malloy, *Ind. and Eng. Chem., Process Design and Development*, **4**, 181 (1965).

suggesting the heterogeneity of the zeolite surface, has been observed with, for example, the benzene propylation over the Rare-earth-Y,[12] the cumene cracking over the H-Y[13] and over the Ca-X,[14] and the hexane isomerization over the Pt/Ca-Y.[15] These results may be interpreted in terms of the variation in acid strength with an increase in the degree of ion exchange, as may be seen in Figs. 2 and 3 for the Ca-X and La-X respectively.

The apparent activation energy for the cumene cracking over the La-X, shown in Figs. 7, seems to decrease at a high level of ion exchange. The change in the activation energy with the degree of ion exchange may be a reflection of the difference in the nature of the two kinds of active sites, S_I and S_{II}. At a lower level of ion exchange calcium ions occupy mainly the S_I site, while at a higher level they occupy S_I and S_{II} sites. The catalytic activities originate from the S_I and S_{II} sites at lower and higher levels of ion exchange respectively. Accordingly, there has been found a change in the activation energy from 32 kcal/mol for the La-X (50.0) to 23 kcal/mol for the La-X (90.4), dependent upon the degree of ion exchange.

Vacuum-ultraviolet Absorption Spectra of Aliphatic Ketones

Hiroyuki Ito,*1 Yoshihiko Nogata,*2 Sanae Matsuzaki and Akira Kuboyama

Government Chemical Industrial Research Institute, Tokyo, Shibuya-ku, Tokyo

(Received January 31, 1969)

The molar-absorptivity curves of various aliphatic ketones, mainly methyl alkyl ketones, in the gaseous state in the region from 1650 to 2000 Å have been obtained. In these ketones the absorption bands near 1950 Å and 1700 Å are denoted as A and B bands respectively. Di-*n*-propyl and diisopropyl ketones show, besides the A and B bands, an absorption band near 1650 Å (C band). The relations between the obtained spectra and the molecular structures of these ketones have been studied. On the basis of this study, the characteristics of the electronic transitions of A, B, and C bands have been discussed.

Up to now, there have been few data about absorption spectra in the vacuum-ultraviolet region. The number of molar absorptivity curves of organic compounds reported in this region have been especially few. Though the absorption spectra in this region are not so easily obtainable as those in the visible and near-ultraviolet regions, they may well provide much important information about structural and analytical chemistry.

Aliphatic ketones have, beside the $n\rightarrow\pi^*$ bands near 2800 Å and the $\pi\rightarrow\pi^*$ bands near 1550 Å, two or three moderately intense absorption bands in the range from 2000 to 1650 Å.[1-5] As for these absorption bands in the range from 2000 to 1650 Å, no accurate molar-absorptivity curves have been reported except for that of acetone.[2] In this work the molar-absorptivity curves of various aliphatic ketones, mainly methyl alkyl ketones, in the gaseous state, have been measured in the region from 2000 to 1650 Å; their relations to the molecular structures of the ketones will be discussed.

Experimental

Measurements. The absorption spectra were measured with a VUV-3 vacuum-ultraviolet self-recording spectrophotometer (the radius of the curvature of the concave grating was one meter) of the Japan Spectroscopic Co., Ltd., at room temperature. This apparatus has a ratio-recording double-beam system using the rotating-cell method.[6] In this method, 30-mm gas-cell blocks, made of stainless steel and containing a sample cell on one side and a reference cell on the other, rotate at 8 Hz and function as "rotating sectors." Fluorite plates 1 mm thick were used as the windows of the cells. As the light source and light detector, a MH-225 Mitsubishi Deuterium Lamp and a photomultiplier (EMI 6256B) were used. The absorption peak of mercury vapor at 1849.6 Å was used for the wavelength calibration. The pressures of sample gases were measured with a mercury manometer with an inner diameter of 16 mm.[7] The mercury levels were read with a measuring microscope. The sensitivity of the pressure reading was *ca.* 0.01 mm. Each absorption spectrum was measured several times.

Materials. The ketones used were obtained from the Tokyo Kasei Kogyo Co., Ltd. Spectro-grade acetone and methyl ethyl ketone were used. Their purity was checked by gas chromatography. Methyl isopropyl, methyl *s*-butyl, methyl *t*-butyl, and diisopropyl ketones were purified by gas chromatography. Deuteroacetone (acetone-d_6) of Ciba Products, Ltd., the isotopic purity of which was greater than 99.5 per cent, was used without further purification.

Results

The molar absorptivity curves obtained are shown in Figs. 1—6. The wavelengths and molar absorptivities of the absorption peaks in these absorptivity curves are given in Table 1. In Table 1 the accuracy of the wavelengths is ±1 Å, and the reproducibility of the molar absorptivities is within 10 per cent. The oscillator strengths (*f*-values) of the A and B bands are given in Table 2. Some photodecomposition of these ketones was found to occur during the measurements. This decomposition was the most remarkable in methyl *n*-amyl and methyl *n*-butyl ketones. In these cases several per cent of the original part was decomposed during the measurements. None of peaks obtained are believed to be characteristic of the photodecomposition products since they all decreased in intensity on continued irradiation. The obtained molar absorptivities of the longest-wavelength absorption peak of the band, near 1950 Å, of acetone and of the absorption maximum of the band, near 1950 Å, of diethyl ketone are in good agreement with those reported by Lake and Harrison[2] and by Barnes and Simpson[3] respectively. The shapes of the absorption bands near 1950 Å of these ketones are in good agreement with those of the transmittance curves of these ketones reported by Horwood and Williams.[4]

Discussion

As may be seen in Figs. 1—6, methyl alkyl ketones and diethyl ketone show two absorption bands, near 1950 Å and 1700 Å. Di-*n*-propyl and diisopropyl ketones show an absorption band near 1650 Å besides these two absorption bands. In this paper these three kinds of absorption bands, near 1950 Å, 1700 Å, and 1650 Å, will be denoted as A, B, and C bands respectively. In these ketones

each of the three kinds of absorption bands is thought to have similar characteristics of the electronic transitions.

Methyl *n*-alkyl ketones, the methyl alkyl ketones in which the α-carbons of the alkyl groups are the secondary or tertiary carbons, and di-(non-methyl)alkyl ketones are classified into Group I, II, and III respectively for convenience. Methyl *s*-butyl ketone is classified in Group I. The following distinct points about the positions and intensities of A and B bands may be found by comparing Fig. 1—6 and Table 2.

(1) As for the position of the A band, the A band of acetone is at wavelengths a little shorter than those of the other ketones.

(2) As for the intensity of the A band, that of acetone is considerably greater than those of other ketones. In methyl *n*-alkyl ketones the intensity generally decreases with the number of carbon atoms in the *n*-alkyl groups. Those of Group II and III are weak, that of diisopropyl ketone bing especially weak.

(3) As for the position of the B band, the B bands of Group II and III are at wavelengths considerably longer than those of Group I, that of diisopropyl ketone being at a wavelength especially much longer than those of Group I.

(4) As for the intensity of the B band, that of acetone is very weak and all those of Group I except for acetone are similar to each other. Those of Group II, especially that of methyl *t*-butyl ketone, are remarkably greater than those of Group I, while those of Group III are close to those of Group I (except for acetone).

As for the shapes of the A and B bands of each ketone, the A band shows a relatively sharp vibrational structure and its shape is very sensitive to the alkyl group. In the B band only that of methyl ethyl ketone shows a sharp vibrational structure. In acetone the frequency of the main vibrational progression is *ca.* 1140 cm^{-1}. On the other hand, that in deuteroacetone is *ca.* 940 cm^{-1}. On the basis of this fact, Lawson and Duncan[8] have safely assigned these frequencies to the C–H(D) bending vibration of the methyl groups. In the A bands of methyl ethyl and methyl *s*-butyl ketones the frequencies of the main vibrational progressions are *ca.* 1240 cm^{-1} and 1220 cm^{-1} respectively. These progressions may be similar to that in acetone. Besides these progressions, we found distinct progressions of two frequencies, 470 cm^{-1} in the A band and 580 cm^{-1} in the B band in methyl ethyl ketone, and two other frequencies, 290 cm^{-1} and 660 cm^{-1}, in the A band of methyl *s*-butyl ketone. The 470 cm^{-1} frequency in the A band of methyl

ethyl ketone is probably that of the C–O bending vibration.[9] The sharp vibrational structure of that of methyl *s*-butyl ketone is remarkable in view of the complex structure of this ketone. This is thought to be due to the particular, rigid three-dimensional molecular structure of this ketone. Recently a study of the infrared spectra of these ketones has shown that the various rotational isomers exist in the liquid and gaseous states.[9,10] The relation between the existence of the various rotational isomers and the band shapes is not clear at this stage. The co-existence of the various rotational isomers in the gas phase may contribute to the broadening of the absorption peaks.

The assignments of the A and B bands have been discussed by many authors. Heretofore, the A band has been identified as the $n\rightarrow\sigma^*$ band on the basis of its position and intensity by many people.[5,11,12] As has been described before, the fact that the frequency of the main vibrational progression in the A band of acetone is that of the C–H bending vibration of the methyl groups is to show that the hyperconjugation of the methyl groups to the carbonyl π-bond plays an important role in the electronic transition of the A band. The large intensity of the A band of acetone, and the very small intensity of the A band of diisopropyl ketone, where the hypercojugation of the isopropyl groups to the CO π-bond is thought to be weak, offer strong support for this theory. Since these hyperconjugations seem not to play an important role in the $n\rightarrow\sigma^*$ transition, this theory does not support the assignment of the A band to the $n\rightarrow\sigma^*$ band. Therefore, further theoretical and experimental examination for this assignment are desireable.

As for the electronic transition of the B band, there are two possible explanations of the remarkable difference in the intensity of the B band between acetone and methyl ethyl ketone. One is that a C–C bond combining with the CO bond plays an important role in the electronic transition of the B band. The other one is that the nonequivalency of the two alkyl groups favors this transition. The fact that the intensity of the B band of methyl isopropyl ketone is far greater than that of diisopropyl ketone seems to support the latter possibility. On the other hand, it is also remarkable that the B band of diisopropyl ketone is at a wavelength considerably longer than that of methyl isopropyl ketone. As for the electronic transition of the C band, its intensity seems to be too weak to assign the C band to the $\pi\rightarrow\pi^*$ band. Further theoretical and experimental examinations for the assignments of B and C bands are also desirable.

In these ketones the Rydberg transitions are expected to appear in the region shorter than 1800 Å. For example, the peak at 1663 Å in acetone and the four peaks in the C band of diisopropyl ketone may be those of Rydberg transitions. However, the Rydberg-transition peaks can not be discussed at this stage.

The authors are grateful to Mr. H. Tomita and Mr. I. Takeda of this Institute for their help with the gas chromatography, and to Dr. K. Kaya of the Institute of Physical and Chemical Research for his helpful advice.

Studies of Ion Exchange Membranes. XXX. The Tetrahydrofuran Extraction of the Ion-exchange Membrane and Its Base Membrane Prepared by the "Paste Method"

Yukio MIZUTANI

Tokuyama Soda Co., Ltd., Tokuyama-shi, Yamaguchi-ken

(Received February 3, 1969)

In order to throw light on the chemical structure of the ion-exchange membrane prepared by the "Paste Method," the ion-exchange membrane and its base membrane were extracted with tetrahydrofuran. The base membrane was composed of polyvinyl chloride and the resin component of the styrene-divinyl benzene system or of the 2-methyl-5-vinyl pyridine-divinyl benzene system, the ion-exchange group was introduced into this resin component. It was established that the resin component was partially extractable through a filter paper. Although the resin component and polyvinyl chloride should be entwined with each other, and although the resin component might be grafted on polyvinyl chloride, it could be concluded that the chemical structure of the ion-exchange membrane prepared by the "Paste Method" is different from that of Amberlite IR-120, *i. e.*, the homogeneously crosslinked gel-structure.

Many procedures have been proposed for the preparation of an ion-exchange membrane.[1-8] However, in most of these procedures the base membrane, with a functional group appropriate for the introduction of an ion-exchange group, is prepared beforehand, and then an ion-exchange group is introduced. Therefore, the preparation of the base membrane has thus far been an important theme.[2-8] The present author has already reported on the "Paste Method."[5-8] Namely, a fine powder of polyvinyl chloride (PVC) and a monomer mixture, consisting mainly of styrene (St)-divinyl benzene (DVB) or 2-methyl-5-vinyl pyridine (MVP)-DVB, was mixed to prepare the paste, and then a Teviron cloth (a reinforcing material) was coated with this paste. This resultant polymer composite was heated in order to polymerize the monomers. An ion-exchange group was introduced to the base membrane by sulfonation or quarternization with methyl iodide. The ion-exchange membrane thus prepared has been used in the electrophoretic concentration[9,10] or desalination[11] of sea water.

Furthermore, this ion-exchange membrane is flexible and thermoplastic. This characteristic of ion-exchange membranes prepared by the "Paste Method" suggests that the structure of the membrane may be different from the homogeneously crosslinked gel-structure.

The base membranes for the cation-exchange membrane (base membrane-C) and for the anion-exchange membrane (base membrane-A) show quite a good transparency. For example, the base membrane-C consists mainly of PVC and the resin component of the St-DVB system. Considering that PVC is immiscible with polystyrene and that the mixture of both polymers is an opaque white, the quite good transparency of the base membrane-C has been explained by the presence

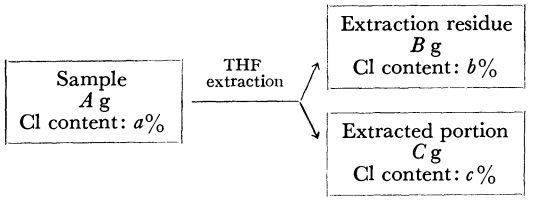
of the graft copolymer of PVC and the resin component.[5]

In order to elucidate the correlation between PVC and the resin component (M-resin) of the St-DVB system or the MVP-DVB system, in this study the ion-exchange membrane and its base membrane were extracted with tetrahydrofuran (THF).

Experimental

The Sample. The ion-exchange membrane and its base membrane were prepared by the "Paste Method."[5-8] Previous to the THF extraction, the sample was extracted with methanol in order to expel the unpolymerized monomer, *etc.*, by using a Soxhlet extractor.

The THF Extraction. The sample was extracted with THF for 30 hr by the use of a Soxhlet extractor.



E_p and E_R were defined as follows:

$$E_p = \frac{\text{Quantity of chlorine in the extraction residue}}{\text{Quantity of chlorine in the base membrane}}$$

$$E_R = \frac{\text{Quantity of the M-resin in the extracted portion}}{\text{Quantity of the M-resin in the base membrane}}$$

The cylindric filter paper used was Toyo Filter Paper No. 84 (Size, 25×90 mm); the particle size retainable by this filter paper is 8 μ.

Results and Discussion

The recovering ratio of the polymer after the THF extraction $[(B+C)/A]$ was larger than 0.98, and the chlorine balance $[(B\cdot b+C\cdot c)/A\cdot a]$ was 1.0 ± 0.2.

The Base Membrane-C. Figures 1—3 show the results of the THF extraction. With the increase in the monomer content [(St+DVB)/PVC] and in the DVB content [DVB/(St+DVB)] of the paste, and with the elevation of the polymerization temperature, the quantity of the extraction residue

increased linearly. The chlorine content of the extracted portion also increased linearly with the increase in the monomer content, but the DVB content in the paste and the polymerization temperature had no effect on the chlorine content in the extracted portion (Figs. 4—6). In all cases, the content of the extracted portion in the base membrane-C (C/A) was smaller than the PVC content of the base membrane-C and the chlorine content of the extracted portion was smaller than that of PVC itself (56.4%). These facts can be explained by the presence of the M-resin in the extracted portion. On the other hand, the chlorine content of the extraction residue was small (1.5—3%), but it showed the presence of PVC inextractable with THF.

○: Extracted portion ●: Extraction residue

It is very significant that a large quantity of the M-resin was found in the extracted portion. Since the M-resin should have a crosslinked structure, the presence of the M-resin in the extracted portion can be understood if the M-resin is very fine. This explanation is supported by Photo 1, which shows

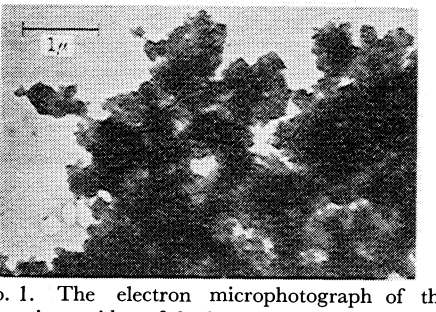

Photo. 1. The electron microphotograph of the extraction residue of the base membrane-C.

that the extraction residue was the aggregate of the fine particle and that its size was less than 50 mμ. When a monomer and DVB polymerize in a medium in which the monomer is soluble, while its polymer is insoluble, a fine powdery polymer with crosslinkage is obtained.[12,13] The formation of the spherical particle of the M-resin is explainable by considering PVC as a polymerization medium in which St and DVB are soluble, while polystyrene is insoluble. The network of the M-resin, formed by the polymerization of St and DVB, may be entwined with the PVC chain, and, furthermore, the M-resin may be grafted onto

PVC. The formation of the graft copolymer is confirmed by the graft copolymer prepared by the polymerization of St in the PVC film.[3] Thus, the presence of the M-resin in the extracted portion is explainable, but the degree of participation of the graft copolymer is still obscure, since the crosslinked M-resin was extracted through the filter paper.

Figures 7—9 show the E_R and E_P values. The E_P values show that the quantity of PVC in the extraction residue was 0.5—2% of the total PVC in the base membrane-C. With the increase in the monomer content of the paste, the E_P value increased and the E_R value decreased from 50% to 10%. These facts can be explained by the tendency for the increase in the monomer content to promote the swelling of the M-resin in the polymerization system, the entanglement of the network of the M-resin with the PVC chain, and the aggregation of the fine powdery resin. This explanation is supported by the observation that the extraction residue, although the E_R value was small, became fibrous or textural more distinct with the increase in the monomer content in the paste. With the increase in the DVB content in the paste, the E_P value increased and the E_R value decreased. These changes can be explained by the increase in the entanglement of the M-resin with the PVC chain. With the elevation of the polymerization temperature, the E_R value decreased, but this factor had no effect on the E_P value.

Table 1. The result of the THF extraction of the cation-exchange membrane

Sample	Base Membrane-C	Cation-exchange membrane	
		H^+ form	Na^+ form
B/A	0.152	0.423	0.525
E_t/E_0	—	0.731	0.878

E_t: Number of the ion-exchange site in the extraction residue.
E_0: Number of the ion-exchange site in the ion-exchange membrane.

The Cation-exchange Membrane. Table 1 shows the results of the THF extraction. By sulfonation with concentrated sulfuric acid, the ratio of the extraction residue (B/A) became larger than that of the base membrane-C. This may be explained by the reaction between PVC and the M-resin during the sulfonation and/or by the fact that the swelling of the cation-exchange membrane in THF is smaller than that of the base membrane-C. Furthermore, it was an important finding that the extracted portion had an ion-exchange capacity. This finding shows that the M-resin with the ion-exchange group was extracted; these observations are consistent with the finding concerning the base membrane-C. The presence of the fine powdery M-resin should be a reason why the cation-exchange membrane and its base

membrane have flexibility and thermoplasticity.

The Base Membrane-A. Table 2 shows the results of the THF extraction. The presence of the M-resin in the extracted portion was confirmed by the presence of nitrogen. Furthermore, the chlorine content of the extracted portion was clearly smaller (55.18%) than that of PVC itself (56.4%), and the E_R value showed that a little of the M-resin was extracted. On the other hand, much PVC was found in the extraction residue, as was shown by both the chlorine content and the E_P value, and the residue was fibrous or textural. The finding concerning the base membrane-A was considerably different from that of the base membrane-C; this difference is probably to be attributed to the difference between the affinity of St for PVC and that of MVP for PVC.

The Anion-exchange Membrane (Chloride-ion Form). Table 3 shows the results of the THF extraction. The membrane does not swell as much as the base membrane-A in Table 2. Also, the shape of the anion-exchange membrane was not destroyed by the THF extraction. The M-resin was partially extractable. This important finding can be explained by the fact, presented above, that there were fine particles of the M-resin extractable through a filter paper.

Conclusion

In order to elucidate the chemical structure of the ion-exchange membrane prepared by the "Paste Method," the ion-exchange membrane and its base membrane were extracted with tetrahydrofuran. Although the matrix of the ion-exchange resin component was complicatedly entwined with the polyvinyl chloride chain, and although the former should be grafted on the latter, the presence of fine particles of the ion-exchange resin component, extractable through a filter paper with tetrahydrofuran, was confirmed. This fact shows conclusively a characteristic of this ion-exchange membrane; it also suggests that the chemical structure of the ion-exchange membrane is different from that of Amberlite IR-120, *i.e.*, the homogeneously crosslinked gel-structure. Furthermore, this characteristic may be a reason why the ion-exchange membrane is flexible and thermoplastic.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 2464—2470 (1969)

Determination of S*–T Transition Probabilities of Some Xanthene and Thiazine Dyes on the Basis of T-Energy Transfer. II. Results in the Aqueous Solution

Masae NEMOTO, Hiroshi KOKUBUN and Masao KOIZUMI

Department of Chemistry, Faculty of Science, Tohoku University, Katahira-cho, Sendai

(Received February 3, 1969)

Intersystem crossing probability φ_{ST}^{A} for fluorescein, eosin, erythrosin, methylene blue and thionine in the aqueous solution of pH 7.2 (only for fluorescein 0.05N NaOH solution) has been determined by comparing the quantum yield of the nonsensitized (Φ) and the sensitized photoreduction (Φ^{S}) on the basis of the relations

$$\Phi = \varphi_{ST}^{A}\beta^{A} \qquad \Phi^{S} = \varphi_{ST}^{D}\beta\gamma^{A},$$

where β^{A} is the fraction of triplet dye molecules that undergo reduction, φ_{ST}^{A} and φ_{ST}^{D} are respectively for acceptor (dye) and donor (sensitizer), and γ is the energy transfer efficiency. This was assumed as unity. ATU and EDTA were used as a reducing agent. 1,5-Naphthalenedisulfonic acid and 1-anthracenesulfonic acid were used as sensitizers. The above relations and assumption have been found to hold satisfactorily. The φ_{ST}^{D} values for two sensitizers were determined using erythrosin as a reference substances for which φ_{ST}^{A} was assumed to be unity. φ_{ST}^{D} obtained was 0.88 for 1,5-naphthalenedisulfonic acid, and 0.82 for 1-anthracenesulfonic acid. φ_{ST}^{A} values for dyes obtained were: fluorescein (0.021) eosin (0.64) erythrosin (1.0) methylene blue (0.52) thionine (0.55). Using these φ_{ST}^{A} values, the rate constants for the following elementary reactions have been evaluated (A, dye: RH_2, reducing agent): $A^{T}+RH_2 \rightarrow$reaction, $A^{T}+RH_2 \rightarrow$deactivation, $A^{T}+A \rightarrow$reaction or deactivation.

In a previous paper[1] the application of the T-energy transfer was successfully applied to the determination of the S*-T transition probabilities of some xanthene and thiazine dyes in ethanol solutions. The method consists of comparison of the quantum yield for the direct photoreduction of dyes (Φ), with that of the sensitized reduction in otherwise similar conditions (Φ^{S}), using suitable aromatic hydrocarbons as sensitizers (donors). In an ideal case, Φ and Φ^{S} are written as

$$\Phi = -\mathrm{d[A]}/\mathrm{d}t/I_{ab} = \varphi_{ST}^{A}\beta^{A} \quad (1)$$

$$\Phi^{S} = -\mathrm{d[A]}/\mathrm{d}t/I_{ab} = \varphi_{ST}^{D}\gamma\beta^{A}, \quad (2)$$

where φ_{ST}^{A} and φ_{ST}^{D} are respectively the transition probabilities of S*–T transition for acceptor (dye) and donor, and β^{A} the fraction of the triplet dye which undergoes the reaction. γ is the efficiency of T-energy transfer between donor and acceptor and is regarded to be unity when the T-energy level of donor is much higher than that of acceptor. By combining (1) and (2) one can easily evaluate φ_{ST}^{A}, since the value of φ_{ST}^{D} is known for many aromatic hydrocarbons.

The purpose of the present paper is to extend the above method to the aqueous solutions. Hitherto there have been reported very few φ_{ST} values for dyes or for the substances dissolved in water. As far as we know, the only reliable data ever published for dyes are Bowers and Porter's.[2] However, their method which relies upon flash technique, appears to require some skill and caution in experiments.

Our method is very simple in principle and requires no particular technique but at present there is no report concerning the suitable sensitizers with the known φ_{ST}^{D} values. Once a set of such sensitizers are found, the method will have a wider scope of application.

As sensitizers, we have employed 1-anthracenesulfonic acid and 1,5-naphthalenedisulfonic acid. To determine the φ_{ST}^{D} value of the latter, erythrosin has been chosen as a reference substance, because its φ_{ST} value in the aqueous solution is, according to Bowers and Porter,[2] 1.0 and the same value has also been found by our experiment in ethanol.[1] In practice, the φ_{ST} value of 1,5-naphthalenedisulfonic acid has been determined by comparing Φ^{S} and Φ for the photoreduction of erythrosin using allylthiourea (ATU) or EDTA as a reducing agent. Then with the use of this φ_{ST}^{D} value, the φ_{ST}^{A} values

5.0×10^{-3}	2.9×10^{-4}	0.89×10^{-2}	1.02×10^{-2}	——	——
3.0×10^{-3}	1.8×10^{-4}	——	——	——	——
2.5×10^{-3}	——	0.45×10^{-2}	0.56×10^{-2}	——	——

of other dyes have been determined. Erythrosin can not be used as a reference substance for 1-anthracenesulfonic acid, because its T-state has almost the same energy as that of the dye. Hence its φ_{ST} value has been determined in reference to methylene blue. The results have been found to be quite consistent and satisfactory.

Experimental

Materials. All the dyes and ATU are the same as in the previous paper.[1] EDTA (Dotile 2NA) of G. R. grade was used without further purification. 1-Anthracenesulfonic acid sodium salt of G. R. grade of Wakojunyaku was passed through a column of activated alumina. 1,5-Naphthalenedisulfonic acid sodium salt of G. R. grade of Wakojunyaku was subjected to recrystallization from 3N HCl solution twice.

Apparatus and Procedures. The apparatus and the method of measurement are the same as in the previous paper.[1] The measurement was usually made at pH 7.2 by employing a phosphate buffer except fluorescein for which 0.05N NaOH solution was used. The concentrations of substances are as follows unless otherwise described: xanthene dyes, 1.0×10^{-5}M; thiazine dyes, 1.5×10^{-5}M; 1,5-naphthalenedisulfonic acid, 2.25×10^{-4}M; 1-anthracenesulfonic acid, 1.0×10^{-4}M; EDTA, 2.0×10^{-2}—1.0×10^{-3}M; ATU, 2.0×10^{-2}—2.5×10^{-3}M. Temperature was 30 ± 0.5°C. The fluorescence measurement was made by a Hitachi MPF-2A spectrofluorimeter whose spectral response was calibrated using standard substances.[3]

Results

Quantum Yields for the Direct Photoreduction of Dyes. Quantum yields for the photoreduction of fluorescein, eosin, erythrosin, methylene blue and thionine by EDTA and ATU in several concentrations are summarized in Table 1. The data for fluorescein,[4] eosin,[5] erythrosin[6] and methylene

blue[7] agree with the published ones within experimental error. There is no value in literature to compare with for thionine. Figure 1 gives the $\ln(e^{E}-1)$ *vs.* t plot (E, optical density), the linearity of which supports the occurrence of D-R mechanism.

Examination on the Applicability of the Method. For the present method to be applicable, there should be no interaction between donor and other components including transient intermediates, except for the energy transfer between donor and acceptor. Thus in the first place, reducing agents must in no sense react with donors. Secondly, donors must react neither with the triplet state of dye nor with any other transient intermediates such as semiquinones of dyes. In addition, high efficiency of the energy transfer is very much desired. In these respects, nothing is known on the system consisting of the present donors and dyes.

Table 2 gives some reference data on the present donors as compared with the mother hydrocarbons.

The fluorescence quantum yields of the two sulfonic acids have been determined by comparing the fluorescence intensities of the aqueous solutions of these two substances with those of the ethanol solutions of naphthalene and anthracene.

The conditions mentioned above have been examined for all the systems. Firstly, it was ascertained that the triplet decays of the donors are not affected by $\sim1.0\times10^{-2}$M of ATU or EDTA of the same concentration. However, it was found by flash experiment that the decays of the triplet state for some dyes are affected by the existence of donor to some extent. In line with this finding, the quantum yield for the direct photoreduction of erythrosin, methylene blue and thionine was found to decrease with the addition of a larger quantity of donor. Figure 2 gives the result for erythrosin. The type of this deactivation seemed to be a mere deactivation, because no decrease in donor concentration was observed after reaction. It was ascertained, however, that in the system of 1,5-naphthalenedisulfonic acid and erythrosin, for example, the concentration of donors two or three times larger than that of the standard concentration, does

not affect the Φ^S value, if the concentration of reductant is larger than 1.0×10^{-2}M.

Lastly, mention should be made on the behavior of energy transfer. Figure 3 gives the plots of optical density against time for eosin as an example, under different conditions.

The linearity of the plot for [dye] $>1.0\times10^{-5}$M ensures that I_{ab}, φ_{ST}^{D} γ and β^A remain constant during the run. In view of the triplet lifetime given in Table 2, the constancy of γ is expected to be secured, if the energy transfer occurs as a diffusion controlled process. Figure 4 gives the decay of the donor triplet in the absence and in the presence of erythrosin; from these data the rate constant for deactivation by erythrosin is estimated to be of the order of 10^9M^{-1} sec^{-1}. Although the exact value of the energy transfer efficiency is yet unknown, the assumption will be made in the following that γ is unity in view of a large difference in triplet energy level between donor and dye.

Determination of φ_{ST}^{D} of the Two Donors. Firstly, φ_{ST}^{D} of 1,5-naphthalenedisulfonic acid has been determined by comparing the Φ^S values of the photoreduction of erythrosin sensitized by this donor, with those of the direct photoreduction of erythrosin listed in Table 1.

Table 3 gives the values of Φ^S of erythrosin and those of φ_{ST} of 1,5-naphthalenedisulfonic acid obtained on the assumption that φ_{ST} of erythrosin is unity.

Table 3. φ_{ST} of 1,5-naphthalenedisulfonic acid and Φ^S

EDTA	2.0×10^{-2}M	4.0×10^{-2}	0.89
	1.5×10^{-2}	3.8×10^{-2}	0.89
	1.0×10^{-2}	3.5×10^{-2}	0.93
	5.0×10^{-3}	1.55×10^{-2}	0.82
ATU	2.0×10^{-2}	1.9×10^{-2}	0.83
	1.5×10^{-2}	1.4×10^{-2}	0.90
	1.0×10^{-2}	1.25×10^{-2}	0.92
		Average	0.88 ± 0.05

Next, φ_{ST} of methylene blue was determined using 1,5-naphthalenedisulfonic acid as a donor. Then from the combination of methylene blue and 1-anthracene sulfonic acid, φ_{ST} of the latter was obtained by use of φ_{ST} of methylene blue, 0.52 ± 0.01. The result was that φ_{ST} of 1-anthracene-

sulfonic acid is 0.82 ± 0.02 (As to the experimental data, see below).

The sums of Φ_F and φ_{ST} for 1,5-naphthalenedisulfonic acid and 1-anthracenesulfonic acid are respectively $0.88+0.12=1.0$ and $0.82+0.18=1.0$. Thus the internal conversion is negligible in these two donors.

Quantum Yields of the Sensitized Photoreduction Φ^S and the φ_{ST} Values of Dyes. Tables 4 and 5 give respectively the quantum yields of the sensitized photoreduction of xanthene and thiazine dyes. The experimental condition was always so selected that the reaction took place in an ideal way. The 1-anthracenesulfonic acid-thionine system was omitted, since the concentration of thionine in the aerated solution gradually decreased even in dark.

In Table 6 are summarized the φ_{ST} values of fluorescein, eosin, methylene blue and thionine obtained by applying Eqs. (1) and (2) to a set of two corresponding experimental data given in Tables 1, 4 and 5. The φ_{ST} values of methylene blue listed in the column of 1-anthracenesulfonic acid are the ones recalculated by putting φ_{ST} for 1-anthracenesulfonic acid as 0.82. Table 6 clearly shows that the φ_{ST} value of each dye is essentially the same independent of reducing agent and donor.

Discussion

Table 7 gives the comparison of the φ_{ST} values of the present work (pH 7.2) with the published data.

The values for xanthene dyes in the aqueous solution are somewhat larger than those in ethanol. The values for thiazine dyes on the other hand are about the same in both solvents. The present value for eosin is very close to Bowers and Porter's in spite of the entirely different method. Gollnick and Schenck's values are somewhat smaller than the present ones (except fluorescein). Their values were based on the assumption that the reaction $A^T+{}^3O_2\rightarrow A+{}^1O_2$ occurs in the presence of ample oxygen, with efficiency 1. It is unlikely that this assumption is correct.

According to our previous investigations, the

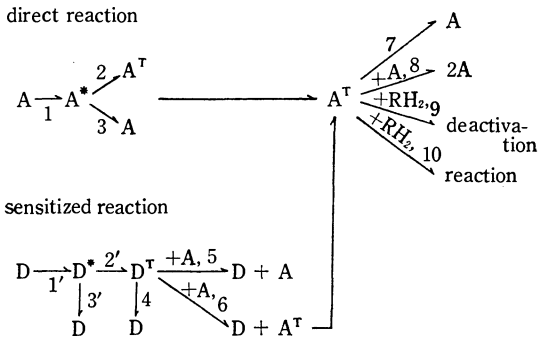
scheme for the present reaction can be described as follows,



Then γ and β in Eqs. (1) and (2) are expressed as follows,

$$\gamma = \frac{k_6[A]}{k_4+(k_5+k_6)[A]} \tag{3}$$

$$\beta_A = \frac{k_{10}[RH_2]}{k_7+k_8[A]+k_9[RH_2]+k_{10}[RH_2]} \tag{4}$$

Insertion of (3) and (4) into Eqs. (1) and (2) allows us to expect that both the $1/\Phi$ *vs.* $1/[RH_2]$ plot and the $1/\Phi^S$ *vs.* $1/[RH_2]$ plot should give the same value for (intercept)/(slope), *i.e.* $(k_9+k_{10})/(k_7+k_8[A])$, if the donor does not interfere with the reaction scheme after the formation of A^T. Table 8 clearly shows that this really holds in all cases.

Furthermore the intercepts of the $1/\Phi$ *vs.* $1/[RH_2]$ plot and $1/\Phi^S$ *vs.* $1/[RH_2]$ plot give respectively $\varphi_{ST}^A\ \beta_{max}$ and $\varphi_{ST}^D\ \gamma\beta_{max}$, and if the relation $\gamma=1$ really holds, the same β_{max}, *i. e.* $k_{10}/(k_9+k_{10})$ should result irrespective of sensitized and nonsensitized reaction and also independent of the kind of sensitizer. In Table 8 are listed also the values of β_{max} evaluated from the intercepts by putting $\gamma=1$. It is evident that β_{max} for each dye-reductant system agree within experimental error. As in the ethanol solution mere deactivation is much larger for ATU than for EDTA. It is remarkable that mere deactivation scarcely occurs in the case of thionine-EDTA.

In the case of eosin and fluorescein, the (k_9+k_{10}) and k_7 values are known from the flash experiments and so the k_9, k_{10} and k_8 values are obtained. The results are given in Table 9.

Lastly, the tentative data reported in the previous papers will be corrected using the reliable φ_{ST} values obtained in the present paper. Since the equation

$$\frac{1}{\Phi} = \frac{1}{\varphi_{ST}^A}\left\{\frac{k_9+k_{10}}{k_9} + \frac{k_7}{k_{10}[RH_2]} + \frac{k_8[A]}{k_{10}[RH_2]}\right\}$$

holds, and $(k_9+k_{10})/k_9$ can be evaluated from the

* The values of intercept for the $1/\Phi$ *vs.* $1/[RH_2]$ plot in the previous paper[5] appears to depend on the dye concentration. But in view of the present result, this is most likely due to experimental error. Hence $\varphi_{ST}=0.64$ was used in all the data.

intercept of the $1/\Phi$ *vs.* $1/[RH_2]$ plot, k_8, k_9 and k_{10} can be evaluated from the experimental data for the dependence of Φ on $[RH_2]$ and on [A], only if k_7 is known from the flash experiment. The knowledge of the (k_9+k_{10}) value from the flash experiment will make the evaluation of these constants more simple and more reliable. The corrected values from the previous data for fluorescein, eosin and methylene blue are given in Table 10.

It is seen that in general the previous k_{10} values are much too large while the k_8-value is correct in the order of magnitude. Moderate agreement is apparent between the data in Tables 9 and 10.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 2471—2475 (1969)

Adsorption of Surface Active Substance at Aqueous Surface Using Tritium Labeled Compounds: Adsorption from Mixed Aqueous Solution of Sodium Dodecylsulfate and Dodecanol

Kazuo TAJIMA, Mitsuo MURAMATSU and Tsunetaka SASAKI

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya-Ku, Tokyo

(Received February 10, 1969)

Adsorbed amount of sodium dodecylsulfate (SDS) and *n*-dodecanol (DOH) at the gas-solution interface of their mixed aqueous solution was directly measured as a function of bulk concentration of DOH by the radiotracer method. For this purpose the surface radioactivity of the mixed solution in which either SDS or DOH was labeled with tritium, was counted by using a 2π windowless gas-flow counter. It was found that the adsorbed amount of DOH rapidly increases with increasing bulk concentration of DOH, while that of SDS gradually decreases. The adsorption of DOH and desorption of SDS are not a simple 1 : 1 replacement. A maximum total adsorption of about 13×10^{-10} mol/cm^2, which exceeds the amount of close-packed monolayer adsorption extends over a wide range of concentration studied. It was suggested that the adsorbed film consists of mixed monolayer or double layers. The latter film is composed of mixed monolyaer of SDS and DOH with adsorbed layer of SDS beneath. The molar ratio of adsorbed amount of DOH to SDS in the surface became unity, when the ratio of the bulk concentration of DOH to SDS was about one hundredth, which shows a stronger adsorption tendency of DOH than that of SDS.

It was reported in a previous paper[1] that the soft β-rays of tritium are very useful for the measurements of the amount of adsorption of a detergent at the surface of an aqueous detergent solution. By using a tritiated SDS it has been confirmed that the amount of saturate adsorption of SDS at the aqueous surface is 5.9×10^{-10} mol/cm^2 at 20°C. In the present paper, the measurements have been extended for studying the competitive adsorption between SDS and DOH at the surface of their mixed solution. It has been reported that the addition of a small amount of alcohol causes marked changes in the surface-chemical properties of a detergent solution, such as foam stability,[2] mechanical strength of adsorbed film,[3,4] and surface tension lowering.[5] These phenomena have been explained by the preferential or mixed adsorption of alcohol for the adsorbed film of the detergent at the aqueous surface.[6] Few papers, however, deal with the direct measurement of adsorption of these components in the mixed film at gas-solution interface under the static condition.

The experiments were carried out to determine the composition of this mixed adsorbed film by the adsorption measurement of the aqueous SDS-DOH system in which either SDS or DOH was labeled with tritium.

Experimental

The tritiated samples were synthesized according to the method reported in the previous papers[1,7] which gave the product of sufficiently high purity both surface-chemically and radiochemically. The solutions were prepared by dissolving in thrice distilled water the solid mixture of the samples, which had been obtained by evaporating to dryness the ethanol solutions of TSDS (tritium-labeled SDS) and DOH or SDS and TDOH (tritium-labeled DOH) of a desired composition. The surface radioactivity was measured by a 2π windowless gas-flow counter (Aloka DC-1001) using a humidified propane gas to prevent the evaporation of solution. The detailed procedures of the adsorption measurement were described.[1] In the present study special precaution was made further for the measurement of TDOH at the surface, since it is slightly volatile even in solution,[8,9]

as mentioned in the later section. The pH of the solution was in the range of 5.8—6.2, and the temperature was kept at 20±0.5°C.

Throughout the measurements, the concentration of the detergent was kept at 5.63×10^{-3} mol/1000 g solution. The value corresponds to the minimum concentration for saturate adsorption attained below the CMC (critical micelle concentration). The amounts of adsorption of SDS and DOH were measured for DOH-TSDS and TDOH-SDS systems respectively.

Results and Discussions

Mixed Solution of TSDS and DOH. The time dependence of surface radioactivity due to TSDS in the mixed solution was measured and the result is shown in Fig. 1. It is noted in this figure that

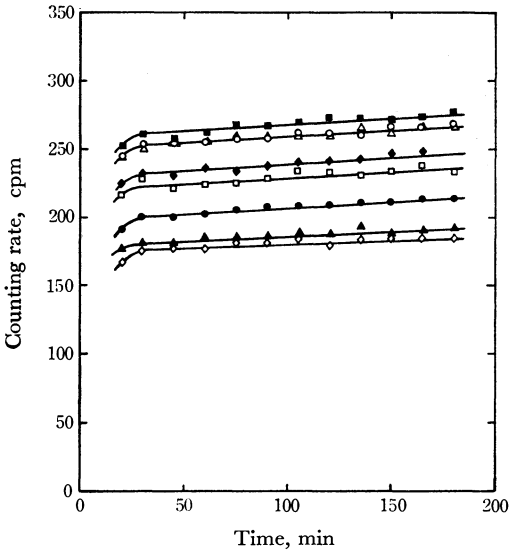

Fig. 1. Time dependence of surface radioactivity of TSDS due to adsorption of SDS from SDS-DOH mixed solution.
Concentration of SDS: 5.63×10^{-3} mol/1000 g solution.
Concentration of DOH (in mol/100 g solution):
■ 0 □ 3.61×10^{-4} △ 6.02×10^{-6}

◆ 2.41×10^{-4} ▲ 1.08×10^{-3}

the radioactivity first increases rapidly, then slowly and linearly with time after about 30—40 min. This seems to indicate both the rapid increase of adsorption towards the equilibrium and the rapid approach of counting efficiency to its steady state as mentioned previously.[1] Therefore, the radioactivity in adsorption equilibrium was evaluated by extrapolating the linear portion of the curve to time zero. The adsorbed amount of SDS in the mixed solution, Γ_{SDS}, was obtained by subtracting the radioactivity due to the bulk of the solution from the counting rate obtained above and multiplying the value obtained by the specific activity.[10] The value of Γ_{SDS} thus obtained is shown as a function of DOH concentration by the curve A of Fig. 2. The

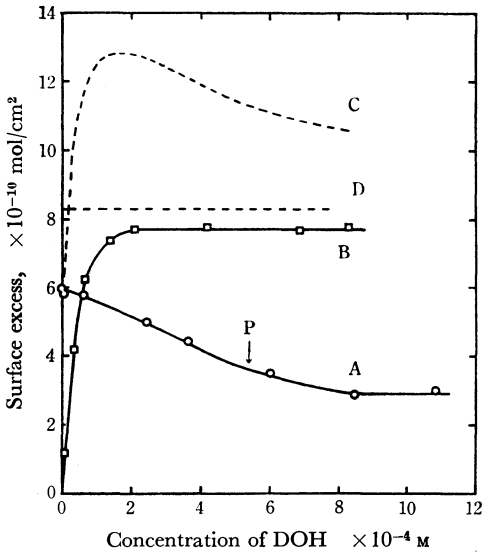

Fig. 2. Adsorbed amounts of SDS (curve A) and DOH (curve B) at aqueous surface for SDS-DOH mixed solution, as a function of DOH concentration at 20°C. Total adsorbed amount (curve C) and monolayer adsorption (curve D).

curve A shows the decrease in Γ_{SDS} with increasing concentration of DOH from the initial value of 5.9×10^{-10} mol/cm² (saturate adsorption from the solution containing SDS alone) to 2.9×10^{-10} mol/cm² and becomes constant beyond the DOH concentration of 8.4×10^{-4} mol/1000 g solution, where the opalesence evidently appeared in the solution. We can confirm from these facts that the amount of adsorption of SDS decreases with an increasing amount of the addition of DOH. The maximum effect appeared in the region beyond the saturation of DOH where its effective concentration became constant.

Mixed Solution of SDS and TDOH. Similar experiments as mentioned above were carried out, except for the use of tritiated DOH instead of SDS. Surface radioactivity due to TDOH in the mixed solution is shown in Fig. 3. It is seen that radioactivity decreases gradually with time over the range of DOH concentration of the mixed solution, approaching a constant value at higher DOH concentration and after sufficient lapse of time (about 90 min). This gradual decrease of radioactivity was considered to be due to the volatile

nature of adsorbed DOH film at the surface.[8,11] In this connection the surface radioactivity of saturate TDOH solution without the addition of SDS is shown in Fig. 4. It is seen from Fig. 4

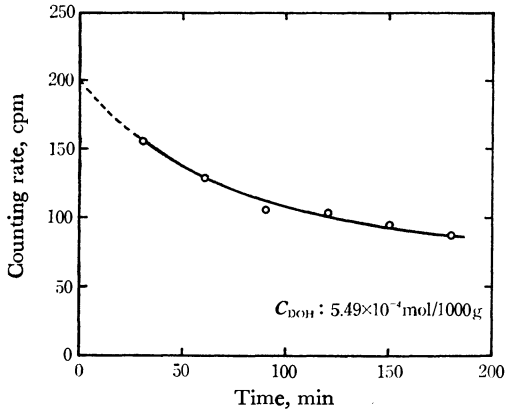

Fig. 4. Time dependence of surface radioactivity of TDOH due to the adsorption of DOH from its aqueous solution.

that surface radioactivity exhibited a similar tendency as in the case of Fig. 3. From these facts, it is presumed that the variation of surface radioactivity in Fig. 3 is partly due to the difference in adsorption rate between SDS and DOH, and partly to the evaporation of adsorbed DOH film as is shown in Fig. 4. The plateau appearing in the curve of Fig. 3 for DOH concentration of more than 2.06×10^{-4} mol/1000 g solution may be explained as a result of the dynamic equilibrium between the rate of adsorption of DOH into the surface layer from the bulk of solution and the rate of evaporation of it from the surface.

Thus, the value of counting rate of DOH corresponding to the equilibrium adsorption over the mixed solution was reasonably obtained by the extrapolation of the curve (as shown by the dotted line in Fig. 3). The extrapolation was made assuming an exponential decrease of the surface radioactivity (A) with time (t). The exponential relation was adopted since it was confirmed to hold fairly well for all experimental data of Figs. 3 and 4 as shown in Fig. 5. The adsorbed amount of DOH

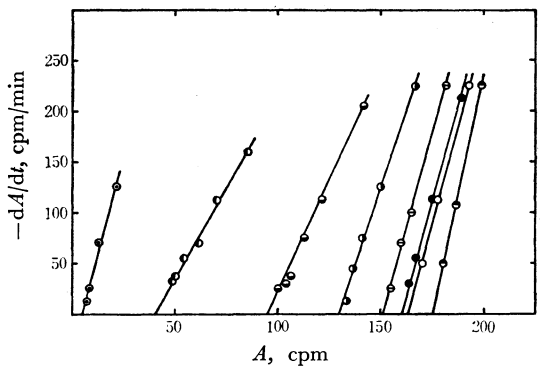

Fig. 5. A *versus* dA/dt plot.

in mixed solution, Γ_{DOH}, was calculated similarly as in the case of Γ_{SDS}. The results are shown by the curve B in Fig. 2. We can confirm in Fig. 2 that in the mixed adsorbed film Γ_{DOH} steeply increases with the DOH concentration contrary to the gradual decrease of Γ_{SDS} and reaches the saturate adsorption of 7.8×10^{-10} mol/cm² in the region of DOH concentration greater than 2.5×10^{-4} mol/1000 g solution. The curves show a strong tendency of DOH adsorption with no marked desorption of SDS.

Composition of Adsorbed Film. Few studies have been reported on the amount of adsorption at the surface of mixed aqueous solution of SDS and DOH by a direct and reliable method.[6,12] As an instance, we can cite the data of Wilson *et al.* obtained by foaming method. They reported $\Gamma_{SDS}=3.4\times10^{-10}$ mol/cm² and $\Gamma_{DOH}=3.9\times10^{-10}$ mol/cm² at 25°C for the mixed aqueous solution containing 8.7×10^{-3} mol/1000 g of SDS and 5.3×10^{-4} mol/1000 g of DOH. Corresponding data of the present study are $\Gamma_{SDS}=3.6\times10^{-10}$ mol/cm² and $\Gamma_{DOH}=7.7\times10^{-10}$ mol/cm² for the aqueous solution containing the same concentration of DOH

as that of Wilson and 5.63×10^{-3} mol/1000 g of SDS as estimated from Fig. 2.

It is confirmed from these data that the two values of Γ_{SDS} are nearly equal, but those of Γ_{DOH} are largely different from each other. This discrepancy will be explained by the solubilization of DOH in aqueous SDS beyond CMC and resulting decrease in DOH activity in Wilson's measurement. A similar effect of the decrease in adsorption due to the solubilization has been reported by Aniansson[13] in the case of solubilization of sodium hexadecysulfate by SDS. Also, the effects of fatty alcohol on CMC and on surface tension *vers.* concentration curve of soap and other surface active substances may be closely related to the phenomena mentioned above.[5,14]

In Fig. 6, the fraction of DOH in the adsorbed

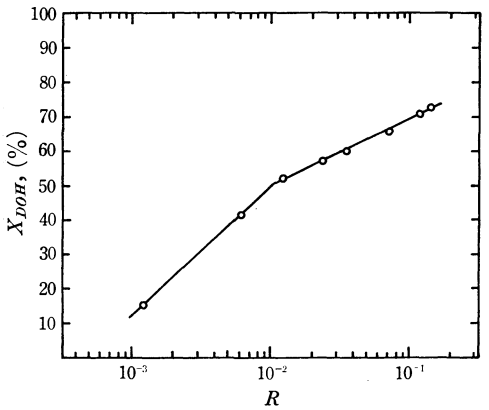

Fig. 6. Relation between X_{DOH} and R.
X_{DOH}: fraction of DOH in adsorbed film,
R: ratio of DOH concentration to SDS concentration in solution.

film, X_{DOH}, is plotted against the logartithm of the ratio, R, of DOH concentration to SDS concentration (constant) in the solution. It is seen in this figure that X_{DOH} shows a high value, although the value of R is still rather small: for instance, at $R=0.01$, $X_{DOH}=0.5$, *i. e.*, Γ_{SDS} is nearly equal to Γ_{DOH}. This means a strong tendency of DOH adsorption already at the small value of X_{DOH}, even in the presence of adsorbed film of SDS. Similar phenomena have been reported by Shinoda.[6] These facts may reasonably explain the remarkable effects of the addition of small amounts of DOH on the surface chemical properties of SDS solution.[2-4]

As for the mixed adsorption layer, the simple replacement of SDS by DOH in the layer cannot be conceivable, since the adsorption of DOH and the desorption of SDS did not occur in a simple ratio. The total amounts of adsorption of Γ_{DOH} and Γ_{SDS} together with the amount of adsorption corresponding to the close-packed monolayer are shown by dotted lines C and D respectively in Fig. 2. This figure shows that it is impossible for such a mixed adsorbed film to form a close-packed monolayer. This suggests that all molecules of SDS and DOH are not in the monomolecular layer at the surface of solution. In this connection it is noticed that the addition of SDS to the sufficiently concentrated solution of DOH (5.49×10^{-4} mol/1000 g solution) hardly affects the amount Γ_{DOH} (comparision of the extrapolated value of $\Gamma_{DOH}=7.4\times10^{-10}$ mol/cm^2 in Fig. 4 with the saturated value of $\Gamma_{DOH}=7.6\times10^{-10}$ mol/cm^2 for the mixed solution P in Fig. 2 containing the same amounts of DOH as in Fig. 4), while the addition of the same amounts of DOH to a solution of SDS markedly decrease the amount of Γ_{SDS} (from 5.9×10^{-10} mol/cm^2 at DOH concentration being zero to 3.6×10^{-10} mol/cm^2 for the mixed solution P in Fig. 2). These facts may suggest that adsorbed SDS molecules in excess of close-packed monolayer go beneath the monolayer at the surface of the solution while all adsorbed DOH appear in the monolayer. As to the structure of such a mixed adsorbed film, Fowkes reported[15] that the transition point is always observed in the pressure—area curve of the insoluble mixed monolayer composed of alkylsulfate and alcohol, when the alcohol content in the film exceeds 50%. He suggested the structure of film from the theory of ideal two-dimensional solution, in which the polar heads of sulfate are considered to be hydrated and placed beneath the surface of water, when the alcohol content of the film is less than 50%, but sulfate ions are dehydrated and occupy the same position as alcohol in the adsorbed film, when the alcohol content is over 50%.

In the present experiments, somewhat different behavior can be observed in the case of soluble adsorbed film composed of surfactant and alcohol. Namely, in the case of DOH composition being less than 50% in film, DOH molecules strongly penetrate into the adsorbed SDS film forming mixed monolayer, without marked desorption of SDS. In case of DOH composition being more than 50%, a mixed monolayer is likely to form, but here the mixed monolayer alone can not explain the total sum of Γ_{SDS} and Γ_{DOH} which exceeds the adsorbed amounts corresponding to the close-packed monolayer indicated by the dotted line D in Fig. 2. In this case a part of adsorbed SDS molecules are considered to form a mixed monolayer with DOH, while the rest of SDS molecules lie beneath the mixed monolayer as mentioned above. Thus, the structure of adsorbed layer is confirmed to be not a monolayer, contrary

to the suggestion of Fowkes in the region of sufficiently large concentration of DOH, and the Fowkes' transition phenomena if it appears may be understood as the change from monolayer to double layers formation.

In order to study the composition of adsorbed mixed film further in detail, it is necessary to use a more improved method of measuring radioactivity. The work is being continued along this direction.

Kinetics of the Adsorption of Water and Electrical Conduction in Amorphous Ferric Oxide

Ryusaburo FURUICHI, Norio SATO and Go OKAMOTO

Department of Applied Chemistry, Faculty of Engineering, Hokkaido University, Sapporo

(Received February 19, 1969)

Amorphous ferric oxide was prepared by precipitation in a mixture of ammonium hydroxide and ferric nitrate at 90°C, after which it was calcinated in air at a constant rate of 10°C/min up to 200°C. The rate of the adsorption on the amorphous oxide was measured by a gravimetric method. An equation of the Elovich type was obtained: $dq/dt=k'p^{0.63}\exp(-\alpha' q/RTp^{0.5})$, where k' and α' are constants; q, the amount of adsorbed water, and p, the pressure. This kinetics can be interpreted by a model of a two-stage adsorption process, the van der Waals adsorption and the charge-transfer adsorption, the latter stage being assumed to be rate-determining. The effect of adsorbed water on the direct-current conductivity of the oxide, i, is formulated as $i=i_0\exp(aq)$. Assuming that the adsorbed water is acting as a donor-type impurity and that the ionization energy decreases with the concentration of impurity, the relation between i and q can be derived from the theory of the semiconduction of an n-type conductor.

Many investigators have reported the adsorption of water on ferric oxide.[1-6] Jurinak,[6] drawing a line between chemisorption and physical-adsorption, measured the amounts of water in the two adsorption states. Blyholder and Richardson[4] have shown, in a study of the infrared absorption, that the water molecule chemisorbs by dissociating to form an OH^- ion and an H^+ ion, the latter of which reacts with a surface O^{2-} ion to form another OH^- ion. Onoda and DeBruyn[7] have suggested the possibility of the transformation of anhydrous ferric oxide to goethite in a study of proton adsorption at the ferric oxide/aqueous solution interface. Kawasaki, Minowa, and Inamatsu[8] found, in studying the "Metallic Oxide Electric Hygrometer," that electrical resistance of oxide decreased with an increase in the relative humidity in the range from 50 to 100%. On the other hand, with various kinds of proteins the effect of adsorbed water on the electrical conductivity has been studied[9,10]; it has been found that the electrical conductivity, i, increased with an increase in the amount of adsorbed water, q, obeying an empirical equation, $i=A\exp(\alpha q)$, where A and α are constants.

It is to be noticed that the water adsorption affects the conductivity in a similar fashion in both inorganic and organic materials. The semiconductivity of inorganics is known to play an important role in the catalytic activity of the inorganic solids.
